Hypertension. ACE inhibitors have an established role in the management of hypertension (p.1171) and appear to have comparable effects to the other main groups of antihypertensives.[1] The Captopril Prevention Project (CAPPP) trial,[2] which compared captopril-based therapy with beta blocker- or diuretic-based therapy, suggested that cardiovascular mortality was lower with captopril, although the risk of stroke was increased in those receiving captopril and overall mortality did not differ between the groups. In the large ALLHAT study,[3] which compared an ACE inhibitor with a calcium-channel blocker or a diuretic, overall mortality did not differ significantly between any of the groups, although there were slightly higher rates of stroke and heart failure in those given the ACE inhibitor compared with the diuretic group. ACE inhibitors are particularly recommended in diabetic patients with nephropathy as they may have beneficial effects on the kidney, and also in patients with heart failure. Other advantages that have been suggested include their lack of adverse effects on serum lipids, a reduction in left ventricular hypertrophy,[4] and a reduction in plasma fibrinogen levels,[5] but the clinical significance of these effects is not established.

The antihypertensive actions of ACE inhibitors may be potentiated by drugs that activate the renin-angiotensin system. Hence, combination therapy with diuretics or with calcium-channel blockers may be particularly useful.

DIAGNOSIS OF RENOVASCULAR HYPERTENSION. Captopril has been used to diagnose renovascular hypertension, since the increase in plasma renin activity after blockade of the conversion of angiotensin I to angiotensin II is greater in renovascular hypertension than in primary hypertension.[1] However, a meta-analysis[2] of various tests used for the diagnosis of renovascular hypertension found that the accuracy of the captopril test is low when compared with imaging methods such as computed tomography or magnetic resonance angiography. Captopril is also used to enhance the sensitivity and specificity of renal scintigraphy.[3] For reference to the use of captopril scintigraphy to diagnose Bartter's syndrome see above.

Ischaemic heart disease. ACE inhibitors have clinical benefits in patients with ischaemic heart disease and other atherosclerotic conditions. They have an established role in the treatment of patients after acute myocardial infarction (see below) and may also have a preventative effect; in the SAVE[1] and SOLVD[2] studies, use of ACE inhibitors in patients with heart failure was noted to lead to a reduction in the incidence of myocardial infarction. In the HOPE study,[3] treatment with ramipril significantly reduced the rate of death, myocardial infarction, and stroke in patients at high risk for cardiovascular disease, while in the EUROPA study[4] perindopril was found to reduce cardiovascular events in patients with stable ischaemic heart disease. In the QUO VADIS study,[5] giving quinapril for 1 year after coronary artery bypass grafting reduced the incidence of clinical ischaemic events although there was no effect on ischaemia during exercise testing or Holter monitoring.

The mechanisms by which ACE inhibitors produce benefit in these patients is less clear. Although a direct action to reduce atherosclerosis (p.1159) has been suggested, studies have failed to confirm this effect. In the TREND study,[6] giving quinapril for 6 months was reported to improve endothelial dysfunction in patients with ischaemic heart disease, but apparently no effects on the progression of atherosclerosis or the incidence of cardiac events were found in the QUIET study[7] which used a lower dose of quinapril given for 3 years. In the PART-2 study,[8] ramipril had no effect on the progression of carotid atherosclerosis, while the PARIS study[9] found an increase in angiographic restenosis after use of quinapril.

A lack of acute anti-ischaemic effect has been found with short-term use of captopril and enalapril in patients with stable angina,[10] and with enalapril in Prinzmetal's angina;[11] however, a further study[12] in patients with stable angina reported an improvement in the results of maximal exercise testing after sublingual captopril dosage. Symptomatic benefit has also been reported[13] in patients with atherosclerotic peripheral arterial disease, and a case-control study[14] has suggested that patients with aortic disease may have a lower risk of ruptured aortic aneurysm if they are taking ACE inhibitors.

Kidney disorders. The effects of ACE inhibitors on the kidney are complex. Although they may reduce renal function and should be used with caution in patients with renal impairment (see Adverse Effects and Treatment, above), ACE inhibitors may also have beneficial effects in diabetic and nondiabetic renal disease. Reducing blood pressure protects renal function regardless of the class of antihypertensive used,[1] since hypertension and the resultant proteinuria both cause kidney damage. A number of studies have shown that ACE inhibitors and other drugs that block the renin-angiotensin-aldosterone system (RAS), such as angiotensin II receptor antagonists, are particularly effective[1] and they may therefore be preferred for blood pressure control in kidney disorders. However, whether they have a specific renoprotective effect beyond their antihypertensive effect is unclear.[2]

Most experience has been gained in patients with diabetic nephropathy (see Diabetic Complications, p.433), which is often associated with hypertension and may progress from microalbuminuria to the nephrotic syndrome and end-stage renal failure. In patients with proteinuria, the use of ACE inhibitors now appears to be of established benefit, whether they are hypertensive or normotensive or whether they have type 1 or type 2 diabetes mellitus. Angiotensin II receptor antagonists are also effective[3,4] and may be used as an alternative, although only ACE inhibitors have been shown to have a mortality benefit;[5] dual therapy with an ACE inhibitor and an angiotensin II receptor antagonist has also been tried and may be more effective than either alone.[6,7] In patients with early diabetic nephropathy, ACE inhibitors also slow progression of microalbuminuria,[4,8] and they have been recommended, in conjunction with tight glycaemic control, in all diabetic patients with microalbuminuria.[9] They may also have benefits in patients with normal renal albumin excretion and have been reported to reduce the incidence of microalbuminuria in both hypertensive and normotensive type 2 diabetics,[10] although the clinical significance remains to be established.

ACE inhibitors may also be of benefit in renal disease unrelated to diabetes, although their role is less established. Proteinuria is an important indicator of glomerular kidney disease (p.1504) of various causes and may range from asymptomatic to severe. A number of studies[11-18] have reported that ACE inhibitors reduce both proteinuria and the rate of decline of renal function in patients with various non-diabetic renal disorders. Meta-analyses[19,20] have concluded that ACE inhibitors are more effective than other antihypertensives, although others suggest this is uncertain.[2] As in diabetic nephropathy, dual therapy with an ACE inhibitor and an angiotensin II receptor antagonist may provide additional benefit,[6] although there is less evidence for angiotensin II receptor antagonists alone in non-diabetic renal disease.[3]

Patients with systemic sclerosis (see Scleroderma, p.1817) are considered to be at high risk of adverse effects from ACE inhibitors; however there is evidence that these drugs are of benefit in the management of scleroderma-associated hypertension and renal crisis.[21]

Malignant neoplasms. *Animal* and *in vitro* studies have suggested that ACE inhibitors may protect against the development of cancer, and there has been a case report[1] of regression of Kaposi's sarcoma in a patient treated with captopril (but see Effects on the Skin, above). A retrospective cohort study[2] suggested that the incidence of cancer in hypertensive patients receiving ACE inhibitors was lower than expected. However, a subsequent case control study[3] in postmenopausal women found no evidence of a reduced risk of breast cancer associated with ACE inhibitor therapy.

See under Heart Failure, above for a suggestion that ACE inhibitors may protect against antineoplastic-induced cardiotoxicity.

Muscular dystrophy. For reference to the use of ACE inhibitors in patients with Duchenne muscular dystrophy see Genetic Disorders, above.

Myocardial infarction. ACE inhibitors may be of benefit in both the prevention and treatment of myocardial infarction (p.1175). They reduce left ventricular remodelling, a process which sometimes follows myocardial infarction and is a recognised precursor of symptomatic heart failure. Studies in patients with evidence of left ventricular dysfunction have shown benefit from long-term oral use of ACE inhibitors such as captopril (the SAVE study),[1] ramipril (the AIRE and AIRE extension (AIREX) studies),[2-4] or trandolapril (the TRACE study)[5,6] started about 3 days, or more, after infarction, and long-term ACE inhibitors are now established therapy in such patients.[7,8]

Early treatment with ACE inhibitors as an adjunct to standard thrombolytic therapy is less well established. Favourable results have been reported in the GISSI-3[9] and the ISIS-4[10] studies where lisinopril and captopril, respectively, were given orally starting within 24 hours of the onset of chest pain and in the Chinese Cardiac Study[11] (CCS-1) where captopril was given orally within 36 hours of the onset of symptoms. In the GISSI-3 study the beneficial effects were maintained at 6 months.[12] However, the CONSENSUS II study was stopped early when it was found that enalapril, given intravenously as enalaprilat and begun within 24 hours of the onset of chest pain, did not improve survival during the 180 days after infarction.[13] A substudy on some of the patients did however suggest that they may have benefited from early treatment since left ventricular dilatation was attenuated.[14] An interaction between aspirin and enalapril was postulated as one of the reasons for the overall lack of benefit seen, and further analysis of the CONSENSUS II results found that the beneficial effect of enalapril was reduced in those patients already taking aspirin,[15] although a systematic overview[16] failed to support this finding. A systematic review of the CONSENSUS II, GISSI-3, ISIS-4, and CCS-1 studies found lower 30-day cumulative mortality and incidence of non-fatal heart failure among ACE inhibitor recipients.[17] However, the size of benefit in these studies of largely unselected patients is much smaller than in the studies of patients with left ventricular dysfunction, and there remains no clear consensus as to whether all patients should be given ACE inhibitors or only those who develop evidence of left ventricular dysfunction.

Raynaud's syndrome. ACE inhibitors are among many drugs that have been tried in Raynaud's syndrome, a vasospastic peripheral vascular disease (p.1178). Variable effects have been reported. In a patient with Raynaud's syndrome captopril improved blood circulation in the fingers both acutely and during long-term therapy with a dose of 37.5 mg daily; the effect was apparently related to its effects on kinins rather than inhibition of angiotensin II formation.[1] However, a double-blind crossover study in 15 patients with Raynaud's phenomenon given captopril 25 mg or placebo three times daily for 6 weeks found that the drug improved blood flow but not the frequency or severity of attacks,[2] and a similar study in patients given enalapril failed to find any subjective or objective benefits.[3]

There has also been a report[4] of a patient in whom peripheral ischaemia induced by ergotamine was rapidly reversed by captopril.

Stroke. Antihypertensive therapy reduces the risk of stroke (p.1185) in patients with hypertension. However, in patients who have had a stroke, antihypertensive therapy has often been avoided due to the perceived risk of reducing cerebral perfusion. A study[1] of blood-pressure lowering with the ACE inhibitor perindopril, alone or with a diuretic, found that the risk of recurrent stroke was reduced in patients with a history of stroke or transient ischaemic attack, irrespective of whether they had a normal or raised blood pressure at study entry. Retrospective studies[2,3] have also suggested that stroke severity may be reduced in patients who are already taking ACE inhibitors. The beneficial effects of ACE inhibitors in stroke may not be entirely due to their antihypertensive effects; in the HOPE study,[4] ramipril reduced the incidence of stroke in patients with high cardiovascular risk despite only a small reduction in blood pressure.

There have also been reports[5,6] that ACE inhibitors may reduce the risk of pneumonia in patients with a history of stroke, possibly by an effect on symptomless dysphagia.[7]

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Acebutolol Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in alcohol; very slightly soluble in acetone and in dichloromethane. A 1% solution in water has a pH of 5.0 to 7.0. Protect from light.

USP 31 (Acebutolol Hydrochloride). A white or almost white crystalline powder. Soluble in water and in alcohol; very slightly soluble in acetone and in dichloromethane; practically insoluble in ether. pH of a 1% solution in water is between 4.5 and 7.0. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Concentrations of acebutolol and its active metabolite diacetolol in breast milk are higher than those in maternal plasma.[1] Pharmacological effects in the neonate, including hypotension, bradycardia, and tachypnoea, have been reported,[1] and the American Academy of Pediatrics therefore considers[2] that acebutolol should be given with caution to breast-feeding mothers.

2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/01/08)

Effects on the liver. Six cases of hepatotoxicity associated with acebutolol were reported[1] in the USA to the FDA between 1985 and 1989. The syndrome consisted of markedly elevated transaminase concentrations, moderately elevated alkaline phosphatase concentrations, and other constitutional symptoms such as fever, nausea, abdominal pain, and headache. The duration of therapy before onset of symptoms ranged from 10 to 31 days; 5 patients received a daily dose of 400 mg; the dose was unspecified in the sixth patient. The syndrome resolved when acebutolol was stopped but reappeared in 2 patients who were rechallenged.

1. Tanner LA, *et al.* Hepatic toxicity after acebutolol therapy. *Ann Intern Med* 1989; **111:** 533–4.

Effects on respiratory function. Bronchospasm is a recognised adverse effect of beta blockers, but other respiratory disorders have also been reported. Pleurisy and pulmonary granulomas developed in a patient given acebutolol and a diuretic; acebutolol was considered to be responsible.[1] Hypersensitivity pneumonitis has also been reported in a patient taking acebutolol.[2]

1. Wood GM, *et al.* Pleurisy and pulmonary granulomas after treatment with acebutolol. *BMJ* 1982; **285:** 936.
2. Akoun GM, *et al.* Acebutolol-induced hypersensitivity pneumonitis. *BMJ* 1983; **286:** 266–7.

Hypersensitivity. See Effects on Respiratory Function, above and Lupus, below.

Lupus. An increase in antinuclear antibodies has been seen with acebutolol.[1] A report of a lupus syndrome in an elderly patient given acebutolol and clonidine described remission of symptoms when acebutolol was withdrawn, but the high antinuclear antibody titre persisted for more than 9 months.[2] Acebutolol was also reported to have caused subacute cutaneous lupus erythematosus in a 57-year-old woman. The condition had resolved completely 4 months after acebutolol was stopped.[3] The authors noted that there had been 9 previous reports of lupus in patients taking acebutolol, but only one had skin manifestations.

2. Hourdebaigt-Larrusse P, *et al.* Une nouvelle observation de lupus induit par acébutolol. *Ann Cardiol Angeiol (Paris)* 1985; **34:** 421–3.
3. Fenniche S,*et al.* Acebutolol-induced subacute cutaneous lupus erythematosus. *Skin Pharmacol Physiol* 2005; **18:** 230–3.

Pregnancy. Both acebutolol and its active metabolite diacetolol cross the placenta. In a study[1] in 29 pregnant women who had received acebutolol for at least one month before delivery, there was evidence of bradycardia in 12 of the 31 offspring and tachypnoea in 6.

1. Boutroy MJ, *et al.* Infants born to hypertensive mothers treated by acebutolol. *Dev Pharmacol Ther* 1982; **4** (suppl 1): 109–15.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Acebutolol is well absorbed from the gastrointestinal tract, but undergoes extensive first-pass metabolism in the liver. Although the bioavailability of acebutolol is reported to be only about 40%, the major metabolite diacetolol is active. After oral doses, peak plasma concentrations of acebutolol and diacetolol are reached in about 2 and 4 hours, respectively.

Acebutolol and diacetolol are widely distributed in the body, but they have low to moderate lipid solubility and penetration into the CSF is poor. They cross the placenta and higher concentrations are achieved in breast milk than in maternal plasma. Acebutolol is only about 26% bound to plasma proteins, but is about 50% bound to erythrocytes. The plasma elimination half-lives for acebutolol and diacetolol are 3 to 4 hours and 8 to 13 hours respectively. Half-life values for acebutolol and diacetolol may be increased in the elderly and the half-life for diacetolol may be prolonged up to 32 hours in patients with severe renal impairment. Acebutolol and diacetolol are excreted in the urine and in the bile and may undergo enterohepatic recycling; acebutolol is also reported to be excreted directly from the intestinal wall, and more than 50% of an oral dose can be recovered from the faeces. Acebutolol and diacetolol are removed by dialysis.

Uses and Administration

Acebutolol is a cardioselective beta blocker (p.1225). It is reported to have some intrinsic sympathomimetic activity and membrane stabilising properties.

Acebutolol is used in the management of hypertension (p.1171), angina pectoris (p.1157), and cardiac arrhythmias (p.1160).

Acebutolol is used as the hydrochloride, but doses are usually expressed in terms of the base; 110.8 mg of acebutolol hydrochloride is equivalent to 100 mg of base. It is generally given orally although slow intravenous injection has been used for the emergency treatment of arrhythmias.

In **hypertension** the usual initial oral dose is 400 mg once daily or 200 mg twice daily, increased if necessary after 2 weeks to 400 mg twice daily. Doses up to 1.2 g daily in divided doses may be given.

The usual oral dose for **angina pectoris** is 400 mg once daily or 200 mg twice daily, but up to 300 mg three times daily may be required for severe cases and total daily doses of 1.2 g have been given.

The usual initial oral dose for **cardiac arrhythmias** is 200 mg twice daily, increased according to response; up to 1.2 g daily in divided doses has been required.

Reduced doses may be required in patients with impaired renal function (see below). Elderly patients may also require lower maintenance doses; doses greater than 800 mg daily should be avoided.

Action. Acebutolol is generally considered to be a cardioselective beta blocker but there has been considerable controversy as to the degree of its selectivity and the selectivity of its primary metabolite, diacetolol.[1-3] In a review of beta blockers,[4] acebutolol was stated to be less cardioselective than other drugs such as atenolol or metoprolol. It was proposed[5] that this may be because the metabolite accumulates during chronic dosage to reach concentrations that affect both $beta_1$ and $beta_2$ receptors since cardioselectivity is only a relative and dose-related phenomenon. This remains uncertain and there is some evidence[6] that at least after single doses, diacetolol is actually more cardioselective than acebutolol itself.

Administration in renal impairment. The dose of acebutolol should be reduced in patients with renal impairment. It is recommended that the dose should be reduced by 50% in patients with a creatinine clearance between 25 and 50 mL/minute and by 75% in those with a creatinine clearance of less than 25 mL/minute. The dose frequency should not exceed once daily.

Preparations

Acenocoumarol *(BAN, rINN)*

Acénocoumarol; Acenocoumarolum; Acenocumarin; Acenocumarol; Acenokumarol; Asenokumarol; G-23350; Nicoumalone; Nikumalon. (*RS*)-4-Hydroxy-3-[1-(4-nitrophenyl)-3-oxobutyl]-coumarin.

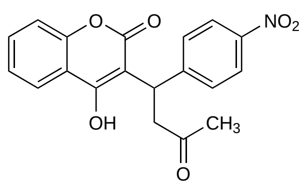
Аценокумарол

$C_{19}H_{15}NO_6$ = 353.3.

CAS — 152-72-7.

ATC — B01AA07.

ATC Vet — QB01AA07.



Pharmacopoeias. In *Br.* and *Pol.*

BP 2008 (Acenocoumarol). An almost white to buff-coloured odourless or almost odourless powder. It exhibits polymorphism. Practically insoluble in water and in ether; slightly soluble in alcohol and in chloroform; dissolves in aqueous solutions of alkali hydroxides.

Adverse Effects, Treatment, and Precautions

As for Warfarin Sodium, p.1425.

Effects on the fetus. In a group of women who received acenocoumarol for anticoagulant prophylaxis of mechanical heart valves during pregnancy,[1] fetal loss occurred in 13 of 61 pregnancies where oral anticoagulation was continued during the first trimester. Apart from 1 case of hydrocephalus no malformations were reported in the remaining neonates.

1. Meschengieser SS, *et al.* Anticoagulation in pregnant women with mechanical heart valve prostheses. *Heart* 1999; **82:** 23–6.

Interactions

The interactions associated with oral anticoagulants are discussed in detail under warfarin (p.1427). Specific references to interactions involving acenocoumarol can be found there under the headings for the following drug groups: analgesics; antiarrhythmics; antibacterials; antidepressants; antifungals; antigout drugs; antihistamines; antineoplastics; antiplatelets; antivirals; diuretics; gastrointestinal drugs; immunosuppressants; lipid regulating drugs; sex hormones; and vaccines.

Pharmacokinetics

Acenocoumarol is readily absorbed from the gastrointestinal tract and is excreted chiefly in the urine mainly as metabolites. It is extensively bound to plasma proteins. Figures reported for elimination half-life vary; UK licensed product information gives a range of 8 to 11 hours. Acenocoumarol crosses the placenta; only small quantities have been detected in breast milk. It is given as a racemic mixture; the *R*-isomer is more potent. The stereo-isomers have different pharmacokinetics. Metabolism of the *S*-isomer is mediated mainly by the cytochrome P450 isoenzyme CYP2C9, which shows genetic polymorphism; other isoenzymes as well are involved in the metabolism of the *R*-isomer.

◊ References.

1. Ufer M. Comparative pharmacokinetics of vitamin K antagonists: warfarin, phenprocoumon and acenocoumarol. *Clin Pharmacokinet* 2005; **44:** 1227–46.

Uses and Administration

Acenocoumarol is an oral coumarin anticoagulant with actions similar to those of warfarin (p.1432). It is used in the management of thromboembolic disorders (p.1187). The usual dose is 4 to 12 mg on the first day and 4 to 8 mg on the second day; subsequent maintenance doses range from 1 to 8 mg depending on the response. Acenocoumarol is given in a single dose at the same time every day.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (β-Acetyldigoxin). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in dichloromethane. Protect from light.

Profile

Acetyldigoxin is a cardiac glycoside with positive inotropic activity. It has the general properties of digoxin (p.1259) and has been used similarly in the management of some cardiac arrhythmias (p.1160) and in heart failure (p.1165). Usual oral maintenance doses for the β-isomer are 200 to 400 micrograms daily; the α-isomer has also been used.

Acipimox *(BAN, rINN)*

Acipimoxum; Asipimoks; Asipimoksi; K-9321. 5-Methylpyrazine-2-carboxylic acid 4-oxide.

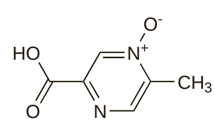
Аципимокс

$C_6H_6N_2O_3$ = 154.1.

CAS — 51037-30-0.

ATC — C10AD06.

ATC Vet — QC10AD06.



Adverse Effects and Precautions

Acipimox may cause peripheral vasodilatation resulting in flushing, itching, and a sensation of heat. Rash and erythema may occur. Gastrointestinal disturbances including heartburn, epigastric pain, nausea, and diarrhoea have been reported, as well as headache, malaise, myalgia, myositis, arthralgia, and dry eye. Urticaria, angioedema, and bronchospasm may occur rarely.

Acipimox is contra-indicated in patients with peptic ulcer disease. It should be used with caution in renal impairment.

Incidence of adverse effects. In a study involving 3009 hyperlipidaemic patients with type 2 diabetes,[1] adverse effects associated with acipimox occurred in 8.8%, resulting in withdrawal in 5.5% of patients. The most frequent adverse effects involved the skin (57.6%), gastrointestinal tract (25.8%), and CNS (9.7%). Labial oedema occurred in 3 cases and an urticarial eruption, collapse, and dyspnoea in another. The incidence of adverse effects was almost twice as high in females as in males, the difference being mainly due to a greater incidence of flushing, pruritus, and skin rashes. The incidence was not affected by age. There was a mean 15.3% reduction in fasting blood-glucose concentrations and an 8.5% reduction in glycosylated haemoglobin during treatment with acipimox.

1. Lavezzari M, *et al.* Results of a phase IV study carried out with acipimox in type II diabetic patients with concomitant hyperlipoproteinaemia. *J Int Med Res* 1989; **17:** 373–80.

Pharmacokinetics

Acipimox is rapidly and completely absorbed from the gastrointestinal tract and peak plasma concentrations occur within 2 hours. It does not bind to plasma proteins and the plasma half-life is about 2 hours. It is not significantly metabolised and is excreted in the urine, largely unchanged.

Uses and Administration

Acipimox is a lipid regulating drug related to nicotinic acid (p.1957). It is used to reduce cholesterol and triglycerides in the management of hyperlipidaemias (see Action, below), including type IIa, IIb, or IV hyperlipoproteinaemias.

Acipimox is given orally in a usual dose of 250 mg two or three times daily, taken with meals. Doses of up to 1200 mg daily have been used. The dose should be adjusted in renal impairment (see below).

Action. Acipimox is used in the management of hyperlipidaemias (p.1169); it is a derivative of nicotinic acid and has similar effects on plasma lipoproteins but is better tolerated.[1] Its primary action is inhibition of lipolysis, leading to a reduction in circulating free fatty acids and consequently a reduction in very-low-density lipoprotein (VLDL) production in the liver. This results in a reduction of triglycerides, particularly in patients with hypertriglyceridaemia;[2] there may also be a decrease in low-density lipoprotein (LDL)-cholesterol and total cholesterol, and an increase in high-density lipoprotein (HDL)-cholesterol. Similar effects have been reported in patients with mixed hyperlipoproteinaemias, although the reduction of triglycerides and LDL-cholesterol was not significant.[3]

Reduction of free fatty acids by acipimox has a number of other physiological effects that have been utilised. Insulin secretion and sensitivity may be modified, and acipimox has been tried in type 2 diabetes mellitus; it improves plasma lipids and may also reduce blood-glucose concentrations,[4] and has been of benefit in patients with type A insulin resistance.[5] Beneficial effects have also been reported[6] in patients with HIV-associated lipodystrophy and insulin resistance. Growth hormone secretion is stimulated in obese subjects, and acipimox has been used in the investigation of growth hormone disorders.[7] There is also an increase in glucose uptake by the heart, and acipimox has been used to enhance myocardial imaging in ^{18}F-fluorodeoxyglucose positron-emission tomography.[8]

Adenosine *(BAN, USAN)*

Adenocin; Adenosiini; Adenosin; Adenosina; Adénosine; Adenosinum; Adenozin; Adenozinas; Adenozyna; SR-96225; SUNY-4001. 6-Amino-9-β-D-ribofuranosyl-9*H*-purine.

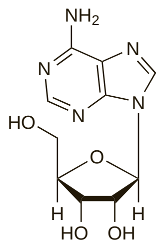
Аденозин

$C_{10}H_{13}N_5O_4$ = 267.2.

CAS — 58-61-7.

ATC — C01EB10.

ATC Vet — QC01EB10.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Adenosine). A white, or almost white, crystalline powder. Slightly soluble in water; soluble in hot water; practically insoluble in alcohol and in dichloromethane; dissolves in dilute mineral acids.

USP 31 (Adenosine). A white, odourless crystalline powder. Slightly soluble in water; practically insoluble in alcohol. Store in airtight containers. Protect from light.

Stability. Adenosine was found to be stable[1] when it was mixed with glucose 5%, lactated Ringer's, sodium chloride 0.9%, or a mixture of glucose 5% and lactated Ringer's and stored in polypropylene syringes or PVC bags.

1. Ketkar VA, *et al.* Stability of undiluted and diluted adenosine at three temperatures in syringes and bags. *Am J Health-Syst Pharm* 1998; **55:** 466–70.

Adverse Effects, Treatment, and Precautions

Adverse effects of adenosine are usually transient, lasting less than a minute, due to its very short plasma half-life. They include nausea, lightheadedness, flushing, headache, angina-like chest pain, apprehension, and dyspnoea. Bronchospasm has been reported. Like other antiarrhythmics, adenosine may worsen arrhythmias. Bradycardia and heart block have been reported. Adenosine is a vasodilator and reduces blood pressure; the larger doses given by intravenous infusion may rarely produce significant hypotension and reflex tachycardia. Infusion may also be associated with abdominal, throat, neck, and jaw discomfort. Treatment is rarely needed for adverse effects but in persistent cases aminophylline or theophylline may be given.

Adenosine is contra-indicated in patients with second- or third-degree AV block or in those with sick sinus syndrome (unless they have a pacemaker) and should be avoided or used with caution in patients with QT prolongation since torsade de pointes has occurred very rarely. It is also contra-indicated in asthmatic subjects and should be used with caution in patients with obstructive pulmonary disease. Intravenous infusion of adenosine should be used with caution in patients who may develop hypotensive complications such as those with autonomic dysfunction, pericarditis, or stenotic valvular heart disease. Patients with recent heart transplantation may have increased sensitivity to the cardiac effects of adenosine.

◊ Use of the *University of Wisconsin solution* [UW Solution; Belzer UW Solution (commercially available as *Viaspan*)] for the hypothermic storage of kidneys before transplantation has been associated with bradycardia, prolonged PR intervals, and heart block.[1,2] The solution contains hetastarch, allopurinol, glutathione, and adenosine. The adenosine was considered to be the arrhythmogenic factor. Some centres had used the solution to flush kidneys before implantation,[2] a use for which it was never intended.[3] When used properly the adenosine in solution is catabolised to hypoxanthine and inosine, which do not cause cardiac problems, but this takes some time in hypothermic conditions.[3]

2. Vanrenterghem Y, *et al.* University of Wisconsin preservation solute and bradyarrhythmia. *Lancet* 1989; **ii:** 745.
3. Belzer FO. Correct use of University of Wisconsin preservation solution. *Lancet* 1990; **335:** 362.

Effects on the heart. Like most antiarrhythmics, adenosine can worsen arrhythmias, and both bradyarrhythmias and tachyarrhythmias have been reported.[1] Atrial fibrillation may develop in patients given adenosine for paroxysmal supraventricular tachycardia, and in a prospective study[2] occurred in 12% of 200 patients. Although most arrhythmias are of minor importance, ventricular arrhythmias and haemodynamic compromise have been reported[3,4] in patients given adenosine for presumed supraventricular tachycardia who were later discovered to have Wolff-Parkinson-White syndrome. Fatal cardiac arrest has also occurred[5] after the use of adenosine for arrhythmias in 2 patients with underlying cardiopulmonary disorders.

There have also been reports[6,7] of myocardial infarction in patients with ischaemic heart disease given adenosine during stress imaging.

For arrhythmias associated with the use of adenosine in organ preservation solutions see above.

Effects on the respiratory system. Acute exacerbation of asthma can be provoked by inhalation of adenosine. Bronchospasm has also been reported in patients with asthma[1,2] or a history of asthma[3] given adenosine intravenously and bronchospasm followed by respiratory failure in a patient with obstructive pulmonary disease.[4] Respiratory arrest has also been reported in an asthmatic patient.[5]

Migraine. A 35-year-old man with a history of migraine developed symptoms identical to those of his usual episodes of migraine immediately after 2 intravenous bolus doses of adenosine.[1]

1. Brown SGA, Waterer GW. Migraine precipitated by adenosine. *Med J Aust* 1995; **162:** 389–91.

Interactions

Dipyridamole inhibits adenosine uptake and therefore may potentiate the action of adenosine; if use of the two drugs is essential the dosage of adenosine should be reduced. Theophylline and other xanthines are competitive antagonists of adenosine. The risk of AV block may be increased if adenosine is used with other drugs that slow AV conduction.

Pharmacokinetics

Intravenous adenosine is rapidly taken up by an active transport system into erythrocytes and vascular endothelial cells where it is metabolised to inosine and adenosine monophosphate. The plasma half-life is less than 10 seconds.

Uses and Administration

Adenosine is an endogenous adenine nucleoside that is one of the components of nucleic acids (p.2355) and many coenzymes; as such, it is involved in many biological processes. It acts as an antiarrhythmic by stimulating adenosine A_1-receptors and slowing conduction through the AV node. It does not fit into the usual classification of antiarrhythmics (p.1153). It also produces peripheral and coronary vasodilatation by stimulating adenosine A_2-receptors.

Adenosine is used to restore sinus rhythm in the treatment of paroxysmal supraventricular tachycardia, including that associated with the Wolff-Parkinson-White syndrome (but see Effects on the Heart, above). It is also used for the differential diagnosis of broad or narrow complex supraventricular tachycardias and in myocardial imaging.

In the treatment of **paroxysmal supraventricular tachycardia**, adenosine may be given in an initial dose of 3 mg by rapid intravenous injection. If this dose is not effective within 1 to 2 minutes, 6 mg may be given and if necessary, 12 mg after a further 1 to 2 minutes. Alternatively, an initial dose of 6 mg followed if necessary by two further doses of 12 mg at 1 to 2 minute intervals may be used, but this higher initial dose should not be given to heart transplant patients as they have an increased sensitivity to adenosine. For differential **diagnosis of supraventricular tachycardias** a similar dosage regimen is used, beginning with a dose of 3 mg followed by 6 mg and then 12 mg at 1 to 2 minute intervals if required. Doses for children with paroxysmal supraventricular tachycardia are discussed below.

In **myocardial imaging** adenosine is given by intravenous infusion in a dose of 140 micrograms/kg per minute for 6 minutes. The radionuclide is injected after 3 minutes of the infusion.

Adenosine and its derivatives, such as adenosine phosphate (p.2247) and adenosine triphosphate (p.2247), have been used in various metabolic disorders because of their role in biological processes. Adenosine triphosphate, as the disodium salt, has been used as an antiarrhythmic.

Administration in children. Adenosine may be used for the management of paroxysmal supraventricular tachycardia in children. Dosage recommendations vary. Licensed product information in the USA states that children weighing less than 50 kg, including neonates and infants, may be given an initial dose of 50 to 100 micrograms/kg; if this is not effective the dose may be increased by 50 to 100 micrograms/kg increments at 1 to 2 minute intervals until the arrhythmia is controlled or a single dose of 300 micrograms/kg is reached. Paediatric advanced cardiac life support guidelines[1] in the USA recommend an initial dose of 100 micrograms/kg (maximum 6 mg) followed by a second dose of 200 micrograms/kg (maximum 12 mg) if required, and are applicable to infants and children. In the UK, the BNFC recommends an initial dose of 100 micrograms/kg for children aged 1 to 12 years, or 150 micrograms/kg for neonates and infants up to 1 year; the dose may be increased by increments of 50 to 100 micrograms/kg at 2 minute intervals, to a maximum single dose of 300 micrograms/kg for neonates and 500 micrograms/kg for infants and children.

Cardiac arrhythmias. Adenosine is used for the termination of paroxysmal supraventricular tachycardia[1-4] (p.1160) and may often be the drug of choice. Bolus intravenous injection of adenosine produces a rapid response and the extremely short plasma half-life (less than 10 seconds) allows dosage titration every 1 to 2 minutes so that most episodes can be controlled within 5 minutes without the danger of drug accumulation.

Adenosine has been used successfully in pregnant women with paroxysmal supraventricular tachycardia[5-8] and cardioversion of fetal supraventricular tachycardia by direct fetal therapy with adenosine has been reported.[9,10]

Adenosine can be used for the differential **diagnosis** of broad complex tachycardia where the mechanism is not known.[1] If the cause is supraventricular, adenosine will terminate the arrhythmia or produce AV block to reveal the underlying atrial rhythm. If the cause is ventricular, adenosine will have no effect on the tachycardia, whereas if an alternative treatment such as verapamil is given to these patients severe hypotension and cardiac arrest can occur.

Ischaemic heart disease. Adenosine produces coronary vasodilatation and may be used to provide a pharmacological stress in patients undergoing assessment of their ischaemic heart disease when exercise stress is inappropriate.[1] It has been used with radionuclide imaging, echocardiography, and magnetic resonance imaging.

Adenosine has also been tried as an adjunct to prevent reperfusion injury in the management of acute myocardial infarction. Improved coronary blood flow has been reported[2] with intracoronary adenosine, and both intracoronary[3] and intravenous[4] adenosine have reduced infarct size, but no improvement in clinical outcomes has been shown.[5-7] A reduction in myonecrosis has also been reported[8] with intracoronary adenosine given at the start of non-urgent percutaneous coronary interventions.

Pain. Adenosine receptors are present in the CNS and there is some evidence[1,2] that adenosine, given intravenously or intrathecally, may have an analgesic effect.

Pulmonary hypertension. Vasodilators have been tried in persistent pulmonary hypertension of the newborn (p.1179), but their use is generally restricted by lack of selectivity for the pulmonary circulation. A randomised placebo-controlled study[1] in 18 term infants with persistent pulmonary hypertension indicated that intravenous infusion of adenosine improved oxygenation without causing hypotension or tachycardia; however, the study was too small to assess any effect on mortality and/or the need for extracorporeal membrane oxygenation. Another observational study[2] in neonates with an inadequate response to inhaled nitric oxide suggested that addition of adenosine infusion also improved oxygenation.

Multi-ingredient: *Belg.:* Vitacic; ***Braz.:*** Aminotox†; Anekron; Betaliver†; Biohepax; Enterofigon; Epativan; Epocler; Hepacitron†; Hepatobe†; Hepatox; Hormo Hepatico†; Necro B-6; ***Cz.:*** Laevadosin†; ***Hung.:*** Vitacic†; ***Mon.:*** Vitacic; ***Philipp.:*** Godex; ***Rus.:*** Oftan Catachrom (Офтан Катахром); Vitacic (Витасик)†; ***Spain:*** Vitaphakol.

Adrenaline *(BAN)* ⊗

Epinephrine *(BAN, rINN)*; Adrenaliini; Adrenalin; Adrenalina; Adrénaline; Adrenalinum; Epinefriini; Epinefrin; Epinefrina; Epinefryna; Épinéphrine; Epinephrinum; Epirenamine; Levorenin; Suprarenin. (*R*)-1-(3,4-Dihydroxyphenyl)-2-methylaminoethanol.

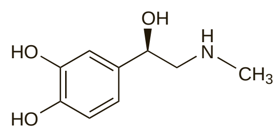
Эпинефрин

$C_9H_{13}NO_3$ = 183.2.

CAS — 51-43-4.

ATC — A01AD01; B02BC09; C01CA24; R01AA14; R03AA01; S01EA01.

ATC Vet — QA01AD01; QB02BC09; QC01CA24; QR01AA14; QR03AA01; QS01EA01.



NOTE. Endogenous adrenaline and the monograph substance are the laevo-isomer.

ADN and EPN are codes approved by the BP 2008 for use on single unit doses of eye drops containing adrenaline where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

US also includes the racemic substances Racepinephrine (Racepinefrine (*rINN*)) and Racepinephrine Hydrochloride (Racepinefrine Hydrochloride (*rINNM*)).

Ph. Eur. 6.2 (Adrenaline). A white or almost white crystalline powder, becoming coloured on exposure to air and light. Practically insoluble in water, in alcohol, and in dichloromethane. It dissolves in hydrochloric acid. Store under nitrogen. Protect from light.

USP 31 (Epinephrine). A white to practically white, odourless, microcrystalline powder or granules, gradually darkening on exposure to light and air. With acids, it forms salts that are readily soluble in water, and the base may be recovered by the addition of ammonia water or alkali carbonates. Very slightly soluble in water and in alcohol; insoluble in chloroform, in ether, and in fixed and volatile oils. Solutions are alkaline to litmus. Store in airtight containers. Protect from light.

Adrenaline Acid Tartrate *(BANM)* ⊗

Epinephrine Bitartrate *(rINNM)*; Adrenaliinitartraatti; Adrenaline Bitartrate; Adrenaline Tartrate; Adrénaline, Tartrate d'; Adrenalini Bitartras; Adrenalini tartras; Adrenalinii Tartras; Adrenalinium Hydrogentartaricum; Adrenalino tartratas; Adrenalin-tartarát; Adrenalintartrat; Bitartrato de epinefrina; Epinefrin-tartarát; Epinefryny wodorowinian; Epinephrine Acid Tartrate *(BANM)*; Épinéphrine, Bitartrate d'; Epinephrine Hydrogen Tartrate; Epinephrini Bitartras; Epinephrini Tartras; Epirenamine Bitartrate.

Эпинефрина Битартрат

$C_9H_{13}NO_3,C_4H_6O_6$ = 333.3.

CAS — 51-42-3.

ATC — A01AD01; B02BC09; C01CA24; R01AA14; R03AA01; S01EA01.

ATC Vet — QA01AD01; QB02BC09; QC01CA24; QR01AA14; QR03AA01; QS01EA01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Adrenaline Tartrate; Adrenaline Acid Tartrate BP 2008; Epinephrine Acid Tartrate BP 2008). A white to greyish-white, crystalline powder. Freely soluble in water; slightly soluble in alcohol. Store in airtight containers, or preferably in a sealed tube under vacuum or under an inert gas. Protect from light.

USP 31 (Epinephrine Bitartrate). A white, or greyish-white or light brownish-grey, odourless, crystalline powder. It slowly darkens on exposure to air and light. Soluble 1 in 3 of water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. Its solutions in water are acid to litmus, having a pH of about 3.5. Store in airtight containers. Protect from light.

Stability. Studies on the stability of adrenaline injections.

Adrenaline Hydrochloride *(BANM)* ⊗

Epinephrine Hydrochloride *(BANM, rINNM)*; Adrenalin Hidroklorür; Épinéphrine, Chlorhydrate d'; Epinephrini Hydrochloridum; Hidrocloruro de epinefrina.

Эпинефрина Гидрохлорид

$C_9H_{13}NO_3$,HCl = 219.7.

CAS — 55-31-2.

ATC — A01AD01; B02BC09; C01CA24; R01AA14; R03AA01; S01EA01.

ATC Vet — QA01AD01; QB02BC09; QC01CA24; QR01AA14; QR03AA01; QS01EA01.

Adverse Effects

Adrenaline is a potent sympathomimetic and may exhibit the adverse effects typical of both alpha- and beta-adrenoceptor stimulation (see p.1407). Adverse effects such as anxiety, dyspnoea, hyperglycaemia, restlessness, palpitations, tachycardia (sometimes with anginal pain), tremors, sweating, hypersalivation, weakness, dizziness, headache, and coldness of extremities may occur even with low doses. Since adrenaline does not readily cross the blood-brain barrier, its central effects may be largely a somatic response to its peripheral effects. Overdosage may cause cardiac arrhythmias and a sharp rise in blood pressure (sometimes leading to cerebral haemorrhage and pulmonary oedema); these effects may occur at normal dosage in susceptible subjects.

Adrenaline is a potent vasoconstrictor and gangrene may occur if adrenaline-containing local anaesthetic solutions are infiltrated into digits. Extravasation of parenteral adrenaline also results in intense vasoconstriction, leading to tissue necrosis and sloughing. Topical application of adrenaline to mucosal surfaces similarly causes vasoconstriction, which may induce hypoxia leading to compensatory rebound congestion of the mucosa. Inhalation of adrenaline has been associated with epigastric pain, which has been attributed to ingestion of some of the inhalation; it can be minimised by rinsing the mouth and throat with water after inhaling.

Adrenaline eye drops may produce severe smarting, blurred vision, and photophobia on instillation; they may also leave melanin-like deposits in the cornea and conjunctiva, and this has led to obstruction of the nasolachrymal ducts. Repeated use may cause oedema, hyperaemia, and inflammation of the eyes.

Effects on the eyes. In addition to the possibility of pigment deposition and local pain (see above) adrenaline eye drops have been associated with maculopathy, particularly in aphakic eyes (those devoid of a lens).[1] In one report,[2] maculopathy was noted in 15 patients over a period of 4 years; the patients were using adrenaline eye drops containing the hydrochloride, acid tartrate, or adrenaline borate complex (epinephryl borate). Blurring and distortion of vision were followed by decreased visual acuity, and by the appearance of oedema and sometimes haemorrhage in the macular region. A few patients developed cysts near the fovea. These effects appeared within a few weeks of, or several months after, starting therapy and were usually reversible. All except 1 of the patients were aphakic, and retrospective studies have suggested that the incidence of this complication may be up to 30% in aphakic patients.[1,2]

2. Kolker AE, Becker B. Epinephrine maculopathy. *Arch Ophthalmol* 1968; **79:** 552–62.

Overdosage. Solutions of racepinefrine for nebulisation have inadvertently been given intravenously, resulting in severe overdosage of adrenaline. A 13-month-old infant[1] was given the equivalent of about 327 micrograms/kg of laevo-adrenaline. Marked pallor, pulselessness, and profound bradycardia developed, but the child responded to cardiopulmonary resuscitation and was subsequently discharged with no evidence of long-term sequelae. However, a 2-year-old child[2] given the equivalent of about 1800 micrograms/kg developed hypertension, tachycardia, and pulmonary oedema, followed by hypotension and subsequent renal failure, requiring transplantation. Subcutaneous overdosage with laevo-adrenaline in another child[3] led to arrhythmias and myocardial ischaemia, and there has also been a report[4] of myocardial infarction and acute renal failure in an adult after injection of the solution from an adrenaline inhaler.

4. Woodard ML, Brent LD. Acute renal failure, anterior myocardial infarction, and atrial fibrillation complicating epinephrine abuse. *Pharmacotherapy* 1998; **18:** 656–8.

Treatment of Adverse Effects

As for Sympathomimetics, p.1407. Adrenaline has a short duration of activity due to inactivation in the body and treatment of severe toxic reactions in hypersensitive patients or after overdose is primarily supportive.

Digital injection. Inadvertent digital injection of adrenaline from autoinjector devices may cause acute ischaemia. Phentolamine injection has been successfully used to reverse the vasoconstriction,[1] and there has also been a report[2] of the use of iloprost infusion followed by a stellate ganglion block.

1. Velissariou I, *et al.* Management of adrenaline (epinephrine) induced digital ischaemia in children after accidental injection from an EpiPen. *Emerg Med J* 2004; **21:** 387–8.
2. Barkhordarian AR, *et al.* Accidental digital injection of adrenaline from an autoinjector device. *Br J Dermatol* 2000; **143:** 1359.

Precautions

As for Sympathomimetics, p.1407. Adrenaline is frequently used in emergency situations and any contra-indications are therefore relative.

Adrenaline may delay the second stage of labour and some licensed product information recommends that it should not be used during this time.

Adrenaline eye drops are contra-indicated in angle-closure glaucoma unless an iridectomy has been carried out.

Contact lenses. Adrenochrome staining of soft-contact lenses of patients using adrenaline eye drops has been reported.[1] Melanin deposits may also become locked into the lens; such deposits may be broken down by hydrogen peroxide. The prodrug, dipivefrine hydrochloride (p.2295) has been used without staining soft lenses.

1. Ingram DV. Spoiled soft contact lenses. *BMJ* 1986; **292:** 1619.

Infection. An open study[1] comparing adrenaline with dopamine for cardiovascular support in 23 patients critically ill with severe sepsis or malaria suggested that use of adrenaline was limited by the development of lactic acidosis. However, it has been pointed out[2] that 20 of the patients had responded to fluids, a situation in which the use of inotropic or vasopressor support was considered questionable, and that adrenaline has been widely used in the treatment of septic shock. A further controlled study[3] found that although adrenaline led to higher lactate concentrations than noradrenaline with dobutamine, the effect was transient. Nevertheless, it has been recommended[4] that adrenaline should only be used in septic shock if other treatments are ineffective.

Interactions

As for Sympathomimetics, p.1407; adrenaline has direct alpha- and beta-agonist actions and its interactions are complex and may be hazardous. Particular caution is needed if adrenaline is given to patients taking beta blockers since severe hypertension may result; patients taking beta blockers may also have an impaired response to adrenaline if it is needed for anaphylaxis.

Local anaesthetics. It is common practice to give adrenaline with a local anaesthetic to produce vasoconstriction; the lowest effective concentration of adrenaline should be used. However, use with *cocaine* may increase the risk of cardiac arrhythmias and particular caution is required. See p.1860 for a report of severe complications with use of such a combination in otolaryngology.

Pharmacokinetics

As a result of enzymatic degradation in the gut and first-pass metabolism in the liver, adrenaline is almost totally inactive when given orally. Systemic absorption can occur after topical application for example of eye drops. Adrenaline acts rapidly after intramuscular and subcutaneous injection; the latter route is, however, sometimes considered to be slower and therefore less reliable for emergency use. Although absorption is slowed by local vasoconstriction it can be hastened by massaging the injection site.

Most adrenaline that is either injected into the body or released into the circulation from the adrenal medulla, is very rapidly inactivated by processes that include uptake into adrenergic neurones, diffusion, and enzymatic degradation in the liver and body tissues. The half-life of circulating adrenaline is only about 1 minute. One of the enzymes responsible for the chemical inactivation of adrenaline is catechol-*O*-methyltransferase (COMT), the other is monoamine oxidase (MAO). In general, adrenaline is methylated to metanephrine by COMT followed by oxidative deamination by MAO and eventual conversion to 4-hydroxy-3-methoxymandelic acid (formerly termed vanillylmandelic acid; VMA), or oxidatively deaminated by MAO and converted to 3,4-dihydroxymandelic acid which, in turn, is methylated by COMT, once again to 4-hydroxy-3-methoxymandelic acid; the metabolites are excreted in the urine mainly as their glucuronide and ethereal sulfate conjugates.

The ability of COMT to effect introduction of a methyl group is an important step in the chemical inactivation of adrenaline and similar catecholamines (in particular, noradrenaline). It means that the termination of the pharmacological response of catecholamines is not simply dependent upon MAO. In its role of neurotransmitter intraneuronal catecholamine (mainly noradrenaline) is, however, enzymatically regulated by MAO.

Adrenaline crosses the placenta to enter fetal circulation.

Uses and Administration

Adrenaline is an endogenous substance that is produced in the adrenal medulla and has important physiological effects. It is also used pharmacologically as a direct-acting sympathomimetic (see p.1408). It is a potent agonist at both alpha and beta adrenoceptors, although the effect on beta adrenoceptors is more marked, particularly at lower doses. These properties explain many aspects of its pharmacology, although the reflex compensating responses of the body also modulate its effects.

The major effects of adrenaline are dose-related and include:

- increased speed and force of cardiac contraction (with lower doses this causes increased systolic pressure yet reduced diastolic pressure since overall peripheral resistance is lowered, but with higher doses both systolic and diastolic pressure are increased as stimulation of peripheral alpha receptors increases peripheral resistance)
- increased blood flow to skeletal muscle (reduced with higher doses); reduced blood flow in the kidneys, mucosa, and skin; little direct effect on cerebral blood flow
- relaxation of bronchial smooth muscle
- hyperglycaemia and markedly increased oxygen consumption due to metabolic effects

Adrenaline has an important role in the management of acute allergic reactions and can be life-saving in patients with anaphylaxis and anaphylactic shock (below). It is also used in advanced cardiac life support (below). Adrenaline has been used in the treatment of acute asthma but more selective drugs are available, and it has no role in the chronic management of asthma (p.1108). It has been given by nebulisation in severe croup (p.1502). Other uses include the control of minor bleeding from the skin and mucous membranes, the management of open-angle (simple) glaucoma (p.1873), and use as an adjunct to local anaesthesia (p.1852). Adrenaline was formerly incorporated into creams used in the treatment of rheumatic and muscular disorders, and in rectal preparations used in the treatment of haemorrhoids. Racepinefrine (racemic adrenaline) and racepinefrine hydrochloride have been used for bronchodilatation.

Adrenaline is usually given by intramuscular injection, although it may also be given subcutaneously. In extreme emergencies, where a more rapid effect is required, adrenaline may be given as a dilute solution (1 in 10 000 or 1 in 100 000) by very slow intravenous injection or by slow intravenous infusion. Alternatively, if intravenous access cannot be obtained, it may also be given by the intraosseous (usually into the marrow of the tibia) or endotracheal routes. Adrenaline has sometimes been injected directly in the heart but current guidelines for the management of cardiac emergencies recommend intravenous injection; this may be into a central vein or peripherally, but in the latter case should be followed by 20 mL of intravenous fluid. Adrenaline may also be applied topically or given by inhalation. Aqueous solutions of adrenaline are usually prepared using the acid tartrate or the hydrochloride but the dosage is generally stated in terms of the equivalent content of adrenaline. Adrenaline acid tartrate 1.8 mg or adrenaline hydrochloride 1.2 mg is equivalent to about 1 mg of adrenaline.

The usual dose of adrenaline in **anaphylactic shock** is 500 micrograms (0.5 mL of a 1 in 1000 solution) by intramuscular injection repeated as necessary every 5 minutes. A dose of 300 micrograms (0.3 mL of a 1 in 1000 solution) may be appropriate for emergency self-administration, for example by autoinjector. The dose for children depends on age and weight, but is usually about 10 micrograms/kg by intramuscular injection. For further details on doses for children and for intravenous doses, see Anaphylaxis and Anaphylactic Shock, below.

In **advanced cardiac life support** the initial dose of adrenaline for adults is 1 mg intravenously (10 mL of a 1 in 10 000 solution) and this may be repeated as often as every 2 to 3 minutes throughout the resuscitation procedure. The dose for children is 10 micrograms/kg intravenously. Higher intravenous doses have been used in both adults and children for the second and subsequent doses but are no longer generally recommended. Intraosseous doses for adults and children are the same as those used intravenously. Endotracheal doses for adults are 2 to 3 times the intravenous dose; children may be given 100 micrograms/kg.

Adrenaline relaxes the bronchial musculature and has sometimes been injected subcutaneously or intramuscularly in the management of **acute asthmatic attacks**. However, in general, the use of adrenaline in asthma has been superseded by beta$_2$ agonists, such as salbutamol, which can alleviate bronchospasm with fewer effects on the heart. If adrenaline is to be used, the adult dose is 0.3 to 0.5 mL of a 1 in 1000 aqueous solution (300 to 500 micrograms); children have received 0.01 mL/kg (10 micrograms/kg) to a maximum of 0.5 mL (500 micrograms). Aqueous solutions with an adrenaline content equivalent to 1 in 100 have occasionally been used by inhalation as a spray to alleviate asthmatic attacks; these solutions must never be confused with the weaker strength used for injection. Pressurised aerosols delivering metered doses equivalent to about 160 micrograms to 275 micrograms of adrenaline have also been used; adults have been given 1 or 2 metered inhalations, repeated, if necessary, after 3 hours.

Adrenaline is often added to **local anaesthetics** to retard diffusion and limit absorption, to prolong the duration of effect, and to lessen the danger of toxicity. A concentration of 1 in 200 000 (5 micrograms/mL) is usually used; adrenaline should not be added when procedures involve digits, ears, nose, penis, or scrotum because of the risk of ischaemic tissue necrosis. A concentration of up to 1 in 80 000 (12.5 micrograms/mL) may be used in dental preparations where the total dose given is small.

Adrenaline constricts arterioles and capillaries and causes blanching when applied locally to mucous membranes and exposed tissues. It is used as an aqueous solution in strengths up to a 1 in 1000 dilution to check capillary **bleeding**, epistaxis, and bleeding from superficial wounds and abrasions, but it does not stop internal haemorrhage. It is usually applied as a spray or on pledgets of cotton wool or gauze.

In ophthalmology, adrenaline solutions of 0.5%, 1%, or 2% are used as eye drops instilled once or twice daily to reduce intra-ocular pressure in open-angle **glaucoma** and ocular hypertension. An adrenaline borate complex (epinephryl borate) is also used.

Advanced cardiac life support. Adrenaline has an important role in advanced cardiac life support (p.1156) since, through its alpha agonist effects, it causes peripheral vasoconstriction, thus increasing myocardial and cerebral blood flow. This should improve the efficacy of cardiopulmonary resuscitation or basic life support procedures, although there is no clinical study evidence for benefit.[1] Depending on the arrhythmia that has led to cardiac arrest, treatment starts with cardiopulmonary resuscitation and defibrillation. If these measures fail to restore a conventional rhythm, the next step involves the use of adrenaline.

For **adults**, adrenaline is given in a dose of 1 mg, ideally intravenously into a central vein. If such venous access is not practicable adrenaline may be given through a peripheral vein followed by a flush of 20 mL or more of sodium chloride injection; however, the response is slower than with central venous injection. This intravenous dose of 1 mg may be given about every 3 to 5 minutes[2-5] in further cycles of cardiopulmonary resuscitation and, if necessary, shocks. A higher dose of 5 mg or 100 micrograms/kg has been given but there is insufficient evidence of benefit and this is not recommended.[2-5] In ventricular fibrillation or pulseless ventricular tachycardia, a resuscitation attempt may reasonably last for anything from 10 minutes to 1 hour with adrenaline being given every 3 to 5 minutes during this period. Where the arrest is associated with asystole it is unlikely that a response will be achieved after 15 to 20 minutes.

The initial dose of 1 mg is reported to be based on the dose that was given by intracardiac injection, so it would be expected that a higher dose would be required for intravenous use. Although myocardial and cerebral perfusion are increased more with higher doses, a meta-analysis[6] of studies in adults found no evidence that this gave any survival benefit.

The intravenous dose for **children** is 10 micrograms/kg. Higher doses of 100 or 200 micrograms/kg have been used for the second and subsequent doses; however, as with adults, the use of the higher dose is not routinely recommended and both retrospective[7] and prospective[8] studies have found no improvement in outcome.

The intraosseous route is a practicable alternative to intravenous injection for adults as well as for children; doses are identical to those given intravenously. Alternatively, adrenaline can be given through the endotracheal tube that will have been inserted, but only if the intravenous or intraosseous route is unavailable. Endotracheal doses for adults should be 2 to 3 times those used intravenously; for children doses of 100 micrograms/kg have been suggested. The adrenaline solution should be diluted and administered deeply using a catheter; several rapid ventilations or inflations should follow. It is recognised that the endotracheal route is imperfect[2-4] and some workers consider it to be ineffective.[9]

Although covering a somewhat different clinical situation some guidelines also include resuscitation of newborn infants (during the first few hours after birth).[2-5] Adrenaline may be used when the heart rate remains below 60 beats/minute despite adequate ventilation and chest compression. The dose of adrenaline is 10 to 30 micrograms/kg given intravenously (generally into the umbilical vein) or by intraosseous injection. If neither of these routes are available, it may be given via the endotracheal tube; standard doses are probably ineffective[10] and doses of up to 100 micrograms/kg may be required, although there is little evidence to support this.[2,4,5]

Anaphylaxis and anaphylactic shock. Anaphylaxis is usually a type 1 hypersensitivity reaction (p.561) in which there is IgE-mediated activation of mast cells and basophils, usually as a result of exposure to allergens such as drugs, foods, latex, and insect venoms. A clinically identical reaction can, however, be provoked by a type II mechanism, as in blood transfusion reactions, or a type III mechanism, as in drug-induced serum sickness reactions; anaphylactoid reactions are similar, but are caused by direct histamine release rather than hypersensitivity. Symptoms of anaphylaxis and anaphylactoid reactions include erythema, pruritus, urticaria, and angioedema; respiratory obstruction may result from oedema of the larynx or epiglottis. Gastrointestinal disturbances, bronchospasm, hypotension, and coma can occur in severe reactions.

Anaphylaxis is a medical emergency and prompt treatment of laryngeal oedema, bronchospasm, and hypotension is necessary. Adrenaline causes bronchodilatation and peripheral vasoconstriction, reducing oedema and increasing blood pressure, and is the cornerstone of management.[1-11] However, it may not always be effective,[5] and its use is not without hazard.[12] Antihistamines and corticosteroids may also have a role.

In early anaphylaxis, adrenaline is given by intramuscular injection. At this stage, vasodilatation is the main pathological change and cardiac output and blood flow to skin and muscle may be increased enabling intramuscular absorption of adrenaline to be sufficiently rapid and effective. The subcutaneous route has been used, especially by patients treating themselves, but intramuscular absorption is more rapid and is generally preferred.[3,5,6] Prefilled syringes for intramuscular or subcutaneous use may be given to those known to be at high risk of developing anaphylactic shock, allowing patients to self-administer their initial emergency treatment; however, they should still seek medical assistance as additional treatment may be required. Adrenaline has been given by inhalation in milder reactions, often with an antihistamine.[13] However, this should not be a substitute for adrenaline injection in patients with severe symptoms or a history of acute attacks, and the number of inhalations required may limit the use of this route in children.[14] As anaphylaxis progresses the intravascular volume becomes depleted, leading to the development of shock. At this stage it is probably necessary to give adrenaline intravenously, since absorption from other routes will be compromised; however, this route is hazardous and should only be used in life-threatening situations,[3,5,12] and by those experienced in its use.[5] The general principles used in the management of hypovolaemia and hypotension in shock are outlined on p.1183.

The dose of adrenaline for intramuscular injection is usually 500 micrograms (0.5 mL of a 1 in 1000 solution); this may be repeated at 5-minute intervals, according to blood pressure and pulse, until improvement occurs. A lower dose of 300 micrograms may be used,[3] and may be the highest dose available as an auto-injector.[5] Similar doses have been given subcutaneously. A more dilute solution of 1 in 10 000 is used intravenously; the dose is 500 micrograms (5 mL) given slowly at a rate of 100 micrograms/minute (1 mL/minute), stopping when a response has been obtained.[3] Alternatively, the UK Resuscitation Council recommends[5] that an intravenous bolus dose of 50 micrograms should be given, titrated according to response.

Various adrenaline dosage regimens have been suggested for children,[2,5,6] although there is little evidence to guide choice.[15] Most regimens are based on a dose of 10 micrograms/kg, and the following age-specific intramuscular doses, given as a 1 in 1000 solution, have been widely used:

- under 6 months: 50 micrograms (0.05 mL)
- 6 months to 6 years: 120 micrograms (0.12 mL)
- 6 to 12 years: 250 micrograms (0.25 mL)

However, to simplify dosing, particularly where auto-injectors are used, the UK Resuscitation Council now recommends[5] an intramuscular dose of 150 micrograms (0.15 mL) for children aged 6 years and younger (including those under 6 months) and 300 micrograms (0.3 mL) for those aged over 6 years; children aged over 12 years may be given 300 or 500 micrograms depending on body size and pubertal status. This may represent a relative overdose in children aged under 6 months but this may be considered acceptable if it allows an auto-injector to be used.[15] Intravenous therapy should only be used in specialist paediatric settings.[5] The *BNFC* recommends use of the 1 in 10 000 solution in a dose of 1 microgram/kg, given by slow intravenous injection over several minutes, repeated as required; a maximum single dose of 50 micrograms should not be exceeded.

A slow intravenous injection of an antihistamine, such as chlorphenamine, may be given immediately after the adrenaline and repeated over the next 24 to 48 hours to prevent relapse. Although antihistamines are particularly effective in the management of angioedema, pruritus, and urticaria, they remain second-line treatment. Intravenous corticosteroids have little place in the immediate management of anaphylaxis, since their beneficial effects are delayed for several hours, but in severely ill patients early use of hydrocortisone may help prevent deterioration after the primary treatment has been given. Patients should also be given oxygen as required.

Continuing deterioration with circulatory collapse, bronchospasm, or laryngeal oedema requires further treatment including intravenous fluids, a nebulised beta$_2$ agonist (such as salbutamol or terbutaline), intravenous aminophylline, assisted respiration (if necessary), and possibly, emergency tracheostomy.[3,4]

Patients taking non-cardioselective beta blockers may be relatively refractory to the effects of adrenaline used for anaphylactic shock (see Interactions for Sympathomimetics, p.1407); in such cases the use of a more selective beta$_2$ agonist such as salbutamol by intravenous injection should be considered. Glucagon is another alternative to adrenaline in such patients.[3,16] Vasopressin has also been used successfully,[17] including in a patient who failed to respond to adrenaline.

Prevention of anaphylaxis is important[7,8] and primarily involves avoidance of known allergens; other measures include desensitisation, particularly in patients who have reacted to bee or wasp venom.

Haemorrhage. Adrenaline has a long history of topical use to check minor bleeding. It constricts arterioles and capillaries and causes blanching. Local injection of adrenaline under endoscopic control is highly effective in controlling bleeding peptic ulcers (p.1702), and has also been combined with other therapies such as a contact thermal probe.[1] Nebulised adrenaline has been reported[2] to successfully control oropharyngeal haemorrhage.

2. Rowlands RG, *et al.* Novel use of nebulised adrenaline in the treatment of secondary oropharyngeal haemorrhage. *J Laryngol Otol* 2002; **116:** 123–4.

Priapism. Alpha agonists such as adrenaline may be effective in the treatment of priapism (see under Metaraminol, p.1333). Low doses of dilute adrenaline solution have been given by intracavernosal injection in priapism caused by alprostadil (see p.2184). Aspiration of blood followed by intracavernosal irrigation with a dilute adrenaline solution was also reported to be effective treatment for priapism in a group of young patients (age range, 3.9 to 18.3 years) with sickle-cell disease.[1]

1. Mantadakis E, *et al.* Outpatient penile aspiration and epinephrine irrigation for young patients with sickle cell anemia and prolonged priapism. *Blood* 2000; **95:** 78–82.

Respiratory-tract disorders. Nebulised adrenaline may be used to reverse airway obstruction in inflammatory disorders such as croup since it relieves inflammation and also causes bronchodilatation. Although some studies in acute viral bronchiolitis (see Respiratory Syncytial Virus Infection, p.860) have shown improvement in clinical scores,[1,2] randomised studies have failed to find any difference in outcome between infants treated with adrenaline and either salbutamol[3] or placebo.[4] A systematic review[5] found insufficient evidence to support the use of adrenaline in inpatients, although there was a suggestion that it might be of short-term benefit in outpatients.

However, the *BNF* states that for severe croup not effectively controlled with corticosteroids, nebulised adrenaline solution 1 in 1000 may be given with close clinical monitoring in a dose of 400 micrograms/kg (up to a maximum of 5 mg) repeated after 30 minutes if necessary. The effects of nebulised adrenaline are expected to last 2 to 3 hours.

There has also been a report[6] of the successful use of nebulised adrenaline in a 15-month-old child with airway inflammation secondary to the ingestion of sodium hypochlorite.

Adverse Effects

Ajmaline depresses the conductivity of the heart, and at high doses can cause heart block. At very high doses it may produce a negative inotropic effect. High doses may cause cardiac arrhythmias, coma, and death. Arrhythmias have also been reported after usual intravenous doses (see below). Adverse neurological effects have been reported including eye twitching, convulsions, and respiratory depression. Hepatotoxicity and agranulocytosis may occasionally occur.

Effects on the heart. Electrophysiologic study[1] in 1955 patients revealed that ajmaline 1 mg/kg given intravenously could induce arrhythmias; 63 developed a supraventricular arrhythmia and 7 an atrioventricular re-entrant tachycardia. Ventricular tachycardia[2,3] and torsade de pointes[4] have been reported during diagnostic use.

1. Brembilla-Perrot B, Terrier de la Chaise A. Provocation of supraventricular tachycardias by an intravenous class I antiarrhythmic drug. *Int J Cardiol* 1992; **34:** 189–98.

3. Pinar Bermúdez E, *et al.* Spontaneous sustained monomorphic ventricular tachycardia after administration of ajmaline in a patient with Brugada syndrome. *Pacing Clin Electrophysiol* 2000; **23:** 407–9.
4. Haverkamp W, *et al.* Torsade de pointes induced by ajmaline. *Z Kardiol* 2001; **90:** 586–90.

Precautions

As for Quinidine, p.1384.

Interactions

Antiarrhythmics. Oral use of *quinidine* with ajmaline increased plasma concentrations of ajmaline considerably in 4 healthy subjects; the elimination half-life of ajmaline was increased about twofold.[1] The pharmacokinetics of quinidine did not seem to be affected by ajmaline.

1. Hori R, *et al.* Quinidine-induced rise in ajmaline plasma concentration. *J Pharm Pharmacol* 1984; **36:** 202–4.

Uses and Administration

Ajmaline is an alkaloid obtained from the root of *Rauwolfia serpentina* (Apocynaceae). It is a class Ia antiarrhythmic (p.1153) used in the treatment of supraventricular and ventricular arrhythmias (p.1160) and for differential diagnosis of Wolff-Parkinson-White syndrome. Ajmaline is given by intravenous injection in a usual dose of 50 mg over at least 5 minutes. It may also be given by intravenous infusion, and has been given orally and by intramuscular injection.

Ajmaline has also been used as the hydrochloride, monoethanolate, and phenobarbital salts.

Brugada syndrome. Brugada syndrome is a congenital disorder affecting myocardial sodium channels and may be associated with sudden cardiac death. Class 1a antiarrhythmics such as ajmaline block the sodium channel and may have a role in the diagnosis of Brugada syndrome, although they are not suitable for treatment.

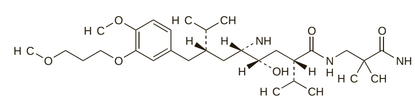
ATC — C09XA02.
ATC Vet — QC09XA02.



(aliskiren)

Adverse Effects and Precautions

Aliskiren is generally well-tolerated but may produce dose-related gastrointestinal adverse effects including diarrhoea, abdominal pain, dyspepsia, and gastro-oesophageal reflux. Other adverse effects include hypotension, headache, dizziness, fatigue, back pain, and cough; rashes, hyperuricaemia, gout, and renal calculi may also occur. Angioedema has been reported rarely, and there have also been reports of seizures. As with other inhibitors of the renin-angiotensin system, dose-related decreases in haemoglobin have been reported.

Aliskiren should be avoided in pregnancy since drugs acting on the renin-angiotensin system have been associated with fetal and neonatal morbidity and mortality. It should be used with caution in patients with renal impairment or renovascular hypertension. Patients with sodium or volume depletion (for example those receiving high-dose diuretics) may experience symptomatic hypotension on starting aliskiren and treatment should begin under close medical supervision.

Interactions

Use of aliskiren with other antihypertensives or drugs that cause hypotension may have an additive effect. Renal function and electrolytes should be monitored in diabetic patients taking aliskiren and ACE inhibitors since there is an increased risk of hyperkalaemia and renal impairment.

Aliskiren is metabolised to a small extent by the cytochrome P450 isoenzyme CYP3A4 but few significant interactions have been reported. Plasma-aliskiren concentrations may be reduced by irbesartan and increased by atorvastatin and ketoconazole but the clinical relevance is not clear. Aliskiren has caused significant decreases in furosemide concentrations.

Pharmacokinetics

Aliskiren is poorly absorbed from the gastrointestinal tract with a bioavailability of about 2.5%. Peak plasma concentrations are reached about 1 to 3 hours after an oral dose. Absorption is reduced when aliskiren is taken with a high-fat meal. Aliskiren is about 50% bound to plasma proteins. It is excreted mainly in the faeces, possibly via the bile; about 25% of the absorbed dose is excreted in the urine as unchanged drug. Aliskiren is a substrate for the cytochrome P450 isoenzyme CYP3A4 but metabolism appears to be minimal. The elimination half-life is about 24 to 40 hours, and steady-state concentrations are reached in about 7 to 8 days.

Uses and Administration

Aliskiren is an orally active renin inhibitor used in the management of hypertension; it prevents the conversion of angiotensinogen into angiotensin I and therefore inhibits the production of angiotensin II and aldosterone. It is given as the fumarate, although licensed product information in some countries specifies the base. Doses are expressed in terms of the base; 165.8 mg of aliskiren fumarate is equivalent to about 150 mg of aliskiren. The usual initial oral dose of aliskiren is 150 mg once daily, increased to 300 mg once daily if necessary. Doses may be taken before or after food, but patients should establish a routine pattern with regard to meals.

Aliskiren is also under investigation in heart failure and diabetic nephropathy.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*
Ph. Eur. 6.2 (Alprenolol Hydrochloride). A white, or almost white, crystalline powder or colourless crystals. Very soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.

Profile

Alprenolol is a non-cardioselective beta blocker (p.1225). It is reported to have intrinsic sympathomimetic activity and some membrane-stabilising properties.

Alprenolol has been given orally, as the benzoate or hydrochloride, in the management of hypertension, angina pectoris, and cardiac arrhythmias.

Alteplase *(BAN, USAN, rINN)*

Alteplaasi; Alteplas; Alteplasa; Altéplase; Alteplasum; Alteplaz; G-11035; G-11044; G-11021 (2-chain form); Recombinant Tissue-type Plasminogen Activator; rt-PA.

Альтеплаза

CAS — 105857-23-6.
ATC — B01AD02; S01XA13.
ATC Vet — QB01AD02; QS01XA13.

Description. Alteplase is a glycosylated protein of 527 residues having the amino acid sequence of human tissue plasminogen activator (t-PA) and produced by recombinant DNA technology.

Pharmacopoeias. In *US. Eur.* (see p.vii) includes Alteplase for Injection.
Ph. Eur. 6.2 (Alteplase for Injection; Alteplasum ad Iniectabile). A sterile, freeze-dried preparation of alteplase, a tissue plasminogen activator produced by recombinant DNA technology. It has a potency of not less than 500 000 units/mg of protein. It is a white or slightly yellow powder or friable mass. The reconstituted preparation has a pH of 7.1 to 7.5. Store in colourless glass containers, under vacuum or an inert gas, at a temperature between 2° and 30°. Protect from light. Alteplase consists of 527 amino acids with carbohydrate moieties attached.
USP 31 (Alteplase). A highly purified glycosylated serine protease with fibrin-binding properties and plasminogen-specific proteolytic activities. It is produced by recombinant DNA synthesis in mammalian cell culture. It has a potency of 522 000 to 667 000 USP units/mg of protein. Store in airtight containers in the frozen state at a temperature of –20° or below.

Incompatibility and stability. Alteplase has been reported[1] to be incompatible with dobutamine, dopamine, glyceryl trinitrate, and heparin, although a subsequent study found no incompatibility between alteplase and glyceryl trinitrate.[2] Another study[3] found that dilution of a proprietary preparation of alteplase (Activase) to 0.09 and 0.16 mg/mL with glucose 5% resulted in precipitation of the drug. Alteplase is formulated with arginine as a solubilising agent, and dilution with glucose 5% to concentrations below 0.5 mg/mL of alteplase makes precipitation possible. Dilution with sodium chloride 0.9% is possible to concentrations down to 0.2 mg/mL before precipitation becomes a risk.

Studies[4,5] have suggested that a 1 mg/mL solution of alteplase retains its activity when frozen at –20° or below for up to 6 months.

5. Wiernikowski JT, *et al.* Stability and sterility of recombinant tissue plasminogen activator at –30°C. *Lancet* 2000; **355:** 2221–2.

Units

The activity of alteplase can be measured in terms of international units using the third International Standard for tissue plasminogen activator recombinant, human, established in 1999, although doses are generally expressed by weight.

Adverse Effects, Treatment, and Precautions

As for Streptokinase, p.1402. Allergic reactions are less likely with alteplase than with streptokinase and repeated use may be possible.

Hypersensitivity. An anaphylactoid reaction to alteplase occurred in a patient with a history of atopy.[1] For comment on this unexpected reaction, see Hypersensitivity under Adverse Effects of Streptokinase, p.1404. (See also ACE Inhibitors under Interactions, below).

1. Purvis JA, *et al.* Anaphylactoid reaction after injection of alteplase. *Lancet* 1993; **341:** 966–7.

Thrombin generation. Alteplase produces considerable thrombin generation which may result from direct activation of the coagulation system by plasmin or by positive feedback of the coagulation system by clot-bound thrombin. This excessive thrombin generation was considered a possible cause of myocardial infarction in a patient undergoing thrombolytic therapy with alteplase for venous thrombosis.[1] Streptokinase produced no evidence of excessive thrombin generation.

1. Baglin TP, *et al.* Thrombin generation and myocardial infarction during infusion of tissue-plasminogen activator. *Lancet* 1993; **341:** 504–5.

Interactions

As for Streptokinase, p.1404.

ACE inhibitors. Angioedema has been reported rarely in patients treated with alteplase, but the risk may be increased in those taking ACE inhibitors. A prospective study[1] found that out of 176 patients treated with alteplase for acute stroke, 9 developed angioedema; the risk was strongly associated with use of an ACE inhibitor (7 of the 9).

1. Hill MD, *et al.* Hemi-orolingual angioedema and ACE inhibition after alteplase treatment of stroke. *Neurology* 2003; **60:** 1525–7.

Glyceryl trinitrate. Although thrombolytics and nitrates are both frequently used in acute myocardial infarction a report suggested that this combination may result in impaired thrombolysis. Giving alteplase and glyceryl trinitrate intravenously to 36 patients with acute myocardial infarction produced lower plasma-antigen concentrations of tissue-plasminogen activator than alteplase given alone to 11 patients.[1] Reperfusion was sustained in only 44% of patients receiving both drugs compared with 91% of patients given alteplase alone. The authors of a subsequent study[2] suggested that these lower plasma concentrations may be due to increased hepatic metabolism of alteplase as a result of glyceryl trinitrate's effect of increasing hepatic blood flow.

1. Nicolini FA, *et al.* Concurrent nitroglycerin therapy impairs tissue-type plasminogen activator-induced thrombolysis in patients with acute myocardial infarction. *Am J Cardiol* 1994; **74:** 662–6.
2. Romeo F, *et al.* Concurrent nitroglycerin administration reduces the efficacy of recombinant tissue-type plasminogen activator in patients with acute anterior wall myocardial infarction. *Am Heart J* 1995; **130:** 692–7.

Pharmacokinetics

Alteplase is cleared rapidly from the plasma, mainly by metabolism in the liver. It has an initial half-life of 4 to 5 minutes and a terminal half-life of about 40 minutes.

◊ References.

1. Krause J. Catabolism of tissue-type plasminogen activator (t-PA), its variants, mutants and hybrids. *Fibrinolysis* 1988; **2:** 133–42.

Uses and Administration

Alteplase is a thrombolytic drug. It is a mainly single-chain form of the endogenous enzyme tissue plasminogen activator and is produced by recombinant DNA technology. Like endogenous tissue plasminogen activator, alteplase converts fibrin-bound plasminogen to the active form plasmin, resulting in fibrinolysis and dissolution of clots. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045. Alteplase has relatively little effect on circulating, unbound plasminogen and thus may be termed a fibrin-specific thrombolytic (see p.1156).

Alteplase is used similarly to streptokinase (p.1404) in the treatment of thromboembolic disorders, particularly myocardial infarction (p.1175) and venous thromboembolism (p.1189), and to clear occluded catheters (see below). Alteplase may also be used in patients with acute ischaemic stroke (p.1185).

In the treatment of acute **myocardial infarction**, alteplase is given intravenously as soon as possible after the onset of symptoms in a total dose of 100 mg; the total dose should not exceed 1.5 mg/kg in patients weighing less than 65 kg. The total dose may be given either over 1½ hours (accelerated or 'front-loaded' alteplase) or over 3 hours. The accelerated schedule has been recommended if given within 6 hours of myocardial infarction, while the 3-hour schedule has been recommended when used more than 6 hours after myocardial infarction. The schedule over $1\frac{1}{2}$ hours is as follows: 15 mg as an intravenous bolus, then 0.75 mg/kg, up to a maximum of 50 mg, by intravenous infusion over 30 minutes, followed by the remainder infused over the subsequent 60 minutes. The schedule over 3 hours is as follows: 10 mg as an intravenous bolus, then 50 mg by intravenous infusion over 1 hour, followed by the remainder infused over the subsequent 2 hours.

In the treatment of acute, massive **pulmonary embolism** a total dose of 100 mg is given; the total dose should not exceed 1.5 mg/kg in patients weighing less than 65 kg. The first 10 mg is given as an intravenous bolus and the remainder by intravenous infusion over 2 hours.

In acute **ischaemic stroke**, alteplase is given within 3 hours of the onset of symptoms in a dose of 0.9 mg/kg up to a maximum total dose of 90 mg. The dose is given intravenously over 60 minutes with 10% of it as a bolus during the first minute.

To **restore function in central venous lines,** alteplase is instilled into the catheter at a concentration of 1 mg/mL. The usual dose is 2 mg, repeated after 2 hours if necessary. A total dose of 4 mg should not be exceeded. For patients weighing less than 30 kg, the dose is 110% of the internal lumen volume of the catheter, but should not exceed 2 mg, and may be repeated after 2 hours if necessary.

Arterial and venous thromboembolism. For the use of alteplase for arterial or venous thromboembolism in children, see Administration in Children under Streptokinase, p.1405.

Catheters and cannulas. Alteplase has been used successfully to clear thrombi in central venous catheters.[1,2] Typical doses have been 2 mg injected as a bolus into the blocked catheter. Children have been treated similarly; in one study[3] where patients' weight started from 3 kg, doses ranged from 0.1 to 2.0 mg (as a 1 mg/mL solution), depending on the size of the catheter. Similarly, a later study using a 1 mg/mL solution gave doses of 2 mg to children weighing 30 kg or more, and a volume equal to 110% of the calculated internal volume of the catheter (rounded to the nearest 0.1 mL and not to exceed 2 mL in total) in children weighing less than 30 kg.[4] The dwell time was up to 2 hours, and doses were repeated once in patients in whom catheter function was not restored after this period. A cohort study[5] used doses of 0.5 mg for children weighing 10 kg or under, and 1 to 2 mg above this weight, with a dwell time of 2 to 4 hours. In another report, 2 children[6] were successfully treated with intravenous alteplase in doses of 0.01 to 0.05 mg/kg per hour for venous thrombosis associated with indwelling intravascular catheters.

Alteplase has also been instilled into central haemodialysis lines to preserve patency between dialysis sessions.[7] Urokinase has been used similarly in children with long-term venous access devices for antineoplastic therapy.[8]

Intracardiac thrombosis. Alteplase has been used, in a dose of 100 mg given intravenously over 2 hours, for thrombosis of prosthetic heart valves.[1]

Alteplase has been used successfully in a neonate to treat intracardiac thrombosis associated with the use of a central venous line.[2] A dose of 500 micrograms/kg given over 10 minutes was followed by infusion of 200 micrograms/kg per hour for 3 days. In another report,[3] 4 preterm infants were treated successfully. All received 400 to 500 micrograms/kg of alteplase in a 20 to 30 minute bolus. This was followed in one case by a 3-hour infusion at 100 micrograms/kg per hour.

Although thrombolytics are usually contra-indicated in patients with infective endocarditis (see Precautions for Streptokinase, p.1404), alteplase has been used successfully in children with indwelling catheters who developed infective endocarditis; coagulation was monitored and fresh frozen plasma was given to maintain fibrinogen concentrations.[4]

4. Levitas A, *et al.* Successful treatment of infective endocarditis with recombinant tissue plasminogen activator. *J Pediatr* 2003; **143:** 649–52.

Microvessel thrombosis. Alteplase has been used in conditions where the underlying pathology is occlusion of small blood vessels by microthrombi.

Purpura and loss of circulation in the hands of a patient recovering from **fulminant meningococcaemia**[1] responded to intra-arterial infusion of alteplase 20 to 40 micrograms/kg per hour for 22 hours in the right hand, and 20 micrograms/kg per hour for 11 hours in the left. Perfusion was successfully restored to both hands, and full function subsequently attained in them. Improvement was also achieved when alteplase was given to 2 infants with septic shock and purpura fulminans caused by meningococcal infection.[2]

Six patients[3] with ulcers caused by **livedoid vasculitis** and refractory to conventional treatment were treated with alteplase 10 mg infused intravenously over 4 hours daily for 14 days. Most ulcers healed rapidly; one patient required re-treatment with concomitant anticoagulation. Healing of ulcers associated with **calciphylaxis** has also been reported[4] with a similar alteplase regimen.

A 4-year-old girl[5] with **haemolytic-uraemic syndrome** (see under Thrombotic Microangiopathies, p.1076) responded to treatment with an intravenous infusion of alteplase 200 micrograms/kg per hour for 5 hours, subsequently reduced to 50 micrograms/kg per hour for 14 days.

Alteplase use has been reviewed[6] and mixed results found, in patients with **veno-occlusive disease of the liver**, a serious complication of bone marrow transplantation that may be caused by diffuse thrombi in the hepatic venules. Although results in patients with established veno-occlusive disease have been disappointing,[7] one study[8] suggested that alteplase given early in the course of the disease improves response rate.

Ocular disorders. Intra-ocular alteplase has been used to treat postoperative fibrinous deposits that can form after procedures such as surgery for cataracts[1] or glaucoma,[2] including cataracts in children.[3] Doses ranging from 6 to 25 micrograms have been used. Intra-ocular bleeding has occurred as a complication of such use.[2,4] Alteplase has also been used prophylactically in children undergoing surgery for congenital cataracts.[5]

Intra-ocular alteplase has also been used for treatment of subhyaloid haemorrhage,[6,7] including that seen in shaken baby syndrome.[8] Successful treatment of subretinal macular haemorrhage with alteplase injected directly into the subretinal area around the clot has also been reported.[9]

Peripheral arterial thromboembolism. Thrombolytics, including alteplase, may be used in the management of peripheral arterial thromboembolism (p.1178). Alteplase has been injected intravenously or intra-arterially directly into the clot as an alternative to surgical treatment of the occlusion. It has also been infused intra-arterially to remove distal clots during a surgical procedure. Alteplase is claimed to produce more rapid thrombolysis than streptokinase although studies have been too small to provide evidence of reduced limb loss or mortality.[1] The most common dose range is 0.5 to 1 mg/hour given *intra-arterially.*[1-3]

An *intravenous* dose of 500 micrograms/kg per hour for the first hour followed by 250 micrograms/kg per hour until clot lysis occurred has been used in infants.[4] Treatment of arterial thrombosis in neonates has been reported, using doses of alteplase ranging from 100 to 500 micrograms/kg per hour *intravenously.*[5,6] The *BNFC* recommends a dose for any intravascular thrombosis in neonates and children of 100 to 500 micrograms/kg per hour by intravenous infusion over 3 to 6 hours; a second dose may be given if needed. The maximum daily dose should not exceed 100 mg. However, a retrospective study[7] of 80 infants and children with arterial or venous thrombi found that although treatment with alteplase may be effective, it is associated with a low safety margin and an unknown risk-benefit ratio.

Where a thrombolytic is used to remove distal clots during a surgical procedure alteplase has been given *intra-arterially* as three doses of 5 mg at 10-minute intervals.[8]

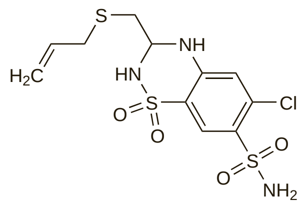
Altizide (rINN) ⊗

Althiazide (USAN); Altizida; Altizidum; P-1779. 3-Allylthiomethyl-6-chloro-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

Альтизид

$C_{11}H_{14}ClN_3O_4S_3$ = 383.9.

CAS — 5588-16-9.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Altizide). A white or almost white powder. Practically insoluble in water; soluble in methyl alcohol; practically insoluble in dichloromethane. It exhibits polymorphism.

Profile

Altizide is a thiazide diuretic (see Hydrochlorothiazide, p.1307) that is used in the treatment of oedema and hypertension. It is frequently used with spironolactone.

Preparations

Proprietary Preparations (details are given in Part 3)

Ambrisentan (BAN, rINN)

Ambrisentán; Ambrisentanum; BSF-208075; LU-208075. (+)-(2*S*)-2-[(4,6-Dimethylpyrimidin-2-yl)oxy]-3-methoxy-3,3-diphenylpropanoic acid.

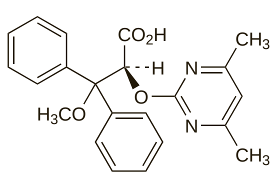
Амбризентан

$C_{22}H_{22}N_2O_4$ = 378.4.

CAS — 177036-94-1.

ATC — C02KX02.

ATC Vet — QC02KX02.



Adverse Effects and Precautions

As for Bosentan, p.1235.

Interactions

Ambrisentan is a substrate for a number of enzymes and transporters and interactions could potentially occur with inducers or inhibitors of the cytochrome P450 isoenzymes CYP3A4 and CYP2C19, P-glycoprotein, uridine diphosphate glucuronosyltransferases, and organic anion transporting polypeptide (OATP).

Pharmacokinetics

Ambrisentan is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations occur about 2 hours after oral doses. It is about 99% bound to plasma proteins. Ambrisentan is excreted mainly by the liver, although the relative contribution of hepatic metabolism and biliary excretion is not known. The terminal elimination half-life is about 15 hours.

Uses and Administration

Ambrisentan is an endothelin receptor antagonist (p.1155) with similar actions to bosentan (p.1235), although it has a higher selectivity for the endothelin ET_A-receptor. It is used in the management of pulmonary hypertension functional class II or III (p.1179). It is given orally in an initial dose of 5 mg once daily; the dose may be increased to 10 mg once daily if tolerated.

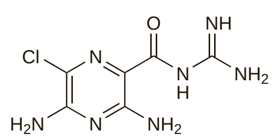
Амилорида Гидрохлорид

$C_6H_8ClN_7O,HCl,2H_2O$ = 302.1.

CAS — 2609-46-3 (amiloride); 2016-88-8 (anhydrous amiloride hydrochloride); 17440-83-4 (amiloride hydrochloride dihydrate).

ATC — C03DB01.

ATC Vet — QC03DB01.



(amiloride)

NOTE. Compounded preparations of amiloride hydrochloride may be represented by the following names:

- Co-amilofruse (*BAN*)—amiloride hydrochloride 1 part and furosemide 8 parts (w/w)
- Co-amilozide (*BAN*)—amiloride hydrochloride 1 part and hydrochlorothiazide 10 parts (w/w)
- Co-amilozide (*PEN*)—amiloride hydrochloride and hydrochlorothiazide.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Amiloride Hydrochloride). A pale yellow to greenish-yellow powder. Slightly soluble in water and in dehydrated alcohol. Protect from light.

USP 31 (Amiloride Hydrochloride). A yellow to greenish-yellow, odourless or practically odourless, powder. Slightly soluble in water; insoluble in acetone, in chloroform, in ether, and in ethyl acetate; freely soluble in dimethyl sulfoxide; sparingly soluble in methyl alcohol.

Adverse Effects

Amiloride can cause hyperkalaemia, particularly in elderly patients, diabetics, and patients with renal impairment. Hyponatraemia has been reported in patients taking amiloride with other diuretics. Amiloride may cause nausea, vomiting, abdominal pain, diarrhoea or constipation, paraesthesia, thirst, dizziness, skin rash, pruritus, weakness, muscle cramps, headache, and minor psychiatric or visual changes. Orthostatic hypotension and rises in blood-urea-nitrogen concentrations have been reported. Other adverse effects of amiloride may include alopecia, cough, dyspnoea, jaundice, encephalopathy, impotence, angina pectoris, arrhythmias, and palpitations.

Effects on electrolyte balance. There have been reports of metabolic acidosis associated with amiloride or triamterene[1] and with co-amilozide.[2]

1. Kushner RF, Sitrin MD. Metabolic acidosis: development in two patients receiving a potassium-sparing diuretic and total parenteral nutrition. *Arch Intern Med* 1986; **146:** 343–5.
2. Wan HH, Lye MDW. Moduretic-induced metabolic acidosis and hyperkalaemia. *Postgrad Med J* 1980; **56:** 348–50.

POTASSIUM. Hyperkalaemia is the main adverse effect when amiloride is given alone but may also occur when amiloride is given with a potassium-wasting diuretic. Severe hyperkalaemia has been reported during co-amilozide therapy, particularly in patients with renal impairment[1,2] and has been accompanied by metabolic acidosis in one such patient.[3]

1. Whiting GFM, *et al.* Severe hyperkalaemia with Moduretic. *Med J Aust* 1979; **1:** 409.
2. Jaffey L, Martin A. Malignant hyperkalaemia after amiloride/hydrochlorothiazide treatment. *Lancet* 1981; **i:** 1272.
3. Wan HH, Lye MDW. Moduretic-induced metabolic acidosis and hyperkalaemia. *Postgrad Med J* 1980; **56:** 348–50.

SODIUM. For reports of severe hyponatraemia in patients taking diuretics such as amiloride with potassium-wasting diuretics, see Hydrochlorothiazide, p.1308.

Effects on the skin. For a report of photosensitivity reactions in patients taking co-amilozide, see Hydrochlorothiazide, p.1309.

Precautions

Amiloride has the same precautions as spironolactone with regard to hyperkalaemia (see p.1400). It should be stopped at least 3 days before glucose-tolerance tests are performed in patients who may have diabetes mellitus because of the risks of provoking severe hyperkalaemia.

Interactions

There is an increased risk of hyperkalaemia if amiloride is given with potassium supplements or with other potassium-sparing diuretics. Hyperkalaemia may also occur in patients given amiloride with ACE inhibitors, angiotensin II receptor antagonists, NSAIDs, ciclosporin, or trilostane. In patients taking amiloride with NSAIDs or ciclosporin the risk of nephrotoxicity may also be increased. Diuretics may reduce the excretion of lithium and increase the risk of lithium toxicity, but this does not appear to occur with amiloride. Severe hyponatraemia may occur in patients taking a potassium-sparing diuretic with a thiazide; this risk may be increased in patients taking chlorpropamide. Amiloride may reduce the ulcer-healing properties of carbenoxolone. As with other diuretics, amiloride may enhance the effects of other antihypertensive drugs.

Digoxin. For the effects of amiloride on digoxin clearance, see p.1262.

Quinidine. For a report of amiloride producing arrhythmias in patients receiving quinidine, see p.1384.

Pharmacokinetics

Amiloride is incompletely absorbed from the gastrointestinal tract; bioavailability is about 50% and is reduced by food. It is not significantly bound to plasma proteins and has a plasma half-life of 6 to 9 hours; the terminal half-life may be 20 hours or more. It is excreted unchanged by the kidneys.

Hepatic impairment. In patients with acute hepatitis the terminal half-life of amiloride was 33 hours compared with 21 hours in healthy subjects.[1] The proportion of the dose excreted in the urine was increased from 49 to 80%.

1. Spahn H, *et al.* Pharmacokinetics of amiloride in renal and hepatic disease. *Eur J Clin Pharmacol* 1987; **33:** 493–8.

Renal impairment. Studies of the pharmacokinetics of amiloride[1,2] have reported an increase in terminal elimination half-life from 20 hours in healthy subjects to 100 hours in patients with end-stage renal disease. The natriuretic effect of amiloride was reduced[1] in patients with creatinine clearance below 50 mL/minute. In patients with renal impairment amiloride could aggravate potassium retention due to renal disease. Studies in elderly patients have found increased half-life[3] and steady-state concentrations[4] associated with reduced renal function.

4. Ismail Z, *et al.* The pharmacokinetics of amiloride-hydrochlorothiazide combination in the young and elderly. *Eur J Clin Pharmacol* 1989; **37:** 167–71.

Uses and Administration

Amiloride is a weak diuretic that appears to act mainly on the distal renal tubules. It is described as potassium-sparing since, like spironolactone, it increases the excretion of sodium and reduces the excretion of potassium. Unlike spironolactone, however, it does not act by specifically antagonising aldosterone. Amiloride does not inhibit carbonic anhydrase. It takes effect about 2 hours after oral dosage and its diuretic action reaches a peak in 6 to 10 hours and has been reported to persist for about 24 hours.

Amiloride diminishes the kaliuretic effects of other diuretics, and may produce an additional natriuretic effect. It is mainly used as an adjunct to thiazide diuretics such as hydrochlorothiazide and loop diuretics such as furosemide, to conserve potassium in those at risk from hypokalaemia during the long-term treatment of oedema associated with hepatic cirrhosis (including ascites, p.1159) and heart failure (p.1165). It is also used with other diuretics in the treatment of hypertension (p.1171). Diuretic-induced hypokalaemia and its management, including the role of potassium-sparing diuretics such as amiloride, is discussed under Effects on Electrolyte Balance in the Adverse Effects of Hydrochlorothiazide, p.1308. Amiloride is sometimes used to manage hypokalaemia in primary hyperaldosteronism (p.1402).

Amiloride by inhalation has also been investigated in the management of cystic fibrosis patients with lung disease (see below).

In the treatment of **oedema** amiloride is given orally as the hydrochloride and doses are expressed in terms of the anhydrous substance. 1 mg of anhydrous hydrochloride is equivalent to about 1.14 mg of the hydrated substance. Treatment may be started with a dose of 5 to 10 mg daily, increased, if necessary, to a maximum of 20 mg daily. An initial dose of 2.5 mg once daily may be used in patients already taking other diuretics or antihypertensives. Similar doses to those given for oedema are used to reduce potassium loss in patients receiving thiazide or loop diuretics.

Potassium supplements should not be given.

Cystic fibrosis. Pulmonary disease is the major cause of mortality in cystic fibrosis (p.166). Experimental treatment aimed at modifying the pulmonary disease process has included giving amiloride by inhalation.[1,2] No evidence of pulmonary or systemic toxicity was seen in 14 patients treated for 25 weeks.[1] The mechanism of action is unclear but could be the sodium-channel blocking effect[1] or anti-inflammatory effects[3] of amiloride. Concern has been expressed[4] over possible consequences of the inhibition of endogenous urokinase by amiloride although others[5] considered this to be unlikely at the concentrations studied. However, a systematic review[6] found no evidence that amiloride was of clinical benefit.

Diabetes insipidus. Thiazide diuretics are commonly used in nephrogenic diabetes insipidus (p.2179) and NSAIDs may also be employed; both result in an overall decrease in urine production. Hydrochlorothiazide with amiloride has been reported to be at least as effective as hydrochlorothiazide plus indometacin in 5 patients.[1] In addition, amiloride obviated the need for potassium supplements. Hydrochlorothiazide with amiloride was also effective and well tolerated in a group of 4 children with nephrogenic diabetes insipidus who were treated for up to 5 years.[2]

1. Knoers N, Monnens LAH. Amiloride-hydrochlorothiazide versus indomethacin-hydrochlorothiazide in the treatment of nephrogenic diabetes insipidus. *J Pediatr* 1990; **117:** 499–502.
2. Kirchlechner V, *et al.* Treatment of nephrogenic diabetes insipidus with hydrochlorothiazide and amiloride. *Arch Dis Child* 1999; **80:** 548–52.

Renal calculi. Patients with idiopathic hypercalciuria and a history of renal calculi (p.2181) are usually given a thiazide diuretic such as hydrochlorothiazide to reduce calcium excretion. In patients with calcium oxalate calculi an inherited cellular defect in oxalate transport may also be involved and this might be corrected by amiloride.[1]

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Amiodarone Hydrochloride). A white or almost white, fine crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane; soluble in methyl alcohol. Store at a temperature not exceeding 30°. Protect from light.

Adsorption. Amiodarone is known to be adsorbed by PVC, although the amount of adsorption has varied in different studies. A study[1] using amiodarone hydrochloride 600 micrograms/mL in glucose 5% found that the concentration fell by 10% in 3 hours followed by a steady decrease to 60% of the initial concentration after 5 days when stored in flexible PVC bags at ambient temperature.[1] However, another study[2] using amiodarone hydrochloride 1.8 to 2 mg/mL in glucose 5% found only that the concentration remained 97.3% of the initial value after 24 hours in PVC infusion bags. In the first study, perfusion of the solution through PVC giving sets resulted in the concentration falling to 82% after 15 minutes, whereas the second study found the concentration fell to 95.1% after 1 hour but then returned to the initial value. No loss was noted in either study when glass or rigid PVC containers were used, suggesting that the losses were caused by the plasticiser, di-2-ethylhexylphthalate (DEHP). Amiodarone may also leach out DEHP and other plasticisers, and it has been suggested that bags and tubing containing DEHP should not be used for giving amiodarone in order to minimise patient exposure.

Incompatibility. Amiodarone injection has been reported to be incompatible with aminophylline,[1] flucloxacillin,[2] heparin,[3] and sodium bicarbonate.[4] A further study[5] reported incompatibility with ampicillin/sulbactam sodium, ceftazidime sodium, digoxin, furosemide, imipenem/cilastatin sodium, magnesium sulfate, piperacillin sodium, piperacillin/tazobactam sodium, potassium phosphate, and sodium phosphate. UK licensed product information states that it is incompatible with sodium chloride solutions.

Adverse Effects and Treatment

Adverse effects are common with amiodarone. Many are dose-related and reversible with reduction in dose; however, because of its long half-life this can take some time and adverse effects may develop after treatment is stopped.

Adverse cardiovascular effects associated with amiodarone include severe bradycardia, sinus arrest, and conduction disturbances. Severe hypotension may follow intravenous use, particularly (though not exclusively) at rapid infusion rates. Amiodarone may also produce ventricular tachyarrhythmias; torsade de pointes has been reported but appears to be less of a problem with amiodarone than other antiarrhythmics. Rarely, heart failure may be precipitated or aggravated.

Amiodarone reduces the peripheral transformation of thyroxine (T_4) to tri-iodothyronine (T_3) and increases the formation of reverse-T_3. It can affect thyroid function and may induce hypo- or hyperthyroidism.

There have been reports of severe pulmonary toxicity including pulmonary fibrosis and interstitial pneumonitis. These effects are usually reversible on withdrawal of amiodarone but are potentially fatal.

Amiodarone can adversely affect the liver. There may be abnormal liver function tests and cirrhosis or hepatitis; fatalities have been reported.

Prolonged use of amiodarone causes the development of benign yellowish-brown corneal microdeposits in the majority of patients, sometimes associated with coloured haloes of light; these are reversible on stopping therapy. Photosensitivity reactions are also common and more rarely blue-grey discoloration of the skin may occur.

Other adverse effects reported include benign intracranial hypertension, haemolytic or aplastic anaemia, peripheral neuropathy, paraesthesias, myopathy, ataxia, tremor, nausea, vomiting, a metallic taste, nightmares, headaches, sleeplessness, fatigue, and epididymitis.

Thrombophlebitis can occur if amiodarone is injected regularly or infused for prolonged periods into a peripheral vein. Rapid intravenous injection has been associated with anaphylactic shock, hot flushes, sweating, and nausea.

It has been suggested that amiodarone-induced phospholipidosis may explain some of its adverse effects. Amiodarone's iodine content contributes to its thyrotoxicity.

Effects on electrolyte balance. Hyponatraemia associated with the syndrome of inappropriate secretion of antidiuretic hormone has been reported[1-4] in patients taking amiodarone. In each case, the hyponatraemia improved when the dose was reduced or amiodarone was stopped.

Effects on the eyes. Slit-lamp examination showed corneal abnormalities in 103 of 105 patients treated with amiodarone for 3 months to 7 years.[1] The most advanced abnormality comprised whorled patterns with uniform granular opacities. The corneal deposits became denser if amiodarone dosage was increased and regressed if dosage was reduced. Ocular symptoms were reported in only 12 patients. Photophobia was reported in 3 patients, while 2 had visual haloes, 1 had blurring of vision, and a further 6 had lid irritation. However, lid irritation was considered a photosensitive skin reaction and blurred vision was probably not due to amiodarone. No patient had any deterioration in visual acuity attributable to amiodarone. In 16 patients amiodarone was withdrawn with complete clearing of corneal abnormalities within 7 months and routine ophthalmological monitoring was considered unnecessary in patients without ocular symptoms. However, optic neuropathy[2-4] and neuritis with visual impairment have been reported with amiodarone and UK licensed product information recommends that annual ophthalmological examinations should be performed.

A sicca syndrome with diminished tear and saliva production has been reported[5] during amiodarone treatment.

Effects on the genitalia. Epididymal swelling and scrotal pain have been reported with amiodarone.[1-3] Time to onset varied from 7 to 71 months after starting treatment, and resolution occurred within 10 weeks despite continuation of amiodarone in some patients. The mechanism of the reaction is unknown, but in 1 patient[2] the concentration of desethylamiodarone in semen was fivefold that in serum.

Brown discoloration of semen and sweat has also been associated with amiodarone therapy.[4]

Effects on the heart. Amiodarone has the potential to provoke arrhythmias; it prolongs the QT interval and there have been reports of torsade de pointes. However, a review of the literature[1] indicated that the frequency of proarrhythmic events was low. The risk of torsade de pointes also appears to be lower with amiodarone than with other class III antiarrhythmics, possibly due to additional actions of amiodarone such as blockade of calcium channels.[2]

Effects on lipid metabolism. Amiodarone increases phospholipid concentrations in tissues and this may be responsible for some of its adverse effects.[1] Although hyperlipidaemia may result from hypothyroidism, amiodarone can also increase serum-cholesterol concentrations independently of any effect on the thyroid.[2,3] The effect on triglyceride concentrations is not clear.[3]

Effects on the liver. Plasma concentrations of liver enzymes are often increased in patients taking amiodarone but this is usually asymptomatic. However, there have been reports of hepatic injury,[1,2] including hepatitis and cirrhosis, with histological changes resembling alcoholic liver disease.[1] Fatal cirrhosis has been reported, usually in patients receiving high doses or long-term therapy,[3-8] and may develop after stopping amiodarone. However, rapidly progressive fatal hepatic failure has occurred[9] only one month after starting treatment. There have also been reports of severe cholestasis, including a case that was reversible,[10] and another that was fatal, despite amiodarone being stopped.[11] Acute hepatitis occurring within 24 hours of intravenous amiodarone has been reported,[12-14] but in 1 case[13] did not recur with subsequent oral therapy, suggesting that the reaction may have been related to the vehicle used in the intravenous formulation.

Effects on the lungs. Pulmonary toxicity is one of the most severe adverse effects associated with amiodarone therapy. Reviews[1] have suggested that it may occur in up to 10% of patients (although the incidence in controlled studies appears to be lower[2]) and fatalities have been reported.[3,4] The onset is usually chronic, and patients often present several months after starting amiodarone with increasing dyspnoea, cough, and pleuritic chest pain; however, the onset may also be more acute, and in one patient[5] occurred within days of starting amiodarone. Acute reactions have also developed in patients undergoing surgery or other procedures;[2,6] two patients with amiodarone pulmonary toxicity died less than 1 hour and 24 hours, respectively after pulmonary angiography.[7] Different forms of toxicity have been reported, including interstitial and alveolar infiltration,[8] fibrosis,[3] and pneumonitis;[9] amiodarone-induced asthma has also been reported.[10] Although there is some evidence that toxicity is dose-related,[8] it has also occurred at low doses,[11] and different mechanisms may be involved;[1,6] some patients have evidence of direct toxicity, while in others[9] an immunological reaction appears to be involved. Most patients recover gradually if amiodarone is stopped, but treatment with corticosteroids may be given if necessary,[1,8] and has been particularly recommended[6] in acute lung injury.

Effects on mental state. There have been isolated reports of patients (age range 54 to 80 years) developing delirium within about 4 to 17 days of starting amiodarone therapy.[1-3] Mental status improved on withdrawal of amiodarone.

Effects on the nervous system. Neurological toxicity is a recognised adverse effect of amiodarone. A study[1] in 10 patients treated with amiodarone for more than 2 years found that 3 had evidence of peripheral neuropathy, possibly correlated with high doses and high serum concentrations of amiodarone.

1. Fraser AG, McQueen INF. Adverse reactions during treatment with amiodarone hydrochloride. *BMJ* 1983; **287:** 612.

Effects on the pancreas. Pancreatitis has been reported[1] in a patient 4 days after starting amiodarone. Symptoms resolved after withdrawal of the drug but returned on re-exposure.

1. Bosch X, Bernadich O. Acute pancreatitis during treatment with amiodarone. *Lancet* 1997; **350:** 1300.

Effects on the skin and hair. The most common adverse skin reaction associated with amiodarone is photosensitivity. This is a phototoxic rather than a photoallergic reaction[1-3] and the wavelengths responsible extend from the long-wave ultraviolet (UVA) into the visible light range.[1] Affected patients should be advised to wear protective clothing and avoid exposure to sunlight. Topical sunblock preparations, such as those containing zinc or titanium oxides, may reduce the risk of reaction and a reduction in amiodarone dosage may also be useful.[1] Although pyridoxine has been reported[4] to protect against amiodarone-induced photosensitivity, results from a double-blind placebo-controlled study[5] indicated that it may enhance the photosensitivity. Photosensitivity may continue for several weeks after withdrawal of amiodarone due to its extensive distribution, and persistence for longer periods has been reported.[6] There have also been reports[7] of basal cell carcinoma, possibly related to amiodarone-induced photosensitivity.

Blue-grey[2,3,8] and golden-brown[3] pigmentation of light-exposed skin have been reported during long-term amiodarone use. The pigmentation is usually slowly reversible on withdrawing amiodarone but may not completely disappear. The mean concentrations of amiodarone and its desethyl metabolite in light-exposed pigmented skin have been found to be 10 times the concentrations in non-exposed skin.[2] Discoloration of semen and sweat has also been noted (see Effects on the Genitalia, above).

Cutaneous vasculitis,[9,10] exfoliative dermatitis,[11] and fatal toxic epidermal necrolysis[12,13] have been reported. Alopecia[14,15] has been associated with amiodarone but increased hair growth,[3] possibly due to the vasodilator activity of amiodarone, has also been reported. Extravasation of amiodarone injection has caused severe skin necrosis.[16]

Effects on thyroid function. Amiodarone has complex effects on thyroid function[1-3] and, while the majority of euthyroid patients receiving amiodarone remain clinically euthyroid, both hypo- and hyperthyroidism may occur. Amiodarone has direct effects on the thyroid gland, but also alters serum concentrations of thyroid hormones, complicating the interpretation of thyroid function tests. Use of amiodarone results in a reduction of the peripheral conversion of thyroxine (T_4) to tri-iodothyronine (T_3) with a resulting increase in T_4, a modest fall in T_3, and an increase in reverse-T_3 concentrations; the basal serum-TSH (thyroid-stimulating hormone; thyrotrophin) concentration rises initially but tends to return to normal after about 3 months of treatment.

The prevalence of clinical hypo- and hyperthyroidism appears to correlate with dietary iodine intake, with hypothyroidism being more common in areas of adequate iodine intake and hyperthyroidism in areas of lower intake; the overall incidence of thyroid disorders has been suggested[2] to be anywhere between 1 to 32%. Although the exact mechanism for the toxicity is not known, amiodarone has a high iodine content (about 75 mg of iodine in each 200-mg tablet) and the large iodine load may affect the thyroid, particularly in patients with an underlying subclinical thyroid defect. Auto-immune mechanisms may also contribute and antithyroid antibodies have been detected during amiodarone therapy. The high iodine load appears to be the main mechanism for hypothyroidism, but for hyperthyroidism two mechanisms may be involved. Type I amiodarone-induced thyrotoxicosis appears to be precipitated by the iodine load, whereas type II amiodarone-induced thyrotoxicosis is a destructive thyroiditis that is probably caused by a direct toxic effect on the thyroid gland.

Assessment of thyroid function is recommended in patients before starting amiodarone treatment and periodically during treatment; TSH concentrations should be measured, along with free T_3 and T_4.

Amiodarone-induced hypothyroidism usually presents similarly to other forms of hypothyroidism[1-3] and treatment is with levothyroxine, starting with a low dose and gradually increasing until control is achieved; amiodarone may be continued.

Amiodarone-induced hyperthyroidism is a more complex problem and may be difficult to diagnose and manage.[1-4] Patients may present with classical symptoms such as tachycardia, tremor, weight loss, nervousness, and irritability, but in other cases reappearance of angina, or a worsening of arrhythmia may be the only indication. Amiodarone is usually stopped if clinical hyperthyroidism develops, but may be continued if necessary while the hyperthyroidism is treated.[1-5] Management depends on whether the patient has type I or type II hyperthyroidism. Treatment of type I is usually with the thiourea drugs carbimazole, thiamazole, or propylthiouracil; in resistant cases potassium perchlorate may be used with a thiourea to reduce the thyroid iodine load. Lithium carbonate has been used as an alternative, but its role is not yet established.[1,2] In type II thyrotoxicosis, treatment is usually with corticosteroids, and they may also be used with thioureas where the type is mixed or unclear. Oral cholecystographic contrast media such as iopanoic acid have also been used, but appear to be less effective.[6] Radio-iodine can be used but may not be effective if the uptake of radio-iodine by the thyroid is low due to the iodine load from amiodarone; radio-iodine has also been used[7] to allow amiodarone to be restarted in patients with a history of amiodarone-induced hyperthyroidism. Thyroidectomy may have a role[1-4,8] in the treatment of resistant amiodarone-induced hyperthyroidism.

2. Sheikhzadeh A, *et al.* Drug-induced lupus erythematosus by amiodarone. *Arch Intern Med* 2002; **162:** 834–6.
3. Kundu AK. Amiodarone-induced systemic lupus erythematosus. *J Assoc Physicians India* 2003; **51:** 216–17.

Precautions

Amiodarone should not be given to patients with bradycardia, sino-atrial block, AV block or other severe conduction disorders (unless the patient has a pacemaker), severe hypotension, or severe respiratory failure. It may be used, but with caution, in patients with heart failure. Electrolyte disorders should be corrected before starting treatment. The use of amiodarone should be avoided in patients with iodine sensitivity, or evidence or history of thyroid disorders. Patients taking amiodarone should avoid exposure to sunlight.

Thyroid function should be monitored regularly in order to detect amiodarone-induced hyper- or hypothyroidism. Thyroxine, tri-iodothyronine, and thyrotrophin (thyroid-stimulating hormone; TSH) concentrations should be measured; clinical assessment is important but is unreliable alone. See also Effects on Thyroid Function under Adverse Effects and Treatment, above.

Tests of liver and pulmonary function should also be carried out regularly in patients on long-term therapy. Ophthalmological examinations should be performed annually. Although urinary excretion is not a major route for the elimination of amiodarone or its metabolites, there is a possibility of iodine accumulation in renal impairment.

Intravenous injections of amiodarone should be given slowly: if prolonged or repeated infusions are envisaged, the use of a central venous catheter should be considered.

Some of the contra-indications for amiodarone may not apply when it is given intravenously in emergency situations.

Administration. For the problems of controlling the delivery rate of amiodarone by intravenous infusion, see under Uses and Administration, below.

Breast feeding. Amiodarone is distributed into breast milk[1,2] and significant amounts may be ingested if infants are breast fed. Licensed product information therefore contra-indicates the use of amiodarone during breast feeding, and the American Academy of Pediatrics considers[3] that the use of amiodarone may be of concern due to the risk of hypothyroidism in the infant. In one study,[2] amiodarone was still detectable in breast milk several weeks after amiodarone was stopped, suggesting that caution is still required. However, there has been a report[4] of an infant who was successfully breast fed with close monitoring of thyroid function; the mother stopped amiodarone at delivery.

Porphyria. Amiodarone is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Pregnancy. Each 200-mg tablet of amiodarone contains about 75 mg of iodine. The potential effect of this iodine load on the fetus has limited the use of amiodarone in pregnancy since iodine freely crosses the placenta and may cause thyroid disorders in the fetus. In addition, amiodarone and desethylamiodarone both cross the placenta, with respective concentrations in cord blood at delivery of about 10% and 25% of the maternal plasma concentrations, and direct effects on the fetus are therefore possible. However, a review[1] of 64 reported cases of amiodarone use during pregnancy found no evidence of an increased incidence of fetal malformations; hypothyroidism occurred in 14 neonates (22%), but only 2 had detectable goitre, and 2 neonates had transient hyperthyroidism. Neurodevelopmental follow-up was limited, but mild abnormalities were reported in some cases; this appeared to be independent of thyroid status, suggesting it may have been due to a direct effect of amiodarone.

Interactions

Amiodarone should be used with caution with other drugs liable to induce bradycardia, such as beta blockers or calcium-channel blockers, and with other antiarrhythmic drugs. Use with arrhythmogenic drugs, particularly drugs that prolong the QT interval such as phenothiazine antipsychotics, tricyclic antidepressants, halofantrine, and terfenadine, should be avoided. Drugs that cause hypokalaemia or hypomagnesaemia may also increase the risk of arrhythmias with amiodarone. Amiodarone is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2C8 and interactions may occur with inhibitors of these enzymes, particularly with inhibitors of CYP3A4 such as HIV-protease inhibitors, cimetidine, and grapefruit juice. Enzyme inducers such as rifampicin and phenytoin may reduce amiodarone concentrations. In addition, amiodarone is an inhibitor of some cytochrome P450 isoenzymes, including CYP3A4 and CYP2D6, resulting in higher plasma concentrations of other drugs metabolised by these enzymes. Examples of these include ciclosporin, clonazepam, digoxin, flecainide, phenytoin, procainamide, quinidine, simvastatin, and warfarin. Amiodarone also inhibits P-glycoprotein and could affect drugs that are P-glycoprotein substrates.

Agalsidase. For the effect of the use of amiodarone with *agalsidase alfa* or *beta*, see p.2252.

Antibacterials. Palpitations and activation of an implantable cardioverter defibrillator occurred[1] in a woman receiving amiodarone when *rifampicin* was added. Serum concentrations of amiodarone were reduced, probably due to induction of metabolising enzymes by rifampicin.

1. Zarembski DG, *et al.* Impact of rifampin on serum amiodarone concentrations in a patient with congenital heart disease. *Pharmacotherapy* 1999; **19:** 249–51.

Antiepileptics. The interaction between *phenytoin* and amiodarone resulting in increased plasma-phenytoin concentrations is widely recognised (see p.498). However, phenytoin is a hepatic enzyme inducer and has been reported[1] to decrease serum-amiodarone concentrations by 32 and 49% after 1 and 2 weeks of use respectively.

1. Nolan PE, *et al.* Effect of phenytoin on the clinical pharmacokinetics of amiodarone. *J Clin Pharmacol* 1990; **30:** 1112–19.

Antivirals. A potential interaction has been suggested between amiodarone and HIV-protease inhibitors due to inhibition of amiodarone metabolism. Raised serum concentrations of amiodarone have been reported[1] in a patient who received *indinavir* for postexposure prophylaxis; no clinical signs of toxicity occurred.

1. Lohman JJHM, *et al.* Antiretroviral therapy increases serum concentrations of amiodarone. *Ann Pharmacother* 1999; **33:** 645–6.

Grapefruit juice. A study[1] in healthy subjects reported that grapefruit juice decreased the metabolism of amiodarone; the area under the plasma concentration-time curve (AUC) and the maximum plasma concentration of amiodarone were both increased.

Histamine H_2-antagonists. *Cimetidine* inhibits hepatic metabolism and an increase in the serum-amiodarone concentration has been reported[1] in 8 out of 12 patients given amiodarone and cimetidine.

1. Hogan C, *et al.* Cimetidine-amiodarone interaction. *J Clin Pharmacol* 1988; **28:** 909.

Theophylline. For a report of increased serum-theophylline concentrations and resultant adverse effects in a patient when amiodarone was added to therapy, see Antiarrhythmics, p.1142.

Pharmacokinetics

Amiodarone is absorbed variably and erratically from the gastrointestinal tract; the average bioavailability is about 50%, but varies widely, and both the rate and extent of absorption are increased by food. It is extensively distributed to body tissues and accumulates notably in fat as well as in skeletal muscles and highly perfused tissues such as liver, lungs, and spleen; it has been reported to be about 96% bound to plasma proteins. The terminal elimination half-life is about 50 days with a range of about 20 to 100 days due to its extensive tissue distribution. On stopping prolonged amiodarone therapy a pharmacological effect is evident for a month or more. A major metabolite, desethylamiodarone, has antiarrhythmic properties. There is very little urinary excretion of amiodarone or its metabolites, the major route of excretion being in faeces via the bile; some enterohepatic recycling may occur. Amiodarone and desethylamiodarone are reported to cross the placenta and to be distributed into breast milk.

After intravenous injection the maximum effect is achieved within 1 to 30 minutes and persists for 1 to 3 hours.

Uses and Administration

Amiodarone is an antiarrhythmic with mainly class III properties (see p.1153). It is used in the control of ventricular and supraventricular arrhythmias, including arrhythmias associated with Wolff-Parkinson-White syndrome. It has been tried for the prevention of arrhythmias in patients with myocardial infarction or heart failure.

Amiodarone hydrochloride is given orally in initial doses of 200 mg three times daily for a week, then 200 mg twice daily for a week, and then a usual maintenance dosage of 200 mg or less daily, according to response. In the USA, amiodarone is only licensed for ventricular arrhythmias and higher doses are used: loading doses of amiodarone hydrochloride are up to 1.6 g daily for 1 to 3 weeks, followed by 600 to 800 mg daily for a month, then a usual maintenance dose of 400 mg daily. Consideration should be given to potential adverse effects, and patients should be given the minimum effective dose.

Amiodarone hydrochloride may be given intravenously where facilities for close monitoring of cardiac function and resuscitation are available. It is usually given as a dilute solution in glucose 5%. Solutions containing less than 600 micrograms/mL are unstable but high concentrations are irritating to the veins, and solutions containing more than 2 mg/mL should be given via a central catheter; a central catheter is also preferred if repeated or continuous infusion is required. The usual dose is 1 to 1.2 g over 24 hours, given by intermittent or continuous infusion as follows:

- in the UK, an initial infusion of 5 mg/kg in 250 mL of glucose 5% is given over 20 to 120 minutes; the infusion may be repeated if required, up to a total dose of 1.2 g in 24 hours, diluted in up to 500 mL of glucose 5%
- in the USA, an initial dose of 150 mg in 100 mL of glucose 5% is given over 10 minutes, followed by 900 mg in 500 mL of glucose 5% over 24 hours, given at a rate of 1 mg/minute for 6 hours and then 500 micrograms/minute for 18 hours; if necessary the maintenance infusion may be continued at a rate of 500 micrograms/minute using a 1 to 6 mg/mL solution
- In emergencies, amiodarone hydrochloride may be given in doses of 150 to 300 mg in 10 to 20 mL of glucose 5% by slow intravenous injection over a period of not less than 3 minutes; a second injection should not be given until at least 15 minutes after the first

For the use of amiodarone in children, see below.

Administration. Addition of amiodarone hydrochloride to an intravenous infusion solution reduces the drop size delivered[1,2] and the reduction in size is greater as the concentration of amiodarone is increased. This resulted[1] in a reduction of about 30% in the expected delivery rate when amiodarone hydrochloride 1.2 g was given in 500 mL of glucose 5%. The reduction in drop size has been attributed to a reduction in surface tension caused by inclusion of Tween 80 (polysorbate 80) in the commercial injection.[1] Allowances should be made for the changes in drop size causing a reduction of the delivery rate of infusions of amiodarone hydrochloride. US licensed product information contra-indicates the use of drop-counter infusion sets and requires the use of a volumetric infusion pump when intravenous amiodarone is given.

Administration in children. Amiodarone has been used orally and intravenously in infants and children[1-3] although use of the injection is generally contra-indicated in neonates because of the presence of benzyl alcohol, a preservative that has been associated with fatalities in neonates due to the 'gasping syndrome' (see Neonates, under Benzyl Alcohol, p.1632) and may cause adverse effects in children up to 3 years old. In the management of cardiac arrhythmias, amiodarone hydrochloride may be given orally in a loading dose of 10 to 20 mg/kg daily (or 500 mg/m^2 daily) for 7 to 10 days, followed by the lowest possible maintenance dose, ranging from 5 to 10 mg/kg daily (or 250 mg/m^2 daily) according to response. It has also been given intravenously in a loading dose of 5 mg/kg given over 20 minutes to 2 hours, followed by a maintenance dose of 10 to 15 mg/kg daily. The *BNFC* suggests intravenous doses of 5 mg/kg given over 30 minutes and repeated every 12 to 24 hours for neonates, and 5 to 10 mg/kg given over 20 minutes to 2 hours and followed by continuous infusion of 300 micrograms/kg per hour (maximum 1.5 mg/kg per hour) for infants and children.

Advanced cardiac life support. Cardiac arrest should be treated by starting full life support measures (see Advanced Cardiac Life Support, p.1156). Amiodarone may be considered in cardiac arrest due to ventricular fibrillation or pulseless ventricular tachycardia that is refractory to rapid defibrillation. Although higher doses have been used, guidelines[1-3] now recommend an intravenous dose of 300 mg, with a further dose of 150 mg if necessary; it may be given by intraosseous injection if the intravenous route is not available.[2] In the UK[1] and European guidelines,[3] this may be followed by an infusion of 900 mg over 24 hours. A study[4] in patients with cardiac arrest outside hospital found that amiodarone improved survival to admission, while another study[5] found that it was more effective than lidocaine in this setting. Retrospective studies[6,7] of its use in cardiac arrest occurring in hospital, however, have not found it to be of benefit.

Cardiac arrhythmias. Amiodarone is an effective drug for the treatment of symptomatic supraventricular and ventricular arrhythmias[1,2] (p.1160); it has a relatively low risk of cardiovascular adverse effects and may be particularly useful in patients with structural heart disease. It is also used to prevent recurrence of both supraventricular and ventricular arrhythmias, although non-cardiac toxicity may limit its long-term use;[2] a small study[3] suggested that short-term use (4 weeks) delayed the recurrence of atrial fibrillation after electrical cardioversion, but the benefits of this approach require confirmation in larger studies. Amiodarone has been used in children (see above), and has been given by various routes to terminate fetal arrhythmias.[4,5]

Perioperative use[6-8] reduces the incidence of atrial fibrillation and other arrhythmias after cardiac surgery. Amiodarone may also have a role in the management of **cardiac arrest** (see Advanced Cardiac Life Support, above); it has been tried for its antiarrhythmic effect in the management of **heart failure** (see below).

Amiodarone has been used for the prevention of sudden cardiac death in patients with asymptomatic ventricular arrhythmias following myocardial infarction, in patients with a history of aborted sudden cardiac death, and in patients with hypertrophic cardiomyopathy or other cardiac disorders that place them at high risk. Although amiodarone may reduce mortality the effect appears to be small,[2,9,10] and early use of high doses after myocardial infarction may be detrimental.[11] For long-term prophylaxis, implantable cardioverter defibrillators are more effective than antiarrhythmic drugs and are usually preferred; amiodarone may have a role as an adjunct to implantable cardioverter defibrillators to prevent frequent shocks,[12] and may also be used in patients who cannot be given an implantable cardioverter defibrillator.

While amiodarone can cause torsade de pointes it appears to do so rarely[13] and patients who have had this form of ventricular tachycardia as a result of other antiarrhythmic therapy have been given amiodarone subsequently without a recurrence.[14]

Heart failure. Sudden deaths in patients with severe heart failure (p.1165) have been attributed to ventricular arrhythmias but routine use of antiarrhythmics is not recommended since many have a negative inotropic effect. Amiodarone, which is not a negative inotrope, is usually the drug of choice in patients with heart failure and symptomatic arrhythmias, but its role for prophylaxis is less clear. In the GESICA study (Grupo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina)[1] amiodarone appeared to reduce mortality in patients with severe chronic heart failure who were without symptomatic ventricular arrhythmias. The decrease in mortality appeared to be greater than could be expected from antiarrhythmic activity alone. However, in the CHF-STAT study (Survival Trial of Antiarrhythmic Therapy in Congestive Heart Failure)[2] involving patients with heart failure and premature ventricular contractions, overall survival did not appear to be improved by amiodarone. A meta-analysis[3] including these and 3 further studies concluded that amiodarone reduced the rate of arrhythmic or sudden death in high-risk patients and that this resulted in an overall reduction in mortality. However a further study[4] found that amiodarone had no effect on long-term survival, whereas implantable cardioverter defibrillators reduced mortality by 23%, and a retrospective analysis[5] of a study in patients with heart failure after acute myocardial infarction found that mortality was higher in those taking amiodarone. Although some studies[1,6,7] have suggested that amiodarone may also improve cardiac function, adverse effects limit its use, and it is not currently recommended in heart failure except in patients with symptomatic ventricular arrhythmias.

Amlodipine Besilate *(BANM, rINNM)*

Amlodipiinibesilaatti; Amlodipin Besilat; Amlodipinbesilat; Amlodipin-besylát; Amlodipin-bezilát; Amlodipine, bésilate d'; Amlodipine Besylate *(USAN)*; Amlodipini besilas; Amlodipino besilatas; Besilato de amlodipino; UK-48340-26; UK-48340-11 (amlodipine maleate). 3-Ethyl 5-methyl 2-(2-aminoethoxymethyl)-4-(2-chlorophenyl)-1,4-dihydro-6-methylpyridine-3,5-dicarboxylate monobenzenesulphonate.

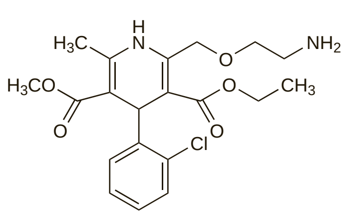
Амлодипина Безилат

$C_{20}H_{25}ClN_2O_5,C_6H_6O_3S = 567.1.$

CAS — 88150-42-9 (amlodipine); 111470-99-6 (amlodipine besilate); 88150-47-4 (amlodipine maleate).

ATC — C08CA01.

ATC Vet — QC08CA01.



(amlodipine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Amlodipine Besilate). A white or almost white powder. Slightly soluble in water and in isopropyl alcohol; sparingly soluble in dehydrated alcohol; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Amlodipine Besylate). A white or almost white powder. Slightly soluble in water and isopropyl alcohol; sparingly soluble in alcohol; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Incidence of adverse effects. Of 1091 patients prescribed amlodipine for hypertension, 128 (11.7%) stopped the drug because of adverse effects.[1] The commonest adverse effects were ankle oedema, flushing, headache, skin rash, and fatigue.

1. Benson E, Webster J. The tolerability of amlodipine in hypertensive patients. *Br J Clin Pharmacol* 1995; **39:** 578P–579P.

Heart failure. Calcium-channel blockers are normally avoided in patients with heart failure but amlodipine has not been found to have any adverse effects on morbidity or mortality in patients with severe heart failure receiving the drug.[1] Therefore, it may be a suitable treatment for angina pectoris or hypertension in such patients. However, a study[2] in hypertensive patients (ALLHAT) found that amlodipine was less effective than the diuretic chlortalidone in preventing the development of heart failure.

1. Packer M, *et al.* Effect of amlodipine on morbidity and mortality in severe chronic heart failure. *N Engl J Med* 1996; **335:** 1107–14.
2. The ALLHAT Officers and Coordinators for the ALLHAT Collaborative Research Group. Major outcomes in high-risk hypertensive patients randomized to angiotensin-converting enzyme inhibitor or calcium channel blocker vs diuretic: The Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT). *JAMA* 2002; **288:** 2981–97. Correction. *ibid.* 2003; **289:** 178.

Porphyria. Although there have been reports[1,2] of the successful use of amlodipine in patients with porphyria, acute exacerbation has also occurred.[3]

1. Gorchein A. Drug treatment of hypertension in acute intermittent porphyria: doxazosin and amlodipine. *Br J Clin Pharmacol* 1997; **43:** 339–40.
2. Cinemre H, *et al.* Safety of amlodipine use in patients with acute intermittent porphyria. *Br J Clin Pharmacol* 2007; **64:** 246–7.
3. Kepple A, Cernek PK. Amlodipine-induced acute intermittent porphyria exacerbation. *Ann Pharmacother* 1997; **31:** 253.

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Amlodipine is well absorbed after oral doses with peak blood concentrations occurring after 6 to 12 hours. The bioavailability varies but is usually about 60 to 65%. Amlodipine is reported to be about 97.5% bound to plasma proteins. It has a prolonged terminal elimination half-life of 35 to 50 hours and steady-state plasma concentrations are not achieved until after 7 to 8 days of use. Amlodipine is extensively metabolised in the liver; metabolites are mostly excreted in urine together with less than 10% of a dose as unchanged drug. Amlodipine is not removed by dialysis.

◊ General reviews.

1. Meredith PA, Elliott HL. Clinical pharmacokinetics of amlodipine. *Clin Pharmacokinet* 1992; **22:** 22–31.
2. Kang D, *et al.* Population analyses of amlodipine in patients living in the community and patients living in nursing homes. *Clin Pharmacol Ther* 2006; **79:** 114–24.

Absorption. Results of studies involving 24 healthy subjects indicated that absorption of amlodipine from a capsule was equivalent to that from a solution, suggesting that the slow transfer of amlodipine into the blood is a property of the drug not of the dosage form; it was also shown that absorption was not affected by food.[1]

1. Faulkner JK, *et al.* Absorption of amlodipine unaffected by food: solid dose equivalent to solution dose. *Arzneimittelforschung* 1989; **39:** 799–801.

Metabolism. The metabolites of amlodipine have been characterised in *animals* and in human subjects.[1] Metabolism of amlodipine is complex and extensive, and in common with other dihydropyridines oxidation to the pyridine analogue represents a major step. About 5% of a dose was recovered from urine as unchanged amlodipine.

1. Beresford AP, *et al.* Biotransformation of amlodipine. *Arzneimittelforschung* 1989; **39:** 201–9.

Uses and Administration

Amlodipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the management of hypertension (p.1171) and angina pectoris (p.1157).

Amlodipine is given orally as the besilate, but doses are usually expressed in terms of the base; amlodipine besilate 6.9 mg is equivalent to about 5 mg of amlodipine. The camsilate, maleate, and mesilate are also used.

In hypertension the usual initial dose is 5 mg once daily, increased, if necessary, to 10 mg once daily. Similar doses are given in the treatment of stable angina and Prinzmetal's angina. Lower initial doses may be used in elderly patients and those with hepatic impairment (see below).

The (*S*)-isomer of amlodipine besilate has also been used.

◊ Reviews.

2. Haria M, Wagstaff AJ. Amlodipine: a reappraisal of its pharmacological properties and therapeutic use in cardiovascular disease. *Drugs* 1995; **50:** 560–86.

Administration in children. Amlodipine has been used to reduce blood pressure in children and adolescents with hypertension. In a study[1] in 28 children aged 3 to 19 years, amlodipine 5 to 10 mg (about 200 to 300 micrograms/kg) once daily significantly reduced blood pressure; therapy was withdrawn in 5 patients due to oedema and flushing. Another study[2] in 268 children aged 6 to 16 years found that amlodipine in a dose of 2.5 or 5 mg (ranging from about 20 to 340 micrograms/kg) once daily was well tolerated; doses above 60 micrograms/kg daily significantly reduced blood pressure. Younger children may need higher doses than older children. In a study[3] in 21 patients aged 6 to 17 years, the mean dose required in children under 13 years was 290 micrograms/kg daily compared with 160 micrograms/kg daily for children 13 years and over. Another study[4] in 55 children aged 13 months to 20 years reported similar mean doses, but also found that many of the younger children needed twice daily dosing. Amlodipine was well tolerated in both studies. The need for a higher dose was supported by a pharmacokinetic study,[5] which found that amlodipine clearance was increased in younger children.

5. Flynn JT, *et al.* Population pharmacokinetics of amlodipine in hypertensive children and adolescents. *J Clin Pharmacol* 2006; **46:** 905–16.

Administration in hepatic impairment. The clearance of amlodipine is reduced in patients with hepatic impairment and lower doses should be considered; an initial dose of 2.5 mg once daily has been recommended.

Preparations

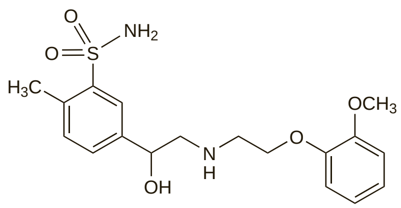
Amosulalol Hydrochloride *(rINNM)* ⊗

Amosulalol, Chlorhydrate d'; Amosulaloli Hydrochloridum; Hidrocloruro de amosulalol; YM-09538. (±)-5-(1-Hydroxy-2-{[2-(*o*-methoxyphenoxy)ethyl]amino}ethyl)-*o*-toluenesulphonamide hydrochloride.

Амосулалола Гидрохлорид

$C_{18}H_{24}N_2O_5S,HCl = 416.9.$

CAS — 85320-68-9 (amosulalol); 70958-86-0 (amosulalol hydrochloride); 93633-92-2 (amosulalol hydrochloride).



(amosulalol)

Profile

Amosulalol is a beta blocker (p.1225); it also has alpha-blocking activity. It has been given orally as the hydrochloride in the management of hypertension.

Amrinone *(BAN, rINN)*

Amrinon; Amrinona; Amrinoni; Amrinonum; Inamrinone *(USAN)*; Win-40680. 5-Amino-3,4′-bipyridyl-6(1*H*)-one.

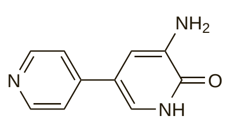
Амринон

$C_{10}H_9N_3O = 187.2.$

CAS — 60719-84-8.

ATC — C01CE01.

ATC Vet — QC01CE01.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Inamrinone). A pale yellow to tan powder; odourless or with a faint odour. Practically insoluble in water and in chloroform; slightly soluble in methyl alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Amrinone Lactate *(BANM, rINNM)*

Amrinone, Lactate d'; Amrinoni Lactas; Lactato de amrinona.

Амринона Лактат

$C_{10}H_9N_3O,C_3H_6O_3 = 277.3.$

CAS — 75898-90-7.

ATC — C01CE01.

ATC Vet — QC01CE01.

Incompatibility. The manufacturer has reported that amrinone lactate injection is physically incompatible with glucose-containing solutions and with furosemide.

Precipitation occurred[1] when amrinone was mixed with sodium bicarbonate injection, probably because of the reduced solubility of amrinone in alkaline solutions.

1. Riley CM, Junkin P. Stability of amrinone and digoxin, procainamide hydrochloride, propranolol hydrochloride, sodium bicarbonate, potassium chloride, or verapamil hydrochloride in intravenous admixtures. *Am J Hosp Pharm* 1991; **48:** 1245–52.

Adverse Effects

Amrinone produces gastrointestinal disturbances that may necessitate withdrawal of treatment. It produces dose-dependent thrombocytopenia. Hepatotoxicity may occur, particularly during long-term oral treatment. Hypotension and cardiac arrhythmias have been reported. Other adverse effects include headache, fever, chest pain, nail discoloration, and decreased tear production. Hypersensitivity reactions including myositis and vasculitis have been reported. Local pain and burning may occur at the site of intravenous injection.

The adverse effects associated with oral use have made this route unacceptable and amrinone is now only given intravenously for short-term use. Studies with other inotropic phosphodiesterase inhibitors have shown that their prolonged oral use can increase the mortality rate.

7. Ross MP, *et al.* Amrinone-associated thrombocytopenia: pharmacokinetic analysis. *Clin Pharmacol Ther* 1993; **53:** 661–7.

Precautions

Amrinone should be used with caution in severe obstructive aortic or pulmonary valvular disease or in hypertrophic cardiomyopathy. Blood pressure and heart rate should be monitored during parenteral use. The fluid and electrolyte balance should be maintained. Platelet counts and liver function should also be monitored.

Pharmacokinetics

Although amrinone is rapidly absorbed from the gastrointestinal tract it is no longer given orally. The half-life is variable and after intravenous injection has been reported to be about 4 hours in healthy subjects and about 6 hours in patients with heart failure. Binding to plasma proteins is generally low. Amrinone is partially metabolised in the liver and excreted in the urine as unchanged drug and metabolites; up to about 40% is excreted as unchanged drug after intravenous use. About 18% of an oral dose has been detected in the faeces over 72 hours.

Infants. For reference to the pharmacokinetics of amrinone in neonates and infants, see under Uses and Administration, below.

Renal impairment. Studies in a child with multi-organ failure and anuria[1] and in 3 adults with anuria after cardiac surgery[2] have shown that amrinone is effectively removed by haemofiltration but clearance varies widely between patients. Non-renal clearance may also be altered in critically ill patients and monitoring of plasma-amrinone concentrations has been suggested.[2]

2. Hellinger A, *et al.* Elimination of amrinone during continuous veno-venous haemofiltration after cardiac surgery. *Eur J Clin Pharmacol* 1995; **48:** 57–9.

Uses and Administration

Amrinone is a phosphodiesterase inhibitor that has vasodilator and positive inotropic properties. It is used in the management of heart failure (p.1165). Although amrinone is effective when given orally this route has been associated with an unacceptable level of adverse effects, and the drug is now only given intravenously for the short-term management of heart failure unresponsive to other forms of therapy.

The mode of action is not fully known, but appears to involve an increase in cyclic adenosine monophosphate concentration secondary to inhibition of phosphodiesterase, leading to an increased contractile force in cardiac muscle.

Amrinone is given intravenously as the lactate and doses are expressed in terms of the base. Amrinone lactate 1.48 mg is equivalent to about 1 mg of amrinone. The initial loading dose is 750 micrograms/kg by slow intravenous injection over 2 to 3 minutes. This is followed by a maintenance infusion, although the loading dose may be repeated after 30 minutes if necessary. Maintenance doses are 5 to 10 micrograms/kg per minute by infusion to a usual maximum total dose (including loading doses) of 10 mg/kg in 24 hours. Doses of up to 18 mg/kg daily have been used for short periods in a limited number of patients.

Administration in infants. Pharmacokinetic and pharmacodynamic studies[1,2] in infants undergoing cardiac surgery indicated that the dose needed for infants to achieve a plasma-amrinone concentration of 2 to 7 micrograms/mL was an initial intravenous bolus of 3 to 4.5 mg/kg in divided doses followed by a continuous infusion of 10 micrograms/kg per minute. Neonates appear to eliminate amrinone more slowly than infants, possibly due to their immature renal function;[1,3] it was therefore suggested[1] that neonates should receive a similar bolus dose to infants, followed by a continuous infusion of 3 to 5 micrograms/kg per minute. In a further study[4] that included mainly infants and older children, amrinone clearance and volume of distribution varied widely between patients but did not appear to be related to age.

Ancrod *(BAN, USAN, rINN)*

Ancrodum.

Анкрод

CAS — 9046-56-4.

ATC — B01AD09.

ATC Vet — QB01AD09.

Description. Ancrod is an enzyme obtained from the venom of the Malayan pit-viper (*Calloselasma rhodostoma = Agkistrodon rhodostoma*).

Adverse Effects and Treatment

Haemorrhage may occur during treatment with ancrod and usually responds to its withdrawal. If haemorrhage is severe, cryoprecipitate can be used to raise plasma fibrinogen concentrations; plasma may be used if cryoprecipitate is not available. An antivenom has been used to neutralise ancrod.

Skin rash, transient chills, and fever have been reported with the use of ancrod.

Precautions

As for Heparin, p.1303.

Ancrod should not be given to patients with severe infections or disseminated intravascular coagulation. It should be used cautiously in patients with cardiovascular disorders that may be complicated by defibrination. It is very important that when ancrod is given by intravenous infusion it should be given slowly to prevent the formation of large amounts of unstable fibrin.

Ancrod is not recommended during pregnancy; high doses in *animals* have caused placental haemorrhage and fetal death.

Interactions

Ancrod should not be used with antifibrinolytics such as aminocaproic acid or with plasma volume expanders such as dextrans.

Uses and Administration

Ancrod is an anticoagulant. It reduces the blood concentration of fibrinogen by the cleavage of microparticles of fibrin which are rapidly removed from the circulation by fibrinolysis or phagocytosis. It reduces blood viscosity but has no effect on established thrombi. Haemostatic concentrations of fibrinogen are normally restored in about 12 hours and normal concentrations in 10 to 20 days.

Ancrod has been used in the treatment of thromboembolic disorders, particularly in deep-vein thrombosis and to prevent thrombosis after surgery in patients requiring anticoagulation but who have developed heparin-induced thrombocytopenia or thrombosis (see Venous Thromboembolism, p.1189). It is under investigation in the treatment of ischaemic stroke and has also been given for priapism.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Arwin.

Angiotensinamide *(BAN, rINN)*

Angiotensiiniamidi; Angiotensin Amide *(USAN)*; Angiotensinamid; Angiotensinamida; Angiotensinamidum; NSC-107678. Asn-Arg-Val-Tyr-Val-His-Pro-Phe; [1-Asparagine,5-valine]angiotensin II.

Ангиотенсинамид

$C_{49}H_{70}N_{14}O_{11}$ = 1031.2.
CAS — 11128-99-7 (angiotensin II); 53-73-6 (angiotensinamide).
ATC — C01CX06.
ATC Vet — QC01CX06.

Profile

Angiotensinamide is a vasopressor related to the naturally occurring peptide angiotensin II. It increases the peripheral resistance mainly in cutaneous, splanchnic, and renal blood vessels. The increased blood pressure is accompanied by a reflex reduction in heart rate, and cardiac output may also be reduced.

Angiotensinamide has been used in the treatment of hypotension associated with shock. It has also been given in the management of overdosage of ACE inhibitors, when conventional therapy has been ineffective.

Angiotensinamide should not be given to patients being treated with an MAOI or within 14 days of stopping such treatment as a hypertensive crisis may be precipitated.

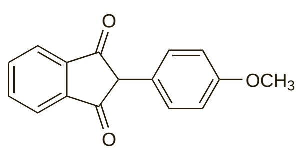
Anisindione *(BAN, rINN)*

Anisindiona; Anisindionum. 2-(4-Methoxyphenyl)indan-1,3-dione.

Анизиндион

$C_{16}H_{12}O_3$ = 252.3.
CAS — 117-37-3.



Profile

Anisindione is an oral indanedione anticoagulant with actions similar to those of warfarin (p.1425). It has been used in the management of thromboembolic disorders (p.1187) but, as the indanediones are generally more toxic than warfarin (see Phenindione, p.1369), its use is limited.

Use of anisindione may colour the urine pink or orange.

Anistreplase *(BAN, USAN, rINN)*

Anisoylated Plasminogen Streptokinase Activator Complex; Anistreplaasi; Anistreplas; Anistreplasa; Anistreplasum; APSAC; BRL-26921. *p*-Anisoylated (human) lys-plasminogen streptokinase activator complex (1:1).

Анистреплаза

CAS — 81669-57-0.
ATC — B01AD03.
ATC Vet — QB01AD03.

Storage. The manufacturer recommends that anistreplase should be stored at 2° to 8°.

Adverse Effects, Treatment, and Precautions

As for Streptokinase, p.1402. Like streptokinase, anistreplase appears to be antigenic and may be neutralised by streptokinase antibodies.

Back pain. For references to back pain associated with anistreplase infusion, see under Streptokinase, p.1402.

Interactions

As for Streptokinase, p.1404.

Pharmacokinetics

Anistreplase is reported to be cleared from plasma at about half the rate of streptokinase and has a fibrinolytic half-life of about 90 minutes. It is metabolised to the plasminogen-streptokinase complex at a steady rate.

◊ References.

1. Gemmill JD, *et al.* A comparison of the pharmacokinetic properties of streptokinase and anistreplase in acute myocardial infarction. *Br J Clin Pharmacol* 1991; **31:** 143–7.

Uses and Administration

Anistreplase is a thrombolytic drug. It consists of a complex of the lys-form of plasminogen and streptokinase with the addition of a *p*-anisoyl group. After intravenous injection the anisoyl group undergoes deacylation at a steady rate to release the active complex which converts plasminogen to plasmin, a proteolytic enzyme that has fibrinolytic effects. The mechanisms of fibrinolysis are discussed further under Haemostasis and Fibrinolysis on p.1045.

Anistreplase is used similarly to streptokinase (p.1404) in the treatment of acute myocardial infarction (p.1175). It is given as a single intravenous injection in a dose of 30 units over 5 minutes, as soon as possible after the onset of symptoms.

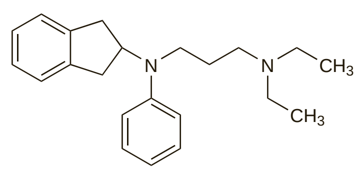
Aprindine Hydrochloride *(BANM, USAN, rINNM)*

AC-1802; Aprindine, Chlorhydrate d'; Aprindini Hydrochloridum; Compound 83846; Compound 99170 (aprindine); Hidrocloruro de aprindina. *N*-(3-Diethylaminopropyl)-*N*-indan-2-ylaniline hydrochloride; *NN*-Diethyl-*N′*-indan-2-yl-*N′*-phenyltrimethylenediamine hydrochloride.

Априндина Гидрохлорид

$C_{22}H_{30}N_2$,HCl = 358.9.
CAS — 37640-71-4 (aprindine); 33237-74-0 (aprindine hydrochloride).
ATC — C01BB04.
ATC Vet — QC01BB04.



(aprindine)

Adverse Effects and Precautions

Adverse effects of aprindine are usually dose-related and most commonly affect the CNS. They include tremor, vertigo, ataxia, diplopia, memory impairment, hallucinations, and convulsions. Gastrointestinal effects include nausea, vomiting, and bloating. There have been reports of agranulocytosis, including fatalities. Hepatitis and cholestatic jaundice have occasionally been reported; blood and liver function tests should be performed during treatment.

Aprindine is contra-indicated in patients with advanced heart failure or severe conduction disturbances. Some licensed product information has recommended that aprindine should not be used in patients with parkinsonism or convulsive disorders. It should be used with caution in patients with bradycardia, hypotension, and hepatic or renal impairment.

Interactions

Antiarrhythmics. Steady-state plasma-aprindine concentrations increased in 2 patients after starting *amiodarone* and this coincided with the appearance of adverse effects.[1]

1. Southworth W, *et al*. Possible amiodarone-aprindine interaction. *Am Heart J* 1982; **104:** 323.

Pharmacokinetics

Aprindine is readily absorbed from the gastrointestinal tract. It has a long plasma half-life, usually between 20 and 27 hours, and is about 85 to 95% bound to plasma proteins. It is excreted in the urine and the bile.

Uses and Administration

Aprindine is a class Ib antiarrhythmic (p.1153) used in the management of ventricular and supraventricular arrhythmias (p.1160).

Aprindine is given as the hydrochloride in usual oral maintenance doses of 50 to 100 mg daily. Initial doses of 150 to 200 mg daily, in divided doses, may be given under strict surveillance for the first 2 to 3 days; up to 300 mg may be given on the first day if necessary. Therapy should be monitored by ECG during initial stabilisation of the dose and intermittently thereafter. Aprindine has also been given intravenously.

Ardeparin Sodium *(USAN, rINN)*

Ardeparina sódica; Ardéparine Sodique; Ardeparinum Natricum; Wy-90493-RD.

Ардепарин Натрий

CAS — 9041-08-1.

Description. Ardeparin sodium is prepared by peroxide degradation of heparin obtained from the intestinal mucosa of pigs. The end chain structure appears to be the same as the starting material with no unusual sugar residues present. The molecular weight of 98% of the components is between 2000 and 15 000 and the average molecular weight is about 5500 to 6500. The degree of sulfation is about 2.7 per disaccharide unit.

Profile

Ardeparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant activity that has been used for the prevention of postoperative venous thromboembolism.

Argatroban *(BAN, USAN, rINN)*

Argatrobanum; Argipidine; DK-7419; GN-1600; MCI-9038; MD-805. (2*R*,4*R*)-4-Methyl-1-[(*S*)-N^2-{[(*RS*)-1,2,3,4-tetrahydro-3-methyl-8-quinolyl]sulfonyl}arginyl]pipecolic acid.

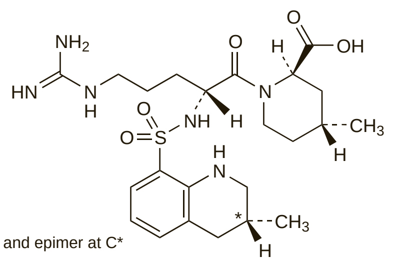
Аргатробан

$C_{23}H_{36}N_6O_5S$ = 508.6.

CAS — 74863-84-6 (anhydrous argatroban); 141396-28-3 (argatroban monohydrate).

ATC — B01AE03.

ATC Vet — QB01AE03.



and epimer at C*

Incompatibility. Trace evidence of precipitation was seen immediately after mixing solutions of argatroban and amiodarone.[1] No visual incompatibility was noted for solutions of argatroban with furosemide, nesiritide, sodium nitroprusside, or a total parenteral nutrition solution, but changes in pH occurred over 24 hours, suggesting such mixtures should be used with caution.[1]

1. Honisko ME, *et al.* Compatibility of argatroban with selected cardiovascular agents. *Am J Health-Syst Pharm* 2004; **61:** 2415–18.

Adverse Effects and Precautions

As for Lepirudin, p.1323.

If argatroban and warfarin are given together there is an effect on the measurement of the INR values. The manufacturer provides guidelines for interpreting the INR during the change from combined therapy to warfarin alone.

Administration in the critically ill. Four critically ill patients became excessively anticoagulated[1] when treatment with argatroban was started after cardiac surgery, despite use of only the recommended doses or lower. All four had relatively normal hepatic function. Clearance of the drug appeared to be prolonged after it was stopped. In a patient[2] who had no significant direct hepatic dysfunction but severe hepatic congestion secondary to acute renal failure, the effect of argatroban was prolonged and reduction in dose was necessary. Haemodialysis had little or no effect on clearance. Further cases of excessive anticoagulation have been reported in patients with multiple organ failure,[3] and in an elderly patient with multiple comorbidities.[4] Patients developing heparin-induced thrombocytopenia after cardiac surgery may also be more sensitive to argatroban, and an initial dose of 500 nanograms/kg per minute has been suggested.[5]

1. Reichert MG, *et al.* Excessive argatroban anticoagulation for heparin-induced thrombocytopenia. *Ann Pharmacother* 2003; **37:** 652–4.
2. de Denus S, Spinler SA. Decreased argatroban clearance unaffected by hemodialysis in anasarca. *Ann Pharmacother* 2003; **37:** 1237–40.
3. Beiderlinden M, *et al.* Argatroban anticoagulation in critically ill patients. *Ann Pharmacother* 2007; **41:** 749–54.
4. Kubiak DW, *et al.* Extensive prolongation of aPTT with argatroban in an elderly patient with improving renal function, normal hepatic enzymes, and metastatic lung cancer. *Ann Pharmacother* 2005; **39:** 1119–23.
5. Hoffman WD, *et al.* Reduced argatroban doses after coronary artery bypass graft surgery. *Ann Pharmacother* 2008; **42:** 309–16.

Overdosage. A critically ill patient receiving low-dose continuous intravenous argatroban for thromboembolism prophylaxis was mistakenly given an additional infusion of 125 mg of argatroban over 1 hour (26.1 micrograms/kg per minute).[1] He was given repeated doses of fresh frozen plasma and no bleeding complications occurred, but the prothrombin time remained prolonged for over 48 hours. Although the total dose given was comparable to doses used in other indications, critically ill patients may be particularly sensitive to the effects of argatroban (see above).

1. Yee AJ, Kuter DJ. Successful recovery after an overdose of argatroban. *Ann Pharmacother* 2006; **40:** 336–9.

Interactions

As for Lepirudin, p.1323.

Warfarin. Although caution is necessary in interpreting the INR when argatroban and warfarin are given together (see Adverse Effects and Precautions, above), a study in healthy subjects[1] showed no pharmacokinetic interaction.

1. Brown PM, Hursting MJ. Lack of pharmacokinetic interactions between argatroban and warfarin. *Am J Health-Syst Pharm* 2002; **59:** 2078–83.

Pharmacokinetics

Argatroban is about 54% bound to plasma proteins. Metabolism, mainly hydroxylation and aromatisation, takes place in the liver, with the main metabolite having weak anticoagulant activity. Anticoagulant effects are seen immediately upon starting infusion; steady-state concentrations occur within 1 to 3 hours and are maintained until the infusion is stopped or the dose adjusted. The terminal elimination half-life of argatroban is between 39 and 51 minutes. It is excreted primarily in the faeces, via the bile as metabolites and as unchanged drug. About 16% of a dose is excreted unchanged in the urine, and at least 14% unchanged in faeces.

Uses and Administration

Argatroban is a synthetic direct thrombin inhibitor (see Lepirudin, p.1323) with anticoagulant and antiplatelet activity. It is used for the treatment and prophylaxis of thromboembolism in patients with heparin-induced thrombocytopenia (see Effects on the Blood under Heparin, p.1302), and as an adjunct in patients undergoing percutaneous coronary interventions (see Reperfusion and Revascularisation Procedures, p.1181) who have or are at risk of heparin-induced thrombocytopenia. It has also been used in other thromboembolic disorders.

In the management of heparin-induced thrombocytopenia, argatroban is given by intravenous infusion in an initial dose of 2 micrograms/kg per minute, adjusted according to the activated partial thromboplastin time (APTT), to a maximum dose of 10 micrograms/kg per minute.

In percutaneous coronary interventions in patients at risk of or with heparin-induced thrombocytopenia, argatroban is given by intravenous infusion in an initial dose of 25 micrograms/kg per minute, and an intravenous injection of 350 micrograms/kg is given simultaneously over 3 to 5 minutes. Close monitoring of the activated clotting time (ACT) is required. If necessary, additional intravenous bolus doses of 150 micrograms/kg may be given, and the infusion rate adjusted to between 15 and 40 micrograms/kg per minute.

Doses should be reduced in patients with hepatic impairment (see below).

8. Boggio LN, Oza VM. Argatroban use in heparin-induced thrombocytopenia. *Expert Opin Pharmacother* 2008; **9:** 1963–7.

Administration in hepatic impairment. In patients with heparin-induced thrombocytopenia with hepatic impairment the initial dose of argatroban should be reduced.[1] US licensed product information recommends an initial dose of 500 nanograms/kg per minute in moderate hepatic impairment. Reversal of anticoagulant effects after stopping argatroban may take more than 4 hours, due to decreased clearance and increased elimination half-life. High doses of argatroban should not be used in patients with significant hepatic impairment undergoing percutaneous coronary interventions.

1. Levine RL, *et al.* Argatroban therapy in heparin-induced thrombocytopenia with hepatic dysfunction. *Chest* 2006; **129:** 1167–75.

Administration in renal impairment. Argatroban is not significantly excreted by the kidneys and dosage adjustment is not usually required in renal impairment, although excessive anticoagulation has been reported in critically ill patients, including some with compromised renal function (see Administration in the Critically Ill under Adverse Effects, above). Argatroban has been successfully used for anticoagulation in patients undergoing chronic haemodialysis who developed thrombocytopenia with heparin.[1] Argatroban was not significantly removed by dialysis and no dosage adjustment was required. The use of argatroban in patients with renal impairment has been reviewed.[2]

Atenolol *(BAN, USAN, rINN)* ⊗

Aténolol; Atenololi; Atenololis; Atenololum; ICI-66082. 2-{*p*-[2-Hydroxy-3-(isopropylamino)propoxy]phenyl}acetamide.

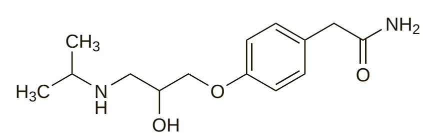
Атенолол

$C_{14}H_{22}N_2O_3$ = 266.3.

CAS — 29122-68-7; 60966-51-0.

ATC — C07AB03.

ATC Vet — QC07AB03.



NOTE. Compounded preparations of atenolol may be represented by the following names:

- Co-tenidone (*BAN*)—atenolol 4 parts and chlortalidone 1 part (w/w)
- Co-tenidone (*PEN*)—atenolol and chlortalidone.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Atenolol). A white or almost white powder. Sparingly soluble in water; soluble in dehydrated alcohol; slightly soluble in dichloromethane.

USP 31 (Atenolol). White or practically white, odourless powder. Slightly soluble in water and in isopropyl alcohol; sparingly soluble in alcohol; freely soluble in methyl alcohol.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Atenolol is distributed into breast milk and there has been a report of cyanosis and bradycardia in a breast-fed neonate whose mother had been taking atenolol (see under Pharmacokinetics, below). The American Academy of Pediatrics therefore considers[1] that it should be given with caution to breast-feeding mothers.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/01/08)

Effects on the eyes. Visual symptoms without headache were associated with atenolol for migraine prophylaxis in a patient who had experienced a similar reaction with nadolol.[1]

1. Kumar KL, Cooney TG. Visual symptoms after atenolol therapy for migraine. *Ann Intern Med* 1990; **112:** 712–13. Correction. *ibid.*; **113:** 257.

Effects on the heart. Beta blockers are used in the management of cardiac arrhythmias. However, atenolol 2.5 mg by intravenous injection induced atrial fibrillation in 6 of 12 predisposed patients.[1]

1. Rassmussen K, *et al*. Atrial fibrillation induced by atenolol. *Eur Heart J* 1982; **3:** 276–81.

Effects on lipid metabolism. For a report of acute pancreatitis due to hypertriglyceridaemia in a patient taking atenolol and metoprolol, see p.1227.

Effects on the liver. Adverse hepatic reactions in patients receiving atenolol have included reversible cholestatic hepatitis in one[1] and hepatic dysfunction in another.[2]

1. Schwartz MS, *et al.* Atenolol-associated cholestasis. *Am J Gastroenterol* 1989; **84:** 1084–6.
2. Yusuf SW, Mishra RM. Hepatic dysfunction associated with atenolol. *Lancet* 1995; **346:** 192.

Overdosage. Atenolol appears to lack membrane-stabilising activity and may have fewer adverse cardiac effects than some other beta blockers. However, cardiovascular toxicity has been noted after massive overdosage: ventricular asystole[1] and hypotension with ECG abnormalities[2] have been reported. Severe cardiovascular effects also occurred[3] in a patient with mixed overdosage including atenolol and diltiazem, and were attributed to additive toxicity.

1. Stinson J, *et al*. Ventricular asystole and overdose with atenolol. *BMJ* 1992; **305:** 693.
2. Love JN, Elshami J. Cardiovascular depression resulting from atenolol intoxication. *Eur J Emerg Med* 2002; **9:** 111–14.
3. Snook CP, *et al.* Severe atenolol and diltiazem overdose. *J Toxicol Clin Toxicol* 2000; **38:** 661–5.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

About 50% of an oral dose of atenolol is absorbed. Peak plasma concentrations are reached in 2 to 4 hours. Atenolol has low lipid solubility. It crosses the placenta and is distributed into breast milk where concentrations higher than those in maternal plasma have been achieved. Only small amounts are reported to cross the blood-brain barrier, and plasma-protein binding is minimal. The plasma half-life is about 6 to 7 hours. Atenolol undergoes little or no hepatic metabolism and is excreted mainly in the urine. It is removed by haemodialysis.

Breast feeding. Atenolol diffuses into breast milk in concentrations similar[1] to or higher[2] than those in maternal blood. Cyanosis and bradycardia associated with ingestion of atenolol in breast milk has been reported in a 5-day-old term infant. The baby improved when breast feeding was stopped.[3]

1. Thorley KJ, McAinsh J. Levels of the beta-blockers atenolol and propranolol in the breast milk of women treated for hypertension in pregnancy. *Biopharm Drug Dispos* 1983; **4:** 299–301.
2. White WB, *et al.* Atenolol in human plasma and breast milk. *Obstet Gynecol* 1984; **63:** 42S–44S.
3. Schimmel MS, *et al.* Toxic effects of atenolol consumed during breast feeding. *J Pediatr* 1989; **114:** 476–8.

Pregnancy. Creatinine clearance increases during pregnancy, and a study in 17 pregnant patients found that the elimination half-life was shorter and renal clearance of atenolol faster during the second and third trimesters compared with three months post partum.[1] In another study,[2] postpartum samples were taken from the maternal and umbilical serum of 6 women who had been taking atenolol for at least 6 days before delivery; atenolol was detected in both maternal and cord blood in about equal concentrations. Atenolol was not detected in the maternal or cord blood of another patient who had stopped taking atenolol one day before delivery; the authors concluded that atenolol levels in the mother and fetus are equal at steady state, and that fetal accumulation does not occur. Atenolol concentrations in 35 term neonates whose mothers had received atenolol were examined.[3] It was found that the elimination rate for the neonates was 4 times slower than in adults, possibly because of immaturity of renal function. Transient bradycardia developed in 14 neonates.

1. Hebert MF, *et al.* Pharmacokinetics and pharmacodynamics of atenolol during pregnancy and postpartum. *J Clin Pharmacol* 2005; **45:** 25–33.
2. Melander A, *et al.* Transplacental passage of atenolol in man. *Eur J Clin Pharmacol* 1978; **14:** 93–4.
3. Rubin PC, *et al.* Atenolol elimination in the neonate. *Br J Clin Pharmacol* 1983; **16:** 659–62.

Uses and Administration

Atenolol is a cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic activity and membrane-stabilising properties.

Atenolol is used in the management of hypertension (p.1171), angina pectoris (p.1157), cardiac arrhythmias (p.1160), and myocardial infarction (p.1175). It may also be used for the prophylaxis of migraine (p.616).

In **hypertension** atenolol is given orally in a dose of 50 to 100 mg daily, as a single dose, although 50 mg daily is generally adequate. The full effect is usually evident within 1 to 2 weeks.

The usual dose for **angina pectoris** is 50 to 100 mg daily orally, given as a single dose or in divided doses. Additional benefit is not usually obtained from higher doses of atenolol although up to 200 mg daily has been given.

For the emergency treatment of **cardiac arrhythmias** atenolol may be given by intravenous injection in a dose of 2.5 mg injected at a rate of 1 mg/minute, repeated if necessary every 5 minutes to a maximum total dosage of 10 mg. Alternatively atenolol may be given by intravenous infusion over 20 minutes in a dose of 150 micrograms/kg. The injection or infusion procedure may be repeated every 12 hours if necessary. When control is achieved maintenance oral doses of 50 to 100 mg daily may be given.

Atenolol is also used in the early management of acute **myocardial infarction**. Treatment should be given within 12 hours of the onset of chest pain; atenolol 5 to 10 mg should be given by slow intravenous injection at a rate of 1 mg/minute, followed after 15 minutes with 50 mg orally, provided no adverse effects result from the injection; alternatively an intravenous dose of 5 mg may be repeated after 10 minutes followed by an oral dose of 50 mg after a further 10 minutes. A further 50 mg may be given orally after 12 hours, and subsequent dosage maintained, after a further 12 hours, with 100 mg daily.

In the prophylaxis of **migraine** an oral dose of 50 to 100 mg daily has been used.

Reduced doses may be required in patients with impaired renal function (see below).

Administration in renal impairment. The dose of atenolol should be reduced in patients with renal impairment, depending on the creatinine clearance (CC) as follows:

- CC 15 to 35 mL/minute per 1.73 m^2: 50 mg daily orally or 10 mg once every two days intravenously
- CC less than 15 mL/minute per 1.73 m^2: 25 mg daily or 50 mg on alternate days orally or 10 mg once every four days intravenously
- dialysis patients: 25 to 50 mg orally after each dialysis.

Preparations

BP 2008: Atenolol Injection; Atenolol Oral Solution; Atenolol Tablets; Co-tenidone Tablets;
USP 31: Atenolol and Chlorthalidone Tablets; Atenolol Injection; Atenolol Oral Solution; Atenolol Tablets.

Proprietary Preparations (details are given in Part 3)
Arg.: Atel; Atenoblock; Atenovit; Cardioblock; Corpaz; Fabotenol; Felobits; Ilaten; Myocord; Plenacor; Prenormine; Telvodin; Tensilol; Tozolden; Vericordin; ***Austral.:*** Anselol; Atehexal; Noten; Tenormin; Tensig; ***Austria:*** Arcablock; Atehexal; Atenolan; Atenotyrol†; Betasyn; Tenormin; ***Belg.:*** Atenotop; Athenol†; Docateno; Tenormin; ***Braz.:*** Ablok; Angipress; Atecard; Atenegran; Ateneo; Atenobal; Atenokin; Atenol; Atenolab; Atenopress†; Atenorm; Atenuol; Atepress; Biotenor†; Ditenol†; Neotenol†; Plenacor; Sifnolol†; ***Canad.:*** Apo-Atenol; Novo-Atenol; Nu-Atenol; Tenolin†; Tenormin; ***Chile:*** Betacar; Grifotenol; Labotensil; Tenormin†; ***Cz.:*** Apo-Atenol; Ateblocor†; Atehexal; Atenobene; Catenol†; Corotenol†; Tenormin; ***Denm.:*** Atenet; Atenodan; Atenor; Tenormin; Uniloc; ***Fin.:*** Atenblock; Atenol; Tenoblock; Tenoprin; ***Fr.:*** Betatop; Tenormine; ***Ger.:*** Ate Lich; Ate†; Atebeta; Atehexal; Atendol†; Ateno; Atenogamma; Blocotenol†; Cuxanorm; duratenol†; Evitocor†; Falitonsin†; Jenatenol; Juvental; Tenormin; ***Gr.:*** Adenamin; Azectol; Blocotenol; Estanolin†; Fealin; Galol†; Hemon†; Mesonex; Mezarid†; Neocardon; Silder†; Synarome; Tenormin; Tradiver†; Umoder; ***Hong Kong:*** Adoll; Antipressan; Apo-Atenol; Ateno†; CP-Atenol; Hypernol; Lo-Ten; Martenol; Normaten; Nortelol; Oraday; Tenormin; Ternolol; Tredol; Vascoten; Velorin; ***Hung.:*** Atenobene; Atenomel; Blokium; Huma-Atenol†; Prinorm; ***India:*** Atecard†; Aten; Beta; Beten; Cadpres; Hipres; Lonol; Teno; Tenolol; Tenormin; Tensimin†; ***Indon.:*** Betablok; Farnormin; Hiblok; Internolol; Tenblok; Tenormin; Tensinorm; Zumablok; ***Irl.:*** Amolin; Atecor; Ateni; Atenogen; Atenomel; Tenormin; Trantalol; ***Israel:*** Normalol; Normiten; ***Ital.:*** Atenol; Atermin; Seles Beta; Tenomax; Tenormin; ***Malaysia:*** Apo-Atenol; Beten; Corotenol†; Loten; Normaten†; Noten; Oraday†; Ranlol; Renotol†; Tenormin; Ternolol†; Uphanormin†; Urosin; Vascoten; ***Mex.:*** Atenol; Atoken; Biofilen; Blotex; Min-T; Nosbal; Tenormin; Trebanol; ***Neth.:*** Tenormin; ***Norw.:*** Alinor†; Tenormin; Uniloc; ***NZ:*** Anselol†; Lo-Ten; ***Philipp.:*** Atestad; Cardioten; Durabeta; Tenor-Bloc; Tenormin; Tenostat; Tensimin; Therabloc; Velorin; ***Pol.:*** Normocard; ***Port.:*** Ancoren†; Atenolac†; Blokium†; Tenormin; Tessifol; ***Rus.:*** Atenolan (Атенолан); Betacard (Бетакард); Catenol (Катенол); Hypoten (Хайпотен); Tenolol (Тенолол); ***S.Afr.:*** Atenoblok; B-Vasc†; Hexa-Blok; Ten-Bloka; Tenormin; Venapulse; ***Singapore:*** Alonet†; Apo-Atenol; Hypernol; Normaten; Noten; Prenolol; Tenolol; Tenormin; Ternolol†; Vascoten; Velorin†; ***Spain:*** Blokium; Neatenol; Tanser; Tenormin; ***Swed.:*** Selinol†; Tenormin; Uniloc†; ***Switz.:*** Atenil; ateno-basan†; Atesifar†; Cardaxen; Primatenol†; Selobloc; Tenormin; ***Thai.:*** Atcard; Atenol; Coratol; Nolol; Nortelol; Oraday; Preloc; Prenolol; Tenocor; Tenol; Tenolol; Tenormin; Tetalin; Vascoten; Velorin; ***Turk.:*** Nortan; Tensidif; Tensinor; ***UAE:*** Tensotin; ***UK:*** Antipressan; Atenix; Tenormin; ***USA:*** Tenormin; ***Venez.:*** Artenolol†; Atenoval†; Beloc; Blokium; Ritmilan; Tenormin.

Interactions

As for Simvastatin, p.1392.

Pharmacokinetics

Atorvastatin is rapidly absorbed from the gastrointestinal tract. It has low absolute bioavailability of about 12% due to presystemic clearance in the gastrointestinal mucosa and/or first-pass metabolism in the liver, its primary site of action. Atorvastatin is metabolised by the cytochrome P450 isoenzyme CYP3A4 to a number of active metabolites. It is 98% bound to plasma proteins. The mean plasma elimination half-life of atorvastatin is about 14 hours although the half-life of inhibitory activity for HMG-CoA reductase is about 20 to 30 hours due to the contribution of the active metabolites. Atorvastatin is excreted as metabolites, primarily in the bile.

Uses and Administration

Atorvastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (or statin), is a lipid regulating drug with actions on plasma lipids similar to those of simvastatin (p.1394). It is used to reduce LDL-cholesterol, apolipoprotein B, and triglycerides, and to increase HDL-cholesterol in the treatment of hyperlipidaemias (p.1169), including hypercholesterolaemias and combined (mixed) hyperlipidaemia (type IIa or IIb hyperlipoproteinaemias), hypertriglyceridaemia (type IV), and dysbetalipoproteinaemia (type III). Atorvastatin can be effective as adjunctive therapy in patients with homozygous familial hypercholesterolaemia who have some LDL-receptor function. It is also used for primary and secondary prophylaxis of cardiovascular events (see Cardiovascular Risk Reduction, p.1164) in patients with multiple risk factors, including diabetes mellitus.

Atorvastatin is given orally as the calcium salt although doses are expressed in terms of the base; 10.82 mg of atorvastatin calcium trihydrate is equivalent to 10 mg of base. The usual initial dose is 10 to 20 mg of atorvastatin once daily; an initial dose of 40 mg daily may be used in patients who require a large reduction in LDL-cholesterol. The dose may be adjusted at intervals of 4 weeks up to a maximum of 80 mg daily.

For patients taking drugs that interact with atorvastatin, dose reduction is advised as follows:

- patients taking *ciclosporin*, maximum dose 10 mg once daily
- patients taking *clarithromycin*, initial dose 10 mg once daily and maximum dose 20 mg once daily
- patients taking *itraconazole*, initial dose 10 mg once daily and maximum dose 40 mg once daily
- patients taking *ritonavir-boosted lopinavir* or *ritonavir-boosted saquinavir*, doses above 20 mg once daily should be used with caution

For the use of atorvastatin in children and adolescents, see below.

Administration in children. In children and adolescents aged 10 to 17 years with hypercholesterolaemia or combined (mixed) hyperlipidaemia, atorvastatin is licensed for use orally in an initial dose of 10 mg once daily, adjusted if necessary at intervals of at least 4 weeks to a maximum dose of 20 mg once daily. A 6-month study[1] with this dose regimen in children with familial or severe hypercholesterolaemia found that atorvastatin was both safe and effective. Atorvastatin has also been used in children with hyperlipidaemia associated with renal[2] or heart[3] transplantation.

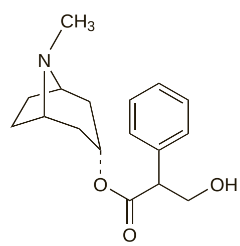
Atropine *(BAN)*

Atropiini; Atropin; Atropina; Atropinas; Atropinum; (±)-Hyoscyamine. (1*R*,3*r*,5*S*,8*r*)-Tropan-3-yl (*RS*)-tropate.

$C_{17}H_{23}NO_3 = 289.4.$
CAS — 51-55-8.
ATC — A03BA01; S01FA01.
ATC Vet — QA03BA01; QS01FA01.



Description. Atropine is an alkaloid that may be obtained from solanaceous plants, or prepared by synthesis.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Atropine). A white or almost white, crystalline powder or colourless crystals. Very slightly soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Atropine). White crystals, usually needle-like, or white crystalline powder. Soluble 1 in 460 of water, 1 in 90 of water at 80°, 1 in 2 of alcohol, 1 in 1 of chloroform, and 1 in 25 of ether; soluble in glycerol. Its saturated solution in water is alkaline to phenolphthalein. Store in airtight containers. Protect from light.

Atropine Methobromide *(BANM)*

Atropina, metilbromuro de; Atropine Methylbromide; Methylatropine Bromide; Méthylatropine, bromure de; Methylatropini bromidum; Methylatropinii Bromidum; Methylatropinium Bromatum; Methylatropinium-bromid; Metilatropin-bromid; Metilatropino bromidas; Metylatropinbromid; Metyyliatropiinibromidi; Mydriasine. (1*R*,3*r*,5*S*)-8-Methyl-3-[(±)-tropoyloxy]tropanium bromide.

$C_{18}H_{26}BrNO_3 = 384.3.$
CAS — 2870-71-5.
ATC — A03BA01.
ATC Vet — QA03BA01.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Methylatropine Bromide; Atropine Methobromide BP 2008). Colourless crystals or a white or almost white crystalline powder. Freely soluble in water; sparingly soluble in alcohol. Protect from light.

Atropine Methonitrate *(BANM, rINN)*

Atrop. Methonit.; Atropiinimetonitraatti; Atropine, Méthonitrate d'; Atropini Methonitras; Atropinmetonitrat; Methylatropine Nitrate *(USAN)*; Méthylatropine, nitrate de; Methylatropini nitras; Methylatropinii Nitras; Methylatropinium nitrát; Metilatropin-nitrát; Metilatropino nitratas; Metilnitrato de atropina; Metonitrato de atropina; Metylatropinnitrat; Metyyliatropiininitraatti. (1*R*,3*r*,5*S*)-8-Methyl-3-[(±)-tropoyloxy]tropanium nitrate.

Атропина Метонитрат

$C_{18}H_{26}N_2O_6 = 366.4.$
CAS — 52-88-0.
ATC — A03BB02.
ATC Vet — QA03BB02.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Methylatropine Nitrate; Atropine Methonitrate BP 2008). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; soluble in alcohol. Protect from light.

Stability. Aqueous solutions of atropine methonitrate are unstable; stability is enhanced in acid solutions of pH below 6.

Atropine Sulfate

Atrop. Sulph.; Atropiinisulfaatti; Atropin Sülfat; Atropina, sulfato de; Atropine, sulfate d'; Atropine Sulphate *(BANM)*; Atropini sulfas; Atropini Sulfas Monohydricus; Atropino sulfatas; Atropinsulfat; Atropin-sulfát monohydrát; Atropin-szulfát; Atropiny siarczan.

$(C_{17}H_{23}NO_3)_2,H_2SO_4,H_2O = 694.8.$
CAS — 55-48-1 (anhydrous atropine sulfate); 5908-99-6 (atropine sulfate monohydrate).
ATC — A03BA01; S01FA01.
ATC Vet — QA03BA01; QS01FA01.

NOTE. Compounded preparations of atropine sulfate may be represented by the following names:

- Co-phenotrope (*BAN*)—atropine sulfate 1 part and diphenoxylate hydrochloride 100 parts (w/w).

ATR is a code approved by the BP 2008 for use on single unit dose eye drops containing atropine sulfate where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Atropine Sulphate). A white or almost white, crystalline powder or colourless crystals. Very soluble in water; freely soluble in alcohol. A 2% solution in water has a pH of 4.5 to 6.2. Protect from light.

USP 31 (Atropine Sulfate). Odourless, colourless crystals or white crystalline powder. It effloresces in dry air. Soluble 1 in 0.5 of water, 1 in 2.5 of boiling water, 1 in 5 of alcohol, and 1 in 2.5 of glycerol. Store in airtight containers.

Incompatibility. Incompatibility between atropine sulfate and hydroxybenzoate preservatives has been seen,[1] resulting in a total loss of the atropine in 2 to 3 weeks.

1. Deeks T. Oral atropine sulphate mixtures. *Pharm J* 1983; **230:** 481.

Adverse Effects

The pattern of adverse effects seen with atropine and other antimuscarinics can mostly be related to their pharmacological actions at muscarinic and, at high doses, nicotinic receptors (see Actions of Antimuscarinics, below). These effects are dose-related and are usually reversible when therapy is stopped. The **peripheral** effects of atropine and other antimuscarinics are a consequence of their inhibitory effect on muscarinic receptors within the autonomic nervous system. At therapeutic doses, adverse effects include dryness of the mouth with difficulty in swallowing and talking, thirst, reduced bronchial secretions, dilatation of the pupils (mydriasis) with loss of accommodation (cycloplegia) and photophobia, flushing and dryness of the skin, transient bradycardia followed by tachycardia, with palpitations and arrhythmias, and difficulty in micturition, as well as reduction in the tone and motility of the gastrointestinal tract leading to constipation. Some of the **central** effects of atropine and other tertiary antimuscarinics seen at toxic doses (see below) may also occur at therapeutic doses.

In **overdosage**, the peripheral effects become more pronounced and other symptoms such as hyperthermia, hypertension, increased respiratory rate, and nausea and vomiting may occur. A rash may appear on the face or upper trunk. Toxic doses also cause CNS stimulation marked by restlessness, confusion, excitement, ataxia, incoordination, paranoid and psychotic reactions, hallucinations and delirium, and occasionally seizures. However, in severe intoxication, central stimulation may give way to CNS depression, coma, circulatory and respiratory failure, and death.

There is considerable variation in susceptibility to atropine; recovery has occurred even after 1 g, whereas deaths have been reported from doses of 100 mg or less for adults and 10 mg for children.

Quaternary ammonium antimuscarinics, such as atropine methobromide or methonitrate and propantheline bromide, have some ganglion-blocking activity and high doses may cause orthostatic hypotension and impotence; in toxic doses non-depolarising neuromuscular block may be produced.

Systemic toxicity may be produced by the **local** instillation of antimuscarinic eye drops, particularly in children and in the elderly. Prolonged application of atropine to the eye may lead to local irritation, hyperaemia, oedema, and conjunctivitis. An increase in intra-ocular pressure may occur, especially in patients with angle-closure glaucoma.

Hypersensitivity to atropine is not uncommon and may occur as conjunctivitis or a skin rash.

Effects on body temperature. Atropine can cause hyperthermia as a result of inhibition of sweating. This may be attenuated by atropine's ability to dilate cutaneous blood vessels. However, there has been a report of hypothermia in a 14-year-old feverish patient after intravenous use of atropine.[1]

For reports of fatal heat stroke in patients taking an antimuscarinic with an antipsychotic see under Interactions in Benzatropine, p.797.

1. Lacouture PG, *et al.* Acute hypothermia associated with atropine. *Am J Dis Child* 1983; **137:** 291–2.

Effects on the eyes. In addition to the expected ocular effects of atropine (see above) there have been instances of acute angle-closure glaucoma in patients receiving nebulised atropine.[1]

1. Berdy GJ, *et al.* Angle closure glaucoma precipitated by aerosolized atropine. *Arch Intern Med* 1991; **151:** 1658–60.

Effects on the gastrointestinal tract. Antimuscarinics reduce gastrointestinal tone and paralytic ileus has been reported[1] in a 77-year-old man with Parkinson's disease who had been receiving atropine sulfate orally to control excess salivation. An increased risk of oesophageal cancer has also been reported[2] with antimuscarinics, possibly due to reductions in lower oesophageal sphincter tone increasing the risk of gastro-oesophageal reflux.

1. Beatson N. Atropine and paralytic ileus. *Postgrad Med J* 1982; **58:** 451–3.
2. Lagergren J, *et al.* Association between medications that relax the lower esophageal sphincter and risk for esophageal adenocarcinoma. *Ann Intern Med* 2000; **133:** 165–75.

Effects on the heart. Atropine sulfate, to a total of 1 mg per 70 kg body-weight, given intravenously to 79 patients before surgery produced arrhythmias in over 20% of patients, especially in the young.[1] Atrioventricular dissociation was the most common disturbance in adults and in children atrial rhythm disturbances were common. In another study[2] premedication including atropine or glycopyrronium given intramuscularly resulted in a significantly greater incidence of tachycardia during anaesthetic induction and intubation compared with controls who received no antimuscarinic drug. Patients who received glycopyrronium also had a higher incidence of tachycardia during surgery than the controls. No significant difference in bradycardia or extrasystoles was found in the atropine- or the glycopyrronium-treated patients. Atrial fibrillation has been reported in 2 elderly glaucoma patients after post-surgical application of atropine ointment or eye drops to the eye.[3]

1. Dauchot P, Gravenstein JS. Effects of atropine on the electrocardiogram in different age groups. *Clin Pharmacol Ther* 1971; **12:** 274–80.

3. Merli GJ, *et al.* Cardiac dysrhythmias associated with ophthalmic atropine. *Arch Intern Med* 1986; **146:** 45–7.

Effects on mental function. A study[1] in patients with Parkinson's disease and healthy control subjects suggested that although short-term memory was impaired in patients receiving long-term antimuscarinic therapy the effect was reversible on stopping. An epidemiological study[2] similarly reported lower cognitive performance in elderly patients receiving antimuscarinics.

Overdosage. Reports of atropine poisoning or overdosage have included a respiratory therapist[1] who had given 10 atropine sulfate aerosol treatments in the preceding 24 hours and children who had taken overdoses of a preparation containing diphenoxylate and atropine.[2]

1. Larkin GL. Occupational atropine poisoning via aerosol. *Lancet* 1991; **337:** 917.
2. McCarron MM, *et al.* Diphenoxylate-atropine (Lomotil) overdose in children: an update (report of eight cases and review of the literature). *Pediatrics* 1991; **87:** 694–700.

Treatment of Adverse Effects

If a patient presents within an hour of an overdose of atropine by mouth the stomach may be emptied or activated charcoal given to reduce absorption. Supportive therapy should be given as required.

Physostigmine has been tried for antimuscarinic poisoning (see p.1884) but such use can be hazardous and is not generally recommended. Diazepam may be given to control marked excitement and convulsions; phenothiazines should not be given as they may exacerbate antimuscarinic effects. Antiarrhythmics are not recommended if arrhythmias develop; hypoxia and acidosis should be corrected and sodium bicarbonate may be given even if acidosis is not present.

Precautions

Atropine should be used with caution in children and the elderly, who may be more susceptible to its adverse effects. It is contra-indicated in patients with prostatic enlargement, in whom it may lead to urinary retention, and in those with paralytic ileus or pyloric stenosis. In patients with ulcerative colitis its use may lead to ileus or megacolon, and its effects on the lower oesophageal sphincter may exacerbate reflux. Caution is generally advisable in any patient with diarrhoea. It should not be given to patients with myasthenia gravis except to reduce adverse muscarinic effects of an anticholinesterase.

Atropine should not be given to patients with angle-closure glaucoma or with a narrow angle between the iris and the cornea, since it may raise intra-ocular pressure and precipitate an acute attack. Acute angle-closure glaucoma has been reported in patients receiving nebulised atropine. Some licensed product information recommends that atropine eye drops should not be used in infants aged less than 3 months due to the possible association between the induced cycloplegia and the development of amblyopia. Systemic reactions have followed the absorption of atropine from eye drops; overdosage is less likely if the eye ointment is used. In the event of blurred vision after topical application of atropine to the eye patients should not drive or operate machinery. Systemic use of antimuscarinics may also cause blurred vision, dizziness, and other effects that may impair a patient's ability to perform skilled tasks such as driving.

Because of the risk of provoking hyperthermia, atropine should not be given to patients, especially children, when the ambient temperature is high. It should also be used cautiously in patients with fever.

Atropine and other antimuscarinics need to be used with caution in conditions characterised by tachycardia such as thyrotoxicosis, heart failure, and in cardiac surgery, where they may further accelerate the heart rate. Care is required in patients with acute myocardial infarction, as ischaemia and infarction may be made worse, and in patients with hypertension.

Atropine may cause confusion, especially in the elderly. Reduced bronchial secretion caused by systemic atropine may be associated with the formation of mucous plugs.

In the treatment of parkinsonism, increases in dosage and transfer to other forms of treatment should be gradual and the antimuscarinic should not be withdrawn abruptly. Minor reactions may be controlled by reducing the dose until tolerance has developed.

Persons with Down's syndrome appear to have an increased susceptibility to some of the actions of atropine, whereas those with albinism may have a reduced susceptibility.

Breast feeding. No adverse effects have been observed in breast-feeding infants whose mothers were receiving atropine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108**: 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 01/06/04)

Interactions

The effects of atropine and other antimuscarinics may be enhanced by use with other drugs having antimuscarinic properties, such as amantadine, some antihistamines, phenothiazine antipsychotics, and tricyclic antidepressants. Inhibition of drug-metabolising enzymes by MAOIs may possibly enhance the effects of antimuscarinics. The reduction in gastric motility caused by antimuscarinics may affect the absorption of other drugs. Antimuscarinics may also antagonise the gastrointestinal effects of cisapride, domperidone, and metoclopramide. Antimuscarinics and parasympathomimetics may counteract each others effects.

Pharmacokinetics

Atropine is readily absorbed from the gastrointestinal tract; it is also absorbed from mucous membranes, the eye, and to some extent through intact skin. It is rapidly cleared from the blood and is distributed throughout the body. It crosses the blood-brain barrier. It is incompletely metabolised in the liver and is excreted in the urine as unchanged drug and metabolites. A half-life of about 4 hours has been reported. Atropine crosses the placenta and traces appear in breast milk.

Quaternary ammonium salts of atropine, such as the methonitrate, are less readily absorbed after oral doses. They are highly ionised in body fluids and being poorly soluble in lipids they do not readily cross the blood-brain barrier.

Pregnancy. Studies of the pharmacokinetics of atropine in mother and fetus in late pregnancy[1-3] indicated that atropine rapidly crosses the placenta. However, whereas peak concentrations of atropine in fetal cord blood were reached about 5 minutes after intravenous doses, the maximum effect on fetal heart rate occurred after about 25 minutes.

Uses and Administration

Atropine is a tertiary amine antimuscarinic alkaloid with both central and peripheral actions (see below). It is usually given as the sulfate. It first stimulates and then depresses the CNS and has antispasmodic actions on smooth muscle and reduces secretions, especially salivary and bronchial secretions; it also reduces perspiration, but has little effect on biliary or pancreatic secretion. Atropine depresses the vagus and thereby increases the heart rate. When given orally atropine reduces smooth-muscle tone and diminishes gastric and intestinal motility but has little effect on gastric secretion in usual therapeutic doses. Quaternary ammonium derivatives, such as the methonitrate, have less effect on the CNS but strong ganglion-blocking activity.

Because of its effects on heart rate, atropine is used in the treatment of bradycardia and asystole of various causes, including in acute cardiopulmonary resuscitation procedures. It has also had many other uses, including: in anaesthetic practice as a premedicant and to counteract the muscarinic effects of anticholinesterases such as neostigmine and other parasympathomimetics; as an antispasmodic in gastrointestinal disorders; as an adjunct to opioid analgesics for the symptomatic relief of biliary or renal colic; to treat or prevent bronchospasm; and in the treatment of poisoning with mushrooms that contain muscarine and in organophosphorus pesticide poisoning. Atropine is used topically as a mydriatic and cycloplegic in ophthalmology.

See under headings below for details of dosage and administration of atropine and its derivatives in specific indications.

Actions of antimuscarinics. Antimuscarinic drugs such as atropine are competitive inhibitors of the actions of acetylcholine at the muscarinic receptors of autonomic effector sites innervated by parasympathetic (cholinergic postganglionic) nerves; they are also inhibitors of the action of acetylcholine on smooth muscle lacking cholinergic innervation. They have been described as parasympatholytic, atropinic, atropine-like, and as anticholinergic, although the latter term should encompass compounds that also have antinicotinic actions.

At least 5 different pharmacologically identifiable types of **muscarinic receptor** (M_1, M_2, M_3, M_4, and M_5) have been described as have 5 different molecular forms (m_1, m_2, m_3, m_4, and m_5) of these receptors. While the traditional antimuscarinics appear to be relatively non-specific, newer compounds like pirenzepine and telenzepine have a selective action on the M_1 receptors within ganglia supplying cholinergic postganglionic nerves to the gastrointestinal tract.

Antimuscarinics can be classified as **tertiary amine** or **quaternary ammonium** compounds. Atropine and other naturally occurring alkaloids such as hyoscine and hyoscyamine are tertiary amines, that is they have a tertiary nitrogen atom; semisynthetic derivatives or synthetic antimuscarinics may be either tertiary (e.g. homatropine or trihexyphenidyl) or quaternary ammonium (e.g. homatropine methylbromide or ipratropium) compounds.

At therapeutic doses tertiary amine antimuscarinics have little effect on the actions of acetylcholine at nicotinic receptors. However, the quaternary ammonium antimuscarinics exhibit a greater degree of antinicotinic potency, and some of their effects at high doses are due to ganglionic blockade; excessively high doses may even produce neuromuscular block. There are also pharmacokinetic differences between tertiary amine and quaternary ammonium antimuscarinics. Quaternary ammonium compounds are less lipid soluble than tertiary amines; their gastrointestinal absorption is poor and they do not readily pass the blood-brain barrier or conjunctiva.

Antimuscarinics can produce a wide range of effects at therapeutic doses. The **peripheral** antimuscarinic effects that are produced as the dose increases are:

- decreased production of secretions from the salivary, bronchial, and sweat glands
- dilatation of the pupils (mydriasis) and paralysis of accommodation (cycloplegia)
- increased heart rate
- inhibition of micturition and reduction in gastrointestinal tone
- inhibition of gastric acid secretion

As for **central** effects, with the exception of hyoscine, which causes CNS depression at therapeutic doses, tertiary amines stimulate the medulla and higher cerebral centres producing mild central vagal excitation and respiratory stimulation. At toxic doses all tertiary amines, including hyoscine, cause stimulation of the CNS with restlessness, disorientation, hallucinations, and delirium. As the dose increases stimulation is followed by central depression and death from respiratory paralysis. Synthetic tertiary amines are less potent in their central effects than natural tertiary amines; quaternary ammonium compounds have negligible central effects.

Anaesthesia. Antimuscarinics, including *atropine, hyoscine,* and *glycopyrronium*, have been used pre-operatively to inhibit salivation and excessive secretions of the respiratory tract during anaesthesia (p.1780), although this use is less important now that less irritating anaesthetics are used. Atropine and glycopyrronium are also given to reduce intra-operative bradycardia and hypotension induced by drugs such as suxamethonium, halothane, or propofol, or following vagal stimulation. Glycopyrronium causes less tachycardia than atropine when given intravenously. When hyoscine is used as a premedicant it also provides some amnesia, sedation, and antiemesis but, unlike atropine, may cause bradycardia rather than tachycardia. Atropine or, preferably, glycopyrronium is also used before, or with, anticholinesterases such as neostigmine to prevent their muscarinic adverse effects (see Uses and Administration of Neostigmine, p.632).

For **premedication** 300 to 600 micrograms of atropine sulfate may be given by subcutaneous or intramuscular injection, usually 30 to 60 minutes before anaesthesia. Alternatively 300 to 600 micrograms of atropine sulfate may be given intravenously immediately before induction of anaesthesia. Suitable paediatric subcutaneous or intramuscular premedication doses of atropine sulfate are:

- children up to 3 kg in weight: 100 micrograms
- children 7 to 9 kg in weight: 200 micrograms
- children 12 to 16 kg in weight: 300 micrograms
- children over 20 kg in weight: the adult dose.

For intra-operative **bradycardia** the *BNF* states that 300 to 600 micrograms may be given intravenously; larger doses may be used in emergencies. Children may be given 10 to 20 micrograms/kg.

To counteract the muscarinic effects of **anticholinesterases** when they are used to reverse the effects of competitive muscle relaxants adults are given atropine sulfate 0.6 to 1.2 mg by intravenous injection before or with the anticholinesterase. Neonates, infants, and children may be given a dose of 20 micrograms/kg (maximum dose 600 micrograms).

Anoxic seizures. A reflex anoxic seizure is a paroxysmal event triggered by a noxious stimulus which, by vagal stimulation, causes pronounced bradycardia or cardiac arrest and consequent relative cerebral ischaemia.[1] Certain features of the attack may lead to a misdiagnosis of epilepsy. To avoid confusion with epileptic seizures (p.465), reflex anoxic seizures have also been called white or type 2 breath holding attacks. Depending on the degree of vagal hypersensitivity or noxious stimulus, attacks may occur infrequently or several times a day.

Infants and young children are mainly affected, however, the condition usually resolves by early childhood. It is generally benign and children do not suffer cardiac or cerebral damage. Treatment is seldom necessary, but atropine has been advocated to prevent vagal hypersensitivity in those children with frequent, persistent attacks. As atropine may require frequent doses with an attendant risk of overdosage, transdermal hyoscine has been tried as an alternative.[2]

Biliary and renal colic. Atropine has been used as an adjunct to opioid analgesics for symptomatic relief of biliary or renal colic (see p.5).

Cardiac disorders. Atropine depresses the vagus and thereby increases the heart rate. It is therefore used in a variety of disorders or circumstances in which bradyarrhythmias occur. It is frequently used in sudden onset bradyarrhythmias and although it may also be given for the initial treatment of chronic arrhythmias (p.1160), cardiac pacing is generally preferred for long-term control. Examples of acute use include the prevention and treatment of arrhythmias associated with anaesthesia (see above), the treatment of other drug-induced arrhythmias, and in cardiac arrest due to asystole or electromechanical dissociation (pulseless electrical activity—p.1156). Atropine sulfate has been used in the management of bradycardia of acute myocardial infarction; however, caution is required, as atropine may exacerbate ischaemia or infarction in these patients.

For **advanced life support** in adults with asystole or electromechanical dissociation, European[1] and UK guidelines[2] recommend atropine in a single dose of 3 mg intravenously; US guidelines[3] recommend repeated doses of 1 mg to a total maximum dose of 3 mg.

In **bradycardia**, atropine is given[1-3] in doses of 500 micrograms intravenously repeated every 3 to 5 minutes to a total dose of 3 mg.

If an intravenous line cannot be established, atropine can be given via an endotracheal tube; 2 to 3 times the intravenous dose should be given, diluted in 10 mL of sterile water or sodium chloride 0.9%.

Eye disorders. Atropine is used to produce mydriasis and cycloplegia (p.1874) for ophthalmic examination. One local application can take up to 40 minutes or more to produce mydriasis, which lasts for a week or more; marked paralysis of accommodation is obtained in 1 to 3 hours with recovery in 6 to 12 days. However, other antimuscarinics such as cyclopentolate, homatropine, or tropicamide may be preferred because they have a more rapid onset and shorter duration of action than atropine. Atropine is also used in the management of uveitis and iritis, and in strabismus. It is used in the treatment of iritis and uveitis to immobilise the ciliary muscle and iris and to prevent or break down adhesions. Because of its powerful cycloplegic action atropine is also used in the determination of refraction in children below the age of 6 and in children with convergent strabismus (p.1874).

In the treatment of **inflammatory eye disorders** such as uveitis or iritis (p.1515), the dose of atropine sulfate for adults is 1 or 2 drops of a 0.5 or 1% solution instilled into the eye(s) up to four times daily. The dose in children is 1 or 2 drops of a 0.5% solution (or one drop of a 1% solution) instilled up to three times daily. For **refraction** in adults the dose is one drop of a 1% solution of atropine sulfate; this may be instilled either twice daily for 1 or 2 days before the procedure or on a single occasion one hour before the procedure. In children the dose for refraction is 1 or 2 drops of a 0.5% solution (or one drop of a 1% solution) instilled twice daily for 1 to 3 days before the procedure, with a further dose given one hour before the procedure. An ophthalmic ointment of atropine sulfate 1% may be preferred for children under 5 years and particularly in infants under 3 months who are at increased risk of systemic effects with eye drops. Some manufacturers recommend that atropine sulfate should not be used in the eyes of children younger than 3 months due to a possible association between the cycloplegia produced and the development of amblyopia.

Atropine borate has also been used in ophthalmic preparations.

Gastrointestinal disorders. Antimuscarinics may be used in gastrointestinal disorders as antispasmodics (see p.1692), because of their marked inhibitory effect on gastrointestinal motility, and for their antisecretory effects. Atropine (as the sulfate or quaternary derivatives such as the methobromide or methonitrate) has been used to reduce smooth-muscle tone and diminish motility, but has little effect on gastric secretion at usual therapeutic doses (about 200 micrograms of atropine sulfate). It has been tried as an adjunct to the treatment of benign gastric and duodenal ulcers and the antispasmodic action of atropine has been used to facilitate radiological examination of the gut. Atropine sulfate has also been used in the treatment of irritable bowel syndrome. Atropine oxide hydrochloride is also used for gastrointestinal disorders.

Poisoning. Atropine is used in the management of overdosage or poisoning due to anticholinesterase compounds including organophosphorus pesticides,[1,2] chemical warfare nerve gases,[3] and parasympathomimetics such as neostigmine. It is also used to antagonise the effects of cholinomimetic substances in the treatment of overdosage with parasympathomimetics such as bethanechol, and in the treatment of poisoning with mushrooms that contain muscarine. Atropine blocks the action of these compounds at muscarinic receptors, reversing bradycardia and decreasing tracheobronchial secretions, bronchoconstriction, intestinal secretions, and intestinal motility.

- In the treatment of poisoning with organophosphorus **pesticides** or chemical warfare **nerve gases** atropine sulfate may be given to adults in an initial dose of 2 mg intramuscularly or intravenously every 10 to 30 minutes until muscarinic effects disappear or signs of atropine toxicity are seen. In severe cases injections have been given as often as every 5 minutes in some centres. Continuous infusion has also been used.[4,5] A dose of at least 50 micrograms/kg has been suggested for children by some;[6] the *BNF* includes a dose of 20 micrograms/kg given every 5 to 10 minutes.
- In moderate to severe poisoning a state of atropinisation is usually maintained for at least 2 days and continued for as long as symptoms are evident. In severely poisoned patients this may entail prolonged treatment.[7,8] As large amounts of atropine may be required it is important to use a preservative-free preparation to avoid the potential toxicity associated with use of excess quantities of preservatives such as benzyl alcohol or chlorobutanol.
- Since atropine is ineffective against any nicotinic effects of these compounds a cholinesterase reactivator such as pralidoxime (p.1460) may be used as an adjunct.

The use of atropine in poisoning or overdosage with **other compounds** having muscarinic actions is similar to that for organophosphorus pesticides but the duration of treatment necessary is usually shorter. An initial dose of 0.6 to 1 mg given subcutaneously, intramuscularly, or intravenously and repeated every 2 hours may be adequate for overdosage with cholinomimetics such as bethanechol.

Respiratory-tract disorders. Although atropine is a potent bronchodilator its use in the management of reversible airways obstruction has largely been replaced by other antimuscarinics such as ipratropium (p.1124). Atropine is sometimes used in combination preparations with antihistamines and decongestants for the symptomatic relief of symptoms of the common cold.

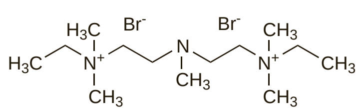
Azamethonium Bromide *(BAN, rINN)*

Azamethonii Bromidum; Azaméthonium, Bromure d'; Bromuro de azametonio; Pentamethazene Bromide; Pentaminum. 2,2′-Methyliminobis(diethyldimethylammonium) dibromide.

Азаметония Бромид

$C_{13}H_{33}Br_2N_3$ = 391.2.
CAS — 60-30-0 (azamethonium); 306-53-6 (azamethonium bromide).



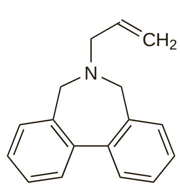
Profile

Azamethonium bromide is a ganglion blocker used in the treatment of hypertension.

Azapetine Phosphate *(BANM)*

Atsapetiinifosfaatti; Azapethine Phosphate; Azapetinfosfat; Azepine Phosphate; Ro-2-3248. 6-Allyl-6,7-dihydro-5*H*-dibenz[*c*,*e*]azepine dihydrogen phosphate.

$C_{17}H_{17}N,H_3PO_4$ = 333.3.
CAS — 146-36-1 (azapetine); 130-83-6 (azapetine phosphate).
ATC — C04AX30.
ATC Vet — QC04AX30.



(azapetine)

Profile

Azapetine is a vasodilator that has been used, as the phosphate, in peripheral vascular disorders.

Preparations

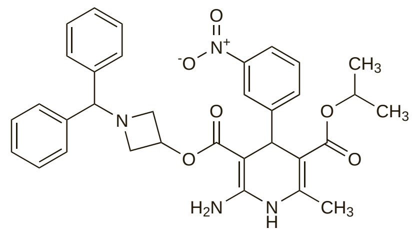
Proprietary Preparations (details are given in Part 3)
Mex.: Peridil.

Azelnidipine *(rINN)*

Azelnidipino; Azelnidipinum; CS-905. 3-[1-(Diphenylmethyl)-3-azetidinyl] 5-isopropyl (±)-2-amino-1,4-dihydro-6-methyl-4-(*m*-nitrophenyl)-3,5-pyridinedicarboxylate.

Азелнидипин

$C_{33}H_{34}N_4O_6$ = 582.6.
CAS — 123524-52-7.



Profile

Azelnidipine is a long-acting dihydropyridine calcium-channel blocker used in the management of hypertension.

Bemiparin Sodium *(BAN, rINN)*

Bemiparina sódica; Bémiparine Sodique; Bemiparinum Natricum.

Бемипарин Натрий

CAS — 9041-08-1.

ATC — B01AB12.

ATC Vet — QB01AB12.

Description. Bemiparin sodium is prepared by alkaline degradation of heparin obtained from the intestinal mucosa of pigs. The majority of the components have a 2-*O*-sulfo-4-enepyranosuronic acid structure at the non-reducing end and a 2-*N*,6-*O*-disulfo-D-glucosamine structure at the reducing end of their chain. The average relative molecular mass is about 3600 (3000 to 4200). The degree of sulfation is about 2 per disaccharide unit.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329.

Severe bleeding with bemiparin sodium may be reduced by intravenous protamine sulfate; 1.4 mg of protamine sulfate is stated to inhibit the effects of 100 units of bemiparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Bemiparin sodium is rapidly absorbed after subcutaneous injection with a bioavailability of about 96%. Peak plasma activity is reached in about 2 to 4 hours, depending on the dose. The elimination half-life is about 5 to 6 hours.

Uses and Administration

Bemiparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant activity. It is used for the prevention and treatment of venous thromboembolism (p.1189), and to prevent clotting during extracorporeal circulation.

In the prophylaxis of **venous thromboembolism** during general surgery with moderate risk, bemiparin sodium is given subcutaneously in a dose of 2500 units once daily, with the first dose given 2 hours before or 6 hours after surgery; in patients undergoing orthopaedic surgery with high risk of thromboembolism the dose should be 3500 units initially and then once daily. Treatment should be continued for at least 7 to 10 days and until the patient is fully ambulant. For treatment of thromboembolism, a dose of 115 units/kg is given subcutaneously once daily.

In some countries bemiparin sodium is used for prophylaxis in non-surgical patients at moderate or high risk of venous thromboembolism, a dose of 2500 or 3500 units being given daily according to risk. Bemiparin sodium is also used in some countries for secondary prevention of venous thromboembolism in patients with transitory risk factors, a dose of 3500 units being given daily for up to 3 months as an alternative to oral anticoagulant therapy.

For the prevention of clotting in the extracorporeal circulation during **haemodialysis**, bemiparin sodium is given into the arterial side of the dialyser in a single dose of 2500 units for patients weighing less than 60 kg and 3500 units for patients weighing more than 60 kg.

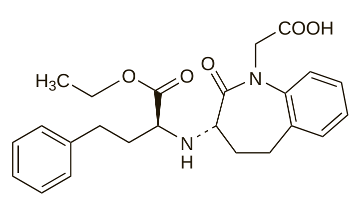
$C_{24}H_{28}N_2O_5$,HCl = 461.0.

CAS — 86541-75-5 (benazepril); 86541-74-4 (benazepril hydrochloride).

ATC — C09AA07.

ATC Vet — QC09AA07.



(benazepril)

Pharmacopoeias. In *US.*

USP 31 (Benazepril Hydrochloride). A white to off-white crystalline powder. Soluble in water, in alcohol, and in methyl alcohol. Store at a temperature below 30°, preferably between 15° and 30°.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Benazepril acts as a prodrug of the diacid benazeprilat, its active metabolite. At least 37% of an oral dose of benazepril is absorbed. Benazepril is almost completely metabolised in the liver to benazeprilat. Peak plasma concentrations of benazeprilat after an oral dose of benazepril have been achieved in 1 to 2 hours in the fasting state or 2 to 4 hours in the nonfasting state. Both benazepril and benazeprilat are about 95% bound to plasma proteins. Benazeprilat is excreted mainly in the urine; about 11 to 12% is excreted in the bile. The effective half-life for accumulation of benazeprilat is 10 to 11 hours after multiple doses of benazepril. The elimination of benazeprilat is slowed in renal impairment, although biliary excretion may compensate to some extent. Small amounts of benazepril and benazeprilat are distributed into breast milk.

4. Macdonald N-J, *et al.* A comparison in young and elderly subjects of the pharmacokinetics and pharmacodynamics of single and multiple doses of benazepril. *Br J Clin Pharmacol* 1993; **36:** 201–4.

Uses and Administration

Benazepril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165).

Benazepril owes its activity to benazeprilat to which it is converted after oral dosage. The haemodynamic effects are seen within 1 hour of a single oral dose and the maximum effect occurs after about 2 to 4 hours, although the full effect may not develop for 1 to 2 weeks during chronic dosing. The haemodynamic action lasts for about 24 hours, allowing once-daily dosing. Benazepril is given orally as the hydrochloride.

In the treatment of **hypertension**, the usual initial dose of benazepril hydrochloride is 10 mg once daily. An initial dose of 5 mg once daily is suggested for patients with renal impairment (see below) or who are receiving a *diuretic*; if possible the diuretic should be withdrawn 2 or 3 days before benazepril is started and resumed later if necessary.

The usual maintenance dose is 20 to 40 mg daily, which may be given in 2 divided doses if control is inadequate with a single dose; doses of up to 80 mg daily have been used.

In the treatment of **heart failure** the usual initial dose of benazepril hydrochloride is 2.5 mg once daily, adjusted according to response to a maximum dose of 20 mg daily.

Administration in children. Experience with benazepril in children is limited. US licensed product information recommends an initial oral dose of 200 micrograms/kg once daily for hypertension in children 6 years of age and over. Maintenance doses up to 600 micrograms/kg daily (maximum 40 mg daily) have been studied. Insufficient evidence is available to recommend doses for younger children or for any children with creatinine clearance below 30 mL/minute.

Administration in renal impairment. In patients with a creatinine clearance of less than 30 mL/minute, the initial dose of benazepril hydrochloride for hypertension is 5 mg once daily and the maintenance dose should not exceed 40 mg daily.

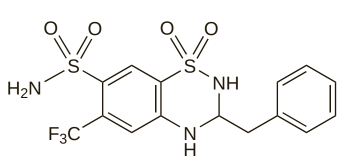
CAS — 73-48-3.

ATC — C03AA01.

ATC Vet — QC03AA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US*.

Ph. Eur. 6.2 (Bendroflumethiazide). A white or almost white crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in acetone.

USP 31 (Bendroflumethiazide). A white to cream-coloured, finely divided, crystalline powder. Is odourless or has a slight odour. Practically insoluble in water; soluble 1 in 23 of alcohol and 1 in 200 of ether; freely soluble in acetone. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Breast feeding. Bendroflumethiazide is used to suppress lactation (see Uses below). However, the American Academy of Pediatrics considers[1] that it is usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 06/07/04)

Porphyria. Bendroflumethiazide is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Overdosage. Tonic-clonic convulsions occurred in a previously healthy 14-year-old girl after ingestion of bendroflumethiazide 150 to 200 mg.[1] The convulsions were not associated with any measurable disturbance of serum electrolytes.

1. Hine KR, *et al.* Bendrofluazide convulsions. *Lancet* 1982; **i:** 564.

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Bendroflumethiazide has been reported to be completely absorbed from the gastrointestinal tract and to have a plasma half-life of about 3 or 4 hours. It is highly bound to plasma proteins. There are indications that bendroflumethiazide is fairly extensively metabolised; about 30% is excreted unchanged in the urine.

◊ References.

1. Beermann B, *et al.* Pharmacokinetics of bendroflumethiazide. *Clin Pharmacol Ther* 1977; **22:** 385–8.
2. Beermann B, *et al.* Pharmacokinetics of bendroflumethiazide in hypertensive patients. *Eur J Clin Pharmacol* 1978; **13:** 119–24.

Uses and Administration

Bendroflumethiazide is a thiazide diuretic with actions and uses similar to those of hydrochlorothiazide (p.1310). It is used for hypertension (p.1171), either alone or with other antihypertensives such as ACE inhibitors and beta blockers. It is also used for oedema, including that associated with heart failure (p.1165), and with renal or hepatic disorders. Other indications have included the suppression of lactation.

Bendroflumethiazide is given orally; diuresis starts in about 2 hours after a dose, peaks after about 3 to 6 hours, and lasts for 12 to 18 hours or longer.

In the treatment of **hypertension** bendroflumethiazide 2.5 mg daily, either alone or with other antihypertensives, is usually adequate although doses of up to 20 mg daily have sometimes been suggested.

In the treatment of **oedema** the usual initial dose is 5 to 10 mg daily or on alternate days; in some cases initial doses of up to 20 mg may be necessary. Maintenance dosage schedules have varied from 2.5 to 10 mg once to three times weekly in the UK to 2.5 to 5 mg daily or intermittently in the USA.

An initial dose for children is up to 400 micrograms/kg daily, reduced to 50 to 100 micrograms/kg for maintenance.

Doses of 5 mg twice daily for about 5 days have been used to **suppress lactation**.

In the management of **idiopathic hypercalciuria** (see Renal Calculi, p.2181) the *BNF* considers that, with increased fluid intake, a sufficient dose is 2.5 mg daily.

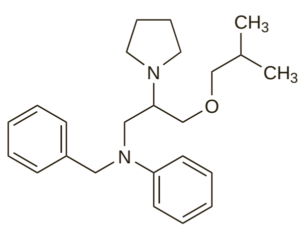
Bepridil Hydrochloride *(BANM, USAN, rINNM)*

Bepridiilihydrokloridi; Bépridil, Chlorhydrate de; Bepridilhydroklorid; Bepridili Hydrochloridum; CERM-1978; Hidrocloruro de bepridil; Org-5730. *N*-Benzyl-*N*-(3-isobutoxy-2-pyrrolidin-1-ylpropyl)aniline hydrochloride monohydrate.

Бепридила Гидрохлорид

$C_{24}H_{34}N_2O,HCl,H_2O$ = 421.0.
CAS — 64706-54-3 (bepridil); 49571-04-2 (bepridil); 64616-81-5 (anhydrous bepridil hydrochloride); 74764-40-2 (bepridil hydrochloride monohydrate).
ATC — C08EA02.
ATC Vet — QC08EA02.



(bepridil)

Profile

Bepridil is a calcium-channel blocker (p.1154). It has similar properties to nifedipine (p.1350) but reduces the heart rate and does not usually cause reflex tachycardia. It also has antiarrhythmic activity. It is not related chemically to other calcium-channel blockers such as diltiazem, nifedipine, or verapamil.

Bepridil is used as the hydrochloride in the management of angina pectoris (p.1157). Ventricular arrhythmias, including torsade de pointes, and agranulocytosis have been associated with bepridil and, as a result, it is usually reserved for patients who have not responded adequately to other anti-anginal drugs. The usual initial dose is 200 mg of bepridil hydrochloride orally once daily. Provided that prolongation of the QT interval has not occurred after 2 to 4 weeks, the dose may be increased, if necessary, to a maximum of 300 mg once daily. Elderly patients and those with hepatic or renal impairment may be given an initial dose of 100 mg once daily; in exceptional circumstances this may be increased to a maximum of 200 mg once daily.

(beraprost)

Profile

Beraprost is a synthetic analogue of epoprostenol (prostacyclin) that causes vasodilatation and prevents platelet aggregation. It is given orally as the sodium salt in the management of pulmonary hypertension (p.1179) and peripheral vascular disease (p.1178).

In primary pulmonary hypertension, beraprost sodium is given in an initial dose of 60 micrograms daily in three divided doses; this may be increased gradually if necessary to 180 micrograms daily in three or four divided doses. For peripheral vascular disease a dose of 120 micrograms daily in three divided doses is used.

Adverse effects of beraprost include headache, flushing, nausea, diarrhoea, and increased liver enzyme, bilirubin, and triglyceride concentrations.

Cardiovascular disorders. References to the use of beraprost for pulmonary hypertension or intermittent claudication;[1-7] results of studies for the latter indication have been conflicting. It has been tried with sildenafil in patients with pulmonary hypertension.[8]

Beta Blockers ⊗

β-Bloqueantes.

Бета-блокаторы

Beta blockers (beta-adrenoceptor blocking drugs or antagonists) are competitive antagonists of catecholamines at beta-adrenergic receptors in a wide range of tissues. Although they have broadly similar properties they differ in their affinity for $beta_1$ or $beta_2$ receptor subtypes, intrinsic sympathomimetic activity, membrane-stabilising activity, blockade of alpha-adrenergic receptors, and pharmacokinetic properties including differences in lipid solubility (see Table 4, below, for some of these characteristics). These differences may affect the choice of drug in specific situations.

Table 4. Characteristics of beta blockers.

Beta blocker	$Beta_1$ selectivity	ISA*	MSA**	Vasodilator activity
Acebutolol	+	+	+	0
Alprenolol	0	+	0	0
Atenolol	+	0	0	0
Betaxolol	+	0	0	0
Bisoprolol	+	0	0	0
Carteolol	0	+	0	0
Carvedilol	0	0	0	+
Celiprolol	+	+	–	+
Esmolol	+	0	0	0
Labetalol	0	0	0	+
Levobunolol	0	0	0	0
Metipranolol	0	0	0	0
Metoprolol	+	0	0	0
Nadolol	0	0	0	0
Nebivolol	+	0	0	+
Oxprenolol	0	+	+	0
Penbutolol	0	0	0	0
Pindolol	0	++	0	0
Propranolol	0	0	++	0
Sotalol	0	0	0	0
Timolol	0	0	0	0

0 = absent or low; + = moderate; ++ = high; – = no information
* ISA = Intrinsic sympathomimetic activity
** MSA = Membrane-stabilising activity

Adverse Effects

Beta blockers are generally well tolerated and most adverse effects are mild and transient. Reactions may be more severe after intravenous than oral doses; ocular use has also been associated with systemic adverse effects. The most frequent and serious adverse effects are related to their beta-adrenergic blocking activity. Among the most serious adverse effects are heart failure, heart block, and bronchospasm. Troublesome subjective effects include fatigue and coldness of the extremities; when beta blockers are used for long-term treatment of asymptomatic diseases such as hypertension, such effects may be an important determinant of patient compliance.

Cardiovascular effects include bradycardia and hypotension; heart failure or heart block may be precipitated or worsened in patients with underlying cardiac disorders. Abrupt withdrawal of beta blockers may exacerbate angina and may lead to sudden death. (For further details on withdrawal of beta blockers, see Precautions, below.)

Bronchospasm, shortness of breath, and dyspnoea may be precipitated, particularly in patients with a history of obstructive airways disease, due to blockade of $beta_2$ receptors in bronchial smooth muscle. Drugs with selectivity for $beta_1$ receptors or with intrinsic sympathomimetic activity at $beta_2$ receptors may be less likely to induce bronchospasm (but see Precautions, below). Pneumonitis, pulmonary fibrosis, and pleurisy have also been reported.

CNS effects include headache, depression, dizziness, hallucinations, confusion, amnesia, and sleep disturbances including nightmares. Coma and convulsions have been reported after beta-blocker overdosage. Beta blockers that are lipid soluble are more likely to enter the brain and would be expected to be associated with a higher incidence of CNS adverse effects, although this is not proven.

Fatigue is a common adverse-effect of beta blockers. Paraesthesia, arthralgia, and myopathies, including muscle cramps, have been reported. Reduced peripheral circulation can produce coldness of the extremities and may exacerbate peripheral vascular disease such as Raynaud's syndrome.

Adverse gastrointestinal effects include nausea and vomiting, diarrhoea, constipation, and abdominal cramping.

Beta blockers interfere with carbohydrate and lipid metabolism and can produce hypoglycaemia, hyperglycaemia, and changes in blood concentrations of triglycerides and cholesterol (see below for further details).

Skin rash, pruritus, exacerbation of psoriasis, excess sweating, and reversible alopecia have occurred with use of beta blockers.

Decreased tear production, blurred vision, conjunctivitis, and soreness are among the ocular symptoms that have been reported. Adverse effects specific to ocular use are also discussed below.

Haematological reactions include nonthrombocytopenic purpura, thrombocytopenia, and rarely agranulocytosis. Transient eosinophilia can occur.

An asymptomatic increase in antinuclear antibodies has occurred with many beta blockers; SLE has also been reported. Other adverse effects reported with some beta blockers include dry mouth, raised liver enzymes, male impotence, sclerosing peritonitis, and retroperitoneal fibrosis.

Carcinogenicity. An apparent excess of deaths from cancer was noted in elderly men, but not women, given atenolol during a study of antihypertensive therapy.[1] However, 2 subsequent studies found no evidence of a link between atenolol and cancer.[2,3]

3. Hole DJ, *et al.* Incidence of and mortality from cancer in hypertensive patients. *BMJ* 1993; **306:** 609–11.

Effects on bones and joints. Adverse effects on the bones and joints have occurred in patients receiving beta blockers. Five cases of arthralgia associated with the use of metoprolol had been reported to the FDA;[1] there had also been 6 reports of similar symptoms with propranolol, and 1 with atenolol. A case of polymyalgia rheumatica-like syndrome has also been reported.[2]

However, epidemiological studies have also suggested that beta blockers may increase bone mineral density[3] and reduce the risk of fractures,[3,4] although another study[5] could not confirm this effect.

Effects on the breast. A 54-year-old woman developed breast pain and swelling a few weeks after starting atenolol for hypertension;[1] it resolved when the atenolol was stopped.

1. Kelleher JA. Atenolol-induced breast pain in a woman with hypertension. *Ann Pharmacother* 2006; **40:** 990–2.

Effects on carbohydrate metabolism. The sympathetic nervous system is involved in the control of carbohydrate metabolism and beta blockers can interfere with carbohydrate and insulin regulation; both hypoglycaemia and hyperglycaemia have been reported in patients with no history of diabetes, as well as in patients with types 1 or 2 diabetes mellitus.

Beta blockers cause hypoglycaemia in non-diabetics, possibly by increasing peripheral glucose uptake through increased insulin sensitivity.[1] Those most at risk include fasting or nutritionally-compromised patients, haemodialysis patients, neonates after maternal treatment with beta blockers, and patients with liver disease;[1] those undertaking vigorous exercise[2] and children may also be at risk. Glucose metabolism is controlled by the action of catecholamines at the $beta_2$ receptor, and therefore cardioselective beta blockers are less likely to cause hypoglycaemia than their non-cardioselective counterparts;[1] however, hypoglycaemia was reported[3] in a non-diabetic patient given the cardioselective beta blocker metoprolol pre-operatively for cardiovascular protection.

Traditionally beta blockers have been considered unsafe in diabetics because of reports that they may precipitate and prolong hypoglycaemia, an effect that was first seen in the 1960s in adult type 1 diabetics taking propranolol; however, in a long-term study[4] in type 2 diabetics, there was no difference in the incidence of hypoglycaemia in patients receiving captopril or the cardioselective beta blocker atenolol, and both significantly improved outcome. A case-control study[5] and a review[6] of the use of beta blockers in diabetic patients both concluded that the incidence of hypoglycaemia was not increased and that beta blockers were appropriate therapy for diabetics. Nonetheless, beta blockers may mask the adrenaline-mediated symptoms of hypoglycaemia such as tachycardia and tremor, and non-cardioselective beta blockers may delay recovery in patients given glucose for hypoglycaemia;[6] cardioselective beta blockers are less likely to mask the signs of hypoglycaemia and are therefore preferred in diabetics.[7]

Both cardioselective and non-cardioselective beta blockers may increase fasting blood glucose concentrations in non-diabetic hypertensive patients,[8,9] and epidemiological studies have shown that the risk of developing diabetes mellitus is increased by beta blockers.[10-12] The mechanism is possibly through inhibition of pancreatic insulin release,[1,13] although it has been suggested that hypertensive patients are predisposed to diabetes mellitus and beta blockers act as a precipitating factor;[10,14] changes in bodyweight in some of the studies may also have confounded the results.[6] Hyperglycaemia can also occur in diabetic patients treated with beta blockers;[14] however, the established benefits generally outweigh the risk.

Although the adverse effects of beta blockers on carbohydrate metabolism are well-established, there is some evidence that the newer, vasodilating beta blockers, such as carvedilol[15,16] and nebivolol,[17,18] may have beneficial effects on insulin resistance or glucose control, and weight gain may be less with carvedilol.[19] New onset diabetes was also more likely to occur with metoprolol than carvedilol in a study on patients with heart failure.[20]

Effects on the circulation. Hypotension is a recognised adverse effect of beta blockers, and severe reactions have been reported. Near-fatal shock occurred[1] in an elderly patient with chronic bronchitis and angina pectoris within 40 minutes of taking acebutolol 400 mg. Hypotension, leading to a rise in serum creatinine indicative of kidney ischaemia, occurred[2] in 2 women after a single oral dose of atenolol 100 mg or 2 oral doses of atenolol 50 mg; both had presented with severe hypertension, hyponatraemia, hypokalaemia, and high renin activity. Renal artery thrombosis believed to be due to the hypotensive effect of atenolol was reported[3] in a 70-year-old man with a history of circulatory and cardiac disorders. He had received atenolol 100 mg for treatment of moderate hypertension.

Beta blockers have been tried in neurally mediated hypotension (see Hypotension under Uses, below), but this may be hazardous: a 27-year-old man had[4] ten episodes of syncope with severe bradycardia after taking atenolol for recurrent vasovagal syncope; episodes ceased on stopping the atenolol. The authors suggested that the atenolol aggravated the vasovagal syncope, and recommended careful monitoring of patients given beta blockers for this condition.

Effects on the gastrointestinal tract. Sclerosing peritonitis was noted as part of the 'oculomucocutaneous syndrome' that occurred with practolol. However, while both sclerosing peritonitis and retroperitoneal fibrosis have also been reported with a number of other beta blockers, including atenolol,[1,2] metoprolol,[3,4] oxprenolol,[5] propranolol,[6] sotalol,[7] and timolol,[8,9] a review[10] of 100 cases of retroperitoneal fibrosis concluded that beta blockers could not be considered as the cause.

Abdominal pain and bloody diarrhoea were reported[11] in a patient the day after treatment was started with propranolol; symptoms were attributed to splanchnic vasoconstriction caused by the drug, which may have exacerbated pre-existing mesenteric ischaemia.

Effects on lipid metabolism. The adrenergic system is involved in the control of lipid metabolism and beta blockers may therefore have effects on plasma-lipid concentrations. In general, beta blocker therapy results in increased concentrations of very-low-density lipoprotein and triglycerides, a reduction in high-density lipoprotein, and no change in low-density lipoprotein.[1] These effects may be less pronounced with $beta_1$ cardioselective drugs, beta blockers with intrinsic sympathomimetic activity, and beta blockers that also block alpha-adrenergic receptors. For example, pindolol,[2,3] a beta blocker with intrinsic sympathomimetic activity, and arotinolol[4] and carvedilol,[5] which possess alpha-adrenergic blocking properties, are reported to have no adverse effects on plasma-lipid concentrations, although acute pancreatitis due to severe hypertriglyceridaemia has been reported[6] in a patient treated with metoprolol followed by atenolol. However, the effects on lipid concentrations are generally fairly small, and a review of the subject[7] concluded that there was little or no evidence that such effects negated the beneficial effects of beta blockers on cardiovascular outcomes.

Effects on mental state. Beta blockers can cross the blood-brain barrier and there are numerous reports of adverse psychiatric effects. Theoretically this is more likely with lipophilic drugs (such as propranolol, timolol, and metoprolol) but there have also been reports of psychosis[1] and delirium[2] with atenolol.

Although beta blockers have been associated with depression,[3] the risk may not be as high as has sometimes been suggested; a review[4] of randomised studies in myocardial infarction, heart failure, or hypertension, which included over 35 000 patients, found no significant increase in the risk of depression in those taking beta blockers.

Effects after ophthalmic use. Ophthalmic use of beta blockers may produce ocular irritation (including hypersensitivity), blepharitis, keratitis, decreased corneal sensitivity, visual disturbances, diplopia, photophobia, and ptosis. Uveitis has been reported with metipranolol eye drops.[1] Iris depigmentation has occurred[2] after the use of topical levobunolol. Older patients using topical beta blockers may be at greater risk of decreased corneal sensitivity or corneal anaesthesia with the consequent risk of keratitis.[3]

Systemic absorption may occur after the use of beta blockers in eye drops. Excess drug can drain into the lachrymal ducts to be absorbed through the nasal mucosa. Absorption also occurs via the ophthalmic and facial veins. After such absorption the beta blocker reaches the systemic circulation without undergoing first-pass hepatic metabolism.

The main systemic effects associated with topical ocular use of beta blockers are on the pulmonary, cardiovascular, and central nervous systems.[4,5]

Both cardioselective and non-cardioselective topical beta blockers have been shown to cause pulmonary effects, and these can occur in patients without a history of obstructive airways disease.[6] Reported events include acute pulmonary oedema associated with use of metipranolol eye drops,[7] and wheezing after a single dose of topical levobunolol, which developed into severe respiratory distress requiring hospitalisation after a second dose.[8] Myocardial infarction has been reported[9] shortly after a single dose of betaxolol eye drops; the patient was also taking atenolol and indapamide for hypertension. Systemic effects have also been reported in patients using timolol eye drops, including depression and bradycardia, with a rise in blood pressure and neurological signs of stroke after rapid withdrawal of the drops,[10] syncope and falls,[11] and severe nausea and vomiting, which resolved within a few days of withdrawal but recurred on rechallenge.[12] A number of cases of alopecia associated with ocular use of beta blockers have also been reported.[13]

Hypersensitivity. For the suggestion that beta blockers may exacerbate anaphylactic reactions, see under Precautions, below.

Overdosage. Many cases of beta-blocker overdosage[1] are uneventful, but some patients develop severe and occasionally fatal cardiovascular depression. Effects can include bradycardia, cardiac conduction block, hypotension, heart failure, and cardiogenic shock. Convulsions, coma, respiratory depression, and bronchoconstriction can also occur, although infrequently. Most reports of serious toxic reactions after overdosage concern beta blockers with significant membrane-stabilising activity, such as propranolol or oxprenolol, which may have quinidine-like effects (see p.1383). Overdosage of beta blockers with intrinsic sympathomimetic activity may present with tachycardia and hypertension. Overdosage of sotalol, a beta blocker with class II and III antiarrhythmic properties, usually presents as ventricular tachyarrhythmia.

1. DeWitt CR, Waksman JC. Pharmacology, pathophysiology and management of calcium channel blocker and β-blocker toxicity. *Toxicol Rev* 2004; **23:** 223–38.

Treatment of Adverse Effects

Beta blockers are generally well tolerated and adverse effects usually respond to a reduction in dose. In overdosage, use of activated charcoal or gastric lavage should be considered if the patient presents within 1 hour of ingestion. Mild hypotension may respond to intravenous fluids. If hypotension continues, intravenous glucagon should be given; sympathomimetics may be used as an alternative or given with glucagon. Isoprenaline has been the sympathomimetic of choice since it acts mainly at beta receptors, but other sympathomimetics are often used; very high doses may be required (see below). Atropine may be given intravenously for bradycardia; sympathomimetics or a cardiac pacemaker may also be required. $Beta_2$ agonists or xanthines may be given for bronchospasm; hypoglycaemia may respond to glucose or glucagon. Haemodialysis may be of benefit for severe overdosage with renally excreted beta blockers, but is usually unnecessary.

Overdosage. Atropine, glucagon, and sympathomimetics are the mainstay of treatment for severe beta blocker overdosage (see above). Very high doses of sympathomimetics have been used in some patients; a woman[1] who had taken acebutolol, labetalol, and trimipramine required isoprenaline at a rate of 1660 micrograms/minute and dopamine at a rate of 200 micrograms/kg per minute to maintain her blood pressure. However, standard therapy is not effective in all patients and alternatives have been tried.

The phosphodiesterase inhibitor enoximone has been used successfully in patients resistant to standard treatment,[2,3] and a dramatic response to calcium chloride has been reported in a patient with electromechanical dissociation after propranolol overdosage.[4] It has been suggested[5,6] that high doses of insulin given with glucose (hyperinsulinaemia/euglycaemia therapy) may be of benefit, although there is no clinical evidence to support this. There has also been a report[7] of the successful use of sodium bicarbonate in a patient with cardiac arrest after overdosage with multiple drugs, including propranolol; it was suggested that the increased sodium load counteracted the sodium-channel blocking effect of propranolol.

Precautions

Beta blockers should not be given to patients with bronchospasm or asthma or to those with a history of obstructive airways disease. This contra-indication generally applies even to those beta blockers considered to be cardioselective. However, cardioselective beta blockers may be used with extreme caution when there is no alternative treatment (see Obstructive Airways Disease, below). Other contra-indications include metabolic acidosis, cardiogenic shock, hypotension, severe peripheral arterial disease, sinus bradycardia, and second- or third-degree AV block; caution should be observed in first-degree block. Although beta blockers are used in the management of heart failure, they should not be given to patients with uncontrolled heart failure and treatment should be begun with great care, starting with a low dose and cautiously titrating upwards. Patients with phaeochromocytoma should not be given beta blockers without alpha-adrenoceptor blocking therapy as well.

Beta blockers may mask the symptoms of hyperthyroidism and of hypoglycaemia. They may unmask myasthenia gravis. Psoriasis may be aggravated. Beta blockers may increase the number of attacks of chest pain in patients with Prinzmetal's angina; this occurs especially with non-cardioselective beta blockers, which should be avoided. Beta blockers increase sensitivity to allergens and also the severity of anaphylactoid reactions; patients with a history of anaphylaxis to an antigen may be more reactive to repeated challenge with the antigen while taking beta blockers (see Hypersensitivity, below).

Abrupt withdrawal of beta blockers has sometimes resulted in angina, myocardial infarction, ventricular arrhythmias, and death. Patients on long-term treatment with a beta blocker should have their medication stopped gradually over a period of 1 to 2 weeks. In patients undergoing surgery, beta blockers may reduce the risk of arrhythmias but increase the risk of hypotension; the decision to withdraw or continue therapy depends on individual patient risk—see Cardiovascular Risk Reduction, below. If beta blockers are withdrawn, this should take place at least 24 to 48 hours before surgery; if they are continued, atropine may be given to counter increases in vagal tone and anaesthetics causing myocardial depression, such as ether, cyclopropane, and trichloroethylene, are best avoided. It is of the greatest importance that the anaesthetist is aware that beta blockers are being taken.

Use of beta blockers in pregnancy shortly before delivery has occasionally resulted in bradycardia and other adverse effects such as hypoglycaemia and hypotension in the neonate. Many beta blockers are distributed into breast milk.

Similar precautions apply when beta blockers are used as eye drops since systemic absorption can occur.

Contact lenses. Beta blockers may reduce tear flow, leading to irritation of the eye in wearers of contact lenses and potentially to the dehydration of soft lenses.[1]

1. McGuire T. Drugs interfering with contact lenses. *Aust J Hosp Pharm* 1987; **17:** 55–6.

Hypersensitivity. Anaphylactic reactions to stings and other antigens may be potentiated by beta blockers[1-3] and the risk of serious reactions may be increased. In addition, beta blockers may antagonise the effects of adrenaline in the management of anaphylaxis (see Interactions under Sympathomimetics, p.1408). Particular caution is necessary when beta blockers are used in patients with a history of anaphylaxis.[3]

3. Lang DM. Anaphylactoid and anaphylactic reactions: hazards of β-blockers. *Drug Safety* 1995; **12:** 299–304.

Obstructive airways disease. Beta blockers may precipitate bronchospasm and are generally contra-indicated in patients with obstructive airways disease.[1,2] However, systematic reviews have suggested that short-term use of cardioselective beta blockers does not produce adverse respiratory effects in patients with mild to moderate asthma[3] or chronic obstructive pulmonary disease.[4] The reviewers concluded that, given the established benefits of beta blockers in cardiovascular disorders, they should not be withheld in such patients, although patients should be carefully monitored since long-term effects were less clear. A retrospective study[5] found that use of beta blockers increased the rate of hospitalisations and emergency department visits in patients with asthma, but not in those with non-asthmatic chronic obstructive pulmonary disease, suggesting that the benefits and risks need to be assessed for each patient individually. Another study[6] found that patients with acute exacerbations of chronic obstructive pulmonary disease who were given beta blockers had lower mortality than those who were not.

Pregnancy. Many beta blockers cross the placenta, and giving them to pregnant women shortly before delivery may result in neonatal adrenergic blockade, with symptoms of bradycardia, hypoglycaemia or hypotension. Furthermore, the treatment of maternal hypertension with beta blockers, particularly atenolol, in early pregnancy or for a long duration has been associated with growth retardation of the fetus.[1-3] However, beta blockers are recommended therapy for maternal conditions such as hypertension, pre-eclampsia, cardiac arrhythmias, and ischaemic heart disease;[4,5] cardioselective agents with no effect on uterine contraction are preferred.[5]

Withdrawal. The abrupt withdrawal of beta blockers may lead to rebound hypertension or overshoot hypertension where the patient's blood pressure is higher than before treatment. Angina can be exacerbated, myocardial infarction induced, and fatalities have occurred.[1,2]

Interactions

Both pharmacodynamic and pharmacokinetic interactions have been reported with beta blockers. **Pharmacodynamic** interactions may occur with drugs whose actions enhance or antagonise the various effects of beta blockers at $beta_1$ and $beta_2$ receptors, including their antihypertensive effect, cardiodepressant effect, effect on carbohydrate metabolism, or effect on bronchial $beta_2$ receptors. The characteristics of the individual beta blocker must therefore be borne in mind when considering likely interactions; for more details on the characteristics of different beta blockers, see Uses and Administration, below.

Drugs that enhance the antihypertensive effects of beta blockers, such as ACE inhibitors, calcium-channel blockers, and clonidine may be useful in controlling hypertension (but see Antihypertensives, below). Drugs that cause hypotension such as aldesleukin and general anaesthetics also enhance the antihypertensive effects of beta blockers while other drugs, for example NSAIDs, antagonise the antihypertensive effects.

Use of beta blockers with other cardiac depressants such as antiarrhythmics and rate-limiting calcium-channel blockers can precipitate bradycardia and heart block; the combination of intravenous verapamil and beta blockers should especially be avoided. Sotalol is particularly prone to interactions with other drugs affecting cardiac conduction (see p.1398). Beta blockers may potentiate bradycardia due to digoxin.

The interaction between beta blockers and sympathomimetics is complex and depends on the selectivity of both drugs (see under Sympathomimetics, p.1408). Patients taking beta blockers may have an exaggerated hypertensive response to adrenaline, caused by unopposed alpha-mediated vasoconstriction, while the bronchodilator effects are inhibited; the response to adrenaline given for anaphylaxis may also be reduced in patients on long-term treatment with beta blockers.

In diabetic patients beta blockers can reduce the response to insulin and oral hypoglycaemics through their effects on pancreatic beta receptors (see Effects on Carbohydrate Metabolism, above).

Pharmacokinetic interactions occur with drugs that alter the absorption or metabolism of beta blockers. Although these interactions may alter the beta blocker plasma concentration, they are not usually clinically significant since there is little association between plasma concentrations and therapeutic effect or toxicity and there are wide interindividual differences in steady-state plasma concentrations of beta blockers.

Drugs that reduce absorption include aluminium salts (but see also Antacids, below) and bile-acid binding resins such as colestyramine.

Metabolism of some beta blockers can be increased by drugs such as barbiturates and rifampicin and decreased with drugs such as cimetidine, erythromycin, fluvoxamine, and hydralazine. Drugs that alter hepatic blood flow also affect metabolism of some beta blockers. For example, cimetidine and hydralazine decrease hepatic blood flow and this contributes to the decreased hepatic clearance seen with these drugs. Drugs that influence hepatic metabolism affect beta blockers that are extensively metabolised, such as labetalol, propranolol, and timolol, while beta blockers that are excreted largely unchanged, for example atenolol and nadolol, are unaffected.

Since systemic absorption can occur after ocular use of beta blockers the possibility of similar interactions should be considered.

Antiarrhythmics. Use of beta blockers with antiarrhythmic drugs and other drugs affecting cardiac conduction can precipitate bradycardia and heart block.

Bradycardia, cardiac arrest, and ventricular fibrillation have been reported shortly after starting beta-blocker therapy in patients receiving *amiodarone*.[1] Amiodarone was found to increase plasma-metoprolol concentrations in patients with cardiac arrhythmias, probably through inhibition of the cytochrome P450 isoenzyme CYP2D6 by the metabolite desethylamiodarone.[2] However, an analysis[3] of the CAMIAT and EMIAT studies in patients after myocardial infarction found that patients taking amiodarone and beta blockers had better outcomes than patients on one, or neither, drug, suggesting that any interaction may not always be detrimental. Use of *flecainide* with propranolol produced additive negative inotropic effects on the heart and increased serum concentrations of both drugs.[4] In a pharmacokinetic study in 12 healthy males, giving *propafenone* with propranolol resulted in increases in serum-propranolol concentrations but only modest enhancement of beta-blocking activity.[5] An increase in serum-metoprolol concentration has been reported after use of propafenone with metoprolol.[6] The metabolism of metoprolol may be decreased by *quinidine*.[7] Both quinidine and beta blockers have a negative inotropic action on the heart; bradycardia[8] and hypotension[9] have occurred in patients given quinidine with beta blockers.

For a report of reduced clearance of *disopyramide* by atenolol, see p.1270.

The interactions of sotalol are discussed on p.1398.

Anticoagulants. For the effect of beta blockers on the pharmacokinetics of some oral anticoagulants, see p.1430.

Antidepressants. Bradycardia and heart block, occurring shortly after starting *fluoxetine* therapy, have been reported in patients receiving metoprolol[1] and propranolol.[2] Possible mechanisms include impaired conduction through the AV node and inhibition by fluoxetine of the oxidative metabolism of beta blockers. Use of fluoxetine also increased the plasma concentration of carvedilol in patients with heart failure but no clinical effects were noted.[3]

Fluvoxamine inhibits oxidative metabolism, and increased plasma concentrations of propranolol have been noted in patients receiving fluvoxamine.

3. Graff DW, *et al.* Effect of fluoxetine on carvedilol pharmacokinetics, CYP2D6 activity, and autonomic balance in heart failure patients. *J Clin Pharmacol* 2001; **41:** 97–106.

Antihypertensives. An enhanced antihypertensive effect is seen when other antihypertensives are given with beta blockers. However, some combinations should be avoided (see Calcium-channel Blockers, below). Beta blockers can potentiate the severe orthostatic hypotension that may follow the initial dose of alpha blockers such as prazosin and can exacerbate rebound hypertension after withdrawal of clonidine treatment (see Precautions, p.1247).

Antimalarials. Antimalarials such as *halofantrine*, *mefloquine*, and *quinine* can cause cardiac conduction defects and caution is necessary if they are used with beta blockers. Cardiopulmonary arrest has occurred after a single dose of mefloquine in a patient taking propranolol.[1]

4. Vestal RE, *et al.* Inhibition of propranolol metabolism by chlorpromazine. *Clin Pharmacol Ther* 1979; **25:** 19–24.

Calcium-channel blockers. Use of calcium-channel blockers with beta blockers has resulted in hypotension, bradycardia, conduction defects, and heart failure.[1]

Beta blockers should be avoided if possible with rate-limiting calcium-channel blockers such as *verapamil* (see p.1422) and *diltiazem*. Although they are reportedly safe with dihydropyridines such as *nifedipine*,[2] heart failure and severe hypotension have been reported (see under Nifedipine, p.1353). Reported pharmacokinetic interactions include increased plasma concentrations of propranolol and of metoprolol with concurrent use of diltiazem[3] or verapamil,[1] and increased plasma concentrations of propranolol with *nicardipine*.[4]

Food. Studies in healthy subjects found that *grapefruit juice* greatly reduced the plasma concentration of celiprolol[1] and talinolol,[2] but had much less effect on acebutolol.[3] An effect on gastrointestinal absorption was suggested as the mechanism.[1,2] Studies with *orange juice* have found a similar effect on celiprolol[4] and, to a lesser extent, atenolol.[5]

5. Lilja JJ, *et al.* Effects of orange juice on the pharmacokinetics of atenolol. *Eur J Clin Pharmacol* 2005; **61** 337–40.

General anaesthetics. Beta blockers are usually continued perioperatively although the anaesthetist must be informed of their use (see Precautions, above). However, the hypotensive effects of beta blockers may be potentiated by general anaesthetics, and anaesthetics that cause myocardial depression, such as *ether, cyclopropane*, and *trichloroethylene* should preferably be avoided.

Histamine H_2-antagonists. Plasma concentrations of propranolol and metoprolol may be increased by *cimetidine*;[1] pharmacokinetic studies indicate that cimetidine exerts its effect by reducing hepatic blood flow and impairing beta blocker metabolism. Cimetidine has been reported to increase the bioavailability of labetalol,[1] and to increase the systemic effects of timolol eye drops.[2]

Local anaesthetics. For details of the effect of beta blockers in reducing the clearance of *bupivacaine*, see p.1855, and of *lidocaine*, see p.1863. For the effects of propranolol with *cocaine*, see p.1860.

Neuromuscular blockers. For the effects of beta blockers on neuromuscular blockers, see under Atracurium, p.1904.

NSAIDs. The antihypertensive effect of beta blockers may be impaired by some NSAIDs, possibly due to their inhibition of renal synthesis of vasodilating prostaglandins. This interaction probably occurs with all beta blockers but may not occur with all NSAIDs. For example, *sulindac* appears to affect blood pressure control less than *indometacin*.[1]

A randomised study[2] in 12 healthy subjects found that *celecoxib* significantly inhibited the metabolism of metoprolol by the cytochrome P450 isoenzyme CYP2D6.

2. Werner U, *et al.* Celecoxib inhibits metabolism of cytochrome P450 2D6 substrate metoprolol in humans. *Clin Pharmacol Ther* 2003; **74:** 130–7.

Opioid analgesics. Bioavailability of propranolol and metoprolol was increased in subjects given *dextropropoxyphene*;[1] dextropropoxyphene is an inhibitor of the cytochrome P450 isoenzyme CYP2D6 and was reported[2] to increase serum concentrations of metoprolol, a CYP2D6 substrate, in a patient given both drugs, resulting in bradycardia. Intravenous *morphine* may increase serum concentrations of esmolol.[3]

Xanthines. For details of reduced *theophylline* clearance in patients receiving some beta blockers, see p.1144.

Pharmacokinetics

Beta blockers differ widely in their pharmacokinetic properties. Differences in lipid solubility contribute to these varying pharmacokinetic properties.

Beta blockers with high lipid solubility (lipophilic beta blockers) include alprenolol and propranolol.

Hydrophilic beta blockers, such as atenolol and nadolol, have low lipid solubility and when compared with lipophilic beta blockers generally:

- tend to be less readily absorbed from the gastrointestinal tract
- are less extensively metabolised
- have low plasma-protein binding
- have relatively long plasma half-lives
- cross the blood-brain barrier less readily

Beta blockers cross the placenta and most are known to distribute into breast milk.

There is no clear correlation between plasma concentrations of beta blockers and therapeutic activity, especially when the beta blocker undergoes metabolism to active metabolites.

Uses and Administration

Beta blockers are competitive antagonists of the effects of catecholamines at beta-adrenergic receptor sites. The different types of adrenergic receptor are described under the Actions and Uses of Sympathomimetics (see p.1408). Blockade of beta receptors has the following effects:

- $beta_1$ blockade mainly affects the heart, reducing heart rate, myocardial contractility, and rate of conduction of impulses through the conducting system (class II antiarrhythmic effect, see p.1153). It also leads to suppression of adrenergic-induced renin release and lipolysis
- $beta_2$ blockade leads to increased bronchial resistance and inhibition of catecholamine-induced glucose metabolism; there may also be an effect on heart rate. $Beta_2$ blockade also appears to be the main mechanism for the reduction in intra-ocular pressure associated with beta blockers
- the role of $beta_3$ blockade is not clear

Beta blockers differ in their affinity for the subtypes of beta receptor, as well as in their actions at other receptors and ancillary properties (see Table 4, p.1225). The cardiovascular effects of beta blockers relate to their action at $beta_1$ receptors, and all clinically used beta blockers are $beta_1$ antagonists. Propranolol and other nonselective beta blockers also have antagonist effects at $beta_2$ receptors, and this may be responsible for many of their adverse effects. Beta blockers with a higher affinity for $beta_1$ than $beta_2$ receptors, such as atenolol and metoprolol, cause fewer noncardiovascular effects and are described as cardioselective or second generation. However, selectivity is relative and, as doses are increased, activity at $beta_2$ receptors becomes clinically important. Beta blockers with additional properties such as vasodilatation have been described as third generation, and include carvedilol, celiprolol, and nebivolol.

Beta blockers such as acebutolol, celiprolol, oxprenolol, and pindolol also possess intrinsic (partial) sympathomimetic activity in that they activate beta receptors in the absence of catecholamines and are therefore partial agonists. Beta blockers with intrinsic sympathomimetic activity produce less resting bradycardia than beta blockers without.

At high blood concentrations, propranolol and some other beta blockers also possess a membrane-stabilising effect. This effect may not be evident at therapeutic doses but may be important in overdose. The non-cardioselective beta blocker sotalol also has class III antiarrhythmic activity.

Beta blockers that cause vasodilatation may do so by a number of mechanisms: carvedilol and labetalol block $alpha_1$ receptors; celiprolol has $beta_2$ agonist effects; and nebivolol has a direct action on the endothelium, possibly involving nitric oxide release.

Beta blockers are used in the treatment of hypertension (p.1171), angina pectoris (p.1157), cardiac arrhythmias (p.1160), and myocardial infarction (p.1175) and also have a role in heart failure (below). They are also used to control symptoms of sympathetic overactivity in the management of alcohol withdrawal (p.1626), in anxiety disorders (below), in hyperthyroidism (p.2165), and in tremor (below). Beta blockers are used in the prophylaxis of migraine (below) and of variceal bleeding associated with portal hypertension (p.2346). They are also used, with an alpha blocker, in the initial management of phaeochromocytoma (below). Some beta blockers are used as eye drops in the management of glaucoma and ocular hypertension (below).

Choice of beta blocker. The selection of a specific beta blocker for an individual patient depends on the condition being treated and patient characteristics such as liver and kidney function or existing disease such as diabetes. Patient tolerance also varies for different beta blockers. The characteristics of the beta blocker, for example, $beta_1$ selectivity and intrinsic sympathomimetic activity may also influence selection, as may additional pharmacological properties such as vasodilator activity. Although the clinical significance of these differences has been debated, only certain beta blockers have a proven benefit in some conditions (for example, heart failure) and this will also influence choice.

Anxiety disorders. Beta blockers have been used in patients with various anxiety disorders,[1] including generalised anxiety disorder (p.952), panic disorder (p.952), and performance anxiety[1] (see under Phobic Disorders, p.953). However, their benefits do not appear to be particularly great and they are probably most useful in reducing symptoms such as tremor or palpitations that are mediated through beta stimulation. Improvement usually occurs within 1 to 2 hours with relatively low doses of beta blockers (propranolol 40 mg, oxprenolol 40 to 80 mg, nadolol 40 mg). Some patients require higher doses and longer periods of treatment for a beneficial effect.

Burns. Beta blockers have been tried in major burn injury (p.1578) to attenuate the hypermetabolism and marked catabolism that may result. A study[1] in children with severe burns found that oral propranolol reduced energy expenditure and muscle-protein catabolism, suggesting beta blockers could have an anabolic effect.

Cardiomyopathy. See Heart Failure, below.

Cardiovascular risk reduction. Beta blockers have established benefits in patients with *ischaemic heart disease*,[1] and long-term therapy with beta blockers has an important role in reducing cardiovascular risk in patients with angina pectoris (p.1157), and particularly in patients who have had a myocardial infarction (p.1175). They have also been used to reduce ischaemia and cardiac events in patients undergoing surgery, but their benefits in this situation are less clear.

Perioperative use of beta blockers is controversial (see Precautions, above); they reduce the risk of ischaemia and arrhythmias, but increase the risk of hypotension, and they have often been stopped pre-operatively to enable better control of blood pressure during surgery. However, there is some evidence that continuing or starting beta blockers perioperatively may be of benefit in patients at risk of cardiovascular events, although not all studies have come to the same conclusions. A systematic review[2] of studies with beta blockers suggested a reduction in myocardial ischaemia, non-fatal myocardial infarction, and mortality from cardiovascular causes in patients at high cardiovascular risk undergoing major noncardiac surgery, and a retrospective study[3] also suggested that perioperative beta blockers reduced in-hospital mortality in high-risk patients, although there was no benefit (and possible harm) in low-risk patients. However, another systematic review and meta-analysis[4] concluded that, while the evidence for the use of beta blockers was encouraging, it was too unreliable for definitive conclusions to be drawn. More recent studies[5,6] using perioperative metoprolol have found no benefit, and a further large study[7] found fewer cardiac events but a higher risk of stroke and death in patients given metoprolol. The conflicting conclusions may relate to the wide range of protocols used in the beta blocker studies, whether patients were already taking beta blockers, and the different selection criteria used for the reviews and analyses. Recognising these limitations, consensus guidelines for non-cardiac surgery in the USA recommend[8] that beta blockers should be continued perioperatively in patients receiving them for accepted indications, and that patients undergoing vascular surgery who are at high risk of cardiovascular events (confirmed by pre-operative testing) should have beta blockers started; in patients at lower risk, use of beta blockers may be considered, but there is less evidence of benefit. It is not clear which beta blockers should be preferred, but a retrospective study[9] found that patients who took atenolol pre- and postoperatively had a lower risk of events than patients who took metoprolol.

Beta blockers may also have benefits in patients undergoing cardiac surgery. Observational studies have found that prior[10] or pre-operative[11] use of beta blockers reduces ischaemic complications, while perioperative[12] and postoperative[13] beta blockers have been shown to reduce the risk of atrial fibrillation, although one study found[14] that the effects on atrial fibrillation only applied to patients already taking beta blockers pre-operatively.

Although beta blockers effectively lower blood pressure, they do not reduce cardiovascular events to the same extent as some other antihypertensives and may not be first choice for *hypertension* (p.1171).[15,16]

Extrapyramidal disorders. Beta blockers (in low doses) have been suggested for the management of antipsychotic-induced akathisia although evidence of benefit is limited (see under Chlorpromazine, p.971).

Glaucoma and ocular hypertension. Topical beta blockers are often the drugs of first choice for the initial treatment and maintenance of open-angle glaucoma and other chronic glaucomas (p.1873). They are believed to inhibit beta receptors in the ciliary epithelium and reduce the secretion of aqueous humour. Clinical studies have established that betaxolol, carteolol, levobunolol, metipranolol, and timolol are effective, generally reducing intra-ocular pressure to a similar extent,[1-5] although a meta-analysis suggested that timolol might be slightly more effective than betaxolol in lowering intra-ocular pressure.[6] The possibility of systemic effects after topical use needs to be borne in mind (see Effects after Ophthalmic Use, above), especially in the elderly.[7]

Beta blockers have also been used for prophylaxis of postoperative ocular hypertension.[8,9]

Heart failure. Beta blockers have negative inotropic properties and have in the past been contra-indicated in patients with heart failure (p.1165). However, there is increasing evidence that they are in fact of benefit since persistent activation of the sympathetic nervous system appears to be associated with disease progression. Reviews,[1-3] meta-analyses,[4,5] and long-term studies[6,7] have confirmed that the beta blockers bisoprolol, carvedilol, and metoprolol all improve mortality in patients with chronic heart failure, and another study[8] has shown benefit with nebivolol in elderly patients. A further meta-analysis[9] found that fewer patients were withdrawn from treatment with beta blockers than placebo, suggesting that the benefits outweigh their adverse effects. Subgroup analysis[10] of one of the large studies also confirmed that metoprolol was well tolerated and of benefit in diabetics, despite potential effects on diabetic control (see Effects on Carbohydrate Metabolism under Adverse Effects, above). Beta blockers have also improved functional status in patients with chronic heart failure.[11] Beta blockers are therefore now recommended, as part of standard therapy, given with ACE inhibitors and diuretics, in all patients with clinically stable heart failure due to left ventricular systolic dysfunction where there are no contra-indications; the benefit in patients with preserved left ventricular function is less clear, although the empirical use of beta blockers to reduce heart rate and improve myocardial ischaemia has been suggested.[12]

The benefit of beta blockers in heart failure may not be a class effect, and in general only those with an established benefit should be used. Not all beta blockers have been studied in heart failure, but there is also evidence that some are ineffective; a study[13] with bucindolol was stopped early because no mortality benefit was found. For those that have been shown to improve mortality, it is not clear if they are all equally effective.[14] A meta-analysis[15] has suggested that vasodilating beta blockers such as carvedilol have a greater effect on overall mortality than those that do not produce vasodilatation, and a large study[16] comparing carvedilol with metoprolol also found a greater mortality reduction with carvedilol, although the equivalence of the doses used in the study has been questioned.[17] The optimum dose is also unclear; many patients are unable to tolerate the target doses used in clinical studies, but an analysis[18] of a study with metoprolol suggested that the mortality benefit was equal in those receiving low or high doses.

Beta blockers may also be of value in some patients with heart failure due to cardiomyopathy (p.1163). A number of beta blockers have provided symptomatic benefit in idiopathic dilated cardiomyopathy, and the heart failure studies that showed a mortality benefit included patients with dilated cardiomyopathy. In hypertrophic cardiomyopathy, beta blockers may be of value for symptomatic management to curtail tachycardia, reduce anginal pain, and prevent syncope.

Hypotension. Beta blockers have a hypotensive effect and are usually used to reduce blood pressure in patients with hypertension, or occasionally to produce controlled hypotension during surgery. Paradoxically, however, they may be used in the management of neurally mediated hypotension in patients who require drug therapy (see p.1174), although there is limited evidence to support their use, and adverse effects may be a concern. Beta blockers with partial agonist activity have been used in orthostatic hypotension due to autonomic failure (p.1530) but are potentially dangerous.

Migraine and tension type headache. Beta blockers (usually propranolol or metoprolol) are considered[1] by many to be the drugs of choice in patients requiring prophylactic treatment for migraine (p.616). Their mechanism of action in this disorder is not fully understood. Other beta blockers reported to be effective include atenolol, nadolol, and timolol; those with intrinsic sympathomimetic activity may not be effective.

Beta blockers may sometimes also be of benefit in patients with chronic tension-type headache (p.617).

Propranolol has been tried in the treatment of children with abdominal migraine (see under Pizotifen, p.624).

1. Limmroth V, Michel MC. The prevention of migraine: a critical review with special emphasis on β-adrenoceptor blockers. *Br J Clin Pharmacol* 2001; **52:** 237–43.

Peripheral vascular disease. Beta blockers may cause coldness of the extremities and have been reported to induce secondary Raynaud's syndrome. However, they may be of some help in the management of erythromelalgia (see under Vasospastic Arterial Disorders on p.1188).

Phaeochromocytoma. Beta blockers are used, with an alpha blocker, in the initial management of phaeochromocytoma (p.1179). Beta blockers reduce the responses to the beta-adrenoceptor stimulating effects of adrenaline. Treatment must be started with the alpha blocker and only when alpha blockade is successfully established can tachycardia be controlled by the cautious use of a beta blocker. A beta$_1$-selective blocker is preferred so that peripheral beta$_2$-mediated vasodilatation is unaffected. In most cases modest doses are sufficient although higher doses may be required for a tumour that is mainly adrenaline-secreting.

Tetanus. Autonomic overactivity, usually due to excessive catecholamine release, may occur as a complication of tetanus and is usually controlled with sedation (see p.1901). Beta blockers have also been used but may produce severe hypertension and are therefore not usually recommended. Labetalol has both alpha- and beta-blocking properties and intravenous labetalol has been used successfully to control the cardiovascular effects of tetanus,[1] although it has not been shown to offer any advantage over propranolol in this situation. Esmolol, a short-acting beta blocker, has also been used.[2]

Tetralogy of Fallot. For the use of beta blockers in the management of tetralogy of Fallot, see under Uses of Propranolol, p.1381.

Tremor. Tremor is a rhythmical oscillation of part of the body caused by involuntary contraction of opposing muscles. It may occur during action, maintenance of posture, or at rest, and varies in frequency and amplitude. Resting tremor is associated mainly with parkinsonism (p.791), whereas action tremor, which includes postural tremor and kinetic tremor, occurs in a wide variety of disorders. Treatment of the underlying disorder may remove the tremor. Drugs such as bronchodilators, tricyclic antidepressants, lithium, and caffeine may induce tremor; withdrawal of the causative drug usually alleviates the tremor. However, tremor often has no known underlying cause. Such tremor is referred to as **essential tremor** or benign essential tremor; it is usually postural and tends to affect the hands, head, voice, and sometimes the legs and trunk. It is exacerbated by emotional stress and anxiety. Essential tremor may appear at any age and is a lifelong condition that may progress with increasing age. In many cases there is a family history of the disorder (familial essential tremor).

Mild cases of essential tremor may not require regular drug treatment. Single doses of a beta blocker or a benzodiazepine may be useful in acute circumstances to control exacerbations provoked by stress. A single dose of propranolol usually produces a maximum effect after 1 to 2 hours and the effect may persist for several hours. Small amounts of alcohol may also provide effective temporary relief of essential tremor, although its regular use is obviously discouraged.

For more severe cases of essential tremor long-term drug treatment may be required (and may also be tried in other forms of tremor).[1-5] A beta blocker (usually a non-cardioselective beta blocker such as propranolol) is often the first drug used. Up to 70% of people have been reported to respond, although the average tremor reduction is only about 50 to 60%. The beneficial effect appears to be mainly due to blockade of peripheral beta$_2$ receptors on extrafusal muscle fibres and muscle spindles, although there may also be a CNS effect. Adverse effects may be troublesome on long-term use. Primidone may also be tried[6] although there may be a high incidence of acute adverse reactions after initial doses. Concern has been expressed that patients may become tolerant to these drugs given long-term. However, 3 small studies found a reduced response on long-term therapy in only a few patients.[7-9] Local injection of botulinum A toxin has been tried in refractory essential tremor. Benzodiazepines, and antimuscarinic or dopaminergic antiparkinsonian drugs may be effective in some forms of tremor.[1] Other drugs that have shown some benefit include gabapentin and topiramate.[1-4,10] Many other drugs have been tried, but there is little evidence to support their use.[10] In very severe disabling cases, surgery (thalamotomy or deep brain stimulation) may have to be considered.

Betaxolol Hydrochloride

(BANM, USAN, rINNM) ⊗

ALO-1401-02; Betaksolol Hidroklorür; Betaksololihydrokloridi; Betaksololio hidrochloridas; Bétaxolol, chlorhydrate de; Betaxolol-hidroklorid; Betaxolol-hydrochlorid; Betaxololhydroklorid; Betaxololi hydrochloridum; Hidrocloruro de betaxolol; SL-75212-10. 1-{4-[2-(Cyclopropylmethoxy)ethyl]phenoxy}-3-isopropylaminopropan-2-ol hydrochloride.

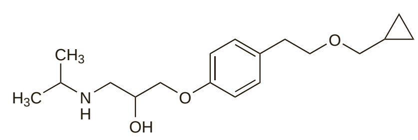
Бетаксолола Гидрохлорид

$C_{18}H_{29}NO_3$,HCl = 343.9.

CAS — 63659-18-7 (betaxolol); 63659-19-8 (betaxolol hydrochloride).

ATC — C07AB05; S01ED02.

ATC Vet — QC07AB05; QS01ED02.



(betaxolol)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Betaxolol Hydrochloride). A white or almost white crystalline powder. Very soluble in water; freely soluble in alcohol; soluble in dichloromethane. Protect from light.

USP 31 (Betaxolol Hydrochloride). A white crystalline powder. Freely soluble in water, in alcohol, in chloroform, and in methyl alcohol. pH of a 2% solution in water is between 4.5 and 6.5. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Betaxolol is completely absorbed from the gastrointestinal tract and undergoes only minimal first-pass metabolism, resulting in a high oral bioavailability of about 90%. It has high lipid solubility. Betaxolol is about 50% bound to plasma proteins. It crosses the placenta and is distributed into breast milk where higher concentrations have been achieved than in maternal blood. The plasma elimination half-life of betaxolol ranges from 14 to 22 hours. The primary route of elimination is via hepatic metabolism and urinary excretion; only about 15% is excreted in the urine as unchanged drug.

Pregnancy and breast feeding. The pharmacokinetics of betaxolol were investigated in the perinatal period in 28 pregnant hypertensive patients receiving doses of 10 to 40 mg daily.[1] Pharmacokinetic values were similar to those seen in non-pregnant patients. Umbilical-cord concentrations were similar to maternal blood concentrations and showed a negative correlation between concentration in cord blood and timing of the last dose of betaxolol. Thus the betaxolol concentration in neonates can be considerably reduced by stopping maternal drug use 16 to 18 hours before birth. The blood-betaxolol half-life in the neonates ranged from 14.8 to 38.5 hours. The mean apparent half-life in infants with gestational age less than 36 weeks was about 32% higher than in full-term neonates. Betaxolol concentrations in milk and/or colostrum were determined in 3 mothers. In all samples the milk-to-blood ratio was greater than 2.

1. Morselli PL, *et al.* Placental transfer and perinatal pharmacokinetics of betaxolol. *Eur J Clin Pharmacol* 1990; **38:** 477–83.

Uses and Administration

Betaxolol is a cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic activity and to have little membrane-stabilising activity.

Betaxolol is used as the hydrochloride in the management of hypertension (p.1171), angina pectoris (p.1157), and glaucoma (p.1873).

In **hypertension** betaxolol hydrochloride is given in an initial oral dose of 10 mg once daily, which may be doubled if necessary after 1 to 2 weeks. Doses above 20 mg daily do not usually give additional benefit, but up to 40 mg daily has been tolerated. Similar doses are used in **angina pectoris**.

An initial dose of 5 mg daily is suggested for elderly patients. Reduced dosages should also be used in patients with severe renal impairment (see below).

Eye drops containing the equivalent of 0.25 or 0.5% betaxolol as the hydrochloride are instilled twice daily to reduce raised intra-ocular pressure in ocular hypertension and open-angle **glaucoma**.

◊ General references.

1. Buckley MM-T, *et al.* Ocular betaxolol: a review of its pharmacological properties, and therapeutic efficacy in glaucoma and ocular hypertension. *Drugs* 1990; **40:** 75–90.

Administration in renal impairment. The clearance of betaxolol is reduced in patients with renal impairment and the dose may therefore need to be reduced. Licensed US product information recommends an initial dose of betaxolol hydrochloride 5 mg daily in patients with severe renal impairment or on dialysis; the dose may be increased by 5 mg every 2 weeks, to a maximum of 20 mg daily.

Speech disorders. A 50-year-old man who had stuttered since childhood obtained striking improvement in his stuttering when he was given betaxolol 20 mg daily for essential hypertension.[1]

(bevantolol)

Profile

Bevantolol is a cardioselective beta blocker (p.1225). It is reported to lack significant intrinsic sympathomimetic activity but has weak membrane-stabilising properties and also has vasodilator activity. It has been given orally as the hydrochloride in the management of hypertension and angina pectoris.

Bezafibrate *(BAN, USAN, rINN)*

Betsafibraatti; Bezafibrát; Bezafibrat; Bezafibratas; Bézafibrate; Bezafibrato; Bezafibratum; BM-15075; LO-44. 2-[4-(2-*p*-Chlorobenzamidoethyl)phenoxy]-2-methylpropionic acid.

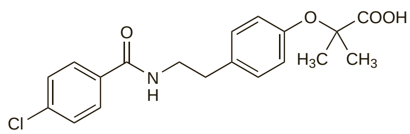
Безафибрат

$C_{19}H_{20}ClNO_4$ = 361.8.

CAS — 41859-67-0.

ATC — C10AB02.

ATC Vet — QC10AB02.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Bezafibrate). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol and in acetone; freely soluble in dimethylformamide; it dissolves in dilute solutions of alkali hydroxides.

Adverse Effects and Precautions

The commonest adverse effects of bezafibrate therapy are gastrointestinal disturbances including anorexia, nausea, and gastric discomfort. Other adverse effects reported to occur less frequently include headache, dizziness, vertigo, fatigue, skin rashes, pruritus, photosensitivity, alopecia, impotence, anaemia, leucopenia, and thrombocytopenia. Raised serum-aminotransferase concentrations have occasionally been reported. Elevated creatine phosphokinase concentrations during bezafibrate therapy may be associated with a syndrome of myositis, myopathy, and rarely rhabdomyolysis; patients with hypoalbuminaemia resulting from nephrotic syndrome or with renal impairment may be at increased risk. Bezafibrate should not be given with statins in patients with risk factors for myopathy. Bezafibrate may increase the lithogenic index, and there have been isolated reports of gallstones, although the risk from fibrates as a class is unclear (see Gallstones, below).

Bezafibrate should not be given to patients with severe hepatic impairment or significant liver disease, gallstones or gallbladder disorders, or hypoalbuminaemic states such as nephrotic syndrome. It should be used with caution in renal impairment and is contra-indicated if creatinine clearance is below 15 mL/minute unless the patient is on dialysis (see under Uses and Administration, below).

◊ Reviews.

Effects on glucose metabolism. Use of fibrates in diabetic patients has generally been reported to either improve[1-3] or have no effect[4-6] on insulin sensitivity and glucose metabolism, and they are considered a suitable treatment for type 2 diabetics with hypertriglyceridaemia.[7] There is also some evidence that fibrates may reduce the incidence or delay the onset of diabetes in patients with obesity[8] or impaired glucose tolerance.[9] However, there has been a report[10] of recurrent hypoglycaemia in a type 2 diabetic when gemfibrozil was added to high-dose insulin therapy although eventually a reduced insulin dosage, with fibrate therapy, produced good glucose control. Gemfibrozil is contra-indicated in patients receiving repaglinide due to the risk of severe hypoglycaemia (see p.458). Conversely, a study in 20 diabetic patients[11] given gemfibrozil reported a slight increase in requirements for antidiabetic therapy (oral hypoglycaemics or insulin) in 9 and a decrease in 1.

Effects on the kidneys. Small increases in creatinine concentration are common during treatment with bezafibrate and have also been reported with other fibrates,[1] although possibly not with gemfibrozil. There have also been reports of acute renal failure associated with treatment with bezafibrate,[2] and with clofibrate,[3,4] and an accelerated decline in renal function has been reported with bezafibrate in patients with chronic renal failure.[5] Renal failure may also occur due to rhabdomyolysis in patients receiving fibrates, including gemfibrozil (see Effects on Skeletal Muscle, below).

Effects on the nervous system. Adverse effects on the peripheral nervous system have been reported with fibrates. Peripheral neuropathy has been reported[1] with bezafibrate, and was substantiated by nerve conduction studies. There have also been reports of peripheral neuropathy with clofibrate,[2] and with fenofibrate,[3] which resolved when therapy was withdrawn. In addition, by 1993, the Adverse Drug Reactions Advisory Committee in Australia had received reports of paraesthesia occurring in 6 patients in association with gemfibrozil treatment.[4]

Effects on the pancreas. Acute pancreatitis has been reported[1] in a patient receiving bezafibrate, and recurred on 2 occasions when bezafibrate was restarted. There has also been a report[2] of acute pancreatitis in a patient receiving both fenofibrate and simvastatin, although simvastatin was considered more likely to be responsible. An increased incidence of pancreatitis was also reported with fenofibrate in the FIELD study,[3] although the number of cases was small.

Effects on sexual function. Sexual dysfunction has occurred with some fibrates. *Erectile dysfunction* and *loss of libido* has been reported in 3 patients[1-3] during gemfibrozil treatment. In 2 of the men[1,2] bezafibrate did not produce this adverse effect. The UK CSM was reported to be aware of a further 6 cases.[2] Of a further 3 cases of erectile dysfunction associated with gemfibrozil reported from Spain, 1 patient had previously reacted similarly to clofibrate.[4] A systematic review,[5] including these and other reports, supported the conclusion that fibrates could cause erectile dysfunction.

Gynaecomastia was reported[6] in a 56-year-old man receiving fenofibrate and recurred on rechallenge; there were no other effects on sexual function.

Effects on skeletal muscle. Muscle disorders including myositis and myopathy are well known to occur with lipid regulating drugs such as fibrates.[1] Rhabdomyolysis, presenting as muscle pain with elevated creatine phosphokinase and myoglobinuria leading to renal failure, has also been reported but appears to be rare. Patients with renal impairment, and possibly with hypothyroidism, may be at increased risk of muscle toxicity. The UK CSM has advised[1] that patients treated with fibrates should consult their doctor if they develop muscle pain, tenderness, or weakness, and treatment should be stopped if muscle toxicity is suspected clinically or if creatine phosphokinase is markedly raised or progressively rising.

Other lipid regulating drugs, particularly the statins, have also been associated with myopathy and the risk of muscle toxicity is increased if fibrates and statins are taken together (see Lipid Regulating Drugs under Interactions of Simvastatin, p.1393); combination therapy may be appropriate in some patients but careful monitoring is required.[2]

Gallstones. Fibrates, including fenofibrate[1-3] and gemfibrozil[4] have been reported to increase indices of bile lithogenicity, and some studies[5,6] have suggested an increased risk of gallstones in patients receiving fibrates. However, in the Helsinki Heart Study[7] no significant increase in gallstone operations was reported among 2051 patients taking gemfibrozil compared with 2030 taking placebo, although a follow-up study[8] reported that cholecystectomies were consistently more common in those receiving gemfibrozil during the entire 8.5-year observation period.

Headache. Severe recurrent headaches have been reported[1] in a patient receiving bezafibrate. The headaches started about 24 hours after therapy with bezafibrate began, and recurred about 1 hour after each dose. Headaches occurred 30 to 90 minutes after each dose of gemfibrozil in 2 patients.[2,3] In both patients, the headaches were accompanied by dry mouth, and in 1 also by blurred vision. The headaches stopped when gemfibrozil was withdrawn and recurred one week after re-exposure.

3. Alvarez-Sabin J, *et al.* Gemfibrozil-induced headache. *Lancet* 1988; **ii:** 1246.

Hyperhomocysteinaemia. Hyperhomocysteinaemia has been associated with an increased risk for cardiovascular disease. Small studies have found that both bezafibrate[1,2] and fenofibrate[1,3] increase plasma-homocysteine concentrations, although the clinical significance of this is not clear.[4] Folic acid and vitamin B_{12} have been given[4,5] with fenofibrate to reduce homocysteine concentrations, but the role of such treatment is not established.

Photosensitivity. Fibrates have been associated with photosensitivity reactions[1] and there may be cross-sensitivity with ketoprofen (see under Adverse Effects of Ketoprofen, p.73).

1. Serrano G, *et al.* Photosensitivity induced by fibric acid derivatives and its relation to photocontact dermatitis to ketoprofen *J Am Acad Dermatol* 1992; **27:** 204–8.

Interactions

Bezafibrate and other fibrates are highly protein-bound and may displace other drugs from protein binding sites. Interactions may also occur through changes in the activity of cytochrome P450 isoenzymes, particularly CYP3A4.

Fibrates may enhance the effects of oral anticoagulants; the dose of anticoagulant should be reduced when treatment with a fibrate is started, and then adjusted gradually if necessary. Recommendations vary; licensed product information for bezafibrate suggests a reduction of up to 50% in the dosage of anticoagulant. The mechanism of the interaction is unclear; fibrates have been reported to displace warfarin from protein binding sites but other mechanisms are probably also involved.

Other drugs that may be displaced from plasma proteins by fibrates include tolbutamide and other sulfonylurea antidiabetics, phenytoin, and, in patients with hypoalbuminaemia, furosemide. The interaction with antidiabetics is complex since fibrates may alter glucose tolerance in diabetic patients (see Effects on Glucose Metabolism, above). The dosage of antidiabetics may need adjusting during bezafibrate therapy.

There is an increased risk of myopathy if fibrates are used with statins (see Lipid Regulating Drugs under Interactions of Simvastatin, p.1393).

Fibrates may interact with ciclosporin, although reports have been conflicting (see p.1827). However, nephrotoxicity associated with increased ciclosporin concentrations has been reported with bezafibrate and renal function should be monitored.

Cholestasis has been reported in a patient given fenofibrate with raloxifene (see p.2128).

Lipid regulating drugs. The bioavailability of gemfibrozil was reduced by *colestipol*, but was unaffected when gemfibrozil was taken either 2 hours before or 2 hours after colestipol.[1]

For discussion of the interaction between fibrates and *statins*, see p.1393.

1. Forland SC, *et al.* Apparent reduced absorption of gemfibrozil when given with colestipol. *J Clin Pharmacol* 1990; **30:** 29–32.

NSAIDs. Acute renal failure due to rhabdomyolysis in a patient has been attributed to an interaction between ciprofibrate and *ibuprofen*.[1] Ibuprofen was believed to have displaced ciprofibrate from protein binding sites. The use of radiological contrast media may also have been a contributory factor.

1. Ramachandran S, *et al.* Acute renal failure due to rhabdomyolysis in presence of concurrent ciprofibrate and ibuprofen treatment. *BMJ* 1997; **314:** 1593.

Pharmacokinetics

Bezafibrate is readily absorbed from the gastrointestinal tract. Plasma protein binding is about 95%. The plasma elimination half-life is about 1 to 2 hours. Most of a dose is excreted in the urine, about half as unchanged drug, the remainder as metabolites including 20% as glucuronides. A small proportion (about 3%) of the dose appears in the faeces. Elimination may be increased by forced diuresis. The drug is not dialysable.

The elderly. In a study comparing the pharmacokinetics of bezafibrate in 19 elderly patients with younger healthy subjects,[1] maximum plasma concentrations were 1.6 times higher in the elderly group (median 12.1 mg/litre against 7.7 mg/litre) and half-life was increased by 3.8 times (median 6.6 hours against 1.7 hours). The differences could not be attributed solely to diminished renal function in elderly patients. Dosage adjustments in elderly patients should not therefore be based on renal function alone.

1. Neugebauer G, *et al.* Steady-state kinetics of bezafibrate retard in hyperlipidemic geriatric patients. *Klin Wochenschr* 1988; **66:** 250–6.

Renal impairment. The half-life of bezafibrate may be prolonged in patients with renal impairment (see under Uses and Administration, below).

Uses and Administration

Bezafibrate, a fibric acid derivative, is a lipid regulating drug. It is used to reduce total cholesterol and triglycerides in the management of hyperlipidaemias (p.1169), including type IIa, type IIb, type III, type IV, and type V hyperlipoproteinaemias. Bezafibrate and other fibrates reduce triglycerides by reducing the concentration of very-low-density lipoprotein (VLDL). They reduce low-density lipoprotein (LDL)-cholesterol to a lesser extent, although the effect is variable, and may also increase high-density lipoprotein (HDL)-cholesterol. Although evidence that this leads to a reduction in cardiovascular events is less good than for statins, some fibrates may have a role in cardiovascular risk reduction (see below).

Bezafibrate is given in a usual oral dose of 200 mg three times daily taken with or after food; gastrointestinal disturbances may be reduced in susceptible patients by increasing the dose gradually over 5 to 7 days; 200 mg twice daily may occasionally be adequate for maintenance particularly in the treatment of hypertriglyceridaemia. A modified-release tablet is also available and is given as a single daily dose of 400 mg.

The dose of bezafibrate should be reduced in patients with renal impairment (see below).

◊ General reviews.

Action. Bezafibrate is a typical member of the fibric acid derivative group of drugs (the fibrates) used in the treatment of hyperlipidaemias (p.1169). One of the primary actions of the fibrates is to promote the catabolism of triglyceride-rich lipoproteins, in particular very-low-density lipoproteins (VLDL), apparently mediated by an enhanced activity of lipoprotein lipase.[1] They may also interfere with the synthesis of VLDL, possibly by inhibiting hepatic acetyl coenzyme A carboxylase. The effect of fibrates on low-density lipoprotein (LDL)-cholesterol depends on the overall lipoprotein status of the patient but concentrations tend to decrease if high at baseline and increase if low at baseline. High-density lipoprotein (HDL)-cholesterol concentrations are increased, although there have been a few reports of unexpected falls in HDL-cholesterol with bezafibrate[2,3] and ciprofibrate.[4,5]

Fibrates have three actions on sterol metabolism:[1] they inhibit the synthesis of cholesterol, they inhibit the synthesis of bile acids, and they enhance the secretion of cholesterol in bile. It is these latter two effects which are responsible for the raised cholesterol saturation of bile, which may lead to the formation of gallstones in some patients (see Gallstones, under Adverse Effects, above).

The effects of fibrates are mediated by their agonist action at peroxisome proliferator-activated receptors (PPARs).[6,7] Fibrates are agonists of PPAR-α, which plays an important role in fatty acid metabolism; some, such as bezafibrate, may also activate other receptors including PPAR-γ (which plays a role in glucose homoeostasis).[7]

Administration in renal impairment. Bezafibrate is mainly excreted in the urine and dosage alterations may be necessary in patients with renal impairment; fibrates may also impair renal function (see Effects on the Kidneys under Adverse Effects, above). Modified-release preparations are contra-indicated in patients with creatinine clearance (CC) below 60 mL/minute and the dosage of conventional-release formulations should be reduced depending on CC, as follows:

- CC 40 to 60 mL/minute: 400 mg daily
- CC 15 to 40 mL/minute: 200 mg daily or on alternate days
- CC less than 15 mL/minute unless on dialysis: contra-indicated
- dialysis patients: 200 mg every 3 days, with careful monitoring

In a study in patients with renal impairment[1] the half-life of bezafibrate was reported to be prolonged to 4.6 hours in 3 patients with CC greater than 40 mL/minute, 7.8 hours in 8 patients with CC of 20 to 40 mL/minute, and 20.1 hours in a patient with CC of 13 mL/minute.

Cardiovascular risk reduction. Lipid lowering therapy has an important role in patients at risk of cardiovascular disease (p.1164). Although the evidence is less good than for statins, several studies have shown that fibrates may reduce both the progression of atherosclerosis and the incidence of cardiovascular events.[1]

In the Bezafibrate Coronary Atherosclerosis Intervention Trial (BECAIT)[2,3] treatment with bezafibrate for 5 years in young men (less than 45 years of age) after myocardial infarction resulted in fewer coronary events and slowed the progression of focal coronary atherosclerosis when compared with placebo. However, in older men with peripheral vascular disease,[4] bezafibrate had no effect on the incidence of coronary events and stroke together, although the severity of intermittent claudication was reduced and, in men under 65 years, there were fewer non-fatal coronary events. In the Diabetes Atherosclerosis Intervention Study (DAIS),[5] fenofibrate reduced the angiographic progression of coronary atherosclerosis in type 2 diabetics, and there were also fewer clinical events in those receiving fenofibrate; further analysis showed[6] reduced progression to microalbuminuria in the fenofibrate group. However, another study in type 2 diabetics, the FIELD study,[7] found no reduction in the risk of major coronary events with fenofibrate, although there were fewer non-fatal myocardial infarctions and revascularisations. A meta-analysis[8] of studies including type 2 diabetics concluded that fibrates reduce the incidence of cardiovascular events, but the effect on mortality was not significant.

The best evidence for a reduction in cardiovascular events is for gemfibrozil. The Helsinki Heart Study[9] assessed gemfibrozil for the primary prevention of ischaemic heart disease in 4081 middle-aged men with hyperlipidaemia. There was an overall reduction of 34% in the incidence of fatal and non-fatal myocardial infarctions and cardiac deaths in the gemfibrozil group compared with the placebo group, with the greatest reduction seen during years 3 to 5. Follow-up for a further 3.5 years[10] suggested that long-term treatment with gemfibrozil seemed to postpone coronary events for about 5 years. The Veterans Affairs High-Density Lipoprotein Cholesterol Intervention Trial (VA-HIT)[11] assessed gemfibrozil for the secondary prevention of ischaemic heart disease in 2531 older men (mean age 64 years) whose primary lipid abnormality was a low HDL-cholesterol level. There was an overall reduction of 22% in the incidence of fatal and non-fatal myocardial infarctions and cardiac deaths in the gemfibrozil group compared with the placebo group, with the beneficial effects of gemfibrozil becoming apparent about 2 years after randomisation. There was also a reduction in the incidence of stroke.[12]

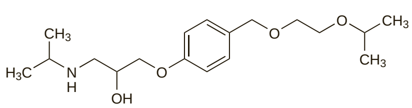
ATC — C07AB07.

ATC Vet — QC07AB07.



(bisoprolol)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Bisoprolol Fumarate). A white or almost white, slightly hygroscopic powder. It exhibits polymorphism. Very soluble in water; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Bisoprolol Fumarate). A white crystalline powder. Very soluble in water and in methyl alcohol; freely soluble in alcohol, in chloroform, and in glacial acetic acid; slightly soluble in acetone and in ethyl acetate. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Bisoprolol is almost completely absorbed from the gastrointestinal tract and undergoes only minimal first-pass metabolism resulting in an oral bioavailability of about 90%. Peak plasma concentrations are reached 2 to 4 hours after oral doses. Bisoprolol is about 30% bound to plasma proteins. It has a plasma elimination half-life of 10 to 12 hours. Bisoprolol is moderately lipid-soluble. It is metabolised in the liver and excreted in urine, about 50% as unchanged drug and 50% as metabolites.

Uses and Administration

Bisoprolol is a cardioselective beta blocker (p.1225). It is reported to be devoid of intrinsic sympathomimetic and membrane-stabilising properties.

Bisoprolol is given as the fumarate in the management of hypertension (p.1171) and angina pectoris (p.1157). It is also used as an adjunct to standard therapy in patients with stable chronic heart failure (p.1165).

In **hypertension** or **angina pectoris** the usual dose of bisoprolol fumarate is 5 to 10 mg orally as a single daily dose; the maximum recommended dose is 20 mg daily. A reduction in dose may be necessary in patients with hepatic or renal impairment (see below).

In **heart failure** the initial oral dose of bisoprolol fumarate is 1.25 mg once daily. If tolerated, the dose should be doubled after 1 week, and then increased gradually at 1 to 4 week intervals to the maximum dose tolerated; this should not exceed 10 mg once daily.

◊ References.

Administration in hepatic or renal impairment. US licensed product information recommends that the initial dose of bisoprolol fumarate for hypertension should be 2.5 mg daily and that the dose should be increased cautiously in patients with severe hepatic impairment or renal impairment (creatinine clearance less than 40 mL/minute). UK licensed product information recommends a maximum dose of 10 mg daily for both angina pectoris and hypertension in patients with severe hepatic impairment or with a creatinine clearance of less than 20 mL/minute. Bisoprolol is not dialysable.

Bivalirudin *(BAN, USAN, rINN)*

BG-8967; Bivalirudina; Bivalirudine; Bivalirudinum; Hirulog.

Бивалирудин

$C_{98}H_{138}N_{24}O_{33}$ = 2180.3.

CAS — 128270-60-0.

ATC — B01AE06.

ATC Vet — QB01AE06.

Incompatibility. The manufacturer of bivalirudin states that it is incompatible with: alteplase, amiodarone hydrochloride, amphotericin B, chlorpromazine hydrochloride, diazepam, prochlorperazine edisilate, reteplase, streptokinase, and vancomycin hydrochloride.

Adverse Effects and Precautions

As for Lepirudin, p.1323.

Interactions

As for Lepirudin, p.1323.

Pharmacokinetics

Bivalirudin is partly metabolised and partly excreted by the kidney. When given intravenously the plasma half-life is about 25 minutes in patients with normal renal function but is prolonged in renal impairment. Bivalirudin does not bind to plasma proteins and is removed by haemodialysis.

◊ References.

1. Robson R, *et al.* Bivalirudin pharmacokinetics and pharmacodynamics: effect of renal function, dose, and gender. *Clin Pharmacol Ther* 2002; **71:** 433–9.

Uses and Administration

Bivalirudin, an analogue of the peptide hirudin (p.1305), is a direct thrombin inhibitor with actions similar to Lepirudin, p.1323. It is used as an anticoagulant in patients undergoing percutaneous coronary interventions, including those with, or at risk of, heparin-induced thrombocytopenia. It is also used in patients with acute coronary syndromes in whom early intervention is planned, and has been investigated in patients with acute coronary syndromes treated medically (see Ischaemic Heart Disease, under Uses and Administration of Lepirudin, p.1323).

Some preparations state that bivalirudin is present as the hydrate of the trifluoroacetate salt but doses are given in terms of bivalirudin.

In the management of patients undergoing **planned percutaneous coronary intervention** (PCI), the initial dose of bivalirudin is 750 micrograms/kg by intravenous injection followed immediately by an intravenous infusion of 1.75 mg/kg per hour; the activated clotting time should be measured 5 minutes after the initial injection and a second injection of 300 micrograms/kg should be given if anticoagulation is inadequate. The infusion should be given for the duration of the procedure and may be continued for up to 4 hours afterwards; licensed prescribing information in the USA allows the infusion to then be continued at a lower dose of 200 micrograms/kg per hour for up to 20 hours if required.

As part of the management of patients with **acute coronary syndromes**, the initial dose of bivalirudin is 100 micrograms/kg by intravenous injection, followed by an intravenous infusion of 250 micrograms/kg per hour. In patients managed *medically*, the infusion may be continued for up to 72 hours. For those who proceed to *PCI or coronary artery bypass surgery without cardiopulmonary bypass*, a further intravenous injection of 500 micrograms/kg should be given, and the infusion should be increased to 1.75 mg/kg per hour for the duration of the procedure; after PCI, the infusion may be continued at a dose of 250 micrograms/kg per hour for a further 4 to 12 hours if required. For those who proceed to *coronary artery bypass surgery with cardiopulmonary bypass*, the infusion should be stopped 1 hour before the procedure and the patient should be treated with unfractionated heparin.

The dose of bivalirudin should be reduced in patients with renal impairment (see below).

Administration in renal impairment. The dose of bivalirudin may need to be adjusted in patients with renal impairment and the activated clotting time should be monitored. UK licensed product information recommends the following doses, depending on the glomerular filtration rate (GFR):

- GFR 30 to 59 mL/minute, usual bolus doses (see Uses and Administration, above) but in those undergoing percutaneous coronary intervention (PCI) for any indication the infusion rate should be reduced to 1.4 mg/kg per hour during the procedure
- GFR below 30 mL/minute or dialysis-dependent, contra-indicated

US licensed product information recommends the following doses for those undergoing PCI, based on creatinine clearance (CC):

- CC 30 to 59 mL/minute, usual bolus and infusion doses
- CC below 30 mL/minute, usual bolus doses but infusion rate reduced to 1 mg/kg per hour
- Haemodialysis patients, usual bolus doses but infusion rate reduced to 250 micrograms/kg per hour

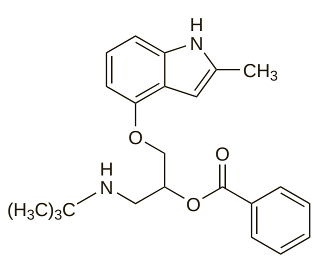
ATC — C07AA17.

ATC Vet — QC07AA17.



(bopindolol)

Profile

Bopindolol is a non-cardioselective beta blocker (p.1225). It is reported to possess some intrinsic sympathomimetic activity.

Bopindolol is given orally as the malonate but doses are expressed in terms of the base; 1.27 mg of bopindolol malonate is equivalent to about 1 mg of base. It is used in the management of hypertension (p.1171) and angina pectoris (p.1157) in daily doses equivalent to 0.5 to 2 mg of bopindolol.

Proprietary Preparations (details are given in Part 3)

Cz.: Sandonorm; ***Ger.:*** Wandonorm†; ***Gr.:*** Sandonorm†; ***Hung.:*** Sandonorm; ***Switz.:*** Sandonorm.

Multi-ingredient: *Switz.:* Sandoretic.

Bosentan *(BAN, USAN, rINN)*

Bosentaani; Bosentán; Bosentano; Bosentanum; Ro-47-0203/029. *p-tert*-Butyl-*N*-[6-(2-hydroxyethoxy)-5-(*o*-methoxyphenoxy)-2-(2-pyrimidinyl)-4-pyrimidinyl]benzenesulfonamide.

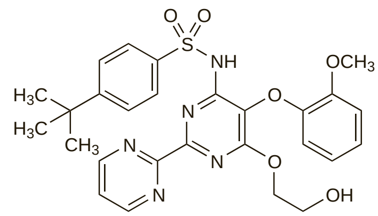
Бозентан

$C_{27}H_{29}N_5O_6S$ = 551.6.

CAS — 147536-97-8 (anhydrous bosentan); 157212-55-0 (bosentan monohydrate).

ATC — C02KX01.

ATC Vet — QC02KX01.



Adverse Effects

Adverse effects reported with bosentan include headache, nasopharyngitis, flushing, oedema, hypotension, dizziness, palpitations, gastrointestinal disturbances, pruritus, skin rashes, fatigue, muscle cramps, and anaemia. Anaphylaxis and angioedema have been reported rarely. Dose-related increases in liver aminotransferases may also occur, and hepatic cirrhosis and liver failure have been reported.

Bosentan is teratogenic in *animals*.

Effects on the liver. In a postmarketing study,[1] increases in liver aminotransferases to more than 3 times the upper limit of normal occurred in 352 (7.6%) of 4623 patients started on bosentan for pulmonary hypertension; treatment was continued or successfully reintroduced after temporary withdrawal in 165 (47%) of these patients.

1. Humbert M, *et al.* Results of European post-marketing surveillance of bosentan in pulmonary hypertension. *Eur Respir J* 2007; **30:** 338–44.

Effects on the skin. Vasculitis was reported[1] in a patient receiving bosentan shortly after the dose was increased to 125 mg twice daily. She was also taking metolazone and acenocoumarol long term, and spironolactone had recently been added. The skin lesions improved slowly over a period of weeks after bosentan was stopped. All other treatment was continued and it was concluded that the lesions were attributable to bosentan alone or to a previously unknown interaction.

1. Gasser S, *et al.* Severe necrotising leucocytoclastic vasculitis in a patient taking bosentan. *BMJ* 2004; **329:** 430.

Precautions

Bosentan is contra-indicated in patients with moderate to severe hepatic impairment (Child-Pugh Class B or C). Liver-aminotransferase concentrations should be measured before starting therapy, at monthly intervals during therapy, and 2 weeks after any increase in dose:

- bosentan therapy should not be *started* in patients with concentrations more than 3 times the upper limit of normal
- if concentrations increase to between 3 and 5 times the upper limit of normal *during* treatment, bosentan should be stopped or the dose reduced and concentrations should be monitored every 2 weeks until they are below the pretreatment value; therapy may then be continued or reintroduced, but aminotransferase concentrations should be checked after 3 days, after a further 2 weeks, and then monthly
- if concentrations increase to more than 5 times the upper limit of normal bosentan should be stopped; reintroduction may be considered when concentrations return to below the pretreatment value
- if concentrations increase above 8 times the upper limit of normal or there are symptoms of hepatotoxicity or increases in total bilirubin levels greater than twice the upper limit of normal, treatment should be stopped and not reintroduced

Haemoglobin concentrations should be monitored every 3 months during therapy, more frequently at the start.

Bosentan should not be given to patients with hypotension. Although there is no evidence of rebound effects after stopping bosentan, it is recommended that therapy should be withdrawn gradually.

Bosentan and related endothelin receptor antagonists are teratogenic in *rats* and should not be used in pregnancy or in women of child-bearing potential who are not using a reliable method of contraception; hormonal contraceptives alone may not be adequate and additional measures may be required (see Interactions, below).

Interactions

Bosentan is metabolised by the cytochrome P450 isoenzymes CYP2C9 and CYP3A4 and is also an inducer of the same isoenzymes. It may also possibly induce CYP2C19. Interactions may therefore occur with other drugs that are either metabolised by, or inhibit, these isoenzymes. Use with ciclosporin is contra-indicated since plasma concentrations of bosentan are significantly increased (see below). There is an increased risk of hepatotoxicity if bosentan is given with glibenclamide and such use should be avoided; the hypoglycaemic effect of glibenclamide may also be reduced. Bosentan has reduced the plasma concentrations of some hormonal contraceptives and additional contraceptive measures are advised (see Endothelin Receptor Antagonists, p.2068).

Anticoagulants. For reports of bosentan decreasing the anticoagulant effect of *warfarin*, see Endothelin Receptor Antagonists, p.1430.

Ciclosporin. There appears to be a complex interaction between bosentan and ciclosporin. In a pharmacokinetic study[1] in healthy subjects given both drugs, doses of ciclosporin needed increasing to achieve target trough ciclosporin concentrations; it was calculated that plasma concentrations of ciclosporin would otherwise have been reduced by about half in the presence of bosentan. In addition, plasma concentrations of bosentan were almost doubled by ciclosporin. Licensed product information for bosentan states that plasma concentrations at steady state are 3 to 4 times higher in the presence of ciclosporin and contra-indicates the combination.

1. Binet I, *et al.* Renal hemodynamics and pharmacokinetics of bosentan with and without cyclosporine A. *Kidney Int* 2000; **57:** 224–31.

Pharmacokinetics

Bosentan is absorbed from the gastrointestinal tract with an absolute bioavailability of about 50%. Peak plasma concentrations occur about 3 to 5 hours after an oral dose. It is more than 98% bound to plasma proteins, mainly to albumin. Bosentan is metabolised in the liver by the cytochrome P450 isoenzymes CYP2C9 and CYP3A4 and is an inducer of these enzymes and possibly also of CYP2C19; after multiple dosing, plasma concentrations of bosentan decrease gradually to 50 to 65% of those seen after a single dose. Bosentan has three metabolites, one of which is active. Bosentan is excreted almost entirely as metabolites in the bile; less than 3% of an oral dose is excreted in the urine. The terminal elimination half-life is about 5 hours.

Uses and Administration

Bosentan is an endothelin receptor antagonist (p.1155) used in the management of pulmonary hypertension (below) and systemic sclerosis (see Scleroderma, below). It has also been investigated in heart failure and in hypertension.

In **pulmonary hypertension**, patients over 12 years of age may be given bosentan orally in an initial dose of 62.5 mg twice daily, increased after 4 weeks to a maintenance dose of 125 mg twice daily. In those with low body weight (below 40 kg) both the initial and maintenance doses are 62.5 mg twice daily. For the use of bosentan in children, see below.

In **systemic sclerosis** with ongoing digital ulcer disease, bosentan is given in the same doses as for pulmonary hypertension; there are no data on safety or efficacy in patients under 18 years of age.

5. Dingemanse J, van Giersbergen PLM. Clinical pharmacology of bosentan, a dual endothelin receptor antagonist. *Clin Pharmacokinet* 2004; **43:** 1089–1115.

Administration in children. A short-term study[1] in 19 children with pulmonary hypertension aged 3 to 15 years found that treatment with bosentan resulted in haemodynamic improvement and was well tolerated, and another small study[2] suggested that addition of bosentan allowed epoprostenol dosage to be reduced or stopped. Longer-term studies[3,4] have reported that benefit is maintained and that bosentan may have a role in children with both idiopathic pulmonary hypertension and pulmonary hypertension secondary to heart or lung disease.

Licensed product information in the UK states that the safety and efficacy of bosentan has not been substantially documented in children under the age of 12 years (some postmarketing data has subsequently been published[5]) but notes that the studies cited above used the following doses; these doses are also recommended in the *BNFC*, but for children aged 3 to 18 years:

- body-weight 10 to 20 kg: initial dose 31.25 mg once daily, increased to 31.25 mg twice daily after 4 weeks
- body-weight 20 to 40 kg: initial dose 31.25 mg twice daily, increased to 62.5 mg twice daily after 4 weeks
- body-weight over 40 kg and age 12 to 18 years: as for adults (see above)

Pulmonary hypertension. Pulmonary hypertension (p.1179) is a progressive and incurable disease associated with an increase in pulmonary arterial pressure. Treatment usually involves the use of vasodilators such as calcium-channel blockers or intravenous epoprostenol, but systemic effects limit their use. Patients with pulmonary hypertension have raised plasma concentrations of the potent vasoconstrictor endothelin I, and endothelin antagonists such as bosentan have therefore been tried. Studies[1,2] with oral bosentan have shown improvement in exercise tolerance and in time to clinical progression; an open study[3] showed sustained benefit with treatment for 1 year or more. However, no effect on mortality has yet been found in randomised studies, although there is some evidence[4,5] that survival may be improved. Bosentan has also been tried with epoprostenol.[6] There was a non-significant trend towards greater improvement in the group receiving both drugs compared with epoprostenol alone.

There is some evidence that bosentan may be of benefit in pulmonary hypertension associated with congenital heart disease,[7,8] including Eisenmenger syndrome,[8-10] and in pulmonary hypertension associated with HIV infection.[11] Positive results have also been reported[12-14] in chronic thromboembolic pulmonary hypertension.

Scleroderma. Bosentan has an established role in pulmonary hypertension secondary to scleroderma (p.1817) or other connective tissue disorders, but may also have additional benefits. Several case reports[1-3] have suggested that treatment with bosentan may be associated with healing of refractory digital ulcers in patients with scleroderma, and a controlled study[4] found that bosentan reduced the incidence of new digital ulcers, although there was no improvement in the healing of existing ulcers. Relatively long-term treatment may need to be given.[5]

Bretylium Tosilate *(BAN, rINN)*

ASL-603; Bretyli Tosilas; Bretylii Tosilas; Brétylium, Tosilate de; Bretylium Tosylate *(USAN)*; Bretyltosilat; Bretyylitosilaatti; Tosilato de bretilio. (2-Bromobenzyl)ethyldimethylammonium toluene-4-sulphonate.

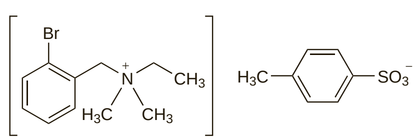
Бретилия Тозилат

$C_{11}H_{17}BrN,C_7H_7O_3S$ = 414.4.

CAS — 59-41-6 (bretylium); 61-75-6 (bretylium tosilate).

ATC — C01BD02.

ATC Vet — QC01BD02.



Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Bretylium Tosilate). A white crystalline powder. M.p. about 98°. It exhibits polymorphism. Freely soluble in water, in alcohol, and in methyl alcohol. A 5% solution in water has a pH of 5.0 to 6.5. Store in airtight containers at a temperature not exceeding 25°. Protect from light.

USP 31 (Bretylium Tosylate). A white, hygroscopic, crystalline powder. Freely soluble in water, in alcohol, and in methyl alcohol; practically insoluble in ether, in ethyl acetate, and in hexane. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

The most common adverse effect of bretylium is hypotension, which may be severe. Bretylium may also cause a transient initial increase in blood pressure and heart rate, and a worsening of cardiac arrhythmias due to a release of noradrenaline. Nausea and vomiting may occur particularly during rapid intravenous infusion. Intramuscular injection of bretylium can lead to local tissue necrosis and muscle atrophy. Caution is required in patients with renal impairment, and in patients with severe aortic stenosis or pulmonary hypertension in whom cardiac output may not increase in response to the fall in peripheral resistance produced by bretylium.

Interactions

Bretylium may exacerbate arrhythmias caused by digitalis toxicity and may enhance the effects of sympathomimetics.

Pharmacokinetics

Bretylium is incompletely absorbed from the gastrointestinal tract. It is well absorbed after intramuscular injection. It is not metabolised and is largely excreted unchanged in the urine. The half-life is reported to be between 4 and 17 hours in patients with normal renal function and is prolonged in patients with renal impairment. Bretylium is dialysable.

Uses and Administration

Bretylium is a quaternary ammonium compound with class II and class III antiarrhythmic activity (p.1153); it causes an initial release of noradrenaline and then blocks adrenergic transmission by preventing noradrenaline release from adrenergic nerve endings. It suppresses ventricular fibrillation and other ventricular arrhythmias, but its exact mode of action is unknown. It has been given parenterally as the tosilate in the management of ventricular arrhythmias.

Bretylium has also been investigated in complex regional pain syndrome.

Preparations

BP 2008: Bretylium Injection;
USP 31: Bretylium Tosylate in Dextrose Injection; Bretylium Tosylate Injection.

Proprietary Preparations (details are given in Part 3)

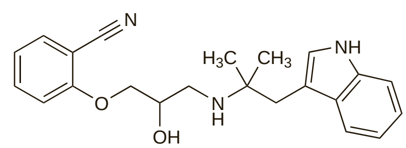
Bucindolol Hydrochloride *(BANM, USAN, rINNM)* ⊗

Bucindolol, Chlorhydrate de; Bucindololi Hydrochloridum; Hidrocloruro de bucindolol; MJ-13105-1. 2-[2-Hydroxy-3-(2-indol-3-yl-1,1-dimethylethylamino)propoxy]benzonitrile hydrochloride.

Буциндолола Гидрохлорид

$C_{22}H_{25}N_3O_2,HCl$ = 399.9.

CAS — 71119-11-4 (bucindolol); 70369-47-0 (bucindolol hydrochloride).



(bucindolol)

Profile

Bucindolol is a non-cardioselective beta blocker (p.1225). It is reported to possess weak alpha$_1$-blocking activity and direct vasodilating activity; the degree of intrinsic sympathomimetic activity is unclear. Bucindolol hydrochloride has been investigated in the management of hypertension, heart failure, and other cardiac disorders, but development was halted. However, it has been suggested that it may be of benefit in a genetically identifiable subgroup of patients.

Buflomedil Hydrochloride *(BANM, rINNM)*

Buflomediilihydrokloridi; Buflomédil, chlorhydrate de; Buflomedil-hidroklorid; Buflomedil-hydrochlorid; Buflomedilhydroklorid; Buflomedili hydrochloridum; Buflomedilio hidrochloridas; Hidrocloruro de buflomedil; LL-1656. 2′,4′,6′-Trimethoxy-4-(pyrrolidin-1-yl)butyrophenone hydrochloride.

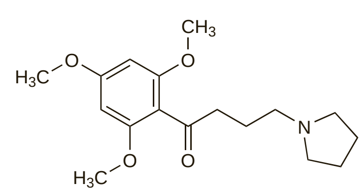
Буфломедила Гидрохлорид

$C_{17}H_{25}NO_4,HCl$ = 343.8.

CAS — 55837-25-7 (buflomedil); 35543-24-9 (buflomedil hydrochloride).

ATC — C04AX20.

ATC Vet — QC04AX20.



(buflomedil)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Buflomedil Hydrochloride). A white or almost white microcrystalline powder. Freely soluble in water; soluble in alcohol; very slightly soluble in acetone. A 5% solution in water has a pH of 5.0 to 6.5.

Adverse Effects

Buflomedil has been reported to cause gastrointestinal disturbances, headache, vertigo, syncope, rash, pruritus, and paraesthesia. Overdosage may produce severe hypotension, tachycardia, and convulsions.

◊ References.

1. Bachand RT, Dubourg AY. A review of long-term safety data with buflomedil. *J Int Med Res* 1990; **18:** 245–52.

Pharmacokinetics

Buflomedil hydrochloride is absorbed from the gastrointestinal tract and peak plasma concentrations are reached 1.5 to 4 hours after oral doses. Buflomedil is subject to first-pass metabolism; bioavailability is reported to be between 50 and 80%.

Buflomedil is widely distributed. Binding to plasma proteins is dose-dependent and varies between 60 and 80% at therapeutic concentrations. Buflomedil is metabolised in the liver and is mainly excreted in the urine both as unchanged drug and metabolites. The elimination half-life is about 2 to 3 hours. Elimination may be impaired in patients with renal or hepatic impairment.

Uses and Administration

Buflomedil hydrochloride is a vasodilator used in the treatment of cerebrovascular (p.1165) and peripheral vascular disease (p.1178). Usual oral doses are 300 to 600 mg daily, doses by intramuscular injection are up to 100 mg daily, by slow intravenous injection up to 200 mg daily, and by intravenous infusion up to 400 mg daily. In patients with hepatic or renal impairment, doses may need to be reduced (see below).

◊ References.

1. Clissold SP, *et al.* Buflomedil: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic efficacy in peripheral and cerebral vascular diseases. *Drugs* 1987; **33:** 430–60.
2. de Backer TLM, *et al.* Buflomedil for intermittent claudication. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2008 (accessed 08/05/08).

Administration in hepatic or renal impairment. The dose of buflomedil should be reduced in patients with hepatic or renal impairment. It should not be used in patients with creatinine clearance (CC) below 30 mL/minute and the maximum oral dose in those with CC between 30 and 80 mL/minute is 150 mg twice daily.

Bumetanide *(BAN, USAN, rINN)* ⊗

Bumetanid; Bumetanida; Bumetanidas; Bumétanide; Bumetanidi; Bumetanidum; Ro-10-6338. 3-Butylamino-4-phenoxy-5-sulphamoylbenzoic acid.

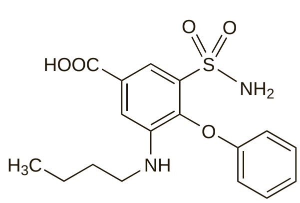
Буметанид

$C_{17}H_{20}N_2O_5S$ = 364.4.

CAS — 28395-03-1.

ATC — C03CA02.

ATC Vet — QC03CA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Bumetanide). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; soluble in alcohol and in acetone; slightly soluble in dichloromethane. It dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Bumetanide). A practically white powder. Slightly soluble in water; soluble in alkaline solutions. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

As for Furosemide, p.1292. Bumetanide may cause muscle pain, particularly at high doses.

Effects on the ears. Early reports suggested that bumetanide might be less ototoxic than furosemide.[1] However, both drugs can cause deafness, especially when given in large doses to patients with renal impairment.

1. Ward A, Heel RC. Bumetanide: a review of its pharmacodynamic and pharmacokinetic properties and therapeutic use. *Drugs* 1984; **28:** 426–64.

Effects on the lungs. Alveolitis, presenting as haemoptysis and steadily increasing dyspnoea in a 79-year-old man, was found to coincide with the use of bumetanide for congestive heart failure.[1] When the diuretic was replaced with furosemide the condition gradually resolved.

1. van Tellingen C. Suspension of disbelief - or the bumetanide paradox. *Neth Heart J* 2007; **15:** 31–2.

Effects on the muscles. Bumetanide, particularly in high doses in patients with chronic renal impairment, may cause severe musculoskeletal pain. A curious muscle stiffness distinct from cramp, with tenderness to compression and pain on movement, was noted in 4 patients with end-stage renal failure.[1] The calf muscles were the first to be affected; shoulder girdle and thigh muscle tenderness also occurred in 2 patients, and 1 patient also had neck stiffness. The adverse effect appeared to be dose-related for the individual patients.

1. Barclay JE, Lee HA. Clinical and pharmacokinetic studies on bumetanide in chronic renal failure. *Postgrad Med J* 1975; **51** (suppl 6): 43–6.

Effects on the skin. Bullous pemphigoid developed in a patient about 6 weeks after starting bumetanide.[1] Healing occurred after withdrawal without the need for corticosteroids.

1. Boulinguez S, *et al.* Bullous pemphigoid induced by bumetanide. *Br J Dermatol* 1998; **138:** 548–9.

Precautions

Bumetanide's precautions and contra-indications are generally dependent on its effects on fluid and electrolyte balance and are similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1309).

Interactions

As for Furosemide, p.1293.

Pharmacokinetics

Bumetanide is almost completely and fairly rapidly absorbed from the gastrointestinal tract; the bioavailability is reported to be about 80 to 95%. It has a plasma elimination half-life of about 1 to 2 hours. It is about 95% bound to plasma proteins. About 80% of the dose is excreted in the urine, about 50% as unchanged drug, and 10 to 20% in the faeces.

5. McCrindle JL, *et al.* Effect of food on the absorption of frusemide and bumetanide in man. *Br J Clin Pharmacol* 1996; **42:** 743–6.

Hepatic impairment. In a study of 8 patients with chronic hepatic disease,[1] the diuretic response to bumetanide 1 mg was impaired but bumetanide excretion rates were normal.

1. Marcantonio LA, *et al.* The pharmacokinetics and pharmacodynamics of the diuretic bumetanide in hepatic and renal disease. *Br J Clin Pharmacol* 1983; **15:** 245–52.

Renal impairment. Renal excretion of bumetanide has been shown to be reduced in patients with chronic renal impairment with a subsequent attenuation of diuretic effect.[1-3] The cumulative pharmacodynamic effects of oral and intravenous doses were essentially similar in patients with renal impairment and transition from intravenous to oral maintenance regimens should pose no special problems.[2]

2. Lau HSH, *et al.* Kinetics, dynamics, and bioavailability of bumetanide in healthy subjects and patients with chronic renal failure. *Clin Pharmacol Ther* 1986; **39:** 635–45.
3. Howlett MR, *et al.* Metabolism of the diuretic bumetanide in healthy subjects and patients with renal impairment. *Eur J Clin Pharmacol* 1990; **38:** 583–6.

Uses and Administration

Although chemically unrelated, bumetanide is a loop diuretic with actions and uses similar to those of furosemide (p.1294). Bumetanide is used in the treatment of oedema associated with heart failure (p.1165) and with renal and hepatic disorders. It is given in high doses in the management of oliguria due to renal failure or insufficiency. Bumetanide has also been used in hypertension (p.1171).

Diuresis starts within about 30 minutes to an hour after an oral dose, reaches a maximum at 1 to 2 hours, and lasts for about 4 hours but may be prolonged to 6 hours after high doses; after intravenous injection its effects are evident within a few minutes and last for about 2 hours. As a general guide bumetanide 1 mg produces a diuretic effect similar to furosemide 40 mg although this should not be used for direct substitution at higher doses.

In the treatment of **oedema** the usual oral dose is 1 mg in the morning or early evening; a second dose may be given 6 to 8 hours later if necessary. A dose of 500 micrograms daily may be adequate in some elderly patients.

In refractory oedema higher doses may be necessary. An initial dose of 5 mg daily has been advocated, increased by 5 mg every 12 to 24 hours as required; however other sources have suggested a maximum total dose of 10 mg daily. Twice daily dosing may be preferred at higher doses. For maintenance therapy doses may be given daily or intermittently. In an emergency or when oral therapy cannot be given 0.5 to 1 mg may be given by intramuscular or slow intravenous injection, subsequently adjusted according to response. A dose for pulmonary oedema is 1 to 2 mg by intravenous injection, repeated 20 minutes later if necessary. Alternatively, 2 to 5 mg may be given over 30 to 60 minutes in 500 mL of a suitable infusion fluid.

In the treatment of **hypertension** bumetanide has been given in oral doses of 0.5 to 1 mg daily, although higher doses have been used.

When very high doses of bumetanide are used careful laboratory control is essential as described under the uses for furosemide (see, p.1294; high-dose therapy).

Calcitonin Gene-related Peptide

CGRP; Péptido relacionado con el gen de la calcitonina.

Profile

Calcitonin gene-related peptide is an endogenous peptide derived from the calcitonin gene. It has vasodilating activity and has been investigated in the management of peripheral vascular disease (Raynaud's syndrome), heart failure, and for ischaemia following neurosurgery for subarachnoid haemorrhage.

Candesartan Cilexetil *(BANM, USAN, rINNM)*

Candésartan, Cilexétil de; Candesartán cilexetilo; Candesartani Cilexetilum; CV-11974 (candesartan); H-212/91; Kandesartan Sileksetil; TCV-116. Cyclohexyl carbonate ester of (±)-1-hydroxyethyl 2-ethoxy-1-[*p*-(*o*-1*H*-tetrazol-5-ylphenyl)benzyl]-7-benzimidazolecarboxylate.

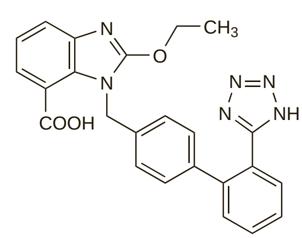
Кандесартана Силексетил

$C_{33}H_{34}N_6O_6$ = 610.7.

CAS — 139481-59-7 (candesartan); 145040-37-5 (candesartan cilexetil).

ATC — C09CA06.

ATC Vet — QC09CA06.



(candesartan)

Adverse Effects and Precautions

As for Losartan Potassium, p.1326.

Interactions

As for Losartan Potassium, p.1327.

Pharmacokinetics

Candesartan cilexetil is an ester prodrug that is hydrolysed during absorption from the gastrointestinal tract to the active form candesartan. The absolute bioavailability for candesartan is about 40% when candesartan cilexetil is given as a solution and about 14% when given as tablets. Peak plasma concentrations of candesartan occur about 3 to 4 hours after oral doses as tablets. Candesartan is more than 99% bound to plasma proteins. It is excreted in urine and bile mainly as unchanged drug and a small amount of inactive metabolites. The terminal elimination half-life is about 9 hours. Candesartan is not removed by haemodialysis.

◊ Reviews.

1. Gleiter CH, Mörike KE. Clinical pharmacokinetics of candesartan. *Clin Pharmacokinet* 2002; **41:** 7–17.

Uses and Administration

Candesartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171) and may also be used in heart failure in patients with impaired left ventricular systolic function, either when ACE inhibitors are not tolerated, or in addition to ACE inhibitors, (see under Losartan Potassium, p.1327).

Candesartan is given orally as the ester prodrug candesartan cilexetil. Onset of antihypertensive action occurs about 2 hours after a dose and the maximum effect is achieved within about 4 weeks of starting therapy.

In the management of **hypertension** the usual initial dose of candesartan cilexetil is 8 mg once daily in the UK, or 16 mg once daily in the USA. The dose should be adjusted according to response; the usual maintenance dose is 8 mg once daily, but doses up to 32 mg daily, as a single dose or in 2 divided doses, may be used. Lower initial doses should be considered in patients with intravascular volume depletion; in the UK an initial dose of 4 mg once daily is suggested. Patients with renal or hepatic impairment may also require lower initial doses (see below).

In **heart failure,** candesartan cilexetil is given in an initial dose of 4 mg once daily; the dose should be doubled at intervals of not less than two weeks up to 32 mg once daily if tolerated.

◊ Reviews.

8. Meredith PA. Candesartan cilexetil—a review of effects on cardiovascular complications in hypertension and chronic heart failure. *Curr Med Res Opin* 2007; **23:** 1693–1705.

Administration in hepatic or renal impairment. The elimination of candesartan may be reduced in patients with hepatic or renal impairment and lower doses may therefore be required. Candesartan may also have adverse effects on renal function and regular monitoring is advised in patients with heart failure.

In the UK, candesartan is contra-indicated in severe hepatic impairment and an initial dose of 2 mg once daily is recommended for hypertension in patients with mild to moderate impairment. In the USA, consideration of a lower dose is recommended for moderate hepatic impairment.

For patients with renal impairment, an initial dose of 4 mg once daily is recommended in the UK for hypertension, including for patients on haemodialysis. In the USA, no initial dose adjustment is recommended for mild renal impairment, although dose reduction may be considered if patients are volume depleted. For patients with heart failure, dose reduction or discontinuation of candesartan may be necessary if renal function deteriorates.

Migraine. For reference to the use of angiotensin II receptor antagonists, including candesartan, in the prophylaxis of migraine, see under Losartan, p.1328.

Canrenone *(USAN, pINN)* ⊗

Canrenona; Canrénone; Canrenonum; SC-9376. 17-Hydroxy-3-oxo-17α-pregna-4,6-diene-21-carboxylic acid γ-lactone.

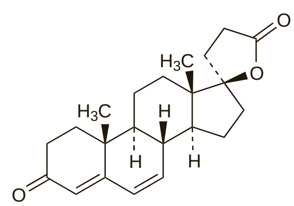
Канренон

$C_{22}H_{28}O_3$ = 340.5.

CAS — 976-71-6.

ATC — C03DA03.

ATC Vet — QC03DA03.



Profile

Canrenone is a potassium-sparing diuretic with properties similar to those of spironolactone (p.1400) and is given orally in the treatment of refractory oedema associated with heart failure (p.1165), renal, or hepatic disease, and in hypertension (p.1171). It is a metabolite of both spironolactone and potassium canrenoate (p.1374). It is given in usual doses of 50 to 200 mg daily. Doses of up to 300 mg daily may be required in some patients.

Captopril *(BAN, USAN, rINN)*

Captoprilum; Kaptopriili; Kaptopril; Kaptoprilis; SQ-14225. 1-[(2*S*)-3-Mercapto-2-methylpropionyl]-L-proline.

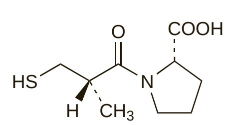
Каптоприл

$C_9H_{15}NO_3S$ = 217.3.

CAS — 62571-86-2.

ATC — C09AA01.

ATC Vet — QC09AA01.



NOTE. Compounded preparations of captopril may be represented by the following names:

- Co-zidocapt (*BAN*)—captopril 2 parts and hydrochlorothiazide 1 part (w/w).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Captopril). A white or almost white crystalline powder. Freely soluble in water, in dichloromethane, and in methyl alcohol. It dissolves in dilute solutions of alkali hydroxides. A 2% solution in water has a pH of 2.0 to 2.6. Store in airtight containers.

USP 31 (Captopril). A white or off-white crystalline powder which may have a characteristic sulfide-like odour. Freely soluble in water, in alcohol, in chloroform, and in methyl alcohol. Store in airtight containers.

Stability. Although captopril itself is relatively stable[1] at temperatures up to 50°, and extemporaneously prepared powders (made by triturating the tablets with lactose) have been reported to be stable for at least 12 weeks at room temperature,[2] aqueous solutions are subject to oxidative degradation, mainly to captopril disulfide,[1] which increases[3] with increase in pH above 4. The manufacturers report that a liquid form of captopril prepared from pulverised tablets in distilled water containing 1 mg/mL retained 96.6% of the original concentration of drug after storage at room temperature for 5 days, but they advise that since it contains no preservative it should be used within 2 days of preparation.[4] Others have reported wide variations in stability depending upon the formulation. In one study[5] the shelf-life of a solution of captopril 1 mg/mL prepared from crushed tablets and tap water was estimated to be 27 days when stored at 5°. However, in another study[6] captopril was much less stable; in sterile water for irrigation captopril was stable for at least 3 days when stored at 5°, but in tap water it disappeared at a much faster rate. Increased stability has been reported after the addition of sodium ascorbate to the solution,[7] and with captopril powder rather than crushed tablets.[8] A 1 mg/mL preparation made with crushed tablets and undiluted syrup has also been reported to be stable for 30 days at 5° and may be more palatable than aqueous formulations.[9]

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Captopril has been reported to cause false positive results in tests for acetone in urine.

Incidence of adverse effects. Results of postmarketing surveillance[1] in 30 515 hypertensive patients taking captopril showed that 4.9% had their therapy stopped because of adverse effects thought to be due to the drug. The mean initial daily dose was 46 mg; at final evaluation the mean daily dose was 58 mg. The adverse effect most commonly reported was headache (in 1.8%); others included dizziness (1.6%), rashes (1.1%), nausea (1.0%), taste disturbances (0.9%), and cough (0.8%). This study excluded patients with renal impairment but an earlier survey[2] in 6737 patients taking captopril alone or in combination found that rash and dysgeusia were more frequent in patients with renal impairment (occurring in 6.2% and 3.2% respectively of those receiving 150 mg daily or less of captopril) than in those with normal serum creatinine (4.3% and 2.2%). The frequency of both symptoms was somewhat higher in those given higher doses. Symptoms of hypotension occurred in about 5% of patients and were not influenced by dose or renal function. The cumulative frequency of withdrawal due to adverse effects was estimated at 5.8% in this study, which is similar to that in the larger survey. In another postmarketing surveillance study[3] involving more than 60 000 patients, captopril was withdrawn in 8.9% because of adverse effects.

For further reference to some of these adverse effects, see under ACE Inhibitors, p.1193.

Breast feeding. Captopril is distributed into breast milk and licensed product information advises that breast feeding should be avoided. However, a study[1] in 12 women found that the concentration of captopril in breast milk was about 1% of maternal blood concentrations, suggesting that the amount ingested by the infant would be very low. No adverse effects were noted in the infants in this study, and the American Academy of Pediatrics considers[2] that captopril is therefore usually compatible with breast feeding.

1. Devlin RG, Fleiss PM. Captopril in human blood and breast milk. *J Clin Pharmacol* 1981; **21:** 110–113.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 05/07/04)

Porphyria. Captopril is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

About 60 to 75% of a dose of captopril is absorbed from the gastrointestinal tract and peak plasma concentrations are achieved within about an hour. Absorption has been reported to be reduced in the presence of food, but this may not be clinically relevant (see below). Captopril is about 30% bound to plasma proteins. It crosses the placenta and is found in breast milk at about 1% of maternal blood concentrations. It is largely excreted in the urine, 40 to 50% as unchanged drug, the rest as disulfide and other metabolites. The elimination half-life has been reported to be 2 to 3 hours but this is increased in renal impairment. Captopril is removed by haemodialysis.

◊ Reviews.

Absorption. The bioavailability and peak plasma concentrations of captopril have been shown to be reduced by 25 to 55% when given with food in single dose studies[1-4] and with chronic dosing.[5] However, this may not be clinically significant since several studies[3,4,6] indicated that food intake had no effect on the antihypertensive activity of captopril.

Renal impairment. A study of 9 patients with chronic renal failure undergoing dialysis found that peak plasma concentrations of captopril were 2.5 times higher and peak concentrations of the disulfide metabolites were 4 times higher than in patients with normal renal function following a single dose of captopril.[1] Peak concentrations occurred later in uraemic patients and the apparent half-life of total captopril was 46 hours in uraemic patients compared with 2.95 hours in patients with normal renal function.

Uses and Administration

Captopril is a sulfhydryl-containing ACE inhibitor (p.1193). It is used in the management of hypertension (p.1171), in heart failure (p.1165), after myocardial infarction (p.1175), and in diabetic nephropathy (see Kidney Disorders, p.1199).

After oral doses captopril produces a maximum effect within 1 to 2 hours, although the full effect may not develop for several weeks during chronic dosing. The duration of action is dose-dependent and may persist for 6 to 12 hours.

In the treatment of **hypertension** the initial oral dose is 12.5 mg twice daily, increased gradually at intervals of 2 to 4 weeks according to the response. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. An initial dose of 6.25 mg twice daily is recommended if captopril is given in addition to a *diuretic* or to elderly patients; if possible the diuretic should be stopped 2 or 3 days before introducing captopril. The usual maintenance dose is 25 to 50 mg twice daily and should not normally exceed 50 mg three times daily. If hypertension is not satisfactorily controlled at this dosage, addition of a second drug or substitution of an alternative drug should be considered. In the USA higher doses of up to 150 mg three times daily have been suggested for patients with hypertension uncontrolled by lower doses of captopril in conjunction with diuretic therapy.

In the treatment of **heart failure** severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus an initial oral dose of 6.25 to 12.5 mg of captopril is given under close medical supervision; the usual maintenance dose is 25 mg two or three times daily, and doses should not normally exceed 50 mg three times daily. Again, in the USA higher doses of up to 150 mg three times daily have been suggested.

After **myocardial infarction**, captopril is used prophylactically in clinically stable patients with symptomatic or asymptomatic left ventricular dysfunction to improve survival, delay the onset of symptomatic heart failure, and reduce recurrent infarction. It may be started 3 days after myocardial infarction in an initial oral dose of 6.25 mg, increased over several weeks to 150 mg daily in divided doses if tolerated.

In **diabetic nephropathy** (microalbuminuria greater than 30 mg/day) in type 1 diabetics, 75 to 100 mg of captopril may be given daily, in divided oral doses. Other antihypertensives may be used with captopril if a further reduction in blood pressure is required.

Doses may need to be reduced in patients with renal impairment (see below).

Administration. Captopril is generally given orally. Sublingual[1] and intravenous[2,3] dosage has also been tried, but these routes are not established.

1. Angeli P, *et al.* Comparison of sublingual captopril and nifedipine in immediate treatment of hypertensive emergencies: a randomized, single-blind clinical trial. *Arch Intern Med* 1991; **151:** 678–82.
2. Savi L, *et al.* A new therapy for hypertensive emergencies: intravenous captopril. *Curr Ther Res* 1990; **47:** 1073–81.
3. Langes K, *et al.* Efficacy and safety of intravenous captopril in congestive heart failure. *Curr Ther Res* 1993; **53:** 167–76.

Administration in children. Experience with captopril in children is limited. UK licensed product information suggests an initial dose of 300 micrograms/kg in children and adolescents; half this dose should be given initially to neonates and infants (including premature infants), and children with renal impairment. The dose is adjusted according to response and is usually given three times daily.

Captopril, given in an initial dose of 250 micrograms/kg daily, increased to up to 2.5 or 3.5 mg/kg daily in 3 divided doses has also been reported to produce benefit in infants with severe heart failure secondary to congenital defects (mainly manifesting as left-to-right shunt).[1,2]

The following doses of captopril are suggested by the *BNFC* for hypertension, heart failure, proteinuria in nephritis, or diabetic nephropathy:

- neonate: test dose, 10 to 50 micrograms/kg (10 micrograms/kg if the neonate is less than 37 weeks postmenstrual age); if tolerated, give 10 to 50 micrograms/kg 2 or 3 times daily, increased as necessary to a maximum of 2 mg/kg daily in divided doses (maximum of 300 micrograms/kg daily in divided doses if the neonate is less than 37 weeks postmenstrual age)
- child 1 month to 12 years: test dose, 100 micrograms/kg (maximum 6.25 mg); if tolerated, give 100 to 300 micrograms/kg 2 or 3 times daily, increased as necessary to a maximum of 6 mg/kg daily in divided doses (maximum of 4 mg/kg daily in divided doses in child 1 month to 1 year)
- child 12 years to 18 years: test dose, 100 micrograms/kg or 6.25 mg; if tolerated, give 12.5 to 25 mg 2 or 3 times daily, increased as necessary to a maximum of 150 mg daily in divided doses

2. Shaw NJ, *et al.* Captopril in heart failure secondary to a left to right shunt. *Arch Dis Child* 1988; **63:** 360–3.

Administration in renal impairment. The dose of captopril should be reduced or the dosage interval increased in adults with renal impairment, depending on their creatinine clearance (CC). The following doses have been suggested:

- CC 21 to 40 mL/minute per 1.73 m^2: initial daily dose 25 mg and maximum daily dose 100 mg
- CC 10 to 20 mL/minute per 1.73 m^2: initial daily dose 12.5 mg and maximum daily dose 75 mg
- CC below 10 mL/minute per 1.73 m^2: initial daily dose 6.25 mg and maximum daily dose 37.5 mg

If a diuretic also needs to be given, a loop diuretic should be chosen rather than a thiazide.

Nitrate tolerance. For reference to the use of captopril as a sulfhydryl donor in the management of nitrate tolerance, see under Precautions for Glyceryl Trinitrate, p.1297.

Preparations

BP 2008: Captopril Tablets;

Carteolol Hydrochloride

(BANM, USAN, rINNM) ⊗

Abbott-43326; Cartéolol, chlorhydrate de; Carteololi hydrochloridum; Hidrocloruro de carteolol; Karteolol Hidroklorür; Karteolol-hidroklorid; Karteolol-hydrochlorid; Karteololhydroklorid; Karteololihydrokloridi; Karteololio hidrochloridas; OPC-1085. 5-(3-*tert*-Butylamino-2-hydroxypropoxy)-3,4-dihydroquinolin-2(1*H*)-one hydrochloride.

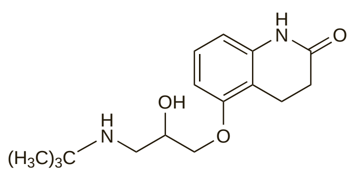
Картеолола Гидрохлорид

$C_{16}H_{24}N_2O_3,HCl = 328.8.$

CAS — 51781-06-7 (carteolol); 51781-21-6 (carteolol hydrochloride).

ATC — C07AA15; S01ED05.

ATC Vet — QC07AA15; QS01ED05.



(carteolol)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Carteolol Hydrochloride). White or almost white crystals or crystalline powder. Soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane; sparingly soluble in methyl alcohol. A 1% solution in water has a pH of 5.0 to 6.0. Store in airtight containers.

USP 31 (Carteolol Hydrochloride). pH of a 1% solution in water is between 5.0 and 6.0.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Carteolol is well absorbed from the gastrointestinal tract with a peak plasma concentration being reached within 1 to 4 hours of oral doses. The bioavailability is about 84%. It has low lipid solubility. About 20 to 30% is protein bound. The plasma half-life is reported to be 3 to 6 hours. The major route of elimination is renal with 50 to 70% of a dose being excreted unchanged in the urine; carteolol therefore accumulates in patients with renal disease. Major metabolites are 8-hydroxycarteolol and glucuronic acid conjugates of carteolol and 8-hydroxycarteolol. The 8-hydroxycarteolol metabolite is active; its half-life is reported to be 8 to 12 hours.

Uses and Administration

Carteolol is a non-cardioselective beta blocker (see p.1225). It is reported to possess intrinsic sympathomimetic activity but lacks significant membrane-stabilising activity.

Carteolol is used as the hydrochloride in the management of glaucoma (p.1873), hypertension (p.1171), and some cardiac disorders such as angina pectoris (p.1157) and cardiac arrhythmias (p.1160).

Eye drops containing carteolol hydrochloride 1% or 2% are instilled twice daily to reduce raised intra-ocular pressure in open-angle **glaucoma** and ocular hypertension.

In **hypertension** carteolol hydrochloride is given orally in a usual dose range of 2.5 to 20 mg daily, adjusted according to response, although up to 40 mg daily has been given. In cardiac disorders such as **angina pectoris** and **arrhythmias** carteolol hydrochloride has been used in doses of up to 30 mg daily.

The oral dose of carteolol hydrochloride should be reduced in patients with renal impairment (see below).

◊ Reviews.

1. Chrisp P, Sorkin EM. Ocular carteolol: a review of its pharmacological properties, and therapeutic use in glaucoma and ocular hypertension. *Drugs Aging* 1992; **2:** 58–77. Correction. *ibid.* 1994; **4:** 62.

Administration in renal impairment. The oral dose of carteolol hydrochloride should be reduced in patients with renal impairment. A suggested regimen based on creatine clearance (CC) for patients with hypertension is as follows:

- CC 30 to 80 mL/minute: 10 mg daily
- CC less than 30 mL/minute: use not recommended

Preparations

BP 2008: Carteolol Eye Drops;
USP 31: Carteolol Hydrochloride Ophthalmic Solution; Carteolol Hydrochloride Tablets.

Carvedilol *(BAN, USAN, rINN)* ⊗

BM-14190; Carvédilol; Carvedilolum; Karvedilol; Karvediloli; Karvedilolis. 1-Carbazol-4-yloxy-3-[2-(2-methoxyphenoxy)ethylamino]propan-2-ol.

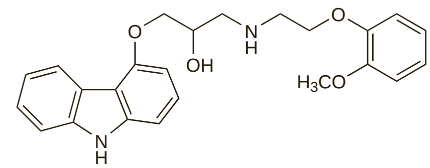
Карведилол

$C_{24}H_{26}N_2O_4 = 406.5.$

CAS — 72956-09-3.

ATC — C07AG02.

ATC Vet — QC07AG02.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Carvedilol). A white or almost white crystalline powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in alcohol; practically insoluble in dilute acids.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Liver function abnormalities, reversible on stopping treatment with carvedilol, have been reported rarely. Carvedilol is extensively metabolised in the liver and is not recommended in patients with hepatic impairment. Acute renal failure and renal abnormalities have been reported in patients with heart failure who also suffered from diffuse vascular disease and/or renal impairment.

The risk of hypotension may be reduced by taking carvedilol with food to decrease the rate of absorption.

Effects on the liver. Pruritus and elevated serum transaminase concentrations occurred[1] in a man who had been taking carvedilol for 6 months. Liver function tests returned to normal within 3 weeks of stopping carvedilol. However, pruritus recurred when the patient was started on metoprolol about 1 year later.

1. Hagmeyer KO, Stein J. Hepatotoxicity associated with carvedilol. *Ann Pharmacother* 2001; **35:** 1364–6.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Carvedilol is well absorbed from the gastrointestinal tract but is subject to considerable first-pass metabolism in the liver; the absolute bioavailability is about 25%. Peak plasma concentrations occur 1 to 2 hours after an oral dose. It has high lipid solubility. Carvedilol is more than 98% bound to plasma proteins. It is extensively metabolised in the liver, primarily by the cytochrome P450 isoenzymes CYP2D6 and CYP2C9, and the metabolites are excreted mainly in the bile. The elimination half-life is about 6 to 10 hours. Carvedilol has been shown to accumulate in breast milk in *animals*.

◊ References.

2. Morgan T. Clinical pharmacokinetics and pharmacodynamics of carvedilol. *Clin Pharmacokinet* 1994; **26:** 335–46.
3. Tenero D, *et al.* Steady-state pharmacokinetics of carvedilol and its enantiomers in patients with congestive heart failure. *J Clin Pharmacol* 2000; **40:** 844–53.

Uses and Administration

Carvedilol is a non-cardioselective beta blocker (p.1225). It has vasodilating properties, which are attributed mainly to its blocking activity at $alpha_1$ receptors; at higher doses calcium-channel blocking activity may contribute. It also has antoxidant properties. Carvedilol is reported to have no intrinsic sympathomimetic activity and only weak membrane-stabilising activity.

Carvedilol is used in the management of hypertension (p.1171) and angina pectoris (p.1157), and as an adjunct to standard therapy in symptomatic heart failure (p.1165). It is also used to reduce mortality in patients with left ventricular dysfunction after myocardial infarction.

In **hypertension** carvedilol is given in an initial oral dose of 12.5 mg once daily, increased after two days to 25 mg once daily. Alternatively, an initial dose of 6.25 mg is given twice daily, increased after one to two weeks to 12.5 mg twice daily. The dose may be increased further, if necessary, at intervals of at least two weeks, to 50 mg once daily or in divided doses. A dose of 12.5 mg once daily may be adequate for elderly patients.

In **angina pectoris** an initial oral dose of 12.5 mg is given twice daily, increased after two days to 25 mg twice daily.

In **heart failure**, the initial oral dose is 3.125 mg twice daily. It should be taken with food to reduce the risk of hypotension. If tolerated, the dose should be doubled after two weeks to 6.25 mg twice daily and then increased gradually, at intervals of not less than two weeks, to the maximum dose tolerated; this should not exceed 25 mg twice daily in patients with severe heart failure or in those weighing less than 85 kg, or 50 mg twice daily in patients with mild to moderate heart failure weighing more than 85 kg. For doses in children, see below.

In patients with **left ventricular dysfunction after myocardial infarction**, the initial dose is 6.25 mg twice daily, increased after 3 to 10 days, if tolerated, to 12.5 mg twice daily and then to a target dose of 25 mg twice daily. A lower initial dose may be used in symptomatic patients.

A controlled-release preparation containing carvedilol phosphate hemihydrate is available in some countries.

Administration in children. Carvedilol has been used in children with heart failure, although experience is limited.[1] Beneficial effects have been reported, including improvement in symptoms and ejection fraction, and delaying the need for heart transplantation, and carvedilol appears to be well tolerated. Doses used have varied, with initial oral doses ranging from 10 to 180 micrograms/kg daily and average oral maintenance doses ranging from 200 to 700 micrograms/kg (maximum 50 mg) daily, usually given in two divided doses. However, a randomised study[2] in 161 children and adolescents with heart failure found that carvedilol was not significantly better than placebo: clinical improvement occurred in 56% of those taking carvedilol and 56% of those taking placebo.

In the UK, the *BNFC* recommends that children aged 2 to 18 years with heart failure may be given an initial oral dose of 50 micrograms/kg (maximum 3.125 mg) twice daily, increased as tolerated, by doubling the dose at intervals of at least 2 weeks, to a maintenance dose of 350 micrograms/kg (maximum 25 mg) twice daily.

2. Shaddy RE, *et al.* Carvedilol for children and adolescents with heart failure: a randomized controlled trial. *JAMA* 2007; **298:** 1171–9.

Administration in the elderly. Licensed product information for carvedilol recommends an initial dose of 12.5 mg daily for all adults with hypertension. A study in 16 elderly hypertensive patients (mean age 70 years) given single doses of 12.5 mg and 25 mg found a high incidence of orthostatic hypotension[1] and the authors suggested that a starting dose lower than 12.5 mg may be necessary in elderly patients.

A retrospective study[2] found that standard initial doses for heart failure (see Uses and Administration, above) were well tolerated in elderly patients and that the mean achieved dose was similar in those aged under 70 years and those aged 70 years and older, after adjustment for weight. Adverse effects were more common in the older group, but could generally be managed without stopping carvedilol.

Celiprolol Hydrochloride

(BANM, USAN, rINNM) ⊗

Céliprolol, chlorhydrate de; Celiprolol-hydrochlorid; Celiprololhydroklorid; Celiprololi hydrochloridum; Celiprololio hidrochloridas; Celiprololu chlorowodorek; Hidrocloruro de celiprolol; Seliprololihydrokloridi. 3-{3-Acetyl-4-[3-(*tert*-butylamino)-2-hydroxypropoxy]phenyl}-1,1-diethylurea hydrochloride.

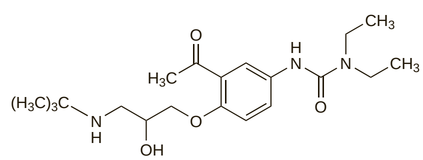
Целипролола Гидрохлорид

$C_{20}H_{33}N_3O_4,HCl = 416.0.$

CAS — 56980-93-9 (celiprolol); 57470-78-7 (celiprolol hydrochloride).

ATC — C07AB08.

ATC Vet — QC07AB08.



(celiprolol)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Celiprolol Hydrochloride). A white or very slightly yellow, crystalline powder. It exhibits polymorphism. Freely soluble in water and in methyl alcohol; soluble in alcohol; very slightly soluble in dichloromethane. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Tremor and palpitations associated with intrinsic sympathomimetic activity at $beta_2$ receptors have been reported.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Celiprolol is absorbed from the gastrointestinal tract in a non-linear fashion; the percentage of the dose absorbed increases with increasing dose. The plasma elimination half-life is about 5 to 6 hours. Celiprolol crosses the placenta. It has low lipid solubility and is about 25% bound to plasma proteins. Metabolism is minimal and celiprolol is mainly excreted unchanged in the urine and faeces.

Uses and Administration

Celiprolol is a cardioselective beta blocker (p.1225). It is reported to possess intrinsic sympathomimetic activity and direct vasodilator activity. Celiprolol is used as the hydrochloride in the management of hypertension (p.1171) and angina pectoris (p.1157). The usual oral dose of celiprolol hydrochloride is 200 to 400 mg once daily before food. Reduced doses may be required in patients with renal impairment (see below).

◊ References.

Certoparin Sodium *(BAN, rINN)*

Certoparin; Certoparina sódica; Certoparine Sodique; Certoparinum Natricum.

Цертопарин Натрий

Description. Certoparin sodium is prepared by amyl nitrite degradation of heparin obtained from the intestinal mucosa of pigs. The majority of the components have a 2-*O*-sulfo-α-L-idopyranosuronic acid structure at the non-reducing end and a 6-*O*-sulfo-2,5-anhydro-D-mannose structure at the reducing end of their chain. The molecular weight of 70% of the components is less than 10 000 and the average molecular weight is about 6000. The degree of sulfation is about 2 to 2.5 per disaccharide unit.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329.

Severe bleeding with certoparin may be reduced by the slow intravenous injection of protamine salts; 1 mg of protamine hydrochloride is stated to inhibit the effects of 80 to 120 units of certoparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Certoparin sodium is rapidly and completely absorbed after subcutaneous injection. Peak plasma activity is reached within 2 to 4 hours. The half-life of anti-factor Xa activity is about 4 hours.

Uses and Administration

Certoparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant activity used for the prevention of postoperative venous thromboembolism (p.1189). It is given by subcutaneous injection in a dose of 3000 units 1 to 2 hours before the procedure, followed by 3000 units daily for 7 to 10 days or until the patient is fully ambulant.

Cetiedil Citrate (USAN, rINNM)

Cétiédil, Citrate de; Cetiedili Citras; Citrato de cetiedil. 2-(Perhydroazepin-1-yl)ethyl α-cyclohexyl-α-(3-thienyl)acetate dihydrogen citrate monohydrate.

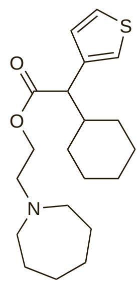
Цетиедила Цитрат

$C_{20}H_{31}NO_2S,C_6H_8O_7,H_2O$ = 559.7.

CAS — 14176-10-4 (cetiedil); 16286-69-4 (anhydrous cetiedil citrate).

ATC — C04AX26.

ATC Vet — QC04AX26.



(cetiedil)

Profile

Cetiedil citrate is a vasodilator with antimuscarinic activity that has been used in the management of peripheral vascular disease.

Chlorothiazide (BAN, rINN) ⊗

Chlorothiazid; Chlorothiazidum; Chlorotiazidas; Chlorotiazyd; Clorotiazida; Klooritiatsidi; Klorotiazid; Klortiazid. 6-Chloro-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

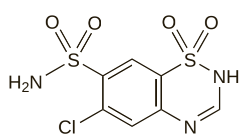
Хлоротиазид

$C_7H_6ClN_3O_4S_2$ = 295.7.

CAS — 58-94-6.

ATC — C03AA04.

ATC Vet — QC03AA04.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Chlorothiazide). A white or almost white crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; sparingly soluble in acetone. It dissolves in dilute solutions of alkali hydroxides.

USP 31 (Chlorothiazide). A white or practically white, odourless, crystalline powder. Very slightly soluble in water; practically insoluble in chloroform, in ether, and in benzene; freely soluble in dimethylformamide and dimethyl sulfoxide; slightly soluble in methyl alcohol and in pyridine. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Stability. Alkaline solutions undergo decomposition due to hydrolysis upon standing or heating.

Chlorothiazide Sodium (BANM, USAN, rINNM) ⊗

Chlorothiazide Sodique; Clorotiazida sódica; Natrii Chlorothiazidum; Sodium Chlorothiazide.

Натрий Хлоротиазид

$C_7H_5ClN_3NaO_4S_2$ = 317.7.

CAS — 7085-44-1.

ATC — C03AA04.

ATC Vet — QC03AA04.

Pharmacopoeias. *US* includes Chlorothiazide Sodium for Injection.

Incompatibility. The alkaline nature of chlorothiazide in injectable form suggests that incompatibilities with acidic drugs could be expected; US licensed product information states that the injection may be diluted with glucose or sodium chloride solutions.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307. Chlorothiazide sodium injection is alkaline: when giving chlorothiazide by intravenous infusion, care should be taken to ensure that extravasation does not occur.

Breast feeding. Chlorothiazide is distributed into breast milk in small amounts. A single 500-mg oral dose of chlorothiazide was given[1] to 11 lactating women and blood and milk samples taken after 1, 2, and 3 hours; all the samples had concentrations below 1 microgram/mL and it was calculated that an infant would receive no more than 1 mg of drug each day. The American Academy of Pediatrics states that no adverse effects have been seen in infants and therefore considers[2] that chlorothiazide is usually compatible with breast feeding.

1. Werthmann MW, Krees SV. Excretion of chlorothiazide in human breast milk. *J Pediatr* 1972; **81:** 781–3.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 06/07/04)

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Chlorothiazide is incompletely and variably absorbed from the gastrointestinal tract. It has been estimated to have a plasma half-life of 45 to 120 minutes although the clinical effects may last for up to about 12 hours. It is excreted unchanged in the urine. Chlorothiazide crosses the placental barrier and small amounts are reported to be distributed into breast milk.

Uses and Administration

Chlorothiazide is a thiazide diuretic with actions and uses similar to those of hydrochlorothiazide (p.1310). It is used for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

After oral doses of chlorothiazide diuresis usually occurs in about 2 hours, reaches a maximum at about 4 hours, and is maintained for 6 to 12 hours.

In the treatment of **oedema** the usual dose of chlorothiazide is 0.25 to 1 g orally once or twice daily; therapy on alternate days or on 3 to 5 days weekly may be adequate. The dose should not normally exceed 2 g daily.

In the treatment of **hypertension** the usual initial dose is 250 to 500 mg daily orally, given as a single or divided dose. A dose of 125 mg may be adequate in some patients. Patients may rarely require up to 1 g daily.

For the use of chlorothiazide in children, see below.

Chlorothiazide has also been given intravenously as the sodium salt, in doses similar to those given orally. Chlorothiazide sodium 537 mg is equivalent to about 500 mg of chlorothiazide. It is not suitable for subcutaneous or intramuscular injection and extravasation should be avoided. The diuretic effect lasts for up to 2 hours after intravenous injection.

Administration in children. Chlorothiazide may be used in children for the management of *heart failure* or *hypertension*. Usual oral doses are as follows:

- neonates and infants aged 1 to 6 months: 10 to 20 mg/kg twice daily
- age 6 months to 12 years: 10 mg/kg twice daily, to a maximum of 1 g daily
- age 12 to 18 years: 0.25 to 1 g once daily or 125 to 500 mg twice daily

For *diabetes insipidus* in children, the *BNFC* suggests an oral dose of 10 to 20 mg/kg twice daily, to a maximum of 1 g daily.

Chlorothiazide also has a hyperglycaemic effect and has been used in children with *chronic hypoglycaemia* (see under Uses of Glucagon, p.1447). It is usually given with diazoxide and has the added benefit of reducing diazoxide-associated sodium and water retention. The *BNFC* suggests an oral dose of 3 to 5 mg/kg twice daily.

Preparations

USP 31: Chlorothiazide Oral Suspension; Chlorothiazide Sodium for Injection; Chlorothiazide Tablets; Methyldopa and Chlorothiazide Tablets; Reserpine and Chlorothiazide Tablets.

Proprietary Preparations (details are given in Part 3)
Singapore: Chlorzide†; ***USA:*** Diurigen; Diuril.

Multi-ingredient: ***Canad.:*** Supres†; ***Gr.:*** Neourizine; ***USA:*** Aldoclor; Diupres.

Chlortalidone (BAN, rINN) ⊗

Chlorotalidon; Chlortalidon; Chlortalidonas; Chlortalidonum; Chlorthalidone (USAN); Clorotalidona; Clortalidona; G-33182; Klooritalidoni; Klórtalidon; Klortalidon; NSC-69200. 2-Chloro-5-(1-hydroxy-3-oxoisoindolin-1-yl)benzenesulphonamide.

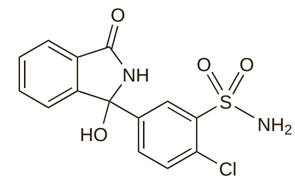
Хлорталидон

$C_{14}H_{11}ClN_2O_4S$ = 338.8.

CAS — 77-36-1.

ATC — C03BA04.

ATC Vet — QC03BA04.



NOTE. Compounded preparations of chlortalidone may be represented by the following names:

- Co-tenidone (*BAN*)—chlortalidone 1 part and atenolol 4 parts (w/w).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Chlortalidone). A white or yellowish-white powder. Very slightly soluble in water; soluble in acetone and in methyl alcohol; practically insoluble in dichloromethane. It dissolves in dilute solutions of alkali hydroxides. It exhibits polymorphism.

USP 31 (Chlorthalidone). A white or yellowish-white crystalline powder. Practically insoluble in water, in chloroform, and in ether; slightly soluble in alcohol; soluble in methyl alcohol.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Breast feeding. Chlortalidone is distributed into breast milk, but a study[1] in 9 women given a dose of 50 mg daily found that the concentration in milk was only about 5% of that in the blood. However, caution was advised since chlortalidone elimination may be slower in neonates. The American Academy of Pediatrics considers[2] that chlortalidone is usually compatible with breast feeding.

1. Mulley BA, *et al.* Placental transfer of chlorthalidone and its elimination in maternal milk. *Eur J Clin Pharmacol* 1978; **13:** 129–31.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 06/07/04)

Interactions

As for Hydrochlorothiazide, p.1309.

Anticoagulants. For references to the interaction between *warfarin* and chlortalidone, see p.1430.

Pharmacokinetics

Chlortalidone is erratically absorbed from the gastrointestinal tract and bioavailability varies according to the preparation used. It has a prolonged elimination half-life from plasma and blood of 40 to 60 hours and is highly bound to red blood cells; the receptor to which it is bound has been identified as carbonic anhydrase. Chlortalidone is much less strongly bound to plasma proteins. Chlortalidone is mainly excreted unchanged in the urine. It crosses the placental barrier and is distributed into breast milk.

4. Mulley BA, *et al.* Pharmacokinetics of chlorthalidone: dependence of biological half life on blood carbonic anhydrase levels. *Eur J Clin Pharmacol* 1980; **17:** 203–7.

Uses and Administration

Chlortalidone is a diuretic with actions and uses similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1310) even though it does not contain a thiazide ring system. It is given orally for hypertension (p.1171), and for oedema, including that associated with heart failure (p.1165). Other indications include diabetes insipidus (p.2179).

Diuresis begins about 2 hours after an oral dose and lasts for 48 to 72 hours.

The usual dose in the treatment of **hypertension** is 25 mg daily, given either alone or with other antihypertensives, increasing to 50 mg daily if necessary.

In the treatment of **oedema** the usual initial dose is 25 to 50 mg daily. In severe cases a daily dose of 100 to 200 mg may be given. If possible lower doses should be used for maintenance; 25 to 50 mg daily or on alternate days may be adequate.

A dose for children is up to 2 mg/kg on alternate days.

In **diabetes insipidus** an initial dose of 100 mg twice daily has been used, reduced to a maintenance dose of 50 mg daily.

In the US, a preparation is available with improved bioavailability; suggested doses range from 15 to 50 mg daily for hypertension and 30 to 120 mg daily for oedema.

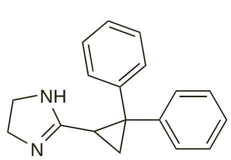
Cibenzoline *(BAN, rINN)*

Cibenzolina; Cibenzolinum; Cifenline *(USAN)*; Ro-22-7796; Ro-22-7796/001 (cibenzoline succinate); UP-339-01. (±)-2-(2,2-Diphenylcyclopropyl)-2-imidazoline.

Цибензолин

$C_{18}H_{18}N_2$ = 262.3.
CAS — 53267-01-9 (cibenzoline); 100678-32-8 (cibenzoline succinate).
ATC — C01BG07.
ATC Vet — QC01BG07.



Adverse Effects and Precautions

Cibenzoline may cause neurological and gastrointestinal adverse effects including vertigo, tremor, nausea, vomiting, and diarrhoea. Other adverse effects include fatigue, visual disturbances, and hypoglycaemia. It prolongs the QT interval and, like other antiarrhythmics, can cause arrhythmias. It also has a negative inotropic effect and may reduce blood pressure.

Cibenzoline is contra-indicated in patients with heart block and severe heart failure. It should be used with caution in the elderly and in renal impairment, and doses should be reduced.

Effects on the neuromuscular system. Myasthenia-like symptoms have been reported[1-3] in patients with renal impairment taking cibenzoline, including severe respiratory depression in some cases.[2,3]

1. Kasuga A, *et al.* Myasthenia-like syndrome induced by overdosage of cibenzoline. *Intern Med* 1996; **35:** 512–14.
2. Similowski T, *et al.* Neuromuscular blockade with acute respiratory failure in a patient receiving cibenzoline. *Thorax* 1997; **52:** 582–4.
3. Inada K, *et al.* A case of severe respiratory depression due to cibenzoline overdosage induced by a transient renal dysfunction. *Int J Cardiol* 2002; **82:** 177–8.

Hypoglycaemia. Cibenzoline therapy was associated with severe hypoglycaemia in a 67-year-old patient.[1] The plasma-cibenzoline concentration was 1800 nanograms/mL which would probably be considered toxic since the accepted therapeutic trough range is 200 to 600 nanograms/mL. A case-control study[2] also suggested that the risk of hypoglycaemia is increased by cibenzoline.

1. Hilleman DE, *et al.* Cibenzoline-induced hypoglycemia. *Drug Intell Clin Pharm* 1987; **21:** 38–40.
2. Takada M, *et al.* The relationship between risk of hypoglycemia and use of cibenzoline and disopyramide. *Eur J Clin Pharmacol* 2000; **56:** 335–42.

Interactions

Cibenzoline should not be used with other drugs that prolong the QT interval since the risk of arrhythmias may be increased.

Histamine H_2-antagonists. Increased blood concentrations and prolonged half-lives of cibenzoline occurred in healthy subjects given *cimetidine* but the clinical importance of this was unknown.[1] The interaction did not occur with *ranitidine*.

1. Massarella JW. The effects of cimetidine and ranitidine on the pharmacokinetics of cifenline. *Br J Clin Pharmacol* 1991; **31:** 481–3.

Pharmacokinetics

Cibenzoline is well absorbed from the gastrointestinal tract after oral use, with a bioavailability of about 90%. It is about 50 to 60% bound to plasma proteins. About 60% of a dose is excreted unchanged in the urine and the elimination half-life is reported to be about 7 hours.

Uses and Administration

Cibenzoline is a class I antiarrhythmic (p.1153) that has been classified as either Ia or Ic; it also has some class III and class IV properties. It is used in the management of ventricular and supraventricular arrhythmias (p.1160). Cibenzoline is given by mouth as the succinate or intravenously as a mixture of the base and succinate, but doses for both routes are expressed in terms of the base; 145 mg of cibenzoline succinate is equivalent to about 100 mg of base. The usual oral dose of cibenzoline succinate is the equivalent of 260 to 390 mg cibenzoline daily. The usual intravenous dose is the equivalent of 1 mg/kg cibenzoline base given over 2 to 5 minutes. Dosage should be reduced in the elderly (below), and in renal impairment (below).

◊ Reviews.

1. Harron DW, *et al.* Cibenzoline: a review of its pharmacological properties and therapeutic potential in arrhythmias. *Drugs* 1992; **43:** 734–59.

Administration in the elderly. The renal and non-renal clearance of cibenzoline was found to decrease with increasing age in healthy subjects.[1] The mean elimination half-life was 7 hours in the 20- to 30-year age group and 10.5 hours in the 70- to 80-year age group. The reduction in renal clearance was considered to be related to the decrease in creatinine clearance with increasing age. The results suggested that older patients may need lower doses than younger patients to maintain therapeutic plasma-cibenzoline concentrations. Licensed product information recommends a dosage of 130 mg daily in two divided doses in elderly patients.

1. Brazzell RK, *et al.* Age and cibenzoline disposition. *Clin Pharmacol Ther* 1984; **36:** 613–19.

Administration in renal impairment. A study[1] in patients with normal or impaired renal function has suggested that in renal impairment initial loading doses of cibenzoline may be equivalent to those used in normal renal function although maintenance doses should be reduced to about two-thirds of normal. Oral doses recommended in licensed product information, based on creatinine clearance (CC), are as follows:

- CC 20 to 40 mL/min: the equivalent of 3 mg/kg daily
- CC 10 to 20 mL/min: the equivalent of 2.5 mg/kg daily

1. Aronoff G, *et al.* Bioavailability and kinetics of cibenzoline in patients with normal and impaired renal function. *J Clin Pharmacol* 1991; **31:** 38–44.

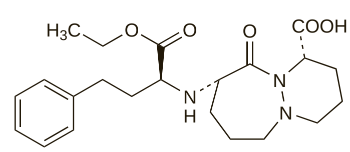
Цилазаприл

$C_{22}H_{31}N_3O_5,H_2O$ = 435.5.
CAS — 88768-40-5 (anhydrous cilazapril); 92077-78-6 (cilazapril monohydrate).
ATC — C09AA08.
ATC Vet — QC09AA08.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Cilazapril). A white or almost white crystalline powder. Slightly soluble in water; freely soluble in dichloromethane and in methyl alcohol. Protect from light.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Cilazapril acts as a prodrug of the diacid cilazaprilat, its active metabolite. After oral dosage and absorption of cilazapril it is rapidly metabolised in the liver to cilazaprilat, the bioavailability of which is about 60%. Peak plasma concentrations of cilazaprilat occur within 2 hours of an oral dose of cilazapril. Cilazaprilat is eliminated unchanged in the urine. The effective half-life of cilazaprilat is reported to be 9 hours after once-daily dosing. The elimination of cilazaprilat is reduced in renal impairment. Both cilazapril and cilazaprilat are removed to a limited extent by haemodialysis.

◊ Reviews.

1. Kelly JG, O'Malley K. Clinical pharmacokinetics of the newer ACE inhibitors: a review. *Clin Pharmacokinet* 1990; **19:** 177–96.
2. Kloke HJ, *et al.* Pharmacokinetics and haemodynamic effects of the angiotensin converting enzyme inhibitor cilazapril in hypertensive patients with normal and impaired renal function. *Br J Clin Pharmacol* 1996; **42:** 615–20.

Uses and Administration

Cilazapril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165).

Cilazapril owes its activity to cilazaprilat to which it is converted after oral doses. The haemodynamic effects are seen within 1 hour of a single oral dose and the maximum effect occurs after about 3 to 7 hours. The haemodynamic action persists for about 24 hours, allowing once-daily dosing. Cilazapril is given orally as the monohydrate, but doses are expressed in terms of the anhydrous substance. Cilazapril 1.04 mg as the monohydrate is equivalent to about 1 mg of anhydrous cilazapril.

In the treatment of **hypertension** the initial dose is 1 mg once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. Usual maintenance doses range from 2.5 to 5 mg daily. In the elderly, in patients with mild to moderate renal impairment, or those taking *diuretics*, a usual initial dose is 500 micrograms daily. If possible the diuretic should be withdrawn 2 to 3 days before cilazapril is started and resumed later if necessary.

In the treatment of **heart failure** severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus therapy should be initiated with a low dose under close medical supervision. Cilazapril is given in an initial dose of 500 micrograms once daily, increased if tolerated to a usual maintenance dose of 1 to 2.5 mg once daily. The usual maximum dose is 5 mg daily.

Reduced doses may be necessary in patients with renal impairment (see below).

◊ References.

1. Deget F, Brogden RN. Cilazapril: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic potential in cardiovascular disease. *Drugs* 1991; **41:** 799–820.

Administration in renal impairment. In patients with a creatinine clearance of 10 to 40 mL/minute, the initial dose of cilazapril is 500 micrograms once daily and the maintenance dose should not exceed 2.5 mg once daily. Cilazapril should be avoided in patients with a creatinine clearance below 10 mL/minute. In patients receiving haemodialysis, cilazapril should be given on the non-dialysis days and the dose should be adjusted according to response.

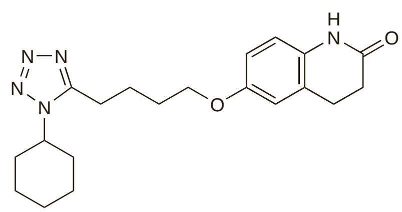
Cilostazol *(BAN, USAN, pINN)*

Cilostazolum; OPC-21; OPC-13013. 6-[4-(1-Cyclohexyl-1*H*-tetrazol-5-yl)butoxy]-3,4-dihydrocarbostyril.

Цилостазол

$C_{20}H_{27}N_5O_2$ = 369.5.

CAS — 73963-72-1.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Cilostazol). White to off-white crystals. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol; freely soluble in chloroform. Store in airtight containers.

Adverse Effects and Precautions

Adverse effects of cilostazol include headache, dizziness, palpitations, and diarrhoea; oedema, nausea and vomiting, other cardiac arrhythmias, chest pain, rhinitis, ecchymosis, and skin rashes have also been reported. Cardiovascular toxicity has been reported in *animal* studies of cilostazol, and prolonged oral use of other phosphodiesterase inhibitors (such as amrinone, p.1215) for the treatment of heart failure has been associated with increased mortality. The use of cilostazol in patients with any degree of heart failure is therefore contra-indicated. It is also contra-indicated in patients with a known predisposition to bleeding, a history of ventricular arrhythmias, QT interval prolongation, severe renal impairment, or moderate to severe hepatic impairment. Cilostazol should be avoided or used in reduced doses in patients taking inhibitors of the cytochrome P450 isoenzymes CYP3A4 or CYP2C19 (see Interactions, below).

Interactions

Cilostazol is extensively metabolised to active and inactive metabolites by cytochrome P450 isoenzymes, mainly CYP3A4 and to a lesser extent CYP2C19. Therefore use with other drugs that inhibit or are metabolised by these hepatic enzymes may result in changes in plasma concentrations of either drug and, possibly, adverse effects. Cilostazol should therefore be used with caution in patients taking drugs metabolised by these enzymes; in patients taking enzyme inhibitors it should be avoided or a reduced dose of 50 mg twice daily should be considered.

Pharmacokinetics

Cilostazol is absorbed after oral doses and absorption is increased if taken with a high fat meal. Cilostazol is extensively metabolised in the liver by cytochrome P450 isoenzymes, mainly CYP3A4 and to a lesser extent CYP2C19, to both active and inactive metabolites; these are mainly excreted in the urine (74%) with the remainder in the faeces (20%). The active metabolites have apparent elimination half-lives of 11 to 13 hours. Cilostazol is 95 to 98% protein bound.

◊ References.

1. Woo SK, *et al.* Pharmacokinetic and pharmacodynamic modeling of the antiplatelet and cardiovascular effects of cilostazol in healthy humans. *Clin Pharmacol Ther* 2002; **71:** 246–52.

Uses and Administration

Cilostazol is a phosphodiesterase inhibitor with antiplatelet and vasodilating activity. It is used in the management of peripheral vascular disease (p.1178).

The usual dose of cilostazol for the reduction of symptoms of intermittent claudication is 100 mg orally twice daily, at least 30 minutes before or 2 hours after food; doses should be reduced in patients taking enzyme inhibitors (see Interactions, above). Response to treatment may occur in 2 to 4 weeks, but up to 12 weeks may be required.

Cilostazol is under investigation for its antiplatelet effect after coronary stent implantation.

Peripheral vascular disease. Intermittent claudication is a major feature of occlusive arterial disease of the lower limbs (a form of peripheral vascular disease, p.1178) and is characterised by pain in the legs, which develops during exercise but usually disappears at rest. Many drugs have been used for symptom control, but none is of established benefit.

Several randomised, double-blind studies[1-4] have shown that cilostazol improves walking distances in patients with intermittent claudication, and one study[5] suggested that it was more effective than pentoxifylline. Cilostazol may therefore have a role for symptom control in patients with intermittent claudication.[6] However, long-term benefit has not been assessed[4] and, since patients with intermittent claudication are at high risk of other cardiovascular events, appropriate therapy to reduce cardiovascular risk (p.1164) is still required.

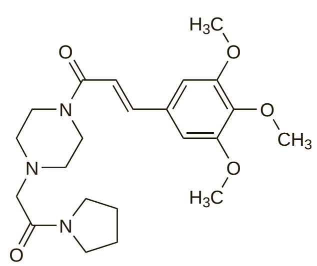
ATC — C04AX27.
ATC Vet — QC04AX27.



(cinepazide)

Profile

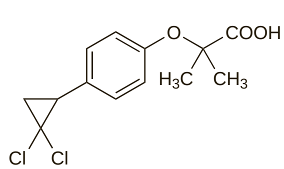
Cinepazide maleate is a vasodilator that has been used in peripheral vascular disorders, but has been withdrawn from the market in some countries after reports of agranulocytosis.

Ciprofibrate *(BAN, USAN, rINN)*

Ciprofibrát; Ciprofibrat; Ciprofibratas; Ciprofibrato; Ciprofibratum; Siprofibraatti; Win-35833. 2-[4-(2,2-Dichlorocyclopropyl)phenoxy]-2-methylpropionic acid.

Ципрофибрат

$C_{13}H_{14}Cl_2O_3$ = 289.2.
CAS — 52214-84-3.
ATC — C10AB08.
ATC Vet — QC10AB08.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Ciprofibrate). A white or slightly yellow, crystalline powder. Practically insoluble in water; freely soluble in dehydrated alcohol; soluble in toluene. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Bezafibrate, p.1232.

Interactions

As for Bezafibrate, p.1232.

Pharmacokinetics

Ciprofibrate is readily absorbed from the gastrointestinal tract; peak plasma concentrations occur within 1 to 4 hours. Ciprofibrate is highly protein bound. It is excreted in the urine as unchanged drug and as glucuronide conjugates. The elimination half-life varies from about 38 to 86 hours in patients on long-term therapy.

Uses and Administration

Ciprofibrate, a fibric acid derivative, is a lipid regulating drug with actions on plasma lipids similar to those of bezafibrate (p.1233).

It is used to reduce total cholesterol and triglycerides in the management of hyperlipidaemias (p.1169), including type IIa, type IIb, type III, and type IV hyperlipoproteinaemias. The usual oral dose is 100 mg daily. The dose should be reduced in renal impairment (see below).

Administration in renal impairment. Ciprofibrate is contra-indicated in patients with severe renal impairment. Licensed product information suggests reducing the dose to 100 mg every other day for patients with moderate renal impairment.

Renal clearance of ciprofibrate was reduced and elimination half-life about doubled in patients with severe renal impairment.[1] Mild renal impairment slowed the urinary excretion of ciprofibrate but not its extent. The clearance of ciprofibrate was unaffected by haemodialysis.

1. Ferry N, *et al.* The influence of renal insufficiency and haemodialysis on the kinetics of ciprofibrate. *Br J Clin Pharmacol* 1989; **28:** 675–81.

Preparations

Proprietary Preparations (details are given in Part 3)

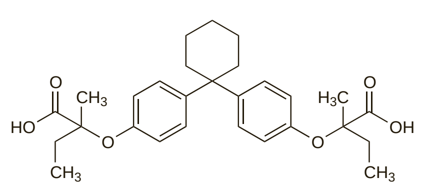
Clinofibrate *(rINN)*

Clinofibrato; Clinofibratum; S-8527. 2,2′-[Cyclohexylidenebis(4-phenyleneoxy)]bis[2-methylbutyric acid].

Клинофибрат

$C_{28}H_{36}O_6$ = 468.6.
CAS — 30299-08-2.



Pharmacopoeias. In *Jpn.*

Profile

Clinofibrate, a fibric acid derivative (see Bezafibrate, p.1232), is a lipid regulating drug used in the treatment of hyperlipidaemias (p.1169). The usual oral dose is 200 mg three times daily.

Preparations

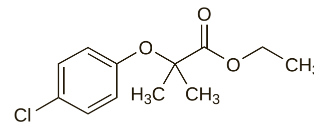
Proprietary Preparations (details are given in Part 3)
Jpn: Lipoclin.

Clofibrate *(BAN, USAN, rINN)*

AY-61123; Clofibrato; Clofibratum; Ethyl *p*-Chlorophenoxyisobutyrate; Ethyl Clofibrate; ICI-28257; Klofibraatti; Klofibrát; Klofibrat; Klofibratas; NSC-79389. Ethyl 2-(4-chlorophenoxy)-2-methylpropionate.

Клофибрат

$C_{12}H_{15}ClO_3$ = 242.7.
CAS — 637-07-0 (clofibrate); 882-09-7 (clofibric acid).
ATC — C10AB01.
ATC Vet — QC10AB01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Clofibrate). A clear, almost colourless liquid. Very slightly soluble in water; miscible with alcohol.
USP 31 (Clofibrate). A colourless to pale yellow liquid with a characteristic odour. Insoluble in water; soluble in alcohol, in acetone, in chloroform, and in benzene. Store in airtight containers. Protect from light.

Aluminium Clofibrate *(BAN, rINN)*

Alufibrate; Aluminii Clofibras; Aluminium, Clofibrate d'; Aluminiumklofibraatti; Aluminiumklofibrat; Aluminum Clofibrate; Clofibrato de aluminio. Bis[2-(4-chlorophenoxy)-2-methylpropionato]hydroxyaluminium.

Алюминия Клофибрат

$C_{20}H_{21}AlCl_2O_7$ = 471.3.
CAS — 24818-79-9; 14613-01-5.
ATC — C10AB03.
ATC Vet — QC10AB03.

Calcium Clofibrate *(rINN)*

Calcii Clofibras; Clofibrate de Calcium; Clofibrato de calcio.

Кальция Клофибрат

$C_{20}H_{20}CaCl_2O_6$ = 467.4.
CAS — 39087-48-4.

Magnesium Clofibrate *(rINN)*

Clofibrato de magnesio; Clomag; Magnesii Clofibras; Magnésium, Clofibrate de; UR-112.

Магния Клофибрат

$C_{20}H_{20}Cl_2MgO_6$ = 451.6.
CAS — 14613-30-0.

Profile

Clofibrate, a fibric acid derivative, is a lipid regulating drug with similar properties to bezafibrate (p.1233). It is used to reduce triglycerides and possibly total cholesterol in the management of hyperlipidaemias (p.1169), particularly in patients with hypertriglyceridaemia. Because of the incidence of adverse effects during long-term treatment it should not be used for the prophylaxis of ischaemic heart disease (see Adverse Effects, below).

The usual oral dose is 2 g daily in divided doses.

The aluminium, calcium, and magnesium salts of clofibrate have also been used.

Adverse effects. Large-scale, long-term studies[1,2] with clofibrate indicated that it was generally well-tolerated but that there was an increased incidence of serious effects, including cholelithiasis, cholecystitis, thromboembolic disorders, and certain cardiac arrhythmias. In one of the studies,[2] an increased mortality rate was unexpectedly found in patients taking clofibrate, producing serious concern over its long-term safety and its use is now generally restricted; the causes of death were spread over a range of malignant and non-malignant disorders.

2. Oliver MF, *et al.* A co-operative trial in the primary prevention of ischaemic heart disease using clofibrate. *Br Heart J* 1978; **40:** 1069–1118.

Neonatal jaundice. Clofibrate has been used in the treatment of jaundice in term infants[1,2] and for prophylaxis in premature infants.[1] In a study[1] involving 93 term infants with jaundice, clofibrate 50 mg/kg as a single oral dose reduced the intensity and duration of jaundice compared with placebo. As a prophylactic measure, clofibrate was shown[1] to reduce the degree of jaundice in premature infants when the plasma concentration of clofibric acid reached 140 micrograms/mL within 24 hours of an oral dose. The dose required to achieve this was estimated to be 100 to 150 mg/kg.

Preparations

BP 2008: Clofibrate Capsules;
USP 31: Clofibrate Capsules.

Proprietary Preparations (details are given in Part 3)
Arg.: Elpi; ***Austria:*** Arterioflexin; ***Hong Kong:*** Lipilim; ***Port.:*** Atromid-S†.

Multi-ingredient: ***Braz.:*** Lipofacton.

Clonidine *(BAN, USAN, rINN)*

Clonidina; Clonidinum; Klonidiini; Klonidin; ST-155-BS. 2-(2,6-Dichloroanilino)-2-imidazoline; 2,6-Dichloro-*N*-(imidazolidin-2-ylidene)aniline.

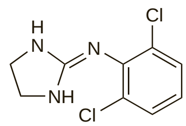
Клонидин

$C_9H_9Cl_2N_3$ = 230.1.

CAS — 4205-90-7.

ATC — C02AC01; N02CX02; S01EA04.

ATC Vet — QC02AC01; QN02CX02; QS01EA04.



Pharmacopoeias. In *US.*

USP 31 (Clonidine). A white to almost white, crystalline powder. Freely soluble in alcohol and in methyl alcohol. Store in airtight containers.

Clonidine Hydrochloride *(BANM, USAN, rINNM)*

Clonidine, chlorhydrate de; Clonidini hydrochloridum; Hidrocloruro de clonidina; Klonidiinihydrokloridi; Klonidin-hidroklorid; Klonidin-hydrochlorid; Klonidinhydroklorid; Klonidino hidrochloridas; Klonidyny chlorowodorek; ST-155.

Клонидина Гидрохлорид

$C_9H_9Cl_2N_3$,HCl = 266.6.

CAS — 4205-91-8.

ATC — C02AC01; N02CX02; S01EA04.

ATC Vet — QC02AC01; QN02CX02; QS01EA04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Clonidine Hydrochloride). A white or almost white crystalline powder. Soluble in water and in dehydrated alcohol. A 5% solution in water has a pH of 4.0 to 5.0.

USP 31 (Clonidine Hydrochloride). pH of a 5% solution in water is between 3.5 and 5.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Treatment

Drowsiness, dry mouth, dizziness, and headache are common when starting therapy with clonidine. Constipation is also common, and other adverse effects reported include depression, anxiety, fatigue, nausea, anorexia, parotid pain, sleep disturbances, vivid dreams, impotence and loss of libido, urinary retention or incontinence, orthostatic hypotension, and dry, itching, or burning sensations in the eye. Fluid retention may occur and is usually transient, but may be responsible for a reduction in the hypotensive effect during continued treatment. Clonidine can cause rashes and pruritus, and these are more common with transdermal delivery systems. Bradycardia, including sinus bradycardia with AV block, other ECG disturbances, heart failure, hallucinations, cramp, Raynaud's syndrome, gynaecomastia, and transient abnormalities in liver function tests have been reported less often. Large doses have been associated with initial increases in blood pressure and transient hyperglycaemia, although these do not persist during continued therapy.

Symptoms of overdosage include transient hypertension or profound hypotension, bradycardia, sedation, miosis, respiratory depression, convulsions, and coma. Treatment consists of general supportive measures. An alpha blocker may be given if necessary for hypertension, and atropine may be required for bradycardia and associated hypotension. Cardiac pacing may be needed rarely.

Sudden withdrawal of clonidine may produce rebound hypertension—see Precautions, below.

Effects on the gastrointestinal tract. Constipation is a relatively common adverse effect of clonidine, US licensed product information reporting an incidence of about 10%. Ileus or pseudo-obstruction of the bowel have been reported;[1-3] withdrawal of clonidine was associated with a return of bowel function to normal. Abdominal pain mimicking acute appendicitis occurred in another patient; symptoms recurred on restarting the drug and subsided on withdrawal.[4]

4. Mjörndal T, Mellbring G. Abdominal pain associated with clonidine. *BMJ* 1986; **292:** 174.

Effects on the heart. Clonidine has been associated with impaired atrioventricular conduction in a few patients,[1,2] although some of these may have had underlying conduction defects and had previously received digitalis, which may have contributed to their condition. Other ECG abnormalities may also occur. Sudden death has been reported in 3 children receiving clonidine and methylphenidate,[3,4] although the significance of these reports has been questioned.[5]

Effects on the skin. Skin reactions have been reported in up to 50% of patients using clonidine transdermal patches.[1] Localised erythema and irritation during early treatment are usually mild, but allergic contact dermatitis may develop.[2-4] Skin reactions may become commoner during prolonged treatment; although only mild skin reactions were seen in a study of transdermal clonidine during 8 to 14 weeks of treatment in 15 patients, severe skin reactions occurred after an average of 20 weeks in 4 of 5 patients who continued treatment.[5] Despite a claim that skin reactions were due to a component in the patch and not to clonidine itself,[6] positive patch tests to clonidine have been obtained.[2,4] Subsequent reaction to oral clonidine in patients who develop skin reactions to the transdermal patch is reported to be rare.[7,8]

Hypersensitivity. See Effects on the Skin, above.

Overdosage. Analysis by the UK National Poisons Information Service[1] of poisoning by clonidine in 133 children and 37 adults between 1976 and 1977 revealed that there were no deaths but clinical features were often severe. Supportive measures were usually adequate but atropine was often needed for severe and persistent bradycardia. Forced diuresis was not advised because hypotension could be enhanced and there was no evidence that excretion of clonidine was increased. More recently, death has been reported[2] in a 23-month old child.

Direct medical evaluation has been recommended[3] for children who have ingested the following amounts: 100 micrograms or more in those aged 4 years and under; more than 200 micrograms in those aged 5 to 8 years; and 400 micrograms or more in older children; 4 hours may be long enough to detect full onset of symptoms. However, others[4] believe that medical evaluation is indicated in any child who has unintentionally ingested more than a weight-appropriate therapeutic dose.

Although naloxone has been suggested as an antidote for clonidine overdose, no reversal of the hypotensive effects of clonidine 300 micrograms was noted in 6 hypertensive subjects given naloxone by intravenous infusion.[5] In a retrospective analysis of 47 children with clonidine poisoning, only 3 of 19 given naloxone showed definite improvement;[6] it was concluded that naloxone is at best an inconsistent antidote for clonidine poisoning.

Severe symptoms of overdosage have also been reported after the ingestion of clonidine transdermal patches,[7] and following probable subcutaneous injection during filling of an epidural pump reservoir.[8]

Precautions

Clonidine should be used with caution in patients with cerebrovascular disease, ischaemic heart disease including myocardial infarction, renal impairment, occlusive peripheral vascular disorders such as Raynaud's disease, or those with a history of depression.

Clonidine causes drowsiness and patients should not drive or operate machinery where loss of attention could be dangerous.

Systemic effects also occur after epidural use and patients should be closely monitored, particularly during the first few days of therapy.

Intravenous injections of clonidine should be given slowly to avoid a possible transient pressor effect especially in patients already taking other antihypertensives such as guanethidine or reserpine.

Withdrawal of clonidine therapy should be gradual as stopping suddenly may cause rebound hypertension, sometimes severe. Symptoms of increased catecholamine release such as agitation, sweating, tachycardia, headache, and nausea may also occur. Beta blockers can exacerbate the rebound hypertension and if both are being used, clonidine should not be stopped until several days after the withdrawal of the beta blocker. Patients should be warned of the risk of missing a dose or stopping the drug without consulting their doctor and should carry a reserve supply.

Although hypotension may occur during anaesthesia in clonidine-treated patients clonidine should not be withdrawn; indeed, if necessary it should be given intravenously during the operation to avoid the risk of rebound hypertension.

Abuse. Despite its central effects and ability to cause a form of physical dependence, WHO rated the likelihood of abuse as very low.[1] However, clonidine may potentiate the psychoactive effects of morphine and abuse has been reported.[2]

1. WHO. WHO expert committee on drug dependence: twenty-fifth report. *WHO Tech Rep Ser 775* 1989. Available at: http://libdoc.who.int/trs/WHO_TRS_775.pdf (accessed 19/08/08)
2. Sullivan JT, *et al.* Does clonidine alter the abuse potential of morphine? *Clin Pharmacol Ther* 1995; **57:** 163.

Diabetes mellitus. The effects of clonidine on carbohydrate metabolism appear to be variable. Some studies suggest that it does not affect carbohydrate metabolism in diabetic[1] or non-diabetic hypertensive patients,[2] although there has been a report of a diabetic patient in whom clonidine was associated with elevated fasting blood-glucose values,[3] and increased insulin requirements were noted in a diabetic child treated with clonidine for tics.[4] Conversely, clonidine was associated with severe hypoglycaemia in children when used as a provocative test for growth hormone deficiency (see Growth Retardation, below). However, a study in 10 diabetic hypertensive patients found that although clonidine impaired response to an acute glucose load, it did not significantly affect diabetic control over a 10-week period.[5] Problems may arise when clonidine is given to diabetics with autonomic neuropathy: both severe orthostatic hypotension[6] and paradoxical hypertension[7] have been reported.

For discussion of the use of clonidine in diabetic diarrhoea see below.

Porphyria. Clonidine hydrochloride has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The hypotensive effect of clonidine may be enhanced by diuretics, other antihypertensives, and drugs that cause hypotension. However, beta blockers may exacerbate rebound hypertension following clonidine withdrawal (see Precautions, above), and tricyclic antidepressants may antagonise the hypotensive effect. The sedative effect of clonidine may be enhanced by CNS depressants.

Antidepressants. Although tricyclic antidepressants commonly cause orthostatic hypotension, they may antagonise the hypotensive effects of clonidine. Blood pressure control was lost in 4 of 5 hypertensive patients taking clonidine and a diuretic when they were given *desipramine* 75 mg daily.[1] Increase in blood pressure generally occurred in the second week of treatment, but 1 patient had a dramatic rise in blood pressure within 24 hours of starting treatment. The mechanism is thought to be due to a central interaction between clonidine and the tricyclic antidepressant, although a peripheral effect cannot be completely excluded.[2] Loss of blood pressure control also occurred in a patient receiving guanfacine, another $alpha_2$-adrenoceptor agonist, when *amitriptyline* was given.[3] The reaction recurred with *imipramine*. However, in another study clonidine was given to 11 patients taking amitriptyline or imipramine, and 10 achieved good blood pressure control, although 4 developed an acute rise in blood pressure when methyldopa or guanethidine was added.[4] *Maprotiline*[5] or *mianserin*[6] do not appear to interact with clonidine.

Immunosuppressants. For a report of clonidine increasing whole blood-*ciclosporin* concentrations, see p.1827.

Pharmacokinetics

Clonidine is well absorbed from the gastrointestinal tract, and peak plasma concentrations occur about 3 to 5 hours after an oral dose. It is about 20 to 40% protein bound. About 50% of a dose is metabolised in the liver. It is excreted in the urine as unchanged drug and metabolites, 40 to 60% of an oral dose being excreted in 24 hours as unchanged drug; about 20% of a dose is excreted in the faeces, probably via enterohepatic circulation. The elimination half-life has been variously reported to range between 6 and 24 hours, extended to up to 41 hours in patients with renal impairment. Clonidine crosses the placenta and is distributed into breast milk.

It is absorbed through the skin; absorption is reported to be better from the chest or arm than from the thigh. Therapeutic plasma concentrations are achieved 2 or 3 days after application of a transdermal patch and are roughly equivalent to trough concentrations achieved after oral dosage. Therapeutic plasma concentrations are maintained for about 8 hours after removal of the delivery system and then decline slowly over several days.

Uses and Administration

Clonidine is an imidazoline antihypertensive that appears to act centrally to reduce sympathetic tone, resulting in a fall in diastolic and systolic blood pressure and a reduction in heart rate. The exact mechanism is unclear; clonidine stimulates $alpha_2$ adrenoceptors and central imidazoline receptors, but it is not known which receptors mediate which effects. It also acts peripherally, and this peripheral activity may be responsible for the transient increase in blood pressure seen during rapid intravenous injection as well as contributing to the hypotensive effect during chronic use. Peripheral resistance is reduced during continuous treatment. Cardiovascular reflexes remain intact so orthostatic hypotension is uncommon.

Clonidine is used in the management of hypertension (p.1171), including hypertensive crises, although other drugs with fewer adverse effects are now generally preferred. It may be given with a thiazide diuretic, but use with a beta blocker should be avoided where possible. Clonidine has also been used in the prophylactic treatment of migraine or recurrent vascular headaches (but see below) and in the treatment of menopausal flushing. It is used with opioids in the management of cancer pain and has been tried for various other forms of pain (below). Other uses of clonidine have included the symptomatic treatment of opioid withdrawal (see under Substance Dependence, below), the diagnosis of phaeochromocytoma (below), and as eye drops in the management of glaucoma (p.1873). It has also been tried in Tourette's syndrome (below) and numerous other disorders.

Clonidine is used as the hydrochloride. When given orally, its haemodynamic effects appear in about 30 to 60 minutes, reaching a maximum after 2 to 4 hours and lasting up to 8 hours. Tolerance to clonidine has been reported. Withdrawal of clonidine should be gradual because of the risk of rebound hypertension.

In **hypertension**, the usual initial oral dose of clonidine hydrochloride is 50 to 100 micrograms three times daily (or in the USA, 100 micrograms twice daily), increased every second or third day according to response; the usual maintenance dose is 300 to 1200 micrograms daily but doses of 1800 micrograms or more daily may sometimes be required. Modified-release preparations have been used. Clonidine may also be given by transdermal delivery systems that are applied once a week and deliver 100 to 300 micrograms of clonidine base daily at a constant rate.

Clonidine hydrochloride may be given by slow intravenous injection over 10 to 15 minutes in hypertensive crises, usually in doses of 150 to 300 micrograms. The effect usually appears within 10 minutes, but transient hypertension may precede hypotension if the injection is given too rapidly. The hypotensive effect reaches a maximum about 30 to 60 minutes after injection and the duration is about 3 to 7 hours; up to 750 micrograms may be given intravenously over 24 hours. Although oral dosage does not produce a sufficiently rapid hypotensive effect for use in an emergency situation, a dose of 100 to 200 micrograms initially followed by 50 to 100 micrograms every hour until control of blood pressure is achieved or a maximum of 500 to 800 micrograms is reached, has been recommended for the control of severe hypertension.

In the prophylaxis of **migraine** or recurrent vascular headaches and in the treatment of **menopausal flushing**, an oral dose of 50 micrograms twice daily has been used, increased, if there is no remission after 2 weeks, to 75 micrograms twice daily.

In the management of severe **cancer pain**, clonidine hydrochloride may be given by continuous epidural infusion with an opioid, in an initial dose of 30 micrograms/hour, adjusted according to response.

Anxiety disorders. Clonidine has been tried in various anxiety disorders but evidence of efficacy is limited. A review[1] of its use in panic disorder (p.952) considered that it might be useful as a last-line anxiolytic in patients unresponsive to standard treatment as occasional success had been obtained in a few patients. There have also been isolated reports of small numbers of patients with post-traumatic stress disorder (p.953) who have benefited from clonidine.[2]

For mention of clonidine as an adjuvant to sedative drugs in the intensive care unit see p.957.

Cardiac arrhythmias. Atrial fibrillation (p.1160) is managed by treatment to slow the increased ventricular responses or by cardioversion. Control of ventricular rate is usually achieved with digoxin, beta blockers, or calcium-channel blockers but clonidine, which reduces sympathetic tone and thus reduces heart rate, has also been tried.[1-3]

Diarrhoea. Some studies have shown that clonidine possesses antidiarrhoeal properties. Clonidine may stimulate $alpha_2$ adrenoceptors on enterocytes thus promoting fluid and electrolyte absorption and inhibiting anion secretion. It may also modify intestinal motility or rectal sphincter tone.

Most experience with clonidine is in diabetic diarrhoea (see Diabetic Complications, p.433). Clonidine 100 to 600 micrograms by mouth every 12 hours reduced diabetic diarrhoea in 3 patients with type 1 diabetes[1] and good results have also been reported in such patients when transdermal clonidine was used.[2,3] Benefit has also been reported in patients with symptoms of diabetic gastroparesis in addition to diarrhoea.[3,4] However, oral (but perhaps not transdermal) clonidine may worsen orthostatic hypotension in patients with diabetic diarrhoea and this may limit its usefulness.[5] Clonidine has also been tried in patients with high intestinal output after small bowel transplantation[6] or jejunostomy,[7] and in diarrhoea-predominant irritable bowel syndrome[8] or for the gastrointestinal effects of opioid withdrawal.[9]

Extrapyramidal disorders. There is limited evidence[1] from small studies that clonidine might reduce symptoms of antipsychotic-induced akathisia and tardive dyskinesia (p.971). However, adverse effects such as sedation and hypotension may limit use.

1. Ahmed I, Takeshita J. Clonidine: a critical review of its role in the treatment of psychiatric disorders. *CNS Drugs* 1996; **6:** 53–70.

Growth retardation. Clonidine has been reported to be a stimulant of growth hormone release, presumably as a result of central alpha-adrenergic stimulation, and has been tried in the diagnosis and management of growth retardation (p.1798). It may be given orally as a provocative test for growth hormone deficiency,[1,2] particularly in children,[3] although some consider measurement of circulating somatomedins (insulin-like growth factors; IGFs) to be more useful than provocative tests. A combination of both may be required to confirm diagnosis;[4] guidelines have been suggested.[5] Caution is required when performing the test in children since severe hypoglycaemia has been reported.[6] Clonidine has also been tried in the treatment of growth retardation, both in children with growth hormone deficiency and in short children without proven deficiency, but results have been contradictory and largely unsatisfactory.[7-9]

Hyperactivity. Drug treatment of attention deficit hyperactivity disorder (ADHD, p.2148) is usually begun with a central stimulant; clonidine has been tried mainly as an adjunct to stimulant therapy. A meta-analysis[1] of clonidine used to treat this disorder occurring alone or with other conditions, including tic disorders (see Tourette's Syndrome, below), concluded that clonidine may be a useful second-line treatment but is less effective than stimulants and is associated with many adverse effects. There have been reports[2] of sudden death when clonidine has been used with stimulants, but the role of the drugs in these events is unclear. A study[3] in children with both ADHD and Tourette's syndrome found that clonidine used with methylphenidate was more effective than either drug alone, and only 1 child had evidence of adverse cardiac effects. Others have since reported on the efficacy[4] and safety[5] of clonidine in ADHD, alone or with methylphenidate.

Clonidine has also been tried in the management of children with disturbed behaviour (p.954).

Menopausal disorders. Although HRT is the mainstay of treatment for menopausal disorders (p.2077) clonidine has been of some use in countering vasomotor symptoms in patients who cannot use HRT;[1,2] however, some studies have failed to show a reduction in hot flushes. The adverse effects reported in normotensive women, including orthostatic hypotension, may mean that it is best reserved for women who are also hypertensive.

Clonidine has also been tried[3] for hot flushes in women receiving tamoxifen.

Migraine. Propranolol is probably the most well established drug for prophylaxis of migraine (p.616). Many other drugs have been used, including clonidine, but a review of clinical studies[1] indicated that it was a poor first choice and seemed unlikely to work even as a last resort. It has been used in patients whose attacks may be precipitated by tyramine-containing foods.

1. Anonymous. Clonidine in migraine prophylaxis—now obsolete. *Drug Ther Bull* 1990; **28:** 79–80.

Orthostatic hypotension. Paradoxically, clonidine has produced beneficial effects in a few patients with orthostatic hypotension (p.1530), including that due to autonomic neuropathy[1] and that possibly due to brimonidine and betaxolol eye drops in a hypertensive woman with glaucoma;[2] clonidine improved both the orthostatic hypotension and the supine hypertension.

2. Brahmbhatt R, *et al.* Normalization of blood pressure in a patient with severe orthostatic hypotension and supine hypertension using clonidine. *Hypertension* 2001; **37:** e24.

Pain. Giving opioids and local anaesthetics by the epidural or intrathecal routes can produce effective analgesia but adverse effects are common. Many other drugs, including clonidine, have been tried by these routes, alone or as adjuncts. Clonidine is thought to produce analgesia by a direct action on alpha$_2$ adrenoceptors in the spinal cord. It has been used in various types of pain, such as postoperative pain (p.4), labour pain (p.7), and the pain associated with cancer (p.5), particularly neuropathic pain (p.8). It has been used alone but is more usually given with local anaesthetics and/or opioids; it has been given by various routes including epidural, intrathecal, intravenous, intramuscular, oral, and transdermal use. An early meta-analysis[1] of postoperative epidural use of clonidine was unable to reach a conclusion owing to the large number of variables. Two subsequent systematic reviews considered that addition of clonidine to intermediate-acting local anaesthetics improved their activity in certain peripheral nerve blocks,[2] and that adding clonidine to intrathecal local anaesthetics reduced intra-operative pain, although it increased the risk of hypotension.[3] However, the role and appropriate dosage of clonidine in local anaesthesia remained unclear.[2,3] For further discussion of pain and its management, see p.2. See also Premedication, below.

Phaeochromocytoma. Clonidine acts centrally to suppress catecholamine release and may be used[1] in the diagnosis of phaeochromocytoma (p.1179). Experience gained with the clonidine suppression test and a review of published studies indicated that it is of value in selected patients with moderately elevated plasma and/or urinary catecholamine concentrations.[2]

2. Lenz T, *et al.* Clonidine suppression test revisited. *Blood Pressure* 1998; **7:** 153–9.

Premedication. Clonidine has been given pre-operatively for its sedative, anxiolytic, and analgesic effects (see also Pain, above), and to provide haemodynamic stability and reduce anaesthetic requirements; it is often given orally, although other routes such as intranasal and intravenous have also been tried. It has often been tried in children,[1] in whom pre-operative use has also been reported to reduce postoperative vomiting[2] (similar results have been reported in adult women[3]). Clonidine may attenuate the perioperative stress response and has been shown to reduce perioperative oxygen consumption, which is a marker of sympathetic activation.[4] It may also reduce the risk of perioperative myocardial ischaemia.[5]

Restless legs syndrome. Numerous drugs have been tried for the treatment of restless legs syndrome (see Sleep-associated Movement Disorders, p.958). Symptomatic improvement has been reported with clonidine in a number of case studies[1,2] and small controlled trials,[3] but adverse effects may limit its use.

Shivering. Numerous drugs, including clonidine, have been tried for the treatment of postoperative shivering (p.1779). Clonidine's central and peripheral effects could both account for its antishivering activity, but some have suggested that it acts by resetting the central threshold temperature for shivering. Several studies[1-3] have suggested that clonidine is effective for the treatment of postoperative shivering. Typical doses of 75 to 150 micrograms intravenously have been used. Clonidine given intra-operatively,[4-7] including to neurosurgical patients after mild hypothermia,[8] has also been reported to reduce the incidence of postoperative shivering. However, one study[9] has found nefopam to be superior to clonidine for prevention of postoperative shivering.

Substance dependence. *ALCOHOL.* Although drug treatment of alcohol withdrawal (p.1626) is usually with a benzodiazepine, clonidine has shown benefit[1] in mild to moderate withdrawal, although it has no effect on convulsions or delirium tremens and should not be used as sole therapy. It may be considered with a benzodiazepine when opioid withdrawal is also taking place.

1. Mayo-Smith MF, *et al.* Pharmacological management of alcohol withdrawal: a meta-analysis and evidence-based practice guideline. *JAMA* 1997; **278:** 144–51.

OPIOID ANALGESICS. Clonidine has been reported to be useful in controlling withdrawal symptoms after abrupt withdrawal of opioids (p.101). However, a systematic review[1] of the use of alpha$_2$-adrenoceptor agonists, including clonidine, concluded that, for gradual withdrawal, they were no more effective than reducing doses of methadone over a period of around 10 days, and patients experienced more adverse effects and stopped treatment sooner with clonidine. Clonidine is usually given orally in three or four divided doses to a maximum of 1 mg daily.

Clonidine has also been used with naltrexone to shorten the withdrawal syndrome, allowing withdrawal to be achieved within 6 days.[2] Subsequent modification to the regimen allowed 38 of 40 patients addicted to methadone to withdraw completely in 4 to 5 days.[3] Patients required a mean of 2.3 mg of clonidine on the first day which reduced, but did not abolish, symptoms. A further modification was reported allowing opioid withdrawal with minimal drop-out over 2 to 3 days.[4]

Clonidine has also been used in the management of neonatal abstinence syndrome (p.102) in infants born to opioid-addicted mothers maintained on methadone.[5,6] Benefit occurred in 6 of 7 such infants given an initial clonidine dose of 0.5 to 1 microgram/kg orally, increased over 1 to 2 days to 3 to 5 micrograms/kg daily in divided doses. Total length of treatment ranged from 6 to 17 days. The infant who failed to respond was born to a mother also given haloperidol, desipramine, and theophylline.[6] However, a systematic review[7] found insufficient evidence to support the use of clonidine in the management of neonatal abstinence syndrome.

SMOKING. Nicotine dependence may be managed using behavioural or psychological counselling. In addition, nicotine replacement therapy (see Smoking Cessation, p.2354) can help alleviate withdrawal symptoms. A number of other drugs, including clonidine, have also been tried. A systematic review[1] found clonidine given in doses of 200 to 400 micrograms daily orally or the equivalent transdermally to be effective; however adverse effects limit its usefulness and clonidine should be reserved for second-line treatment under close medical supervision in those who experience severe agitation and anxiety when stopping smoking.

Some individual studies have found clonidine to be more effective in women although the authors of the systematic review[1] recommended that these results be interpreted cautiously since some studies also found that women were less successful in giving up smoking unaided than men; treatment with clonidine, however, resulted in similar success rates in both men and women.

1. Gourlay SG, *et al.* Clonidine for smoking cessation. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2004 (accessed 26/09/05).

Tourette's syndrome. Clonidine is one of many drugs that have been tried in the management of Tourette's syndrome (see Tics, p.954).

Disturbance of monoamine metabolism (including dopamine, noradrenaline, and serotonin) has been implicated in Tourette's syndrome. Clonidine is thought to reduce central noradrenergic activity and may also affect other neurochemical systems, and these properties may account for its beneficial effects in this disorder. Studies of clonidine in Tourette's syndrome have produced mixed results,[1-5] although this may reflect the difficulty in study design for a disease that can vary considerably in severity and presence of comorbid conditions and whose symptoms wax and wane. A retrospective study[6] in juvenile patients given clonidine suggested that those showing improvement in the attention deficit hyperactivity disorder associated with Tourette's syndrome had previously had a longer duration of vocal tics; older children had a better overall response than younger children, who tended to suffer more from clonidine-induced drowsiness. However, no predictors of response could be identified. Nevertheless, clonidine is increasingly favoured for first-line treatment in patients with mild to moderate symptoms, because of a relative lack of serious adverse effects when compared to the commonly used antipsychotics pimozide and haloperidol, although exacerbation of tics and a marked sensation of heat have been reported[7] in one patient. Clonidine has also been reported to successfully control symptoms in some children with Tourette's syndrome unresponsive to haloperidol.[1]

Clonidine has also been used with stimulants in children with Tourette's syndrome and attention deficit hyperactivity disorder, although there have been concerns about the toxicity of such combinations (see Hyperactivity, above).

Clopamide *(BAN, USAN, rINN)* ⊗

Clopamida; Clopamidum; DT-327; Klopamid; Klopamidi. 4-Chloro-*N*-(2,6-dimethylpiperidino)-3-sulphamoylbenzamide; *cis*-3-(Aminosulphonyl)-4-chloro-*N*-(2,6-dimethyl-1-piperidinyl)benzamide.

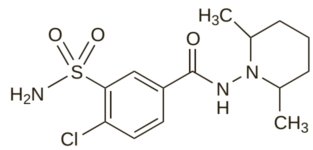
Клопамид

$C_{14}H_{20}ClN_3O_3S = 345.8$.

CAS — 636-54-4.

ATC — C03BA03.

ATC Vet — QC03BA03.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Clopamide). A white or almost white, hygroscopic, crystalline powder. It exhibits polymorphism. Slightly soluble in water and in anhydrous alcohol; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Profile

Clopamide is a diuretic with properties similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1307) even though it does not contain a thiazide ring system. It is used for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Diuresis starts in 1 to 2 hours after an oral dose, reaches a maximum in about 3 to 6 hours, and lasts for up to 24 hours.

In the treatment of oedema the usual oral dose is 10 to 20 mg daily or on alternate days. For hypertension doses of 5 to 10 mg daily, either alone, or with other antihypertensives have been used.

Clopidogrel Bisulfate *(USAN, rINNM)*

Bisulfato de clopidogrel; Clopidogrel, Bisulfate de; Clopidogrel Bisulphate *(BANM)*; Clopidogrel Hydrogen Sulphate; Clopidogreli Bisulfas; PCR-4099 (clopidogrel); SR-25990C. Methyl (*S*)-2-chlorophenyl(4,5,6,7-tetrahydrothieno[3,2-*c*]pyridin-5-yl)acetate bisulphate; Methyl (+)-(*S*)-α-(*o*-chlorophenyl)-6,7-dihydrothieno-[3,2-*c*]pyridine-5(4*H*)-acetate sulphate.

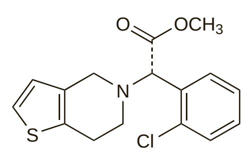
Клопидогрела Бисульфат

$C_{16}H_{16}ClNO_2S,H_2SO_4 = 419.9$.

CAS — 113665-84-2 (clopidogrel); 94188-84-8 (clopidogrel); 120202-66-6 (clopidogrel bisulfate).

ATC — B01AC04.

ATC Vet — QB01AC04.



(clopidogrel)

Pharmacopoeias. In *US.*

USP 31 (Clopidogrel Bisulfate). A white to off-white powder. Freely soluble in water and in methyl alcohol; practically insoluble in ether.

Adverse Effects and Precautions

As for Ticlopidine, p.1411.

The incidence of adverse effects, particularly blood dyscrasias, is lower with clopidogrel, although fatalities have been reported (see Effects on the Blood, p.1411). Routine blood counts are not necessary, although they should be performed promptly when clinical signs suggest blood dyscrasias. Other adverse effects, reported rarely, include serum sickness, interstitial pneumonitis, erythema multiforme, Stevens-Johnson syndrome, lichen planus, and myalgia.

Consideration should be given to stopping clopidogrel 5 to 7 days before elective surgery.

Effects on the blood. For reports of blood dyscrasias associated with clopidogrel therapy see under Adverse Effects of Ticlopidine, p.1411.

Effects on taste. Loss of taste occurred in 2 patients 6 to 8 weeks after starting treatment with clopidogrel, but recovered fully when clopidogrel was withdrawn.[1] Rechallenge in 1 of the patients led to recurrence of the taste loss, which persisted when treatment was stopped.

1. Golka K, *et al.* Reversible ageusia as an effect of clopidogrel treatment. *Lancet* 2000; **355:** 465–6.

Hypersensitivity. Clopidogrel has been associated with hypersensitivity reactions including angioedema.[1] There have also been reports[2-5] of a hypersensitivity syndrome comprising fever, rash, and varying additional symptoms.

5. Doogue MP, *et al.* Clopidogrel hypersensitivity syndrome with rash, fever, and neutropenia. *Mayo Clin Proc* 2005; **80:** 1368–70.

Resistance. Results from platelet aggregation studies suggest that there is considerable variation in response to clopidogrel, although the clinical relevance of a low response (clopidogrel resistance) is unclear.[1,2] There is some evidence that the risk of cardiovascular events is higher in patients with clopidogrel resistance,[3] but this is not established. Factors that may contribute to clopidogrel resistance include drug interactions and genetic variation in platelet sensitivity or clopidogrel metabolism.[1,2] Patients with diabetes mellitus also appear to have a lower response.[4]

4. Geisler T, *et al.* Platelet response to clopidogrel is attenuated in diabetic patients undergoing coronary stent implantation. *Diabetes Care* 2007; **30:** 372–4.

Interactions

Clopidogrel should be used with caution in patients receiving other drugs that increase the risk of bleeding, including anticoagulants, other antiplatelets, and NSAIDs. Clopidogrel may inhibit the cytochrome P450 isoenzyme CYP2C9 and interactions with drugs metabolised by this isoenzyme are theoretically possible; it may also inhibit CYP2B6 (see Bupropion, below).

Antifungals. A study[1] in healthy subjects found that *ketoconazole* decreased the plasma concentration of the active metabolite of clopidogrel; platelet inhibitory action was also reduced.

1. Farid NA, *et al.* Cytochrome P450 3A inhibition by ketoconazole affects prasugrel and clopidogrel pharmacokinetics and pharmacodynamics differently. *Clin Pharmacol Ther* 2007; **81:** 735–41.

Bupropion. A study[1] in healthy subjects found that clopidogrel reduced the conversion of bupropion to its active metabolite, suggesting that clopidogrel inhibits the cytochrome P450 isoenzyme CYP2B6.

1. Turpeinen M, *et al.* Effect of clopidogrel and ticlopidine on cytochrome P450 2B6 activity as measured by bupropion hydroxylation. *Clin Pharmacol Ther* 2005; **77:** 553–9.

Ciclosporin. For reports of rhabdomyolysis developing in patients when given clopidogrel in addition to ciclosporin and a statin, see Statins, below.

Statins. There have been reports of rhabdomyolysis developing in patients when given clopidogrel in addition to ciclosporin and a statin (atorvastatin[1,2], lovastatin[3], or simvastatin[3]). Rhabdomyolysis is a recognised adverse effect when ciclosporin and statins are used together (see Immunosuppressants under Interactions of Simvastatin, p.1393), but the patients in these reports had previously received the combination without incident and developed rhabdomyolysis 1 to 3 weeks after clopidogrel was started. It has been suggested[2] that the mechanism is a three way interaction involving competition for binding sites on the cytochrome P450 isoenzyme CYP3A4 between statins and clopidogrel, exacerbated by ciclosporin-mediated enzyme inhibition.

Although it has been suggested that statins may decrease the antiplatelet effect of clopidogrel, evidence for such an interaction is conflicting and the clinical relevance has not been established.[4]

Pharmacokinetics

Clopidogrel is rapidly but incompletely absorbed after oral doses; absorption appears to be at least 50%. It is a prodrug and is extensively metabolised in the liver, mainly to the inactive carboxylic acid derivative; metabolism is mediated by the cytochrome P450 isoenzymes CYP3A4 and CYP2B6, and to a lesser extent by CYP1A2, CYP1A1, and CYP2C19. The active metabolite appears to be a thiol derivative; it has been identified *in vitro* but appears to be too unstable to be isolated from plasma. Clopidogrel and the carboxylic acid derivative are highly protein bound. Clopidogrel and its metabolites are excreted in urine and in faeces; about 50% of an oral dose is recovered from the urine and about 46% from the faeces.

Uses and Administration

Clopidogrel is a thienopyridine antiplatelet drug used in thromboembolic disorders. It is an analogue of ticlopidine (p.1411) and acts by inhibiting adenosine diphosphate-mediated platelet aggregation. It is given prophylactically as an alternative to aspirin in patients with atherosclerosis who are at risk of thromboembolic disorders such as myocardial infarction (p.1175), peripheral arterial disease (p.1178), and stroke (p.1185). Clopidogrel is also used with aspirin in acute coronary syndromes, including acute myocardial infarction and unstable angina (p.1157), and in coronary stenting (see Reperfusion and Revascularisation Procedures, below).

Clopidogrel is given orally as the bisulfate, but doses are expressed in terms of the base; 97.86 mg of clopidogrel bisulfate is equivalent to 75 mg of base.

For the **prophylaxis of thromboembolic events**, the usual dose of clopidogrel is 75 mg once daily.

In the management of **acute ST-elevation myocardial infarction**, clopidogrel is used with aspirin as an adjunct in medically-treated patients. It is given in a dose of 75 mg once daily; patients under 75 years of age may be given a loading dose of 300 mg. Treatment should be continued for at least 4 weeks.

In the management of **unstable angina** and **non-Q-wave myocardial infarction**, clopidogrel is used with aspirin as an adjunct to either medical or interventional treatment, including coronary stenting. A single loading dose of 300 mg is given, followed by 75 mg once daily.

Administration in children. Clopidogrel is not licensed for paediatric use in either the UK or the USA, although it has been given to small numbers of patients.

A retrospective study[1] of the use of clopidogrel in 15 children aged from 6 weeks to 16 years, 14 of whom had congenital heart disease, found that it was safe and effective; nearly all of the children were also taking aspirin and/or anticoagulants, and severe bleeding was reported in only 1 of them. The usual dose ranged from 1 to 3 mg/kg once daily, although a dose of 6 mg/kg daily was tolerated when given in error to 1 patient. A cohort study[2] of the use of clopidogrel alone or with aspirin in 17 children aged 1.5 to 17 years with arterial ischaemic stroke found that a daily dose of 0.5 to 2.4 mg/kg (target dose 1 mg/kg) was well tolerated, although subdural haematomas developed in 2 patients who were also taking aspirin.

Atherosclerotic disorders. The use of aspirin to reduce the risk of cardiovascular events in patients with atherosclerotic vascular disorders is well established. Clopidogrel may have a role as an alternative. The CAPRIE trial[1] compared clopidogrel with aspirin in 19 185 patients at risk of ischaemic events, and found that clopidogrel reduced the risk of ischaemic stroke, myocardial infarction, or death from vascular causes to a greater extent than aspirin, although the absolute difference was small.

In acute coronary syndromes, clopidogrel may provide benefit when used in addition to aspirin. In patients with *unstable angina or non-ST elevation myocardial infarction*, the CURE trial[2] found that the risk of cardiovascular death, myocardial infarction, or stroke was lower in patients treated with clopidogrel and aspirin, compared with those receiving aspirin alone. Clopidogrel was given in a loading dose of 300 mg, started within 24 hours of the onset of symptoms, followed by 75 mg daily for 3 to 12 months.

Similar results have been reported in patients with acute *ST-elevation myocardial infarction*. Clopidogrel given with aspirin and thrombolytic therapy improved the patency of the affected artery and reduced the incidence of ischaemic complications at 30 days,[3] while a further study[4] found that addition of clopidogrel to aspirin and standard therapy (including thrombolytics in over half of the patients) also reduced early mortality.

Use of clopidogrel with aspirin has also been studied in *ischaemic stroke* but any benefit appears to be outweighed by an increased risk of bleeding. In the MATCH study,[5] adding aspirin to clopidogrel did not reduce the incidence of vascular events compared with clopidogrel alone, but the risk of major or life-threatening bleeding was increased. Similarly, in the CHARISMA study in patients with *stable atherosclerotic disease or multiple risk factors*, addition of clopidogrel to aspirin had no significant effect on the incidence of cardiovascular events, but the risk of moderate to severe bleeding was increased.[6]

Reperfusion and revascularisation procedures. Percutaneous coronary intervention (PCI) has an established role in the management of both acute and stable coronary disease (see p.1181). Adjunctive antiplatelet therapy is given to reduce the risk of thrombosis, both during and after the procedure; a regimen of clopidogrel with aspirin improves outcomes[1] and is now generally recommended,[2,3] particularly if coronary stents are used. Although ticlopidine with aspirin was used initially in patients receiving stents, clopidogrel appears to be as effective as ticlopidine[4,5] but has a lower risk of haematological toxicity and is now generally preferred. A randomised study (CLASSICS)[6] found that, in patients given long-term aspirin, clopidogrel in a dose of 75 mg daily for 28 days, with or without a 300-mg loading dose, was as effective as ticlopidine; it was also better tolerated.

Pretreatment with clopidogrel appears to be most effective, but the increased bleeding risk may be of concern if emergency surgery is required. Use of a 300-mg loading dose shortly before the procedure appears to be safe, but efficacy may be reduced if it is given less than 6 hours before the intervention, and there is some evidence that it needs to be given at least 15 hours before.[7] A higher dose of 600 mg may be effective if given at least 2 hours before PCI,[8,9] and has been recommended in patients undergoing PCI for non-ST elevation acute coronary syndromes.[2]

The duration of combination therapy depends on the clinical situation. For patients given bare-metal stents, clopidogrel in a dose of 75 mg daily is usually given with aspirin for 2 to 4 weeks, and aspirin is then continued indefinitely. In patients with drug-eluting stents, the risk of occlusion persists for longer and combination therapy is usually recommended for at least 3 to 6 months; there is some evidence[10-12] that extending the duration further may provide additional benefit, and treatment for 12 months or longer has been suggested.[3] Prolonged combination therapy may also be of benefit in patients undergoing PCI for unstable angina, whether or not they receive stents.[1]

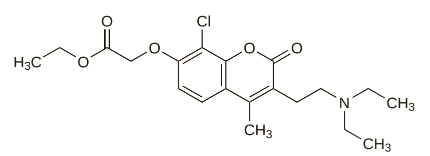
Cloricromen *(rINN)*

Cloricromène; Cloricromeno; Cloricromenum. Ethyl ({8-chloro-3-[2-(diethylamino)ethyl]-4-methyl-2-oxo-2*H*-1-benzopyran-7-yl}oxy)acetate.

Клорикромен

$C_{20}H_{26}ClNO_5$ = 395.9.
CAS — 68206-94-0.
ATC — B01AC02.
ATC Vet — QB01AC02.



Profile

Cloricromen is an antiplatelet drug with vasodilating activity and is used in thromboembolic disorders (p.1187). It is given as the hydrochloride in arterial vascular disorders where there is a risk of thrombosis. It may be given orally in a dose of 100 mg two or three times daily or intravenously in a dose of 30 mg daily.

Preparations

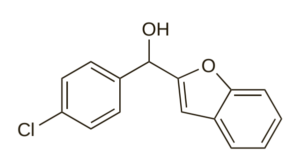
Proprietary Preparations (details are given in Part 3)
Ital.: Proendotel.

Cloridarol *(rINN)*

Clobenfurol; Cloridarolum. α-(Benzofuran-2-yl)-α-(4-chlorophenyl)methanol.

Клоридарол

$C_{15}H_{11}ClO_2$ = 258.7.
CAS — 3611-72-1.
ATC — C01DX15.
ATC Vet — QC01DX15.



Profile

Cloridarol is a vasodilator that has been used in ischaemic heart disease.

Colesevelam Hydrochloride

(USAN, rINNM)

Colésévélam, Chlorhydrate de; Colesevelami Hydrochloridum; GT31-104HB; Hidrocloruro de colesevelam. Allylamine polymer with epichlorohydrin (1-chloro-2,3-epoxypropane), [6-(allylamino)hexyl]trimethylammonium chloride and *N*-allyldecylamine, hydrochloride.

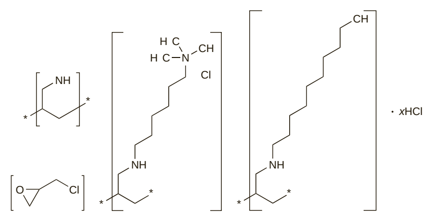
Колесевелама Гидрохлорид

$(C_3H_7N)_m(C_3H_5ClO)_n(C_{12}H_{27}ClN_2)_o(C_{13}H_{27}N)_p$,xHCl.

CAS — 182815-44-7.

ATC — C10AC04.

ATC Vet — QC10AC04.



Adverse Effects and Precautions

As for Colestyramine, p.1252.

Interactions

Colesevelam, like colestyramine (see p.1253), has the potential to interfere with the absorption of other drugs; those with a narrow therapeutic range should be given at least 1 hour before or 4 hours after colesevelam unless there is known to be no interaction.

◊ References.

1. Donovan JM, *et al.* Drug interactions with colesevelam hydrochloride, a novel, potent lipid-lowering agent. *Cardiovasc Drugs Ther* 2000; **14:** 681–90.

Uses and Administration

Colesevelam hydrochloride is a nonabsorbable hydrogel. It binds bile acids in the intestine and has actions similar to those of colestyramine (p.1253). It is used for the treatment of hypercholesterolaemia (p.1169), particularly type IIa hyperlipoproteinaemia, either alone or with a statin. It may also be used as an adjunct to improve glycaemic control in type 2 diabetes mellitus (p.431). The usual oral dose is 3.75 g daily, as a single dose or in two divided doses, with meals. When used as monotherapy for hypercholesterolaemia, the dose may be increased to 4.375 g daily if required. When used with a statin, the dose is 2.5 to 3.75 g daily.

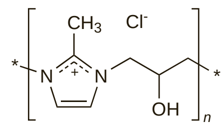
Colestilan Chloride *(USAN)*; Colestilanum; Colestimide; MCI-196. 2-Methylimidazole polymer with 1-chloro-2,3-epoxypropane.

Колестилан

$(C_4H_6N_2.C_3H_5ClO)_n$.

CAS — 95522-45-5.



Profile

Colestilan, a bile-acid binding resin, is a lipid regulating drug with similar properties to colestyramine (p.1252). It is used to reduce cholesterol in the management of hyperlipidaemias (p.1169) and is given orally in a usual dose of 1.5 g twice daily. It is also under investigation in diabetes mellitus and as a phosphate binder in haemodialysis patients.

Colestipol Hydrochloride

(BANM, USAN, rINNM)

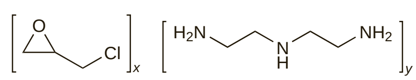
Colestipol, chlorhydrate de; Colestipoli hydrochloridum; Hidrocloruro de colestipol; Kolestipol Hidroklorür; U-26597A.

Колестипола Гидрохлорид

CAS — 26658-42-4 (colestipol); 50925-79-6 (colestipol); 37296-80-3 (colestipol hydrochloride).

ATC — C10AC02.

ATC Vet — QC10AC02.



(colestipol)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Colestipol Hydrochloride). A copolymer of diethylenetriamine and epichlorohydrin (1-chloro-2,3-epoxypropane). Each g binds not less than 1.1 mEq and not more than 1.7 mEq of sodium cholate, calculated as the cholate binding capacity and with reference to the dried substance. Yellow to orange hygroscopic beads. Swells but does not dissolve in water and in dilute solutions of acids or alkalis. Practically insoluble in alcohol and in dichloromethane. The supernatant of a 10% w/w suspension in water has a pH of 6.0 to 7.5. Store in airtight containers.

USP 31 (Colestipol Hydrochloride). A basic anion-exchange resin. It is the hydrochloride of a copolymer of diethylenetriamine and epichlorohydrin (1-chloro-2,3-epoxypropane). Each g binds not less than 1.1 mEq and not more than 1.6 mEq of sodium cholate, calculated as cholate binding capacity. Yellow to orange beads. Swells but does not dissolve in water or dilute aqueous solutions of acids or alkalis. Insoluble in common organic solvents. The supernatant of a 10% w/w suspension in water has a pH of 6.0 to 7.5. Store in airtight containers.

Adverse Effects and Precautions

As for Colestyramine, p.1252.

Effects on thyroid function. Reductions in total serum-thyroxine and thyroxine-binding globulin concentrations were found during routine monitoring of thyroid function in patients receiving colestipol and nicotinic acid, but were considered to be benign.[1] This effect has been used therapeutically in patients with hyperthyroidism (see under Uses of Colestyramine, p.1253).

1. Cashin-Hemphill L, *et al.* Alterations in serum thyroid hormonal indices with colestipol-niacin therapy. *Ann Intern Med* 1987; **107:** 324–9.

Interactions

As for Colestyramine, p.1253.

Uses and Administration

Colestipol hydrochloride is a bile-acid binding resin and lipid regulating drug with actions similar to those of colestyramine (p.1253). It is used to reduce cholesterol in the treatment of hyperlipidaemias (p.1169), particularly type IIa hyperlipoproteinaemia.

Colestipol hydrochloride is available as granules and is given orally as a suspension in water or a flavoured vehicle. The initial dose is 5 g daily or twice daily, increasing gradually at intervals of 1 to 2 months to up to 30 g daily in a single dose or two divided doses as necessary.

Colestipol hydrochloride is also available as tablets; doses range from 2 to 16 g daily.

Preparations

BP 2008: Colestipol Granules;
USP 31: Colestipol Hydrochloride for Oral Suspension; Colestipol Hydrochloride Tablets.

Colestyramine *(BAN, rINN)*

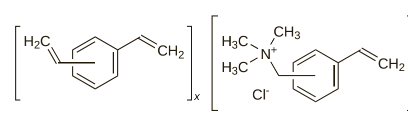
Cholestyramine; Cholestyramine Resin; Colestiramina; Colestyraminum; Divistyramine; Kolestiramin; Kolestiraminas; Kolestyramiini; Kolestyramin; Kolestyramina; MK-135.

Колестирамин

CAS — 11041-12-6.

ATC — C10AC01.

ATC Vet — QC10AC01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Colestyramine). A strongly basic anion-exchange resin in the chloride form, consisting of styrene-divinylbenzene copolymer with quaternary ammonium groups. Each g exchanges not less than 1.8 g and not more than 2.2 g of sodium glycocholate, calculated with reference to the dried material. A white or almost white, fine, hygroscopic powder. Insoluble in water, in alcohol, and in dichloromethane. A 1% suspension in water has a pH of 4.0 to 6.0 after standing for 10 minutes. Store in airtight containers.

USP 31 (Cholestyramine Resin). A strongly basic anion-exchange resin containing quaternary ammonium functional groups which are attached to a styrene-divinylbenzene copolymer. Each g exchanges not less than 1.8 g and not more than 2.2 g of sodium glycocholate, calculated on the dried basis. It is used in the chloride form. A white to buff-coloured, hygroscopic, fine powder, odourless or has not more than a slight amine-like odour. It loses not more than 12% of its weight on drying. Insoluble in water, in alcohol, in chloroform, and in ether. A 1% slurry in water has a pH of 4.0 to 6.0. Store in airtight containers.

Adverse Effects

The most common adverse effect of colestyramine is constipation; faecal impaction may develop and haemorrhoids may be aggravated. Other gastrointestinal adverse effects include abdominal discomfort or pain, heartburn, flatulence, nausea, vomiting, and diarrhoea.

Colestyramine in high doses may cause steatorrhoea by interfering with the absorption of fats from the gastrointestinal tract and therefore decreased absorption of fat-soluble vitamins, such as vitamins A, D, E, and K, may occur. Chronic use of colestyramine may thus result in an increased bleeding tendency due to hypoprothrombinaemia associated with vitamin K deficiency; it also has a potential to cause osteoporosis due to impaired calcium and vitamin D absorption.

Colestyramine is the chloride form of an anion-exchange resin and prolonged use may produce hyperchloraemic acidosis, particularly in children.

Skin rashes and pruritus of the tongue, skin, and perianal region have occasionally occurred.

◊ Reviews.

1. Jacobson TA, *et al.* Safety considerations with gastrointestinally active lipid-lowering drugs. *Am J Cardiol* 2007; **99** (Issue 6 suppl 1): 47C–55C.

Incidence of adverse effects. Results of the Lipid Research Clinics Coronary Primary Prevention Trial[1] involving 3806 men given colestyramine or placebo for an average of 7.4 years showed that gastrointestinal adverse effects occurred frequently in both groups but especially in the colestyramine group. In the first year 68% of the colestyramine group had at least 1 gastrointestinal adverse effect compared with 43% of the placebo group; by the seventh year the incidence had fallen to 29% and 26% respectively. Constipation and heartburn, especially, were more frequent in the colestyramine group, which also reported more abdominal pain, belching or bloating, gas, and nausea. These adverse effects were usually not severe and could be dealt with by standard clinical means.

The incidence of malignant neoplasms was similar in the 2 groups although there were differences in incidence at some sites. In particular, there were 21 cases of malignancy in the gastrointestinal tract (8 fatal) in the colestyramine group compared with 11 cases (1 fatal) in the placebo group. Rare cancers of the buccal cavity or pharynx were more common with colestyramine; during the study[1] there were 6 cases in the colestyramine group and none in the placebo group, and after follow-up[2] for a further 6 years and reassessment of the original diagnoses the incidences were 8 and 2, respectively. However, there was no clear dose relationship, and cigarette smoking may have been a confounder.[2] Colorectal malignancies were similar in the 2 groups, although at follow-up more non-malignant colorectal neoplasms had occurred in the colestyramine group.[2]

Precautions

Colestyramine powder should be given as a suspension in water or a flavoured vehicle to minimise the risk of oesophageal obstruction.

Colestyramine should not be used in patients with complete biliary obstruction as it is unlikely to be effective.

Because of the risk of vitamin deficiencies, supplements of vitamins A, D, E, and K should be considered during prolonged therapy with colestyramine; if given orally they need to be in a water-miscible form. Parenteral supplementation, particularly of vitamin K for hypoprothrombinaemia, may be necessary if a deficiency becomes established. Reduced serum-folate concentrations have also been reported in children with familial hypercholesterolaemia and supplementation with folic acid should be considered in such circumstances.

Interactions

Colestyramine may delay or reduce the absorption of other drugs, particularly acidic drugs. Enterohepatic circulation may be reduced. Delayed or reduced absorption of thiazide diuretics, propranolol, digoxin and related glycosides, loperamide, phenylbutazone, barbiturates, oestrogens, progestogens, thyroid hormones, warfarin, and some antibacterials, has either been reported or may be expected. It is therefore recommended that other drugs should be taken at least 1 hour before, or 4 to 6 hours after, the use of colestyramine.

Uses and Administration

Colestyramine is a bile-acid binding resin and lipid regulating drug. It is used to reduce cholesterol in the treatment of hyperlipidaemias (p.1169), particularly type IIa hyperlipoproteinaemia, and for the primary prevention of ischaemic heart disease (see Cardiovascular Risk Reduction, p.1164) in middle-aged men with primary hypercholesterolaemia. Colestyramine is also used for the relief of diarrhoea associated with ileal resection, Crohn's disease, vagotomy, diabetic vagal neuropathy, and radiation, and to relieve the pruritus associated with the deposition in dermal tissue of excess bile acids in patients with partial biliary obstruction or primary biliary cirrhosis.

Colestyramine is not absorbed from the gastrointestinal tract and binds with bile acids in the intestine to form an insoluble complex that is excreted in the faeces. The normal reabsorption of bile acids is thus prevented and this leads to an increased oxidation of cholesterol to bile acids to replace those partially removed from the enterohepatic circulation, and an increased synthesis of low-density lipoprotein (LDL)-cholesterol receptors on hepatocytes. The overall effect is a reduction of total plasma-cholesterol concentration, mainly by lowering LDL-cholesterol; this may be accompanied by moderate increases in plasma triglyceride and high-density lipoprotein (HDL)-cholesterol concentrations. Since the uses of colestyramine are based upon the removal of intestinal bile acids it is unlikely that a response will be achieved in patients with complete biliary obstruction.

Colestyramine may be introduced gradually over 3 to 4 weeks to minimise gastrointestinal effects.

In hyperlipidaemias and diarrhoea the usual oral dose is 12 to 24 g daily, given either as a single dose or in up to 4 divided doses. Dosage should be adjusted according to the patient's response and may be increased to 36 g daily if necessary. Lower doses may be adequate in some forms of hyperlipidaemia.

In pruritus doses of 4 to 8 g daily are usually sufficient.

For the use of colestyramine in children, see below.

Colestyramine should be given as a suspension in water or a flavoured vehicle.

◊ General references.

Administration in children. Colestyramine has been used in children and small studies[1,2] have found that it is effective in familial hypercholesterolaemia with no adverse effects on physical growth when taken long-term;[2] however, compliance may be a problem.[1]

For *hypercholesterolaemia*, the *BNFC* gives the usual oral dose for children aged 6 to 12 years as 4 g once daily, increased to 4 g up to 3 times daily according to response. Children aged 12 to 18 years may be given an initial dose of 4 g once daily, increased to 4 to 8 g up to 4 times daily, with a maximum daily dose of 36 g. Alternatively, licensed doses are calculated from body weight, either as a percentage of the adult (70 kg) dose, or as a dose of 240 mg/kg daily in divided doses.

For *pruritus* or *diarrhoea*, the *BNFC* recommends the following oral doses based on age:

- 1 month to 1 year: initially 1 g once daily, adjusted according to response to a maximum dose of 9 g daily in 2 to 4 divided doses
- 1 to 6 years: initially 2 g once daily, adjusted according to response to a maximum dose of 18 g daily in 2 to 4 divided doses
- 6 to 12 years: initially 4 g once daily, adjusted according to response to a maximum dose of 24 g daily in 2 to 4 divided doses
- 12 to 18 years: initially 4 to 8 g once daily, adjusted according to response to a maximum dose of 36 g daily in 2 to 4 divided doses

2. Tonstad S, *et al.* Efficacy and safety of cholestyramine therapy in peripubertal and prepubertal children with familial hypercholesterolemia. *J Pediatr* 1996; **129:** 42–9.

Antibiotic-associated colitis. Colestyramine binds *Clostridium difficile* toxins and there are a few reports of use as an alternative, or as an adjunct, to vancomycin or metronidazole in patients with diarrhoea associated with *C. difficile* toxins after antibiotic therapy (p.171). However, evidence of benefit is limited and in general its use is not recommended.

Biliary disorders. Colestyramine is used to relieve diarrhoea (p.1694) associated with bile acid malabsorption and to manage pruritus and hypercholesterolaemia in patients with primary biliary cirrhosis (p.2408). It has been used for pruritus in cholestasis of pregnancy,[1] although such use has been associated with severe fetal intracranial haemorrhage.[2] Beneficial responses have been reported with colestyramine in the management of congenital nonobstructive nonhaemolytic hyperbilirubinaemia (Crigler-Najjar disease)[3,4] and in sclerosing cholangitis.[5]

5. Polter DE, *et al.* Beneficial effect of cholestyramine in sclerosing cholangitis. *Gastroenterology* 1980; **79:** 326–33.

Diabetes mellitus. Bile acids may have a role in modulating carbohydrate metabolism and small studies have shown that bile-acid binding resins such as colestyramine reduce blood glucose.[1] Their role in type 2 diabetes mellitus (p.431) is under investigation; colesevelam (p.1252) may be used as an adjunct to standard therapy to improve glycaemic control.

1. Staels B, Kuipers F. Bile acid sequestrants and the treatment of type 2 diabetes mellitus. *Drugs* 2007; **67:** 1383–92.

Diarrhoea. In addition to its use in diarrhoea (p.1694) associated with biliary disorders (above), colestyramine has been investigated in the management of diarrhoea and faecal incontinence from other causes.[1-4] See also Antibiotic-associated Colitis, above.

Hyperthyroidism. Bile-acid binding resins also bind thyroid hormones and may interfere with their enterohepatic circulation. Reduced serum-thyroxine concentrations have occurred in patients given bile-acid binding resins for hyperlipidaemias (see Effects on Thyroid Function under Colestipol, p.1252) and both colestyramine[1,2] and colestipol[3] have been tried as adjunctive treatment for hyperthyroidism (p.2165). Colestyramine has also been used in thyroxine overdose.[4,5]

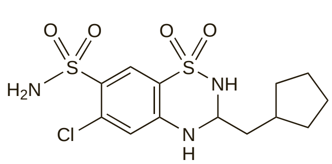
Циклопентиазид

$C_{13}H_{18}ClN_3O_4S_2$ = 379.9.
CAS — 742-20-1.
ATC — C03AA07.
ATC Vet — QC03AA07.



NOTE. Compounded preparations of cyclopenthiazide may be represented by the following names:

- Co-prenozide (*BAN*)—cyclopenthiazide 1 part and oxprenolol hydrochloride 640 parts (w/w).

Pharmacopoeias. In *Br.*
BP 2008 (Cyclopenthiazide). A white, odourless or almost odourless powder. Practically insoluble in water; soluble in alcohol and in acetone; practically insoluble in chloroform; very slightly soluble in ether.

Profile

Cyclopenthiazide is a thiazide diuretic with properties similar to those of hydrochlorothiazide (p.1307). It is given orally for hypertension (p.1171), and for oedema, including that associated with heart failure (p.1165).

Diuresis is induced in 1 to 3 hours after an oral dose, reaches a maximum in 4 to 8 hours, and lasts up to about 12 hours.

In the treatment of hypertension the usual dose is 250 to 500 micrograms daily either alone, or with other antihypertensives. In the treatment of oedema the usual initial dose is 250 to 500 micrograms daily; up to 1 mg daily may be given in heart failure but higher doses rarely achieve any further benefit. The dose should be reduced to the lowest effective dose for maintenance.

Porphyria. Cyclopenthiazide is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Preparations

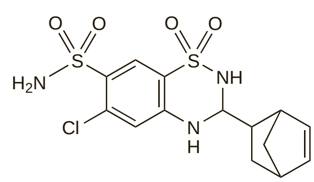
CAS — 2259-96-3.
ATC — C03AA09.
ATC Vet — QC03AA09.



Profile

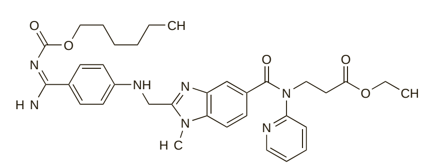
Cyclothiazide is a thiazide diuretic (see Hydrochlorothiazide, p.1307) that has been used, usually in combination preparations, in the management of hypertension and oedema.

Dabigatran Etexilate *(rINN)*

BIBR-1048; BIBR-953 (dabigatran); Dabigatran Étexilate; Dabigatrán etexilato; Dabigatranum Etexilatum. Ethyl 3-({[2-({[4-({[(hexyloxy)carbonyl]amino}iminomethyl)phenyl]amino}methyl)-1-methyl-1*H*-benzimidazol-5-yl]carbonyl}(pyridin-2-yl)amino)propanoate.

Дабигатран Этексилат

$C_{34}H_{41}N_7O_5$ = 627.7.
CAS — 211914-51-1 (dabigatran); 211915-06-9 (dabigatran etexilate).
ATC — B01AE07.
ATC Vet — QB01AE07.



Adverse Effects and Treatment

The most common adverse effect with dabigatran is bleeding. Raised liver enzyme values have been reported but are uncommon. There is no antidote to dabigatran. If haemorrhagic complications occur treatment should be stopped; surgical haemostasis or transfusion of fresh frozen plasma may be considered.

Precautions

Dabigatran should not be used in patients with clinically significant bleeding or who are at high risk for bleeding. It should be used with caution in patients with hepatic or renal impairment and is contra-indicated if creatinine clearance is less than 30 mL/minute.

Interactions

Dabigatran should not be given with other drugs that affect coagulation, such as anticoagulants, thrombolytics, or antiplatelet drugs. It should be used with caution with NSAIDs since the risk of bleeding may be increased. Dabigatran is a substrate for the efflux transporter P-glycoprotein and interactions may occur with drugs that affect P-glycoprotein function; use of dabigatran with quinidine is contra-indicated, and the dose of dabigatran should be reduced in patients receiving amiodarone (see Uses and Administration, below).

Pharmacokinetics

When given orally, dabigatran etexilate is rapidly and completely hydrolysed to its active metabolite, dabigatran, by an esterase-catalysed reaction. The absolute oral bioavailability of dabigatran when given as dabigatran etexilate is about 6.5%. Peak plasma concentrations of dabigatran occur within 0.5 to 2 hours after an oral dose. Food delays the time to peak concentrations but the bioavailability is not affected. Dabigatran has low plasma-protein binding. It is metabolised to a limited extent to active acylglucuronide conjugates; about 85% of a dose is excreted in the urine, mainly as unchanged dabigatran. The terminal plasma half-life is about 12 to 17 hours. Dabigatran is removed by dialysis.

◊ Reviews.

1. Stangier J. Clinical pharmacokinetics and pharmacodynamics of the oral direct thrombin inhibitor dabigatran etexilate. *Clin Pharmacokinet* 2008; **47:** 285–95.

Uses and Administration

Dabigatran is a direct thrombin inhibitor that is used for the prophylaxis of venous thromboembolism (p.1189) in patients undergoing elective orthopaedic surgery; it has also been investigated in other thromboembolic disorders.

Dabigatran is given orally as the mesilate of the prodrug dabigatran etexilate. The usual initial dose is the equivalent of 110 mg of dabigatran etexilate given within 1 to 4 hours of the completion of surgery, followed by 220 mg once daily; the dose should be reduced in the elderly and in patients with renal impairment (see below). Treatment should be continued for a total of 10 days after knee replacement and 28 to 35 days after hip replacement.

◊ References.

1. Stangier J, *et al.* The pharmacokinetics, pharmacodynamics and tolerability of dabigatran etexilate, a new oral direct thrombin inhibitor, in healthy male subjects. *Br J Clin Pharmacol* 2007; **64:** 292–303.
2. Eriksson BI, *et al.* Oral dabigatran etexilate vs. subcutaneous enoxaparin for the prevention of venous thromboembolism after total knee replacement: the RE-MODEL randomized trial. *J Thromb Haemost* 2007; **5:** 2178–85.
3. Eriksson BI, *et al.* RE-NOVATE Study Group. Dabigatran etexilate versus enoxaparin for prevention of venous thromboembolism after total hip replacement: a randomised, double-blind, non-inferiority trial. *Lancet* 2007; **370:** 949–56.
4. Ezekowitz MD, *et al.* Dabigatran with or without concomitant aspirin compared with warfarin alone in patients with nonvalvular atrial fibrillation (PETRO Study). *Am J Cardiol* 2007; **100:** 1419–26.
5. Sanford M, Plosker GL. Dabigatran etexilate. *Drugs* 2008; **68:** 1699–1709.

Administration in the elderly. There is limited clinical experience with dabigatran in patients over the age of 75 years but plasma concentrations appear to be higher in older subjects[1] and dose reduction is recommended. UK licensed product information recommends an initial dose of 75 mg of dabigatran etexilate (as the mesilate) given within 1 to 4 hours of the completion of surgery, followed by 150 mg once daily for a total of 10 days after knee replacement and 28 to 35 days after hip replacement.

1. Stangier J, *et al.* Pharmacokinetics and pharmacodynamics of the direct oral thrombin inhibitor dabigatran in healthy elderly subjects. *Clin Pharmacokinet* 2008; **47:** 47–59.

Administration in renal impairment. Dabigatran is excreted mainly by the kidneys but there is limited clinical experience with its use in renal impairment. It is contra-indicated in patients with creatinine clearance (CC) below 30 mL/minute. In patients with CC between 30 and 50 mL/minute the initial dose should be the equivalent of 75 mg of dabigatran etexilate given within 1 to 4 hours of the completion of surgery, followed by 150 mg once daily for a total of 10 days after knee replacement and 28 to 35 days after hip replacement.

Dalteparin Sodium *(BAN, USAN, rINN)*

Daltepariininatrium; Dalteparin sodná sůl; Dalteparin Sodyum; Dalteparina sódica; Daltéparine sodique; Dalteparinnatrium; Dalteparin-nátrium; Dalteparino natrio druska; Dalteparinum natricum; Dalteparyna sodowa; Kabi-2165; Tedelparin Sodium.

Дальтепарин Натрий

CAS — 9041-08-1.

ATC — B01AB04.

ATC Vet — QB01AB04.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dalteparin Sodium). The sodium salt of a low-molecular-mass heparin that is obtained by nitrous acid depolymerisation of heparin from porcine intestinal mucosa. The majority of the components have a 2-*O*-sulfo-α-L-idopyranosuronic acid structure at the non-reducing end and a 6-*O*-sulfo-2,5-anhydro-D-mannitol structure at the reducing end of their chain. The mass-average relative molecular mass ranges between 5600 and 6400, with a characteristic value of about 6000. The mass percentage of chains lower than 3000 is not more than 13.0% and the mass percentage of chains higher than 8000 ranges between 15.0% and 25.0%. The degree of sulfation is 2.0 to 2.5 per disaccharide unit.

The potency is not less than 110 units and not more than 210 units of anti-factor Xa activity per mg with reference to the dried substance, and the ratio of anti-factor Xa activity to anti-factor IIa activity is between 1.9 and 3.2.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329.

Severe bleeding with dalteparin may be reduced by the slow intravenous injection of protamine sulfate; 1 mg of protamine sulfate is stated to inhibit the effects of 100 units of dalteparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Dalteparin is almost completely absorbed after subcutaneous doses, with a bioavailability of about 87%. Peak plasma activity is reached in about 4 hours. The terminal half-life is about 2 hours after intravenous injection and 3 to 5 hours after subcutaneous injection. Dalteparin is excreted via the kidneys and the half-life is prolonged in patients with renal impairment.

Uses and Administration

Dalteparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant properties. It is used in the treatment and prophylaxis of venous thromboembolism (p.1189) and to prevent clotting during extracorporeal circulation. It is also used in the management of unstable angina (p.1157).

Dalteparin is given by subcutaneous or intravenous injection. Doses are expressed in terms of units of anti-factor Xa activity.

For *prophylaxis* of **venous thromboembolism** during surgical procedures, dalteparin is usually started preoperatively.

- For patients at moderate risk of thrombosis 2500 units of dalteparin sodium are given by subcutaneous injection 1 to 2 hours before the procedure, followed by 2500 units once daily for 5 to 7 days or until the patient is fully ambulant.
- For patients at high risk, such as those undergoing orthopaedic surgery, 2500 units are given 1 to 2 hours before and 8 to 12 hours after the procedure followed by 5000 units daily. Alternatively, 5000 units may be given the evening before surgery followed by 5000 units each subsequent evening. This dosage may be continued for up to 5 weeks after hip replacement surgery.
- A further option in patients undergoing hip replacement surgery is to omit the pre-operative dose; treatment is begun with a dose of 2500 units given 4 to 8 hours postoperatively followed by 5000 units daily.
- For prophylaxis in medical patients, a dose of 5000 units once daily may be given for 14 days or longer.

In the *treatment* of established deep-vein thrombosis, pulmonary embolism, or both, dalteparin sodium is given subcutaneously in a dose of 200 units/kg daily. This may be given as a single dose or, in patients at higher risk of bleeding complications, in two divided doses. The maximum recommended dose is 18 000 units daily. Patients with symptomatic venous thromboembolism and cancer may be given 200 units/kg subcutaneously once daily for 30 days, followed by 150 units/kg once daily for up to 5 months.

For prevention of clotting in the extracorporeal circulation during **haemodialysis** or **haemofiltration** in adults with chronic renal impairment an intravenous injection of dalteparin sodium 30 to 40 units/kg is followed by an intravenous infusion of 10 to 15 units/kg per hour. A single injection of 5000 units may be given for a haemodialysis or haemofiltration session lasting less than 4 hours. The dose of dalteparin sodium should be reduced in patients at high risk of bleeding complications or who are in acute renal failure; in such patients an intravenous injection of 5 to 10 units/kg is followed by an infusion of 4 to 5 units/kg per hour.

In the management of **unstable angina**, dalteparin sodium is given subcutaneously in a dose of 120 units/kg every 12 hours; the maximum dose is 10 000 units every 12 hours. Treatment is continued for 5 to 8 days and low-dose aspirin should also be given. For patients who require treatment for longer than 8 days while awaiting a revascularisation procedure, a dose of 5000 units (7500 units in men weighing 70 kg or over and women weighing 80 kg or over) may be given every 12 hours for up to 45 days until the procedure is performed.

Danaparoid Sodium *(BAN, USAN, rINN)*

Danaparoid sodná sůl; Danaparoid sodowy; Danaparoide sódico; Danaparoïde sodique; Danaparoidum natricum; Lomoparan; Org-10172.

Данапароид Натрий

CAS — 83513-48-8.

ATC — B01AB09.

ATC Vet — QB01AB09.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Danaparoid Sodium). A preparation containing the sodium salts of a mixture of sulfated glycosaminoglycans present in porcine tissues. It is prepared from the intestinal mucosa of pigs and the major constituents are suleparoid (heparan sulfate) (p.1406) and dermatan sulfate (p.1256). It has a potency of 11.0 to 17.0 anti-factor Xa units per milligram, calculated with reference to the dried substance. A white or almost white, hygroscopic powder. Freely soluble in water. A 1% solution in water has a pH of 5.5 to 7.0. Store in airtight containers.

Adverse Effects and Treatment

Haemorrhage may occur after use of danaparoid sodium, although there is a possible decreased risk of bleeding complications compared with heparin. Liver enzymes may be transiently elevated. Other adverse effects include hypersensitivity reactions, thrombocytopenia, and pain at the site of injection.

Protamine sulfate only partially neutralises the anticoagulant effect of danaparoid sodium and cannot be relied on to reverse bleeding associated with overdosage.

Precautions

As for Heparin, p.1303.

Danaparoid sodium should not be given to patients who have developed thrombocytopenia with heparin if they show cross-reactivity in an *in-vitro* test.

Pharmacokinetics

After subcutaneous dosage danaparoid sodium is well absorbed and peak anti-factor Xa activity is reached in about 4 to 5 hours. The elimination half-lives of anti-factor Xa and anti-factor IIa (antithrombin) activities are about 25 and 7 hours, respectively. Danaparoid sodium is excreted in the urine.

Uses and Administration

Danaparoid sodium is a low-molecular-weight heparinoid. It is an anticoagulant and, like heparin (p.1303), enhances the action of antithrombin III. Like low-molecular-weight heparins (p.1329) it has a higher ratio of anti-factor Xa to anti-factor IIa (antithrombin) activity than heparin, but is reported to be a much more selective inhibitor of factor Xa than the low-molecular-weight heparins. It was therefore hoped that danaparoid might be associated with a low incidence of bleeding complications, although this has not been established.

Danaparoid sodium is used in the prophylaxis of venous thromboembolism (p.1189) in patients undergoing surgery. It may be used as an anticoagulant for prophylaxis or treatment in patients with heparin-induced thrombocytopenia providing there is no cross-reactivity. Danaparoid has been investigated in acute ischaemic stroke.

Doses of danaparoid sodium are expressed in terms of units of anti-factor Xa activity. In the prophylaxis of venous thromboembolism it is given by subcutaneous injection in a dose of 750 units twice daily for 7 to 10 days. The first dose should be given 1 to 4 hours before surgery.

For patients with heparin-induced thrombocytopenia requiring anticoagulation, danaparoid sodium is given intravenously. The initial bolus dose is 2500 units (or 1250 units for patients weighing less than 55 kg, or 3750 units for patients weighing more than 90 kg) followed by an infusion of 400 units/hour for 2 hours, then 300 units/hour for 2 hours, then 200 units/hour for 5 days. Monitoring of plasma anti-factor Xa activity is recommended for patients with renal impairment, or those weighing more than 90 kg.

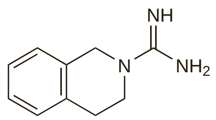
ATC — C02CC04.

ATC Vet — QC02CC04.



(debrisoquine)

Pharmacopoeias. In *Br.*

BP 2008 (Debrisoquine Sulphate). A white, odourless or almost odourless, crystalline powder. Sparingly soluble in water; very slightly soluble in alcohol; practically insoluble in chloroform and in ether. A 3% solution in water has a pH of 5.3 to 6.8. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Guanethidine Monosulfate, p.1300.

Diarrhoea is rare with debrisoquine sulfate. Treatment should not be stopped abruptly as this may lead to rebound hypertension.

The metabolism of debrisoquine is subject to genetic polymorphism and non-metabolisers may show a marked response to doses that have little or no effect in metabolisers.

Interactions

As for Guanethidine Monosulfate, p.1300.

Pharmacokinetics

Debrisoquine is rapidly absorbed from the gastrointestinal tract. The major metabolite is 4-hydroxydebrisoquine; metabolism is subject to genetic polymorphism.

◊ A study[1] in 15 hypertensive patients and 4 healthy subjects indicated that debrisoquine undergoes pre-systemic metabolism to 4-hydroxydebrisoquine, but the mechanism appears to be saturable and increases in the dose of debrisoquine could therefore produce disproportionate decreases in blood pressure. The estimated half-life of elimination for debrisoquine and 4-hydroxydebrisoquine ranged from 11.5 to 26 hours and from 5.8 to 14.5 hours respectively.

1. Silas JH, *et al*. The disposition of debrisoquine in hypertensive patients. *Br J Clin Pharmacol* 1978; **5:** 27–34.

Genetic polymorphism. Debrisoquine, along with sparteine and a number of other drugs, is a substrate for the cytochrome P450 isoenzyme CYP2D6, a polymorphic enzyme coded by a gene mapped to chromosome 22. Patients homozygous for the mutant allele are termed *poor metabolisers* and express little or no active enzyme. The prevalence of the poor-metaboliser phenotype is about 5% in most Caucasian populations, while studies in other genetic groups have indicated a range of about 2 to 10% although in some groups, such as the Japanese, poor metabolisers have yet to be identified. Poor metabolisers of debrisoquine are unable to 4-hydroxylate the drug adequately to its inactive metabolite and are thus prone to excessive hypotension. Many other drugs are metabolised by the same enzyme, but the clinical consequences of polymorphism in patients taking them depends on the relative activity and toxicity of parent drug and metabolite, and the availability and relative importance of other routes of metabolism. Phenotype has been determined by giving a drug that is metabolised by this enzyme and assaying parent drug and metabolite in urine collected over a defined period of time, but DNA-based tests may represent a more convenient and safer alternative.

2. Zanger UM, *et al*. Cytochrome P450 2D6: overview and update on pharmacology, genetics, biochemistry. *Naunyn Schmiedebergs Arch Pharmacol* 2004; **369:** 23–37.

Uses and Administration

Debrisoquine is an antihypertensive with actions and uses similar to those of guanethidine (p.1300), but it causes less depletion of noradrenaline stores. When given orally, debrisoquine acts within about 4 to 10 hours and has effects lasting for 9 to 24 hours. It has been used in the management of hypertension (p.1171), but has largely been superseded by other drugs.

For reference to the use of debrisoquine in identifying metabolic phenotypes, see Genetic Polymorphism, above.

Defibrotide *(BAN, rINN)*

Defibrotida; Défibrotide; Defibrotidum.

Дефибротид

CAS — 83712-60-1.

ATC — B01AX01.

ATC Vet — QB01AX01.

Profile

Defibrotide consists of polydeoxyribonucleotides from bovine lung; the molecular weights range between 45 000 and 55 000. Preparations derived from porcine tissues and with a lower molecular weight range are also used. Defibrotide has antithrombotic and fibrinolytic properties, although its mechanism of action is uncertain; it appears to increase levels of prostaglandin E_2 and prostacyclin, to alter platelet activity, and to increase tissue plasminogen activator function at the same time as decreasing activity of tissue plasminogen activator inhibitor. It is used in the management of thromboembolic disorders. Oral and parenteral formulations have been used in doses of up to 800 mg daily.

Defibrotide is being investigated for use in the treatment of hepatic veno-occlusive disease and thrombotic thrombocytopenic purpura.

Dermatan Sulfate Sodium

Chondroitin Sulfate B Sodium; Dermatan Sulphate Sodium.

CAS — 54328-33-5.

ATC — B01AX04.

ATC Vet — QB01AX04.

Profile

Dermatan sulfate is a naturally occurring glycosaminoglycan used as an anticoagulant for prophylaxis of venous thromboembolism (p.1189). It is given as the sodium salt in a dose of 100 to 300 mg daily by intramuscular injection. The dose may be increased to 300 mg twice daily in patients at high risk of thromboembolism, such as those undergoing major orthopaedic surgery.

Dermatan sulfate is a component of sulodexide (p.1406) and its sodium salt is a component of danaparoid sodium (p.1255).

Dermatan sulfate has been investigated for the treatment of venous thromboembolism, heparin-induced thrombocytopenia, and to prevent clotting during haemodialysis. Low-molecular-weight (depolymerised) dermatan sulfate has also been studied.

CAS — 120993-53-5.

ATC — B01AE01.

ATC Vet — QB01AE01.

Adverse Effects and Precautions

As for Lepirudin, p.1323.

Teratogenicity has been observed in *animals*.

Interactions

As for Lepirudin, p.1323.

Pharmacokinetics

Maximum plasma concentrations of desirudin are reached 1 to 3 hours after subcutaneous injection. Desirudin is metabolised and excreted by the kidney, and 40 to 50% of a dose is excreted unchanged in the urine. After subcutaneous or intravenous injection the terminal elimination half-life of desirudin is 2 to 3 hours.

◊ References.

1. Lefèvre G, *et al.* Effect of renal impairment on the pharmacokinetics and pharmacodynamics of desirudin. *Clin Pharmacol Ther* 1997; **62:** 50–9.

Uses and Administration

Desirudin is a recombinant hirudin (p.1305) that is a direct inhibitor of thrombin with actions similar to Lepirudin, p.1323. It is used as an anticoagulant for the prevention of postoperative venous thromboembolism (p.1189) in patients undergoing orthopaedic surgery. It has been investigated in arterial thromboembolic disorders such as myocardial infarction and unstable angina, and as an adjunct in angioplasty procedures (see Ischaemic Heart Disease, under Uses and Administration of Lepirudin, p.1323).

In the prevention of venous thromboembolism, desirudin is given subcutaneously in a dose of 15 mg twice daily, the first dose 5 to 15 minutes before surgery, but after induction of regional block anaesthesia, if used. Treatment is continued until the patient is fully ambulant, usually for 9 to a maximum of 12 days.

Response to desirudin should be monitored using activated partial thromboplastin time (APTT) in patients with hepatic or renal impairment, or increased risk of bleeding. Doses may need to be reduced in patients with renal impairment (see below).

◊ References.

1. Matheson AJ, Goa KL. Desirudin: a review of its use in the management of thrombotic disorders. *Drugs* 2000; **60:** 679–700.

Administration in renal impairment. The dose of desirudin should be reduced in patients with renal impairment, depending on creatinine clearance (CC) and activated partial thromboplastin time (APPT), which should be measured daily. US licensed product information recommends the following doses:

- CC 31 to 60 mL/minute per 1.73 m^2, initial dose 5 mg every 12 hours, subsequently adjusted according to APPT
- CC below 31 mL/minute per 1.73 m^2, initial dose 1.7 mg every 12 hours, subsequently adjusted according to APPT

Preparations

Proprietary Preparations (details are given in Part 3)

Deslanoside (BAN, rINN)

Deacetyl-lanatoside C; Desacetyl-lanatoside C; Deslanosid; Deslanosídeo; Deslanosidi; Deslanósido; Deslanosidum; Deslanozidas; Dezlanozid. 3-[(*O*-β-D-Glucopyranosyl-(1→4)-*O*-2,6-dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-*O*-2,6-dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-*O*-2,6-dideoxy-β-D-*ribo*-hexopyranosyl)-oxy]-12,14-dihydroxy-3β,5β,12β-card-20(22)-enolide.

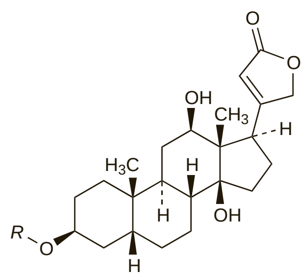
Дезланозид

$C_{47}H_{74}O_{19}$ = 943.1.

CAS — 17598-65-1.

ATC — C01AA07.

ATC Vet — QC01AA07.



R = β-D-glucose–(β-D-digitoxose)$_3$

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Deslanoside). A white or almost white, crystalline or finely crystalline hygroscopic powder. Practically insoluble in water; very slightly soluble in alcohol. In an atmosphere of low relative humidity, it loses water. Store in airtight, glass containers at a temperature below 10°. Protect from light.

USP 31 (Deslanoside). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Deslanoside, a cardiac glycoside with positive inotropic activity, is a derivative of lanatoside C. It has the general properties of digoxin (p.1259) and has been used similarly in the management of some cardiac arrhythmias and in heart failure.

Preparations

USP 31: Deslanoside Injection.

Proprietary Preparations (details are given in Part 3)

Braz.: Cedilanide.

Detajmium Bitartrate (rINN)

Bitartrato de detajmio; Detajmii Bitartras; Détajmium, Bitartrate de. 4-[3-(Diethylamino)-2-hydroxypropyl]ajmalinium hydrogen tartrate monohydrate.

Детаймия Битартрат

$C_{31}H_{47}N_3O_9,H_2O$ = 623.7.

CAS — 53862-81-0.

Profile

Detajmium is a class I antiarrhythmic (p.1153). It is given orally as the bitartrate, in the treatment of supraventricular and ventricular arrhythmias (p.1160). The dose range is from 75 to 300 mg daily depending upon the arrhythmia.

Preparations

Proprietary Preparations (details are given in Part 3)

Cz.: Tachmalcor; ***Ger.:*** Tachmalcor.

Diazoxide (BAN, USAN, rINN)

Diatsoksidi; Diazoksidas; Diazoksit; Diazoxid; Diazóxido; Diazoxidum; NSC-64198; Sch-6783; SRG-95213. 7-Chloro-3-methyl-2*H*-1,2,4-benzothiadiazine 1,1-dioxide.

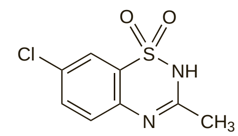
Диазоксид

$C_8H_7ClN_2O_2S$ = 230.7.

CAS — 364-98-7.

ATC — C02DA01; V03AH01.

ATC Vet — QC02DA01; QV03AH01.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Diazoxide). A white or almost white, fine or crystalline powder. Practically insoluble in water; slightly soluble in alcohol; freely soluble in dimethylformamide; very soluble in dilute solutions of alkali hydroxides.

USP 31 (Diazoxide). White or cream-white crystals or crystalline powder. Practically insoluble to sparingly soluble in water and in most organic solvents; freely soluble in dimethylformamide; very soluble in strong alkaline solutions. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects

In addition to inappropriate hypotension and hyperglycaemia (which includes ketoacidosis and hyperosmolar nonketotic coma), adverse effects often include oedema due to salt and water retention, which may precipitate heart failure. Other adverse effects include: dysgeusia, nausea, anorexia, and other gastrointestinal disturbances; mild hyperuricaemia; extrapyramidal symptoms; eosinophilia and thrombocytopenia; dyspnoea; hypertrichosis; and headache, dizziness, tinnitus, and blurred vision. Hypersensitivity has occurred, manifesting as rashes, leucopenia, and fever.

During intravenous therapy, particularly after large bolus injections, adverse effects may be associated with too rapid a reduction in blood pressure and include: coronary ischaemia leading to angina, cardiac arrhythmias, marked ECG changes, tachycardia, palpitations, and bradycardia; cerebral ischaemia leading to confusion, convulsions, loss of consciousness, and neurological deficit; renal impairment; and symptoms of vasodilatation.

Diazoxide may cause a burning sensation in the injected vein; extravasation of the alkaline solution is painful.

Effects on the blood. A 26-year-old man with hypertension developed reversible haemolytic anaemia when treated with diazoxide orally on 3 separate occasions.[1]

1. Best RA, Clink HM. Haemolysis associated with diazoxide, used for the control of hypertension. *Postgrad Med J* 1975; **51:** 402–4.

Effects on the hair. *Hirsutism* and *hypertrichosis* are different types of excessive hair growth, but the terms have often been used interchangeably. Hirsutism is androgen-related whereas hypertrichosis is thought to be independent of hormone stimulation. Hypertrichosis is acknowledged to be a frequent adverse effect of diazoxide in children receiving long-term treatment for idiopathic hypoglycaemia.[1] Two such children had unusually deep (low-pitched) voices as well as marked hypertrichosis.[2] A woman on continuous diazoxide therapy who developed so-called hirsutism without signs of virilisation had raised serum concentrations of androgens.[3]

Alopecia has been reported[4] in 4 infants born to mothers who had been on long-term treatment with diazoxide during pregnancy; the condition was still present to some extent when the infants were last observed at the ages of 5 months to 1 year.

1. Burton JL, *et al.* Hypertrichosis due to diazoxide. *Br J Dermatol* 1975; **93:** 707–11.
2. West RJ. Side effects of diazoxide. *BMJ* 1978; **2:** 506.
3. Hallengren B, Hökfelt B. Increase of serum androgens during diazoxide treatment. *Lancet* 1984; **ii:** 1044–5.
4. Milner RDG, Chouksey SK. Effects of fetal exposure to diazoxide in man. *Arch Dis Child* 1972; **47:** 537–43.

Extrapyramidal effects. In a study[1] of 100 hypertensive patients receiving diazoxide, the incidence of extrapyramidal symptoms was 15%.

1. Pohl JEF. Development and management of extrapyramidal symptoms in hypertensive patients treated with diazoxide. *Am Heart J* 1975; **89:** 401–2.

Pancreatitis. Ten patients with severe hypertension and renal failure were treated with diazoxide in a last attempt to avert nephrectomy; 1 patient developed acute pancreatitis and another diabetic ketoacidosis.[1] Both patients recovered from these effects when diazoxide was withdrawn.

1. De Broe M, *et al*. Oral diazoxide for malignant hypertension. *Lancet* 1972; **i:** 1397.

Voice changes. See Effects on the Hair, above.

Treatment of Adverse Effects

Treatment is largely symptomatic. Severe hyperglycaemia may be corrected by giving insulin: less severe hyperglycaemia may respond to oral hypoglycaemics. Hypotension may be managed with intravenous fluids. Severe hypotension may require sympathomimetics. Antiparkinsonian drugs, such as procyclidine, have been given to control extrapyramidal effects while a diuretic may be required for salt and water retention. Diazoxide can be removed from the body by dialysis but recovery is relatively low owing to extensive protein binding.

Precautions

Diazoxide should be used with care in patients with impaired cardiac or cerebral circulation and in patients with aortic coarctation, arteriovenous shunt, heart failure, or other cardiac disorders in which an increase in cardiac output could be detrimental. During prolonged therapy blood-glucose concentrations and blood pressure should be monitored and the blood should be examined regularly for signs of leucopenia and thrombocytopenia; in children, bone and psychological maturation, and growth, should be regularly assessed. Caution is necessary in patients with renal impairment.

If given during labour, diazoxide may cause cessation of uterine contractions and delay delivery unless oxytocin is also given.

Pregnancy. Transplacental transfer of diazoxide was considered[1] to be responsible for an inappropriately low plasma-insulin concentration in an infant whose mother had received a dose of 150 mg daily for 47 days prior to delivery. For reference to alopecia in neonates whose mothers had received diazoxide during pregnancy, see Effects on the Hair under Adverse Effects, above.

For reports of sedation, hypotonia, or apnoea among infants born to mothers given both diazoxide and clomethiazole for the treatment of toxaemia of pregnancy, see Precautions, Pregnancy, in Clomethiazole Edisilate, p.978. Diazoxide is nonetheless one of the drugs that has been used for hypertensive emergencies in pregnancy (see Hypertension, p.1171) and a study found that mini-boluses of diazoxide 15 mg intravenously successfully reduced blood pressure and were well tolerated.[2]

1. Smith MJ, *et al*. Neonatal hyperglycaemia after prolonged maternal treatment with diazoxide. *BMJ* 1982; **284:** 1234.
2. Hennessy A, *et al*. A randomised comparison of hydralazine and mini-bolus diazoxide for hypertensive emergencies in pregnancy: the PIVOT trial. *Aust N Z J Obstet Gynaecol* 2007; **47:** 279–85.

Interactions

The hyperglycaemic, hyperuricaemic, and hypotensive actions of diazoxide may be enhanced by diuretics. Use of diazoxide with other antihypertensives or vasodilators may lead to increased risk of hypotension.

Chlorpromazine. Chlorpromazine was reported[1] to enhance the hyperglycaemic effect of diazoxide in a 2-year-old child.

1. Aynsley-Green A, Illig R. Enhancement by chlorpromazine of hyperglycaemic action of diazoxide. *Lancet* 1975; **ii:** 658–9.

Phenytoin. For the effect of diazoxide on serum-phenytoin concentrations, see Antihypertensives, p.499.

Pharmacokinetics

Diazoxide is readily absorbed from the gastrointestinal tract and more than 90% bound to plasma proteins, although protein binding is decreased in uraemic patients. Its plasma half-life has been estimated to range from about 20 to 45 hours but values of up to 60 hours have been reported. The half-life is reported to be prolonged in renal impairment and shorter for children. The plasma half-life greatly exceeds the duration of vascular activity. Diazoxide is partly metabolised in the liver and is excreted in the urine both unchanged and in the form of metabolites; only small amounts are recovered from the faeces. It crosses the placenta and the blood-brain barrier.

Children. In 4 children with hypoglycaemia the plasma half-life of diazoxide was 9.5 to 24 hours, which is considerably shorter than that in adults.[1]

1. Pruitt AW, *et al*. Disposition of diazoxide in children. *Clin Pharmacol Ther* 1973; **14:** 73–82.

Uses and Administration

Diazoxide increases the concentration of glucose in the plasma; it inhibits the secretion of insulin by the beta cells of the pancreas, and may increase the hepatic output of glucose. When given intravenously, it produces a fall in blood pressure by a vasodilator effect on the arterioles and a reduction in peripheral resistance. Diazoxide is closely related structurally to the thiazide diuretics, but has an antidiuretic action and thus produces fluid and electrolyte retention; it may be given with a diuretic to reduce fluid retention.

Diazoxide is used orally in the management of intractable hypoglycaemia (p.1447) and intravenously in the management of hypertensive crises (p.1171), particularly when first-line drugs such as sodium nitroprusside are ineffective or unsuitable. Diazoxide is not suitable for the chronic treatment of hypertension because of its severe adverse effects.

In **hypoglycaemia**, the initial dose is 3 to 5 mg/kg daily in 2 or 3 divided oral doses, then adjusted according to response. Usual maintenance doses are from 3 to 8 mg/kg daily but total doses of up to 1 g daily have been given to adults with insulinomas (see Carcinoid Tumours and other Secretory Neoplasms, p.643). In neonates the initial dose is 5 mg/kg twice daily; usual maintenance doses range from 3 to 9 mg/kg daily, although up to 21 mg/kg daily may be required. In children from 1 month of age, the initial dose is 1.7 mg/kg three times daily, and the usual maintenance doses are as for neonates; up to 15 mg/kg daily may be required. The hyperglycaemic effect normally begins within 1 hour of a dose and lasts for up to 8 hours. The doses for neonates and children may be given intravenously if necessary.

In **hypertensive crises**, a bolus intravenous injection of 1 to 3 mg/kg is given within 30 seconds, up to a maximum dose of 150 mg, and repeated after 5 to 15 minutes if required.

Reduced doses may be necessary in patients with renal impairment.

Preparations

BP 2008: Diazoxide Injection; Diazoxide Tablets;
USP 31: Diazoxide Capsules; Diazoxide Injection; Diazoxide Oral Suspension.

Proprietary Preparations (details are given in Part 3)

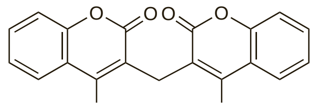
Dicoumarol *(rINN)*

Bishydroxycoumarin; Dicoumarin; Dicoumarolum; Dicumarol *(USAN)*; Dikumarol; Dikumaroli; Melitoxin. 3,3′-Methylenebis(4-hydroxycoumarin).

Дикумарол

$C_{19}H_{12}O_6$ = 336.3.
CAS — 66-76-2.
ATC — B01AA01.
ATC Vet — QB01AA01.



Pharmacopoeias. In *Int.*

Adverse Effects, Treatment, and Precautions

As for Warfarin Sodium, p.1425, although gastrointestinal adverse effects are reported to occur more frequently. The absorption of dicoumarol is affected by food.

Breast feeding. No adverse effects have been seen in breast-feeding infants whose mothers were receiving dicoumarol, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 06/07/04)

Interactions

The interactions associated with oral anticoagulants are discussed in detail under warfarin (p.1427). Specific references to interactions involving dicoumarol can be found under the headings for the following drug groups: analgesics; antiarrhythmics; antibacterials; antidepressants; antidiabetics; antiepileptics; antigout drugs; anxiolytic sedatives; gastrointestinal drugs; lipid regulating drugs; sex hormones; and vitamins.

Pharmacokinetics

Dicoumarol is slowly and erratically absorbed from the gastrointestinal tract and is extensively bound to plasma proteins. It is metabolised in the liver and is excreted in the urine, mainly as metabolites.

Uses and Administration

Dicoumarol is an oral coumarin anticoagulant with actions similar to those of warfarin (p.1432). It has been used in the management of thromboembolic disorders (p.1187). The usual daily maintenance dose, adjusted according to coagulation tests, is 25 to 200 mg.

Because of its unpredictability of response and high incidence of gastrointestinal effects, dicoumarol has been largely replaced by warfarin.

Digitalis Leaf

Digit. Fol.; Digit. Leaf; Digital, hoja de; Digitale Pourprée; Digitale Pourprée, Feuille de; Digitaliksenlehti; Digitalis; Digitalis Folium; Digitalis purpureae folium; Digitalisblad; Feuille de Digitale; Fingerhutblatt; Folha de Dedaleira; Foxglove Leaf; Hoja de Digital; List náprstníku červeného; Piros gyűszűviráglevél; Rusmenių lapai.

ATC — C01AA03.
ATC Vet — QC01AA03.

NOTE. The term 'digitalis' is often used to describe the entire class of cardiac glycosides.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Digitalis Leaf). The dried leaf of *Digitalis purpurea*. It contains not less than 0.3% of cardenolic glycosides, expressed as digitoxin, and calculated with reference to the drug dried at 100° to 105°. Protect from light and moisture.

USP 31 (Digitalis). The dried leaf of *Digitalis purpurea* (Scrophulariaceae). The potency is such that, when assayed as directed, 100 mg is equivalent to not less than 1 USP unit. Store in containers that protect it from absorbing moisture.

Profile

Digitalis leaf contains a number of cardiac glycosides with positive inotropic activity, including digitoxin, gitoxin, and gitaloxin. It has the general properties described under digoxin (p.1259) and has been used similarly in the management of heart failure. However, when treatment with a cardiac glycoside is required a single glycoside is preferred to digitalis, and digoxin or digitoxin are most commonly used.

Digitalis is used in herbal medicine.

Homoeopathy. Digitalis leaf has been used in homoeopathic medicines under the following names: Digitalis; Digitalis purpurea; Dig. pur.

Preparations

USP 31: Digitalis Capsules; Digitalis Tablets.

Proprietary Preparations (details are given in Part 3)
Ger.: Digophton†.

Multi-ingredient: ***Austria:*** Augentropfen Stulln; ***Ger.:*** Augentropfen Stulln Mono; Unguentum lymphaticum; ***Switz.:*** Augentonicum; Collypan; ***Venez.:*** Linfoderm.

Digitalis Lanata Leaf

Austrian Digitalis; Austrian Foxglove; Digitalis lanata, hoja de; Digitalis Lanatae Folium; Woolly Foxglove Leaf.

CAS — 17575-20-1 (lanatoside A).

Profile

Digitalis lanata leaf consists of the dried leaves of the woolly foxglove, *Digitalis lanata* (Scrophulariaceae), containing about 1 to 1.4% of a mixture of cardioactive glycosides, including digoxin, digitoxin, acetyldigoxin, acetyldigitoxin, lanatoside A, and deslanoside.

Digitalis lanata leaf is used as a source for the manufacture of digoxin and other glycosides.

◊ There have been reports[1] of toxicity after ingestion of dietary supplements contaminated with digitalis lanata.

1. Slifman NR, *et al.* Contamination of botanical dietary supplements by digitalis lanata. *N Engl J Med* 1998; **339:** 806–11.

Digitoxin *(BAN, rINN)*

Digitaline Cristallisée; Digitoksiini; Digitoksinas; Digitoksyna; Digitoxina; Digitoxine; Digitoxinum; Digitoxoside; Dijitoksin. 3β-[(*O*-2,6-Dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-*O*-2,6-dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-2,6-dideoxy-β-D-*ribo*-hexopyranosyl)oxy]-14β-hydroxy-5β-card-20(22)-enolide.

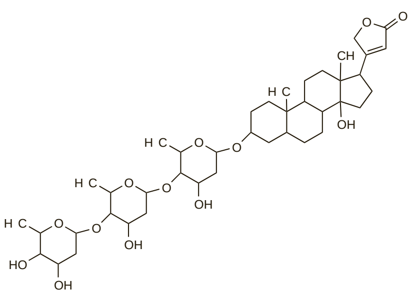
Дигитоксин

$C_{41}H_{64}O_{13}$ = 764.9.

CAS — 71-63-6.

ATC — C01AA04.

ATC Vet — QC01AA04.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Digitoxin). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol; freely soluble in a mixture of equal volumes of chloroform and methyl alcohol. Protect from light.

USP 31 (Digitoxin). A cardiotonic glycoside obtained from *Digitalis purpurea*, *Digitalis lanata* (Scrophulariaceae), or other suitable species of *Digitalis.* A white or pale buff-coloured, odourless, microcrystalline powder. Practically insoluble in water; soluble 1 in 150 of alcohol and 1 in 40 of chloroform; very slightly soluble in ether. Store in airtight containers.

Adsorption. Binding to an in-line intravenous filter containing a cellulose ester membrane accounted for a reduction[1] in digitoxin concentration of up to 25% from solutions of digitoxin 200 micrograms in 50 mL of glucose 5% or sodium chloride 0.9%. Pretreatment of the filter with a polymer coating reduced adsorption by about half.[2]

Digitoxin was found to be adsorbed onto glass and plastic in substantial amounts from simple aqueous solutions but not from solutions in 30% alcohol, or in plasma, or urine.[3]

1. Butler LD, *et al.* Effect of inline filtration on the potency of low-dose drugs. *Am J Hosp Pharm* 1980; **37:** 935–41.
2. Kanke M, *et al.* Binding of selected drugs to a "treated" inline filter. *Am J Hosp Pharm* 1983; **40:** 1323–8.
3. Molin L, *et al.* Solubility, partition, and adsorption of digitalis glycosides. *Acta Pharm Suec* 1983; **20:** 129–44.

Adverse Effects, Treatment, and Precautions

As for Digoxin, below. Toxicity may be more prolonged after withdrawal of digitoxin because of the longer half-life.

◊ References.

7. Hippius M, *et al.* Adverse drug reaction monitoring—digitoxin overdosage in the elderly. *Int J Clin Pharmacol Ther* 2001; **39:** 336–43.

Interactions

As for Digoxin, below. Since digitoxin is significantly metabolised in the liver it may be affected by drugs that induce microsomal enzymes, including rifampicin (see below) and antiepileptics such as phenobarbital.

Antibacterials. Acute heart failure has been reported in a patient taking digitoxin when treatment with *rifampicin* and isoniazid was started; plasma-digitoxin concentrations fell from a pretreatment steady-state value of 27 nanograms/mL to 10 nanograms/mL. The reduction in the digitoxin concentration was attributed to induction of digitoxin metabolism by rifampicin.[1]

Digitoxin toxicity has been described in 2 patients after addition of *azithromycin* to their therapy.[2]

1. Boman G, *et al.* Acute cardiac failure during treatment with digitoxin—an interaction with rifampicin. *Br J Clin Pharmacol* 1980; **10:** 89–90.
2. Thalhammer F, *et al.* Azithromycin-related toxic effects of digitoxin. *Br J Clin Pharmacol* 1998; **45:** 91–2.

Antineoplastics. A mean overall increase of 109% was seen in digitoxin clearance in 5 patients also given *aminoglutethimide*. The interaction was attributed to the induction of hepatic enzymes by aminoglutethimide.[1]

1. Lønning PE, *et al.* Effect of aminoglutethimide on antipyrine, theophylline, and digitoxin disposition in breast cancer. *Clin Pharmacol Ther* 1984; **36:** 796–802.

Calcium-channel blockers. Steady-state plasma concentrations of digitoxin increased by an average of 35% over 2 to 3 weeks in 8 of 10 patients when *verapamil* 240 mg daily was added to their therapy. Total body clearance and extra-renal clearance of digitoxin were reduced by 27% and 29% respectively although renal excretion was unchanged. Plasma-digitoxin concentrations increased by a mean of 21% in 5 of 10 patients treated with *diltiazem* but were not increased by *nifedipine*.[1]

1. Kuhlman J. Effects of verapamil, diltiazem, and nifedipine on plasma levels and renal excretion of digitoxin. *Clin Pharmacol Ther* 1985; **38:** 667–73.

Diuretics. *Spironolactone* has been reported to decrease the half-life and the urinary elimination of unchanged digitoxin when given for at least 10 days to 8 patients on oral maintenance digitoxin therapy.[1] However, increased digitoxin half-life has been reported[2] in 3 healthy subjects when spironolactone was added to digitoxin therapy. The interaction was judged to be of minor clinical importance.

1. Wirth KE, *et al.* Metabolism of digitoxin in man and its modification by spironolactone. *Eur J Clin Pharmacol* 1976; **9:** 345–54.
2. Carruthers SG, Dujovne CA. Cholestyramine and spironolactone and their combination in digitoxin elimination. *Clin Pharmacol Ther* 1980; **27:** 184–7.

Pharmacokinetics

Digitoxin is readily and completely absorbed from the gastrointestinal tract. Therapeutic plasma concentrations may range from 10 to 35 nanograms/mL but there is considerable interindividual variation. Digitoxin is more than 90% bound to plasma proteins. It is very slowly eliminated from the body and is metabolised in the liver. Most metabolites are inactive; the major active metabolite is digoxin. Enterohepatic recycling occurs and digitoxin is excreted in the urine, mainly as metabolites. It is also excreted in the faeces and this route becomes significant in renal impairment. Digitoxin has an elimination half-life of up to 7 days or more. The half-life is generally unchanged in renal impairment.

The pharmacokinetics of digitoxin may be affected by age and by concurrent diseases (see under Uses and Administration, below).

Uses and Administration

Digitoxin is a cardiac glycoside with positive inotropic activity. It has actions similar to those of digoxin (below) and is used in the management of some cardiac arrhythmias (p.1160) and in heart failure (p.1165).

Digitoxin is the most potent of the digitalis glycosides and is the most cumulative in action. The onset of its action is slower than that of the other cardiac glycosides and it may therefore be less suitable than digoxin for rapid digitalisation; after oral doses its effects may be evident in about 2 hours and its full effects in about 12 hours. Its effects persist for about 3 weeks.

As described under digoxin, dosage should be carefully adjusted to the needs of the individual patient. Steady-state therapeutic plasma concentrations of digitoxin may range from 10 to 35 nanograms/mL; higher values may be associated with toxicity. In adults 1 to 1.5 mg has been given orally in divided doses over 24 hours for rapid digitalisation, while for slow digitalisation an oral dose of 200 micrograms twice daily for 4 days has been given. The usual maintenance dose is 100 to 200 micrograms daily, but 100 micrograms on alternate days may be adequate. Digitoxin may also be given by slow intravenous injection when vomiting or other conditions prevent oral use; maintenance doses of 70 to 100 micrograms daily have been used. It has also been given intramuscularly but injections may be irritant.

Administration in children. Children were found to have a greater volume of distribution of digitoxin than adults and a shorter mean half-life, although individual variation was considerable. The increase in total clearance in children compared with adults was attributed to greater metabolic clearance. Digitalisation doses of 20 micrograms/kg were well tolerated.[1]

1. Larsen A, Storstein L. Digitoxin kinetics and renal excretion in children. *Clin Pharmacol Ther* 1983; **33:** 717–26.

Administration in the elderly. Digitoxin half-life, apparent volume of distribution, and clearance were not found to differ in elderly subjects compared with young adults after intravenous injection in a single-dose study. The long half-life may make once weekly dosing possible in poorly compliant patients.[1]

1. Donovan MA, *et al.* The effect of age on digitoxin pharmacokinetics. *Br J Clin Pharmacol* 1981; **11:** 401–2.

Administration in renal disease. The pharmacokinetics of digitoxin were changed significantly in 5 patients with nephrotic syndrome. The apparent volume of distribution of digitoxin was increased and protein binding decreased. Such patients should be maintained at lower serum-digitoxin concentrations than other patients but will need larger doses because of the shortened serum half-life and the increased renal excretion of digitoxin and its cardioactive metabolites.[1]

1. Storstein L. Studies on digitalis VII: influence of nephrotic syndrome on protein binding, pharmacokinetics, and renal excretion of digitoxin and cardioactive metabolites. *Clin Pharmacol Ther* 1976; **20:** 158–66.

Malignant neoplasms. There has been some interest in the potential anticancer activity of digitoxin and related compounds.

Preparations

BP 2008: Digitoxin Tablets;
USP 31: Digitoxin Injection; Digitoxin Tablets.

Proprietary Preparations (details are given in Part 3)
Austria: Digimerck; Ditaven†; ***Belg.:*** Digitaline†; ***Braz.:*** Digitaline; ***Ger.:*** Coramedan†; Digimed; Digimerck; Tardigal†; ***Hung.:*** Digimerck; ***Swed.:*** Digitrin†; ***USA:*** Crystodigin.

Digoxin *(BAN, rINN)*

Digoksiini; Digoksin; Digoksinas; Digoksyna; Digoxina; Digoxine; Digoxinum; Digoxosidum. 3β-[(*O*-2,6-Dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-*O*-2,6-dideoxy-β-D-*ribo*-hexopyranosyl-(1→4)-2,6-dideoxy-β-D-*ribo*-hexopyranosyl)oxy]-12β,14β-dihydroxy-5β-card-20(22)-enolide.

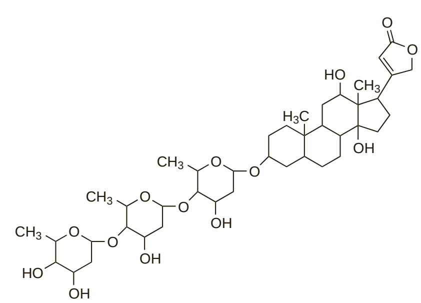
Дигоксин

$C_{41}H_{64}O_{14}$ = 780.9.

CAS — 20830-75-5.

ATC — C01AA05.

ATC Vet — QC01AA05.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Digoxin). A white or almost white powder or colourless crystals. Practically insoluble in water; slightly soluble in alcohol; freely soluble in a mixture of equal volumes of dichloromethane and methyl alcohol. Protect from light.

USP 31 (Digoxin). A cardiotonic glycoside obtained from the leaves of *Digitalis lanata* (Scrophulariaceae). Clear to white, odourless, crystals, or a white, odourless, crystalline powder. Practically insoluble in water and in ether; slightly soluble in diluted alcohol and in chloroform; freely soluble in pyridine. Store in airtight containers.

Adverse Effects

Digoxin and the other cardiac glycosides commonly produce adverse effects because the margin between the therapeutic and toxic doses is small; plasma concentrations of digoxin in excess of 2 nanograms/mL are considered to be an indication that the patient is at special risk although there is considerable interindividual variation. There have been many fatalities, particularly due to cardiac toxicity.

Nausea, vomiting, and anorexia may be among the earliest symptoms of digoxin toxicity or overdosage; diarrhoea and abdominal pain may occur. Certain neurological effects are also common symptoms of digoxin overdosage and include headache, facial pain, fatigue, weakness, dizziness, drowsiness, disorientation, mental confusion, bad dreams and more rarely delirium, acute psychoses, and hallucinations. Convulsions have been reported. Visual disturbances including blurred vision may occur; colour vision may be affected with objects appearing yellow or, less frequently, green, red, brown, blue, or white. Hypersensitivity reactions are rare; thrombocytopenia has been reported. The cardiac glycosides may have some oestrogenic activity and occasionally cause gynaecomastia at therapeutic doses.

Rapid intravenous injection of digoxin may cause vasoconstriction and transient hypertension. Intramuscular or subcutaneous injection can cause local irritation.

The most serious adverse effects are those on the heart. Toxic doses may cause or aggravate heart failure. Supraventricular or ventricular arrhythmias and defects of conduction are common and may be an early indication of excessive dosage, particularly in children. In general the incidence and severity of arrhythmias is related to the severity of the underlying heart disease. Almost any arrhythmia may ensue, but particular note should be made of supraventricular tachycardia, especially AV junctional tachycardia and atrial tachycardia with block. Ventricular arrhythmias including extrasystoles, sinoatrial block, sinus bradycardia, and AV block may also occur.

Hypokalaemia predisposes to digoxin toxicity; adverse reactions to digoxin may be precipitated if hypokalaemia occurs, for example after prolonged use of diuretics. Hyperkalaemia occurs in acute digoxin overdosage.

As digoxin has a shorter half-life than digitalis or digitoxin any toxic effects will tend to resolve more rapidly.

Effects on the blood. Thrombocytopenia has been reported[1] in a small number of patients taking digoxin. An association between several cardiovascular drugs, including digitalis glycosides (digoxin and acetyldigoxin), and agranulocytosis was also found in an international study[2] although again the incidence was low.

Effects in the elderly. Elderly patients may be particularly susceptible to digoxin toxicity, even at therapeutic plasma concentrations.[1] Adverse effects reported in elderly patients with toxic plasma-digoxin concentrations have included chorea,[2] profuse watery diarrhoea,[3] and dysphagia with dysphonia.[4]

Hypersensitivity. Hypersensitivity reactions to cardiac glycosides are rare but skin reactions have been reported. An 86-year-old man developed a generalised, pruritic, erythematous rash after digoxin was given intravenously.[1] The rash recurred on rechallenge with digoxin tablets.

Treatment of Adverse Effects

In *acute poisoning*, gastric lavage may be considered if the patient presents within one hour of ingestion. Repeated doses of activated charcoal may be given to reduce the absorption and enterohepatic recycling of cardiac glycosides; colestyramine and colestipol have also been tried. Attempts to remove cardiac glycosides by haemodialysis or peritoneal dialysis have generally been ineffective and the value of haemoperfusion is controversial. Forced diuresis with furosemide is generally ineffective and may be dangerous; serious electrolyte imbalance may result from the use of such potent diuretics.

Cardiac toxicity in acute or chronic poisoning should be treated under ECG control and serum electrolytes should be monitored. Antiarrhythmic treatment may be necessary and should be determined by the specific arrhythmia present (see p.1160). Atropine is given intravenously to correct bradycardia and in patients with heart block. Pacing may be necessary if atropine is not effective. Potassium chloride may be given in hypokalaemic patients provided that renal function is normal and heart block is not present. Potassium has also been given to normokalaemic patients but caution is needed since hyperkalaemia can occur rapidly. Other electrolyte imbalances should be corrected.

In *massive overdosage* progressive hyperkalaemia occurs and is fatal unless reversed. Soluble insulin with glucose has been given and, if the hyperkalaemia is refractory, dialysis may be tried. Massive life-threatening overdosage has been treated successfully with digoxin-specific antibody fragments (p.1443).

For the treatment of *chronic poisoning* temporary withdrawal of digoxin or other cardiac glycosides may be all that is necessary, with subsequent doses adjusted according to the needs of the patient. Serum electrolytes should be measured and the ECG monitored. Potassium supplements should be given to correct hypokalaemia.

Precautions

Digoxin is generally contra-indicated in patients with hypertrophic obstructive cardiomyopathy unless there is severe cardiac failure, since the outflow obstruction may be worsened. It is also contra-indicated in patients with the Wolff-Parkinson-White syndrome or other evidence of an accessory pathway, especially if it is accompanied by atrial fibrillation, since ventricular tachycardia or fibrillation may be precipitated. Digoxin is not an appropriate form of therapy for any ventricular arrhythmia.

Digoxin toxicity is common and may result from raised plasma concentrations or an increase in sensitivity to digoxin. Almost any deterioration in the condition of the heart or circulation may increase the sensitivity to digoxin and it should be used with caution in all patients with cardiovascular disease. Early signs of digoxin toxicity should be watched for and the heart rate should generally be maintained above 60 beats per minute. Toxicity may result from giving loading doses too rapidly and from accumulation of maintenance doses as well as from acute poisoning. Even with intravenous doses a response may take a number of hours, and persistence of tachycardia is therefore not a reason to exceed the recommended intravenous dose.

Digoxin should be used with caution in partial heart block since complete heart block may be induced; it should also be used with care in sinus node disorders. Caution is also required in acute myocarditis (such as rheumatic carditis), in acute myocardial infarction, in advanced heart failure, and in severe pulmonary disease, due to the increased myocardial sensitivity. Digoxin may also enhance the occurrence of arrhythmias in patients undergoing cardioversion and should be withdrawn 1 to 2 days before such procedures if possible. If cardioversion is essential and digoxin has already been given, low energy shocks must be used.

Electrolyte imbalances may affect the sensitivity to digoxin, as may thyroid dysfunction. The effects of digoxin are enhanced by hypokalaemia, hypomagnesaemia, hypercalcaemia, hypoxia, and hypothyroidism and doses may need to be reduced until these conditions are corrected. Resistance to the effects of digoxin may occur in hyperthyroidism. Digoxin should be given with care, and possibly in reduced dosage, to patients who have received it or other cardiac glycosides within the previous 2 to 3 weeks.

Digoxin doses should generally be reduced and plasma-digoxin concentrations monitored in patients with renal impairment, in the elderly, and in premature infants (see Uses and Administration, below).

Breast feeding. Studies[1,2] have shown that digoxin is distributed into breast milk, although the amount was considered too small to have an effect on the child. No adverse effects have been seen in breast-feeding infants whose mothers were receiving digoxin, and the American Academy of Pediatrics considers[3] that it is therefore usually compatible with breast feeding.

Gastrointestinal disorders. Absorption from tablets of digoxin may be decreased due to inadequate dissolution in patients with malabsorption syndromes or small bowel resections and it has been recommended that liquid dosage forms of digoxin should be used in the latter case.[1] However, only 40 to 60% of a digoxin dose given as elixir was absorbed in a patient with a small bowel resection[2] compared with about 80% in patients with normal gastrointestinal function, suggesting a need for slightly increased oral maintenance doses of digoxin in patients with resections. In a further patient with a similar resection[3] a therapeutic plasma-digoxin concentration was not achieved with any oral formulation.

Heart surgery. Patients undergoing cardiac surgery appear to have increased sensitivity to digoxin toxicity and thus an increased risk of arrhythmias.[1] Digoxin has been found[2] to be no better than placebo in preventing postoperative arrhythmias after coronary artery bypass surgery, and actually induced supraventricular arrhythmias in 2 patients. Arrhythmias compatible with digoxin intoxication have occurred postoperatively[1] although serum-digoxin concentrations ranged from 0 to 2.8 nanograms/mL; therefore, the arrhythmias may have been due to either the surgical procedures or to increased sensitivity to digoxin.

Interference with digoxin assays. The presence of endogenous digoxin-like substances in neonates, and in patients with liver or kidney dysfunction, may be responsible for elevated values or false-positive results in some plasma-digoxin assays.[1] Some patients may have antibodies that react with the assay system and produce falsely elevated values.[2]

Some drugs may also interfere with plasma-digoxin assays; these include prednisolone[1] and ginseng.[3] Raised serum-digoxin concentrations (but without signs of digoxin toxicity) were noted in an elderly man after the use of Siberian ginseng (*Eleutherococcus senticosus*). However, concentrations remained high even when digoxin was discontinued and returned to the therapeutic range only after the ginseng was stopped. Siberian ginseng contains eleutherosides, which are chemically related to cardiac glycosides such as digoxin, and the assay may have measured these compounds, or their derivatives, as well as digoxin. Although it has been suggested that this reaction may have been due to the substitution of the unrelated cardiotoxic herb *Periploca sepium*,[4] both ginseng and Siberian ginseng have been shown to interfere with some digoxin assays *in vitro* and *in vivo*.[5] Spironolactone may interfere with digoxin assays but may also produce changes in digoxin concentrations (see Diuretics under Interactions, below).

Pregnancy. There is considerable evidence that digoxin crosses the placenta freely with serum-digoxin concentrations at term similar in the newborn and mother. No significant adverse effects attributed to digoxin have been noted in the fetus or neonate although adverse fetal effects, including fetal death, have been reported in mothers with digitalis toxicity. Some concern has been expressed that maternal digitalis therapy may occasionally cause low birth-weights in infants of mothers with heart disease, but the underlying disease might also be important.[1] The presence of endogenous digoxin-like immunoreactive substances in the serum of pregnant women and neonates could make the interpretation of digoxin assays difficult. In one study,[2] high concentrations of endogenous digoxin-like immunoreactivity in cord blood suggested that it might be synthesised during delivery, in which case the placental transfer of digoxin might be overestimated.

Interactions

There may be interactions between digoxin and drugs that alter its absorption, interfere with its excretion, or have additive effects on the myocardium. Drugs that cause electrolyte disturbances increase the risk of toxicity from cardiac glycosides. Thiazides and loop *diuretics* cause hypokalaemia and also hypomagnesaemia which may lead to cardiac arrhythmias. Other causes of hypokalaemia include treatment with *corticosteroids, beta$_2$ agonists* (such as salbutamol), *amphotericin B, sodium polystyrene sulfonate, carbenoxolone,* and dialysis. Hypercalcaemia may also increase toxicity and intravenous use of *calcium salts* is best avoided in patients taking cardiac glycosides. Serum-digoxin concentrations may be significantly increased by *quinidine, amiodarone,* and *propafenone* and reduction of digoxin dosage may be required. Other antiarrhythmics may have additive effects on the myocardium increasing the likelihood of adverse effects; *beta blockers* may potentiate bradycardia due to digoxin. *Calcium-channel blockers* may increase digoxin concentrations.

Digoxin is a substrate for P-glycoprotein and interactions may occur with drugs that affect P-glycoprotein function (see Metabolism and Excretion under Pharmacokinetics, below).

2. Magnani B, Malini PL. Cardiac glycosides: drug interactions of clinical significance. *Drug Safety* 1995; **12:** 97–109.

ACE inhibitors. Although increased serum-digoxin concentrations have been reported in patients with severe chronic heart failure given *captopril*,[1] other studies have failed to confirm this effect.[2,3] Studies with various other ACE inhibitors have also failed to show any significant effect on serum-digoxin concentrations. However, ACE inhibitors may cause a deterioration in renal function and this could lead to an increase in serum-digoxin concentration due to impaired digoxin excretion.[4]

4. Mignat C, Unger T. ACE inhibitors: drug interactions of clinical significance. *Drug Safety* 1995; **12:** 334–47.

Alpha blockers. *Prazosin*[1] has been reported to increase the mean plasma-digoxin concentration in patients receiving a maintenance dose of digoxin.

1. Çopur S, *et al.* Effects of oral prazosin on total plasma digoxin levels. *Fundam Clin Pharmacol* 1988; **2:** 13–17.

Angiotensin II receptor antagonists. In a study[1] in healthy subjects, *telmisartan* increased peak serum-digoxin concentrations but trough concentrations were unaffected and it was suggested that the effect was unlikely to be clinically significant. No interaction was found when digoxin was given with *losartan*[2] or with *eprosartan*[3] in healthy subjects.

3. Martin DE, *et al.* Lack of effect of eprosartan on the single dose pharmacokinetics of orally administered digoxin in healthy male volunteers. *Br J Clin Pharmacol* 1997; **43:** 661–4.

Antiarrhythmics. *AMIODARONE.* An interaction between digoxin and amiodarone resulting in increased plasma-digoxin concentrations has been reported[1-5] on several occasions; the concentration may be doubled.[5] An increase in serum-digoxin concentrations of 68 to 800% has been reported[2] during amiodarone therapy in children. The interaction does not appear to be due to a reduction in urinary excretion alone[3,4] and seems to be dose-related. It has been recommended[1,6] that the initial dose of digoxin should be halved when amiodarone is given.

6. Naccarelli GV, *et al.* Adverse effects of amiodarone: pathogenesis, incidence and management. *Med Toxicol Adverse Drug Exp* 1989; **4:** 246–53.

DISOPYRAMIDE. Disopyramide appears to have no clinically significant effect on the pharmacokinetics of digoxin in healthy subjects[1,2] but has been reported to modify the cardiovascular effects of digoxin.[1]

2. Risler T, *et al.* On the interaction between digoxin and disopyramide. *Clin Pharmacol Ther* 1983; **34:** 176–80.

FLECAINIDE. Giving flecainide 200 mg twice daily to 15 healthy subjects taking digoxin caused a mean increase of 24% in predose digoxin concentrations and of 13% in digoxin concentrations 6 hours after the digoxin dose.[1] It was considered that in most cases these increases in plasma-digoxin concentrations would not present a clinical problem, but that patients with higher plasma-digoxin concentrations or atrioventricular nodal dysfunction should be monitored.

1. Weeks CE, *et al.* The effect of flecainide acetate, a new antiarrhythmic, on plasma digoxin levels. *J Clin Pharmacol* 1986; **26:** 27–31.

PROPAFENONE. Increased serum-digoxin concentrations have been reported when propafenone is also given.[1-4] There is considerable interindividual variation in the extent of the interaction; increases in serum-digoxin concentrations of up to 254% have been reported. If digoxin and propafenone are given together, the dose of digoxin should be reduced and serum-digoxin concentration should be monitored.

4. Bigot M-C, *et al.* Serum digoxin levels related to plasma propafenone levels during concomitant treatment. *J Clin Pharmacol* 1991; **31:** 521–6.

QUINIDINE. Quinidine causes an increase in serum-digoxin concentration in almost all patients given the two drugs together.[1-3] The serum-digoxin concentration may be increased by up to 500% but is usually approximately doubled.[1] Signs and symptoms of digoxin toxicity may occur although some workers[4] have suggested that these may be accounted for by an additive effect of the 2 drugs rather than by the effect on serum-digoxin concentration. The exact mechanism of interaction is not clear but a substantial decrease in the renal and nonrenal clearance of digoxin has been found.[5] The distribution volume of digoxin may also be reduced[2] reflecting impaired tissue binding, and there is increased systemic availability.[1] It is generally recommended that the dose of digoxin is halved in digitalised patients who are to be given quinidine.[2] Subsequently, serum-digoxin concentrations should be monitored, especially during the first 1 to 2 weeks after which the new steady-state digoxin concentration should be achieved.[2]

VERAPAMIL. For a discussion on the interaction between digoxin and verapamil, see under Calcium-channel Blockers, below.

Antibacterials. About 10% of patients receiving digoxin may metabolise 40% or more of the drug to cardio-inactive metabolites.[1] Gut flora contribute greatly to this process, and the use of antibacterials such as *erythromycin* or *tetracycline* in these patients appears to reduce this metabolic process resulting in higher serum concentrations.[2] Digoxin toxicity has been reported in digitalised patients given erythromycin,[3,4] *azithromycin*,[5] *clarithromycin*,[6-8] and *roxithromycin*.[9] It has been postulated[5,10] that the macrolide antibacterials may also inhibit P-glycoprotein-mediated renal tubular secretion of digoxin. Oral *neomycin* may reduce serum-digoxin concentrations by reducing digoxin absorption.

Rifampicin may reduce serum-digitoxin concentrations by inducing its metabolism (see p.1259) although a study[11] in healthy subjects suggested that this reduction might rather be due to induction of intestinal P-glycoprotein. Digoxin is mainly excreted unchanged in the urine but rifampicin increased digoxin dose requirements substantially in 2 patients dependent on dialysis.[12] When rifampicin was stopped digoxin requirements fell by about 50%.

Antidepressants. In a study[1] in healthy subjects, use of digoxin together with an extract of *St John's wort* for 10 days resulted in a significant decrease in the plasma-digoxin concentration. It was suggested that the interaction might be due to induction of the P-glycoprotein transporter. In a study[2] in healthy male subjects, *nefazodone* increased steady-state plasma-digoxin concentrations by about 30% but no adverse or clinical effects were associated with the increase. However, due to the narrow therapeutic range of digoxin, it was suggested that plasma-digoxin concentrations should be monitored in patients also given nefazodone. Similar recommendations have been made for *trazodone*.

Digoxin toxicity developed in a patient shortly after starting *paroxetine* and was associated with increased serum-digoxin concentrations.[3] However, the role of paroxetine in the reaction has been queried.[4,5]

1. Johne A, *et al.* Pharmacokinetic interaction of digoxin with an herbal extract from St John's wort (Hypericum perforatum). *Clin Pharmacol Ther* 1999; **66:** 338–45.

5. Hallberg P, Melhus H. Digitalis intoxication induced by paroxetine co-administration. *Lancet* 2006; **368:** 1963.

Antidiabetics. Subtherapeutic plasma-digoxin concentrations were noted in a diabetic woman receiving *acarbose* and digoxin.[1] The plasma concentration of digoxin increased to a therapeutic level when acarbose was stopped. A study[2] in healthy subjects suggested that the interaction was due to inhibition of the absorption of digoxin by acarbose.

1. Serrano JS, *et al.* A possible interaction of potential clinical interest between digoxin and acarbose. *Clin Pharmacol Ther* 1996; **60:** 589–92.
2. Miura T, *et al.* Impairment of absorption of digoxin by acarbose. *J Clin Pharmacol* 1998; **38:** 654–7.

Antiepileptics. *Phenytoin* caused a marked decrease in steady-state serum-digoxin concentrations when given with digoxin and acetyldigoxin to 6 healthy subjects for 7 days.[1] Total digoxin clearance was increased by an average of 27% and elimination half-life was reduced by an average of 30%. This interaction may be more likely with digitoxin, since digitoxin is more dependent on the liver for elimination.

A brief report of an open study[2] in 12 subjects indicated a slight but significant decrease in digoxin bioavailability when *topiramate* was also given, although half-life and renal clearance of digoxin did not appear to be affected.

1. Rameis H. On the interaction between phenytoin and digoxin. *Eur J Clin Pharmacol* 1985; **29:** 49–53.
2. Liao S, Palmer M. Digoxin and topiramate drug interaction study in male volunteers. *Pharm Res* 1993; **10** (suppl): S405.

Antifungals. Two men given *itraconazole* while receiving digoxin developed signs and symptoms of digoxin toxicity and elevated serum-digoxin concentrations.[1,2] A further case report[3] suggested that the interaction was due to a reduction in the renal clearance of digoxin when itraconazole was given.

Additive adverse effects due to hypokalaemia may occur when digoxin is given with *amphotericin B*.

3. Alderman CP, Allcroft PD. Digoxin-itraconazole interaction: possible mechanisms. *Ann Pharmacother* 1997; **31:** 438–40.

Antimalarials. In 6 subjects given *quinine sulfate*, total body clearance of digoxin after an intravenous dose was decreased by 26%, primarily through a reduction in nonrenal clearance.[1] Increased urinary excretion of digoxin was consistent with alterations in the nonrenal clearance of digoxin and might be due to changes in the metabolism or biliary secretion of digoxin. Quinine increased the mean elimination half-life of digoxin from 34.2 to 51.8 hours but did not consistently change the volume of distribution.

An increase in the plasma-digoxin concentration, but without symptoms of toxicity, was noted in 2 women given *hydroxychloroquine* (for rheumatoid arthritis) in addition to long-term digoxin therapy.[2]

1. Wandell M, *et al.* Effect of quinine on digoxin kinetics. *Clin Pharmacol Ther* 1980; **28:** 425–30.
2. Leden I. Digoxin–hydroxychloroquine interaction? *Acta Med Scand* 1982; **211:** 411–12.

Antineoplastics. A study[1] in patients undergoing antineoplastic therapy found that the absorption of digoxin from tablets was reduced by an average of 46.5%, whereas that of digoxin from liquid-filled capsules was not significantly changed. Another study[2] in similar patients found that the steady-state concentration of digoxin after giving acetyldigoxin was reduced, but that digitoxin concentrations were maintained. It was suggested that the interaction was due to reduced absorption of digitalis glycosides through the damaged gastrointestinal mucosa and that liquid-filled capsules or digitoxin might be preferred in these patients.

Licensed product information for *lenalidomide* states that it may increase plasma exposure of digoxin and recommends that digoxin concentrations should be monitored.

2. Kuhlmann J. Inhibition of digoxin absorption but not of digitoxin during cytostatic drug therapy. *Arzneimittelforschung* 1982; **32:** 698–704.

Antithyroid drugs. Reduced peak serum-digoxin concentrations were noted in 9 of 10 healthy subjects after a single oral dose of *carbimazole* although conversely in the tenth subject digoxin concentrations rose.[1] Caution is also needed since changes in thyroid function may independently affect sensitivity to digoxin (see Precautions, above).

1. Rao BR, *et al.* Influence of carbimazole on serum levels and haemodynamic effects of digoxin. *Clin Drug Invest* 1997; **13:** 350–4.

Antivirals. A woman stabilised on digoxin and tolerating lamivudine, indinavir and stavudine for HIV infection, developed symptoms of digoxin toxicity 3 days after *ritonavir* was added to her treatment.[1] It was suggested that the interaction might be due to inhibition of the P-glycoprotein transporter system by ritonavir. A pharmacokinetic study[2] showing significant inhibition of renal digoxin clearance by ritonavir seemed to support this hypothesis.

1. Phillips EJ, *et al.* Digoxin toxicity and ritonavir: a drug interaction mediated through p-glycoprotein? *AIDS* 2003; **17:** 1577–8.
2. Ding R, *et al.* Substantial pharmacokinetic interaction between digoxin and ritonavir in healthy volunteers. *Clin Pharmacol Ther* 2004; **76:** 73–84.

Benzodiazepines. Raised serum-digoxin concentrations have been reported in patients also taking *diazepam*[1] or *alprazolam*.[2,3] The clearance of digoxin was reduced by these benzodiazepines.

1. Castillo-Ferrando JR, *et al.* Digoxin levels and diazepam. *Lancet* 1980; **ii:** 368.

3. Guven H, *et al.* Age-related digoxin-alprazolam interaction. *Clin Pharmacol Ther* 1993; **54:** 42–4.

Beta$_2$ agonists. A single intravenous[1,2] or oral[3] dose of *salbutamol* has been reported to decrease steady-state serum-digoxin concentrations by up to 16% and 22% respectively in healthy subjects. Although salbutamol had no significant effect on the concentration of digoxin in skeletal muscle, it was considered that increased binding to skeletal muscle could explain the interaction. Beta$_2$ agonists such as salbutamol can also cause hypokalaemia which may increase susceptibility to digoxin-induced arrhythmias.

3. Edner M, Jogestrand T. Oral salbutamol decreases serum digoxin concentration. *Eur J Clin Pharmacol* 1990; **38:** 195–7.

Beta blockers. Beta blockers may increase the risk of heart block and bradycardia with digoxin. In addition, *carvedilol* has been reported[1-3] to increase plasma concentrations of digoxin, although the effect is generally small and probably not clinically significant. However, a study[4] in 8 children (aged 2 weeks to 7.8 years) found that the clearance of digoxin was about halved by carvedilol and 2 of the children developed digoxin toxicity. An increase in digoxin bioavailability has also been reported with *talinolol*.[5]

5. Westphal K, *et al.* Oral bioavailability of digoxin is enhanced by talinolol: evidence for involvement of intestinal P-glycoprotein. *Clin Pharmacol Ther* 2000; **68:** 6–12.

Calcium-channel blockers. Studies on interactions between digoxin and calcium-channel blockers appear to show that *verapamil* increases plasma-digoxin concentrations[1-3] by up to 70%. The effect of *nifedipine* is not as clear. Although it has been reported[1] to produce a 45% increase in plasma-digoxin concentrations, other studies[4,5] have reported little or no increase and the interaction is unlikely to be of clinical significance for most patients. Studies on the interaction between digoxin and *diltiazem* have also produced conflicting results. Increases in plasma-digoxin concentrations of 20% and up to 59% have been reported[6,7] and an increase in metildigoxin concentrations[7] of up to 51%. However, other studies[8,9] have shown no diltiazem-induced change in digoxin pharmacokinetics or plasma concentration. *Bepridil*,[10] *gallopamil*,[1] *mibefradil*,[11] *nisoldipine*,[12] and *nitrendipine*[13] have all been reported to increase plasma-digoxin concentrations. Bepridil increased the concentration by 34% and it was recommended that patients given this combination be monitored carefully. *Felodipine*[14,15] and *isradipine*[3] have both been reported to increase peak serum-digoxin concentrations, but steady-state digoxin concentrations were not affected and the interactions were unlikely to be of clinical relevance.

The mechanism of interaction between calcium-channel blockers and digoxin is not completely understood but appears to be related to decreased renal and nonrenal clearance of digoxin. The pharmacodynamic effects of digoxin and calcium-channel blockers may also be additive.

Diuretics. *Amiloride* increased renal clearance of digoxin and reduced the extrarenal digoxin clearance in 6 healthy subjects after a single intravenous dose of digoxin.[1] Amiloride also inhibited the digoxin-induced positive inotropic effect, but the clinical implications in cardiac patients are unknown. A further study[2] failed to confirm this effect.

Spironolactone and its metabolites have been reported to interfere with serum-digoxin determinations by radio-immunoassay or fluorescence-polarisation immunoassay resulting in falsely elevated measurements.[3,4] The interference with digoxin assays is neither consistent nor predictable and falsely low readings have also been reported.[5] Serum-digoxin concentrations should be interpreted with caution when digoxin is given together with spironolactone or *canrenoate*, especially since spironolactone has also been reported to decrease digoxin clearance by a median of 26% resulting in a true increase in the serum-digoxin concentration.[6]

Diuretic therapy with *triamterene* in association with a thiazide or loop diuretic increased the mean serum-digoxin concentration; this interaction was considered unlikely to be of clinical importance, except perhaps in patients with renal impairment.[7]

Gastrointestinal drugs. Some gastrointestinal drugs can affect the absorption of digoxin by binding to it or by changing gastrointestinal motility. The problem has often been related to the bioavailability of the digoxin formulation and appears to be less important with currently used preparations. Some *antacids*,[1,2] particularly liquid formulations, and *adsorbents*[1] such as kaolin-pectin, can reduce the absorption of digoxin from the gastrointestinal tract and doses should probably be separated by at least 2 hours. *Activated charcoal*, and *ion-exchange resins* such as colestyramine and colestipol, also reduce digoxin absorption. *Sucralfate*[3] may also reduce the absorption of digoxin.

Omeprazole and possibly other gastric acid inhibitors may reduce the gastrointestinal metabolism and enhance the absorption of unchanged digoxin,[4] although the clinical relevance of this is uncertain.[5]

Drugs that increase gastrointestinal motility can reduce the absorption of digoxin, especially if digoxin is given as a slowly dissolving formulation. Reduced absorption of digoxin has occurred when digoxin and *metoclopramide* have been given together,[6] and a similar effect has been reported with *cisapride*[7] and *tegaserod*.[8] Conversely, *anticholinergics* reduce motility, and propantheline has increased digoxin absorption.

Sulfasalazine has been found to impair the absorption of digoxin and to reduce the serum-digoxin concentration,[9] but the mechanism is unclear.

Ginseng. Varieties of ginseng may interfere with plasma-digoxin assays (see under Precautions, above).

Immunosuppressants. Increased serum-digoxin concentrations with symptoms of toxicity have been reported in patients when *ciclosporin* was added to their digoxin therapy.[1,2]

1. Dorian P, *et al.* Digoxin-cyclosporine interaction: severe digitalis toxicity after cyclosporine treatment. *Clin Invest Med* 1988; **ii:** 108–12.
2. Robieux I, *et al.* The effects of cardiac transplantation and cyclosporine therapy on digoxin pharmacokinetics. *J Clin Pharmacol* 1992; **32:** 338–43.

Lipid regulating drugs. Small increases in plasma-digoxin concentrations have been reported with some *statins*, although the clinical significance is not clear. *Atorvastatin* at doses of 80 mg, but not of 10 mg, has been shown[1] to increase plasma-digoxin concentrations by about 20%. This may be due to the inhibition of P-glycoprotein-mediated secretion of digoxin in the intestine by atorvastatin.

1. Boyd RA, *et al.* Atorvastatin coadministration may increase digoxin concentrations by inhibition of intestinal P-glycoprotein-mediated secretion. *J Clin Pharmacol* 2000; **40:** 91–98.

Neuromuscular blockers. *Pancuronium* or *suxamethonium* may interact with digitalis glycosides resulting in an increased incidence of arrhythmias; the interaction is more likely with pancuronium.[1]

1. Bartolone RS, Rao TLK. Dysrhythmias following muscle relaxant administration in patients receiving digitalis. *Anesthesiology* 1983; **58:** 567–9.

NSAIDs. An increase in serum-digoxin concentration has been reported with *aspirin*, *ibuprofen*, *indometacin*, *fenbufen*, and *diclofenac*.[1] Potentially toxic serum-digoxin concentrations occurred in preterm infants[2] with patent ductus arteriosus receiving digoxin when given indometacin orally in a mean total dose of 320 micrograms/kg; it was recommended that the dose of digoxin should be halved initially if indometacin is also given. (For the possible effect of digoxin on indometacin see Half-life, under Pharmacokinetics of Indometacin, p.68.) Lack of increase in serum-digoxin concentrations has also been reported with aspirin or indometacin, as well as with *ketoprofen*, and *tiaprofenic acid*,[1] and also with *rofecoxib*,[3] but some of these studies were in healthy subjects and it is advised that digoxin therapy be monitored carefully whenever any NSAID is started or stopped in digitalised patients.

Pharmacokinetics

The absorption of digoxin from the gastrointestinal tract is variable depending upon the formulation used. About 70% of a dose is absorbed from tablets which comply with BP or USP specifications, 80% is absorbed from an elixir, and over 90% is absorbed from liquid-filled soft gelatin capsules. The generally accepted therapeutic plasma concentration range is 0.5 to 2.0 nanograms/mL but there is considerable interindividual variation. Digoxin has a large volume of distribution and is widely distributed in tissues, including the heart, brain, erythrocytes, and skeletal muscle. The concentration of digoxin in the myocardium is considerably higher than in plasma. From 20 to 30% is bound to plasma proteins. Digoxin has been detected in CSF and breast milk; it also crosses the placenta. It has an elimination half-life of 1.5 to 2 days.

Digoxin is mainly excreted unchanged in the urine by glomerular filtration and tubular secretion; reabsorption also occurs. Extensive metabolism has been reported in a minority of patients (see under Metabolism and Excretion, below). Excretion of digoxin is proportional to the glomerular filtration rate. After intravenous injection 50 to 70% of the dose is excreted unchanged. Digoxin is not removed from the body by dialysis, and only small amounts are removed by exchange transfusion and during cardiopulmonary bypass.

3. Mooradian AD. Digitalis: an update of clinical pharmacokinetics, therapeutic monitoring techniques and treatment recommendations. *Clin Pharmacokinet* 1988; **15:** 165–79.

Absorption. Studies in 6 healthy subjects found that food decreased the rate but not the extent of absorption of digoxin.[1]

1. Johnson BF, *et al.* Effect of a standard breakfast on digoxin absorption in normal subjects. *Clin Pharmacol Ther* 1978; **23:** 315–19.

Bioavailability. Large variations in the content, disintegration, and dissolution of solid dosage forms of digoxin preparations have led to large variations in plasma concentrations from different proprietary preparations. Other factors involved in varying bioavailability include the pharmaceutical formulation and presentation (capsules, solution, or tablets), particle size, and biological factors. Serious problems occurred in the UK[1] in 1972 and in Israel[2] in 1975 after changes in the manufacturing procedure for *Lanoxin* led to a twofold increase in bioavailability.

Distribution and protein binding. Digoxin has been reported to be 5 to 60% bound to plasma proteins,[1] depending partly on the method of measurement, but the figure is usually around 20%. Protein binding is reduced in patients undergoing haemodialysis; mean reductions of about 8 and 10% have been reported.[1,2] Injection of heparin has produced a similar reduction.[2]

Digoxin is widely distributed to tissues and serum-digoxin concentrations have been reported to be increased during immobilisation[3] and decreased during exercise[4,5] due to changes in binding to tissues such as skeletal muscle.

The elderly. For references to alterations in the pharmacokinetics of digoxin in the elderly, see under Uses and Administration, below.

Infants and neonates. Digoxin has been widely used in the treatment of cardiac disorders in neonates and infants and its pharmacokinetics in this age group have been reviewed.[1,2] In full-term neonates or infants, 80 to 90% of a dose of digoxin given orally in liquid form is absorbed, with peak plasma concentrations occurring within 30 to 120 minutes. The rate of absorption may be slower in preterm and low birth-weight infants, with peak concentrations achieved at 90 to 180 minutes, and may be significantly reduced in severe heart failure and in malabsorption syndromes. After digoxin is given intravenously there is a rapid distribution phase with an apparent half-life of 20 to 40 minutes followed by a slower exponential decay of plasma concentrations. In full-term neonates, digoxin has an apparent volume of distribution of 6 to 10 litres/kg. Low birth-weight infants have a volume of distribution of 4.3 to 5.7 litres/kg while in older infants the volume may range from 10 to 22 litres/kg which is 1.5 to 2 times reported adult values. This large volume of distribution in full-term neonates and infants is thought to be due to increased tissue binding, a larger extracellular fluid volume, and slightly lower plasma protein binding.

The apparent plasma half-life in healthy and sick neonates is generally very long and may range from 20 to 70 hours in full-term neonates or from 40 to 180 hours in preterm neonates. Digoxin is eliminated at a considerably faster rate in infants than in neonates and, in parallel with maturation of kidney function, a marked increase in clearance rate is usually observed between the second and third month of life. The large apparent volume of distribution, higher clearance values, and greater concentrations of digoxin in the myocardial tissue and red cells of infants might justify the traditional assumption that infants tolerate digoxin better than adults and that higher doses are consequently needed in infants. However, studies have shown that in infants, as in adults, toxic signs become evident at plasma-digoxin concentrations above 3 nanograms/mL and that the therapeutic range may be 1.5 to 2 nanograms/mL.

Metabolism and excretion. Although digoxin is reported to be excreted mainly unchanged in the urine there is evidence to suggest that metabolism may sometimes be extensive. Metabolites that have been detected in the urine include digoxigenin, dihydrodigoxigenin, the mono- and bisdigitoxosides of digoxigenin, and dihydrodigoxin. Digoxigenin mono- and bisdigitoxosides are known to be cardioactive whereas dihydrodigoxin is probably much less active than digoxin.[1]

In about 10% of patients there is considerable reduction to cardio-inactive metabolites, chiefly dihydrodigoxin, and 40% or more of a dose may be excreted in the urine as dihydrodigoxin.[2-4] Bacterial flora in the gastrointestinal tract appear to be responsible for this metabolism and antibacterials can reduce the process. Oral digoxin formulations with a high bioavailability are mostly absorbed in the stomach and upper small intestine and little digoxin is available in the lower intestine for bacterial degradation to dihydrodigoxin.[4]

The excretion of digoxin is thought to be mediated by the efflux pump, P-glycoprotein,[5] which transports its substrates out of the cell. This may be the basis for some interactions hitherto poorly understood,[6] although the hypothesis has been questioned.[7]

Renal impairment. For references to alterations in the pharmacokinetics of digoxin in patients with renal impairment, see under Uses and Administration, below.

Uses and Administration

Digoxin is a cardiac glycoside used in the management of supraventricular arrhythmias, particularly atrial fibrillation (p.1160), and in heart failure (p.1165).

The principal actions of digoxin are an increase in the force of myocardial contraction (positive inotropic activity) and a reduction in the conductivity of the heart, particularly in conduction through the atrioventricular (AV) node. Digoxin also has a direct action on vascular smooth muscle and indirect effects mediated primarily by the autonomic nervous system, and particularly by an increase in vagal activity. There are also reflex alterations in autonomic activity due to the effects on the circulation. Overall, these actions result in positive inotropic effects, negative chronotropic effects, and decreased AV nodal activity.

Cardiac arrhythmias. In atrial arrhythmias digoxin's actions cause a decrease in the conduction velocity through the AV node and an increase in the effective refractory period, thus reducing ventricular rate. In addition there is a decrease in the refractory period of the cardiac muscle and depression of the sinus node partly in response to the increase in vagal activity.

Digoxin is thus given to slow the increased ventricular rate that occurs in response to *atrial fibrillation*, although other drugs may be preferred; treatment is usually long term. In patients with the Wolff-Parkinson-White syndrome and atrial fibrillation, digoxin can cause rapid ventricular rates, and possibly ventricular fibrillation, and should be avoided. In *atrial flutter*, the ventricular rate is normally more difficult to control with digoxin. Drug therapy is not the preferred method of treatment, but treatment with digoxin may restore sinus rhythm, or it may convert the flutter to fibrillation and sinus rhythm may then be induced by subsequent withdrawal of digoxin. Digoxin may be given to relieve an attack of *paroxysmal supraventricular tachycardia* and has also been given to prevent further attacks.

Heart failure. Digoxin and other cardiac glycosides directly inhibit the activity of the enzyme sodium-potassium adenosine triphosphatase (Na/K-ATPase), which is required for the active transport of sodium from myocardial cells. The result is a gradual increase in the intracellular sodium concentration and a decrease in the intracellular potassium concentration. The increased concentration of sodium inside the cells leads, by stimulation of sodium-calcium exchange, to an increase in the intracellular calcium concentration with enhancement of mechanical contractile activity and an increased inotropic effect.

When used in heart failure the increased force of myocardial contraction results in increased cardiac output, decreased end-systolic volume, decreased heart size, and decreased end-diastolic pressure and volume. Increased blood flow through the kidneys results in diuresis with a reduction in oedema and blood volume. The decrease in pulmonary venous pressure relieves dyspnoea and orthopnoea. Digoxin may thus provide symptomatic improvement in patients with heart failure and is mainly used for adjunctive therapy.

Dosage. When given orally, digoxin may take effect within about 2 hours and the maximum effect may be reached in about 6 hours. Initially a loading dose may be given to digitalise the patient, although this may not be necessary in, for example, mild heart failure.

Dosage should be carefully adjusted to the needs of the individual patient. Factors which may be considered include the patient's age, lean body-mass, renal status, thyroid status, electrolyte balance, degree of tissue oxygenation, and the nature of the underlying cardiac or pulmonary disease. Bearing in mind the above factors, steady-state plasma-digoxin concentrations (in a sample taken at least 6 hours after a dose) of 0.5 to 2 nanograms/mL are generally considered acceptable, although in patients with heart failure concentrations at the lower end of the range may be more appropriate. For reference to therapeutic drug monitoring, see below.

If rapid digitalisation is required then a loading dose is given to allow for the large volume of distribution. A total loading dose of 750 to 1500 micrograms of digoxin may be given by mouth during the initial 24-hour period, either as a single dose, or where there is less urgency or greater risk of toxicity, in divided doses at 6-hourly intervals. In some patients, for example those with mild heart failure, a loading dose may not be necessary, and digitalisation may be achieved more slowly with doses of 250 micrograms once or twice daily; steady-state plasma concentrations are achieved in about 7 days in patients with normal renal function. The usual maintenance dose of digoxin is 125 to 250 micrograms by mouth daily, but may range from 62.5 to 500 micrograms daily. In elderly patients therapy should generally start gradually and with smaller doses (but see under Administration in the Elderly, below).

In urgent cases, provided that the patient has not received cardiac glycosides during the previous 2 weeks, digoxin may be given intravenously initially. The intravenous dose ranges from 500 to 1000 micrograms and generally produces a definite effect on the heart rate in about 10 minutes, reaching a maximum within about 2 hours. It is given by intravenous infusion, either as a single dose given over 2 or more hours, or in divided doses each over 10 to 20 minutes. Maintenance treatment is then usually given by mouth. Digoxin has also been given intramuscularly but this route is not generally recommended since such injections may be painful and tissue damage has been reported. Digoxin should not be given subcutaneously as intense local irritation may occur.

Children's doses are complex. They are based on body-weight and the developmental stage of the child as well as on response. Premature infants are especially sensitive to digoxin but, along with all other neonates, infants, and children up to about 10 years of age, still require doses that are higher per kg body-weight than those used for adults. Preterm infants receive lower doses than full-term infants, while children aged 2 to 10 years require lower doses than children up to 2 years of age. As an indication of the doses used, oral loading doses recommended by licensed product information in the UK range from 25 to 45 micrograms/kg over 24 hours and in the USA the range is 20 to 60 micrograms/kg; the range for intravenous loading doses given over 24 hours is 20 to 35 micrograms/kg in the UK and 15 to 50 micrograms/kg in the USA.

Doses should be reduced in patients with renal impairment (see below).

Administration in the elderly. The volume of distribution of digoxin and the elimination half-life increase with age.[1] Therefore there are problems in giving digoxin to elderly patients since steady-state plasma concentrations may not be reached for up to 2 weeks. Fears of toxicity have led some practitioners to use a fixed 'geriatric' dose of 62.5 micrograms daily. However, such a dose can produce subtherapeutic concentrations.[2] The routine use of very low doses of digoxin in the elderly is inappropriate and dosage should be individualised.

Administration in renal impairment. The pharmacokinetics of cardiac glycosides in patients with renal impairment have been reviewed.[1] The rate but not the extent of digoxin absorption is reduced in renal impairment but this is unlikely to be clinically important. Plasma-protein binding may also be reduced but since digoxin is poorly bound to these proteins and has a large apparent volume of distribution this also is unlikely to be important. The apparent volume of distribution is reduced by one-third to one-half and the loading dose of digoxin should therefore be reduced; an oral loading dose of 10 micrograms/kg is suggested (but see also under Therapeutic Drug Monitoring, below). Non-renal clearance of digoxin is unaffected or only slightly reduced but renal clearance is reduced, the extent being closely related to creatinine clearance. The elimination half-life of digoxin is prolonged and it therefore takes longer to reach steady state and longer for toxicity to resolve. Because of the reduction in renal clearance of digoxin, maintenance doses must be reduced in line with renal function. Serum-digoxin concentration should be monitored although the presence of digoxin-like immunoreactive substances may make interpretation difficult. In addition, the presence of hyperkalaemia in patients with renal impairment may reduce sensitivity to the effects of digoxin.[2]

Since digoxin has such a large distribution volume, procedures such as peritoneal dialysis and haemodialysis remove only very small amounts of drug from the body and no dosage supplement is needed.

Therapeutic drug monitoring. Digoxin has a narrow therapeutic index. It is generally considered that plasma-digoxin concentrations required for a therapeutic effect are usually between 0.5 and 2.0 nanograms/mL,[1-3] although some studies[4-6] have suggested that concentrations of 0.5 to 0.9 nanograms/mL are adequate for heart failure; concentrations at the upper end of the range may be associated with worse outcomes.[5,6] The factor for converting nanograms/mL to nanomoles/litre is 1.28.

Digoxin dosage can be calculated in uncomplicated cases by considering the patient's weight, renal function, and clinical status. Therapeutic drug monitoring is *not* considered to be necessary in patients with a satisfactory clinical response to conventional doses in the absence of signs or symptoms of toxicity.[1,2] Measurement of plasma-digoxin concentrations is useful if poor compliance is suspected, if response is poor or there is a deterioration in response without apparent reason, if renal function is fluctuating, when it is unknown if a cardiac glycoside has been previously taken, during drug interactions, and to confirm clinical toxicity.[1,3,7] A plasma concentration should never be considered in isolation and should be used with other patient data as an important component in clinical decision making. This is particularly important in the diagnosis of digoxin toxicity since signs and symptoms of toxicity may be difficult to distinguish from the underlying disease and can occur within the usual therapeutic range.

A number of factors may influence the response to digoxin and thus the interpretation of digoxin assays. These include renal impairment, extremes of age, thyroid disease, patient compliance, drug interactions, and electrolyte disturbances.[1-3,7] Variations in the bioavailability of different digoxin preparations have also caused problems. Renal impairment and hypokalaemia are two of the most important factors affecting dosage of digoxin and whenever plasma-digoxin concentrations are assayed renal function and plasma potassium should also be measured. A dosing nomogram has been proposed[8] relating dose in patients with heart failure to renal function and either height or ideal body weight: for most patients with moderate or severe renal impairment (creatinine clearance below 60 mL/minute) an oral dose of 125 micrograms every other day was considered sufficient. The interpretation of digoxin assays is further confounded by the presence of digoxin-like immunoreactive substances in patients with renal or hepatic impairment, in pregnant women, and in neonates. Blood samples for digoxin assay should be taken at least 6 hours after a dose to allow for distribution.[1,3,7]

The usefulness of plasma-digoxin concentrations in the diagnosis of toxicity in children is unclear. For children older than 12 months the adult guidelines can probably be followed, and for younger children the trend for increased risk of toxicity at increased plasma-digoxin concentrations appears to hold but the threshold for toxicity may be higher, especially in children less than 3 months old.[1]

Dihydralazine Sulfate *(rINNM)*

Dihidralazino sulfatas, hidratuotas; Dihidralazin-szulfát-hidrát; Dihydralatsiinisulfaatti, hydratoitu; Dihydralazine, Sulfate de; Dihydralazine (sulfate de) hydraté; Dihydralazine Sulphate *(BANM)*; Dihydralazini Sulfas; Dihydralazini sulfas hydricus; Dihydralazinsulfát; Dihydralazinsulfat, hydratiserat; Dihydralazinum Sulfuricum; Dihydralazyny siarczan; Dihydrallazine Sulphate; Sulfato de dihidralazina. Phthalazine-1,4-diyldihydrazine sulfate hemipentahydrate.

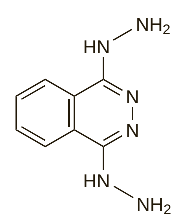
Дигидралазина Сульфат

$C_8H_{10}N_6,H_2SO_4,2\frac{1}{2}H_2O = 333.3.$

CAS — 484-23-1 (dihydralazine); 7327-87-9 (dihydralazine sulfate).

ATC — C02DB01.

ATC Vet — QC02DB01.



(dihydralazine)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dihydralazine Sulphate, Hydrated). A white or slightly yellow crystalline powder. Slightly soluble in water; practically insoluble in dehydrated alcohol. It dissolves in dilute mineral acids.

Profile

Dihydralazine is a vasodilator with actions and uses similar to those of hydralazine (p.1305). It is given orally as the sulfate. Dihydralazine sulfate hemipentahydrate 14.45 mg is equivalent to about 12.5 mg of anhydrous dihydralazine sulfate. In hypertension (p.1171) the usual initial dose is the equivalent of 12.5 mg of anhydrous dihydralazine sulfate twice daily and the maximum recommended dose is 50 mg twice daily. Higher doses have been used in the management of heart failure.

Other salts of dihydralazine that have been used in oral preparations include the hydrochloride and the tartrate. The mesilate is given by injection.

Porphyria. Dihydralazine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Nepresol; ***Belg.:*** Nepresol; ***Cz.:*** Nepresol†; ***Fr.:*** Nepressol; ***Ger.:*** Depressan; Nepresol; ***Gr.:*** Nepresol; ***Hong Kong:*** Nepresol†; ***Hung.:*** De-

pressan; ***India:*** Nepresol; ***Malaysia:*** Nepresol†; ***S.Afr.:*** Nepresol†; ***Swed.:*** Nepresol†; ***Switz.:*** Nepresol†; ***Thai.:*** Nepresol.

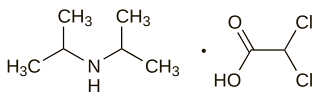
Di-isopropylammonium Dichloroacetate

Diisopropilamina, dicloroacetato de; Di-isopropylamine Dichloroacetate; Di-isopropylamine Dichloroethanoate; DIPA-DCA.

$C_8H_{17}Cl_2NO_2$ = 230.1.

CAS — 660-27-5.



Profile

Di-isopropylammonium dichloroacetate is a vasodilator that has been given in peripheral and cerebral vascular disorders. Preparations containing it have sometimes been described as 'pangamic acid' (p.2362).

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Disotat†; Oxypangam†; ***Mex.:*** Ditrei.

Multi-ingredient: ***Hong Kong:*** Liverall†; ***Spain:*** Vitaber A E.

Dilazep Hydrochloride *(rINNM)*

Asta C-4898; Dilazep, Chlorhydrate de; Dilazepi Hydrochloridum; Hidrocloruro de dilazep. Perhydro-1,4-diazepin-1,4-diylbis(trimethylene 3,4,5-trimethoxybenzoate) dihydrochloride.

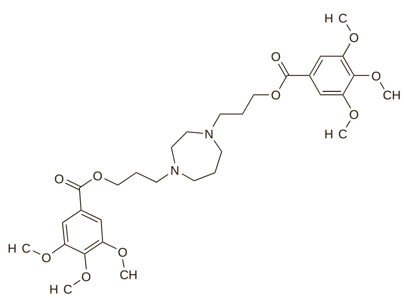
Дилазепа Гидрохлорид

$C_{31}H_{44}N_2O_{10}$,2HCl = 677.6.

CAS — 35898-87-4 (dilazep); 20153-98-4 (dilazep hydrochloride).

ATC — C01DX10.

ATC Vet — QC01DX10.



(dilazep)

Pharmacopoeias. *Jpn* includes the monohydrate.

Profile

Dilazep hydrochloride is a vasodilator that is used in ischaemic heart disease.

Preparations

Proprietary Preparations (details are given in Part 3)
India: Cormelian; ***Jpn:*** Comelian.

Diltiazem Hydrochloride

(BANM, USAN, rINNM)

CRD-401; Diltiatseemihydrokloridi; Diltiazem, chlorhydrate de; Diltiazem Hidroklorür; Diltiazem hydrochlorid; Diltiazem-hidroklorid; Diltiazemhydroklorid; Diltiazemi hydrochloridum; Diltiazemo hidrochloridas; Diltiazemu chlorowodorek; Hidrocloruro de diltiazem; Latiazem Hydrochloride; MK-793 (diltiazem malate). (+)-*cis*-3-Acetoxy-5-(2-dimethylaminoethyl)-2,3-dihydro-2-(4-methoxyphenyl)-1,5-benzothiazepin-4(5*H*)-one hydrochloride; (2*S*,3*S*)-5-(2-Dimethylaminoethyl)-2,3,4,5-tetrahydro-2-(4-methoxyphenyl)-4-oxo-1,5-benzothiazepin-3-yl acetate hydrochloride.

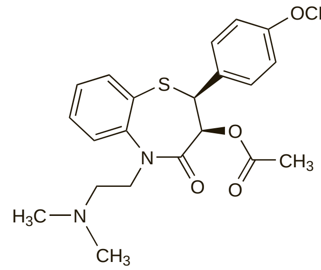
Дилтиазема Гидрохлорид

$C_{22}H_{26}N_2O_4S$,HCl = 451.0.

CAS — 42399-41-7 (diltiazem); 33286-22-5 (diltiazem hydrochloride); 144604-00-2 (diltiazem malate).

ATC — C08DB01.

ATC Vet — QC08DB01.



(diltiazem)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Diltiazem Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water, in dichloromethane, and in methyl alcohol; slightly soluble in dehydrated alcohol. The pH of a 1% solution in water is 4.3 to 5.3. Store in airtight containers. Protect from light.

USP 31 (Diltiazem Hydrochloride). A white, odourless, crystalline powder, or small crystals. Freely soluble in water, in chloroform, in formic acid, and in methyl alcohol; sparingly soluble in dehydrated alcohol; insoluble in ether. Store in airtight containers. Protect from light.

Adverse Effects

Treatment with diltiazem is generally well tolerated. Headache, ankle oedema, hypotension, dizziness, flushing, fatigue, and nausea and other gastrointestinal disturbances (including anorexia, vomiting, constipation or diarrhoea, taste disturbances, and weight gain) may occur. Gingival hyperplasia has been reported. Rashes, possibly due to hypersensitivity, are normally mild and transient, but in a few cases erythema multiforme or exfoliative dermatitis has developed; photosensitivity reactions may also occur. Transient elevations in liver enzyme values, and occasionally hepatitis, have been reported.

Diltiazem may depress cardiac conduction and has occasionally led to AV block, bradycardia, and rarely asystole or sinus arrest.

Overdosage with diltiazem may be associated with bradycardia, with or without AV conduction defects, and hypotension.

Diltiazem has been shown to cause teratogenicity in *animal* studies.

Effects on mortality. For discussion of the possibility that calcium-channel blockers might be associated with increased cardiovascular mortality, see under Adverse Effects of Nifedipine, p.1350.

Angioedema. Periorbital angioedema, accompanied by pruritus or burning and erythema developed in 2 patients given diltiazem.[1]

1. Sadick NS, *et al.* Angioedema from calcium channel blockers. *J Am Acad Dermatol* 1989; **21:** 132–3.

Effects on the blood. Thrombocytopenia has been reported in association with diltiazem.[1,2]

1. Lahav M, Arav R. Diltiazem and thrombocytopenia. *Ann Intern Med* 1989; **110:** 327.
2. Michalets EL, Jackson DV. Diltiazem-associated thrombocytopenia. *Pharmacotherapy* 1997; **17:** 1345–8.

Effects on carbohydrate metabolism. Although raised blood-glucose concentrations and insulin requirements have been reported[1] in a patient with type 1 diabetes mellitus during diltiazem therapy, particularly at high doses, a study[2] in 11 obese black women, who were nondiabetic but had a family history of type 2 diabetes, failed to find any effect of diltiazem 240 mg daily on plasma-glucose and C-peptide concentrations, nor any clinical signs of glucose intolerance.

1. Pershadsingh HA, *et al.* Association of diltiazem therapy with increased insulin resistance in a patient with type I diabetes mellitus. *JAMA* 1987; **257:** 930–1.
2. Jones BJ, *et al.* Effects of diltiazem hydrochloride on glucose tolerance in persons at risk for diabetes mellitus. *Clin Pharm* 1988; **7:** 235–8.

Effects on the ears. There have been isolated reports[1] of tinnitus associated with several calcium-channel blockers including nifedipine, nicardipine, nitrendipine, diltiazem, verapamil, and cinnarizine.

1. Narváez M, *et al.* Tinnitus with calcium-channel blockers. *Lancet* 1994; **343:** 1229–30.

Effects on the gastrointestinal tract. Gastrointestinal disturbances including nausea, vomiting, and constipation, may occur with calcium-channel blockers. A case[1] of intestinal pseudo-obstruction was reported in a 74-year-old neutropenic man receiving chemotherapy for leukaemia after diltiazem was added to treat new-onset atrial fibrillation. A diagnosis of neutropenic enterocolitis was ruled out and symptoms resolved when diltiazem was stopped; it was concluded that diltiazem was the probable cause.

A similar case attributed to verapamil[2] has been reported.

1. Young RP, Wu H. Intestinal pseudo-obstruction caused by diltiazem in a neutropenic patient. *Ann Pharmacother* 2005; **39:** 1749–51.
2. Schultz HS, Vernon B. Intestinal pseudo-obstruction related to using verapamil. *West J Med* 1989; **151:** 556–8.

Effects on the heart. *AV BLOCK.* AV block appears to be uncommon in patients receiving diltiazem, but is potentially serious when it occurs. Prescription-event monitoring[1] of a cohort of 10 119 patients for 1 year revealed 22 reports of AV block during diltiazem treatment. At least 8 patients had third-degree heart block, and 12 required a pacemaker; 3 died within 72 hours of the onset of heart block. A high proportion of these patients were also receiving beta blockers, which is in line with other reports.[2,3] (See also Beta Blockers under Interactions, below.) There is some evidence that the incidence of this effect may depend on the serum concentration of diltiazem. In a study[4] in patients receiving diltiazem after myocardial infarction, patients with serum-diltiazem concentrations greater than 150 nanograms/mL were more likely to experience AV block than patients with concentrations of diltiazem below this value.

1. Waller PC, Inman WHW. Diltiazem and heart block. *Lancet* 1989; **i:** 617.
2. Hossack KF. Conduction abnormalities due to diltiazem. *N Engl J Med* 1982; **307:** 953–4.

4. Nattel S, *et al.* Determinants and significance of diltiazem plasma concentrations after acute myocardial infarction. *Am J Cardiol* 1990; **66:** 1422–8.

MYOCARDIAL INFARCTION. Results from at least one large multicentre study (the Multicenter Diltiazem Postinfarction Trial) suggest that diltiazem, although apparently of benefit after myocardial infarction in patients with normal left ventricular function (as indicated by absence of pulmonary congestion), was associated with an increased risk of cardiac death or nonfatal re-infarction in patients with impaired left ventricular function.[1] Long-term follow-up[2] indicated that diltiazem also increased the risk of late-onset heart failure in postinfarction patients with left ventricular dysfunction.

WITHDRAWAL. Life-threatening coronary vasospasm, which was fatal in one patient, occurred in 4 patients after coronary revascularisation for unstable angina.[1] Treatment with a calcium-channel blocker (diltiazem or nifedipine) had been discontinued between 8 and 18 hours before the procedure and this abrupt withdrawal was thought to be responsible for the rebound vasospasm. The coronary vasospasm was managed with glyceryl trinitrate and nifedipine.

Withdrawal of diltiazem over a 4-day period from a patient with stable angina pectoris was followed by recurrence of anginal attacks.[2] Ambulatory ECG monitoring confirmed worsening myocardial ischaemia that responded to re-introduction of diltiazem. Two further patients had a similar withdrawal effect.

2. Subramanian VB, *et al.* Calcium antagonist withdrawal syndrome: objective demonstration with frequency-modulated ambulatory ST-segment monitoring. *BMJ* 1983; **286:** 520–1.

Effects on the kidneys. Diltiazem may be of benefit in various kidney disorders (see under Uses, below). However, there are a few reports of acute renal failure associated with diltiazem use.[1,2] Acute interstitial nephritis has been proposed as a mechanism.[2,3]

1. ter Wee PM, *et al.* Acute renal failure due to diltiazem. *Lancet* 1984; **ii:** 1337–8.
2. Abadín JA, *et al.* Probable diltiazem-induced acute interstitial nephritis. *Ann Pharmacother* 1998; **32:** 656–8.
3. Achenbach V, *et al.* Acute renal failure due to diltiazem. *Lancet* 1985; **i:** 176.

Effects on mental function. By September 1989, the WHO collaborative programme for international drug monitoring had gathered 8 cases of mental depression (severe in 2) associated with diltiazem therapy.[1] Time of onset of symptoms varied from a few hours to a few months after starting treatment with diltiazem. There was some evidence that the problem might be dose-related as 5 of the 8 cases were receiving doses of 180 mg daily or more.

Psychoses have been reported rarely in association with diltiazem. A patient[2] who developed hallucinations (both auditory and visual) and paranoid delusions after 2 days of diltiazem therapy was subsequently treated with nifedipine without abnormal effects. Another patient[3] with bipolar affective disorder that had been well-controlled by lithium carbonate for some years developed acute psychosis with extrapyramidal symptoms of cogwheel rigidity and ataxia, which was thought to represent an interaction between diltiazem and lithium.

1. Biriell C, *et al.* Depression associated with diltiazem. *BMJ* 1989; **299:** 796.
2. Bushe CJ. Organic psychosis caused by diltiazem. *J R Soc Med* 1988; **81:** 296–7.
3. Binder EF. Diltiazem-induced psychosis and a possible diltiazem-lithium interaction. *Arch Intern Med* 1991; **151:** 373–4.

Effects on the mouth. A study involving 115 patients given nifedipine, diltiazem, or verapamil for at least 3 months indicated that gingival hyperplasia is an important side-effect that may occur with calcium-channel blockers.[1]

1. Steele RM, *et al.* Calcium antagonist-induced gingival hyperplasia. *Ann Intern Med* 1994; **120:** 663–4.

Effects on the nervous system. Akathisia has been reported in a patient the day after starting treatment with diltiazem. Symptoms disappeared when diltiazem was withdrawn and recurred on rechallenge after the third dose.[1] Similar symptoms in association with mania have also been reported in another patient given diltiazem.[2]

1. Jacobs MB. Diltiazem and akathisia. *Ann Intern Med* 1983; **99:** 794–5.
2. Brink DD. Diltiazem and hyperactivity. *Ann Intern Med* 1984; **100:** 459–60.

PARKINSONISM. Parkinsonism developed in an elderly patient with heart disease and hypertension when diltiazem was added to existing drug therapy.[1] Symptoms worsened over 3 months but improved significantly when diltiazem was slowly withdrawn. On rechallenge severe tremor, impaired gait, and cogwheel rigidity recurred, but resolved when the drug was stopped again except for slight residual cogwheel rigidity.

An acute parkinsonian syndrome also developed[2] in a patient taking lithium and tiotixene when diltiazem was added, and was thought to represent an interaction between lithium and diltiazem. See also Effects on Mental Function, above.

2. Valdiserri EV. A possible interaction between lithium and diltiazem: case report. *J Clin Psychiatry* 1985; **46:** 540–1.

Effects on the skin. A variety of skin disorders have been associated with diltiazem therapy, including acute pustular dermatitis,[1-3] cutaneous vasculitis,[4,5] erythema multiforme,[6,7] pruritic macular rashes,[3,8] severe toxic erythema,[9] subacute lupus erythematosus-like eruptions,[10] and photosensitivity reactions.[11] Analysis of cutaneous adverse reactions to diltiazem indicated that acne, rash, and urticaria were among the commonest.[12] There have also been a few reports of exfoliative dermatitis, erythema multiforme, Stevens Johnson syndrome, and toxic epidermal necrolysis.[3,12]

For a report of periorbital skin rash associated with diltiazem, see Angioedema, above.

Cross-sensitivity, manifest as a pruritic maculopapular rash, has been reported between diltiazem and amlodipine.[13]

Overdosage. See under Treatment of Adverse Effects, below.

Treatment of Adverse Effects

As for Nifedipine, p.1352, but see also below.

Diltiazem and its metabolites are poorly dialysable.

Overdosage. The consequences and treatment of diltiazem overdosage are similar to nifedipine (p.1352), although death and life-threatening complications might be more common with diltiazem.[1] Up to 1994, 6 cases of fatal overdose with diltiazem had been reported in the literature.[2] Measurement of diltiazem concentrations to assist in diagnosis and management of overdosage has been suggested,[2] but others[3] have disputed its value.

The following are individual reports of overdosage with diltiazem:

- A patient who took about 10.8 g of diltiazem developed hypotension and complete heart block. Dopamine, isoprenaline, and calcium chloride were required to maintain the blood pressure. The ECG reverted to sinus rhythm after 31 hours. The plasma-diltiazem concentration was 1670 nanograms/mL 43 hours after ingestion and fell to 12.1 nanograms/mL over a further 55.5 hours with an elimination half-life of 7.9 hours.[4]
- In a further case a patient took 5.88 g of diltiazem with alcohol, and developed severe junctional bradycardia, hypotension, and reduced cardiac function that did not respond to intravenous calcium gluconate. The maximum plasma-diltiazem concentration of 6090 nanograms/mL occurred 7 hours after presentation. About half of the dose was vomited after treatment with activated charcoal. The patient was treated with cardiac pacing and a dopamine infusion; he reverted to sinus rhythm within 24 hours, and a subsequent episode of atrial fibrillation was treated successfully with digoxin.[5]
- Charcoal haemoperfusion had a limited effect in improving the clearance of diltiazem in a patient who had taken 14.94 g of diltiazem.[6] The patient developed severe hypotension, complete heart block, and acute renal failure. Supportive care included cardiac pacing and numerous vasopressors including intravenous glucagon and infusions of dopamine, adrenaline, and noradrenaline.

6. Williamson KM, Dunham GD. Plasma concentrations of diltiazem and desacetyldiltiazem in an overdose situation. *Ann Pharmacother* 1996; **30:** 608–11.

Precautions

Diltiazem is contra-indicated in patients with the sick sinus syndrome, pre-existing second- or third-degree AV block, or marked bradycardia, and should be used with care in patients with lesser degrees of AV block or bradycardia. Diltiazem has been associated with the development of heart failure and great care is required in patients with impaired left ventricular function. Sudden withdrawal of diltiazem might be associated with an exacerbation of angina.

Treatment with diltiazem should begin with reduced doses in elderly patients and in patients with hepatic or renal impairment.

Abuse. Abuse of diltiazem by body builders and rugby players has been alleged. Such abuse is possibly because of evidence that diltiazem increases maximum oxygen consumption after training. A body builder who admitted to taking diltiazem in high doses suffered severe abdominal cramps.[1]

1. Richards H, *et al.* Use of diltiazem in sport. *BMJ* 1993; **307:** 940.

Breast feeding. Diltiazem is distributed into breast milk; in a woman receiving oral diltiazem 60 mg four times daily, concentrations in breast milk were similar to those in serum.[1] The manufacturers therefore recommend that diltiazem should generally be avoided during breast feeding. However, in another report,[2] a mother breast fed twins for at least 6 months while receiving diltiazem and no adverse effects were reported in the infants. Since there have been no reports of adverse effects, the American Academy of Pediatrics considers[3] that diltiazem is usually compatible with breast feeding.

Porphyria. Diltiazem is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Renal impairment. A patient with end-stage renal failure requiring haemodialysis developed hypotension, bradycardia, metabolic acidosis, hyperkalaemia, and acute congestive heart failure about 60 hours after his last haemodialysis.[1] The patient had been taking diltiazem 60 mg three times daily. The symptoms were attributed to diltiazem toxicity due to accumulation of diltiazem and its metabolites which are poorly dialysed and normally excreted partially in the urine.

1. Patel R, *et al.* Toxic effects of diltiazem in a patient with chronic renal failure. *J Clin Pharmacol* 1994; **34:** 273–4.

Interactions

Increased depression of cardiac conduction with risk of bradycardia and AV block may occur when diltiazem is given with drugs such as amiodarone, beta blockers, digoxin, and mefloquine. Enhanced antihypertensive effect may occur if used with other antihypertensive drugs or drugs that cause hypotension such as aldesleukin and antipsychotics. Diltiazem is extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4 and may also inhibit the metabolism of drugs sharing the same pathway. Interactions may also be expected with enzyme inducers, such as carbamazepine, phenobarbital, phenytoin, and rifampicin, and with enzyme inhibitors, such as cimetidine and HIV-protease inhibitors.

Antidepressants. For a report of diltiazem increasing the bioavailability of *imipramine* and *nortriptyline*, see Calcium-channel Blockers under the Interactions of Amitriptyline, p.380.

Antiepileptics. For reports of diltiazem use precipitating *carbamazepine* and *phenytoin* toxicity, see p.475 and p.499, respectively.

Anxiolytics. For the effect of diltiazem on plasma-*buspirone* concentrations, see p.966.

Benzodiazepines. For the effects of diltiazem on plasma concentrations of *midazolam* or *triazolam*, see Calcium-channel Blockers under Interactions of Diazepam, p.990.

Beta blockers. Profound bradycardia has been reported in a number of patients when diltiazem was used with a beta blocker.[1,2] Diltiazem decreases the clearance of a single dose of *propranolol* or *metoprolol*, though not *atenolol*, and elevated concentrations of beta blocker may be responsible for the bradycardic effects.[3] This is unlikely to be the full story, however, since atenolol, which was unaffected in this study, has been implicated in producing bradycardia when diltiazem was added in a patient with myocardial ischaemia.[2]

1. Hassell AB, Creamer JE. Profound bradycardia after the addition of diltiazem to a β blocker. *BMJ* 1989; **298:** 675.
2. Nagle RE, *et al.* Diltiazem and heart block. *Lancet* 1989; **i:** 907.
3. Tateishi T, *et al.* Effect of diltiazem on the pharmacokinetics of propranolol, metoprolol and atenolol. *Eur J Clin Pharmacol* 1989; **36:** 67–70.

Calcium-channel blockers. For the effect of diltiazem and *nifedipine* on each other's plasma concentrations, see p.1353.

Ciclosporin. For reports of a potentially beneficial interaction between diltiazem and ciclosporin, see Transplantation under Uses and Administration, below.

Corticosteroids. Diltiazem has been reported to reduce the clearance of *methylprednisolone* (see Calcium-channel Blockers, p.1495).

Digoxin. For a discussion of interactions between digoxin and calcium-channel blockers including diltiazem, see p.1262.

General anaesthetics. Two patients on diltiazem therapy developed impaired myocardial conduction during anaesthesia with *enflurane*;[1] one of the patients had severe sinus bradycardia that progressed to asystole. Additive cardiodepressant effects of diltiazem and enflurane were considered responsible.

1. Hantler CB, *et al.* Impaired myocardial conduction in patients receiving diltiazem therapy during enflurane anesthesia. *Anesthesiology* 1987; **67:** 94–6.

Histamine H_2-antagonists. *Cimetidine* caused increases in plasma-diltiazem concentrations and in plasma-deacetyldiltiazem concentrations in 6 subjects given a single oral dose of diltiazem 60 mg. *Ranitidine* produced a similar, though less marked effect.[1]

1. Winship LC, *et al.* The effect of ranitidine and cimetidine on single-dose diltiazem pharmacokinetics. *Pharmacotherapy* 1985; **5:** 16–19.

Lithium. Neurotoxicity has been reported in patients receiving lithium and diltiazem, see Effects on Mental Function and Parkinsonism under Effects on the Nervous System, above.

Theophylline. For the effect of diltiazem on plasma-theophylline concentrations, see p.1144.

Pharmacokinetics

Diltiazem is almost completely absorbed from the gastrointestinal tract after oral doses, but undergoes extensive first-pass hepatic metabolism. Peak plasma concentrations occur about 3 to 4 hours after an oral dose. The bioavailability has been reported to be about 40%, although there is considerable interindividual variation in plasma concentrations. Diltiazem is about 80% bound to plasma proteins. It is distributed into breast milk. It is extensively metabolised in the liver, primarily by the cytochrome P450 isoenzyme CYP3A4; one of the metabolites, desacetyldiltiazem, has been reported to have 25 to 50% of the activity of the parent compound. The half-life of diltiazem is reported to be about 3 to 5 hours. About 2 to 4% of a dose is excreted in urine as unchanged diltiazem with the remainder excreted as metabolites in bile and urine. Diltiazem and its metabolites are poorly dialysable.

◊ General reviews.

1. Kelly JG, O'Malley K. Clinical pharmacokinetics of calcium antagonists: an update. *Clin Pharmacokinet* 1992; **22:** 416–33.

Bioavailability. Studies of the pharmacokinetics of diltiazem in healthy subjects after single and multiple doses,[1-3] indicated that bioavailability was increased after multiple doses, probably because of decreased presystemic elimination.[3]

1. Höglund P, Nilsson L-G. Pharmacokinetics of diltiazem and its metabolites after repeated multiple-dose treatments in healthy volunteers. *Ther Drug Monit* 1989; **11:** 543–50.
2. Höglund P, Nilsson L-G. Pharmacokinetics of diltiazem and its metabolites after repeated single dosing in healthy volunteers. *Ther Drug Monit* 1989; **11:** 551–7.
3. Höglund P, Nilsson L-G. Pharmacokinetics of diltiazem and its metabolites after single and multiple dosing in healthy volunteers. *Ther Drug Monit* 1989; **11:** 558–66.

Renal impairment. The pharmacokinetics of diltiazem and its major metabolite desacetyldiltiazem in patients with severe renal impairment were similar to those in patients with normal renal function.[1] Nevertheless, reduced doses may be necessary in patients with renal impairment (see under Uses and Administration below). See also under Precautions, above.

1. Pozet N, *et al*. Pharmacokinetics of diltiazem in severe renal failure. *Eur J Clin Pharmacol* 1983; **24:** 635–8.

Uses and Administration

Diltiazem is a benzothiazepine calcium-channel blocker (p.1154) and class IV antiarrhythmic (p.1153). It is a peripheral and coronary vasodilator with limited negative inotropic activity but its vasodilator properties are less marked than those of the dihydropyridine calcium-channel blocker nifedipine (p.1350). Unlike nifedipine, diltiazem inhibits cardiac conduction, particularly at the sino-atrial and atrioventricular nodes.

Diltiazem hydrochloride is given orally in the management of angina pectoris (p.1157) and hypertension (p.1171) and is available in a number of formulations for dosage once, twice, or three times daily. In some countries it is available for intravenous use in the treatment of various cardiac arrhythmias (atrial fibrillation or flutter and paroxysmal supraventricular tachycardia) (p.1160). It has also been used topically in the management of anal fissure (see below).

The variety of formulations means that dosage is dependent on the preparation used. Reduced doses may be required in the elderly or those with renal or hepatic impairment (see below).

In **angina pectoris** an initial dose is 60 mg orally three times daily (or 30 mg four times daily in the USA), increased if necessary to 360 mg daily; up to 480 mg daily has sometimes been given. Formulations suitable for once- or twice-daily use may be given in doses of 120 to 480 mg daily; up to 540 mg daily has been given.

In **hypertension** diltiazem hydrochloride may be given as modified-release capsules or tablets. Depending on the formulation, an initial dose is 60 to 120 mg twice daily, increased as required to a maximum of 360 mg daily. Formulations suitable for once-daily dosage may be given in similar daily doses, although up to 540 mg daily has been given.

In **cardiac arrhythmias** an initial dose of 250 micrograms/kg by bolus intravenous injection over 2 minutes has been suggested; a further dose of 350 micrograms/kg may be given after 15 minutes if the response is inadequate. Subsequent doses should be individualised for each patient. For those with atrial fibrillation or flutter, a continued reduction in heart rate may be achieved with an intravenous infusion of diltiazem hydrochloride after the bolus injection. An initial infusion rate of 5 to 10 mg/hour, may be increased as necessary in increments of 5 mg/hour up to a rate of 15 mg/hour. The infusion may be continued for up to 24 hours.

◊ General reviews.

Action. The haemodynamic and electrophysiological effects of diltiazem appear to resemble those of verapamil more than those of nifedipine.[1] It inhibits sino-atrial and atrioventricular nodal function in doses used clinically. The effects on sino-atrial function are more pronounced than those observed after verapamil. Diltiazem causes a decrease in the rate-pressure product indicating that decreased oxygen demand is a likely mechanism of action in relieving angina pectoris. Like verapamil, but unlike nifedipine, diltiazem does not appear to cause significant increases in coronary blood flow. The negative inotropic effect of diltiazem is presumably counteracted by afterload reduction.

1. Soward AL, *et al*. The haemodynamic effects of nifedipine, verapamil and diltiazem in patients with coronary artery disease: a review. *Drugs* 1986; **32:** 66–101.

Administration in hepatic or renal impairment. The dose of diltiazem hydrochloride may need to be reduced in patients with hepatic or renal impairment, and in the elderly. In the UK an initial dose of 120 mg daily is usually suggested, as a single dose or in 2 divided doses by mouth depending on the formulation. The dose may be increased cautiously, but only if the heart rate remains above 50 beats/minute.

Anorectal disorders. Beneficial responses to diltiazem reported[1,2] in 2 patients with *proctalgia fugax* may have been due to smooth muscle relaxation. The resting pressure of the internal anal sphincter was decreased by a mean of 20.6% in all but 1 of 13 subjects given a single 60-mg oral dose of diltiazem.[2] A small study[3] has compared oral with topical diltiazem in the management of *anal fissure* (p.1891). Despite a higher response rate with the topical drug, no significant difference in benefit was seen between the 2 routes. A subsequent study[4] suggested topical diltiazem (2%) might be of benefit in patients with anal fissure unresponsive to topical nitrates. Sustained benefit after a 6-week treatment course has also been reported in some patients.[5]

Cardiomyopathies. Although calcium-channel blockers should be used with caution in patients with heart failure, symptomatic improvement has been reported in patients with dilated cardiomyopathy (p.1163) given diltiazem.[1]

1. Figulla HR, *et al*. Diltiazem improves cardiac function and exercise capacity in patients with idiopathic dilated cardiomyopathy: results of the Diltiazem in Dilated Cardiomyopathy Trial. *Circulation* 1996; **94:** 346–52.

Connective tissue and muscular disorders. Subcutaneous deposition of calcium (calcinosis) can occur in a number of inflammatory conditions, particularly in juvenile dermatomyositis (see Polymyositis and Dermatomyositis, p.1510). Treatment of calcinosis is difficult, but there have been a number of reports of the successful use of diltiazem in children[1,2] and adults[3] with dermatomyositis, as well as in adults with CREST (calcinosis, Raynaud's phenomenon, esophageal dysmotility, sclerodactyly, telangiectasias) syndrome,[4] scleroderma,[5] and lupus panniculitis.[6] Another study,[7] however, found only a limited response in patients with systemic sclerosis.

7. Vayssairat M, *et al*. Clinical significance of subcutaneous calcinosis in patients with systemic sclerosis: does diltiazem induce its regression? *Ann Rheum Dis* 1998; **57:** 252–4.

Kidney disorders. Calcium-channel blockers may be of benefit in various forms of kidney disorder (see Nifedipine, p.1355). Diltiazem has been reported to reduce urinary protein excretion without exacerbating pre-existing renal dysfunction in diabetic patients.[1,2] A small study[3] in 15 hypertensive patients with type 2 diabetes mellitus, albuminuria, and renal impairment found that diltiazem only reduced urinary albumin excretion when patients received a restricted dietary sodium intake of 50 mmol daily.

Diltiazem may also reduce the nephrotoxicity associated with certain drugs. Reduced nephrotoxicity has been reported when diltiazem is given to healthy subjects receiving netilmicin,[4] but diltiazem does not appear to modify the acute renal failure associated with tubular damage which may be caused by methotrexate.[5] Diltiazem may reduce ciclosporin-induced nephrotoxicity (see Transplantation, below).

Migraine. For reference to the use of calcium-channel blockers, including diltiazem, in the management of migraine, see under Nifedipine, p.1355.

Myocardial infarction. For reference to the use of diltiazem in the acute and long-term management of myocardial infarction, see under Uses of Verapamil, p.1424.

Transplantation. Diltiazem increases blood-ciclosporin concentrations when given by mouth in doses of 60 to 180 mg daily to transplant patients receiving ciclosporin therapy.[1-3] In consequence, ciclosporin doses can be reduced by about one-third, at a considerable saving in cost.[2,3] However, the effect may not occur in all patients,[4] and may vary with differing formulations,[5] and it has been suggested that blood-ciclosporin concentrations should be closely monitored if diltiazem is used for this purpose. In addition to this effect, which is apparently due to non-competitive inhibition of ciclosporin metabolism by diltiazem,[6] there is evidence of improved renal graft-function in patients given the combined therapy, suggesting that diltiazem may reduce ciclosporin-induced nephrotoxicity.[1,2] However, a 4-year follow-up study in patients treated with ciclosporin and diltiazem found that diltiazem had no effect on the progression to chronic allograft nephropathy.[7] Improved survival has been reported[8] in a retrospective study of patients given diltiazem for its ciclosporin-sparing effect, but it was unclear if this was a direct effect of diltiazem or was related to other factors associated with its use.

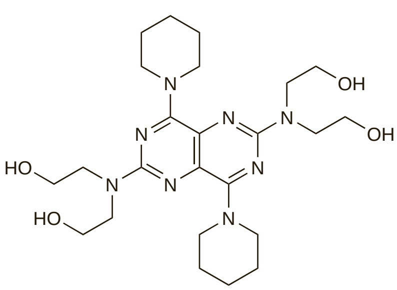
Дипиридамол

$C_{24}H_{40}N_8O_4 = 504.6.$

CAS — 58-32-2.

ATC — B01AC07.

ATC Vet — QB01AC07.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Dipyridamole). A bright yellow crystalline powder. Practically insoluble in water; soluble in dehydrated alcohol; freely soluble in acetone. It dissolves in dilute solutions of mineral acids. Protect from light.

USP 31 (Dipyridamole). An intensely yellow, crystalline powder or needles. Slightly soluble in water; very soluble in chloroform, in alcohol, and in methyl alcohol; very slightly soluble in acetone and in ethyl acetate. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

Gastrointestinal disturbances, including nausea, vomiting, and diarrhoea, headache, dizziness, faintness, hypotension, facial flushing, and skin rash and other hypersensitivity reactions may occur after use of dipyridamole. Dipyridamole can also induce chest pain or lead to a worsening of the symptoms of angina. Cardiac arrhythmias have been reported in patients given dipyridamole during thallium-201 imaging. Aminophylline may reverse some of the adverse effects.

Dipyridamole should be used with caution in patients with hypotension, unstable angina, aortic stenosis, recent myocardial infarction, heart failure, or coagulation disorders. Intravenous dipyridamole should not be given to patients with these conditions or to those with arrhythmias, conduction disorders, asthma, or a history of bronchospasm (but see Myocardial Imaging, below). Oral dipyridamole should be stopped 24 hours before intravenous use for stress testing.

Effects on the biliary tract. Gallstones containing unconjugated dipyridamole were removed from 2 patients who had been taking dipyridamole for 15 and 10 years, respectively.[1] A gallstone containing unconjugated dipyridamole recurred in a patient who continued to take the drug after endoscopic removal of a similar stone 18 months earlier.[2]

2. Sautereau D, *et al.* Recurrence of biliary drug lithiasis due to dipyridamole. *Endoscopy* 1997; **29:** 421–3.

Effects on the heart. Transient myocardial ischaemia occurred in 4 patients with unstable angina and multivessel coronary artery disease during oral treatment with dipyridamole.[1] See Myocardial Imaging, below, for additional reports.

1. Keltz TN, *et al.* Dipyridamole-induced myocardial ischemia. *JAMA* 1987; **257:** 1515–16.

Effects on the muscles. Symptoms resembling acute pseudopolymyalgia rheumatica developed in a patient taking dipyridamole.[1]

1. Chassagne P, *et al.* Pseudopolymyalgia rheumatica with dipyridamole. *BMJ* 1990; **301:** 875.

Effects on taste. A disagreeable taste associated with other gastrointestinal symptoms occurred in a patient taking dipyridamole.[1] Two similar cases had been reported to the UK CSM.

1. Willoughby JMT. Drug-induced abnormalities of taste sensation. *Adverse Drug React Bull* 1983; **100:** 368–71.

Myocardial imaging. Dipyridamole may be used in association with thallium-201 in myocardial stress imaging. Safety data from over 3900 patients has been summarised.[1] Adverse effects which occurred within 24 hours of dipyridamole intravenously (mean dose 560 micrograms/kg) were recorded. Ten patients had major adverse effects and 1820 patients experienced minor adverse effects. Myocardial infarction occurred in 4 patients, 3 of whom had unstable angina before scanning. Six patients developed acute bronchospasm, 4 of whom had a history of asthma or had wheezing before using dipyridamole. Adverse effects considered to be minor included chest pain in 19.7% of patients, ST-T-segment depression in 7.5%, ventricular extrasystoles in 5.2%, headache in 12.2%, dizziness in 11.8%, nausea in 4.6%, and hypotension in 4.6%. Aminophylline was effective in relieving symptoms of adverse effects in 97% of 454 patients.

Hypersensitivity reactions including anaphylaxis and angioedema have been reported.[2,3]

UK licensed product information contra-indicates intravenous dipyridamole in patients with hypotension, unstable angina, aortic stenosis, recent myocardial infarction, heart failure, coagulation disorders, arrhythmias, conduction disorders, asthma, or a history of bronchospasm. However, a review[4] of pharmacological stress testing suggested that with appropriate patient selection and adequate monitoring, the incidence of life-threatening adverse reactions is negligible. It was also considered that dipyridamole-thallium-201 imaging could be safely performed in the early post-myocardial infarction period.

4. Beller GA. Pharmacologic stress imaging. *JAMA* 1991; **265:** 633–8.

Interactions

Dipyridamole may enhance the actions of oral anticoagulants due to its antiplatelet effect. It inhibits the reuptake of adenosine and may enhance its effects; the dose of adenosine must be reduced if both drugs are given. Dipyridamole may also inhibit the uptake of fludarabine and may reduce its efficacy.

The absorption of dipyridamole may be reduced by drugs such as antacids that increase gastric pH.

Anticoagulants. Dipyridamole may induce bleeding in patients receiving oral anticoagulants without altering prothrombin times (see Antiplatelets, under Warfarin, Interactions, p.1429).

Xanthines. Xanthines may antagonise some of the effects of dipyridamole due to their action as adenosine antagonists. *Aminophylline* may be used to reverse some of the adverse effects of dipyridamole. Intravenous *caffeine* has been reported[1] to attenuate the haemodynamic response to dipyridamole and it has been suggested that caffeine should be avoided for at least 24 hours before the test in patients receiving dipyridamole for myocardial imaging.

1. Smits P, *et al.* Dose-dependent inhibition of the hemodynamic response to dipyridamole by caffeine. *Clin Pharmacol Ther* 1991; **50:** 529–37.

Pharmacokinetics

Dipyridamole is incompletely absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 75 minutes after an oral dose. Dipyridamole is more than 90% bound to plasma proteins. A terminal half-life of 10 to 12 hours has been reported. Dipyridamole is metabolised in the liver and is mainly excreted as glucuronides in the bile. Excretion may be delayed by enterohepatic recirculation. A small amount is excreted in the urine. Dipyridamole is distributed into breast milk.

Uses and Administration

Dipyridamole is an adenosine reuptake inhibitor and phosphodiesterase inhibitor with antiplatelet and vasodilating activity and is used in thromboembolic disorders (p.1187). Oral dipyridamole is used for the prophylaxis of thromboembolism after cardiac valve replacement (p.1187) and in the management of stroke (below); it has also been used in the management of myocardial infarction (p.1175). Dipyridamole given intravenously results in marked coronary vasodilatation and is used in stress testing in patients with ischaemic heart disease (see Myocardial Imaging, below).

For the prophylaxis of **thromboembolism** after cardiac valve replacement, dipyridamole is given with an oral anticoagulant. The usual adult dose is 300 to 600 mg daily by mouth in divided doses before meals. Children have been given 5 mg/kg by mouth daily in divided doses.

For the secondary prevention of **stroke** or transient ischaemic attack dipyridamole is given as a modified-release preparation, alone or with aspirin, in a dose of 200 mg twice daily.

Myocardial imaging. Perfusion abnormalities due to coronary artery disease are usually absent at rest but are present during stress, and stress imaging may therefore be used in the assessment of myocardial function. The stress is usually supplied by exercise, but when exercise is inappropriate pharmacological methods such as dipyridamole may be used.

Dipyridamole has been used with thallium-201 scintigraphy in adults and children and is usually given intravenously in a dose of 567 micrograms/kg over 4 minutes. Thallium-201 is given within 3 to 5 minutes after completion of the infusion of dipyridamole. Initial images are obtained after 5 minutes and delayed images are obtained 2.5 to 4 hours later. Dipyridamole (300 to 400 mg) has also been given as an oral suspension; thallium-201 is given about 45 minutes later to coincide with peak dipyridamole-serum concentrations.

Dipyridamole has also been used in echocardiography.[1,2] The intravenous dipyridamole dose used to obtain maximum sensitivity is often higher (750 to 840 micrograms/kg) than the dose used in scintigraphy.[1]

Stroke. The value of long-term antiplatelet therapy with aspirin in patients who have suffered an ischaemic stroke (p.1185) or transient ischaemic attack is well-established, with a reduction in the risk of both stroke and other vascular events.[1] The use of dipyridamole has been more controversial. Early studies with dipyridamole, used alone or with aspirin, failed to show any benefit over aspirin alone. The European Stroke Prevention Study-2 (ESPS-2),[2] which compared aspirin and dipyridamole, alone or together, with placebo, found that both drugs reduced the risk of stroke and that the effects appeared to be additive. The study used a low dose of aspirin and a modified-release formulation of dipyridamole, which may explain the discrepancy with earlier studies.[3] Subsequent meta-analyses[3-6] have confirmed that dipyridamole, alone or with aspirin, reduces the risk of recurrent stroke, but have been based mainly on the ESPS-2, which may be a limitation.[3] However, a further large study[7] comparing aspirin alone with aspirin and dipyridamole also found that the incidence of vascular events (including stroke) was lower in those receiving both drugs. Most guidelines[8,9] therefore now recommend aspirin with dipyridamole as one of the preferred options for long-term management of ischaemic stroke.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Disopyramide). A white or almost white powder. Slightly soluble in water; soluble in alcohol; freely soluble in dichloromethane. Protect from light.

Disopyramide Phosphate *(BANM, USAN, rINNM)*

Disopyramide, phosphate de; Disopyramidfosfat; Disopyramidfosfát; Disopyramidi phosphas; Disopyramidifosfaatti; Dizopiramid Fosfata; Dizopiramid-foszfát; Dizopiramido fosfatas; Dyzopiramidu fosforan; Fosfato de disopiramida; SC-13957.

Дизопирамида Фосфат

$C_{21}H_{29}N_3O,H_3PO_4$ = 437.5.
CAS — 22059-60-5.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Disopyramide Phosphate). A white or almost white powder. Soluble in water; sparingly soluble in alcohol; practically insoluble in dichloromethane. A 5% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 31 (Disopyramide Phosphate). A white or practically white, odourless powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. pH of a 5% solution in water is between 4.0 and 5.0. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

The adverse effects most commonly associated with disopyramide relate to its antimuscarinic properties and are dose-related. They include dry mouth, blurred vision, urinary hesitancy, impotence, and constipation; the most serious effect is urinary retention. Gastrointestinal effects, which are less common, include nausea, bloating, and abdominal pain. Other adverse effects reported include skin rashes, hypoglycaemia, dizziness, fatigue, muscle weakness, headache, and urinary frequency. Insomnia and depression have also been associated with disopyramide. There have been rare reports of psychosis, cholestatic jaundice, elevated liver enzymes, thrombocytopenia, and agranulocytosis. Disopyramide prolongs the QT interval and may induce or worsen arrhythmias, particularly ventricular tachycardia and fibrillation; heart block and conduction disturbances may occur. It is also a negative inotrope and may cause heart failure, and hypotension.

Over-rapid intravenous injection of disopyramide may cause profuse sweating and severe cardiovascular depression.

In overdose cardiovascular and antimuscarinic effects are pronounced, and there may be apnoea, loss of consciousness, loss of spontaneous respiration, and asystole. Treatment of overdosage is symptomatic and supportive. Activated charcoal may be considered if the patient presents within 1 hour of ingestion.

1. Kim SY, Benowitz NL. Poisoning due to class IA antiarrhythmic drugs quinidine, procainamide and disopyramide. *Drug Safety* 1990; **5:** 393–420.

Incidence of adverse effects. During long-term therapy with disopyramide 400 to 1600 mg daily in 40 patients, 28 (70%) had one or more adverse effects.[1] Dry mouth occurred in 15 (38%), constipation in 12 (30%), blurred vision in 11 (28%), urinary hesitancy in 9 (23%), nausea in 9 (23%), impotence in 2 (5%), and dyspareunia in one patient (3%). In addition 3 of the 9 patients with pre-existing heart failure had worsening of their condition due to disopyramide. Adverse effects were sufficiently severe for disopyramide to be stopped in 7 patients, and for dosage reductions in another 7.

1. Bauman JL, *et al.* Long-term therapy with disopyramide phosphate: side effects and effectiveness. *Am Heart J* 1986; **111:** 654–60.

Effects on the blood. Granulocytopenia was associated on 2 occasions with the use of disopyramide phosphate in a 61-year-old man.[1]

1. Conrad ME, *et al.* Agranulocytosis associated with disopyramide therapy. *JAMA* 1978; **240:** 1857–8.

Effects on the eyes. The antimuscarinic activity of disopyramide may cause adverse effects such as dilated pupils,[1] severe blurring of vision,[1] and acute glaucoma.[2,3] Disopyramide should be avoided in patients with glaucoma and used with caution if there is a family history of glaucoma.

1. Frucht J, *et al.* Ocular side effects of disopyramide. *Br J Ophthalmol* 1984; **68:** 890–1.
2. Trope GE, Hind VMD. Closed-angle glaucoma in patient on disopyramide. *Lancet* 1978, **i:** 329.
3. Ahmad S. Disopyramide: pulmonary complications and glaucoma. *Mayo Clin Proc* 1990; **65:** 1030–1.

Effects on the heart. Disopyramide has a strong negative inotropic effect and reversible heart failure has been reported[1] after its use. As many as 50% of patients with a history of heart failure may have a recurrence of the disease with an incidence of less than 5% in other patients.

As disopyramide can prolong the QT interval it can induce ventricular tachyarrhythmias. A case of fatal torsade de pointes has been reported.[2]

1. Podrid PJ, *et al.* Congestive heart failure caused by oral disopyramide. *N Engl J Med* 1980; **302:** 614–17.
2. Schattner A, *et al.* Fatal torsade de pointes following jaundice in a patient treated with disopyramide. *Postgrad Med J* 1989; **65:** 333–4.

Effects on the liver. Cholestatic jaundice with raised liver enzyme values has been associated with disopyramide.[1-3] Laboratory and clinical abnormalities disappear on withdrawal although liver enzyme values may remain elevated for several months.

Severe hepatocellular damage with disseminated intravascular coagulation[4] has also been reported.

1. Craxi A, *et al.* Disopyramide and cholestasis. *Ann Intern Med* 1980; **93:** 150–1.
2. Edmonds ME, Hayler AM. *Eur J Clin Pharmacol* 1980; **18:** 285–6.
3. Bakris GL, *et al.* Disopyramide-associated liver dysfunction. *Mayo Clin Proc* 1983; **58:** 265–7.
4. Doody PT. Disopyramide hepatotoxicity and disseminated intravascular coagulation. *South Med J* 1982; **75:** 496–8.

Effects on mental state. Agitation and distress leading to paranoia and auditory and visual hallucinations have been reported[1,2] in patients shortly after starting disopyramide therapy. Complete recovery occurred on withdrawal.

1. Falk RH, *et al.* Mental distress in patient on disopyramide. *Lancet* 1977; **i:** 858–9.
2. Padfield PL, *et al.* Disopyramide and acute psychosis. *Lancet* 1977; **i:** 1152.

Effects on the nervous system. Peripheral neuropathy affecting the feet and severe enough to prevent walking was associated with disopyramide in a 72-year-old patient.[1] There was gradual improvement on withdrawal of disopyramide with the patient being symptom-free after 4 months. Another patient[2] developed a peripheral polyneuropathy 4 years after starting disopyramide; symptoms improved over a number of months after disopyramide was stopped.

A 75-year-old woman with atrial fibrillation suffered a tonic-clonic seizure followed by respiratory arrest after receiving disopyramide 150 mg intravenously over a period of 10 minutes.[3] On recovery she complained of a dry mouth and blurred vision and it was considered that the seizure was caused by the antimuscarinic action of disopyramide, although it may have been due to a direct stimulant action.

1. Dawkins KD, Gibson J. Peripheral neuropathy with disopyramide. *Lancet* 1978; **i:** 329.
2. Briani C, *et al.* Disopyramide-induced neuropathy. *Neurology* 2002; **58:** 663.
3. Johnson NM, *et al.* Epileptiform convulsion with intravenous disopyramide. *Lancet* 1978; **ii:** 848.

Effects on sexual function. Impotence has been reported[1-3] in patients receiving disopyramide, and is usually attributed to its antimuscarinic effects, although other antimuscarinic symptoms may not be apparent. In one patient[1] full recovery of sexual function occurred when the dose was reduced (plasma concentration reduced from 14 to 3 micrograms/mL); another patient[3] developed impotence shortly after starting disopyramide, despite a low plasma concentration (1.5 micrograms/mL), but the condition resolved without changing therapy.

1. McHaffie DJ, *et al.* Impotence in patient on disopyramide. *Lancet* 1977; **i:** 859.
2. Ahmad S. Disopyramide and impotence. *South Med J* 1980; **73:** 958.
3. Hasegawa J, Mashiba H. Transient sexual dysfunction observed during antiarrhythmic therapy by long-acting disopyramide in a male Wolff-Parkinson-White patient. *Cardiovasc Drugs Ther* 1994; **8:** 277.

Effects on the urinary tract. In a report of 9 cases of urinary retention associated with disopyramide and a review of the literature,[1] it was noted that urinary retention secondary to disopyramide use was most likely to develop in male patients over the age of 65 in whom there was some pre-existing renal dysfunction; there was an increased risk in patients with evidence of prostatic hyperplasia.

1. Danziger LH, Horn JR. Disopyramide-induced urinary retention. *Arch Intern Med* 1983; **143:** 1683–6.

Hypersensitivity. Worsening of ventricular arrhythmia and an anaphylactoid reaction occurred in a 58-year-old man after a single oral dose of disopyramide 300 mg.[1] Two hours later he complained of a swollen tongue and difficulty in breathing. He became cyanotic but his respiratory status improved when given diphenhydramine 25 mg intravenously.

1. Porterfield JG, *et al.* Respiratory difficulty after use of disopyramide. *N Engl J Med* 1980; **303:** 584.

Hypoglycaemia. After the manufacturer received reports of hypoglycaemia associated with disopyramide, 2 controlled studies were conducted in healthy subjects.[1] Disopyramide produced a small decrease in blood-glucose concentration but there were no symptoms of hypoglycaemia, although it was considered that the glucose-lowering effect might be clinically significant in patients with hepatic or renal impairment. A review[2] found that renal impairment, advanced age, and malnutrition were the main risk factors for hypoglycaemia, and hypoglycaemia with reduced insulin requirements has also been reported[3] in a patient with type 2 diabetes mellitus. An interaction with clarithromycin has also been reported as a possible cause (see Antibacterials under

Interactions, below). However, the overall incidence appears to be low[2] and a case-control study[4] in 91 patients with hypoglycaemia failed to confirm an association with disopyramide.

1. Strathman I, *et al*. Hypoglycemia in patients receiving disopyramide phosphate. *Drug Intell Clin Pharm* 1983; **17:** 635–8.

4. Takada M, *et al*. The relationship between risk of hypoglycemia and use of cibenzoline and disopyramide. *Eur J Clin Pharmacol* 2000; **56:** 335–42.

Overdosage. A 2-year-old boy suffered hypotension, cardiac arrhythmias, and convulsions and died 28 hours after ingestion of 600 mg of disopyramide.[1] In a report[2] of 5 cases of fatal overdosage with disopyramide the most common clinical finding appeared to be an early loss of consciousness after an episode of respiratory arrest. Four of the patients responded to resuscitation at first but then deteriorated rapidly, with cardiac arrhythmias and loss of spontaneous respiration; in 4 of the cases post-mortem examination found pulmonary congestion secondary to left ventricular failure.

1. Hutchison A, Kilham H. Fatal overdosage of disopyramide in a child. *Med J Aust* 1978; **2:** 335–6.
2. Hayler AM, *et al*. Fatal overdosage with disopyramide. *Lancet* 1978; **i:** 968–9.

Precautions

Disopyramide is contra-indicated in complete heart block (unless the patient has a pacemaker) and in cardiogenic shock. It should be used with extreme caution in patients with other conduction disorders or uncompensated heart failure. As for quinidine (see Precautions for Quinidine, p.1384), if disopyramide is used to treat atrial tachycardia it may be necessary to pre-treat with digoxin. Hypokalaemia should be corrected before disopyramide is started. Care should be taken in patients susceptible to hypoglycaemia, including those with heart failure, hepatic or renal impairment, and patients taking drugs that affect glucose metabolism.

Intravenous injections of disopyramide should be given slowly to avoid hypotension and it is recommended that facilities for cardiac monitoring and defibrillation should be available when the injection is used.

Dosage reduction may be necessary in patients with hepatic or renal impairment and in patients with heart failure.

Owing to its antimuscarinic properties, disopyramide should be avoided in patients with glaucoma or a tendency to urinary retention, as in benign prostatic hyperplasia, and also in patients with myasthenia gravis because of the risk of precipitating a myasthenic crisis. It should be used with caution in patients with a family history of glaucoma.

◊ For dosage adjustments in the elderly and in patients with hepatic or renal impairment, see under Uses and Administration, below.

Breast feeding. Disopyramide is distributed into breast milk and milk to plasma ratios of 0.4, about 0.5, and 0.9 have been reported.[1-3] Disopyramide has been detected in the plasma of breast-fed infants, but was not associated with adverse effects. The American Academy of Pediatrics considers[4] that it is therefore usually compatible with breast feeding. However, the infant should be monitored for adverse effects, especially antimuscarinic effects.

Pregnancy. Disopyramide is not usually recommended in pregnancy since it may induce uterine contractions. Although no adverse effects were noted in a patient given disopyramide 200 mg every 8 hours from 26 weeks of gestation until delivery,[1] another patient who was given 4 oral doses of disopyramide 100 to 300 mg at six-hourly intervals in week 32 of pregnancy had uterine contractions 1 to 2 hours after each dose.[2] A further patient[3] given disopyramide at 36 weeks of gestation developed painful uterine contractions 40 minutes after a single 150-mg dose orally; active labour and haemorrhage developed after a second dose was given, and an emergency caesarean section was required. A double-blind, placebo-controlled study[4] involving 20 women hospitalised for induction of labour confirmed that disopyramide induces uterine contractions. All 10 women given disopyramide 150 mg every 6 hours for 48 hours began contractions and in 8 delivery was induced.

Interactions

Disopyramide should be used cautiously with drugs that have negative inotropic effects or that affect conduction, including beta blockers and other class I antiarrhythmics; it prolongs the QT interval and should not be given with other arrhythmogenic drugs. Disopyramide is metabolised by the cytochrome P450 isoenzyme CYP3A4 and interactions may occur with inhibitors or inducers of this enzyme and with other drugs metabolised by CYP3A4. Use of disopyramide with other antimuscarinic drugs produces enhanced antimuscarinic effects.

Anti-anginals. For reference to disopyramide reducing the effectiveness of sublingual *isosorbide dinitrate*, see p.1318.

Antiarrhythmics. The effects of disopyramide on cardiac conduction are additive to those of other class I antiarrhythmic drugs.[1] Disopyramide may prolong the QT interval, a factor associated with torsade de pointes, particularly when given with drugs that have a similar effect; this effect was noted in a few patients given *amiodarone* with disopyramide.[2] Also the serum concentration of disopyramide has been increased by *quinidine*;[3] there was a reciprocal decrease in the serum-quinidine concentration but this was less important clinically.

1. Ellrodt G, Singh BN. Adverse effects of disopyramide (Norpace): toxic interactions with other antiarrhythmic agents. *Heart Lung* 1980; **9:** 469–74.
2. Tartini R, *et al*. Dangerous interaction between amiodarone and quinidine. *Lancet* 1982; **i:** 1327–9.
3. Baker BJ, *et al*. Concurrent use of quinidine and disopyramide: evaluation of serum concentrations and electrocardiographic effects. *Am Heart J* 1983; **105:** 12–15.

Antibacterials. The metabolism of disopyramide may be increased by enzyme inducers such as *rifampicin*;[1,2] the increased clearance of disopyramide may lead to subtherapeutic plasma concentrations.

Conversely, enzyme inhibitors may increase serum-disopyramide concentrations[3] and ventricular arrhythmias have been noted in patients given azithromycin,[4] clarithromycin,[5-7] and erythromycin.[3] Hypoglycaemia attributed to increased disopyramide concentrations has also been reported[8,9] with clarithromycin.

7. Choudhury L, *et al*. Torsades de pointes due to drug interaction between disopyramide and clarithromycin. *Heart Dis* 1999; **1:** 206–7.
8. Iida H, *et al*. Hypoglycemia induced by interaction between clarithromycin and disopyramide. *Jpn Heart J* 1999; **40:** 91–96.
9. Morlet-Barla N, *et al*. Hypoglycémie grave et récidivante secondaire à l'interaction disopyramide-clarithromicine. *Presse Med* 2000; **29:** 1351.

Antiepileptics. The clearance of disopyramide may be increased by enzyme inducers such as *phenytoin* and *phenobarbital*, and a small study[1] found that phenytoin reduced serum-disopyramide concentrations.

1. Aitio M-L, *et al*. The effect of enzyme induction on the metabolism of disopyramide in man. *Br J Clin Pharmacol* 1981; **11:** 279–85.

Beta blockers. Beta blockers have negative inotropic effects that may be potentiated if they are given with disopyramide. A pharmacokinetic interaction may also occur with beta blockers since the clearance of disopyramide has been reported[1] to be reduced by about 16% during *atenolol* therapy.

1. Bonde J, *et al*. Atenolol inhibits the elimination of disopyramide. *Eur J Clin Pharmacol* 1985; **28:** 41–3.

Pharmacokinetics

Disopyramide is readily and almost completely absorbed from the gastrointestinal tract, peak plasma concentrations being attained about 0.5 to 3 hours after oral doses.

Disopyramide is partially metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4. The major metabolite is mono-*N*-dealkylated disopyramide which retains some antiarrhythmic and antimuscarinic activity. The major route of excretion is through the kidney, about 50% as the unchanged drug, 20% as the *N*-dealkylated metabolite, and 10% as other metabolites. About 10% is excreted in the faeces. The clearance of disopyramide does not appear to be influenced by urinary pH.

Disopyramide protein binding varies with the plasma concentration, limiting the usefulness of plasma concentration monitoring as a guide to therapy; protein binding is reported to be 50 to 65% at therapeutic plasma concentrations (about 2 to 4 micrograms/mL). Estimations of the plasma half-life of disopyramide range from about 4 to 10 hours. The half-life is increased in hepatic and renal impairment, and in heart failure.

Disopyramide crosses the placental barrier and is distributed into breast milk.

◊ Reviews.

1. Siddoway LA, Woosley RL. Clinical pharmacokinetics of disopyramide. *Clin Pharmacokinet* 1986; **11:** 214–22.

Uses and Administration

Disopyramide is a class Ia antiarrhythmic (p.1153) with an action on the heart similar to that of quinidine (p.1385). It also has antimuscarinic and negative inotropic properties.

Disopyramide is used in the management of supraventricular and ventricular arrhythmias (p.1160).

It may be given orally as either the base or the phosphate or intravenously as the phosphate; doses are expressed in terms of the base. Disopyramide phosphate 1.3 g is equivalent to about 1 g of disopyramide. The usual oral dose is 300 to 800 mg daily in divided doses adjusted according to response. A modified-release preparation can be used, enabling 12-hourly dosage intervals.

Disopyramide may be given by slow intravenous injection in a dose of 2 mg/kg to a maximum of 150 mg, at a rate not exceeding 30 mg/minute; this is followed by 200 mg orally immediately on completion of the injection and every 8 hours for 24 hours. If the arrhythmia recurs the intravenous injection may be repeated, but a total intravenous dose of 4 mg/kg (maximum 300 mg) should not be exceeded in the first hour, nor should the total by both intravenous and oral routes exceed 800 mg in 24 hours. Alternatively, the initial intravenous injection may be followed by intravenous infusion of 400 micrograms/kg per hour (or 20 to 30 mg/hour) to a maximum of 800 mg daily. Patients receiving disopyramide intravenously or in high oral doses should be monitored by ECG.

Dosage reduction and/or increased dosage interval may be necessary in patients with hepatic or renal impairment (see below) and in some elderly patients (see, below). Doses should also be adjusted in patients with heart failure to compensate for the prolonged half-life.

For the dosage of disopyramide in children, see below.

Action. A study in 6 patients with atrial flutter suggested that the antiarrhythmic activity of racemic disopyramide resides in the S(+)-enantiomer.[1]

1. Lima JJ, *et al*. Antiarrhythmic activity and unbound concentrations of disopyramide enantiomers in patients. *Ther Drug Monit* 1990; **12:** 23–8.

Administration in children. An optimum dosage regimen for children has not been fully established, but US product information suggests the following oral doses:

- under 1 year: 10 to 30 mg/kg daily
- age 1 to 4 years: 10 to 20 mg/kg daily
- age 4 to 12 years: 10 to 15 mg/kg daily
- age 12 to 18 years: 6 to 15 mg/kg daily

Administration in the elderly. The clearance of disopyramide was reduced in elderly non-smoking patients compared with young subjects, but the reduction was less marked in elderly patients who smoked more than 20 cigarettes daily.[1] It was recommended that the dose of disopyramide should be reduced by about 30% in elderly non-smokers.

1. Bonde J, *et al*. The influence of age and smoking on the elimination of disopyramide. *Br J Clin Pharmacol* 1985; **20:** 453–8.

Administration in hepatic impairment. The plasma half-life of disopyramide may be increased in hepatic impairment and dosage reduction should be considered; US licensed product information recommends an oral dose of 400 mg daily in divided doses. In patients with liver cirrhosis there is also a significant reduction in the plasma concentration of α_1-acid glycoprotein;[1,2] in addition, its binding capacity for disopyramide is reduced.[1] This is associated with an increase in the free fraction of disopyramide such that measurement of total disopyramide in plasma may not be a safe indicator for dosing, and a therapeutic range 50% lower than in patients with normal hepatic function should be considered.[2]

1. Bonde J, *et al.* Kinetics of disopyramide in decreased hepatic function. *Eur J Clin Pharmacol* 1986; **31:** 73–7.
2. Echizen H, *et al.* Protein binding of disopyramide in liver cirrhosis and in nephrotic syndrome. *Clin Pharmacol Ther* 1986; **40:** 274–80.

Administration in renal impairment. Disopyramide is excreted mainly in the urine and a reduction in clearance with an increase in elimination half-life has been reported[1] in patients with renal impairment. Dosage reduction should therefore be considered. US licensed product information recommends the following oral doses based on creatinine clearance (CC):

- CC greater than 40 mL/minute: 400 mg daily in divided doses
- CC 30 to 40 mL/minute: 100 mg every 8 hours
- CC 15 to 30 mL/minute: 100 mg every 12 hours
- CC less than 15 mL/minute: 100 mg every 24 hours

Modified-release preparations should be avoided in patients with CC less than 40 mL/minute.

At therapeutic concentrations disopyramide is not significantly removed by haemodialysis;[2] the half-life is similar both on and off dialysis (16.8 versus 16.1 hours). An increased free fraction of disopyramide has been seen[3] during haemodialysis associated with an elevation in free fatty acids in plasma and in such cases free plasma-disopyramide concentrations should be monitored.

3. Horiuchi T, *et al.* Inhibitory effect of free fatty acids on plasma protein binding of disopyramide in haemodialysis patients. *Eur J Clin Pharmacol* 1989; **36:** 175–80.

Hypertrophic cardiomyopathy. Patients with hypertrophic cardiomyopathy (p.1163) may have exercise intolerance due to left ventricular outflow obstruction. Beta blockers are usually used when symptoms are associated with exercise or emotional factors, but may not be effective in patients with symptoms at rest. Disopyramide has been used for its negative inotropic effect in such patients and a retrospective study[1] found that it improved symptoms without having a proarrhythmic effect.

1. Sherrid MV, *et al.* Multicenter study of the efficacy and safety of disopyramide in obstructive hypertrophic cardiomyopathy. *J Am Coll Cardiol* 2005; **45:** 1251–8.

Hypotension. Disopyramide has been widely used in the management of neurally mediated hypotension (p.1174) but there is limited evidence to support its use. Although some reports[1,2] have suggested benefit, a controlled study[3] found that it was no more effective than placebo in preventing tilt-induced syncope. Adverse effects also limit the use of disopyramide, and it is generally no longer considered first line.

1. Milstein S, *et al.* Usefulness of disopyramide for prevention of upright tilt-induced hypotension-bradycardia. *Am J Cardiol* 1990; **65:** 1339–44.

Dobutamine Hydrochloride

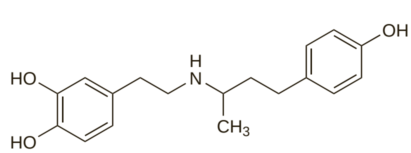
(BANM, USAN, rINNM)

46236; Compound 81929 (dobutamine); Dobutamiinihydrokloridi; Dobutamine, chlorhydrate de; Dobutamin-hidroklorid; Dobutamin-hydrochlorid; Dobutaminhydroklorid; Dobutamini hydrochloridum; Dobutamino hidrochloridas; Hidrocloruro de dobutamina; LY-174008 (dobutamine tartrate). (±)-4-(2-{[3-(*p*-Hydroxyphenyl)-1-methylpropyl]amino}ethyl)pyrocatechol hydrochloride.

Добутамина Гидрохлорид

$C_{18}H_{23}NO_3$,HCl = 337.8.

CAS — 34368-04-2 (dobutamine); 49745-95-1 (dobutamine hydrochloride); 101626-66-8 (dobutamine tartrate).
ATC — C01CA07.
ATC Vet — QC01CA07.



(dobutamine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Dobutamine Hydrochloride). A white or almost white crystalline powder. Sparingly soluble in water and in alcohol; soluble in methyl alcohol. Protect from light.

USP 31 (Dobutamine Hydrochloride). A white to practically white crystalline powder. Sparingly soluble in water and in methyl alcohol; soluble in alcohol and in pyridine. Store in airtight containers at a temperature of 15° to 30°.

Incompatibility. Dobutamine is incompatible with alkaline solutions such as sodium bicarbonate 5% and alkaline drugs such as aminophylline, furosemide,[1] and thiopental sodium;[1] physical incompatibility with bumetanide, calcium gluconate, insulin, diazepam, and phenytoin has also been suggested. There have also been reports of incompatibility with alteplase,[2] heparin,[3] and warfarin sodium.[4]

1. Chiu MF, Schwartz ML. Visual compatibility of injectable drugs used in the intensive care unit. *Am J Health-Syst Pharm* 1997; **54:** 64–5.
2. Lee CY, *et al.* Visual and spectrophotometric determination of compatibility of alteplase and streptokinase with other injectable drugs. *Am J Hosp Pharm* 1990; **47:** 606–8.
3. Yamashita SK, *et al.* Compatibility of selected critical care drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1996; **53:** 1048–51.
4. Bahal SM, *et al.* Visual compatibility of warfarin sodium injection with selected medications and solutions. *Am J Health-Syst Pharm* 1997; **54:** 2599–2600.

Adverse Effects and Treatment

As for Sympathomimetics, p.1407. Dobutamine has mainly beta$_1$-agonist properties and its principal adverse effects include dose-related increases in heart rate and blood pressure, ectopic beats, angina or chest pain, and palpitations; dosage should be reduced or temporarily stopped if they occur. Ventricular tachycardia may occur rarely; cardiac rupture has been reported rarely during dobutamine stress testing.

Effects on body temperature. A 71-year-old woman with heart failure developed a fever on 2 separate occasions 8 to 12 hours after starting an infusion of dobutamine.[1]

1. Robison-Strane SR, Bubik JS. Dobutamine-induced fever. *Ann Pharmacother* 1992; **26:** 1523–4.

Effects on the cardiovascular system. For reference to severe cardiovascular complications of dobutamine stress echocardiography, see Diagnosis and Testing under Uses and Administration, below.

For reference to fatalities occurring in patients given dobutamine, see Heart Failure under Uses and Administration, below.

Effects on the neuromuscular system. Myoclonus has been reported[1,2] in patients with renal impairment given dobutamine infusion for heart failure.

1. Wierre L, *et al.* Dobutamine-induced myoclonia in severe renal failure. *Nephrol Dial Transplant* 2004; **19:** 1336–7.
2. Boord A, Benson B. Myoclonus associated with continuous dobutamine infusion in a patient with end-stage renal disease. *Am J Health-Syst Pharm* 2007; **64:** 2241–3.

Effects on the skin. Troublesome pruritus of the scalp has been reported[1] in a patient receiving dobutamine infusions. It was suggested that this might be a direct effect of dobutamine since the reaction was so localised.

1. McCauley CS, Blumenthal MS. Dobutamine and pruritus of the scalp. *Ann Intern Med* 1986; **105:** 966.

Hypersensitivity. Hypersensitivity reactions have been reported in patients receiving dobutamine infusions, possibly due to sodium sulfite in the formulation. Redness, swelling, itching, and a sensation of warmth developed[1] around the infusion site in a patient receiving dobutamine; the reaction recurred when the infusion was repeated a week later. Eosinophilic reactions have also been reported, including hypersensitivity myocarditis[2-4] and asthma.[5]

1. Cernek PK. Dermal cellulitis—a hypersensitivity reaction from dobutamine hydrochloride. *Ann Pharmacother* 1994; **28:** 964.
2. Spear GS. Eosinophilic explant carditis with eosinophilia: ?hypersensitivity to dobutamine infusion. *J Heart Lung Transplant* 1995; **14:** 755–60.
3. Takkenberg JJM, *et al.* Eosinophilic myocarditis in patients awaiting heart transplantation. *Crit Care Med* 2004; **32:** 714–21.
4. Butany J, *et al.* Hypersensitivity myocarditis complicating hypertrophic cardiomyopathy heart. *Can J Cardiol* 2004; **20:** 911–14.
5. Aranda JM, *et al.* Dobutamine-related asthma in a patient awaiting cardiac transplantation: the eosinophilic dilemma. *J Heart Lung Transplant* 2004; **23:** 260–1.

Overdosage. A patient received an accidental overdose[1] of dobutamine when given an intravenous infusion at a rate of more than 130 micrograms/kg per minute for 30 minutes, this being three times the recommended maximum. Characteristic adverse effects such as emesis, palpitations, chest pain, dyspnoea, and paraesthesia developed, together with urinary incontinence, an effect not previously associated with dobutamine.

1. Paulman PM, *et al.* Dobutamine overdose. *JAMA* 1990; **264:** 2386–7.

Precautions

As for Sympathomimetics, p.1407. Dobutamine has primarily inotropic effects and should be avoided or used only with great caution in patients with marked obstruction of cardiac ejection, such as idiopathic hypertrophic subaortic stenosis. It should also be used with caution in patients with acute myocardial infarction, and in cardiogenic shock complicated by severe hypotension. Hypovolaemia should be corrected before treatment.

Interference with diagnostic tests. Contamination of blood samples with dobutamine has been reported to produce falsely decreased creatinine values in an enzymatic test.[1] Colorimetric measurements of creatinine were not affected.

1. Daly TM, *et al.* "Bouncing" creatinine levels. *N Engl J Med* 1996; **334:** 1749–50.

Interactions

As for Sympathomimetics, p.1407. Most interactions with dobutamine are due to its direct $beta_1$ agonist effects on the heart, but use with beta blockers may allow its alpha- and $beta_2$-agonist effects to become apparent.

Pharmacokinetics

Like adrenaline (p.1204), dobutamine is inactive when given orally, and it is rapidly inactivated in the body by similar processes. It has a half-life of about 2 minutes. Conjugates of dobutamine and its major metabolite 3-*O*-methyldobutamine are excreted primarily in urine, with small amounts eliminated in the faeces.

◊ The primary mechanism of clearance of dobutamine appears to be distribution to other tissues, and not metabolism or elimination. It has a half-life of about 2 minutes and plasma concentrations of dobutamine reach steady state about 10 to 12 minutes after the start of an infusion. Dobutamine is used mainly for the short-term treatment of heart failure and any pharmacokinetic changes in this condition have no clinical implications in dosage titration.[1]

The pharmacokinetics of dobutamine and other cardiovascular drugs in children have been reviewed.[2]

1. Shammas FV, Dickstein K. Clinical pharmacokinetics in heart failure: an updated review. *Clin Pharmacokinet* 1988; **15:** 94–113.
2. Steinberg C, Notterman DA. Pharmacokinetics of cardiovascular drugs in children: inotropes and vasopressors. *Clin Pharmacokinet* 1994; **27:** 345–67.

Uses and Administration

Dobutamine is a sympathomimetic (p.1408) with direct effects on $beta_1$-adrenergic receptors, giving it a prominent inotropic action on the heart. It also has some alpha- and $beta_2$-agonist properties. Although it is structurally related to dopamine (p.1273), it has no specific dopaminergic properties; however, like dopamine, the inotropic action of dobutamine on the heart is associated with less cardiac-accelerating effect than that of isoprenaline.

Dobutamine is used to increase the contractility of the heart in acute heart failure, as occurs in cardiogenic shock (p.1183) and myocardial infarction (p.1175); it is also used in septic shock. Other circumstances in which its inotropic activity may be useful are during cardiac surgery and positive end-expiratory pressure ventilation.

Dobutamine is used as the hydrochloride but doses are expressed in terms of the base; 1.12 micrograms of the hydrochloride is equivalent to about 1 microgram of base. It is given by intravenous infusion as a dilute solution (0.25 to 5 mg/mL), in glucose 5% or sodium chloride 0.9%; other fluids may also be suitable and the manufacturers' guidelines should be consulted.

In the management of **acute heart failure**, dobutamine is given at a usual rate of 2.5 to 10 micrograms/kg per minute, according to the patient's heart rate, blood pressure, cardiac output, and urine output. A range of 0.5 up to 40 micrograms/kg per minute has occasionally been required. It has been recommended that treatment with dobutamine should be discontinued gradually.

Dobutamine is also used as an alternative to exercise in **cardiac stress testing**. A solution containing 1 mg/mL is given via an infusion pump in a dose of 5 micrograms/kg per minute for 8 minutes. The dose is then increased by increments of 5 micrograms/kg per minute up to a usual maximum of 20 micrograms/kg per minute, with each dose being infused for 8 minutes before the next increase; doses of up to 40 micrograms/kg per minute have sometimes been used. The ECG should be monitored continuously and the infusion stopped if arrhythmias, marked ST segment depression, or other adverse effects occur.

Action. Although dobutamine is usually considered to be a $beta_1$ agonist, *animal* studies suggest that its ability to stimulate $alpha_1$- and $beta_2$-adrenergic receptors may be as great as its $beta_1$-stimulant properties. It has been proposed that the inotropic action results from a combination of alpha-stimulant activity on myocardial $alpha_1$ receptors, a property residing mainly in the (−)-enantiomer, with $beta_1$ stimulation by the (+)-enantiomer; peripherally, alpha-mediated vasoconstriction would be opposed by the $beta_2$-agonist properties of the (+)-enantiomer, resulting in the net inotropic action with relatively little effect on blood pressure seen with the racemic mixture used clinically.[1]

Dobutamine has a thermogenic effect,[2] increasing oxygen delivery and utilisation in healthy volunteers. However, using it for this purpose in critically ill patients did not improve patient outcome and in some cases might have been harmful.[3]

1. Ruffolo RR. The mechanism of action of dobutamine. *Ann Intern Med* 1984; **100:** 313–14.
2. Bhatt SB, *et al.* Effect of dobutamine on oxygen supply and uptake in healthy volunteers. *Br J Anaesth* 1992; **69:** 298–303.
3. Hayes MA, *et al.* Elevation of systemic oxygen delivery in the treatment of critically ill patients. *N Engl J Med* 1994; **330:** 1717–22.

Administration in children. Dobutamine and dopamine are both used for inotropic support in children. A study[1] in children undergoing cardiac surgery suggested that dobutamine may be preferred to dopamine since the latter could cause pulmonary vasoconstriction (see under Precautions for Dopamine, p.1273). In preterm infants, one study[2] reported that dobutamine may have a greater effect on systemic blood flow than dopamine, but a systematic review[3] found that dopamine was more effective than dobutamine in the short-term treatment of hypotension although there was insufficient evidence of long-term benefit or safety with either drug for firm recommendations to be made.

1. Booker PD, *et al.* Comparison of the haemodynamic effects of dopamine and dobutamine in young children undergoing cardiac surgery. *Br J Anaesth* 1995; **74:** 419–23.

Diagnosis and testing. Dynamic exercise is the established mode of stress for the assessment of cardiac function. In patients who are unable to exercise, a dobutamine infusion is one of the best alternative ways of producing a pharmacological stress.[1,2] It is widely used as an adjunct in echocardiography, often combined with atropine, and may give better sensitivity than adenosine or dipyridamole;[1,3] it may also have a role with other imaging techniques such as magnetic resonance imaging.[4] However there have been instances of severe cardiovascular complications attributable to dobutamine.[5]

1. Cheitlin MD, *et al.* ACC/AHA/ASE 2003 guideline update for the clinical application of echocardiography: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (ACC/AHA/ASE Committee to Update the 1997 Guidelines for the Clinical Application of Echocardiography). Summary article: *Circulation* 2003; **108:** 1146–62. Full text: http://www.americanheart.org/downloadable/heart/1060182581039Echocleanfulltext.pdf (accessed 07/10/05)

Heart failure. Dobutamine may be used in the management of acute heart failure, including decompensated chronic heart failure (see Cardiogenic Shock, under Shock, p.1183). It may also have a role in patients with severe chronic heart failure (p.1165), either as a bridge to transplantation or for palliative therapy. In less severe cases, intermittent infusions of dobutamine have been tried. A study[1] using pulsed therapy with dobutamine (30 minutes daily for 4 days each week for 3 weeks) reported symptomatic improvements similar to those achieved with exercise, but another study[2] using intermittent therapy (24 hours every 2 to 3 weeks for 6 months) failed to show any benefit. There have also been reports of sudden death in patients receiving dobutamine as infusions for 48 hours per week, and another study[3] was halted for this reason. Long-term use of intermittent dobutamine is therefore not generally recommended.[4]

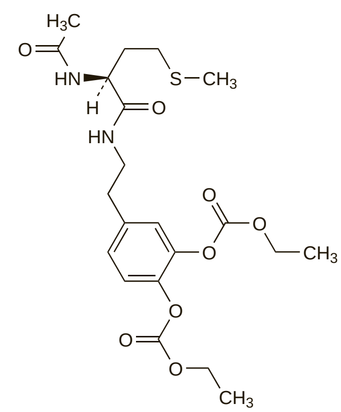
Docarpamine *(rINN)*

Docarpamina; Docarpaminum; TA-870; TA-8704. (−)-(*S*)-2-Acetamido-*N*-(3,4-dihydroxyphenethyl)-4-(methylthio)butyramide bis(ethyl carbonate) ester.

Докарпамин

$C_{21}H_{30}N_2O_8S$ = 470.5.
CAS — 74639-40-0.



Profile

Docarpamine is an orally active prodrug of dopamine (p.1273) that has been used in the treatment of acute heart failure.

Preparations

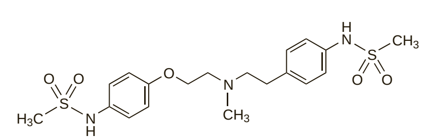
Proprietary Preparations (details are given in Part 3)
Jpn: Tanadopa†.

Dofetilide *(BAN, USAN, rINN)*

Dofetilid; Dofetilida; Dofétilide; Dofetilidi; Dofetilidum; UK-68798. β-[(*p*-Methanesulfonamidophenethyl)methylamino]methanesulfono-*p*-phenetidide.

Дофетилид

$C_{19}H_{27}N_3O_5S_2$ = 441.6.
CAS — 115256-11-6.
ATC — C01BD04.
ATC Vet — QC01BD04.



Adverse Effects and Precautions

The most frequent adverse effects with dofetilide are headache, chest pain, and dizziness. Dofetilide prolongs the QT interval and may cause severe ventricular arrhythmias, including torsade de pointes; it should not be given to patients with congenital or acquired long QT syndromes. Hypokalaemia increases the risk of arrhythmias and potassium concentrations should be corrected before starting dofetilide. The dosage of dofetilide must be individualised according to QT interval and creatinine clearance, which must be measured before starting therapy; dofetilide is contra-indicated if the corrected QT interval is above 440 milliseconds (or above 500 milliseconds in patients with ventricular conduction abnormalities) or if the creatinine clearance is less than 20 mL/minute. Treatment should begin under ECG monitoring, which must be continued for at least 3 days, and both ECG and renal function should be monitored at least every 3 months during treatment.

Interactions

Dofetilide should not be given with other drugs that prolong the QT interval. Class I or class III antiarrhythmics should be stopped at least 3 half-lives before dofetilide is given. Potassium-depleting diuretics may cause hypokalaemia or hypomagnesaemia, increasing the potential for torsade de pointes; US licensed product information for dofetilide states that hydrochlorothiazide is contra-indicated since it also causes significant increases in plasma-dofetilide concentrations. Dofetilide is metabolised to a small extent by the cytochrome P450 isoenzyme CYP3A4, and drugs or foods that inhibit this isoenzyme, such as macrolide antibacterials, HIV-protease inhibitors, diltiazem, and grapefruit juice, should be used with caution. Cimetidine, trimethoprim, ketoconazole, prochlorperazine, and megestrol, should not be given as they inhibit the renal excretion of dofetilide; verapamil is also contra-indicated as it too may substantially increase dofetilide concentrations.

◊ References.

1. Yamreudeewong W, *et al.* Potentially significant drug interactions of class III antiarrhythmic drugs. *Drug Safety* 2003; **26:** 421–38.

Pharmacokinetics

The oral bioavailability of dofetilide is more than 90%. Peak plasma concentrations occur after 2 to 3 hours and steady state concentrations after 2 to 3 days. The terminal half-life is about 10 hours. Protein binding is 60 to 70%. Dofetilide undergoes limited metabolism. About 80% of a dose is excreted in the urine, with about 80% of this as unchanged drug and 20% as 5 minimally active or inactive metabolites; metabolism may be mediated to some extent by the cytochrome P450 isoenzyme CYP3A4. Renal elimination involves both glomerular filtration and active tubular secretion via the cation transport system. The clearance of dofetilide decreases with decreasing creatinine clearance.

◊ References.

1. Allen MJ, *et al.* The pharmacokinetics and pharmacodynamics of oral dofetilide after twice daily and three times daily dosing. *Br J Clin Pharmacol* 2000; **50:** 247–53.

Uses and Administration

Dofetilide is a class III antiarrhythmic (p.1153); it selectively blocks one of the potassium channels involved in repolarisation and therefore prolongs the action potential. It is used in the treatment of atrial fibrillation and flutter (p.1160) in patients who are highly symptomatic. The initial oral dose in patients with a corrected QT interval of 440 milliseconds or less is 500 micrograms twice daily; the maintenance dose must be reduced if the QT interval becomes prolonged after the first dose, and treatment should be stopped if the QT interval exceeds 500 milliseconds. Doses should be reduced in renal impairment (see below).

4. Roukoz H, Saliba W. Dofetilide: a new class III antiarrhythmic agent. *Expert Rev Cardiovasc Ther* 2007; **5:** 9–19.

Administration in renal impairment. Doses of dofetilide should be reduced in patients with renal impairment based on creatinine clearance (CC). Initial doses are:

- CC 40 to 60 mL/minute: 250 micrograms twice daily
- CC 20 to 39 mL/minute: 125 micrograms twice daily
- CC below 20 mL/minute: contra-indicated

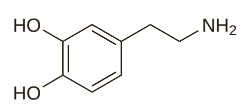
Допамина Гидрохлорид

$C_8H_{11}NO_2,HCl = 189.6.$

CAS — 51-61-6 (dopamine); 62-31-7 (dopamine hydrochloride).

ATC — C01CA04.

ATC Vet — QC01CA04.



(dopamine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Dopamine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water; soluble in alcohol; sparingly soluble in acetone and in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Dopamine Hydrochloride). A white to off-white crystalline powder that may have a slight odour of hydrochloric acid. Freely soluble in water and in aqueous solutions of alkali hydroxides; insoluble in chloroform and in ether; soluble in methyl alcohol. pH of a 4% solution in water is between 3.0 and 5.5. Store in airtight containers.

Incompatibility. Dopamine is inactivated in alkaline solutions such as sodium bicarbonate 5% and is incompatible with alkaline drugs such as furosemide[1] and thiopental sodium;[1] incompatibility with insulin[2] and with alteplase[3] has also been reported, and licensed product information states that it is incompatible with ampicillin and with amphotericin B, and that mixtures with gentamicin sulfate, cefalotin sodium, or oxacillin sodium should be avoided.

3. Lee CY, *et al.* Visual and spectrophotometric determination of compatibility of alteplase and streptokinase with other injectable drugs. *Am J Hosp Pharm* 1990; **47:** 606–8.

Adverse Effects and Treatment

As for Sympathomimetics, p.1407; dopamine may have adverse effects relating to both its alpha- and beta-agonist properties.

Dopamine has a short duration of action and most adverse effects respond to stopping the infusion or reducing its rate; infiltration with phentolamine may relieve pain and prevent necrosis following extravasation.

Effects on the CNS. Movement disorders are well known adverse effects of the dopamine precursor, levodopa (p.804) but do not usually occur with dopamine since it does not enter the CNS. However, there has been a report[1] of choreoathetosis in a patient receiving dopamine infusion; it was suggested that there must have been disruption to her blood-brain barrier to allow this to occur.

1. Walker VA, Massoumi M. Choreoathetosis with dopamine. *Ann Intern Med* 2005; **142:** 478–9.

Effects on the endocrine system. Dopamine has complex actions on the anterior pituitary[1] and dopamine infusion is associated with a number of endocrine effects, including suppression of prolactin, growth hormone, and thyroid hormone release. In postoperative or critically ill patients, dopamine infusion may affect the endocrine response to stress, even when given in low doses. Depression of serum-prolactin concentrations has been reported[2] in critically ill patients given dopamine in a dose of 2.5 micrograms/kg per minute to maintain renal blood flow, while a study[3] in postoperative patients given dopamine 5 micrograms/kg per minute to maintain splanchnic blood flow found that serum concentrations of both prolactin and thyroid stimulating hormone were decreased. It was suggested that these changes could adversely affect immunological function and add to morbidity in such patients.

3. Schilling T, *et al.* Endocrine effects of dopexamine vs. dopamine in high-risk surgical patients. *Intensive Care Med* 2001; **27:** 1908–15.

Effects on the heart. For mention of the arrhythmogenic effects of dopamine on the heart, see p.1407.

Ischaemia and gangrene. Dopamine is converted to noradrenaline, a powerful vasoconstrictor, and there have been reports[1-3] of ischaemia and gangrene of the extremities in patients receiving dopamine infusion, as well as local necrosis after extravasation.[4] Extravasation of catecholamines is usually treated with an alpha blocker such as phentolamine, but there have also been reports of the use of topical glyceryl trinitrate ointment to improve capillary blood flow in patients with dopamine-induced ischaemia of the digits. The ointment was applied either to the affected area,[5] or to the warmest area of skin,[6] such as the chest or abdominal wall.

Precautions

As for Sympathomimetics, p.1407.

Children. There have been reports of increased pulmonary artery pressure with the use of dopamine in children after cardiac surgery,[1] and in premature infants with hypotension.[2] It has therefore been suggested that dopamine should be used with caution in children at risk of developing pulmonary hypertension.

1. Booker PD, *et al.* Comparison of the haemodynamic effects of dopamine and dobutamine in young children undergoing cardiac surgery. *Br J Anaesth* 1995; **74:** 419–23.
2. Liet J-M, *et al.* Dopamine effects on pulmonary artery pressure in hypotensive preterm infants with patent ductus arteriosus. *J Pediatr* 2002; **140:** 373–5.

Interactions

As for Sympathomimetics, p.1407. Dopamine has both direct and indirect actions and may therefore interact with MAOIs; the dose of dopamine should be substantially reduced in patients taking MAOIs, and an initial dose of one-tenth the usual dose has been suggested.

Antiepileptics. Following a report in 1976 to the FDA of hypotension in patients given *phenytoin* in addition to dopamine infusion, a study[1] of this potential interaction found that dopamine given by intravenous infusion with phenytoin infusion to *dogs,* did not alter the CNS effects of phenytoin nor result in hypotension and cardiovascular collapse. Large doses of phenytoin alone had a reproducible hypotensive effect that was reduced by dopamine, suggesting a possible supportive role in phenytoin-induced hypotension.

1. Smith RD, Lomas TE. Modification of cardiovascular responses to intravenous phenytoin by dopamine in dogs: evidence against an adverse interaction. *Toxicol Appl Pharmacol* 1978; **45:** 665–73.

Dopaminergics. Severe hypertension occurred[1] in a patient who had been receiving *selegiline* for Parkinson's disease when a dopamine infusion was started. Although selegiline is considered to be a selective monoamine oxidase type B inhibitor, at higher doses it also affects monoamine oxidase type A and could have reduced the metabolism of dopamine in this patient. Caution may be necessary if dopamine is given to patients who have been receiving selegiline within the previous 2 weeks.

1. Rose LM, *et al.* A hypertensive reaction induced by concurrent use of selegiline and dopamine. *Ann Pharmacother* 2000; **34:** 1020–4.

Pharmacokinetics

The vasoconstrictor properties of dopamine preclude its use by the subcutaneous or intramuscular route. Like adrenaline (p.1204) it is inactive when given orally, and it is rapidly inactivated in the body by similar processes, with a half-life of about 2 minutes. Dopamine is a metabolic precursor of noradrenaline and a proportion is excreted as the metabolites of noradrenaline. Nevertheless, the majority appears to be directly metabolised into dopamine-related metabolites.

Uses and Administration

Dopamine is a catecholamine sympathomimetic (p.1408) with both direct and indirect effects. It is formed in the body by the decarboxylation of levodopa, and is both a neurotransmitter in its own right (notably in the brain) and a precursor of noradrenaline. Dopamine differs from adrenaline and noradrenaline in dilating renal and mesenteric blood vessels and increasing urine output, apparently by a specific dopaminergic mechanism. This effect is predominant at low infusion rates (about 2 micrograms/kg per minute); at slightly higher infusion rates (around 2 to 10 micrograms/kg per minute) it also stimulates $beta_1$-adrenergic receptors in the myocardium, and at 10 to 20 micrograms/kg per minute the effects of alpha-adrenergic stimulation, such as vasoconstriction, predominate. The inotropic action of dopamine on the heart is associated with less cardiac-accelerating effect, and a lower incidence of arrhythmias, than that of isoprenaline.

Dopamine also inhibits release of prolactin from the anterior pituitary.

Dopamine is used in acute heart failure, as occurs in cardiogenic shock (p.1183) and myocardial infarction (p.1175); it is also used in renal failure (but see below, under Surgery and Intensive Care), in cardiac surgery, and in septic shock.

Dopamine is given as the hydrochloride by intravenous infusion as a dilute solution (usually 1.6 or 3.2 mg/mL, although more dilute solutions may be used where fluid expansion is not a problem), in glucose 5%, sodium chloride 0.9%, or other suitable diluents; many fluids are suitable and licensed product information should be consulted. The initial rate is 1 to 5 micrograms/kg per minute, gradually increased by up to 5 to 10 micrograms/kg per minute according to the patient's blood pressure, cardiac output, and urine output. Up to 20 to 50 micrograms/kg per minute may be required in seriously ill patients; higher doses have been given. A reduction in urine flow, without hypotension, may indicate a need to reduce the dose. To avoid tissue necrosis dopamine is best given via a large vein high up in a limb, preferably the arm. When gradually stopping dopamine it is advised that care be taken to avoid undue hypotension associated with very low dosage levels, where vasodilatation could predominate.

Surgery and intensive care. Dopamine has an established role as an inotrope in cardiogenic shock and in cardiac surgery; it has also been used as a **renal protectant,** due to the apparently beneficial effects of lower doses on renal function. Studies in healthy *animals* and human subjects have shown that low-dose dopamine increases renal blood flow, natriuresis, diuresis, and possibly glomerular filtration rate. Low doses of dopamine (sometimes termed 'renal-dose' dopamine) have therefore been widely used in patients at risk of renal failure, such as those undergoing major surgery or in intensive care, as well as for the treatment of acute renal failure. However, clinical studies have failed to convincingly demonstrate that low-dose dopamine is effective in either preventing acute renal failure in patients at high risk, or in improving renal function or outcome in patients with established acute renal failure. A placebo-controlled, randomised study[1] in critically-ill patients with early renal dysfunction and meta-analyses[2,3] including studies of varying design, failed to show any clinical benefit in those receiving dopamine. It is now generally considered[2,4,5] that low-dose dopamine has no place as a renal protectant in the routine management of critically ill patients.

Dopexamine, which like dopamine acts as a peripheral dopamine agonist, has been used similarly but evidence of benefit is limited and it is generally not recommended (see Critical Care under Dopexamine, p.1274).

Dopexamine Hydrochloride

(BANM, USAN, rINNM) ⊗

Dopeksamiinihydrokloridi; Dopeksamin Hidroklorür; Dopéxamine, Chlorhydrate de; Dopexamine, dichlorhydrate de; Dopexamine dihydrochloride; Dopexaminhydroklorid; Dopexamini dihydrochloridum; Dopexamini Hydrochloridum; FPL-60278 (dopexamine); FPL-60278AR; Hidrocloruro de dopexamina. 4-{2-[6-(Phenethylamino)hexylamino]ethyl}pyrocatechol dihydrochloride.

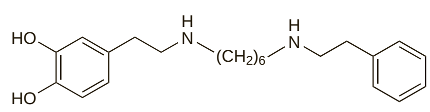
Допексамина Гидрохлорид

$C_{22}H_{32}N_2O_2,2HCl = 429.4.$

CAS — 86197-47-9 (dopexamine); 86484-91-5 (dopexamine dihydrochloride).

ATC — C01CA14.

ATC Vet — QC01CA14.



(dopexamine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dopexamine Dihydrochloride). A white or almost white, crystalline powder. Soluble in water; sparingly soluble in alcohol and in methyl alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 3.7 to 5.7. Protect from light.

Incompatibility. Dopexamine is inactivated in alkaline solutions such as sodium bicarbonate 5%.

Adverse Effects and Precautions

As for Sympathomimetics, p.1407. Dopexamine has mainly beta-agonist and dopaminergic actions; its most common adverse effect is tachycardia, and transient hypotension may also occur. Dopexamine may cause a small reduction in platelet counts and should not be given to thrombocytopenic patients.

Interactions

As for Sympathomimetics, p.1407. The interactions of dopexamine are mainly due to its beta-agonist and dopaminergic actions; it may also potentiate the effects of noradrenaline and some other sympathomimetics by inhibiting neuronal uptake of noradrenaline.

Pharmacokinetics

Dopexamine has a short half-life in blood of about 6 to 7 minutes. It is excreted as metabolites in bile and in urine.

Uses and Administration

Dopexamine is a sympathomimetic (p.1408) with direct and indirect effects. It stimulates $beta_2$ adrenoceptors and peripheral dopamine receptors and also inhibits the neuronal reuptake of noradrenaline. These actions result in an increased cardiac output, peripheral vasodilatation, and an increase in renal and mesenteric blood flow.

Dopexamine hydrochloride is used to provide short-term haemodynamic support, for example after cardiac surgery or in exacerbations of chronic heart failure. It is given as an intravenous infusion of either 400 or 800 micrograms/mL in glucose 5%, sodium chloride 0.9%, or other suitable diluents, through a central or large peripheral vein; more concentrated solutions may be given via a central vein but concentrations should not exceed 4 mg/mL. The initial dose is generally 0.5 micrograms/kg per minute and is then increased to 1 microgram/kg per minute; further increases, in increments of 0.5 to 1 microgram/kg per minute at intervals of not less than 15 minutes, may be made up to a total of 6 micrograms/kg per minute if necessary. Heart rate, blood pressure, urine output, and cardiac output should be monitored. On withdrawal, the dose should be reduced gradually.

Critical care. Dopexamine has been reported to increase splanchnic blood flow and it has been used with the aim of preventing renal and gastrointestinal dysfunction in critically-ill patients.[1] Although there may be a reduction in ischaemic damage to the gut,[2] a study[3] in critically-ill patients failed to show any improvement in outcome with the use of dopexamine. Studies[4,5] using dopexamine to increase oxygen delivery in high-risk surgical patients have also failed to show any benefit in terms of postoperative mortality or organ function, and a systematic review[6] found insufficient evidence to recommend the use of dopexamine in either patient group. A later meta-analysis[7] found that overall, perioperative dopexamine infusion reduced the length of hospital stay in patients having major surgery, but showed no survival benefit; however, at low doses (up to 1 microgram/kg per minute) dopexamine infusion seemed also to be associated with improved survival.

Use of low-dose dopamine for renal protection is not recommended (see Surgery and Intensive Care, p.1274).

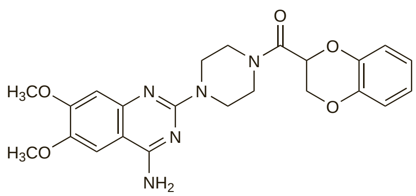
ATC — C02CA04.

ATC Vet — QC02CA04.



(doxazosin)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*.

Ph. Eur. 6.2 (Doxazosin Mesilate). A white or almost white crystalline powder. It exhibits polymorphism and some forms may be hygroscopic. Slightly soluble in water and in methyl alcohol; soluble in a mixture of 15 volumes of water and 35 volumes of tetrahydrofuran; practically insoluble in acetone. Store in airtight containers.

USP 31 (Doxazosin Mesylate). A white to tan-coloured powder. Very slightly soluble in water and in methyl alcohol; freely soluble in formic acid. Store at a temperature below 30°.

Adverse Effects, Treatment, and Precautions

As for Prazosin Hydrochloride, p.1375.

Effects on mental function. For a report of acute psychosis associated with doxazosin use, see under Adverse Effects of Prazosin Hydrochloride, p.1375.

Hypotension. Six of 18 hypertensive patients had first-dose orthostatic hypotension after receiving doxazosin 1 mg; three others had substantial but asymptomatic reductions in supine systolic blood pressure after the first dose.[1] The effect might have been exacerbated since all these patients were also receiving beta blockers or diuretics, or both. A further patient, who was also taking methyldopa, withdrew from the study with persistent orthostatic hypotension.

1. Oliver RM, *et al.* The pharmacokinetics of doxazosin in patients with hypertension and renal impairment. *Br J Clin Pharmacol* 1990; **29:** 417–22.

Urinary incontinence. For reference to urinary incontinence associated with doxazosin, see under Adverse Effects of Prazosin Hydrochloride, p.1375.

Pharmacokinetics

Doxazosin is well absorbed after oral doses, peak plasma concentrations occurring 2 to 3 hours after a dose. Oral bioavailability is about 65%. It is extensively metabolised in the liver, and excreted in faeces as metabolites and a small amount of unchanged drug. Elimination from plasma is biphasic, with a mean terminal half-life of about 22 hours. The pharmacokinetics are not altered in patients with renal impairment. Doxazosin is about 98% bound to plasma proteins and is not removed by dialysis.

◊ Reviews.

1. Elliott HL, *et al.* Pharmacokinetic overview of doxazosin. *Am J Cardiol* 1987; **59:** 78G–81G.

Uses and Administration

Doxazosin is an alpha$_1$-adrenoceptor blocker (p.1153) with actions and uses similar to those of prazosin (p.1376), but a longer duration of action. It is used in the management of hypertension and in benign prostatic hyperplasia to relieve symptoms of urinary obstruction (below).

Doxazosin is given orally as the mesilate, but doses are usually expressed in terms of the base. Doxazosin mesilate 1.2 mg is equivalent to about 1 mg of doxazosin. After an oral dose maximum reduction in blood pressure is reported to occur in 2 to 6 hours and the effects are maintained for 24 hours, permitting once daily dosage.

To avoid the risk of collapse which may occur in some patients after the first dose, the initial dose is 1 mg, preferably at bedtime. Dosage may be increased after 1 or 2 weeks according to response. Usual maintenance doses for **hypertension** are up to 4 mg once daily; doses of 16 mg daily should not be exceeded. For **benign prostatic hyperplasia** the usual maintenance dose is 2 to 4 mg daily; doses of 8 mg daily should not be exceeded.

Doxazosin may also be given as a modified-release preparation.

Hypertension. Alpha blockers are among the drug groups that have been used as first-line therapy for hypertension (p.1171). However, in the Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial (ALLHAT)[1] the doxazosin arm of the study was terminated early due to an increased incidence of heart failure in patients receiving doxazosin compared with those receiving chlortalidone and alpha blockers are now only recommended for third-line therapy unless indicated for another reason.

Enalapriilimaleaatti; Enalapril Maleat; Énalapril, maléate d'; Enalapril maleinát; Enalaprili maleas; Enalaprilio maleatas; Enalaprilmaleat; Enalapril-maleát; Maleato de enalapril; MK-421. *N*-{*N*-[(*S*)-1-Ethoxycarbonyl-3-phenylpropyl]-L-alanyl}-L-proline hydrogen maleate.

Эналаприла Малеат

$C_{20}H_{28}N_2O_5,C_4H_4O_4 = 492.5.$

CAS — 76095-16-4.

ATC — C09AA02.

ATC Vet — QC09AA02.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Enalapril Maleate). A white or almost white crystalline powder. Sparingly soluble in water; practically insoluble in dichloromethane; freely soluble in methyl alcohol. It dissolves in dilute solutions of alkali hydroxides. A 1% solution in water has a pH of 2.4 to 2.9. Protect from light.

USP 31 (Enalapril Maleate). An off-white crystalline powder. Sparingly soluble in water; soluble in alcohol; freely soluble in dimethylformamide and in methyl alcohol; slightly soluble in semipolar organic solvents; practically insoluble in nonpolar organic solvents.

Stability. Enalapril has been reported[1,2] to be stable for at least 56 days in extemporaneously compounded oral liquids containing enalapril maleate 1 mg/mL in a number of vehicles.

1. Nahata MC, *et al.* Stability of enalapril maleate in three extemporaneously prepared oral liquids. *Am J Health-Syst Pharm* 1998; **55:** 1155–7.
2. Allen LV, Erickson MA. Stability of alprazolam, chloroquine phosphate, cisapride, enalapril maleate, and hydralazine hydrochloride in extemporaneously compounded oral liquids. *Am J Health-Syst Pharm* 1998; **55:** 1915–20.

Enalaprilat *(BAN, USAN, rINN)*

Énalaprilate; Énalaprilate dihydraté; Enalaprilatum; Enalaprilatum dihydricum; Enalaprilic acid; MK-422. *N*-{*N*-[(*S*)-1-Carboxy-3-phenylpropyl]-L-alanyl}-L-proline dihydrate.

Эналаприлат

$C_{18}H_{24}N_2O_5,2H_2O = 384.4.$

CAS — 76420-72-9 (anhydrous enalaprilat); 84680-54-6 (enalaprilat dihydrate).

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Enalaprilat Dihydrate). A white or almost white, hygroscopic, crystalline powder. It exhibits pseudopolymorphism. Very slightly soluble or slightly soluble in water; sparingly soluble in methyl alcohol; practically insoluble in acetonitrile. Store in airtight containers.

USP 31 (Enalaprilat). A white to nearly white, hygroscopic, crystalline powder. Soluble 1 in 200 of water, 1 in 40 of dimethylformamide, and 1 in 68 of methyl alcohol; very slightly soluble in alcohol, in acetone, and in hexane; practically insoluble in acetonitrile and in chloroform; slightly soluble in isopropyl alcohol.

Incompatibility. Enalaprilat was visually incompatible[1] with phenytoin sodium in sodium chloride 0.9%, producing a crystalline precipitate; there was also some visual evidence of incompatibility when mixed with amphotericin B in glucose 5%.

1. Thompson DF, *et al.* Visual compatibility of enalaprilat with selected intravenous medications during simulated Y-site injection. *Am J Hosp Pharm* 1990; **47:** 2530–1.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Incidence of adverse effects. Postmarketing surveillance for enalapril was carried out by prescription-event monitoring of 12 543 patients.[1] There were 374 skin events including facial oedema or angioedema in 29 (leading to withdrawal of treatment in 10), 15 cases of photosensitivity, and urticaria in 32 (leading to withdrawal in 5). Syncope and dizziness occurred in 155 and 483 patients respectively, sometimes in association with hypotension. Hypotension occurred in 218 patients, 71 in the first month. Treatment was stopped in 121 patients with hypotension, and dosage reduced in 36. Other adverse effects reported included headache in 310 patients, paraesthesias in 126, taste disturbances in 25, conjunctivitis in 67, tachycardia in 194, cough in 360, renal failure in 82, muscle cramp in 96, diarrhoea in 236, and nausea and vomiting in 326. Of 1098 deaths only 10, due to renal failure, were thought possibly related to enalapril therapy. Dysgeusia and skin reactions appeared to be less common than has been reported for captopril, but precise comparisons were difficult; the range of adverse effects was similar.[2]

Deafness was a possible side-effect of enalapril noted earlier;[2] it was reported in 19 of the 12 543 patients monitored, but only while they were taking enalapril, there being no record of deafness after treatment stopped.

For further reference to some of these adverse effects, see under ACE Inhibitors, p.1193.

2. Inman WHW, Rawson NSB. Deafness with enalapril and prescription event monitoring. *Lancet* 1987; **i:** 872.

Breast feeding. After a single dose of enalapril 20 mg in 5 women enalaprilat was detected[1] in breast milk in concentrations of 1 to 2.3 nanograms/mL (mean peak 1.72 nanograms/mL); enalapril was also present (mean peak 1.74 nanograms/mL). This compared with peak serum values of 39 to 112 nanograms/mL for enalaprilat and 92 to 151 nanograms/mL for enalapril. Another study[2] found no detectable enalaprilat in the milk of 3 women, while in a further woman[3] both enalapril and enalaprilat were detected, but the concentrations were low. Although enalapril and its metabolite are thus present in small amounts in breast milk it was calculated that the average total daily dose to the neonate would only be about 2 micrograms of enalaprilat.[1] The American Academy of Pediatrics[4] lists no reports of any clinical effect on the infant associated with the use of enalapril by breast-feeding mothers, and states that therefore it may be considered to be usually compatible with breast feeding.

Porphyria. Enalapril has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Enalapril acts as a prodrug of the diacid enalaprilat, its active form, which is poorly absorbed orally. About 60% of an oral dose of enalapril is absorbed from the gastrointestinal tract and peak plasma concentrations are achieved within about 1 hour. Enalapril is extensively hydrolysed in the liver to enalaprilat; peak plasma concentrations of enalaprilat are achieved 3 to 4 hours after an oral dose of enalapril. Enalaprilat is 50 to 60% bound to plasma proteins. After an oral dose, enalapril is excreted in the urine and in faeces, as enalaprilat and unchanged drug, with the urinary route predominating; more than 90% of an intravenous dose of enalaprilat is excreted in the urine. The elimination of enalaprilat is multiphasic but the effective half-life for accumulation after multiple doses of enalapril is reported to be about 11 hours in patients with normal renal function. Enalaprilat is removed by haemodialysis and by peritoneal dialysis.

Renal impairment. Comparison of the pharmacokinetics of enalapril in 6 diabetics with persistent proteinuria and glomerular filtration rates (GFR) of 44.1 to 58.4 mL/minute with those in 8 age-matched controls showed that in the diabetic group the peak serum concentration of enalaprilat was higher, the time to peak concentration longer, renal clearance lower, and the areas under the concentration/time curve greater than in controls.[1] Renal clearance of enalaprilat in the diabetics ranged from 56 to 66 mL/minute compared with 105 to 133 mL/minute in controls; clearance correlated with GFR.

Uses and Administration

Enalapril is an ACE inhibitor (p.1193) used in the treatment of hypertension (p.1171) and heart failure (p.1165). It may also be given prophylactically to patients with asymptomatic left ventricular dysfunction to delay the onset of symptomatic heart failure, and has been used in patients with left ventricular dysfunction to reduce the incidence of coronary ischaemic events, including myocardial infarction (p.1175).

Enalapril owes its activity to enalaprilat to which it is converted after oral doses. The haemodynamic effects are seen within 1 hour of a single oral dose and the maximum effect occurs after about 4 to 6 hours, although the full effect may not develop for several weeks during chronic dosing. The haemodynamic action lasts for about 24 hours, allowing once-daily dosing. Enalapril is given orally as the maleate.

Enalaprilat is not absorbed orally but is given by intravenous injection; its haemodynamic effects develop within 15 minutes of injection and reach a peak in 1 to 4 hours. The action lasts for about 6 hours at recommended doses. Enalaprilat is given as the dihydrate, but doses are expressed in terms of the anhydrous substance. Enalaprilat 1.38 mg as the dihydrate is equivalent to about 1.25 mg of anhydrous enalaprilat.

In the treatment of **hypertension**, an initial oral dose of 5 mg of enalapril maleate daily may be given. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. An initial dose of 2.5 mg daily should be given to patients with renal impairment or to those who are receiving a *diuretic*; if possible, the diuretic should be withdrawn 2 or 3 days before enalapril is started and resumed later if necessary. The usual maintenance dose is 10 to 20 mg given once daily, although doses of up to 40 mg daily may be required in severe hypertension. It may be given in 2 divided doses if control is inadequate with a single dose.

When oral therapy of hypertension is impractical enalaprilat may be given in a dose of 1.25 mg by slow intravenous injection or infusion over at least 5 minutes, repeated every 6 hours if necessary; the initial dose should be halved in patients with renal impairment (creatinine clearance less than 30 mL/minute) or those who are receiving a diuretic.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should begin with a low dose under close medical supervision. In patients with heart failure or asymptomatic left ventricular dysfunction enalapril maleate is given orally in an initial dose of 2.5 mg daily. The usual maintenance dose is 20 mg daily as a single dose or in 2 divided doses although up to 40 mg daily in 2 divided doses has been given.

Administration in children. Enalapril may be used in the management of hypertension in children.[1] The initial dose is 80 micrograms/kg once daily, with a maximum of 5 mg, adjusted according to response. Alternatively, children weighing 20 to below 50 kg may be given an initial dose of 2.5 mg once daily, increased to a maximum of 20 mg daily, while children weighing 50 kg or over may be given an initial dose of 5 mg once daily, increased to a maximum of 40 mg daily. Doses above 580 micrograms/kg or 40 mg daily have not been studied.

Enalapril has also been given to infants with severe heart failure in doses of 100 to 500 micrograms/kg daily as an oral suspension produced by suspending a crushed tablet in water.[2] In this study one infant, with severe myocarditis, developed hypotension and the drug had to be withdrawn; the remaining 7 showed clinical improvement on a mean enalapril dose of 260 micrograms/kg daily and were able markedly to reduce the dose of concomitant diuretic required. Another study in 10 infants found that enalapril was less bioavailable and probably had a shorter duration of action in infants than in adults, and that doses of 80 micrograms/kg daily were inadequate in the treatment of infant heart failure.[3] A larger study in 63 infants and children (median age 5.4 months) with heart failure found enalapril 360 micrograms/kg daily to be of benefit, whereas there was no improvement with a lower dose of 240 micrograms/kg daily.[4]

Эноксапарин Натрий

CAS — 9041-08-1; 679809-58-6.
ATC — B01AB05.
ATC Vet — QB01AB05.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Enoxaparin Sodium). The sodium salt of a low-molecular-mass heparin that is obtained by alkaline depolymerisation of the benzyl ester derivative of heparin from porcine intestinal mucosa. The majority of the components have a 4-enopyranose uronate structure at the non-reducing end of their chain; 15 to 25% of the components have a 1,6-anhydro structure at the reducing end of their chain. The mass-average molecular mass ranges between 3800 and 5000 with a characteristic value of about 4500. The degree of sulfation is about 2 per disaccharide unit.

The potency is not less than 90 units and not more than 125 units of anti-factor Xa activity per mg, calculated with reference to the dried substance. The anti-factor IIa activity is not less than 20 units and not more than 35 units per mg, calculated with reference to the dried substance. The ratio of anti-factor Xa activity to anti-factor IIa activity is between 3.3 and 5.3.

A 10% solution in water has a pH of 6.2 to 7.7.

USP 31 (Enoxaparin Sodium). The sodium salt of a depolymerised heparin obtained by alkaline depolymerisation of the benzyl ester derivative of heparin from porcine intestinal mucosa. Enoxaparin sodium consists of a complex set of oligosaccharides that have not yet been completely characterised. The majority of the components have a 4-enopyranose uronate structure at the non-reducing end of their chain. About 20% of the components contain a 1,6-anhydro derivative on the reducing end of the chain. The mass-average molecular weight of enoxaparin sodium is 4,500, the range being between 3,800 and 5,000.

It has a potency of not less than 90 units and not more than 125 units of anti-factor Xa per mg, and not less than 20 units and not more than 35 units of anti-factor IIa per mg, calculated with reference to the dried substance. The ratio of anti-factor Xa activity to anti-factor IIa activity is between 3.3 and 5.3.

A 10% solution in water has a pH of 6.2 to 7.7. Store in airtight containers at a temperature below 40°.

Units

As for Low-molecular-weight Heparins, p.1329.

Adverse Effects, Treatment, and Precautions

As for Low-molecular-weight Heparins, p.1329. Patients with low body-weight (women below 45 kg, men below 57 kg) may be at higher risk of bleeding with prophylactic doses of enoxaparin and require careful monitoring.

Severe bleeding with enoxaparin may be reduced by the slow intravenous injection of protamine sulfate; 1 mg of protamine sulfate is stated to inhibit the effects of 1 mg (100 units) of enoxaparin sodium.

Interactions

As for Low-molecular-weight Heparins, p.1329.

Pharmacokinetics

Enoxaparin is rapidly and almost completely absorbed after subcutaneous injection with a bioavailability of about 100%. Peak plasma activity is reached within 1 to 5 hours. The elimination half-life is about 4 to 5 hours but anti-factor Xa activity persists for up to 24 hours after a 40-mg dose. Elimination is prolonged in patients with renal impairment. Enoxaparin is metabolised in the liver and excreted in the urine, as unchanged drug and metabolites.

Uses and Administration

Enoxaparin sodium is a low-molecular-weight heparin (p.1329) with anticoagulant properties. It is used in the treatment and prophylaxis of venous thromboembolism (p.1189) and to prevent clotting during extracorporeal circulation. It is also used in the management of unstable angina (p.1157) and in ST-elevation myocardial infarction (p.1175).

In the *prophylaxis* of **venous thromboembolism** during surgical procedures, enoxaparin sodium is given by subcutaneous injection; treatment is continued for 7 to 10 days or until the patient is ambulant.

- Patients at low to moderate risk are given 20 mg (2000 units) once daily with the first dose about 2 hours pre-operatively.
- In patients at high risk, such as those undergoing orthopaedic surgery, the dose should be increased to 40 mg (4000 units) once daily with the initial dose given about 12 hours before the procedure. Alternatively, a dose of 30 mg (3000 units) may be given subcutaneously twice daily, starting within 12 to 24

hours after operation. After hip replacement surgery, enoxaparin sodium may be continued in a dose of 40 mg (4000 units) once daily for a further 3 weeks.

- For the prophylaxis of thromboembolism in immobilised medical patients, the dose is 40 mg (4000 units) once daily for at least 6 days; treatment should be continued until the patient is fully ambulant, up to a maximum of 14 days.

For the *treatment* of deep-vein thrombosis enoxaparin sodium is given subcutaneously in a dose of 1 mg/kg (100 units/kg) every 12 hours, or 1.5 mg/kg (150 units/kg) once daily, for at least 5 days and until oral anticoagulation is established.

For prevention of clotting in the extracorporeal circulation during **haemodialysis**, enoxaparin sodium 1 mg/kg (100 units/kg) is introduced into the arterial line of the circuit at the beginning of the dialysis session. A further dose of 0.5 to 1 mg/kg (50 to 100 units/kg) may be given if required. The dose should be reduced in patients at high risk of haemorrhage.

In the management of **unstable angina**, enoxaparin sodium is given subcutaneously in a dose of 1 mg/kg (100 units/kg) every 12 hours. Treatment is usually continued for 2 to 8 days.

In acute ST-elevation **myocardial infarction** the initial dose of enoxaparin is 30 mg (3000 units) intravenously, with a subcutaneous dose of 1 mg/kg (100 units/kg) given at the same time. Further doses of 1 mg/kg (100 units/kg) should be given subcutaneously every 12 hours for 8 days or until hospital discharge. The first 2 subcutaneous doses should not exceed 100 mg (10 000 units) each. For patients who undergo a percutaneous coronary intervention, an additional intravenous dose of 300 micrograms/kg (30 units/kg) should be given at the time of the procedure if the last subcutaneous dose was given more than 8 hours previously. Patients aged 75 years and older with acute myocardial infarction should be given subcutaneous doses only; the recommended dose is 750 micrograms/kg (75 units/kg) every 12 hours, with a maximum of 75 mg (7500 units) for each of the first 2 doses.

The dose of enoxaparin sodium should be reduced in patients with severe renal impairment (see below).

Administration in infants and children. Increasing numbers of infants and children are given anticoagulants for the management of thromboembolism. Few controlled studies have been carried out in this age group and recommendations for therapy have generally been adapted from adult guidelines. Low-molecular-weight heparins may have a number of advantages in children. Enoxaparin has been used for the prophylaxis[1] of thromboembolism in children including neonates, and for treatment in children including neonates[1-3] and preterm infants.[1,3-5] Younger children may require a higher dose than older children. US guidelines recommend the following doses for *treatment*[6] of thromboembolism:

- under 2 months of age: 1.5 mg/kg (150 units/kg) every 12 hours
- over 2 months of age: 1 mg/kg (100 units/kg) every 12 hours

Doses for *prophylaxis*[6] are:

- under 2 months of age: 750 micrograms/kg (75 units/kg) every 12 hours
- over 2 months of age: 500 micrograms/kg (50 units/kg) every 12 hours

Similar doses are recommended in the UK by the *BNFC*, although it specifies slightly modified doses in neonates, in whom it recommends 1.5 to 2 mg/kg twice daily for *treatment* and 750 micrograms/kg twice daily for *prophylaxis*.

Administration in renal impairment. Careful monitoring is required when enoxaparin sodium is given to patients with mild to moderate renal impairment.[1] In severe renal impairment (creatinine clearance less than 30 mL/minute) the dose should be reduced. For prophylaxis of venous thromboembolism, UK licensed product information recommends a dose of 20 mg (2000 units) subcutaneously once daily whereas US licensed product information recommends a subcutaneous dose of 30 mg (3000 units) once daily. For treatment of venous thromboembolism, unstable angina, or acute myocardial infarction in patients aged 75 years or older, a dose of 1 mg/kg (100 units/kg) subcutaneously once daily is advised; patients under 75 years with myocardial infarction should additionally be given a single intravenous dose of 30 mg (3000 units) with the first subcutaneous dose. However, the adequacy of a once-daily dose in patients with acute coronary syndromes has been questioned and alternative dosage regimens have been suggested.2,3

Enoximone *(BAN, USAN, rINN)*

Enoksimoni; Enoximon; Enoximona; Énoximone; Enoximonum; Fenoximone; MDL-17043; MDL-19438; RMI-17043; YMDL-17043. 4-Methyl-5-[4-(methylthio)benzoyl]-4-imidazolin-2-one.

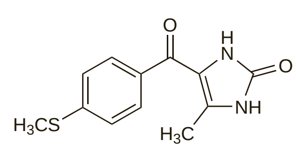
Эноксимон

$C_{12}H_{12}N_2O_2S$ = 248.3.

CAS — 77671-31-9.

ATC — C01CE03.

ATC Vet — QC01CE03.



Incompatibility. Crystal formation has occurred when enoximone injection was mixed in glass containers or syringes; the manufacturer recommends that only plastic containers or syringes are used for dilutions. The manufacturer also recommends that only sodium chloride 0.9% or water be used as diluents. Glucose solutions should not be used for dilution as crystal formation may occur.

Adverse Effects

Long-term oral treatment with enoximone has been reported to increase the mortality rate and enoximone is now only given intravenously for short-term use.

Enoximone may cause ventricular and supraventricular tachyarrhythmias, ectopic beats, and hypotension. Adverse effects of enoximone affecting the gastrointestinal tract include diarrhoea, nausea, and vomiting. Other adverse effects include headache, insomnia, chills, oliguria, fever, urinary retention, and limb pain. There have been reports of thrombocytopenia and abnormal liver enzyme values.

Effects on the nervous system. Tonic-clonic convulsions have been reported[1] in a patient given enoximone 6 micrograms/kg per minute by intravenous infusion. The convulsions subsided when enoximone was stopped.

1. Appadurai I, *et al.* Convulsions induced by enoximone administered as a continuous intravenous infusion. *BMJ* 1990; **300:** 613–14.

Hyperosmolality. Hyperosmolality occurred in an infant during intravenous infusion of enoximone 20 micrograms/kg per minute. The probable cause was propylene glycol in the enoximone injection providing a dose of 2.4 mg/kg per minute.[1]

1. Huggon I, *et al.* Hyperosmolality related to propylene glycol in an infant treated with enoximone infusion. *BMJ* 1990; **301:** 19–20.

Precautions

Enoximone should be used with caution in patients with hypertrophic cardiomyopathy or severe obstructive aortic or pulmonary valvular disease.

Blood pressure, heart rate, ECG, fluid and electrolyte status, and renal function should be monitored during therapy. Platelet count and liver enzyme values should also be monitored.

The injection has a high pH (about 12) and must be diluted before use (but see Incompatibility, above). Extravasation should be avoided.

Doses may need to be reduced in hepatic or renal impairment (see under Uses and Administration, below).

Pharmacokinetics

Although enoximone is absorbed from the gastrointestinal tract it is no longer given orally. The plasma elimination half-life varies widely; it may be about 1 to 4 hours in healthy subjects and about 3 to 8 hours in patients with heart failure, but longer times have been reported. Enoximone is about 85% bound to plasma proteins. It is metabolised in the liver and is excreted in the urine, mainly as metabolites. After intravenous doses about 70% of a dose is excreted in the urine as metabolites and less than 1% as unchanged drug.

2. Booker PD, *et al.* Enoximone pharmacokinetics in infants. *Br J Anaesth* 2000; **85:** 205–10.

Uses and Administration

Enoximone is a phosphodiesterase inhibitor similar to amrinone (p.1215) with positive inotropic and vasodilator activity. It is given intravenously in the short-term management of heart failure. In some long-term studies it was given orally, but an increased mortality rate was reported.

The usual initial dose of enoximone by intravenous injection is 0.5 to 1.0 mg/kg given at a rate not greater than 12.5 mg/minute. This may be followed by doses of 500 micrograms/kg every 30 minutes until a satisfactory response is obtained or a total dose of 3 mg/kg has been given. Alternatively, the initial dose may be given as a continuous intravenous infusion in a dose of 90 micrograms/kg per minute over 10 to 30 minutes until the desired response is achieved.

For maintenance therapy the initial dose (up to a total of 3 mg/kg) may be repeated as required every 3 to 6 hours or a continuous or intermittent infusion may be given in a dose of 5 to 20 micrograms/kg per minute. The total dose over 24 hours should not exceed 24 mg/kg.

Dosage may need to be reduced in patients with hepatic or renal impairment (see below).

◊ General references.

1. Vernon MW, *et al.* Enoximone: a review of its pharmacological properties and therapeutic potential. *Drugs* 1991; **42:** 997–1017.

Administration in hepatic and renal impairment. The elimination half-life of enoximone after intravenous administration was 2.16 hours in a patient with hepatic impairment and 1.33 hours in a patient with renal impairment. The mean elimination half-life in patients with normal hepatic and renal function was 1.26 hours. It was suggested that patients with renal impairment should be monitored and have plasma concentrations measured during continuous infusions and that in hepatic disease the dosage may need to be modified.[1] Similarly, in a study[2] in paediatric patients receiving intravenous enoximone clearance was reduced in those with renal or hepatic impairment and it was suggested that the infusion rate should be decreased in such patients.

2. Booker PD, *et al.* Enoximone pharmacokinetics in infants. *Br J Anaesth* 2000; **85:** 205–10.

Beta blocker overdosage. Enoximone, given intravenously as a bolus dose of 0.5 mg/kg followed by an infusion of 15 micrograms/kg per minute, successfully increased the cardiac output and stroke volume in a woman who had ingested 10 g of metoprolol.[1] It was suggested that enoximone may be useful in such patients since its action does not involve the beta-adrenergic system. Use to treat propranolol overdose has also been described.[2]

2. Sandroni C, *et al.* Enoximone in cardiac arrest caused by propranolol: two case reports. *Acta Anaesthesiol Scand* 2006; **50:** 759–61.

Heart failure. Enoximone is one of several drugs that may be used in heart failure (p.1165), but because of an increased mortality rate reported following long-term oral use it is only given intravenously for short-term management of heart failure unresponsive to other treatments. In a comparison of oral enoximone and placebo in patients with moderate to moderately severe heart failure,[1] enoximone was no better than placebo in improving exercise duration over the 16-week study period. Although the overall incidence of adverse effects was similar in the two groups, 5 patients receiving enoximone died compared with none in the placebo group. Low doses of oral enoximone (generally 25 or 50 mg three times daily) have been tried in an attempt to wean patients with severe (NYHA class IV) heart failure from intravenous inotropic support, but with little or only limited success.[2]

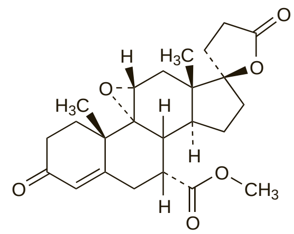
ATC Vet — QC03DA04.



Adverse Effects

As for Spironolactone, p.1400. Hypercholesterolaemia, hypertriglyceridaemia, and increases in liver enzymes have also occurred.

Precautions

As for Spironolactone, p.1400.

Interactions

As for Spironolactone, p.1401.

Eplerenone is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4, and significantly increased plasma concentrations of eplerenone have occurred when potent inhibitors of this enzyme have been given. These include clarithromycin, telithromycin, itraconazole, ketoconazole, nefazodone, nelfinavir, and ritonavir, and use with eplerenone is contra-indicated. Mild to moderate inhibitors of this enzyme, such as erythromycin, fluconazole, saquinavir, and verapamil, have a less marked effect, although a reduced dose of eplerenone may be necessary (see under Uses, below). Grapefruit juice causes only a small increase in exposure to eplerenone. Conversely, inducers of this enzyme system, such as carbamazepine, St John's wort, phenobarbital, phenytoin, and rifampicin, may reduce plasma concentrations of eplerenone.

Pharmacokinetics

Peak plasma concentrations of eplerenone are reached about 1.5 hours after an oral dose; they are dose proportional for doses of 25 to 100 mg, and less than proportional above 100 mg. Protein binding, primarily to α_1-acid glycoprotein, is about 50%. Eplerenone metabolism is mainly mediated by the cytochrome P450 isoenzyme CYP3A4; less than 5% of a dose is excreted unchanged. About 32% of a dose is excreted in the faeces, and the remainder in the urine. The elimination half-life is about 4 to 6 hours. Eplerenone is not removed by dialysis.

◊ References.

1. Ravis WR, *et al.* Pharmacokinetics of eplerenone after single and multiple dosing in subjects with and without renal impairment. *J Clin Pharmacol* 2005; **45:** 810–21.

Uses and Administration

Eplerenone is an aldosterone antagonist with properties similar to those of spironolactone (p.1401) but with a higher selectivity for the aldosterone receptor. It is given orally in the management of hypertension (p.1171) and heart failure (p.1165).

In the management of **hypertension**, eplerenone may be given alone or with other antihypertensives. It is given in an initial dose of 50 mg daily, increasing if necessary to a maximum of 50 mg twice daily. While eplerenone should not be given with potent CYP3A4 inhibitors (see Interactions, above), patients taking mild to moderate inhibitors may be given eplerenone; the initial dose should be reduced to 25 mg daily.

For the management of **heart failure** after myocardial infarction, eplerenone is given in an initial dose of 25 mg daily, increasing to 50 mg daily within 4 weeks if tolerated. Eplerenone should be withdrawn or the dose should be reduced to 25 mg daily, or on alternate days, if hyperkalaemia develops. Eplerenone may be used in patients given mild to moderate CYP3A4 inhibitors, at a dose not exceeding 25 mg daily.

CAS — 61849-14-7.
ATC — B01AC09.
ATC Vet — QB01AC09.

Stability in solution. Epoprostenol is unstable at physiological pH and solutions for infusion are prepared in an alkaline glycine buffer at pH 10.5. The half-life in aqueous solution of pH 7.4 has been reported[1] to be less than 3 minutes at 37°, but increased stability has been reported in plasma, albumin, or whole blood.[1,2]

1. El Tahir KEH, *et al.* Stability of prostacyclin in human plasma. *Clin Sci* 1980; **59:** 28P–29P.
2. Mikhailidis DP, *et al.* Infusion of prostacyclin (epoprostenol). *Lancet* 1982; **ii:** 767.

Adverse Effects and Precautions

The incidence of adverse reactions to epoprostenol is dose-related. Adverse effects during intravenous infusion commonly include hypotension, increased heart rate, flushing, and headache. Dosage should be reduced or the epoprostenol infusion stopped if excessive hypotension occurs. Bradycardia with pallor, sweating, nausea, and abdominal discomfort may occur. Erythema over the intravenous infusion site has been noted. Other adverse effects reported have included nausea and vomiting, diarrhoea, jaw pain or nonspecific musculoskeletal pain, anxiety, nervousness, tremor, flu-like symptoms, hyperglycaemia, drowsiness, and chest pain.

Coagulation of blood in the dialysis circuit has been reported rarely in patients given epoprostenol but no conventional anticoagulant. The use of epoprostenol for pulmonary hypertension is contra-indicated in patients with congestive heart failure due to severe left ventricular systolic dysfunction, and in patients who develop pulmonary oedema during dose-ranging. Sudden withdrawal of epoprostenol should be avoided because of the risk of rebound pulmonary hypertension. Haematological and cardiovascular monitoring is required in patients receiving epoprostenol infusions. Care should be taken to avoid extravasation.

Incidence of adverse effects. A study in 24 healthy subjects investigated the incidence of adverse effects with intravenous infusions of epoprostenol of up to 10 nanograms/kg per minute for up to 100 minutes.[1] Subjects varied in their susceptibility to epoprostenol but the same sequence of events was usually present. A change in pre-ejection period and facial flushing was often apparent at an infusion rate of 2 to 2.5 nanograms/kg per minute. A rise in heart rate and change in other cardiovascular variables was present when the infusion rate had increased to 4 to 5 nanograms/kg per minute; headache, generally the dose-limiting factor, was usually present at this dose and increased as the dose was raised, as did the other effects. Erythema over the vein and 'vagal reflex' only appeared after at least 1 hour of infusion; 'vagal reflex' took only a few seconds to develop.

Early studies showing that high doses were well tolerated had been conducted using a form of epoprostenol probably only half as potent as the commercially available product. It was proposed that 4 nanograms/kg per minute should in general be the maximum infusion rate for prolonged infusions, although higher rates could be tolerated in anaesthetised patients. Careful attention to infusion technique is necessary and monitoring of the heart rate is advisable in view of the suddenness with which the 'vagal reflex' can occur. Most of the adverse effects reported here have responded to a reduction in dosage.

1. Pickles H, O'Grady J. Side effects occurring during administration of epoprostenol (prostacyclin, PGI), in man. *Br J Clin Pharmacol* 1982; **14:** 177–85.

Effects on the blood. Reports of rebound platelet activation during continuous epoprostenol infusion.[1,2]

2. Sinzinger H, *et al.* Rebound platelet activation during continuous epoprostenol infusion. *Lancet* 1984; **ii:** 759.

Effects on the cardiovascular system. Evidence that epoprostenol and its analogue iloprost can induce myocardial ischaemia in patients with coronary artery disease.[1]

1. Bugiardini R, *et al.* Myocardial ischemia induced by prostacyclin and iloprost. *Clin Pharmacol Ther* 1985; **38:** 101–8.

Effects on mental state. Symptoms of depression were associated with intravenous epoprostenol therapy in 4 patients.[1]

1. Ansell D, *et al.* Depression and prostacyclin infusion. *Lancet* 1986; **ii:** 509.

Hypersensitivity. Severe erythroderma occurred in a woman with undifferentiated connective tissue disease who was treated with epoprostenol for pulmonary hypertension.[1] Diffuse erythema, pruritus, and scaling, with chills, nausea, vomiting, and diarrhoea, developed about 2 months after starting therapy, and resolved with epoprostenol withdrawal and corticosteroid treatment.

1. Ahearn GS, *et al.* Severe erythroderma as a complication of continuous epoprostenol therapy. *Chest* 2002; **122:** 378–80.

Interactions

Since epoprostenol is a potent vasodilator and inhibitor of platelet aggregation, care should be taken in patients receiving other vasodilators or anticoagulants. Epoprostenol may slightly increase serum concentrations of digoxin, and may reduce the thrombolytic effect of alteplase by increasing its hepatic clearance. The hypotensive effects of epoprostenol may be exacerbated by using acetate in dialysis fluids.

Anticoagulants. The incidence of bleeding complications was examined in a retrospective review[1] of 31 patients with primary pulmonary hypertension who had been treated with continuous intravenous epoprostenol and oral *warfarin*. Nine patients developed 11 bleeding episodes, including 9 episodes of alveolar haemorrhage. The international normalised ratio (INR) was maintained in the therapeutic range for 8 of these patients, suggesting that the effect was not caused by overdose of warfarin. The risk of bleeding appeared to be increased in patients who received high-dose epoprostenol (mean dose 89 nanograms/kg per minute).

1. Ogawa A, *et al.* Risk of alveolar hemorrhage in patients with primary pulmonary hypertension—anticoagulation and epoprostenol therapy. *Circ J* 2005; **69:** 216–20.

Pharmacokinetics

Endogenous prostacyclin is a product of arachidonic acid metabolism with a very short half-life. On intravenous infusion epoprostenol is hydrolysed rapidly to the more stable but much less active 6-keto-prostaglandin $F_{1\alpha}$ (6-oxo-prostaglandin $F_{1\alpha}$). A second metabolite, 6,15-diketo-13,14-dihydro-prostaglandin $F_{1\alpha}$, is formed by enzymatic degradation. Unlike many other prostaglandins, epoprostenol is not inactivated in the pulmonary circulation.

Uses and Administration

Epoprostenol is a prostaglandin (p.2374) that causes vasodilatation and prevents platelet aggregation. The endogenous substance is termed prostacyclin. Epoprostenol is used mainly in extracorporeal procedures and in pulmonary hypertension.

Epoprostenol is given as the sodium salt and doses are expressed in terms of the base; 1.06 nanograms of epoprostenol sodium is equivalent to about 1 nanogram of epoprostenol. The drug is unstable in solution at physiological pH and also has a very short duration of action because of its rapid hydrolysis *in vivo*. It must therefore be given by continuous infusion. Great care must be taken in preparing a suitably diluted solution for infusion and only diluent as supplied by the manufacturer should be used to reconstitute epoprostenol.

Epoprostenol is used to **prevent platelet aggregation** when blood is brought into contact with nonbiological surfaces in procedures such as extracorporeal circulation, especially in renal dialysis patients. It is indicated for use when heparin carries a high risk of causing or exacerbating bleeding, or is otherwise contra-indicated. Epoprostenol is given by continuous intravenous infusion or into the blood supplying the extracorporeal circulation. The usual dose for renal dialysis is 4 nanograms/kg per minute intravenously before dialysis, then 4 nanograms/kg per minute into the arterial inlet of the dialyser during dialysis.

In the long-term treatment of primary **pulmonary hypertension** or pulmonary hypertension associated with scleroderma a dose-ranging procedure is performed first. Epoprostenol infusion is started at a rate of 2 nanograms/kg per minute, then increased by increments of 2 nanograms/kg per minute at intervals of at least 15 minutes until the maximum haemodynamic benefit or dose-limiting effects occur. Epoprostenol is then given by continuous infusion through a central venous catheter, the initial rate being 4 nanograms/kg per minute *less than* the maximum-tolerated infusion rate; if the maximum-tolerated infusion rate is less than 5 nanograms/kg per minute, then the initial rate should be one-half of this maximum rate. The maintenance dose is subsequently adjusted according to the patient's response. If symptoms recur or if adverse effects occur the dosage may be increased or decreased by steps of 1 to 2 nanograms/kg per minute at intervals of at least 15 minutes until a new maintenance dose is established.

For the use of epoprostenol in neonates and children, see below.

Action. The discovery, properties, and clinical applications of prostacyclin have been reviewed.[1] Prostacyclin is the main product of arachidonic acid in vascular tissues, endothelial cells from vessel walls being the most active producers. It is a strong hypotensive agent through vasodilatation of vascular beds, including the pulmonary and cerebral circulations, and is also a potent endogenous inhibitor of platelet aggregation. Inhibition of aggregation is achieved by stimulation of adenylate cyclase, leading to an increase in cyclic adenosine monophosphate (cAMP) levels in the platelets. By inhibiting several steps in the activation of the arachidonic acid metabolic cascade, prostacyclin exerts an overall control of platelet aggregability.

Endogenous prostacyclin and thromboxane A_2 may be of more physiological and pathological importance[2] than the more classical prostanoids prostaglandin E_2 and prostaglandin F_2 . They have directly opposing pharmacological actions in many systems, such as on platelet function, vascular smooth muscle, bronchopulmonary function, and gastrointestinal integrity. Thus prostanoid-mediated control of cellular and tissue function may reflect an interactive modulation between prostacyclin and thromboxane A_2 with imbalance resulting in dysfunction, for example in platelet and vascular disorders. Thromboxane A_2 has both bronchoconstrictor and pulmonary irritant actions and has brought about marked changes in respiratory function in experimental models; prostacyclin may oppose these effects on both the pulmonary vasculature and bronchial smooth muscle. Thromboxane A_2 has induced marked renal vasoconstriction *in vitro* whereas renal vasodilatation and stimulation of the release of renin has followed the administration of epoprostenol [exogenous prostacyclin] in *animals*. In contrast to the pro-ulcerogenic actions of thromboxane A_2, epoprostenol and its analogues, like other prostaglandins, have potent gastrointestinal anti-ulcer properties which can be disassociated from their gastric antisecretory properties. The term 'cytoprotection' has been used to describe this ability of exogenous prostaglandins to prevent gastrointestinal damage; endogenous prostaglandins might have a similar protective role. Epoprostenol also has a cytoprotective effect against experimental damage in the gastric mucosa, myocardium, and liver whereas thromboxane A_2 has a cytolytic effect.

3. van Heerden PV, *et al.* Dose-response to inhaled aerosolized prostacyclin for hypoxemia due to ARDS. *Chest* 2000; **117:** 819–27.

Administration in children. Although epoprostenol is not licensed for the treatment of children, it has been used successfully in children with primary pulmonary hypertension[1,2] and in neonates with persistent pulmonary hypertension of the newborn.[3] It is usually given by continuous intravenous infusion, but in neonates the inhaled[4] and endotracheal[5] routes have also been used.

For children aged 1 month to 18 years with *primary pulmonary hypertension*, the *BNFC* suggests that epoprostenol may be given by continuous intravenous infusion in an initial dose of 2 nanograms/kg per minute, increasing as necessary to 40 nanograms/kg per minute. Children on prolonged treatment can become tolerant to epoprostenol and higher doses have been used.[1,2]

For neonates with *persistent pulmonary hypertension of the newborn*, the *BNFC* suggests that epoprostenol may be given by continuous intravenous infusion in an initial dose of 2 nanograms/kg per minute, adjusted according to response up to a usual maximum of 20 nanograms/kg per minute (rarely up to 40 nanograms/kg per minute).

Peripheral vascular disease. Various prostaglandins including epoprostenol have been used for their vasodilating effect in the treatment of peripheral vascular disease (p.1178), particularly in severe Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188), but do not constitute mainline therapy.

Pulmonary hypertension. Epoprostenol was originally introduced into the management of end-stage pulmonary hypertension (p.1179) to sustain patients long enough for them to have heart-lung transplantation. However, long-term therapy may also have a role as an alternative to transplantation; sustained clinical improvement and improved survival have been reported[1-4] in some patients with idiopathic pulmonary arterial hypertension given long-term intravenous therapy using portable infusion pumps, as well as in patients with pulmonary arterial hypertension associated with other diseases.[4-7]

Inhaled epoprostenol, a route that may overcome some of the adverse effects associated with parenteral use, has had some success in adults[8,9] with pulmonary hypertension and in neonates[10,11] with persistent pulmonary hypertension.

Stroke. Results with epoprostenol in patients with acute stroke have been inconclusive and a systematic review of randomised studies concluded that too few patients had been studied for the effect of epoprostenol on survival to be determined.[1]

Thrombotic microangiopathies. Platelet aggregation has a major role in the pathogenesis of thrombotic thrombocytopenic purpura and the related disorder, haemolytic-uraemic syndrome (p.1076). Prostacyclin deficiency has been demonstrated in both conditions, but case reports of epoprostenol[1,2] or iloprost[3,4] treatment have indicated variable results.

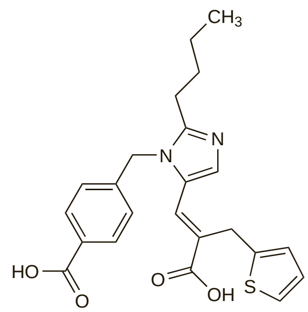
CAS — 133040-01-4 (eprosartan); 144143-96-4 (eprosartan mesilate).

ATC — C09CA02.

ATC Vet — QC09CA02.



(eprosartan)

Adverse Effects and Precautions

As for Losartan Potassium, p.1326.

Interactions

As for Losartan Potassium, p.1327.

Pharmacokinetics

Eprosartan is absorbed from the gastrointestinal tract with an absolute oral bioavailability of about 13%. Peak plasma concentrations occur about 1 to 2 hours after an oral dose in the fasted state; giving doses with food delays absorption but this is not clinically significant. Eprosartan is about 98% bound to plasma proteins. It is excreted in the bile and in the urine, primarily as the unchanged drug; after oral doses approximately 7% of the drug is excreted in the urine, with about 2% as the acyl glucuronide. The terminal elimination half-life is about 5 to 9 hours.

2. Tenero DM, *et al.* Effect of age and gender on the pharmacokinetics of eprosartan. *Br J Clin Pharmacol* 1998; **46:** 267–70.

Uses and Administration

Eprosartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171).

Eprosartan is given orally as the mesilate but doses are expressed in terms of the base; eprosartan mesilate 1.2 mg is equivalent to about 1 mg of eprosartan. The onset of antihypertensive effect occurs about 1 to 2 hours after administration and the maximum effect is achieved within 2 to 3 weeks after initiating therapy.

In the management of hypertension, eprosartan is given in an initial dose of 600 mg once daily. A lower initial dose of 300 mg once daily may be used in elderly patients over 75 years and has been recommended in renal or hepatic impairment (but see below). The dose should be adjusted according to response; the usual maintenance dose is 400 to 800 mg daily in a single dose or in two divided doses.

Administration in hepatic or renal impairment. In the UK a lower initial dose of 300 mg daily of eprosartan is recommended in patients with renal impairment (creatinine clearance less than 60 mL/minute) or mild to moderate hepatic impairment; this seems to be due to lack of clinical experience in such patients. In the USA, however, no reduction in the initial dose is considered necessary in hepatic or renal impairment, but a maximum dose of 600 mg daily is recommended for patients with moderate or severe renal impairment.

Adverse Effects

Bleeding is the most common adverse effect of eptifibatide. Hypotension has been reported. Antibodies to eptifibatide have not been detected.

Effects on the blood. Thrombocytopenia is an established adverse effect of the glycoprotein IIb/IIIa-receptor antagonist abciximab (see p.1192) but appears to be less common with eptifibatide. However, there have been several reports[1-5] of severe thrombocytopenia associated with eptifibatide.

5. Refaat M, *et al.* Eptifibatide-induced thrombocytopenia. *J Thromb Thrombolysis* 2008; **25:** 204–6.

Precautions

As for Abciximab, p.1192.

Pharmacokinetics

Antiplatelet effects of eptifibatide persist for about 4 hours after stopping a continuous infusion. Plasma elimination half-life is about 2.5 hours. Eptifibatide is about 25% bound to plasma proteins. Renal clearance, as eptifibatide and metabolites excreted in the urine, accounts for about 50% of total body clearance.

Uses and Administration

Eptifibatide is an antiplatelet drug that reversibly inhibits binding of fibrinogen, von Willebrand factor, and other adhesive molecules to the glycoprotein IIb/IIIa receptor of platelets. It is used, usually in combination with aspirin and heparin, in the management of unstable angina and in patients undergoing coronary angioplasty and stenting procedures.

In the management of **unstable angina**, eptifibatide is given in an initial dose of 180 micrograms/kg by intravenous injection, followed by 2 micrograms/kg per minute by intravenous infusion, for up to 72 hours. If percutaneous coronary intervention is performed during eptifibatide therapy, the infusion should be continued for 18 to 24 hours after the procedure, to a maximum total duration of 96 hours of therapy.

In patients undergoing **angioplasty**, though not presenting with unstable angina, eptifibatide is given in an initial dose of 180 micrograms/kg by intravenous injection immediately before the procedure, followed by 2 micrograms/kg per minute by intravenous infusion, with a second 180 micrograms/kg intravenous injection given 10 minutes after the first. The infusion should be continued until hospital discharge or for up to 18 to 24 hours; a minimum of 12 hours is recommended.

The dose of eptifibatide may need to be reduced in patients with renal impairment (see below).

5. Zeymer U, Wienbergen H. A review of clinical trials with eptifibatide in cardiology. *Cardiovasc Drug Rev* 2007; **25:** 301–15.

Administration in renal impairment. The clearance of eptifibatide is reduced in renal impairment and plasma-eptifibatide concentrations are about doubled in patients with a creatinine clearance (CC) below 50 mL/minute.[1] Eptifibatide should not be used in severe renal impairment; it is contra-indicated in patients with CC below 30 mL/minute in the UK, and in dialysis-dependent patients in the USA. In patients with moderate renal impairment (CC below 50 mL/minute), the same bolus doses may be given as in those with normal renal function but the infusion dose should be reduced to 1 microgram/kg per minute.

1. Gretler DD, *et al.* Pharmacokinetic and pharmacodynamic properties of eptifibatide in subjects with normal or impaired renal function. *Clin Ther* 2004; **26:** 390–398.

Ischaemic heart disease. Patients with acute coronary syndromes may be treated either medically or with percutaneous coronary interventions such as angioplasty or stenting. In patients with *unstable angina* (p.1157), eptifibatide has been used as an adjunct to both medical and interventional therapy. In the PURSUIT study,[1] which compared eptifibatide with placebo in over 10 000 patients with ischaemic chest pain, the incidence of death and non-fatal myocardial infarction up to 30 days after treatment was reduced in those receiving eptifibatide; most patients also received aspirin and heparin and the number of percutaneous interventions was similar in each group.

Eptifibatide has also been of benefit as an adjunct to standard therapy in patients undergoing *elective percutaneous interventions* (see Reperfusion and Revascularisation Procedures, p.1181). In the IMPACT-II study[2] of over 4000 patients undergoing elective or emergency percutaneous coronary revascularisation, the incidence of death, myocardial infarction, and further unplanned coronary intervention was reduced in those receiving eptifibatide compared with placebo. Similar results were also obtained in a further study (ESPRIT)[3] in patients who were undergoing percutaneous coronary revascularisation with stent implantation, and benefit was maintained at 6-month follow-up.[4] Although most studies have given eptifibatide with unfractionated heparin, use with low-molecular-weight heparin also appears to be safe.[5]

In patients with *acute myocardial infarction* (p.1175), eptifibatide has been tried as an adjunct to thrombolysis or percutaneous intervention. In a study (INTRO AMI)[6] comparing eptifibatide and thrombolysis with thrombolysis alone, early patency rates were improved in those receiving eptifibatide but there was no significant difference in outcomes at 30 days. In patients undergoing interventional therapy, an observational study[7] found that eptifibatide was less effective than abciximab, but other studies[8,9] have reported similar outcomes in patients treated with abciximab or eptifibatide. Positive results have also been seen[10] with eptifibatide given in addition to thrombolytics before percutaneous intervention.

There have been reports of successful intracoronary use[11] of eptifibatide, and also prolonged intravenous use[12] in a patient unable to take oral antiplatelet drugs.

Eritrityl Tetranitrate *(rINN)*

Érititryle, Tétranitrate d'; Eritrityli Tetranitras; Eritrityltetranitrat; Eritrityylitetranitraatti; Erythritol Tetranitrate; Erythrityl Tetranitrate *(USAN)*; Erythrol Nitrate; Erythrol Tetranitrate; Nitroerythrite; Nitroerythrol; NSC-106566; Tetranitrato de eritritilo; Tetranitrol. Butane-1,2,3,4-tetrol tetranitrate.

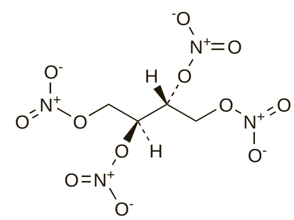
Эритритила Тетранитрат

$C_4H_6(NO_3)_4 = 302.1.$

CAS — 7297-25-8.

ATC — C01DA13.

ATC Vet — QC01DA13.



Profile

Eritrityl tetranitrate is a vasodilator with general properties similar to those of glyceryl trinitrate (p.1296). It has been used in angina pectoris.

Diluted eritrityl tetranitrate is a mixture of eritrityl tetranitrate and lactose or other suitable inert excipients, the excipients being added to minimise the risk of explosion.

Handling. Undiluted eritrityl tetranitrate can be exploded by percussion or excessive heat.

Esatenolol *(rINN)* ⊗

(−)-Atenolol; *S*-Atenolol; Ésaténolol; Esatenololum. 2-{*p*-[(2*S*)-2-Hydroxy-3-(isopropylamino)propoxy]phenyl}acetamide.

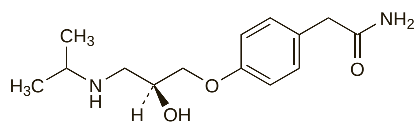
Эзатенолол

$C_{14}H_{22}N_2O_3 = 266.3.$

CAS — 93379-54-5.

ATC — C07AB11.

ATC Vet — QC07AB11.



Profile

Esatenolol, the *S*(−)-isomer of atenolol, has been used similarly to atenolol (p.1217) in the treatment of cardiovascular disorders in usual oral doses of 25 to 100 mg daily.

◊ References.

Esmolol Hydrochloride

(BANM, USAN, rINNM) ⊗

ASL-8052; Esmolol, Chlorhydrate d'; Esmolol Hidroklorür; Esmololi Hydrochloridum; Hidrocloruro de esmolol. Methyl 3-[4-(2-hydroxy-3-isopropylaminopropoxy)phenyl]propionate hydrochloride.

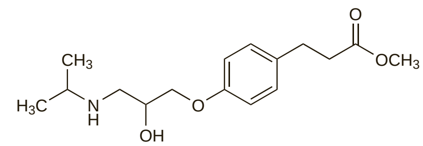
Эсмолола Гидрохлорид

$C_{16}H_{25}NO_4,HCl = 331.8.$

CAS — 81147-92-4 (esmolol); 84057-94-3 (esmolol); 103598-03-4 (esmolol); 81161-17-3 (esmolol hydrochloride).

ATC — C07AB09.

ATC Vet — QC07AB09.



(esmolol)

Incompatibility. Licensed product information advises against admixture of esmolol hydrochloride with sodium bicarbonate because of incompatibility. There has also been a report[1] of immediate haze formation after admixture of esmolol hydrochloride with warfarin sodium.

1. Bahal SM, *et al.* Visual compatibility of warfarin sodium injection with selected medications and solutions. *Am J Health-Syst Pharm* 1997; **54:** 2599–2600.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Hypotension is the most frequently reported adverse effect associated with the infusion of esmolol hydrochloride; it generally resolves within 30 minutes once the dosage is reduced or the infusion is stopped. Local irritation at the site of infusion, inflammation, induration, and thrombophlebitis have occurred and necrosis is a hazard of extravasation. These local effects have occurred with concentrations of 20 mg/mL and it is recommended that concentrations of standard formulations should not normally exceed 10 mg/mL, particularly if given peripherally, and that the infusion should not be made into a small vein.

Effects on the CNS. Generalised tonic-clonic seizures occurred in an elderly patient given esmolol hydrochloride.[1]

1. Das G, Ferris JC. Generalized convulsions in a patient receiving ultra short-acting beta-blocker infusion. *Drug Intell Clin Pharm* 1988; **22:** 484–5.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

After intravenous doses esmolol is rapidly hydrolysed by esterases in the red blood cells. Steady-state blood concentrations are reached within 30 minutes with doses of 50 to 300 micrograms/kg per minute. The time to steady state may be reduced to 5 minutes by giving an appropriate loading dose. Blood concentrations decline in a biphasic manner with a distribution half-life of about 2 minutes and an elimination half-life of about 9 minutes. Esmolol has low lipid solubility and is about 55% bound to plasma proteins. It is excreted in urine, primarily as the de-esterified metabolite.

Uses and Administration

Esmolol is a cardioselective short-acting beta blocker (p.1225). It is reported to be lacking in intrinsic sympathomimetic and membrane-stabilising properties.

Esmolol is used as the hydrochloride in the management of supraventricular arrhythmias (p.1160). It is also used for the control of hypertension (p.1171) and tachycardia during the perioperative period.

Esmolol hydrochloride is given intravenously at a concentration usually not exceeding 10 mg/mL.

For the rapid temporary control of ventricular rate in patients with **supraventricular arrhythmias**, a loading dose of 500 micrograms/kg given over 1 minute is followed by an initial maintenance infusion of 50 micrograms/kg per minute for 4 minutes. If the response is satisfactory this maintenance infusion should be continued at 50 micrograms/kg per minute. If a suitable response is not obtained within the first 5 minutes a further loading dose of 500 micrograms/kg over 1 minute may be given and the maintenance infusion may be increased to 100 micrograms/kg per minute for 4 minutes. If necessary, this procedure may be repeated once or twice more, until a satisfactory response is obtained, increasing the maintenance infusion each time by 50 micrograms/kg per minute to a maximum of 200 micrograms/kg per minute. Little additional benefit is obtained from further increases in maintenance dosage. Once a satisfactory response is obtained infusion may be continued, if necessary, for up to 48 hours.

When transferring a patient to another antiarrhythmic drug, the infusion rate of esmolol hydrochloride is reduced by 50% thirty minutes after starting the alternative drug, and may be stopped one hour after the second dose of that drug.

In the control of perioperative **hypertension** and/or **tachycardia**, esmolol hydrochloride may be given intravenously as follows:

- *during* anaesthesia, a loading dose of 80 mg over 15 to 30 seconds followed by an infusion of 150 micrograms/kg per minute, increased as necessary up to 300 micrograms/kg per minute
- on *waking* from anaesthesia, an infusion of 500 micrograms/kg per minute for 4 minutes, followed by an infusion of 300 micrograms/kg per minute as required
- *postoperatively*, a stepped dosage schedule, as described under control of supraventricular arrhythmias above, although maintenance infusions may be increased up to 300 micrograms/kg per minute as necessary.

◊ References.

Tetralogy of Fallot. Beta blockers have been used in the management of tetralogy of Fallot (see under Uses of Propranolol, p.1381). The *BNFC* recommends that neonates may be given esmolol hydrochloride in an initial dose of 600 micrograms/kg by intravenous injection over 1 to 2 minutes; if necessary, this may be followed by an intravenous infusion at a dose of 300 to 900 micrograms/kg per minute.

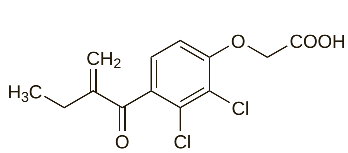
[2,3-Dichloro-4-(2-ethylacryloyl)phenoxy]acetic acid; [2,3-Dichloro-4-(2-methylene-1-oxobutyl)phenoxy]acetic acid.

Этакриновая Кислота

$C_{13}H_{12}Cl_2O_4$ = 303.1.
CAS — 58-54-8.
ATC — C03CC01.
ATC Vet — QC03CC01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Etacrynic Acid). A white or almost white, crystalline powder. Very slightly soluble in water; freely soluble in alcohol. It dissolves in ammonia and in dilute solutions of alkali hydroxides and carbonates.

USP 31 (Ethacrynic Acid). A white or practically white, odourless or practically odourless, crystalline powder. Very slightly soluble in water; soluble 1 in 1.6 of alcohol, 1 in 6 of chloroform, and 1 in 3.5 of ether. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Sodium Etacrynate *(BANM, rINNM)* ⊗

Etacrinato sódico; Étacrynate de Sodium; Etacrynate Sodium; Ethacrynate Sodium *(USAN)*; Natrii Etacrynas; Sodium Ethacrynate.

Натрий Этакринат

$C_{13}H_{11}Cl_2NaO_4$ = 325.1.
CAS — 6500-81-8.
ATC — C03CC01.
ATC Vet — QC03CC01.

Pharmacopoeias. In *Chin.*
Pol. and *US* include sodium etacrynate for injection.

Stability. Solutions in water of sodium etacrynate containing the equivalent of etacrynic acid 0.1% have a pH of 6.3 to 7.7. Solutions are relatively stable at about pH 7 at room temperatures for short periods and less stable at higher pH values and temperatures. They are incompatible with solutions with a pH below 5. The injection should be protected from light.

Adverse Effects

As for Furosemide, p.1292. Gastrointestinal disturbances may be more common and severe with etacrynic acid; profuse watery diarrhoea is an indication for stopping therapy. Gastrointestinal bleeding has been associated with etacrynic acid. Tinnitus and deafness, particularly after high parenteral doses, may also be more common. Other adverse effects include confusion, fatigue, nervousness, and apprehension. Haematuria has been reported rarely.

Local irritation and pain may follow intravenous injection.

Effects on carbohydrate metabolism. Although etacrynic acid is generally considered to have less pronounced effects on carbohydrate metabolism than furosemide or the thiazide diuretics, adverse effects have been reported. Reductions in glucose tolerance[1] after etacrynic acid 200 mg daily for 6 weeks were similar to those produced by hydrochlorothiazide 200 mg daily. The effect was most pronounced in diabetic patients. Hyperosmolar hyperglycaemic coma[2] and symptomatic hypoglycaemia with convulsions[3] have been reported in patients receiving high doses of etacrynic acid.

1. Russell RP, *et al.* Metabolic and hypotensive effects of ethacrynic acid: comparative study with hydrochlorothiazide. *JAMA* 1968; **205:** 11–16.
2. Cowley AJ, Elkeles RS. Diabetes and therapy with potent diuretics. *Lancet* 1978; **i:** 154.
3. Maher JF, Schreiner GE. Studies on ethacrynic acid in patients with refractory edema. *Ann Intern Med* 1965; **62:** 15–29.

Effects on the ears. Drug-induced deafness occurred in 2 of 184 patients given etacrynic acid intravenously.[1,2] Deafness accompanied by nystagmus was reported in a patient[3] after an intravenous infusion of etacrynic acid. Symptoms resolved within 1 hour. He had previously been taking furosemide and etacrynic acid orally.

1. Boston Collaborative Drug Surveillance Program. Drug-induced deafness: a cooperative study. *JAMA* 1973; **224:** 515–16.
2. Porter J, Jick H. Drug-induced anaphylaxis, convulsions, deafness, and extrapyramidal symptoms. *Lancet* 1977; **i:** 587–8.
3. Gomolin IH, Garshick E. Ethacrynic acid-induced deafness accompanied by nystagmus. *N Engl J Med* 1980; **303:** 702.

Precautions

Etacrynic acid's precautions and contra-indications are generally dependent on its effects on fluid and electrolyte balance and are similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1309). Etacrynic acid, especially in the form of dust, is irritating to the skin, eyes, and mucous membranes.

Interactions

As for Furosemide, p.1293. The risks of gastrointestinal bleeding may be enhanced by use of etacrynic acid with other gastric irritants or with anticoagulants.

Anticoagulants. For reference to the interaction between *warfarin* and etacrynic acid, see p.1430.

Pharmacokinetics

Etacrynic acid is fairly rapidly absorbed from the gastrointestinal tract. The plasma half-life is 30 to 60 minutes. It is excreted both in the bile and the urine, partly unchanged and partly in the form of metabolites. It is extensively bound to plasma proteins.

Uses and Administration

Although chemically unrelated, etacrynic acid is a loop diuretic with actions and uses similar to those of furosemide (p.1294). Etacrynic acid is used in the treatment of oedema associated with heart failure (p.1165) and with renal and hepatic disorders.

Diuresis begins within about 30 minutes after an oral dose, and lasts for about 6 to 8 hours; after intravenous injection of its sodium salt, the effects are evident within a few minutes and last for about 2 hours.

In the treatment of **oedema**, the usual initial oral dose is 50 mg in the morning. The dose may be increased, if necessary, by 25- to 50-mg increments daily to the minimum effective dose. Severe cases have required gradual titration of the dose up to a maximum of 400 mg daily, but the effective range is usually between 50 and 150 mg daily. Dosage of more than 50 mg daily should be given in divided doses. All doses should be taken with food. Maintenance doses may be taken daily or intermittently.

In emergencies, such as acute pulmonary oedema, or when oral therapy cannot be given, etacrynic acid may be given intravenously. It is given as its salt, sodium etacrynate, but doses are expressed in terms of the acid. 10.7 mg of sodium etacrynate is equivalent to about 10 mg of etacrynic acid. The usual dose is 50 mg, or 0.5 to 1 mg/kg, as a 1 mg/mL solution in glucose 5% (provided the pH is above 5) or sodium chloride 0.9%, given by slow intravenous injection either directly or into the tubing of a running infusion. Should a subsequent injection be required the site should be changed to avoid thrombophlebitis. Single doses of 100 mg have been given intravenously in critical situations. It is not suitable for subcutaneous or intramuscular injection.

For children over 2 years of age an initial dose of etacrynic acid is 25 mg daily by mouth, cautiously increased as necessary by 25 mg daily.

If very high doses of etacrynic acid are used careful laboratory control is essential as described for furosemide (p.1294; high-dose therapy).

Preparations

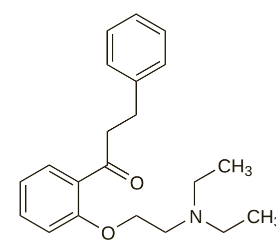
Etafenone Hydrochloride *(rINNM)*

Étafénone, Chlorhydrate d'; Etafenoni Hydrochloridum; Hidrocloruro de etafenona; LG-11457. 2′-(2-Diethylaminoethoxy)-3-phenylpropiophenone hydrochloride.

Этафенона Гидрохлорид

$C_{21}H_{27}NO_2$,HCl = 361.9.
CAS — 90-54-0 (etafenone); 2192-21-4 (etafenone hydrochloride).
ATC — C01DX07.
ATC Vet — QC01DX07.



(etafenone)

Profile

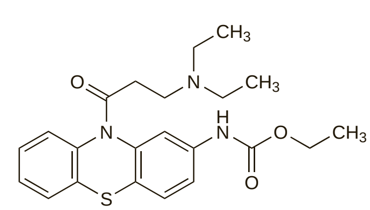
Etafenone hydrochloride is a vasodilator that has been used in ischaemic heart disease.

Ethacizine

Aethacizin; Etacizin; Ethacizin; Ethacyzin; EZ-55; NIK-244. Ethyl 10-[3-(diethylamino)propionyl]phenothiazine-2-carbamate.

Этацизин

$C_{22}H_{27}N_3O_3S$ = 413.5.
CAS — 33414-33-4 (ethacizine); 57530-40-2 (ethacizine hydrochloride).



Profile

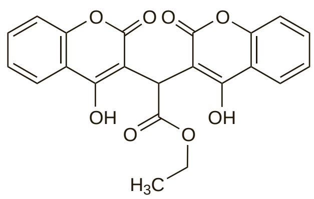
Ethacizine, an analogue of moracizine (p.1344), is reported to be a class Ic antiarrhythmic. It is used in the treatment of ventricular and supraventricular arrhythmias and has been given orally in doses starting at 50 mg three times daily, increased if necessary to a maximum of 100 mg three times daily. It has also been given intravenously.

Ethyl Biscoumacetate *(BAN, rINN)*

Aethylis Biscoumacetas; Biscumacetato de etilo; Ethyldicoumarol; Éthyle, Biscoumacétate d'; Ethylis Biscoumacetas; Neodicumarinum. Ethyl bis(4-hydroxycoumarin-3-yl)acetate.

Этил Бискумацетат

$C_{22}H_{16}O_8$ = 408.4.
CAS — 548-00-5.
ATC — B01AA08.
ATC Vet — QB01AA08.



Profile

Ethyl biscoumacetate is an oral coumarin anticoagulant with actions similar to those of warfarin (p.1432). It has been used in the management of thromboembolic disorders.

Preparations

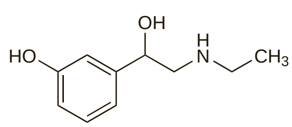
Proprietary Preparations (details are given in Part 3)
Cz.: Pelentan†; Pelentanettae†.

Etilefrine Hydrochloride *(BANM, rINNM)* ⊗

Ethyladrianol Hydrochloride; Ethylnorphenylephrine Hydrochloride; Etilefriinihydrokloridi; Étiléfrine, chlorhydrate d'; Etilefrin-hidroklorid; Etilefrin-hydrochlorid; Etilefrinhydroklorid; Etilefrini hydrochloridum; Etilefrino hidrochloridas; Hidrocloruro de etilefrina; M-I-36. 2-Ethylamino-1-(3-hydroxyphenyl)ethanol hydrochloride.

Этилэфрина Гидрохлорид

$C_{10}H_{15}NO_2,HCl$ = 217.7.
CAS — 709-55-7 (etilefrine); 943-17-9 (etilefrine hydrochloride).
ATC — C01CA01.
ATC Vet — QC01CA01.



(etilefrine)

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Etilefrine Hydrochloride). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; soluble in alcohol; practically insoluble in dichloromethane. Store in airtight containers. Protect from light.

Profile

Etilefrine is a direct-acting sympathomimetic (p.1407) with $beta_1$-agonist properties, and some alpha- and $beta_2$-agonist actions. It is used for the treatment of hypotensive states (p.1174). It is given orally as the hydrochloride in usual doses of 5 or 10 mg three times daily; modified-release dosage forms may be given in doses of 25 mg once or twice daily. Etilefrine hydrochloride can also be given parenterally.

Etilefrine polistirex has been used in the management of rhinitis.

Priapism. Priapism is a common complication of sickle-cell disease (p.1044) and is often treated with intracavernosal alpha agonists (see under Uses of Metaraminol, p.1333). There have also been reports of the successful use of etilefrine, both by intracavernosal injection for acute treatment,[1,2] and orally for prophylaxis.[1-3]

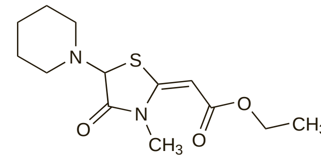
ATC Vet — QC03CX01.



Profile

Etozolin is a loop diuretic with properties similar to those of furosemide (p.1292), but with a longer duration of action. It has been used in the treatment of oedema and hypertension (p.1171). Etozolin is reported to be rapidly metabolised to ozolinone which also has diuretic activity.

Preparations

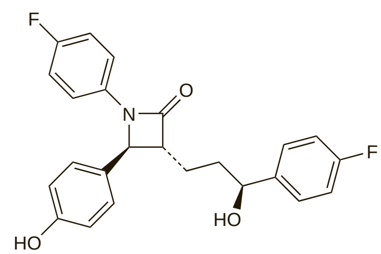
Proprietary Preparations (details are given in Part 3)
Ital.: Elkapin†.

Ezetimibe *(BAN, USAN, rINN)*

Ezetimiba; Ézétimibe; Ezetimibum; Sch-58235. (3*R*,4*S*)-1-(*p*-Fluorophenyl)-3-[(3*S*)-3-(*p*-fluorophenyl)-3-hydroxypropyl]-4-(*p*-hydroxyphenyl)-2-azetidinone.

Эзетимиб

$C_{24}H_{21}F_2NO_3$ = 409.4.
CAS — 163222-33-1.
ATC — C10AX09.
ATC Vet — QC10AX09.



Adverse Effects and Precautions

Ezetimibe is generally well tolerated. The most common adverse effects include headache, abdominal pain, and diarrhoea; other gastrointestinal disorders, hypersensitivity reactions including rash and angioedema, fatigue, chest pain, and arthralgia have also been reported. Rare adverse effects include raised liver enzymes or hepatitis, pancreatitis, thrombocytopenia, cholelithiasis, and cholecystitis. Myalgia has occurred in patients taking ezetimibe either alone or when added to a statin (see below). Ezetimibe should be stopped if myopathy is suspected or creatine phosphokinase increases significantly.

Ezetimibe should be avoided in patients with moderate or severe hepatic impairment.

◊ Reviews.

2. Kashani A, *et al.* Review of side-effect profile of combination ezetimibe and statin therapy in randomized clinical trials. *Am J Cardiol* 2008; **101:** 1606–13.

Effects on the liver. Ezetimibe may cause an increase in liver enzymes and there have also been reports of acute hepatitis,[1] sometimes developing after addition of ezetimibe to long-term statin therapy.[2,3] Both auto-immune[2,3] and cholestatic hepatitis[3] have been described. In some patients,[1,2] symptoms resolved and liver enzymes normalised when ezetimibe was stopped, and in 1 patient a statin was successfully restarted.[2] However, of 2 patients who had been receiving ezetimibe and atorvastatin, 1 required treatment with corticosteroids,[3] while the other[3] had persistent liver changes 4 months later, despite both drugs being stopped in each case.

3. Stolk MF, *et al.* Severe hepatic side effects of ezetimibe. *Clin Gastroenterol Hepatol* 2006; **4:** 908–11.

Effects on the pancreas. Pancreatitis has been reported[1] in patients taking ezetimibe. In one case,[2] acute pancreatitis developed 2 weeks after starting ezetimibe and resolved when the drug was stopped, suggesting an immunological cause.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Drug induced pancreatitis. *Aust Adverse Drug React Bull* 2006; **25:** 22. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0612.pdf (accessed 30/05/08)
2. Ahmad I, *et al.* Ezetimibe-induced acute pancreatitis. *South Med J* 2007; **100:** 409–10.

Effects on skeletal muscle. Muscle disorders such as myalgia and myopathy are well known to occur with lipid regulating drugs such as statins and fibrates and have also been reported with ezetimibe, both alone,[1,2] and when added to treatment with statins;[1,3] rhabdomyolysis has also occurred, but is rare in patients taking ezetimibe alone. Up to August 2005, the Australian Adverse Drug Reactions Advisory Committee[4] had received 44 reports of muscle disorders with ezetimibe, including myalgia, muscle cramp, weakness and pain; in 5 of these cases a statin was also being taken.

Interactions

Colestyramine reduces the absorption of ezetimibe and should not be given at the same time of day. Ciclosporin has been reported to increase the plasma concentration of ezetimibe (see below) and patients receiving both drugs should be carefully monitored; the effect may be greater in patients with severe renal impairment. An increased INR has been reported in patients given ezetimibe and oral anticoagulants.

Ciclosporin. Pharmacokinetic studies[1] have shown that plasma-ezetimibe concentrations are higher in renal transplant patients taking ciclosporin than in historical controls, and there has been a report[2] of a supratherapeutic response to ezetimibe in a heart transplant patient taking ciclosporin. Ezetimibe causes a small increase in plasma-ciclosporin concentrations,[3] but the clinical relevance of this is not clear.

3. Bergman AJ, *et al.* Effects of ezetimibe on cyclosporine pharmacokinetics in healthy subjects. *J Clin Pharmacol* 2006; **46:** 321–7.

Pharmacokinetics

Ezetimibe is rapidly absorbed when given orally and undergoes extensive conjugation in the small intestine and liver to an active glucuronide metabolite, which is the main circulating form. Both ezetimibe and the glucuronide are more than 90% bound to plasma proteins. Ezetimibe is excreted primarily in the faeces via bile and undergoes enterohepatic recycling; after an oral dose, about 78% is excreted in the faeces, mainly as ezetimibe, and about 11% is excreted in the urine, mainly as the glucuronide. The elimination half-life for both ezetimibe and the glucuronide is about 22 hours. Ezetimibe is distributed into breast milk in *rats*.

◊ Reviews

1. Kosoglou T, *et al.* Ezetimibe: a review of its metabolism, pharmacokinetics and drug interactions. *Clin Pharmacokinet* 2005; **44:** 467–94.

Uses and Administration

Ezetimibe is an inhibitor of intestinal sterol absorption and inhibits the absorption of cholesterol and plant sterols. It is used to reduce total cholesterol, low-density lipoprotein (LDL)-cholesterol, and apolipoprotein B in the management of hyperlipidaemias (below), and to reduce sitosterol and campesterol in patients with homozygous familial sitosterolaemia. It is given orally in a usual dose of 10 mg once daily.

2. Mauro VF, Tuckerman CE. Ezetimibe for management of hypercholesterolemia. *Ann Pharmacother* 2003; **37:** 839–48.

Hyperlipidaemias. Ezetimibe inhibits the absorption of dietary cholesterol[1] and, although there is a compensatory increase in cholesterol synthesis in the liver,[1] overall plasma LDL-cholesterol concentrations are reduced.[2] Ezetimibe may be used alone in the management of hyperlipidaemias (p.1169) but use with lipid regulating drugs that act by reducing cholesterol synthesis may produce additive effects. In patients already taking statins, addition of ezetimibe results in a further reduction in LDL-cholesterol,[3] which may increase the number of patients achieving lipid targets, or allow lower doses of statins to be used. However, the clinical relevance of this is unclear; a study[4] in patients with familial hypercholesterolaemia found no difference in the progression of carotid atherosclerosis (measured by intima-media thickness) in those given ezetimibe with simvastatin compared with those given simvastatin alone, despite a larger reduction in LDL-cholesterol. Similar effects on LDL-cholesterol have been reported[5] for ezetimibe with fibrates.

As well as inhibiting cholesterol absorption, ezetimibe also blocks the absorption of plant sterols such as campesterol and sitosterol, and may be effective in patients with sitosterolaemia,[6] an inherited disorder in which increased absorption of plant sterols leads to premature atherosclerosis.

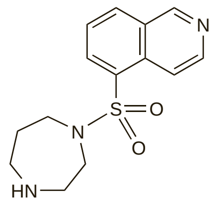
ATC — C04AX32.

ATC Vet — QC04AX32.



(fasudil)

Profile

Fasudil is a selective inhibitor of Rho-kinase, a protein kinase involved in contraction of vascular smooth muscle. Fasudil is used as the hydrochloride for its vasodilating properties in the management of cerebrovascular disorders including vasospasm after surgery for subarachnoid haemorrhage. It is under investigation for the treatment of angina pectoris, acute cerebral thrombosis, and pulmonary hypertension.

Felodipine *(BAN, USAN, rINN)*

Felodipiini; Felodipin; Felodipinas; Félodipine; Felodipino; Felodipinum; H-154/82. Ethyl methyl 4-(2,3-dichlorophenyl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate.

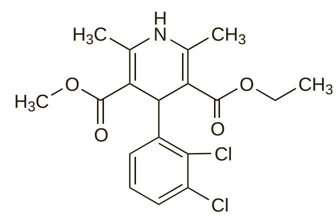
Фелодипин

$C_{18}H_{19}Cl_2NO_4$ = 384.3.

CAS — 72509-76-3; 86189-69-7.

ATC — C08CA02.

ATC Vet — QC08CA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Felodipine). A white or light yellow, crystalline powder. Practically insoluble in water; freely soluble in dehydrated alcohol, in acetone, in dichloromethane, and in methyl alcohol. Protect from light.

USP 31 (Felodipine). A light yellow to yellow, crystalline powder. Insoluble in water; freely soluble in acetone and in methyl alcohol; very slightly soluble in heptane. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Felodipine is almost completely absorbed from the gastrointestinal tract after oral doses but undergoes extensive first-pass metabolism, with a bioavailability of about 15% (range 10 to 25%). It is extensively metabolised in the gut and the liver and is excreted almost entirely as metabolites, about 70% of a dose being excreted in urine and the remainder in faeces. The terminal elimination half-life is reported to be about 11 to 16 hours after oral dosage with an immediate-release preparation, but longer with a modified-release formulation. Felodipine is about 99% bound to plasma proteins (mainly albumin).

◊ General reviews.

1. Dunselman PHJM, Edgar B. Felodipine clinical pharmacokinetics. *Clin Pharmacokinet* 1991; **21:** 418–30.

Uses and Administration

Felodipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the management of hypertension (p.1171) and angina pectoris (p.1157).

Felodipine is given orally, generally in a modified-release formulation for use once daily in the morning. In **hypertension** the usual initial dose is 5 mg daily, adjusted as required; the usual maintenance dose is 2.5 to 10 mg daily and doses above 20 mg daily are not usually needed. In **angina** the usual initial dose is 5 mg daily increased if necessary to 10 mg daily.

Lower doses may be required in patients with hepatic impairment (see below) and in the elderly.

◊ Reviews.

1. Todd PA, Faulds D. Felodipine: a review of the pharmacology and therapeutic use of the extended release formulation in cardiovascular disorders. *Drugs* 1992; **44:** 251–77.
2. Walton T, Symes LR. Felodipine and isradipine: new calcium-channel-blocking agents for the treatment of hypertension. *Clin Pharm* 1993; **12:** 261–75.

Administration in hepatic impairment. In 9 patients with liver cirrhosis given felodipine 750 micrograms by intravenous infusion over 20 minutes and 10 mg orally as single doses on separate occasions the mean oral bioavailability was 17.1% which was not significantly different from published values in healthy subjects, but the maximum plasma concentrations were almost twice as high as normal, apparently due to reduced systemic clearance and volume of distribution.[1] The fact that bioavailability was not increased suggests that much pre-systemic metabolism takes place in the gut rather than the liver. Although increased adverse effects were not associated with the raised felodipine concentrations in this study it is recommended that therapy in cirrhotic patients begin at lower doses than in patients with normal liver function. US licensed product information recommends that an initial dose of 2.5 mg once daily should be used in patients with hepatic impairment.

USP 31 (Fenofibrate). A white or almost white, crystalline powder. M.p. 79° to 82°. Practically insoluble in water; slightly soluble in alcohol; very soluble in dichloromethane. Protect from light.

Adverse Effects and Precautions

As for Bezafibrate, p.1232.

Interactions

As for Bezafibrate, p.1232.

UK licensed product information for fenofibrate suggests that in patients taking oral anticoagulants, the dose of anticoagulant should be reduced by about one-third when treatment with fenofibrate is started, and then adjusted gradually if necessary.

Pharmacokinetics

Fenofibrate is readily absorbed from the gastrointestinal tract when taken with food; absorption may be reduced if fenofibrate is given on an empty stomach, although this depends on the formulation (see Bioavailability, below). It is rapidly hydrolysed to its active metabolite fenofibric acid which is about 99% bound to plasma albumin. The plasma elimination half-life is about 20 hours. Fenofibric acid is excreted mainly in the urine, mainly as the glucuronide conjugate, but also as a reduced form of fenofibric acid and its glucuronide. It is not removed by haemodialysis.

◊ References.

1. Chapman MJ. Pharmacology of fenofibrate. *Am J Med* 1987; **83** (suppl 5B): 21–5.

Bioavailability. Fenofibrate is poorly soluble in water and has a low bioavailability when given orally.[1] Bioavailability is increased by food, particularly if there is a high fat content, and fenofibrate is therefore usually given with meals. Changes to the formulation, particularly with regard to the particle size, have been made to improve solubility,[1] with the aim of increasing bioavailability and reducing the influence of food. Micronisation improves bioavailability to a certain extent, and allows a lower dose to be given; 300 mg of non-micronised fenofibrate is usually considered equivalent to about 200 mg of the standard micronised form. Microcoating may further improve bioavailability,[2] but absorption is still affected by the presence of food.[3] Nanoparticle,[4] stabilised microparticle,[3] or semi-solid formulations,[5] however, appear to have a more consistent bioavailability and may be given with or without food.

5. Sonet B, *et al.* Randomised crossover studies of the bioequivalence of two fenofibrate formulations after administration of a single oral dose in healthy volunteers. *Arzneimittelforschung* 2002; **52:** 200–4.

Uses and Administration

Fenofibrate, a fibric acid derivative, is a lipid regulating drug with actions on plasma lipids similar to those of bezafibrate (p.1233).

It is used to reduce low-density lipoprotein (LDL)-cholesterol, total cholesterol, triglycerides, and apolipoprotein B, and to increase high-density lipoprotein (HDL)-cholesterol, in the management of hyperlipidaemias (p.1169), including type IIa, type IIb, type III, type IV, and type V hyperlipoproteinaemias.

Fenofibrate is given orally. It is usually given with food to improve bioavailability although this may not be necessary with all preparations (see Bioavailability, above). It is available in a range of formulations with differing bioavailabilities and the dose is therefore specific to the preparation.

Standard micronised formulations of fenofibrate are available as 67-mg capsules to be taken several times daily, or as 200- or 267-mg capsules for once daily dosage. The usual initial dose is 67 mg three times daily or 200 mg once daily; the dose may be reduced to 67 mg twice daily or increased to 67 mg four times daily or 267 mg once daily according to response.

Preparations with improved bioavailability may be given in doses of around 40 to 160 mg once daily.

Non-micronised formulations may also be available and are given in an initial dose of 200 to 300 mg daily in divided doses, adjusted according to response to between 200 and 400 mg daily; 100 mg of non-micronised fenofibrate is therapeutically equivalent to 67 mg of the standard micronised form.

The dose of fenofibrate should be reduced in renal impairment (see below). For the dose of fenofibrate in children, see also below.

◊ Reviews.

1. Keating GM, Croom KF. Fenofibrate: a review of its use in primary dyslipidaemia, the metabolic syndrome and type 2 diabetes mellitus. *Drugs* 2007; **67:** 121–53.

Administration in children. Experience with fenofibrate in children is limited and it should only be given under specialist advice. The dose depends on the formulation:

- For *standard micronised* fenofibrate the *BNFC* recommends that children are given the 67-mg capsule formulation. The oral dose is one 67-mg capsule per 20 kg body-weight daily for children aged 4 to 15 years; those aged 15 to 18 years may be given the adult dose (see above).
- *Non-micronised* fenofibrate is licensed for use in some countries in children from the age of 10 years, in an oral dose of 5 mg/kg daily.

Administration in renal impairment. A single-dose study[1] in patients with mild (creatinine clearance (CC) 30 to 50 mL/minute) or severe renal impairment (CC below 10 mL/minute or undergoing haemodialysis) found that the plasma elimination half-life of fenofibric acid was prolonged, with a range of 54 to 362 hours; no correlation was found between half-life and serum creatinine or CC. Fenofibrate metabolites were not removed by haemodialysis, and repeated dosing in patients undergoing regular haemodialysis led to significant accumulation of fenofibric acid.[1]

Fenofibrate is therefore not generally recommended in patients with severe renal impairment although UK licensed product information allows a dose of 134 mg of standard micronised fenofibrate daily for patients with CC between 20 and 60 mL/minute and 67 mg daily for patients with CC below 20 mL/minute. US licensed product information for improved bioavailability formulations suggests initial daily doses of about 40 to 50 mg (equivalent to about 67 mg of standard micronised fenofibrate) in patients with renal impairment, but contra-indicates use in those with severe impairment.

Fenoldopam Mesilate *(BANM, rINNM)*

Fénoldopam, Mésilate de; Fenoldopam Mesylate *(USAN)*; Fenoldopami Mesilas; Mesilato de fenoldopam; SKF-82526-j. 6-Chloro-2,3,4,5-tetrahydro-1-(*p*-hydroxyphenyl)-1*H*-3-benzazepine-7,8-diol methanesulfonate.

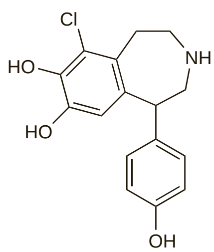
Фенолдопама Мезилат

$C_{16}H_{16}ClNO_3,CH_4O_3S$ = 401.9.

CAS — 67227-56-9 (fenoldopam); 67227-57-0 (fenoldopam mesilate).

ATC — C01CA19.

ATC Vet — QC01CA19.



(fenoldopam)

Pharmacopoeias. In *US*.

USP 31 (Fenoldopam Mesylate). A white to off-white powder. Soluble in water. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from moisture.

Incompatibility. Physical incompatibility has been reported[1] with fenoldopam 80 micrograms/mL (as the mesilate) in 0.9% sodium chloride injection and the following drugs during simulated Y-site administration: aminophylline; ampicillin sodium; amphotericin B; bumetanide; cefoxitin sodium; dexamethasone sodium phosphate; diazepam; fosphenytoin sodium; furosemide; ketorolac tromethamine; methohexital sodium; methylprednisolone sodium succinate; pentobarbital sodium; phenytoin sodium; prochlorperazine edisilate; sodium bicarbonate; and thiopental sodium.

1. Trissel LA, *et al.* Compatibility of fenoldopam mesylate with other drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 2003; **60:** 80–5.

Stability. Fenoldopam mesilate, at concentrations ranging from 4 to 300 micrograms/mL in glucose 5% or sodium chloride 0.9%, has been reported[1] to be stable for 72 hours when stored at temperatures of 4° or 23°.

1. Trissel LA, *et al.* Stability of fenoldopam mesylate in two infusion solutions. *Am J Health-Syst Pharm* 2002; **59:** 846–8.

Adverse Effects and Precautions

The adverse effects of fenoldopam are mainly due to vasodilatation and include hypotension, flushing, dizziness, headache, and reflex tachycardia. Nausea and vomiting, and ECG abnormalities have also been reported. Hypokalaemia has occurred and serum-electrolyte concentrations should be monitored during therapy; blood pressure and heart rate should also be monitored. Fenoldopam may increase intra-ocular pressure and it should be used with caution in patients with glaucoma. Caution is also required in patients in whom hypotension could be deleterious, such as those with acute cerebral infarction or haemorrhage.

Effects on the heart. Although fenoldopam is usually associated with reflex tachycardia, precipitous bradycardia in 2 patients given fenoldopam infusion in a clinical study[1] forced the drug to be stopped.

1. Taylor AA, *et al.* Sustained hemodynamic effects of the selective dopamine-1 agonist, fenoldopam, during 48-hour infusions in hypertensive patients: a dose-tolerability study. *J Clin Pharmacol* 1999; **39:** 471–9.

Interactions

The hypotensive effects of fenoldopam may be enhanced by other drugs with hypotensive actions. Beta blockers may block fenoldopam-induced reflex tachycardia and use of the drugs together is not recommended.

Pharmacokinetics

Steady-state plasma concentrations of fenoldopam are reached about 20 minutes after starting continuous intravenous infusion. Fenoldopam is extensively metabolised with only about 4% of a dose being excreted unchanged. It is metabolised by conjugation (mainly glucuronidation, methylation, and sulfation). Fenoldopam and its metabolites are excreted mainly in the urine, and the remainder in the faeces. The elimination half-life of fenoldopam is about 5 minutes.

Uses and Administration

Fenoldopam is a dopamine agonist that is reported to have a selective action at dopamine D_1-receptors, leading to vasodilatation. It is used in the short-term management of severe hypertension (below) and has also been tried in heart failure.

Fenoldopam is given intravenously as the mesilate, although doses are expressed in terms of the base; 1.31 micrograms of fenoldopam mesilate is equivalent to about 1 microgram of fenoldopam.

In the management of hypertensive crises, fenoldopam mesilate is given by continuous intravenous infusion for up to 48 hours, as a solution containing 40 micrograms/mL of fenoldopam. The dose should be adjusted according to response, in usual increments of 50 to 100 nanograms/kg per minute at not less than 15-minute intervals. The usual dose range is from 100 to 1600 nanograms/kg per minute.

In the management of hypertensive crises in children, fenoldopam mesilate is given by continuous intravenous infusion for up to 4 hours, as a solution containing 60 micrograms/mL of fenoldopam. US licensed product information states that the initial dose used in clinical studies was 200 nanograms/kg per minute; adjustments according to response every 20 to 30 minutes up to 500 nanograms/kg per minute were usually well-tolerated. No benefit was seen from doses above 800 nanograms/kg per minute.

Hypertension. Fenoldopam has a rapid onset of action and short elimination half-life and may be used as an alternative to sodium nitroprusside in the management of hypertensive crises (see under Hypertension, p.1171). Its use has been reviewed.[1-3] Comparative studies with sodium nitroprusside in patients with acute severe hypertension have shown fenoldopam to be equally effective in rapidly lowering blood pressure. Additionally, in contrast to nitroprusside, urine output, creatinine clearance, and sodium excretion may be increased by fenoldopam. Fenoldopam may therefore be particularly useful in patients with renal impairment, although this remains to be established.

3. Murphy MB, *et al.* Fenoldopam: a selective peripheral dopamine-receptor agonist for the treatment of severe hypertension. *N Engl J Med* 2001; **345:** 1548–57.

Nephrotoxicity. Fenoldopam increases renal blood flow and has been tried to reduce the renal toxicity that may be associated with use of contrast media (see Effects on the Kidneys under Adverse Effects of Amidotrizoic Acid, p.1476). Small studies in patients at risk of renal toxicity have shown benefit with fenoldopam,[1,2] but larger randomised trials[3,4] have found no advantage with fenoldopam plus hydration compared with hydration using sodium chloride 0.45% alone. However, a later meta-analysis[5] in patients undergoing cardiovascular surgery, who are at risk of acute renal failure, found that fenoldopam consistently reduced the need for renal replacement therapy, and reduced mortality.

A study[6] in patients undergoing liver transplantation (p.1815) suggested that fenoldopam may have a role in preserving renal function, possibly by counteracting the renal toxicity associated with ciclosporin.

Fenquizone *(USAN, rINN)* ⊗

Fenquizona; Fenquizonum; MG-13054. 7-Chloro-1,2,3,4-tetrahydro-4-oxo-2-phenylquinazoline-6-sulphonamide.

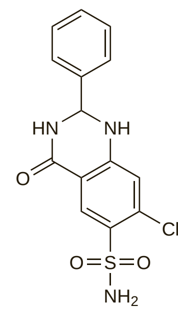
Фенхизон

$C_{14}H_{12}ClN_3O_3S$ = 337.8.

CAS — 20287-37-0.

ATC — C03BA13.

ATC Vet — QC03BA13.



Fenquizone Potassium *(rINNM)* ⊗

Fenquizona potásica; Fenquizone Potassique; Kalii Fenquizonum.

Калия Фенхизон

$C_{14}H_{12}ClN_3O_3S,K$ = 376.9.

CAS — 52246-40-9.

ATC — C03BA13.

ATC Vet — QC03BA13.

Profile

Fenquizone potassium is a diuretic that is given orally in the treatment of oedema and hypertension (p.1171) in doses equivalent to 10 to 20 mg of fenquizone daily. 11.2 mg of the potassium salt is equivalent to about 10 mg of the base.

Fibrinolysin

Fibrinolysin (Human) *(BAN, rINN)*; Fibrinase; Fibrinolisina (humana); Fibrinolysine (humaine); Fibrinolysinum (humanum); Plasmiini; Plasmin; Plasminum.

Фибринолизин (Человека)

CAS — 9001-90-5 (fibrinolysin); 9004-09-5 (human fibrinolysin).

ATC — B01AD05.

ATC Vet — QB01AD05.

NOTE. In *Martindale* the term fibrinolysin is used for the exogenous substance and plasmin for the endogenous substance.

Profile

Fibrinolysin is a proteolytic enzyme derived from the activation of human plasminogen. Fibrinolysin derived from cattle (bovine fibrinolysin) and other animals is also available. Fibrinolysin converts fibrin into soluble products and also hydrolyses some other proteins. The role of plasmin (endogenous fibrinolysin) in the control of haemostasis is described further on p.1045.

Fibrinolysin is used (generally as bovine fibrinolysin) with deoxyribonuclease for the debridement of wounds. It was formerly given parenterally for the treatment of thrombotic disorders. A modified form of fibrinolysin, microplasmin, is under investigation for use in ophthalmic surgery.

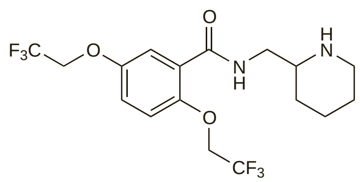
Флекаинида Ацетат

$C_{17}H_{20}F_6N_2O_3,C_2H_4O_2$ = 474.4.

CAS — 54143-55-4 (flecainide); 54143-56-5 (flecainide acetate).

ATC — C01BC04.

ATC Vet — QC01BC04.



(flecainide)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Flecainide Acetate). A white or almost white, very hygroscopic crystalline powder. Soluble in water and in dehydrated alcohol; freely soluble in dilute acetic acid; practically insoluble in dilute hydrochloric acid. A 2.5% solution in water has a pH of 6.7 to 7.1. Protect from light.

USP 31 (Flecainide Acetate). A white to slightly off-white crystalline powder; pK_a is 9.3. Soluble in water; freely soluble in alcohol.

Stability. Storage of an extemporaneously prepared flecainide syrup in a refrigerator led to crystallisation of the drug and a toxic dose being given.[1] It was suggested that oral liquid formulations of flecainide should be freshly reconstituted from a powder before each dose. However, other extemporaneous formulations have been reported[2,3] to be stable at room temperature and under refrigeration.

Adverse Effects

The most common adverse effects caused by flecainide affect the CNS and include dizziness, visual disturbances, and lightheadedness. Nausea, vomiting, headache, tremor, peripheral neuropathy, ataxia, and paraesthesia may also occur. These effects are generally transient and respond to dosage reduction. Other adverse CNS effects that have been reported rarely include hallucinations, amnesia, confusion, depression, dyskinesias, and convulsions. Skin reactions, including rare cases of urticaria, have also occurred and there have been isolated cases of photosensitivity. Disturbances of liver function have been reported rarely. Corneal deposits, pulmonary fibrosis, and pneumonitis have occurred during long-term therapy. Cardiovascular effects are less common than those on the CNS, but can be serious and sometimes fatal. Ventricular tachyarrhythmias have been reported, particularly in patients with a history of ventricular tachyarrhythmias and taking high doses of flecainide. Chest pain and myocardial infarction have also occurred. Flecainide produced an increased mortality rate when it was assessed for the control of asymptomatic ventricular arrhythmias in patients who had previously suffered a myocardial infarction (see Cardiac Arrhythmias under Uses and Administration, below).

Incidence of adverse effects. In a report of the non-cardiac adverse effects of flecainide from 1 short-term and 3 longer-term studies,[1] the most common adverse effects during both short- and long-term studies were dizziness and visual disturbances, which occurred in about 30% of patients. Headache and nausea both occurred in about 10% of patients. Other adverse effects reported include dyspnoea, chest pain, asthenia, fatigue, and tremor. Therapy was stopped because of non-cardiac adverse effects in 10% of patients in the short-term trial, and in 6% of those in the chronic studies. A review of 60 studies using flecainide[2] reported that non-cardiac adverse effects (mainly gastrointestinal and CNS adverse effects) occurred in 12% of patients. The UK CSM stated in June 1991 that it had received reports of neurological (4 patients with sensory neuropathy, 2 with ataxia), corneal (2 with corneal deposits), and pulmonary (3 with pulmonary fibrosis and pneumonitis) reactions associated with the long-term use of flecainide.[3]

1. Gentzkow GD, Sullivan JY. Extracardiac adverse effects of flecainide. *Am J Cardiol* 1984; **53:** 101B–105B.
2. Hohnloser SH, Zabel M. Short- and long-term efficacy and safety of flecainide acetate for supraventricular arrhythmias. *Am J Cardiol* 1992; **70:** 3A–10A.
3. Committee on Safety of Medicines. Multi-system adverse reactions following long-term flecainide therapy. *Current Problems 31* 1991. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024449&RevisionSelectionMethod=LatestReleased (accessed 08/05/07)

Effects on the blood. Severe granulocytopenia believed to be related to flecainide occurred in a 66-year-old man 3 months after starting therapy.[1] Haematological findings suggested an immune-mediated reaction in which flecainide binds to normal neutrophils with subsequent recognition by specific antibodies resulting in enhanced destruction of mature granulocytes in peripheral blood and bone marrow.

1. Samlowski WE, *et al.* Flecainide-induced immune neutropenia: documentation of a hapten-mediated mechanism of cell destruction. *Arch Intern Med* 1987; **147:** 383–4.

Effects on the eyes. In addition to visual disturbance, symptomatic corneal deposits have been reported[1] in patients taking flecainide. A study[2] in 38 patients found small corneal deposits in 14.5%, but visual function tests were normal.

1. Ulrik H, *et al.* Corneal deposits associated with flecainide. *BMJ* 1991; **302:** 506–7.
2. Ikäheimo K, *et al.* Adverse ocular effects of flecainide. *Acta Ophthalmol Scand* 2001; **79:** 175–6.

Effects on the heart. Like most antiarrhythmics, flecainide can have proarrhythmic effects,[1] and severe ventricular arrhythmias have been reported,[2] including fatal ventricular fibrillation[3] in a neonate given flecainide for supraventricular tachycardia. There has also been a report[4] of torsade de pointes, although this is generally less common with class Ic than with class Ia antiarrhythmics. For reports of increased cardiac mortality in patients given flecainide for asymptomatic arrhythmias, see Cardiac Arrhythmias under Uses and Administration, below.

1. Herre JM, *et al.* Inefficacy and proarrhythmic effects of flecainide and encainide for sustained ventricular tachycardia and ventricular fibrillation. *Ann Intern Med* 1990; **113:** 671–6.
2. Falk RH. Flecainide-induced ventricular tachycardia and fibrillation in patients treated for atrial fibrillation. *Ann Intern Med* 1989; **111:** 107–11.
3. Ackland F, *et al.* Flecainide induced ventricular fibrillation in a neonate. *Heart* 2003; **89:** 1261.
4. Nogales Asensio JM, *et al.* Torsade-de-pointes in a patient under flecainide treatment: an unusual case of proarrhythmicity. *Int J Cardiol* 2007; **114:** e65–e67.

Effects on the liver. Elevated liver enzymes and jaundice, reversible on stopping treatment, have been reported rarely with flecainide.

Conjugated hyperbilirubinaemia with jaundice developed in a newborn infant after maternal treatment with flecainide for fetal supraventricular tachycardia.[1]

1. Vanderhal AL, *et al.* Conjugated hyperbilirubinemia in a newborn infant after maternal (transplacental) treatment with flecainide acetate for fetal tachycardia and fetal hydrops. *J Pediatr* 1995; **126:** 988–90.

Effects on the lungs. There have been reports[1-4] of interstitial pneumonitis associated with flecainide. See also under Incidence of Adverse Effects, above.

1. Akoun GM, *et al.* Flecainide-associated pneumonitis. *Lancet* 1991; **337:** 49.
2. Hanston P, *et al.* Flecainide-associated interstitial pneumonitis. *Lancet* 1991; **337:** 371–2.
3. Robain A, *et al.* Flecainide-associated pneumonitis with acute respiratory failure in a patient with the LEOPARD syndrome. *Acta Cardiol* 2000; **55:** 45–7.
4. Pesenti S, *et al.* Diffuse infiltrative lung disease associated with flecainide: report of two cases. *Respiration* 2002; **69:** 182–5.

Effects on mental state. Dysarthria and visual hallucinations were associated with elevated plasma concentration of flecainide (2500 nanograms/mL) in a patient.[1] A serial rise and fall in plasma-bilirubin concentration during flecainide therapy also suggested possible direct hepatotoxicity. There has also been a report[2] of paranoid psychosis in a patient receiving flecainide for neuropathic pain.

1. Ramhamadany E, *et al.* Dysarthria and visual hallucinations due to flecainide toxicity. *Postgrad Med J* 1986; **62:** 61–2.
2. Bennett MI. Paranoid psychosis due to flecainide toxicity in malignant neuropathic pain. *Pain* 1997; **70:** 93–4.

Effects on the nervous system. Peripheral neuropathy, reversible on stopping treatment, has been reported[1,2] in patients receiving flecainide long-term. The authors of one report[1] stated that, at the time (1992), the UK CSM had received 4 other reports possibly associated with flecainide and 3 reports of aggravation of pre-existing neuropathy;[1] not all cases were reversible.

1. Palace J, *et al.* Flecainide induced peripheral neuropathy. *BMJ* 1992; **305:** 810.
2. Malesker MA, *et al.* Flecainide-induced neuropathy. *Ann Pharmacother* 2005; **39:** 1580.

Lupus erythematosus. There has been a report[1] of a patient who developed painful eye movement during flecainide therapy. The pain resolved on withdrawal but recurred when flecainide was restarted, and was accompanied by lateral rectus spasm, a facial rash, and positive antinuclear factor, suggestive of lupus erythematosus.

1. Skander M, Isaacs PET. Flecainide, ocular myopathy, and antinuclear factor. *BMJ* 1985; **291:** 450.

Treatment of Adverse Effects

In oral overdosage with flecainide activated charcoal may be considered if the patient presents within 1 hour of ingestion. Treatment is largely symptomatic and supportive and may need to be continued for extended periods of time because of the long half-life and the possibility of non-linear elimination at very high doses. Haemodialysis or haemoperfusion are unlikely to enhance elimination.

Overdosage. Severe cardiovascular toxicity in flecainide overdosage may be resistant to pacing and inotropes, and hypoperfusion of the kidneys and liver may reduce the elimination of flecainide, prolonging the toxic effects. Gastric decontamination is of uncertain benefit; forced diuresis has been used,[1] but probably had a negligible effect, and haemodialysis and haemoperfusion are not effective.[2] Patients may therefore require intensive and prolonged supportive treatment,[1,3] and there have been reports of the use of extracorporeal membrane oxygenation,[4] cardiopulmonary bypass,[5,6] or intra-aortic balloon pumping,[7] to maintain organ perfusion and allow flecainide elimination to occur, with complete recovery in some cases.[3,4,6,7] There have been reports[8,9] of the successful use of intravenous hypertonic sodium bicarbonate, and it has been suggested that it may antagonise the sodium channel blockade produced by flecainide, as well as reversing the metabolic acidosis that commonly occurs.

Precautions

Flecainide treatment should be started in hospital or under specialist supervision and pacing rescue should be available when it is used in patients with conduction defects. Its use is limited to serious or life-threatening arrhythmias and it should not be given to control asymptomatic arrhythmias especially in patients with a history of myocardial infarction (see Cardiac Arrhythmias under Uses and Administration, below). Flecainide has some negative inotropic activity and may precipitate or aggravate heart failure in patients with compromised left ventricular function; it should therefore be used with extreme caution, if at all, in patients with heart failure. Flecainide has been shown to increase the endocardial pacing threshold and should be used with caution in patients with pacemakers. Electrolyte imbalances should be corrected before starting flecainide therapy. Reduction of dosage may be necessary in patients with renal impairment; extreme caution is needed in patients with pronounced hepatic impairment.

Breast feeding. Flecainide is distributed into breast milk but there have been no reports of infant exposure. Flecainide 100 mg was given orally every 12 hours to 11 healthy women, beginning 1 day after delivery and continuing for 5 ⁄ days.[1] The mean elimination half-life of flecainide from milk was 14.7 hours, very similar to the plasma elimination half-life. The mean milk to plasma ratios on study days 2 to 5 were 3.7, 3.2, 3.5, and 2.6 respectively but it was considered that the risk to breast-fed infants of ingesting toxic amounts of flecainide in breast milk would be very low. In another woman[2] who had been taking flecainide 100 mg twice daily since before pregnancy for ventricular arrhythmias, the ratio was 1.57 on day 5 postpartum and 2.18 on day 7. The American Academy of Pediatrics considers[3] flecainide to be usually compatible with breast feeding.

2. Wagner X, *et al.* Coadministration of flecainide acetate and sotalol during pregnancy: lack of teratogenic effects, passage across the placenta, and excretion in human breast milk. *Am Heart J* 1990; **119:** 700–2.
3. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/07/07)

Pregnancy. Flecainide crosses the placenta (see under Pharmacokinetics, below) and has been used for transplacental therapy of fetal cardiac arrhythmias (see under Uses and Administration, below). However, hyperbilirubinaemia was reported in an infant after maternal treatment with flecainide (see Effects on the Liver, above).

Interactions

Use of flecainide with other antiarrhythmics or arrhythmogenic drugs may increase the incidence of cardiac arrhythmias. Use with a beta blocker produces additive negative inotropic effects. Flecainide undergoes hepatic metabolism and its activity may be influenced by drugs that affect the enzymes responsible for its metabolism, including the cytochrome P450 isoenzyme CYP2D6.

Antiarrhythmics. *Amiodarone* increases the plasma-flecainide concentration when the two drugs are given together.[1] It has been recommended that the dose of flecainide should be reduced by about one-half, but because the effect of amiodarone differs widely between patients, plasma-flecainide concentrations should be monitored. The clearance of flecainide may be decreased by *quinidine* in patients who are extensive metabolisers, since quinidine inhibits the enzyme responsible for the metabolism of flecainide.[2] Cardiogenic shock and asystole occurred in 2 patients receiving flecainide when *verapamil* was added to their therapy.[3]

1. Shea P, *et al.* Flecainide and amiodarone interaction. *J Am Coll Cardiol* 1986; **7:** 1127–30.
2. Birgersdotter UM, *et al.* Stereoselective genetically-determined interaction between chronic flecainide and quinidine in patients with arrhythmias. *Br J Clin Pharmacol* 1992; **33:** 275–80.
3. Buss J, *et al.* Asystole and cardiogenic shock due to combined treatment with verapamil and flecainide. *Lancet* 1992; **340:** 546.

Antimalarials. *Quinine* has been reported[1] to inhibit metabolism of flecainide in healthy subjects without altering its renal elimination, resulting in a reduction of total clearance and prolongation of the elimination half-life.

1. Munafo A, *et al.* Altered flecainide disposition in healthy volunteers taking quinine. *Eur J Clin Pharmacol* 1990; **38:** 269–73.

Beta blockers. Use of flecainide and *propranolol* in healthy subjects increases the plasma concentration of both drugs. The negative inotropic effects of the two drugs on cardiac function are at most only additive, but combined treatment should be started with caution in patients with impaired left ventricular function.[1] Addition of *sotalol* to flecainide has produced profound bradycardia and AV block followed by cardiac arrest and death in a man with ventricular tachycardia.[2]

1. Holtzman JL, *et al.* The pharmacodynamic and pharmacokinetic interaction of flecainide acetate with propranolol: effects on cardiac function and drug clearance. *Eur J Clin Pharmacol* 1987; **33:** 97–9.
2. Warren R, *et al.* Serious interactions of sotalol with amiodarone and flecainide. *Med J Aust* 1990; **152:** 277.

Digoxin. For reference to an interaction between flecainide and digoxin leading to increased concentrations of digoxin, see Antiarrhythmics, under Interactions of Digoxin, p.1261.

Food. *Milk* feeds reduced the absorption of flecainide in an infant who required a dose of 40 mg/kg daily to control supraventricular tachycardias. When milk feeds were replaced by glucose, the serum-flecainide concentration increased from 990 to 1824 nanograms/mL. Milk-fed infants on high doses of flecainide should have the dose reduced if milk is stopped or reduced.[1]

1. Russell GAB, Martin RP. Flecainide toxicity. *Arch Dis Child* 1989; **64:** 860–2.

Histamine H_2-antagonists. *Cimetidine* has been reported to increase the bioavailability of flecainide in healthy subjects, probably due to a decrease in the metabolism of flecainide. Elimination half-life and renal clearance were unchanged.[1]

1. Tjandra-Maga TB, *et al.* Altered pharmacokinetics of oral flecainide by cimetidine. *Br J Clin Pharmacol* 1986; **22:** 108–10.

Pharmacokinetics

Flecainide is almost completely absorbed after oral doses and does not undergo extensive first-pass hepatic metabolism. Although absorption is not affected by food or antacids, milk may inhibit absorption in infants (see above). Flecainide is metabolised to 2 major metabolites, *m-O*-dealkylated flecainide and *m-O*-dealkylated lactam of flecainide; both may have some activity, but this is unlikely to be clinically significant. Metabolism of flecainide appears to involve the cytochrome P450 isoenzyme CYP2D6 and is subject to genetic polymorphism (see Metabolism, below). It is excreted mainly in the urine, about 30% as unchanged drug and the remainder as metabolites. About 5% is excreted in the faeces. Excretion of flecainide is decreased in renal impairment, heart failure, and in alkaline urine. Haemodialysis removes only about 1% of an oral dose as unchanged flecainide.

The therapeutic plasma concentration range is generally accepted as 200 to 1000 nanograms/mL. The elimination half-life of flecainide is about 20 hours and it is about 40% bound to plasma proteins.

Flecainide crosses the placenta and is distributed into breast milk.

Metabolism. Oxidative metabolism is an important route of flecainide elimination.[1] It is mediated by the cytochrome P450 isoenzyme CYP2D6, which shows genetic polymorphism. The mean elimination half-life of flecainide in poor metabolisers (5 to 10% of the population) was found to be 11.8 hours compared with 6.8 hours in extensive metabolisers and the amounts of a dose excreted as unchanged drug in the urine were 51% and 31% respectively. These differences in pharmacokinetics will not usually be of clinical importance. However, in patients with renal impairment who are poor metabolisers, special care should be taken with dosage adjustments.

1. Mikus G, *et al.* The influence of the sparteine-debrisoquin phenotype on the disposition of flecainide. *Clin Pharmacol Ther* 1989; **45:** 562–7.

Pregnancy. A study of the pharmacokinetics of flecainide, given to a mother during the third trimester of pregnancy for the treatment of fetal supraventricular tachycardia,[1] indicated that close to term flecainide crosses the placenta easily without accumulating in fetal blood, but with a high concentration in the amniotic fluid.

See also Effects on the Liver, above.

1. Bourget P, *et al.* Flecainide distribution, transplacental passage and accumulation in the amniotic fluid during the third trimester of pregnancy. *Ann Pharmacother* 1994; **28:** 1031–4.

Uses and Administration

Flecainide is a class Ic antiarrhythmic (p.1153) used for the treatment of severe symptomatic ventricular arrhythmias such as sustained ventricular tachycardia; for premature ventricular contractions or non-sustained ventricular tachycardia resistant to other therapy; and for severe symptomatic supraventricular arrhythmias (AV nodal reciprocating tachycardia, arrhythmias associated with the Wolff-Parkinson-White syndrome, and paroxysmal atrial fibrillation in the absence of left ventricular dysfunction).

Flecainide is given orally or intravenously as the acetate. Treatment should be started in hospital. Doses should be adjusted after 3 to 5 days and reduced once control has been achieved. A suggested therapeutic plasma concentration range is 200 to 1000 nanograms/mL.

In ventricular arrhythmias the usual initial oral dose of flecainide acetate is 100 mg twice daily; the maximum total dose is 400 mg daily although most patients will not need more than 300 mg daily. In supraventricular arrhythmias the usual initial oral dose is 50 mg twice daily and the maximum total dose is 300 mg daily.

For rapid control of arrhythmias flecainide acetate 2 mg/kg may be given intravenously over 10 to 30 minutes, to a maximum dose of 150 mg; the ECG should be monitored. If longer term parenteral therapy is necessary it is started with intravenous injection of 2 mg/kg over 30 minutes, as above, then continued by intravenous infusion of 1.5 mg/kg over the first hour, and 100 to 250 micrograms/kg per hour thereafter. The maximum cumulative dose in the first 24 hours should not exceed 600 mg. Infusion should not generally continue for more than 24 hours and oral therapy should be substituted as soon as possible.

The dose of flecainide should be reduced in renal impairment (see below).

For the use of flecainide in children, see below.

Flecainide has also been tried in the treatment of refractory neuropathic pain.

Administration. Flecainide is usually given orally or intravenously, but rapid and reliable absorption has been reported from a rectal solution in healthy subjects.[1] The mean time to achieve peak serum concentration was 0.67 hours and the mean bioavailability was 98%, compared with 1 hour and 78% for an oral solution and 4 hours and 81% for a tablet. The absorption of flecainide given rectally to 2 critically ill patients was good in one but poor in the other[2] and it was recommended that rectal dosage be reserved for patients unresponsive to maximal parenteral therapy and in whom the oral or nasogastric routes cannot be used.

1. Lie-A-Huen L, *et al.* Absorption kinetics of oral and rectal flecainide in healthy subjects. *Eur J Clin Pharmacol* 1990; **38:** 595–8.
2. Quattrocchi FP, Karim A. Flecainide acetate administration by enema. *DICP Ann Pharmacother* 1990; **24:** 1233–4.

Administration in children. Flecainide has been used successfully to treat arrhythmias in children,[1,2] and beneficial results have also been reported[3] with flecainide and sotalol together. US licensed product information recommends an initial oral dose of flecainide acetate 50 mg/m^2 daily in divided doses for those aged under 6 months and 100 mg/m^2 daily for those aged over 6 months; a dose of 200 mg/m^2 daily should not be exceeded.

The *BNFC* recommends the following doses of flecainide acetate:

- neonates: an **oral** dose of 2 mg/kg 2 or 3 times daily, adjusted according to response, or 1 to 2 mg/kg **intravenously** over 10 to 30 minutes, followed if necessary by continuous infusion at a rate of 100 to 250 micrograms/kg per hour until arrhythmia is controlled
- children aged 1 month to 12 years: an **oral** dose of 2 mg/kg 2 or 3 times daily, adjusted according to response to a maximum of 8 mg/kg or 300 mg daily, or 2 mg/kg **intravenously** over 10 to 30 minutes, followed if necessary by continuous infusion at a rate of 100 to 250 micrograms/kg per hour until arrhythmia is controlled (maximum cumulative dose 600 mg in 24 hours)
- children aged 12 to 18 years: as for adults (see Uses and Administration, above); the maximum oral dose should not exceed 300 mg daily

1. Perry JC, Garson A. Flecainide acetate for treatment of tachyarrhythmias in children: review of world literature on efficacy, safety, and dosing. *Am Heart J* 1992; **124:** 1614–21.
2. O'Sullivan JJ, *et al.* Digoxin or flecainide for prophylaxis of supraventricular tachycardia in infants? *J Am Coll Cardiol* 1995; **26:** 991–4.
3. Price JF, *et al.* Flecainide and sotalol: a new combination therapy for refractory supraventricular tachycardia in children <1 year of age. *J Am Coll Cardiol* 2002; **39:** 517–20.

Administration in renal impairment. The plasma elimination half-life for flecainide may be prolonged in patients with renal impairment[1-3] and doses should be reduced. For patients with a creatinine clearance equal to or less than 35 mL/minute per 1.73 m^2 licensed product information states that the initial oral dose of flecainide acetate should not exceed 100 mg daily and plasma concentrations should be monitored; intravenous doses should be halved.

Special care with dosage adjustments should be taken in patients with renal impairment who are also poor metabolisers (see under Metabolism, above).

3. Williams AJ, *et al.* Pharmacokinetics of flecainide acetate in patients with severe renal impairment. *Clin Pharmacol Ther* 1988; **43:** 449–55.

Cardiac arrhythmias. Flecainide has an established role in the management of ventricular and supraventricular arrhythmias (p.1160). It has been used in children (see above) and has also been successfully given to pregnant women (transplacental therapy) to treat fetal arrhythmias,[1,2] although there have been reports[3,4] of neonatal toxicity.

Use in patients with asymptomatic arrhythmias after myocardial infarction is not recommended since an increase in mortality was found in the Cardiac Arrhythmia Suppression Trial (CAST), in which flecainide[5-7] and the related class Ic antiarrhythmics encainide[5-7] and moracizine[8] were used in an attempt to reduce the risk of sudden death in post-infarction patients with premature ventricular contractions.

Flecainide has also been used in the diagnosis of Brugada syndrome.[9] This syndrome is characterised by syncope or aborted cardiac arrest due to ventricular tachycardia in the absence of organic heart disease, and is thought to be due to a deficiency in the inward sodium current in cardiac cells. Flecainide, because of its sodium-channel blocking action, exaggerates this deficiency and the resulting ST-segment elevation, and aids in diagnosis; however, it may precipitate serious ventricular arrhythmias[10] and must not be used for treatment.

Pain. Class Ic antiarrhythmics such as flecainide are among the drugs that have been used as analgesic adjuvants in neuropathic pain (p.8), although the evidence for benefit with flecainide is limited. A positive response has been reported[1,2] in patients with severe pain due to nerve infiltration, but a controlled trial had to be stopped[3] when supplies of the drug were withdrawn after the finding of increased mortality in a study in post-infarction patients (CAST; see Cardiac Arrhythmias, above), and a later study[4] found that flecainide was effective in only a minority of patients with cancer pain. A small study[5] has suggested that flecainide may be effective in postherpetic neuralgia.

Flosequinan *(BAN, USAN, rINN)*

BTS-49465; Flosequinan; Flosequinán; Flosequinanum. 7-Fluoro-1-methyl-3-methylsulphinyl-4-quinolone.

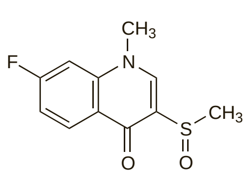
Флосехинан

$C_{11}H_{10}FNO_2S = 239.3.$

CAS — 76568-02-0.

ATC — C01DB01.

ATC Vet — QC01DB01.



Profile

Flosequinan is a direct-acting arteriovenous vasodilator that was used as an adjunct to the conventional treatment of heart failure, but was withdrawn from the market after findings of excess mortality.

◊ References.

1. Kamali F, Edwards C. Possible role of metabolite in flosequinan-related mortality. *Clin Pharmacokinet* 1995; **29:** 396–403.

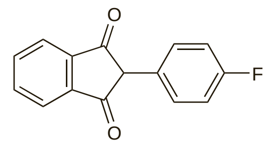
Fluindione *(rINN)*

Fluindiona; Fluindionum; Fluorindione; LM-123. 2-(4-Fluorophenyl)indan-1,3-dione.

Флуиндион

$C_{15}H_9FO_2 = 240.2.$

CAS — 957-56-2.



Profile

Fluindione is an oral indanedione anticoagulant with actions similar to those of warfarin (p.1425). It is used in the management of thromboembolic disorders (p.1187) but, as the indanediones are generally more toxic than warfarin (see Phenindione, p.1369), its use is limited.

The usual initial dose is 20 mg daily; the dose is then adjusted according to coagulation tests.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Previscan.

Fluvastatin Sodium *(BANM, USAN, rINNM)*

Fluvastatina sódica; Fluvastatine sodique; Fluvastatinum natricum; Natrii Fluvastatinum; XU-62-320. Sodium (±)-(3*R**,5*S**,6*E*)-7-[3-(*p*-Fluorophenyl)-1-isopropylindol-2-yl]-3,5-dihydroxy-6-heptenoate.

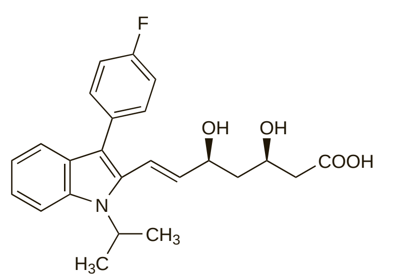
CAS — 93957-54-1 (fluvastatin); 93957-55-2 (fluvastatin sodium).

ATC — C10AA04.

ATC Vet — QC10AA04.



(fluvastatin)

Pharmacopoeias. In *US.*

USP 31 (Fluvastatin Sodium). A white to pale yellow, brownish-pale yellow, or reddish-pale yellow, hygroscopic powder. Soluble in water, in alcohol, and in methyl alcohol. A 1% solution in water has a pH of 8.0 to 10.0. Store in airtight containers at a temperature not exceeding 40°. Protect from light and moisture.

Adverse Effects and Precautions

As for Simvastatin, p.1390.

Interactions

The interactions of statins with other drugs are described under simvastatin (p.1392). Fluvastatin is metabolised mainly by the cytochrome P450 isoenzyme CYP2C9 and does not have the same interactions with CYP3A4 inhibitors as simvastatin, although caution has been advised when such combinations are used. However, interactions may occur with inhibitors of CYP2C9, such as fluconazole; use with rifampicin, a CYP2C9 inducer, may reduce the bioavailability of fluvastatin by about 50%.

Pharmacokinetics

Fluvastatin is rapidly and completely absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism in the liver, its primary site of action. Metabolism is mainly by the cytochrome P450 isoenzyme CYP2C9, with only a small amount metabolised by CYP3A4. An absolute bioavailability of about 24% has been reported. It is more than 98% bound to plasma proteins. About 90% is excreted in the faeces, mainly as metabolites, with only about 6% being excreted in the urine.

◊ General reviews.

1. Scripture CD, Pieper JA. Clinical pharmacokinetics of fluvastatin. *Clin Pharmacokinet* 2001; **40:** 263–81.

Uses and Administration

Fluvastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (or statin), is a lipid regulating drug with actions on plasma lipids similar to those of simvastatin (p.1394). It is used to reduce total cholesterol, LDL-cholesterol, apolipoprotein B, and triglycerides, and to increase HDL-cholesterol, in the treatment of hyperlipidaemias (p.1169), including hypercholesterolaemias and combined (mixed) hyperlipidaemia (type IIa or IIb hyperlipoproteinaemias). It is also given as secondary prophylaxis for cardiovascular risk reduction (p.1164) in patients with ischaemic heart disease, including patients who have had a percutaneous coronary intervention.

Fluvastatin is given orally as the sodium salt, but doses are expressed in terms of the base; 21.06 mg of fluvastatin sodium is equivalent to about 20 mg of base. The usual initial dose is 20 to 40 mg of fluvastatin once daily in the evening. This may be increased, if necessary, at intervals of 4 weeks or more, up to 80 mg daily, in two divided doses or as a once-daily modified-release preparation; patients requiring a large reduction in LDL-cholesterol may be started on the 80 mg daily dose. A dose of 80 mg daily may also be used in patients who have had a percutaneous coronary intervention.

For the use of fluvastatin in children, see below.

Administration in children. Fluvastatin may be used in the management of children aged 10 to 16 years with heterozygous familial hypercholesterolaemia.[1] US licensed product information recommends an initial oral dose of 20 mg once daily, increased as required, at intervals of 6 weeks, to a maximum dose of 80 mg daily in 2 divided doses or as a once-daily modified-release preparation.

Fondaparinux Sodium *(BAN, USAN, rINN)*

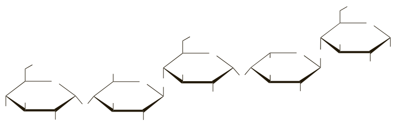
Fondaparin Sodium; Fondaparinuks Sodyum; Fondaparinuuksinatrium; Fondaparinux sódico; Fondaparinux Sodique; Fondaparinuxnatrium; Fondaparinuxum Natricum; Fondaparinuxum Natrium; Org-31540; SR-90107A.

Фондапаринукс Натрия

CAS — 114870-03-0.

ATC — B01AX05.

ATC Vet — QB01AX05.



(fondaparinux)

Adverse Effects

As for Heparin, p.1301.

Treatment of Adverse Effects

If bleeding occurs fondaparinux should be stopped and appropriate therapy given. Unlike heparin, there is no specific antidote for fondaparinux (but see below).

Overdosage. Activated eptacog alfa (recombinant factor VIIa) given 2 hours after an injection of fondaparinux was found[1] in healthy subjects to normalise coagulation times and thrombin generation for up to 6 hours, suggesting that it may be useful to treat bleeding complications, or if acute surgery is needed.

1. Bijsterveld NR, *et al.* Ability of recombinant factor VIIa to reverse the anticoagulant effect of the pentasaccharide fondaparinux in healthy volunteers. *Circulation* 2002; **106:** 2550–54.

Precautions

As for Heparin, p.1303.

Fondaparinux should not be given to patients who have developed thrombocytopenia with heparin and who have a positive *in-vitro* platelet aggregation test (that is, cross-reactivity) in the presence of fondaparinux itself.

Fondaparinux is contra-indicated in severe renal impairment, and special care is required in patients with body-weight below 50 kg.

Interactions

As for Heparin, p.1303.

Pharmacokinetics

After subcutaneous injection fondaparinux sodium is rapidly and completely absorbed, with bioavailability of 100%. It is extensively bound in plasma, predominantly to antithrombin III. It is excreted in the urine, with 64 to 77% of a dose excreted unchanged. The elimination half-life is between 17 and 21 hours, but is prolonged in patients with renal impairment, in the elderly, and in those weighing less than 50 kg.

◊ References.

1. Donat F, *et al.* The pharmacokinetics of fondaparinux sodium in healthy volunteers. *Clin Pharmacokinet* 2002; **41** (suppl 2): 1–9.
2. Paolucci F, *et al.* Fondaparinux sodium mechanism of action: identification of specific binding to purified and human plasma-derived proteins. *Clin Pharmacokinet* 2002; **41** (suppl 2): 11–18.

Pregnancy. Although an *in vitro* study[1] reported that fondaparinux does not cross the placenta, a small study[2] in pregnant women who had received fondaparinux found that anti-factor Xa activity was elevated in umbilical cord blood, suggesting that a small amount of placental transfer had taken place.

1. Lagrange F, *et al.* Fondaparinux sodium does not cross the placental barrier: study using the in-vitro human dually perfused cotyledon model. *Clin Pharmacokinet* 2002; **41** (suppl 2): 47–9.
2. Dempfle C-EH. Minor transplacental passage of fondaparinux in vivo. *N Engl J Med* 2004; **350:** 1914–15.

Uses and Administration

Fondaparinux is a synthetic pentasaccharide that acts as a selective inhibitor of activated factor X. It is used as the sodium salt as an anticoagulant in the management of venous thromboembolism (p.1189), unstable angina (p.1157), and acute myocardial infarction (p.1175). It has also been used in patients with heparin-induced thrombocytopenia (see Effects on the Blood under Adverse Effects of Heparin, p.1302).

For *prophylaxis* of **venous thromboembolism** in abdominal and orthopaedic surgery, fondaparinux sodium is given by subcutaneous injection in a dose of 2.5 mg once daily, starting 6 to 8 hours after surgery and continued for at least 5 to 9 days, or up to 32 days in hip fracture. For prophylaxis in high-risk medical patients, the same dose is given once daily for 6 to 14 days.

In the initial *treatment* of venous thromboembolism, fondaparinux sodium is given by subcutaneous injection once daily at a dose of 5 mg for patients weighing less than 50 kg, 7.5 mg for weight 50 to 100 kg, and 10 mg for weight over 100 kg. Treatment is usually continued for 5 to 9 days, and at least until oral anticoagulation is established.

Fondaparinux is also used in **unstable angina** and acute ST-elevation **myocardial infarction**, but is only indicated in patients for whom urgent percutaneous coronary intervention is not planned. It is given in a dose of 2.5 mg subcutaneously once daily for up to 8 days, with the first dose given intravenously in acute ST-elevation myocardial infarction. Heparin should be given at the time of the procedure if percutaneous coronary intervention is performed and fondaparinux should be restarted when clinically appropriate.

Doses of fondaparinux may need to be reduced in patients with renal impairment (see below).

Administration in renal impairment. Fondaparinux is eliminated renally and should be used with caution in patients with renal impairment. US licensed product information contra-indicates its use in patients with creatinine clearance (CC) below 30 mL/minute, and advises caution in those with CC between 30 and 50 mL/minute. UK licensed product information contra-indicates its use in patients with creatinine clearance (CC) below 20 mL/minute; for patients with CC between 20 and 50 mL/minute a subcutaneous dose of 1.5 mg once daily is recommended for prophylaxis of venous thromboembolism, but no dosage alteration is required for unstable angina or myocardial infarction.

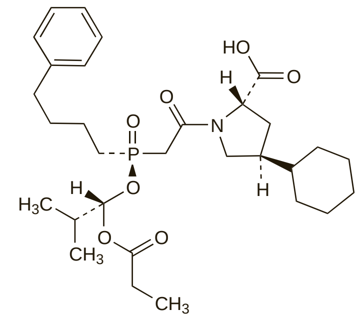
ATC Vet — QC09AA09.



(fosinopril)

Pharmacopoeias. In *US.*

USP 31 (Fosinopril Sodium). Store in airtight containers at a temperature of 20° to 25°, excursions permitted between 15° and 30°.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Fosinopril acts as a prodrug of the diacid fosinoprilat, its active metabolite. About 36% of an oral dose of fosinopril is absorbed. Fosinopril is rapidly and completely hydrolysed to fosinoprilat in both gastrointestinal mucosa and liver. Peak plasma concentrations of fosinoprilat are achieved about 3 hours after an oral dose of fosinopril. Fosinoprilat is more than 95% bound to plasma proteins. It is excreted both in urine and in the faeces via the bile; it has been detected in breast milk. The effective half-life for accumulation of fosinoprilat after multiple doses of fosinopril is about 11.5 hours in patients with hypertension and about 14 hours in patients with heart failure.

Renal impairment. Total body clearance of fosinoprilat, the active metabolite of fosinopril, is slower in patients with renal impairment. However, pharmacokinetic studies in patients with varying degrees of impairment,[1-5] including those requiring dialysis, indicate that decreases in renal clearance may be compensated for, at least in part, by increases in hepatic clearance.

Uses and Administration

Fosinopril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165).

Fosinopril owes its activity to fosinoprilat to which it is converted after oral doses. The haemodynamic effects are seen within 1 hour of a single oral dose and the maximum effect occurs after 2 to 6 hours, although the full effect may not develop for several weeks during chronic dosing. The haemodynamic action lasts for about 24 hours, allowing once-daily dosing. Fosinopril is given orally as the sodium salt.

In the treatment of **hypertension**, the initial dose of fosinopril sodium is 10 mg once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. Usual maintenance doses range from 10 to 40 mg once daily. In patients already taking diuretic therapy the diuretic should be withdrawn if possible several days before starting fosinopril, and resumed later if necessary.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should begin with a low dose under close medical supervision. Fosinopril sodium is given in an initial dose of 10 mg once daily and, if well tolerated, increased to a maximum of 40 mg once daily. An initial dose of 5 mg may be given in patients at high risk of hypotension.

Furosemide *(BAN, USAN, rINN)* ⊗

Frusemide; Furosemid; Furosemida; Furosémide; Furosemidi; Furosemidum; Furoszemid; Furozemidas; LB-502. 4-Chloro-*N*-furfuryl-5-sulphamoylanthranilic acid.

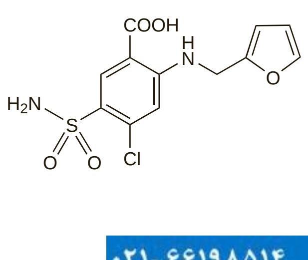
Фуросемид

$C_{12}H_{11}ClN_2O_5S$ = 330.7.

CAS — 54-31-9.

ATC — C03CA01.

ATC Vet — QC03CA01.



NOTE. Compounded preparations of furosemide may be represented by the following names:

- Co-amilofruse (*BAN*)—furosemide 8 parts and amiloride hydrochloride 1 part (w/w).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Furosemide). A white or almost white, crystalline powder. Practically insoluble in water and in dichloromethane; sparingly soluble in alcohol; soluble in acetone. It dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Furosemide). A white to slightly yellow, odourless, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in acetone, in dimethylformamide, and in solutions of alkali hydroxides; very slightly soluble in chloroform; slightly soluble in ether; soluble in methyl alcohol. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Solutions for injection are prepared with the aid of sodium hydroxide, giving solutions with a pH of 8.0 to 9.3.

Incompatibility. Solutions of furosemide for injection are alkaline and should not be mixed or diluted with glucose injection or other acidic solutions.

Furosemide injection has been reported[1] to be visually incompatible with injections of diltiazem hydrochloride, dobutamine hydrochloride, dopamine hydrochloride, labetalol hydrochloride, midazolam hydrochloride, milrinone lactate, nicardipine hydrochloride, and vecuronium bromide. Incompatibility has also been noted with parenteral nutrient solutions,[2] with cisatracurium besilate,[3] with levofloxacin,[4] with phenylephrine,[5] and with vasopressin.[5]

5. Faria CE, *et al.* Visual compatibility of furosemide with phenylephrine and vasopressin. *Am J Health-Syst Pharm* 2006; **63:** 906–8.

Stability. A study[1] showed that furosemide injection (10 mg/mL) in 25% human albumin solution was stable for 48 hours at room temperature when protected from light, and for 14 days under refrigeration. No bacterial or fungal growth was found.

1. Elwell RJ, *et al.* Stability of furosemide in human albumin solution. *Ann Pharmacother* 2002; **36:** 423–6.

Adverse Effects

Most adverse effects of furosemide occur with high doses, and serious effects are uncommon. The most common adverse effect is fluid and electrolyte imbalance including hyponatraemia, hypokalaemia, and hypochloraemic alkalosis, particularly after large doses or prolonged use. Signs of electrolyte imbalance include headache, hypotension, muscle cramps, dry mouth, thirst, weakness, lethargy, drowsiness, restlessness, oliguria, cardiac arrhythmias, and gastrointestinal disturbances. Hypovolaemia and dehydration may occur, especially in the elderly. Because of their shorter duration of action, the risk of hypokalaemia may be less with loop diuretics such as furosemide than with thiazide diuretics. Unlike the thiazides, furosemide increases the urinary excretion of calcium and nephrocalcinosis has been reported in preterm infants.

Furosemide may cause hyperuricaemia and precipitate gout in some patients. It may provoke hyperglycaemia and glycosuria, but probably to a lesser extent than the thiazide diuretics.

Pancreatitis and cholestatic jaundice seem to occur more often than with the thiazides. Other adverse effects include blurred vision, yellow vision, dizziness, headache, and orthostatic hypotension. Other adverse effects occur rarely. Skin rashes and photosensitivity reactions may be severe; hypersensitivity reactions include interstitial nephritis and vasculitis; fever has also been reported. Bone marrow depression may occur: there have been reports of agranulocytosis, thrombocytopenia, and leucopenia. Tinnitus and deafness may occur, in particular during rapid high-dose parenteral furosemide. Deafness may be permanent, especially in patients taking other ototoxic drugs.

Incidence of adverse effects. In a survey of 553 hospital inpatients[1] receiving furosemide 220 patients (40%) had 480 adverse reactions. Electrolyte disturbances occurred in 130 (23.5%) patients and extracellular volume depletion in 50 (9%). Adverse reactions were more common in those with liver disease, and hepatic coma occurred in 20 patients with hepatic cirrhosis. A similar survey in 585 hospital inpatients[2] revealed 177 adverse effects in 123 (21%). These included volume depletion in 85 patients (14.5%), hypokalaemia in 21 (3.6%), and hyponatraemia in 6 (1%). Hypokalaemia was considered to be life-threatening in 2 patients. Hyperuricaemia occurred in 54 patients (9.2%), of whom 40 also had volume depletion, and clinical gout developed in 2.

Carcinogenicity. See under Hydrochlorothiazide, p.1308.

Effects on the ears. Ototoxicity and deafness during furosemide therapy is most frequently associated with elevated blood concentrations resulting from rapid intravenous infusion[1] or delayed excretion in patients with renal impairment.[2] Of 29 cases of furosemide-induced deafness reported to the FDA[3] in the USA, most patients had renal disease or had received the drug intravenously. Eight patients had also received another ototoxic drug. However, deafness occurred in 11 patients after oral use, and in 4 of these hearing loss occurred in the absence of renal disease or other ototoxic drugs. Hearing loss was generally transient, lasting from one-half to 24 hours, but permanent hearing loss occurred in 3 patients, one of whom had taken furosemide orally. Deafness was not always associated with high doses; six patients had received a total of 200 mg or less of furosemide.

Effects on electrolyte balance. *CALCIUM.* Furosemide increases renal calcium excretion. There is a danger of hypocalcaemic tetany during furosemide use in hypoparathyroid patients[1] and it has also been reported[2] in a patient with latent hypoparathyroidism following thyroidectomy.

The decrease in serum-calcium concentrations could also induce hyperparathyroidism. In a study involving 36 patients with heart failure, furosemide was associated with elevations in both parathyroid hormone and alkaline phosphatase concentrations, possibly indicating accelerated bone remodelling such as that found in primary hyperparathyroidism.[3]

For reports of hypercalciuria, rickets, renal calculi, and hyperparathyroidism in neonates given furosemide, see Effects in Infants and Neonates, below.

MAGNESIUM, POTASSIUM, AND SODIUM. For discussions of the effects of diuretics on these electrolytes see under the Adverse Effects of Hydrochlorothiazide, p.1308.

Effects in infants and neonates. Furosemide is commonly used in the treatment of cardiac and pulmonary disorders in premature infants and neonates. This age group appears to be particularly susceptible to adverse effects arising from the increase in urinary calcium excretion which occurs during long-term use. Increases in parathyroid hormone concentration[1,2] and evidence of bone resorption[1,3] support the suggestion that the increased calcium loss causes secondary hyperparathyroidism. There have been reports of decreased mineral content of bone,[1,3] rickets,[4] fractures,[3] and renal calcification.[1,5-7] An observation[5] that renal calcification could be reversed by the addition of a thiazide diuretic was supported by other workers.[6] There is evidence[8] that furosemide-related renal calcifications in very low birth-weight infants might be associated with long-term renal impairment. Renal calcification has also been reported after furosemide use in older infants.[9]

It has been suggested[10] that a sodium deficit in infants given furosemide for heart failure may contribute to a failure to thrive.

Concern has been expressed over the finding[11] that furosemide use in premature infants with respiratory distress syndrome increases the incidence of patent ductus arteriosus. The mechanism is thought to be connected with stimulation of renal prostaglandin E_2. However, the increased incidence of patent ductus arteriosus did not adversely affect the mortality in infants given furosemide, and a subsequent study[12] failed to find any increase in the incidence of patent ductus arteriosus in infants treated with furosemide compared with a control group. Paradoxically, furosemide has been used in the management of delayed closure of ductus (see Patent Ductus Arteriosus under Uses and Administration, below). There is a possibility that furosemide may not be effective in infants given indometacin[13] but it can prevent the decline in urine output which occurs during indometacin use.[14,15]

Effects on lipid metabolism. Most studies into the effects of diuretics on blood-lipid concentrations have used thiazides (see Hydrochlorothiazide, p.1308). The few studies into the effects of furosemide suggest that, like thiazides, it may adversely influence blood-lipid concentrations during short-term use.[1]

1. Ames RP. The effects of antihypertensive drugs on serum lipids and lipoproteins I: diuretics. *Drugs* 1986; **32:** 260–78.

Precautions

Precautions and contra-indications for furosemide that are dependent on its effects on fluid and electrolyte balance are similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1309). Although furosemide is used in high doses for oliguria due to chronic or acute renal impairment it should not be given in anuria or in renal failure caused by nephrotoxic or hepatotoxic drugs nor in renal failure associated with hepatic coma. Furosemide should not be given in pre-comatose states associated with hepatic cirrhosis. It should be used with care in patients with prostatic hyperplasia or impairment of micturition since it can precipitate acute urinary retention.

To reduce the risk of ototoxicity, licensed product information recommends that furosemide should not be injected intravenously at a rate exceeding 4 mg/minute although the *BNF* advises that a single dose of up to 80 mg may be given more rapidly.

Furosemide should be used with caution during pregnancy and breast feeding since it crosses the placenta and also appears in breast milk. Furosemide may compromise placental perfusion by reducing maternal blood volume; it may also inhibit lactation.

Hepatic impairment. In patients with chronic heart failure and moderate liver congestion, high-dose furosemide therapy could produce increases in liver enzymes suggestive of hepatitis.[1] Special care should be taken with the dosage and mode of administration of furosemide in such patients to avoid severe ischaemic liver damage caused by a drop in systemic blood pressure.

As with the thiazides, furosemide should be avoided in patients with severe hepatic impairment.

1. Lang I, *et al.* Furosemide and increases in liver enzymes. *Ann Intern Med* 1988; **109:** 845.

Hypersensitivity. Furosemide is a sulfur-containing diuretic and hypersensitivity reactions may occur, although they are rare; cross-reactivity with other sulfur-containing drugs is also possible. However, 2 patients who had in the distant past shown serious adverse reactions to sulfur-containing diuretics were successfully treated[1] with furosemide using a rechallenge protocol. They were given an initial dose of 50 micrograms which was increased gradually each day to 20 mg by day 10, and were discharged from hospital on a maintenance dose of 40 mg twice daily. Another patient[2] with a history of sulfonamide-induced pancreatitis developed pancreatitis with furosemide, which recurred with bumetanide and torasemide and on rechallenge with furosemide. She underwent a rapid desensitisation regimen and was subsequently successfully stabilised on oral furosemide.

Hypoparathyroidism. For comments on the possibility of hypocalcaemic tetany in hypoparathyroid patients taking furosemide, see Effects on Electrolyte Balance, above.

Infants and neonates. Caution must be exercised in using furosemide in infants, particularly for long periods. The immaturity of the renal system can result in unexpectedly high blood concentrations and extended half-lives. Fluid and electrolyte balances should therefore be monitored carefully. Neonates appear to be particularly susceptible to increases in urinary calcium concentrations after long-term use. There have also been reports[1] of an increased incidence of patent ductus arteriosus in infants given furosemide, although this did not adversely affect mortality.

Secondly, several studies[2-4] have shown furosemide to be a potent displacer of bilirubin from albumin binding sites and it should be used with caution in jaundiced infants. On a molar basis chlorothiazide, furosemide, and etacrynic acid were at least as potent as sulfafurazole in displacing bilirubin from albumin.[3] Doses of furosemide 1 mg/kg probably do not produce a significant increase in free bilirubin in most jaundiced infants,[3,4] although doses greater than 1.5 mg/kg or repeated dosing could potentially do so.[4] Chlorothiazide 15 to 20 mg/kg would not be an appropriate alternative to furosemide[3] since it could produce higher plasma bilirubin concentrations in jaundiced infants.

In addition, there is some evidence from an *in vitro* study[5] that bilirubin may displace furosemide from binding sites to a greater extent in neonates than in adults. The clearance of furosemide is much slower in neonates than in adults, with an eightfold prolongation in plasma half-life, and this should be taken into account during repeat dosing.[4]

Porphyria. Furosemide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The interactions of furosemide that are due to its effects on fluid and electrolyte balance are similar to those of hydrochlorothiazide (see p.1309).

Furosemide may enhance the nephrotoxicity of cephalosporin antibacterials such as cefalotin and can enhance the ototoxicity of aminoglycoside antibacterials and other ototoxic drugs.

Aliskiren. Licensed product information for aliskiren states that it may significantly decrease furosemide concentrations.

Antiepileptics. The diuretic effect of furosemide has been shown to be substantially reduced by mixed antiepileptic therapy that included *phenytoin*.[1,2] The mean diuretic effect of furosemide 20 mg or 40 mg by mouth in patients on such therapy was 68% and 51% that of healthy controls respectively.[1]

For the effect of furosemide on *phenobarbital*, see p.493.

Symptomatic hyponatraemia has been associated with the use of furosemide or hydrochlorothiazide with *carbamazepine*.[3]

3. Yassa R, *et al.* Carbamazepine, diuretics, and hyponatremia: a possible interaction. *J Clin Psychiatry* 1987; **48:** 281–3.

Diuretics. Severe electrolyte disturbances may occur in patients given *metolazone* with furosemide.

Hypnotics. A syndrome of flushing, tachycardia, elevated blood pressure, and severe diaphoresis was reported after intravenous dosage of furosemide in 6 patients who had taken *cloral hydrate* orally during the preceding 24 hours.[1] The reaction recurred in 1 patient on a subsequent occasion when given both drugs but not when furosemide was used without cloral hydrate. A subsequent retrospective study[2] among 43 patients who had received both cloral hydrate and furosemide showed that 1 patient had suffered a similar reaction; of 2 further patients who had possibly been affected, 1 had subsequently taken both drugs without adverse effects. A similar interaction has been reported in an 8-year-old child.[3]

3. Dean RP, *et al.* Interaction of chloral hydrate and intravenous furosemide in a child. *Clin Pharm* 1991; **10:** 385–7.

Lithium. For reports of a possible increase in plasma-lithium concentrations in patients receiving loop diuretics, see p.405.

NSAIDs. NSAIDs may antagonise the diuretic effect of furosemide and other diuretics.[1] Use of NSAIDs with diuretics may increase the risk of nephrotoxicity, although it has also been suggested that furosemide may protect against the renal effects of *indometacin* in infants (see Effects in Infants and Neonates, above).

1. Webster J. Interactions of NSAIDs with diuretics and β-blockers: mechanisms and clinical implications. *Drugs* 1985; **30:** 32–41.

Probenecid. Probenecid has been shown[1-4] to reduce the renal clearance of furosemide, and to reduce the diuretic effect.[2,3]

Tobacco. The effects of tobacco smoking on the pharmacokinetics of furosemide have been reviewed.[1,2] Nicotine inhibits diuresis and diminishes the diuretic effect of furosemide. However, this effect is attenuated in habitual smokers.

Xanthines. For the effect of furosemide on *theophylline*, see p.1144.

Pharmacokinetics

Furosemide is fairly rapidly absorbed from the gastrointestinal tract; bioavailability has been reported to be about 60 to 70% but absorption is variable and erratic. The half-life of furosemide is up to about 2 hours although it is prolonged in neonates and in patients with renal and hepatic impairment. Furosemide is up to 99% bound to plasma albumin, and is mainly excreted in the urine, largely unchanged. There is also some excretion via the bile and non-renal elimination is considerably increased in renal impairment. Furosemide crosses the placental barrier and is distributed into breast milk. The clearance of furosemide is not increased by haemodialysis.

◊ The pharmacokinetics of furosemide have been extensively reviewed.[1-6] The development of an analytical method using HPLC with fluorescence has produced greater sensitivity and more consistent results. Absorption after oral use is erratic and is subject to large inter- and intra-individual variation. It is influenced by the dosage form, underlying disease processes, and by the presence of food. Furosemide absorption in patients with heart failure has been reported to be even more erratic than in healthy subjects. The bioavailability of furosemide from oral dosage forms is also highly variable with reported values ranging from 20 to 100%. It is influenced by factors affecting absorption but the poor solubility of furosemide does not appear to have a major influence on bioavailability and *in vitro* dissolution data may not reflect *in vivo* bioavailability. Bioavailability tends to be decreased by about 10% in patients with renal disease, and slightly increased in liver disease. Values are erratic in patients with heart disease.

Furosemide is highly bound to plasma proteins, almost exclusively to albumin. The proportion of free (unbound) furosemide is higher in patients with heart disease, renal impairment, and cirrhosis of the liver. Patients with liver disease also have an increased apparent volume of distribution which is proportionally greater than the observed decrease in protein binding. Patients with nephrotic syndrome have significant proteinuria and secondary hypoalbuminaemia. This results in reduced protein binding in the blood, particularly at higher blood concentrations, and binding to proteins present in the urine, which may account for the resistance to furosemide therapy reported in these patients.

A glucuronide metabolite of furosemide is produced in varying amounts. The site of metabolism is unknown at present. There is debate over another potential metabolite, 4-chloro-5-sulfamoyl anthranilic acid (CSA). It has been argued[3] that it is an artefact produced during the extraction procedures although there is some evidence to refute this.[4]

A half-life for furosemide in healthy subjects has generally been reported in the range of 30 to 120 minutes. In patients with end-stage renal disease the average half-life is 9.7 hours. The half-life may be slightly longer in patients with hepatic dysfunction and a range of 50 to 327 minutes has been reported in patients with heart failure. In severe multi-organ failure the half-life may range from 20 to 24 hours.

Furosemide clearance is influenced by age, underlying disease state, and drug interactions. Clearance reduces with increasing age, probably due to declining renal function. Renal impairment in renal or cardiac disease reduces renal clearance, although this may be compensated for by increases in non-renal clearance. Hepatic impairment has little impact on clearance. Renal and non-renal clearance may be reduced by probenecid and indometacin.

The effectiveness of furosemide as a diuretic depends upon it reaching its site of action, the renal tubules, unchanged. About one-half to two-thirds of an intravenous dose or one-quarter to one-third of an oral dose are excreted unchanged, the difference being largely due to the poor bioavailability from the oral route. The effect of furosemide is more closely related to its urinary excretion than to the plasma concentration. Urinary excretion may be reduced in renal impairment due to reduced renal blood flow and reduced tubular secretion.

Infants and neonates. The half-life of furosemide in term and preterm neonates is markedly prolonged compared with that in adults.[1,2] Half-lives of 4.5 to 46 hours have been reported and it has been suggested that the prolongation may be greater in preterm than in term neonates. This effect is due primarily to immature renal function and if repeated doses are necessary over a short period accumulation may occur.[1]

Uses and Administration

Furosemide is a potent diuretic with a rapid action. Like the other loop or high-ceiling diuretics it is used in the treatment of oedema associated with heart failure (below), including pulmonary oedema, and with renal and hepatic disorders (but see Precautions, above) and may be effective in patients unresponsive to thiazide diuretics. It is also used in high doses in the management of oliguria due to renal failure or insufficiency. Furosemide is also used in the treatment of hypertension (p.1171), either alone or with other antihypertensives.

Furosemide inhibits the reabsorption of electrolytes primarily in the thick ascending limb of the loop of Henle and also in the distal renal tubules. It may also have a direct effect in the proximal tubules. Excretion of sodium, potassium, calcium, and chloride ions is increased and water excretion enhanced. It has no clinically significant effect on carbonic anhydrase. See Action, below, for further reference to its mechanism of action.

Administration and dosage. Furosemide's effects are evident within 30 minutes to 1 hour after an oral dose, peak at 1 to 2 hours, and last for about 4 to 6 hours; after intravenous injection its effects are evident in about 5 minutes and last for about 2 hours. It is given orally, usually in the morning. Alternatively it may be given intramuscularly or intravenously as the sodium salt; doses are expressed in terms of furosemide base. 10.7 mg of furosemide sodium is equivalent to about 10 mg of furosemide base. Licensed product information recommends that whether by direct intravenous injection or by infusion the rate of intravenous dosage should not exceed 4 mg/minute although the *BNF* advises that a single dose of up to 80 mg may be given more rapidly.

Unlike the thiazide diuretics where, owing to their flat dose-response curve, very little is gained by increasing the dose, furosemide has a steep dose-response curve, which gives it a wide therapeutic range.

In the treatment of **oedema**, the usual initial oral dose is 40 mg once daily, adjusted as necessary according to response. Mild cases may respond to 20 mg daily or 40 mg on alternate days. Some patients may need doses of 80 mg or more daily given as one or two doses daily, or intermittently. Severe cases may require gradual titration of the furosemide dosage up to 600 mg daily. In an emergency or when oral therapy cannot be given, 20 to 50 mg of furosemide may be given by slow intravenous injection; intramuscular injection may be given in exceptional cases but is not suitable for acute conditions. If necessary further doses may be given, increasing by 20-mg increments and not given more often than every 2 hours. If doses above 50 mg are required they should be given by slow intravenous infusion. For pulmonary oedema, if an initial slow intravenous injection of 40 mg does not produce a satisfactory response within one hour, a further 80 mg may be given slowly intravenously.

For children, the usual oral dose is 1 to 3 mg/kg daily up to a maximum of 40 mg daily; doses by injection are 0.5 to 1.5 mg/kg daily up to a maximum of 20 mg daily.

In the treatment of **hypertension**, furosemide is given in oral doses of 40 to 80 mg daily, either alone, or with other antihypertensives.

High-dose therapy. In the management of **oliguria** in acute or chronic renal failure where the glomerular filtration rate is less than 20 mL/minute but greater than 5 mL/minute, furosemide 250 mg diluted to 250 mL in a suitable diluent is infused over one hour. If urine output is insufficient within the next hour, this dose may be followed by 500 mg added to an appropriate infusion fluid, the total volume of which must be governed by the patient's state of hydration, and infused over about 2 hours. If a satisfactory urine output has still not been achieved within one hour of the end of the second infusion then a third dose of 1 g may be infused over about 4 hours. The rate of infusion should never exceed 4 mg/minute. In oliguric patients with significant fluid overload, the injection may be given without dilution directly into the vein, using a constant rate infusion pump with a micrometer screw-gauge adjustment; the rate should still never exceed 4 mg/minute. Patients who do not respond to a dose of 1 g probably require dialysis. If the response to either dosage method is satisfactory, the effective dose (of up to 1 g) may then be repeated every 24 hours. Dosage adjustments should subsequently be made according to the patient's response. Alternatively, oral treatment may be maintained; 500 mg should be given orally for each 250 mg required by injection.

When used in chronic renal impairment, an initial oral dose of 250 mg may be given, increased, if necessary in steps of 250 mg every 4 to 6 hours to a maximum of 1.5 g in 24 hours; in exceptional cases up to 2 g in 24 hours may be given. Dosage adjustments should subsequently be made according to the patient's response.

During treatment with these high-dose forms of furosemide therapy, careful laboratory control is essential. Fluid balance and electrolytes should be carefully controlled and, in particular, in patients with shock, measures should be taken to correct the blood pressure and circulating blood volume, before commencing this type of treatment. High-dose furosemide therapy is contra-indicated in renal failure caused by nephrotoxic or hepatotoxic drugs, and in renal failure associated with hepatic coma.

Action. The mechanism of action of furosemide is not fully understood.[1] It appears to act primarily by inhibiting active reabsorption of chloride ions in the ascending limb of the loop of Henle. Urinary excretion of sodium, chloride, potassium, hydrogen, calcium, magnesium, ammonium, bicarbonate, and possibly phosphate is increased; the chloride excretion exceeds that of sodium and there is an enhanced exchange of sodium for potassium leading to greater excretion of potassium. The resulting low osmolality of the medulla inhibits the reabsorption of water by the kidney. There is a possibility that furosemide may also act at a more proximal site.

In addition to its diuretic actions, furosemide has been shown to increase peripheral venous capacitance and reduce forearm blood flow. It also reduces renal vascular resistance with a resultant increase in renal blood flow the degree of which is proportional to the initial resistance.

Furosemide has been shown to increase plasma-renin activity, plasma-noradrenaline concentrations, and plasma-arginine-vasopressin concentrations. Alterations in the renin-angiotensin-aldosterone system may play a part in the development of acute tolerance. Furosemide increases renal-prostaglandin concentrations but it is not known whether this is due to increased synthesis or inhibition of degradation or both. Prostaglandins appear to mediate the diuretic/natriuretic action. The primary effects appear to be alterations in renal haemodynamics with subsequent increases in electrolyte and fluid excretion.

The diuretic response to furosemide is related to the concentration in the urine, not to that in the plasma. Furosemide is delivered to the renal tubules by a non-specific organic acid pump in the proximal tubules.[1]

In some cases sodium intake may be sufficient to overcome the diuretic effect, and limiting sodium intake could restore responsiveness.[2]

2. Brater DC. Resistance to loop diuretics: why it happens and what to do about it. *Drugs* 1985; **30:** 427–43.

Administration. Continuous intravenous infusion of loop diuretics may be more effective than intermittent intravenous bolus injection and may provide a more consistent urine flow with fewer alterations in urine balance.[1,2] Bumetanide was more effective by continuous infusion than as bolus doses in 8 patients with severe chronic renal impairment.[3] In 20 patients with chronic heart failure requiring high-dose furosemide therapy, furosemide given by continuous infusion was more effective than the same dose by bolus injection.[4] The lower plasma concentrations associated with continuous infusion may also reduce the risk of toxicity.

Ascites. Dietary sodium restriction and diuretics are mainstays of the management of cirrhotic ascites (p.1159). Spironolactone is usually the diuretic of first choice, but furosemide may be added to therapy as necessary.

Bronchopulmonary dysplasia. Bronchopulmonary dysplasia is a major cause of chronic lung disease in infants. Treatment often involves the use of corticosteroids (see p.1500). Additional supportive therapy may include the use of diuretics such as furosemide.

Alternate-day therapy with oral furosemide 4 mg/kg has produced modest benefits in pulmonary status in the absence of a diuretic effect, and few adverse effects.[1] Improved pulmonary function has occurred in infants given furosemide 1 mg/kg parenterally after packed red blood cell transfusions, given to improve oxygen-carrying capacity.[2] The successful use of nebulised furosemide in a dose of 1 mg/kg has been reported;[3,4] again pulmonary status was improved without production of diuresis or renal side-effects. However, a single inhaled dose of 1 mg/kg failed to improve pulmonary mechanics in another study involving older infants with more severe disease.[5] Systematic reviews of the use of intravenous or oral,[6] or nebulised[7] diuretics in preterm infants with chronic lung disease concluded that, although there were improvements in pulmonary function, there was insufficient evidence to recommend routine use.

Haemolytic-uraemic syndrome. Renal failure is a possible consequence of the haemolytic-uraemic syndrome (see Thrombotic Microangiopathies, p.1076). Correction of any hypovolaemic state with adequate fluids and of oliguria by inducing diuresis with furosemide may be used to prevent this.

Of 54 children with haemolytic-uraemic syndrome given intravenous furosemide 2.5 to 4 mg/kg every 3 to 4 hours immediately after diagnosis 24% eventually required dialysis.[1] In contrast, a retrospective analysis of 39 patients treated conservatively showed that 82% had required dialysis. The results therefore suggested that high-dose furosemide could prevent the progression of oliguria to anuria in these patients by increasing urate clearance.

1. Rousseau E, *et al.* Decreased necessity for dialysis with loop diuretic therapy in hemolytic uremic syndrome. *Clin Nephrol* 1990; **34:** 22–5.

Heart failure. Diuretics have been the mainstay in the treatment of heart failure (p.1165) but drugs such as ACE inhibitors that have been shown to improve mortality are now generally recommended for first-line therapy along with diuretics. Diuretics provide very effective symptomatic control in patients with peripheral or pulmonary oedema and rapidly relieve dyspnoea. If symptoms of fluid retention are only mild, a thiazide diuretic such as bendroflumethiazide or hydrochlorothiazide, may be adequate. However, in most cases, especially in moderate or severe fluid retention, a loop diuretic such as furosemide will be necessary. Combination treatment with diuretics that behave synergistically by acting at different sites (the principle of sequential nephron blockade), namely a loop diuretic with a thiazide or potassium-sparing diuretic, may be needed in some patients, especially when there is diuretic resistance.

Patients have been successfully treated using continuous intravenous infusions[1] or high doses (up to 8 g daily) of furosemide given by intravenous infusion[2,3] or orally.[3] A patient who was successfully maintained on intravenous furosemide at home has been described.[4] Combination of furosemide with thiazide diuretics[5] or metolazone[6,7] has been reported. There is a danger of overdiuresis with both of these strategies, and careful monitoring of electrolytes and renal function is essential.[8] Delivery of furosemide to the renal tubules may be enhanced by combined therapy with hydralazine[9] or captopril.[10] The use of captopril and furosemide may also correct hyponatraemia without fluid restriction.[11] In elderly patients not responding adequately to low-dose furosemide together with optimum doses of ACE inhibitors, increasing the dose of furosemide (to an average of 297 mg daily orally) has been reported[12] to be of benefit. However, caution is necessary when using furosemide with antihypertensives and especially ACE inhibitors since these combinations can result in sudden and profound hypotension and renal toxicity. Low-dose dopamine infusion has been suggested as an alternative to high-dose furosemide infusion and may cause less toxicity. In a study[13] in patients with severe refractory heart failure given optimal therapy with ACE inhibitors, oral diuretics, nitrates, and digoxin, additional therapy with low-dose intravenous dopamine (4 micrograms/kg per minute) and low-dose oral furosemide (80 mg daily) was as effective as intravenous high-dose furosemide (10 mg/kg daily) but caused less hypokalaemia and renal impairment. Use of intravenous hypertonic saline has also been reported[14] to augment the effect of furosemide.

Hypercalcaemia. Hypercalcaemia (p.1668) usually results from an underlying disease and long-term management involves treating the cause. However, if significant symptoms are present, treatment is necessary to reduce plasma-calcium concentrations. This primarily involves rehydration, but loop diuretics such as furosemide have been used after rehydration, to promote urinary calcium excretion. Doses used have ranged from 20 to 240 mg of furosemide daily, given intravenously.

Obstructive airways disease. In patients with *asthma*, furosemide given by oral inhalation has been found to protect against bronchoconstriction induced by exercise[1] and external stimuli,[2,3] although it did not improve bronchial hyperresponsiveness in a 4-week study[4] and provided no additional benefit when added to salbutamol for the treatment of acute asthma in a small study in children.[5] A number of mechanisms have been suggested for the protective effect of furosemide, including inhibition of electrolyte transport across epithelium, inhibition of inflammatory mediators, or an effect on mast cell function.[6] The potential for clinical applications remains unclear[6] and furosemide is not a part of the accepted schedules for the treatment of asthma (p.1108).

A small study[7] in patients with *chronic obstructive pulmonary disease* found that inhalation of furosemide relieved bronchoconstriction and dyspnoea induced by exercise.

Inhaled furosemide has also been used to relieve *dyspnoea in patients with terminal cancer*.[8]

Patent ductus arteriosus. The usual initial treatment for a haemodynamically significant ductus is reduction of fluid intake, correction of anaemia, support of respiration, and giving a diuretic. If that fails to control symptoms then indometacin is generally given to promote closure of the ductus (see p.68).

Furosemide is often the diuretic chosen. It is effective and widely used but there has been concern that it might delay closure (and even increase the incidence of patent ductus arteriosus in infants treated for respiratory distress syndrome — see Effects in Infants and Neonates under Adverse Effects, above). A systematic review[1] of those treated for patent ductus concluded that this did not seem to be the case, and that the diuretic might reduce adverse renal effects of indometacin; however, the evidence for this was limited and it was felt that there was not enough evidence to support the use of furosemide in infants treated with indometacin.

1. Brion LP, Campbell DE. Furosemide for prevention of morbidity in indomethacin-treated infants with patent ductus arteriosus. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley, 2001 (accessed 12/07/05).

Raised intracranial pressure. Osmotic diuretics such as mannitol are first-line drugs for the management of raised intracranial pressure (p.1181) but loop diuretics such as furosemide may be used as adjuncts.

Tinnitus. Furosemide is one of many drugs that have been tried in tinnitus (p.1866), but although reported to be effective in some patients, it is rarely used because of problems with adverse effects.

Preparations

BP 2008: Co-amilofruse Tablets; Furosemide Injection; Furosemide Tablets;
USP 31: Furosemide Injection; Furosemide Oral Solution; Furosemide Tablets.

Proprietary Preparations (details are given in Part 3)

Gallopamil Hydrochloride *(BANM, rINNM)*

D-600 (gallopamil); Gallopamil, Chlorhydrate de; Gallopamilhydroklorid; Gallopamilli Hydrochloridum; Gallopamillihydrokloridi; Hidrocloruro de galopamilo; Methoxyverapamil Hydrochloride. 5-[*N*-(3,4-Dimethoxyphenethyl)-*N*-methylamino]-2-(3,4,5-trimethoxyphenyl)-2-isopropylvaleronitrile hydrochloride.

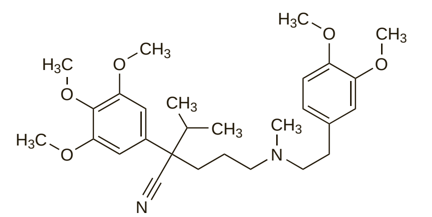
Галлопамила Гидрохлорид

$C_{28}H_{40}N_2O_5,HCl = 521.1.$

CAS — 16662-47-8 (gallopamil); 16662-46-7 (gallopamil hydrochloride).

ATC — C08DA02.

ATC Vet — QC08DA02.



(gallopamil)

Profile

Gallopamil is a calcium-channel blocker (see p.1154) with antiarrhythmic activity and is chemically related to verapamil. It is used in the management of angina pectoris (p.1157), cardiac arrhythmias (p.1160), and hypertension (p.1171). Gallopamil hydrochloride is given by mouth in doses of 25 to 50 mg every 6 to 12 hours up to a maximum total dose of 200 mg daily. Modified-release preparations are also available and are given once or twice daily in similar total daily doses.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Gemfibrozil). A white or almost white, waxy, crystalline powder. M.p. 58° to 61°. Practically insoluble in water; freely soluble in dehydrated alcohol and in methyl alcohol; very soluble in dichloromethane. Protect from light.

USP 31 (Gemfibrozil). A white waxy crystalline solid. M.p. 58° to 61°. Practically insoluble in water; soluble in alcohol, in methyl alcohol, and in chloroform. Store in airtight containers.

Adverse Effects and Precautions

As for Bezafibrate, p.1232.

Incidence of adverse effects. In the Helsinki Heart Study,[1] 11.3% of 2051 patients taking gemfibrozil reported various moderate to severe upper gastrointestinal tract symptoms during the first year of treatment compared with 7% of 2030 patients taking placebo. No differences were seen between gemfibrozil and placebo groups in haemoglobin concentrations, urinary-protein, or urinary-sugar concentrations.

There was no significant difference in the total number of cancers between the gemfibrozil and placebo groups nor in the number of operations for gallstones or for cataract surgery. A higher number of deaths in the gemfibrozil group was mainly due to accident or violence and intracranial haemorrhage.

A follow-up study[2] reported that gastrointestinal symptoms remained more common in patients taking gemfibrozil. Although there was no significant difference between the gemfibrozil and placebo groups cholecystectomies were consistently more common in those receiving gemfibrozil during the entire 8.5-year observation period. Cancer occurred equally in both groups, but there was increased mortality attributable to cancer in the gemfibrozil group, mainly during the last 1.5 years of follow-up; this difference was no longer apparent after 18 years.[3]

3. Tenkanen L, *et al.* Gemfibrozil in the treatment of dyslipidemia: an 18-year mortality follow-up of the Helsinki Heart Study. *Arch Intern Med* 2006; **166:** 743–8.

Effects on the skin. Psoriasis was exacerbated in a patient within 2 weeks of starting gemfibrozil therapy and recurred when gemfibrozil was subsequently reintroduced.[1]

1. Fisher DA, *et al.* Exacerbation of psoriasis by the hypolipidemic agent, gemfibrozil. *Arch Dermatol* 1988; **124:** 854–5.

Interactions

As for Bezafibrate, p.1232.

Gemfibrozil is an inhibitor of a number of cytochrome P450 isoenzymes, including CYP2C8, CYP2C9, CYP2C19, and CYP1A2 and may increase the plasma concentration of drugs metabolised by these isoenzymes; it also inhibits some UDP-glucuronosyltransferases. Increased plasma concentration of bexarotene (see p.686), pioglitazone (see p.456), and rosiglitazone (see p.459) have been reported with gemfibrozil, and use of gemfibrozil in patients receiving repaglinide is contra-indicated due to the risk of serious hypoglycaemia (see p.458).

Pharmacokinetics

Gemfibrozil is readily absorbed from the gastrointestinal tract; bioavailability is close to 100% and is highest when gemfibrozil is taken 30 minutes before food. Peak concentrations in plasma occur within 1 to 2 hours; the half-life is about 1.5 hours. Plasma protein binding of gemfibrozil is about 98%. About 70% of a dose is excreted in the urine mainly as glucuronide conjugates of gemfibrozil and its metabolites; little is excreted in the faeces.

Uses and Administration

Gemfibrozil, a fibric acid derivative, is a lipid regulating drug with actions on plasma lipids similar to those of bezafibrate (p.1233).

Gemfibrozil is used to reduce total cholesterol and triglycerides in the management of hyperlipidaemias (p.1169), including type IIa, type IIb, type III, type IV, and type V hyperlipoproteinaemias. It is also indicated for the primary prevention of ischaemic heart disease (see Cardiovascular Risk Reduction, p.1164) in hyperlipidaemic men: in the USA this use is restricted to type IIb patients who also have low HDL-cholesterol concentrations and who have not responded to dietary and other measures. The usual oral dose is 1.2 g daily in 2 divided doses given 30 minutes before the morning and evening meals. Alternatively, a single daily dose of 900 mg has been given 30 minutes before the evening meal.

◊ Reviews.

Administration in renal impairment. Gemfibrozil is contra-indicated in patients with severe renal impairment. However, UK licensed prescribing information allows its use in patients with mild to moderate impairment (glomerular filtration rate 30 to 80 mL/minute per 1.73 m^2); the initial dose should be reduced to 900 mg daily and renal function should be assessed before increasing the dose.

In a study[1] of the pharmacokinetics of gemfibrozil in 17 patients with stable chronic renal failure the mean plasma half-life was 1.8 and 1.9 hours after multiple and single doses respectively, which was comparable with that reported in patients with normal renal function. Gemfibrozil clearance was independent of renal function, but the kinetics of gemfibrozil metabolites were not evaluated.

Beneficial responses[2] were seen in lipid and lipoprotein concentrations in 5 of 6 uraemic patients treated with gemfibrozil 1.2 g daily for six months and in 6 nephrotic patients given gemfibrozil 800 mg daily for 4 months. No significant adverse effects or signs of organ toxicity were seen. Results of a secondary prevention study[3] also suggested that gemfibrozil at a dose of 1.2 g daily was safe and effective in patients with mild to moderate renal impairment.

Glyceryl Trinitrate

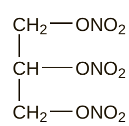
Glicerin-trinitrát; Glicerolio trinitratas; Gliseril Trinitrat; Glonoin; Glyceroli Trinitras; Glyceroli trinitratis; Glycerol-trinitrát; Glycéryle, trinitrate de; Glyceryltrinitrat; Glyseryylitrinitraatti; GTN; Nitroglicerina; Nitrogliserin; Nitroglycerin; Nitroglycerol; NTG; Trinitrin; Trinitroglycerin. Propane-1,2,3-triol trinitrate.

$C_3H_5(NO_3)_3$ = 227.1.

CAS — 55-63-0.

ATC — C01DA02; C05AE01.

ATC Vet — QC01DA02; QC05AE01.



Pharmacopoeias. *Chin., Eur.* (see p.vii), *US,* and *Viet.* include glyceryl trinitrate as diluted solutions.

Ph. Eur. 6.2 (Glyceryl Trinitrate Solution). An ethanolic solution containing 1 to 10% w/w of glyceryl trinitrate. It is a clear, colourless or slightly yellow solution. Miscible with dehydrated alcohol and with acetone.

Pure glyceryl trinitrate is practically insoluble in water; freely soluble in dehydrated alcohol; miscible with acetone.

Protect from light. Diluted solutions (1%) should be stored at 2° to 15°; more concentrated solutions may be stored at 15° to 20°.

USP 31 (Diluted Nitroglycerin). A mixture of glyceryl trinitrate with lactose, glucose, alcohol, propylene glycol, or other suitable inert excipient, usually containing not more than 10% glyceryl trinitrate. When diluted in either alcohol or propylene glycol it is a clear, colourless, or pale yellow liquid. When diluted with lactose, it is a white odourless powder. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Prevent exposure to temperatures above 40°. Protect from light.

Undiluted glyceryl trinitrate is a white to pale yellow, thick, flammable, explosive liquid. Slightly soluble in water; soluble in alcohol, in acetone, in carbon disulfide, in chloroform, in dichloromethane, in ether, in ethyl acetate, in glacial acetic acid, in methyl alcohol, in benzene, in toluene, in nitrobenzene, and in phenol.

Handling. Undiluted glyceryl trinitrate can be exploded by percussion or excessive heat and only exceedingly small amounts should be isolated.

Incompatibility. Studies have found glyceryl trinitrate to be incompatible with phenytoin,[1] alteplase,[2] and levofloxacin.[3]

1. Klamerus KJ, *et al.* Stability of nitroglycerin in intravenous admixtures. *Am J Hosp Pharm* 1984; **41:** 303–5.

3. Saltsman CL, *et al.* Compatibility of levofloxacin with 34 medications during simulated Y-site administration. *Am J Health-Syst Pharm* 1999; **56:** 1458–9.

Stability. *INTRAVENOUS SOLUTIONS.* The loss of glyceryl trinitrate from solution by adsorption or absorption into some plastics of intravenous giving sets has been recognised for some years,[1,2] although adsorption does not appear to occur to any great extent with polyolefin[3,4] or polyethylene.[5-7] It is not only infusion containers and plastic tubing that may be involved; some in-line filters can adsorb glyceryl trinitrate.[8,9]

TABLETS. Many studies have shown that glyceryl trinitrate tablets are unstable and subject to considerable loss of potency in contact with packaging components such as adhesive labels, cotton and rayon fillers, and plastic bottles and caps. Both the Council of the Royal Pharmaceutical Society of Great Britain and the FDA in the USA have issued packaging and dispensing guidelines. Glyceryl trinitrate tablets should be dispensed only in glass containers sealed with a foil lined cap and containing no cotton wool wadding. In addition, the Council of the Royal Pharmaceutical Society of Great Britain recommends that no more than 100 tablets should be supplied and that the container should be labelled with an indication that any tablets should be discarded after 8 weeks in use.

Adverse Effects

Glyceryl trinitrate may cause flushing of the face, dizziness, tachycardia, and throbbing headache. Large doses cause vomiting, restlessness, blurred vision, hypotension (which can be severe), syncope, and rarely cyanosis, and methaemoglobinaemia; impairment of respiration and bradycardia may ensue. Contact dermatitis has been reported in patients using topical glyceryl trinitrate preparations; local irritation and erythema may also occur. Preparations applied to the oral mucosa frequently produce a localised burning sensation.

Chronic poisoning may occur in industry but tolerance develops when glyceryl trinitrate is regularly handled and nitrate dependence can lead to severe withdrawal symptoms in subjects abruptly removed from chronic exposure. Loss of such tolerance is rapid and may cause poisoning on re-exposure. Tolerance may occur during clinical use and is usually associated with preparations that produce sustained plasma concentrations.

Effects on the heart. Tachycardia, hypotension, and bradycardia are recognised adverse cardiac effects of glyceryl trinitrate. Rarely reported adverse effects include asystole[1] and complete heart block.[2]

1. Ong EA, *et al.* Nitroglycerin-induced asystole. *Arch Intern Med* 1985; **145:** 954.
2. Lancaster L, Fenster PE. Complete heart block after sublingual nitroglycerin. *Chest* 1983; **84:** 111–12.

Effects on taste. A 61-year-old man experienced loss of bitter and salty taste sensations 2 weeks after addition of glyceryl trinitrate patches to his post-myocardial infarction drug regimen.[1] The patient had complete loss of taste after 6 weeks; his taste sensation returned to normal within 1 week of stopping glyceryl trinitrate patches. Taste sensation was again altered on rechallenge.

1. Ewing RC, *et al.* Ageusia associated with transdermal nitroglycerin. *Clin Pharm* 1989; **8:** 146–7.

Hypersensitivity. Contact dermatitis has been reported in patients using glyceryl trinitrate ointment and patches.[1] Both glyceryl trinitrate and formulation components may be involved in these reactions.

1. Carmichael AJ. Skin sensitivity and transdermal drug delivery: a review of the problem. *Drug Safety* 1994; **10:** 151–9.

Intravenous administration. Some formulations of glyceryl trinitrate for intravenous use may contain substantial quantities of alcohol in the solvent. There have been several reports of alcohol intoxication occurring in patients during high-dose intravenous glyceryl trinitrate infusion.[1-3] In a patient[3] who required glyceryl trinitrate 2 mg/minute, a blood-alcohol concentration of 2.67 mg/mL was reported. PVC tubing had been used for the infusion and it was suggested that adsorption of glyceryl trinitrate onto the tubing may have increased the dose requirement and thus the amount of alcohol given.

Propylene glycol is also used as a solvent in some formulations of glyceryl trinitrate. Infusion of solutions with propylene glycol can lead to hyperosmolarity: see under Propylene Glycol, p.2374, for details.

2. Daly TJ, *et al.* "Cocktail"-coronary care. *N Engl J Med* 1984; **310:** 1123.
3. Korn SH, Comer JB. Intravenous nitroglycerin and ethanol intoxication. *Ann Intern Med* 1985; **102:** 274.

Treatment of Adverse Effects

Syncope and hypotension should be treated by keeping the patient in a recumbent position with the head lowered; pressor agents may be necessary in extreme hypotension. Oxygen, with assisted respiration, may be needed in severe poisoning and infusion of plasma expanders or suitable electrolyte solutions may be required to maintain the circulation. If methaemoglobinaemia occurs methylthioninium chloride may be given intravenously. In the case of severe poisoning with tablets the stomach may be emptied by lavage. If large amounts have been ingested within 1 hour, activated charcoal may be considered.

Precautions

Glyceryl trinitrate should not be used in patients with severe hypotension, hypovolaemia, marked anaemia, heart failure due to obstruction (including constrictive pericarditis), or raised intracranial pressure due to head trauma or cerebral haemorrhage. Although it has been suggested that glyceryl trinitrate may increase intra-ocular pressure in patients with angle-closure glaucoma and should be avoided in such patients there appears to be no evidence for such a contra-indication.

Glyceryl trinitrate should be used with caution in patients with severe renal or severe hepatic impairment, hypothyroidism, malnutrition, or hypothermia. Metal-containing transdermal patches should be removed before cardioversion or diathermy.

Nitrate tolerance. Although organic nitrates are effective anti-anginal drugs, their use is limited by the development of tolerance and the loss or attenuation of their anti-anginal and anti-ischaemic effects.[1,2] This can occur with all of the organic nitrates, particularly if frequent or continuous dosing is used.[1-3]

The mechanisms of nitrate tolerance are incompletely understood. The vasodilator effect of organic nitrates may depend on their conversion to nitric oxide, a process which requires the presence of a sulfhydryl donor such as cysteine or another thiol. Repeated doses of a nitrate exhaust tissue stores of sulfhydryl groups and this is one mechanism that may account for the development of tolerance.[1,2] The activation of neurohormonal systems, which releases vasoconstrictor hormones that counteract the effects of organic nitrates, has also been proposed as a mechanism.[1,2] An increase in free-radical production during nitrate therapy has also been suggested,[1] and may inhibit bioactivation of the nitrate.[3] Nitrate-induced expansion of plasma volume may also contribute, leading to reversal of the effects of nitrates on ventricular preload.[1,2]

The method most commonly used to avoid the development of tolerance is to provide a nitrate-free interval.[1,2] The optimum duration is not clear, but a nitrate-free period of 10 to 12 hours has been suggested.[1,2] With transdermal glyceryl trinitrate systems, the patch can be removed at night. For oral, buccal, and ointment preparations, the dose given at the end of the day can be omitted. However, rebound myocardial ischaemia may occur during this time,[1] and may require the use of short-acting nitrate preparations.[2] Whether a nitrate-free interval is necessary for all patients is unknown as many patients using continuous nitrates do not experience clinical tolerance. A transdermal patch with a higher release rate during the first part of a 24-hour period has been found not to prevent the development of tolerance.[4]

Various drugs have been reported to reduce the development of nitrate tolerance, including sulfhydryl donors and drugs with antoxidant properties, but none has an established role.[1,3]

4. Wiegand A, *et al.* Pharmacodynamic and pharmacokinetic evaluation of a new transdermal delivery system with a time-dependent release of glyceryl trinitrate. *J Clin Pharmacol* 1992; **32:** 77–84.

Transdermal patches. An explosion occurred during defibrillation in a patient with a glyceryl trinitrate transdermal patch on the left side of the chest.[1] There was no visible injury to the patient. Subsequent studies suggested that this was caused by an electrical arc between the defibrillator paddle and the aluminium backing of the patch rather than explosion of the glyceryl trinitrate.

Although removal of transdermal patches before diathermy is usually recommended, a maximum rise in patch temperature of only 2.2° was reported when patches were exposed to power densities up to 800 watts/m^2. It was considered that exposure of transdermal patches to microwave diathermy, for example as part of physiotherapy treatment, was unlikely to cause direct thermal injury to the wearer.[2]

Interactions

The hypotensive effects of glyceryl trinitrate may be enhanced by alcohol, and by vasodilators and other drugs with hypotensive actions. The effectiveness of sublingual and buccal tablet preparations may be reduced by drugs that cause dry mouth since dissolution may be delayed.

Anticoagulants. For the effects of glyceryl trinitrate on *heparin*, see p.1303.

Antimuscarinics. Delayed dissolution of glyceryl trinitrate tablets due to dry mouth has been reported in a patient taking *imipramine*[1] and in a patient treated with *atropine*;[2] this effect should be considered whenever glyceryl trinitrate sublingual tablets are given to patients taking other drugs that can cause dry mouth. Use of the lingual spray[2] rather than a sublingual tablet or addition of 1 mL of saline under the tongue[3] may be used to overcome the problem.

Ergot alkaloids. For the effects of glyceryl trinitrate on *dihydroergotamine*, see under Interactions of Ergotamine, p.621.

Phosphodiesterase type-5 inhibitors. The concurrent use of nitrates and phosphodiesterase type-5 inhibitors such as sildenafil is contra-indicated. Significant hypotension may occur due to potentiation of the vasodilator actions of nitrates.[1] Deaths due to a possible interaction have been reported.[2]

Thrombolytics. For the effects of glyceryl trinitrate on *alteplase*, see p.1207.

Pharmacokinetics

Glyceryl trinitrate is rapidly absorbed from the oral mucosa. It is also well absorbed from the gastrointestinal tract and through the skin. Bioavailability is less than 100% when given by any of these routes due to pre-systemic clearance; bioavailability is further reduced after oral use owing to extensive first-pass metabolism in the liver.

Therapeutic effect is apparent within 1 to 3 minutes of use of sublingual tablets, sublingual spray, or buccal tablets; within 30 to 60 minutes of applying an ointment or transdermal patch; and within 1 to 2 minutes after intravenous doses.

Duration of action is about 30 to 60 minutes with sublingual tablets or spray and 3 to 5 hours with modified-release buccal tablets. Transdermal patches are designed to release a stated amount of drug over 24 hours, while therapeutic effects after application of glyceryl trinitrate ointment 2% persist for up to 8 hours. Duration of action after intravenous dosage is about 3 to 5 minutes.

Glyceryl trinitrate is widely distributed with a large apparent volume of distribution. It is taken up by smooth muscle cells of blood vessels and the nitrate group is cleaved to inorganic nitrite and then to nitric oxide. This reaction requires the presence of cysteine or another thiol. Glyceryl trinitrate also undergoes hydrolysis in plasma and is rapidly metabolised in the liver by glutathione-organic nitrate reductase to dinitrates and mononitrates. The dinitrates are less potent vasodilators than glyceryl trinitrate; the mononitrates may have some vasodilator activity.

Uses and Administration

Glyceryl trinitrate is a nitrovasodilator used in the management of angina pectoris (p.1157), heart failure (p.1165), and myocardial infarction (below). Other indications include inducing hypotension and controlling hypertension during surgery.

Glyceryl trinitrate is believed to exert its vasodilator effect through release of nitric oxide, which causes stimulation of guanylate cyclase in the vascular smooth muscle cells; this results in an increase in cyclic guanosine monophosphate. This nucleotide induces relaxation, probably by lowering the free calcium concentration in the cytosol. In its action on vascular muscle, venous dilatation predominates over dilatation of the arterioles. Venous dilatation decreases venous return as a result of venous pooling, and lowers left ventricular diastolic volume and pressure (termed a reduction in preload). The smaller or less important dilatation of arterioles reduces both peripheral vascular resistance and left ventricular pressure at systole (termed a reduction in afterload). The consequent effect is a reduction in the primary determinants of myocardial oxygen demand. The effect on preload is not shared by beta blockers or calcium-channel blockers. Glyceryl trinitrate also has a coronary vasodilator effect, which improves regional coronary blood flow to ischaemic areas resulting in improved oxygen supply to the myocardium.

Glyceryl trinitrate may be given by the sublingual, buccal, oral, transdermal, or intravenous route. The dose and choice of formulation depend upon the clinical situation.

In the management of **acute angina** glyceryl trinitrate is given as sublingual tablets, a sublingual aerosol spray, or buccal tablets, which all produce a rapid onset of therapeutic effect and provide rapid relief of anginal pain. These dosage forms may also be used before an activity or stress which might provoke an attack. One sublingual tablet (usual strength 300 to 600 micrograms) is placed under the tongue. The dose may be repeated as required but patients should be advised to seek medical care if pain persists after a total of 3 doses within 15 minutes. If an aerosol spray is used one or two sprays of 400 micrograms each are directed onto or under the tongue, then the mouth is closed; three sprays may be used if necessary. Buccal tablets of glyceryl trinitrate are placed between the upper lip and gum (see below for precautions to be observed during use). The usual dose is 2 mg when required, increased to 3 mg if necessary; a dose of 5 mg may be given in severe angina.

In the long-term management of **stable angina** glyceryl trinitrate is given as modified-release tablets or capsules, transdermal formulations, or buccal tablets, which all provide a long duration of action. Dosage varies according to the specific formulation. In the UK, for example, modified-release oral tablets are available that allow doses of up to 12.8 mg to be given up to three times daily. The transdermal formulations available are ointments and patches. With the ointment a measured amount (½ to 2 inches of glyceryl trinitrate ointment 2%) is applied 3 or 4 times daily, or every 3 to 4 hours if necessary, to the chest, arm, thigh, or back. Transdermal patches applied to the chest, upper arm, or shoulder are more convenient. Patches are generally designed to release glyceryl trinitrate at a constant rate; they are available in a range of sizes, releasing about 0.1 to 0.8 mg/hr (equivalent to about 2.5 to 20 mg in 24 hours, although the patches are generally removed for part of this period to prevent tolerance developing). A maximum daily dose of 20 mg has been suggested. Glyceryl trinitrate ointment and patches should be applied to a fresh area of skin and several days should elapse before re-application to formerly used sites. Buccal tablets are used in doses of 2 to 5 mg three times daily. The tablets are retained in the buccal cavity; the rate of dissolution of the tablet can be increased by touching the tablet with the tongue or drinking hot liquids. It is common practice to remove the tablets at bedtime because of the risk of aspiration. Also patients using buccal tablets should be advised to alternate placement sites and pay close attention to oral hygiene to reduce the risk of dental caries. The tablets are not intended to be chewed; if the buccal tablet is inadvertently swallowed, another may be placed in the buccal cavity.

Tolerance tends to develop in the majority of patients on continuous nitrate therapy and nitrate-free intervals are often employed to avoid this problem (see above under Precautions, Nitrate Tolerance for further details).

In the management of **unstable angina** glyceryl trinitrate may be given by intravenous infusion. Manufacturers' guidelines for dilution of glyceryl trinitrate injection specify glucose 5% or sodium chloride 0.9% as the diluent. During intravenous use of glyceryl trinitrate there should be haemodynamic monitoring of the patient with the dose being adjusted gradually to produce the desired response. The plastic used in the infusion equipment may adsorb glyceryl trinitrate (see Stability, above) and allowance may have to be made for this. The usual initial dose for unstable angina is 5 to 10 micrograms/minute. Most patients respond to doses between 10 and 200 micrograms/minute. The sublingual and buccal routes may also be used; doses of up to 5 mg as buccal tablets may be required to relieve pain in patients with unstable angina.

In the management of acute **heart failure** glyceryl trinitrate is given intravenously in an initial dose of 5 to 25 micrograms/minute. Buccal tablets have been used in doses of 5 mg repeated as needed until symptoms are controlled. In chronic heart failure buccal tablets may be given in doses of 5 to 10 mg three times daily.

Glyceryl trinitrate is also used intravenously in acute **myocardial infarction**, and to induce hypotension or control hypertension during **surgery**. The initial dose is 5 to 25 micrograms/minute, adjusted according to response. The usual range is 10 to 200 micrograms/minute but some surgical patients may require up to 400 micrograms/minute.

Glyceryl trinitrate has also been used as transdermal patches in the prophylactic treatment of **phlebitis and extravasation** secondary to venous cannulation. One 5-mg patch is applied distal to the intravenous site; the patch should be replaced at a different skin site either daily or after 3 to 4 days, depending on the patch. This treatment should continue only as long as the intravenous infusion is maintained.

Glyceryl trinitrate may also be used as a 0.4% ointment for the relief of pain due to chronic **anal fissure** (below). A measured amount equivalent to about 1.5 mg is applied intra-anally every 12 hours for up to 8 weeks.

Anal fissure. Nitrates such as glyceryl trinitrate are used for the treatment of chronic anal fissure (p.1891) because of their ability to relax the anal sphincter. Topical application of glyceryl trinitrate ointment in concentrations of 0.2 to 0.8% has relieved pain and aided healing of anal fissures both in uncontrolled[1-3] and controlled studies,[4,5] although only the effect on pain appears to be significant.[6] One study[5] found that a concentration of 0.6% had no additional benefit over 0.2%. Follow-up[5,7] of some of the patients indicated that after 6 to 38 months most had not had further problems or had had occasional recurrences (relapses of about one-quarter to one-third) which in the majority of cases had responded to further topical treatment. A small placebo-controlled study specifically in children, however, did not find topical glyceryl trinitrate to be of benefit in this patient population.[8]

There is evidence that application of a glyceryl trinitrate patch may be as effective as topical application of a 0.2% ointment.[9]

Encouraging results have also been obtained in an uncontrolled study using a 1% ointment of isosorbide dinitrate.[10]

Erectile dysfunction. Erectile dysfunction (p.2179) has been managed by the penile injection of drugs such as papaverine or alprostadil although oral treatment with drugs such as sildenafil is now available. Penile injections are not always acceptable to the patient and a number of studies have investigated topical therapies, mostly glyceryl trinitrate applied either as ointment or as a transdermal patch to the penis.[1-4] Such treatment can produce erections in some subjects, although response rates vary. However, patients must wear a condom to protect their partner against potential adverse effects resulting from the transfer of glyceryl trinitrate. The action of glyceryl trinitrate is believed to be due to smooth muscle relaxation and vasodilatation which are necessary prerequisites for penile erection.

Topical application of a cream containing isosorbide dinitrate, codergocrine mesilate, and aminophylline produced satisfactory erections in 21 of 36 men with erectile dysfunction due to various causes.[5] Eight out of 9 men with erectile dysfunction of psychogenic origin reported a satisfactory response. However, another study[6] was abandoned after the cream produced no effect in 10 consecutive patients. A further study in 14 patients who received a total of 77 applications of the cream reported no benefit over placebo.[7] Topical treatment with a cream containing isosorbide dinitrate, codergocrine mesilate, and testosterone has also been tried for erectile dysfunction; in a study in 42 men with low sexual interest and low or slightly depressed testosterone levels, 28 reported beneficial results.[8]

It should be noted that topical nitrates must not be employed in patients already using sildenafil (see Phosphodiesterase Type-5 Inhibitors, under Interactions, above).

Gallstones. Endoscopic removal of gallstones (p.2409) in a small series of 15 patients was facilitated by glyceryl trinitrate 1.2 to 3.6 mg applied as a spray to the tongue. Glyceryl trinitrate 1.2 mg was shown to relax the sphincter of Oddi to about 30% of its normal pressure.[1] The ability of glyceryl trinitrate to relax smooth muscle has also been used to relieve biliary colic (p.5) in 3 patients with gallstones;[2] in one of these patients standard managements for the pain such as oral opioids had been only moderately effective.

2. Hassel B. Treatment of biliary colic with nitroglycerin. *Lancet* 1993; **342:** 1305.

Migraine. Although use of glyceryl trinitrate may precipitate or exacerbate migraine (p.616) inhalation of glyceryl trinitrate at the onset of a migraine aura aborted attacks in a patient at risk of permanent neurological damage from migraine. Standard prophylactic therapy had previously been unsuccessful.[1]

1. Mitchell GK. Nitroglycerine by inhaler as treatment for migraine causing cerebral ischaemia. *Med J Aust* 1999; **171:** 336.

Myocardial infarction. Intravenous nitrates are widely used in acute myocardial infarction (p.1175), although evidence to support their use in patients undergoing reperfusion is limited. An overview of studies carried out before reperfusion (thrombolysis or percutaneous coronary intervention) became routine found that the use of intravenous nitrates (glyceryl trinitrate or sodium nitroprusside) within 24 hours of the onset of pain was associated with a reduction in mortality,[1] but whether they are of benefit in addition to reperfusion is less clear. However, empirical use of intravenous glyceryl trinitrate appears to be safe, and it should therefore be given where clinically indicated for ongoing ischaemic pain. In the GISSI-3 study,[2] glyceryl trinitrate was given by intravenous infusion during the first 24 hours, starting at 5 micrograms/minute and increasing by 5 to 20 micrograms/minute every 5 minutes for the first half hour until systolic blood pressure fell by at least 10% provided it remained above 90 mmHg; after 24 hours it was replaced by a transdermal patch providing 10 mg daily.

Long-term use of nitrates after myocardial infarction may be indicated in patients with myocardial ischaemia or poor left ventricular function, but there is no evidence to support their routine use. In the GISSI-3 study there was no significant benefit from the use of transdermal glyceryl trinitrate when assessed 6 weeks[2] and 6 months[3] post-infarction and in the ISIS-4 study[4] oral isosorbide mononitrate apparently had no effect on 35-day mortality.

Obstetrics and gynaecology. The smooth muscle relaxant properties of glyceryl trinitrate have been used in various obstetric or gynaecological situations although most reports are anecdotal or include small numbers of patients. The intravenous injection of glyceryl trinitrate 50 to 100 micrograms repeated to a total dose of 200 micrograms if necessary has produced sufficient uterine relaxation in postpartum women for the manual extraction of retained placentas.[1,2] Use as a sublingual spray has also successfully aided breech extraction in a set of twins.[3]

Glyceryl trinitrate has been given as a sublingual spray to relax the cervix before IUD insertion. In a series of over 100 patients one or two doses of 400 micrograms sublingually were usually adequate.[4]

Beneficial results have been reported in women with possible premature labour (p.2003) after application of glyceryl trinitrate patches to the abdomen.[5,6] In one study[7] this was as effective as ritodrine infusion, but another[8] found transdermal glyceryl trinitrate to be less effective than beta agonists. A study[9] comparing glyceryl trinitrate and magnesium sulfate, both given intravenously, found that glyceryl trinitrate was associated with a higher failure rate and a greater reduction in maternal blood pressure. A systematic review[10] concluded that there was insufficient evidence to support the routine use of glyceryl trinitrate.

Transdermal glyceryl trinitrate has been tried for controlling pain in severe and moderate-to-severe dysmenorrhoea[11,12] (p.6).

Glyceryl trinitrate has been given intravenously in the management of pre-eclampsia (see under Hypertension, p.1171) and is reported to reduce blood pressure without compromising uterine blood flow.[13]

Isosorbide mononitrate given vaginally has been found to produce cervical ripening[14] and although there is some evidence[15] that it is less effective, it may be an alternative to standard treatments such as prostaglandins (see Termination of Pregnancy p.2004). Isosorbide dinitrate has been used similarly after missed abortion.[16]

Oesophageal motility disorders. Achalasia is obstruction caused by failure of the lower oesophageal sphincter to relax and permit passage of food into the stomach. Nitrates such as isosorbide dinitrate have been reported to produce effective relaxation and to reduce symptoms when given sublingually. They have a role when mechanical dilatation of the sphincter or surgery are not feasible (see Oesophageal Motility Disorders, p.1702).

Nitrates may also be employed in oesophageal disorders such as variceal haemorrhage (see below).

Pain. Nitrates have been tried topically in the management of pain. Beneficial results have been reported with glyceryl trinitrate, applied as patches[1] or as a spray,[2] and isosorbide dinitrate spray,[3] in patients with painful diabetic neuropathy. Glyceryl trinitrate has also been used topically in musculoskeletal disorders[4] (see also Soft-tissue Rheumatism, below), and in surgical pain,[5] and intravenously as an adjunct to regional anaesthesia.[6]

Glyceryl trinitrate is also used topically to relieve pain in patients with anal fissure (above). For reference to its use in biliary colic, see Gallstones, above.

5. McCabe JE, *et al*. A randomized controlled trial of topical glyceryl trinitrate before transrectal ultrasonography-guided biopsy of the prostate. *BJU Int* 2007; **100:** 536–8.
6. Sen S, *et al*. The analgesic effect of nitroglycerin added to lidocaine on intravenous regional anesthesia. *Anesth Analg* 2006; **102:** 916–20.

Peripheral vascular disease. In peripheral vascular disease (p.1178) nitrates have been tried as vasodilators and smooth muscle relaxants in order to improve resting blood flow. Glyceryl trinitrate has been applied topically in patients with Raynaud's syndrome[1-3] and in distal limb ischaemia[4] resulting in some benefit but this form of therapy is not widely used in these disorders.

1. Franks AG. Topical glyceryl trinitrate as adjunctive treatment in Raynaud's disease. *Lancet* 1982; **i:** 76–7.
2. Coppock JS, *et al*. Objective relief of vasospasm by glyceryl trinitrate in secondary Raynaud's phenomenon. *Postgrad Med J* 1986; **62:** 15–18.

4. Fletcher S, *et al*. Locally applied transdermal nitrate patches for the treatment of ischaemic rest pain. *Int J Clin Pract* 1997; **51:** 324–5.

Pulmonary hypertension. Glyceryl trinitrate reduces total pulmonary resistance in most patients with pulmonary arterial hypertension (p.1179),[1,2] including when given by inhalation.[3] However, other vasodilators such as calcium-channel blockers, epoprostenol, or bosentan are generally preferred for long-term treatment.

1. Pearl RG, *et al*. Acute hemodynamic effects of nitroglycerin in pulmonary hypertension. *Ann Intern Med* 1983; **99:** 9–13.

3. Goyal P, *et al*. Efficacy of nitroglycerin inhalation in reducing pulmonary arterial hypertension in children with congenital heart disease. *Br J Anaesth* 2006; **97:** 208–14.

Quinine oculotoxicity. Intravenous nitrate has been suggested for the management of quinine oculotoxicity (p.613) and its benefit may be due to an increase in retinal vascular bed flow.[1]

1. Moore D, *et al*. Research into quinine ocular toxicity. *Br J Ophthalmol* 1992; **76:** 703.

Soft-tissue rheumatism. There is evidence from animal studies that nitric oxide plays an important role in tendon healing, and randomised studies in patients with tennis elbow (epicondylitis), Achilles tendinosis (tendinitis), and supraspinatus tendinosis showed enhanced subjective and objective recovery when a glyceryl trinitrate patch (releasing 1.25 mg over 24 hours) was applied over the area of tenderness once daily.[1] Glyceryl trinitrate has also been tried in musculoskeletal pain (see Pain, above). For the general management of soft-tissue rheumatism see p.13.

1. Murrell GAC. Using nitric oxide to treat tendinopathy. *Br J Sports Med* 2007; **41:** 227–31.

Variceal haemorrhage. The usual treatment in variceal haemorrhage (p.2346) is injection sclerotherapy or banding ligation which may be performed during the emergency endoscopy procedure. Where endoscopy is unavailable drug therapy may be used; it may also have a role when sclerotherapy fails and some have suggested that initial drug therapy may be preferable to sclerotherapy. Vasoconstrictors that are used include vasopressin and its analogue terlipressin, given with glyceryl trinitrate which counteracts the adverse cardiac effects of vasopressin while potentiating its beneficial effects on portal pressure; somatostatin is also used.

Prophylaxis of a first bleed in patients with portal hypertension is controversial since about 70% of patients who have varices will never bleed. It is postulated that a reduction in portal pressure to below 12 mmHg is necessary to reduce the incidence of variceal bleeding and that treatment with beta blockers alone does not achieve this. More effective drugs are being sought and isosorbide mononitrate (as adjunctive therapy with a beta blocker) is under investigation, both for prophylaxis of a first bleed[1,2] and in the prevention of rebleeding.[3] Early emergency treatment (before endoscopy) with terlipressin given intravenously and glyceryl trinitrate transdermally controlled bleeding and lowered mortality rates in patients with gastrointestinal bleeding and a history or clinical signs of cirrhosis.[4] However, use of oral isosorbide mononitrate with somatostatin infusion for acute variceal bleeding was less effective than somatostatin alone and induced more adverse effects.[5]

Venepuncture. Glyceryl trinitrate patches applied to skin adjacent to intravenous infusion sites are used in the prophylactic treatment of phlebitis and extravasation.[1]

Local application of glyceryl trinitrate 1 to 2 mg as ointment was found to be a useful aid to venepuncture in a study of 50 patients undergoing surgery,[2] but conflicting results have been reported in children and neonates.[3,4]

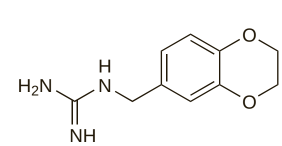
Guabenxan *(rINN)*

Guabenxán; Guabenxane; Guabenxanum. (1,4-Benzodioxan-6-ylmethyl)guanidine.

Гуабенксан

$C_{10}H_{13}N_3O_2$ = 207.2.

CAS — 19889-45-3.



Profile

Guabenxan is an antihypertensive with properties similar to guanethidine (below). It has been given orally as the sulfate.

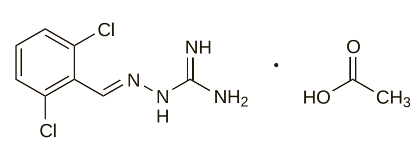
Guanabenz Acetate *(USAN, rINNM)*

Acetato de guanabenzo; Guanabenz, Acétate de; Guanabenzi Acetas; NSC-68982 (guanabenz); Wy-8678 (guanabenz). (2,6-Dichlorobenzylideneamino)guanidine acetate.

Гуанабенза Ацетат

$C_8H_8Cl_2N_4,C_2H_4O_2$ = 291.1.

CAS — 5051-62-7 (guanabenz); 23256-50-0 (guanabenz acetate).



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Guanabenz Acetate). A white or almost white powder with not more than a slight odour. Sparingly soluble in water and in 0.1N hydrochloric acid; soluble in alcohol and in propylene glycol. A 0.7% solution in water has a pH of 5.5 to 7.0. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Clonidine Hydrochloride, p.1247.

Overdosage. Overdosage with guanabenz has been reported.[1] The main symptoms were lethargy, drowsiness, bradycardia, and hypotension. A 45-year-old woman who had taken 200 to 240 mg of guanabenz with alcohol recovered after gastric lavage and intravenous fluids; a 3-year-old child who had taken 12 mg of guanabenz responded to atropine and dopamine. Naloxone had little effect in either patient.

1. Hall AH, *et al*. Guanabenz overdose. *Ann Intern Med* 1985; **102:** 787–8.

Interactions

As for Clonidine Hydrochloride, p.1248.

Pharmacokinetics

About 75% of an oral dose of guanabenz is absorbed and undergoes extensive first-pass metabolism. Peak plasma concentrations occur about 2 to 5 hours after a dose. It is about 90% bound to plasma proteins. Guanabenz is mainly excreted in urine, almost entirely as metabolites, with less than 1% as unchanged drug; about 10 to 30% is excreted in faeces. The average elimination half-life is reported to range from 4 to 14 hours.

Uses and Administration

Guanabenz is an alpha$_2$-adrenoceptor agonist with actions and uses similar to those of clonidine (p.1248). It is used in the management of hypertension (p.1171), either alone or with other antihypertensives, particularly thiazide diuretics.

Guanabenz is given orally as the acetate, but doses are usually expressed in terms of the base. Guanabenz acetate 5 mg is equivalent to about 4 mg of guanabenz.

In hypertension, the usual dose is 4 mg twice daily initially; the daily dose may be increased by amounts of 4 to 8 mg every 1 to 2 weeks according to response. Doses of up to 32 mg twice daily have been used.

Preparations

USP 31: Guanabenz Acetate Tablets.

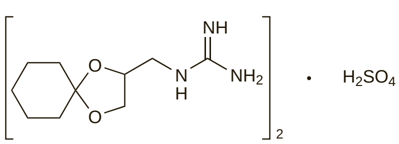
Proprietary Preparations (details are given in Part 3)
Braz.: Lisapres; ***USA:*** Wytensin.

Guanadrel Sulfate *(USAN, rINNM)*

CL-1388R; Guanadrel, Sulfate de; Guanadrel Sulphate; Guanadreli Sulfas; Sulfato de guanadrel; U-28288D. 1-(Cyclohexanespiro-2′-[1′,3′]dioxolan-4′-ylmethyl)guanidine sulfate; 1-(1,4-Dioxaspiro[4.5]dec-2-ylmethyl)guanidine sulfate.

Гуанадрела Сульфат

$(C_{10}H_{19}N_3O_2)_2,H_2SO_4 = 524.6.$
CAS — 40580-59-4 (guanadrel); 22195-34-2 (guanadrel sulfate).



Pharmacopoeias. In *US.*

USP 31 (Guanadrel Sulfate). A white to off-white crystalline powder. Soluble in water; slightly soluble in alcohol and in acetone; sparingly soluble in methyl alcohol.

Adverse Effects, Treatment, and Precautions

As for Guanethidine Monosulfate, below. Guanadrel has been reported to cause less diarrhoea, and less orthostatic hypotension on rising in the morning, than guanethidine, but orthostatic symptoms seem to occur with a similar frequency to guanethidine during the day.

Interactions

As for Guanethidine Monosulfate, below.

Pharmacokinetics

Guanadrel is rapidly and almost completely absorbed from the gastrointestinal tract, with a bioavailability of about 85%. It is widely distributed throughout the body and about 20% is bound to plasma proteins. It is reported not to cross the blood-brain barrier. Plasma concentrations decline in a biphasic manner: the half-life varies widely between individuals, in the initial phase from 1 to 4 hours, and in the terminal phase from 5 to 45 hours, with a mean of about 10 hours. Guanadrel is metabolised in the liver and about 85% is excreted in the urine over 24 hours as the unchanged drug and its metabolites. About 40 to 50% of the drug is excreted unchanged.

Uses and Administration

Guanadrel is an antihypertensive with actions and uses similar to those of guanethidine (below). After oral administration, guanadrel acts within 2 hours with the maximum effect after 4 to 6 hours. The hypotensive effect is reported to last for 4 to 14 hours following a single dose. It has been given orally as the sulfate in the management of hypertension, although it has largely been superseded by other drugs less likely to cause orthostatic hypotension.

Preparations

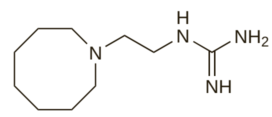
USP 31: Guanadrel Sulfate Tablets.

Guanethidine Monosulfate *(USAN, rINNM)*

Guanéthidine, monosulfate de; Guanethidine Monosulphate *(BANM)*; Guanethidini Monosufas; Guanethidini monosulfas; Guanethidini Sulfas; Guanethidin-monosulfát; Guanetidiinimonosulfaatti; Guanetidinmonosulfat; Guanetidin-monoszulfát; Guanetidino monosulfatas; Monosulfato de guanetidina; NSC-29863 (guanethidine hemisulfate); Su-5864 (guanethidine hemisulfate). 1-[2-(Perhydroazocin-1-yl)ethyl]guanidine monosulfate.

Гуанетидина Моносульфат

$C_{10}H_{22}N_4,H_2SO_4 = 296.4.$
CAS — 55-65-2 (guanethidine); 60-02-6 (guanethidine hemisulfate); 645-43-2 (guanethidine monosulfate).
ATC — C02CC02; S01EX01.
ATC Vet — QC02CC02; QS01EX01.



(guanethidine)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*
Chin. includes the hemisulfate.

Ph. Eur. 6.2 (Guanethidine Monosulphate). A colourless crystalline powder. Freely soluble in water; practically insoluble in alcohol. A 2% solution in water has a pH of 4.7 to 5.5. Protect from light.

USP 31 (Guanethidine Monosulfate). A white to off-white crystalline powder. Very soluble in water; sparingly soluble in alcohol; practically insoluble in chloroform. A 2% solution in water has a pH of 4.7 to 5.7.

Adverse Effects

The commonest adverse effects of guanethidine are severe postural and exertional hypotension and diarrhoea which may be particularly troublesome during the initial stages of therapy and during dose adjustment. Dizziness, syncope, muscle weakness, and lassitude are liable to occur, especially on rising from sitting or lying. Orthostatic hypotension may be severe enough to provoke angina, renal impairment, and transient cerebral ischaemia. Other frequent adverse effects are bradycardia, failure of ejaculation, fatigue, headache, and salt and water retention and oedema, which may be accompanied by breathlessness and may occasionally precipitate overt heart failure.

Nausea, vomiting, dry mouth, nasal congestion, parotid tenderness, blurring of vision, depression, myalgia, muscle tremor, paraesthesias, hair loss, dermatitis, disturbed micturition, priapism, aggravation or precipitation of asthma, and exacerbation of peptic ulcer disease have also been reported. Guanethidine may possibly cause anaemia, leucopenia, and thrombocytopenia.

When guanethidine is used as eye drops, common adverse effects are conjunctival hyperaemia and miosis. Burning sensations and ptosis have also occurred. Superficial punctate keratitis has been reported particularly after prolonged use of high doses.

Treatment of Adverse Effects

Withdrawal of guanethidine or dose reduction reverses many adverse effects. Diarrhoea may also be controlled by giving codeine phosphate or antimuscarinics. If overdosage occurs the benefit of gastric decontamination is uncertain, but activated charcoal may be given if the patient presents within 1 hour. Hypotension may respond to placing the patient in the supine position with the feet raised. If hypotension is severe it may be necessary to give intravenous fluid replacement and small doses of vasopressors may be given cautiously. The patient must be monitored for several days.

Precautions

Guanethidine should not be given to patients with phaeochromocytoma, as it may cause a hypertensive crisis, or to patients with heart failure not caused by hypertension.

It should be used with caution in patients with renal impairment, cerebrovascular disorders, or ischaemic heart disease, or with a history of peptic ulcer disease or asthma. Exercise and heat may increase the hypotensive effect of guanethidine, and dosage requirements may be reduced in patients who develop fever.

There may be an increased risk of cardiovascular collapse or cardiac arrest in patients undergoing surgery while taking guanethidine, but authorities have differed as to whether the drug should be stopped before elective surgery. Former US licensed product information recommended stopping up to 2 or 3 weeks beforehand. In patients undergoing emergency procedures or where treatment has not been interrupted large doses of atropine should be given before induction of anaesthesia.

Patients undergoing treatment with eye drops containing guanethidine should be examined regularly for signs of conjunctival damage.

Interactions

Patients taking guanethidine may show increased sensitivity to the action of adrenaline, amfetamine, and other sympathomimetics, resulting in exaggerated pressor effects. The hypotensive effects may also be antagonised by tricyclic antidepressants, MAOIs, and phenothiazine derivatives and related antipsychotics (although phenothiazines may also exacerbate orthostatic hypotension, which may be more relevant clinically). In the UK licensed product information suggests that MAOIs should be stopped at least 14 days before beginning guanethidine, although in the USA a minimum of a week has been recommended as adequate. It has been reported that oral contraceptives may reduce the hypotensive action of guanethidine. Use of digoxin or other digitalis derivatives with guanethidine may cause excessive bradycardia.

The hypotensive effects of guanethidine may be enhanced by thiazide diuretics, other antihypertensives, and levodopa. Alcohol may cause orthostatic hypotension in patients taking guanethidine.

Pharmacokinetics

Guanethidine is variably and incompletely absorbed from the gastrointestinal tract with less than 50% of the dose reaching the systemic circulation. It is actively taken up into adrenergic neurones by the mechanism responsible for noradrenaline reuptake. A plasma concentration of 8 nanograms/mL is reported to be necessary for adrenergic blockade, but the dose required to achieve this varies between individuals due to differences in absorption and metabolism. Guanethidine is partially metabolised in the liver, and is excreted in the urine as metabolites and unchanged guanethidine. It has a terminal half-life of about 5 days. Guanethidine does not penetrate the blood-brain barrier significantly.

Uses and Administration

Guanethidine is an antihypertensive that acts by selectively inhibiting transmission in postganglionic adrenergic nerves. It is believed to act mainly by preventing the release of noradrenaline at nerve endings. Guanethidine causes the depletion of noradrenaline stores in peripheral sympathetic nerve terminals but does not prevent the secretion of catecholamines by the adrenal medulla.

When given orally its maximal effects may take 1 to 3 weeks to appear on continued dosing and persist for 1 to 3 weeks after treatment has been stopped. It causes an initial reduction in cardiac output but its main hypotensive effect is to cause peripheral vasodilatation; it reduces the vasoconstriction which normally results from standing up and which is the result of reflex sympathetic nervous activity. In the majority of patients it reduces standing blood pressure but has a lesser effect on supine blood pressure. When applied topically to the eye guanethidine reduces the production of aqueous humour.

Guanethidine is used in the management of hypertension (p.1171). Eye drops of guanethidine have been used for open-angle glaucoma (p.1873) and for lid retraction associated with hyperthyroidism. Guanethidine has also been used in the management of neuropathic pain syndromes (see below).

Guanethidine is used in the treatment of hypertension when other drugs have proved inadequate, but it has largely been superseded by other drugs less likely to cause orthostatic hypotension. Tolerance to guanethidine has occurred in some patients; this may be countered by concomitant diuretic therapy.

In **hypertension**, the usual initial oral dose of guanethidine monosulfate has been 10 mg daily. This is increased by increments of 10 to 12.5 mg, not more often than every 5 to 7 days, according to response. The usual maintenance dose has been 25 to 50 mg once daily.

Children have been given 200 micrograms/kg daily with increments of 200 micrograms/kg every 7 to 10 days until a satisfactory response is achieved.

Guanethidine monosulfate has been given intramuscularly in the treatment of hypertensive crises, including severe pre-eclampsia, but more suitable drugs are available. An intramuscular dose of 10 to 20 mg is reported to produce a fall in blood pressure within 30 minutes.

Eye drops containing guanethidine monosulfate have been used in the treatment of open-angle **glaucoma** (usually combined with adrenaline), and for the lid retraction that may accompany hyperthyroidism.

Pain syndromes. Sympathetic nerve blocks may be used in the management of acute or chronic pain associated with a well-defined anatomical site. Guanethidine is one of a number of drugs that have been used for intravenous regional sympathetic block in the management of neuropathic pain (see Complex Regional Pain Syndrome, p.6), to reduce pain and to maintain blood flow.

However, reviews and studies[1,2] in patients with reflex sympathetic dystrophy failed to find any benefit from guanethidine.

1. Jadad AR, *et al.* Intravenous regional sympathetic blockade for pain relief in reflex sympathetic dystrophy: a systematic review and a randomized, double-blind crossover study. *J Pain Symptom Manage* 1995; **10:** 13–20.

Pharmacopoeias. In *US.*

USP 31 (Guanfacine Hydrochloride). Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Clonidine Hydrochloride, p.1247. Rebound hypertension may occur but is delayed due to the longer half-life.

◊ Reviews.

1. Jerie P. Clinical experience with guanfacine in long-term treatment of hypertension, part II: adverse reactions to guanfacine. *Br J Clin Pharmacol* 1980; **10** (suppl 1): 157S–164S.
2. Board AW, *et al.* A postmarketing evaluation of guanfacine hydrochloride in mild to moderate hypertension. *Clin Ther* 1988; **10:** 761–75.

Withdrawal. Rapid reduction of the guanfacine dosage resulted in rebound hypertension leading to generalised seizures and coma in a 47-year-old patient with renal failure who was receiving haemodialysis.[1] Use with phenobarbital may have enhanced the metabolism of guanfacine and contributed to the development of the withdrawal effect.

1. Kiechel JR, *et al.* Pharmacokinetic aspects of guanfacine withdrawal syndrome in a hypertensive patient with chronic renal failure. *Eur J Clin Pharmacol* 1983; **25:** 463–6.

Interactions

As for Clonidine Hydrochloride, p.1248.

Pharmacokinetics

Guanfacine is rapidly absorbed after oral doses and peak plasma concentrations occur 1 to 4 hours after ingestion. The oral bioavailability is reported to be about 80%. It is about 70% bound to plasma proteins. It is excreted in urine as unchanged drug and metabolites; about 50% of a dose is reported to be eliminated unchanged. The normal elimination half-life ranges from 10 to 30 hours, tending towards the upper range in older patients.

Renal impairment. A study[1] in patients with normal or impaired renal function found that guanfacine clearance and serum concentrations were not significantly different in the 2 groups, suggesting that non-renal elimination plays an important role in patients with renal impairment.

1. Kirch W, *et al.* Elimination of guanfacine in patients with normal and impaired renal function. *Br J Clin Pharmacol* 1980; **10** (suppl 1): 33S–35S.

Uses and Administration

Guanfacine is a centrally acting alpha$_2$-adrenoceptor agonist with actions and uses similar to those of clonidine (p.1248). It is used in the management of hypertension (p.1171), although other drugs are usually preferred. It may be used alone or with other antihypertensives, particularly thiazide diuretics. It has also been tried in the management of opioid withdrawal and in hyperactivity disorders.

Guanfacine is given orally as the hydrochloride, but doses are usually expressed in terms of the base. Guanfacine hydrochloride 1.15 mg is equivalent to about 1 mg of guanfacine. In hypertension the usual initial dose is 1 mg daily increasing after 3 to 4 weeks to 2 mg daily if necessary.

◊ Reviews.

1. Cornish LA. Guanfacine hydrochloride: a centrally acting antihypertensive agent. *Clin Pharm* 1988; **7:** 187–97.

Tourette's syndrome. Guanfacine may be used as an alternative to clonidine in the management of patients with mild to moderate symptoms of Tourette's syndrome (see Tics, p.954). First-line use of these drugs is increasingly favoured in such patients because of a relative lack of serious adverse effects when compared with the commonly used antipsychotics.

Preparations

USP 31: Guanfacine Tablets.

Proprietary Preparations (details are given in Part 3)
Belg.: Estulic; ***Cz.:*** Estulic†; ***Fr.:*** Estulic; ***Hung.:*** Estulic; ***Jpn:*** Estulic†; ***Neth.:*** Estulic†; ***Rus.:*** Estulic (Эстулик); ***USA:*** Tenex.

Heparin *(BAN)*

Hepariini; Heparina; Heparinum; Heparyna.

CAS — 9005-49-6.

ATC — B01AB01; C05BA03; S01XA14.

ATC Vet — QB01AB01; QC05BA03; QS01XA14.

Description. Heparin is an anionic polysaccharide of mammalian origin with irregular sequence. It consists principally of alternating iduronate and glucosamine residues, most of which are sulfated. It may be described as a sulfated glucosaminoglycan. Heparin has the characteristic property of delaying the clotting of freshly shed blood. It may be prepared from the lungs of oxen or the intestinal mucosa of oxen, pigs, or sheep.
Heparin is often described in the literature as standard heparin or unfractionated heparin to distinguish it from low-molecular-weight heparins.

Heparin Calcium *(BANM)*

Calcium Heparin; Hepariinikalsium; Heparin Kalsiyum; Heparin Sodyum; Heparin vápenatá sůl; Heparina cálcica; Héparine calcique; Heparinkalcium; Heparino kalcio druska; Heparinum calcicum; Heparyna wapniowa.

CAS — 37270-89-6.

ATC — B01AB01; C05BA03; S01XA14.

ATC Vet — QB01AB01; QC05BA03; QS01XA14.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Heparin Calcium). The potency of heparin calcium intended for parenteral use is not less than 150 international units per mg and the potency of heparin calcium not intended for parenteral use is not less than 120 international units per mg, both calculated with reference to the dried substance. A white or almost white, hygroscopic powder. Freely soluble in water. A 1% solution in water has a pH of 5.5 to 8.0. Store in airtight containers.

USP 31 (Heparin Calcium). The calcium salt of heparin with a potency, calculated on the dried basis, of not less than 140 USP units in each mg. USP heparin units are not equivalent to international units. The source of the material is usually the intestinal mucosa or other suitable tissues of domestic mammals used for food by man and should be stated on the label. A 1% solution in water has a pH of 5.0 to 7.5. Store in airtight containers at temperatures below 40°, preferably between 15 and 30°.

Incompatibility. See Heparin Sodium, below.

Heparin Sodium *(BANM, rINN)*

Hepariininatrium; Heparin sodná sůl; Heparina sódica; Héparine sodique; Heparinnatrium; Heparino natrio druska; Heparinum natricum; Heparyna sodowa; Sodium Heparin; Soluble Heparin.

Гепарин Натрий

CAS — 9041-08-1.

ATC — B01AB01; C05BA03; S01XA14.

ATC Vet — QB01AB01; QC05BA03; QS01XA14.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Heparin Sodium). The potency of heparin sodium intended for parenteral use is not less than 150 international units per mg and the potency of heparin sodium not intended for parenteral use is not less than 120 international units per mg, both calculated with reference to the dried substance. A white or almost white, hygroscopic powder. Freely soluble in water. A 1% solution in water has a pH of 5.5 to 8.0. Store in airtight containers.

USP 31 (Heparin Sodium). The sodium salt of heparin with a potency, calculated on the dried basis, of not less than 140 USP units in each mg. USP heparin units are not equivalent to international units. The source of the material is usually the intestinal mucosa or other suitable tissues of domestic mammals used for food by man and should be stated on the label. A white or pale-coloured amorphous, odourless or almost odourless, hygroscopic powder. Soluble 1 in 20 of water. A 1% solution in water has a pH of 5.0 to 7.5. Store in airtight containers at temperatures below 40°, preferably between 15 and 30°.

Incompatibility. Incompatibility has been reported between heparin calcium or sodium and alteplase, amikacin sulfate, amiodarone hydrochloride, ampicillin sodium, aprotinin, benzylpenicillin potassium or sodium, cefalotin sodium, ciprofloxacin lactate, cytarabine, dacarbazine, daunorubicin hydrochloride, diazepam, dobutamine hydrochloride, doxorubicin hydrochloride, droperidol, erythromycin lactobionate, gentamicin sulfate, haloperidol lactate, hyaluronidase, hydrocortisone sodium succinate, kanamycin sulfate, meticillin sodium, netilmicin sulfate, some opioid analgesics, oxytetracycline hydrochloride, some phenothiazines, polymyxin B sulfate, streptomycin sulfate, tetracycline hydrochloride, tobramycin sulfate, vancomycin hydrochloride, and vinblastine sulfate. Heparin sodium has also been reported to be incompatible with cisatracurium besilate,[1] labetalol hydrochloride,[2] levofloxacin,[3] nicardipine hydrochloride,[4] reteplase,[5] and vinorelbine tartrate.[6] Although visually compatible,[7] cefmetazole sodium is reported to inactivate heparin sodium.

Glucose can have variable effects,[8,9] but glucose-containing solutions are generally considered suitable diluents for heparin. Incompatibility has also been reported between heparin and fat emulsion.

Units

The fifth International Standard for unfractionated heparin was established in 1998. The USP 31 states that USP and international units are not equivalent, although doses expressed in either appear to be essentially the same.

Adverse Effects

Heparin can give rise to haemorrhage as a consequence of its action. It can also cause thrombocytopenia, either through a direct effect or through an immune effect producing a platelet-aggregating antibody. Consequent platelet aggregation and thrombosis may therefore exacerbate the condition being treated. The incidence of thrombocytopenia is reported to be greater with bovine than porcine heparin.

Hypersensitivity reactions may occur, as may local irritant effects, and skin necrosis. Alopecia and osteoporosis resulting in spontaneous fractures have occurred after prolonged use of heparin.

Effects on the adrenal glands. Heparin inhibits the secretion of aldosterone and so may cause hyperkalaemia.[1] Although all patients treated with heparin may develop reduced aldosterone concentrations, most are able to compensate through the renin-angiotensin system. Patients on prolonged heparin therapy or those unable to compensate, such as patients with diabetes mellitus or renal impairment or those also receiving potassium-sparing drugs such as ACE inhibitors, may present with symptoms of hyperkalaemia. The UK CSM suggests[2] that plasma-potassium concentration should be monitored in all patients with risk factors, particularly those receiving heparin for more than 7 days. The hyperkalaemia is usually transient or resolves when heparin is stopped and treatment is not generally required; fludrocortisone was successfully used to treat resistant hyperkalaemia in a patient in whom continued heparin therapy was necessary.[3]

Adrenal insufficiency secondary to adrenal haemorrhage has also been associated with heparin; heparin-induced thrombocytopenia may be implicated.[4]

Effects on the blood. *Haemorrhage* is a recognised risk with heparin.[1] The risk of major bleeding may be lower with continuous intravenous infusion than with intermittent intravenous injection; risk may increase with heparin dose and patient age.[2]

Heparin has been associated with the development of *thrombocytopenia*. The reported incidence has varied greatly; up to 6% appears to be a reasonable estimate[3,4] although up to 10% has also been quoted.[5] Thrombocytopenia induced by heparin may be of two types. The first is an acute, but usually mild, fall in platelet count occurring within 1 to 4 days of starting therapy and which often resolves without stopping treatment. A direct effect of heparin on platelet aggregation appears to be responsible. The second type of thrombocytopenia, which has an immunological basis, is more serious. It usually occurs after 5 to 11 days although its onset may be more rapid in patients previously exposed to heparin;[6] delayed presentation up to 40 days after stopping heparin has also been reported.[7-9] It is often associated with thromboembolic complications due to platelet-rich thrombi (the 'white clot syndrome') or, more rarely, bleeding. Of 34 cases of heparin-associated thrombocytopenia reported to the UK CSM from 1964 to 1989, bleeding or thromboembolic complications occurred in 11 patients, 7 of whom died.[3] This type of thrombocytopenia appears to occur more often with bovine heparin than with heparin from other species,[10] and least frequently with low-molecular-weight-heparins;[11] the mechanism appears to be development of antibodies to a complex formed between heparin and platelet factor-4 (found on platelets and endothelial cells), which then cause platelet activation and thrombin generation.[12] Patients with lupus anticoagulant may also be more susceptible.[13] The reaction is independent of dose or route of administration; there have been reports of thrombocytopenia after use of heparin flushes[14] or heparin-coated catheters.[15]

Monitoring of platelet counts is therefore advised in patients given heparin. A baseline platelet count should be obtained in all patients. This should be repeated at least every 2 to 3 days in those given therapeutic doses of unfractionated heparin;[11] monitoring on alternate days from days 4 to 14 is recommended when unfractionated heparin is used for prophylaxis.[11,16] For low-molecular-weight heparins the risk may be lower but monitoring is recommended in most patients; platelet counts should be checked every 2 to 4 days from days 4 to 14.[16] Patients exposed to heparin within the previous 100 days may be sensitised to it and after re-exposure should have a platelet count within 24 hours.[11,16]

The **management** of heparin-induced thrombocytopenia has been reviewed.[11,12,16-19] Heparin should be stopped immediately in those who develop thrombocytopenia. It should be noted, however, that thrombosis has occurred in patients whose reduction in platelet count was relatively mild and who may not be considered to be thrombocytopenic.[20-23] On withdrawal of heparin, a heparinoid such as danaparoid[16,24,25] may be tried, provided that an *in-vitro* platelet aggregation test shows that there is no cross-reactivity with heparin. Alternatively, the direct thrombin inhibitors lepirudin[16,25,26] or argatroban[25,27] may be used; bivalirudin[11,12,19] or fondaparinux[11,28] are further options. Similar recommendations have been made for children.[29] Low-molecular-weight heparins have been used; they are associated with a lower incidence of induced thrombocytopenia than unfractionated heparin[30] but the rate of cross-reactivity is high and they are not generally recommended.[16,25,27] Oral anticoagulants have also been used, but an increased risk of venous limb gangrene has been reported[31] with warfarin and it should not be given until the platelet count has recovered.[11,16] Dermatan sulfate[32] has also been used. Thrombocytopenia has been managed with aspirin and dipyridamole or with normal immunoglobulin.[33] A fibrinolytic such as urokinase has been used in a few cases of occlusive thrombosis.[34,35]

There may be a relationship between heparin-induced thrombocytopenia and skin necrosis (see below).

There have been reports[36] of spinal haematomas developing spontaneously after the use of low-molecular-weight heparins.

Effects on the bones. Osteoporosis is a rare complication of long-term heparin therapy. Treatment and prophylaxis of thromboembolism in pregnancy is one of the few indications for long term use of heparin, so most reports and studies of heparin-induced osteoporosis have been in pregnant women.[1] The incidence of symptomatic osteoporosis in patients given heparin long term has been estimated to be about 2%.[1,2] Subclinical reduction in bone density occurs in up to one-third of patients,[2] but it is not possible to predict which of these patients will develop osteoporotic fractures. Pregnancy normally causes reversible bone demineralisation, so the combination of pregnancy and heparin therapy may therefore result in symptomatic osteoporosis in susceptible individuals.[1,3] Bone changes may be reversible.[1] Although some evidence suggests that bone demineralisation is dose- and duration-dependent, this has not been conclusively established.[1,3] Use of low-molecular-weight heparins is associated with a lower risk of heparin-induced osteoporosis.[2]

Effects on electrolyte balance. See Effects on the Adrenal Glands, above.

Effects on lipid metabolism. Use of heparin leads to the release of lipoprotein lipase into the plasma. Postprandial lipidaemia is reduced due to increased hydrolysis of triglycerides into free fatty acids and glycerol. Raised concentrations of free fatty acids have been reported after heparin use but the magnitude of this effect may have been overestimated.[1] Rebound hyperlipidaemia may occur when heparin is withdrawn. With long-term use reserves of lipoprotein lipase may be depleted; severe hypertriglyceridaemia reported in a pregnant woman was attributed to long-term heparin prophylaxis that was thought to have resulted in lipoprotein lipase deficiency.[2]

2. Watts GF, *et al.* Lipoprotein lipase deficiency due to long-term heparinization presenting as severe hypertriglyceridaemia in pregnancy. *Postgrad Med J* 1991; **67:** 1062–4.

Effects on the liver. Increases in transaminase values, usually reversible on discontinuing therapy, have been reported in patients given therapeutic[1-3] or prophylactic[3] doses of heparin. A prospective study[4] found increased transaminases that were assessed as probably due to heparin in 8 of 54 patients; the reaction seemed to occur more frequently with therapeutic doses. Increased transaminases have also been reported[5] in 2 patients receiving low-molecular-weight-heparins.

5. Hui C-K, *et al.* Low molecular weight heparin-induced liver toxicity. *J Clin Pharmacol* 2001; **41:** 691–4.

Effects on sexual function. There have been several reports of priapism associated with the use of heparin. The prognosis is poor, impotence following more often than in priapism of other aetiologies. The mechanism of heparin-induced priapism is unclear.[1]

1. Baños JE, *et al.* Drug-induced priapism: its aetiology, incidence and treatment. *Med Toxicol* 1989; **4:** 46–58.

Effects on the skin. Skin necrosis is a rare complication of heparin use.[1,2] It may be a localised reaction at the site of subcutaneous injection or possibly be related to heparin-induced thrombocytopenia (see Effects on the Blood, above). An immune mechanism may be responsible.

Eczematous plaque reactions have developed several days after starting subcutaneous heparin. A type IV hypersensitivity reaction has been implicated.[3] Low-molecular-weight heparins may be an alternative but cross-reactivity can occur.[4]

Recurrent fixed eczematous lesions have been attributed to heparin used intravenously during haemodialysis.[5]

5. Mohammed KN. Symmetric fixed eruption to heparin. *Dermatology* 1995; **190:** 91.

Hypersensitivity. An increased incidence of severe hypersensitivity reactions, including fatalities, was reported with some heparin preparations in early 2008;[1] it was suggested that the presence of an over-sulfated chondroitin sulfate contaminant may have been responsible.[1,2]

See Effects on the Blood and Effects on the Skin, above, for further hypersensitivity reactions associated with heparin.

2. Kishimoto TK, *et al.* Contaminated heparin associated with adverse clinical events and activation of the contact system. *N Engl J Med* 2008; **358:** 2457–67.

Treatment of Adverse Effects

Slight haemorrhage due to overdosage can usually be treated by stopping heparin. Severe bleeding may be reduced by the slow intravenous injection of protamine sulfate (p.1461). The dose is dependent on the amount of heparin to be neutralised and ideally should be titrated against assessments of the coagulability of the patient's blood. As heparin is being continuously excreted, the dose of protamine should be reduced if it is more than 15 minutes since the last dose of heparin; for example, if protamine sulfate is given 30 minutes after heparin the dose may be reduced to about one-half. Not more than 50 mg of protamine sulfate should be injected for any one dose; patients should be carefully monitored as further doses may be required. The Ph. Eur. 6.2 specifies that 1 mg of protamine sulfate precipitates not less than 100 international units of heparin, but adds that this potency is based on a specific reference batch of heparin sodium. UK licensed product information has stated that each mg of protamine sulfate will usually neutralise the anticoagulant effect of at least 80 international units of heparin (lung) or at least 100 international units of heparin (mucous), and US information that each mg of protamine sulfate neutralises approximately 90 USP units of heparin (lung) or about 115 USP units of heparin (mucous).

Thrombocytopenia. For reference to the treatment of heparin-induced thrombocytopenia and associated thromboembolic complications, see Effects on the Blood under Adverse Effects, above.

Precautions

Heparin should not be given to patients who are haemorrhaging. In general it should not be given to patients at serious risk of haemorrhage, although it has been used with very careful control; patients at risk include those with haemorrhagic blood disorders, thrombocytopenia, peptic ulcer disease, cerebrovascular disorders, bacterial endocarditis, severe hypertension, oesophageal varices, or patients who have recently undergone surgery at sites where haemorrhage would be an especial risk. Caution is required in hepatic and renal impairment; severe hepatic or renal impairment may be a contra-indication. Heparin should not be given by intramuscular injection. Since heparin has caused thrombocytopenia with severe thromboembolic complications, platelet counts should be monitored in all patients (see Effects on the Blood, under Adverse Effects, above). Heparin should be stopped if thrombocytopenia develops. A test dose has been recommended for patients with a history of allergy.

Dosage of heparin may need to be reduced in the elderly; elderly women appear to be especially susceptible to haemorrhage after use of heparin.

Catheters and cannulas. Serum concentrations of sodium and potassium could be falsely elevated in samples obtained through heparin-bonded umbilical catheters due to release of benzalkonium chloride used in the manufacturing process of some catheters.[1] It was unknown if the amount released would be toxic to small premature neonates.

1. Gaylord MS, *et al.* Release of benzalkonium chloride from a heparin-bonded umbilical catheter with resultant factitious hypernatremia and hyperkalemia. *Pediatrics* 1991; **87:** 631–5.

Hyperkalaemia. For recommendations concerning the monitoring of patients susceptible to developing hyperkalaemia, such as those with diabetes mellitus or renal impairment, see Effects on the Adrenal Glands under Adverse Effects, above.

Pregnancy. Heparin does not cross the placenta, and therefore adverse effects on the fetus would not be expected.[1,2] A review[1] of the literature, however, indicated 2 spontaneous abortions and 17 still-births in 135 pregnancies exposed to heparin; 29 infants were premature, 10 of whom died. Another literature review[2] found adverse outcomes in 21.7% of heparin-treated patients, but this dropped to 10.4% when pregnancies with co-morbid conditions were excluded. A further drop to 3.6% was observed when cases of prematurity with normal outcome were also excluded. The death rate of 2.5% and prematurity rate of 6.8% in heparin-treated patients was similar to that found in the normal population. It was concluded that heparin appears safer for the fetus than warfarin when used during pregnancy. Similar results have also been reported with low-molecular-weight heparins; a systematic review[3] found an adverse outcome in 9.3% of 486 pregnancies in which low-molecular-weight heparin was used, but this dropped to 3.1% in women without comorbid conditions.

For further details on the use of heparin and low-molecular-weight heparins in pregnancy, see under Uses and Administration, below.

3. Sanson B-J, *et al.* Safety of low-molecular-weight heparin in pregnancy: a systematic review. *Thromb Haemost* 1999; **81:** 668–72.

Preservative. The preservatives used in heparin preparations have been implicated in unwanted effects. Benzyl alcohol in heparinised flushing solutions has been suspected of causing toxicity in neonates (see p.1631). Chlorobutanol present in another heparin preparation caused a sharp fall in blood pressure (see Effects on the Cardiovascular System under Chlorobutanol, p.1639).

Spinal anaesthesia. Spinal and epidural haematomas, sometimes leading to paralysis, have occurred after spinal or epidural anaesthesia or analgesia in patients given heparin or low-molecular-weight heparins. The risk of haematoma appears to be higher in patients with indwelling epidural catheters or in those also given other drugs that affect haemostasis.[1] It is generally recommended that central nerve block should be avoided in patients on full-dose anticoagulation.[2] However, the use of prophylactic doses of anticoagulants with central nervous blockade is less clear.[2,3] The reported risk of haematoma with low-molecular-weight heparins has been higher in the USA where higher doses have been used for prophylaxis.[3] Recommendations to reduce the risk of spinal haematoma include waiting until after blockade has been completed to give prophylactic heparin or low-molecular-weight heparin. Where anticoagulant prophylaxis has already been given, blockade should be delayed if possible until 4 to 6 hours after heparin, and the catheter should not be removed until 4 hours after heparin.[2] It is recommended that low-molecular-weight heparin should not be given within 8 to 10 hours before or after central nerve block or catheter removal.[2,3]

There have also been cases of spontaneous spinal haematomas (unrelated to trauma, surgery, or lumbar puncture) occurring after use of low-molecular-weight heparins (see Effects on the Blood, above).

3. Dolenska S. Neuroaxial blocks and LMWH thromboprophylaxis. *Hosp Med* 1998; **59:** 940–3.

Interactions

Heparin should be used with care with oral anticoagulants or drugs, such as aspirin and dipyridamole, that affect platelet function. NSAIDs may also increase the risk of haemorrhage. Other drugs that affect the coagulation process and which may therefore increase the risk of haemorrhage include dextrans, thrombolytic enzymes such as streptokinase, high doses of penicillins and some cephalosporins, some contrast media, asparaginase, and epoprostenol; for use of heparin with drotrecogin alfa (activated) see p.1078. Estimations of oral anticoagulant control may be modified by heparin's action on prothrombin.

ACE inhibitors. For reference to hyperkalaemia in patients on heparin and ACE inhibitors, see Effects on the Adrenal Glands under Adverse Effects, above.

Alcohol. Heavy drinkers were found to be at greater risk of major heparin-associated bleeding than moderate drinkers or non-drinkers.[1]

1. Walker AM, Jick H. Predictors of bleeding during heparin therapy. *JAMA* 1980; **244:** 1209–12.

Aprotinin. For comment on the use of heparin with aprotinin, see Effects on Coagulation Tests under Aprotinin, p.1055.

Glyceryl trinitrate. Glyceryl trinitrate has been reported to reduce the activity of heparin when both drugs are given simultaneously by the intravenous route.[1] This effect has been seen even with low doses of glyceryl trinitrate.[2] Propylene glycol present in the glyceryl trinitrate formulation may[3] or may not[1] contribute to the effect. No interaction was reported when glyceryl trinitrate was given immediately after heparin.[4]

4. Bode V, *et al.* Absence of drug interaction between heparin and nitroglycerin. *Arch Intern Med* 1990; **150:** 2117–19.

Tobacco. Reduced half-life and increased elimination of heparin have been reported in smokers compared with non-smokers.[1]

1. Cipolle RJ, *et al.* Heparin kinetics: variables related to disposition and dosage. *Clin Pharmacol Ther* 1981; **29:** 387–93.

Pharmacokinetics

Heparin is not absorbed from the gastrointestinal tract. After intravenous or subcutaneous injection heparin is extensively bound to plasma proteins. It does not cross the placenta and it is not distributed into breast milk. The half-life of heparin depends on its dose and route as well as the method of calculation and is subject to wide inter- and intra-individual variation; a range of 1 to 6 hours with an average of 1.5 hours has been cited. It may be slightly prolonged in renal impairment, decreased in patients with pulmonary embolism, and either increased or decreased in patients with liver disorders. Heparin is taken up by the reticuloendothelial system. It is excreted in the urine, mainly as metabolites, although after large doses up to 50% may be excreted unchanged.

Uses and Administration

Heparin is an anticoagulant used principally in the treatment and prophylaxis of thromboembolic disorders (p.1187). It is often described as standard heparin or unfractionated heparin to distinguish it from low-molecular-weight heparins (p.1329).

Heparin inhibits clotting of blood *in vitro* and *in vivo* by enhancing the action of antithrombin III. Antithrombin III, which is present in plasma, inhibits the activity of activated clotting factors including thrombin (factor IIa) and activated factor X (factor Xa). Heparin increases the rate of this inhibition, but in a manner that is dependent on its dose. With normal therapeutic doses heparin has an inhibitory effect on both thrombin and factor Xa. The inhibition of thrombin blocks the conversion of fibrinogen to fibrin, and the inhibition of factor Xa blocks the conversion of prothrombin to thrombin. The low doses that are given subcutaneously for the prophylaxis of thromboembolism have a selective effect on inhibition of factor Xa. Very high doses are reported to reduce the activity of antithrombin III. Heparin also has some effect on platelet function, inhibits the formation of a stable fibrin clot, and has an antilipidaemic effect. For an explanation of the coagulation cascade, see Haemostasis and Fibrinolysis, p.1045.

Heparin is used in the treatment and prophylaxis of venous thromboembolism (deep-vein thrombosis and pulmonary embolism, p.1189), especially prophylaxis in surgical patients and in those pregnant women at particular risk. It is also used in the management of arterial thromboembolism including that associated with unstable angina pectoris (p.1157), myocardial infarction (p.1175), acute peripheral arterial occlusion (p.1178), and stroke (p.1185). It is often used as a precursor to oral anticoagulation and is withdrawn once the oral anticoagulant is exerting its full effect.

Heparin has been tried in the treatment of disseminated intravascular coagulation. It is also used to prevent coagulation during haemodialysis and other extracorporeal circulatory procedures such as cardiopulmonary bypass. Other uses include the anticoagulation of blood for transfusion or blood samples and the flushing of catheters and cannulas to maintain patency.

Heparin and its salts are constituents of many topical preparations for the treatment of various inflammatory disorders.

Administration and dosage. Heparin is given intravenously, preferably by continuous infusion, or by subcutaneous injection. It may be given as the calcium or sodium salt and it is generally accepted that there is little difference in their effects. Oral formulations of heparin are under investigation.

Doses of heparin for treatment (sometimes termed 'full-dose' heparin), and in some cases prophylaxis, of thromboembolism should be monitored and determined as discussed below under Control of Heparin Therapy. The subcutaneous doses of heparin commonly used for prophylaxis (often termed 'low-dose') do not require routine monitoring. A test dose has been recommended for patients with a history of allergy. Although international and USP units are not strictly equivalent, doses expressed in either appear to be essentially the same.

For **treatment of venous thromboembolism**, an intravenous loading dose of 5000 units (10 000 units may be required in severe pulmonary embolism) is followed by continuous intravenous infusion of 1000 to 2000 units/hour or subcutaneous injection of

15 000 units every 12 hours. Alternatively, intermittent intravenous injection of 5000 to 10 000 units every 4 to 6 hours is suggested in some product literature. Children and small adults are given a lower intravenous loading dose followed by maintenance with continuous intravenous infusion of 15 to 25 units/kg per hour or subcutaneous injection of 250 units/kg every 12 hours.

For **prophylaxis** of **postoperative venous thromboembolism**, subcutaneous doses used are 5000 units 2 hours before surgery then every 8 to 12 hours for 7 days or until the patient is ambulant. Similar doses are used to prevent thromboembolism during pregnancy in women with a history of deep-vein thrombosis or pulmonary embolism; the dosage may need to be increased to 10 000 units every 12 hours during the third trimester.

In the management of **unstable angina** or acute **peripheral arterial embolism,** heparin may be given by continuous intravenous infusion in the same doses as those recommended for the treatment of venous thromboembolism. Doses that have been recommended for the prevention of re-occlusion of the coronary arteries following thrombolytic therapy in **myocardial infarction** include 5000 units intravenously followed by 1000 units/hour intravenously with alteplase; a dose of 12 500 units subcutaneously every 12 hours for at least 10 days may be used to prevent mural thrombosis.

Control of heparin therapy. Treatment with full-dose heparin must be monitored to ensure that the dose is providing the required effect on antithrombin III. The most commonly used test to monitor the action of heparin is the activated partial thromboplastin time (APTT). The APTT of patients on full-dose heparin should generally be maintained at 1.5 to 2.5 times the control value although the optimum therapeutic range varies between individual laboratories depending on the APTT reagent in use. Regular monitoring is essential, preferably on a daily basis. Prophylaxis with low-dose subcutaneous heparin is not routinely monitored; the APTT is not significantly prolonged in these patients. A dose-adjusted regimen to maintain minimal prolongation of the APTT may be required in patients with malignancy or undergoing orthopaedic surgery to ensure adequate protection against thromboembolism. Other tests used include the activated clotting time (ACT). The value of measurements of heparin concentration in the blood remains to be established.

Action. Heparin is well established as an anticoagulant and antithrombotic and acts primarily by binding to, and enhancing the activity of, antithrombin III. However, the physiological role of endogenous heparin has not been clearly defined, despite its presence in mast cells, its ability to interact with numerous proteins, and its close structural similarity to heparan sulfate (suleparoid), the ubiquitous cell-surface glycosaminoglycan.[1,2] Endogenous heparin activity may have a role in protecting against atherosclerosis.[3] Non-anticoagulant properties of heparin or low-molecular-weight heparins have been reported to include anti-inflammatory activity, with a possible application in, for example, asthma[4-6] or inflammatory bowel disease; however, studies in patients with active ulcerative colitis have not found any benefit.[7] For mention of the use of aerosolised heparin with acetylcysteine to treat inhalation injury, see Burns, under Acetylcysteine, p.1549. The risk of bleeding is a major obstacle to the use of heparin for non-anticoagulant purposes.

Administration. The activated partial thromboplastin time (APTT) is the test most commonly used to monitor intravenous full-dose heparin therapy. Heparin dosing algorithms have been developed[1,2] so that the time taken to achieve a therapeutic APTT and maintain it in the therapeutic range (usually 1.5 to 2.5 times the control value) is shortened and thus the risk of recurrent thrombosis and major bleeding complications is reduced. An automated method of monitoring and regulation has been tried.[3] Although use of ideal body-weight for dosage calculation in obese patients has been suggested, actual body-weight may be more appropriate,[4,5] but maximum bolus doses and infusion rates should be set, to avoid overdosage in morbidly obese patients.

However, the therapeutic ranges used in such algorithms are not applicable to all APTT reagents because the latter vary in their sensitivity to heparin.[6] The optimum therapeutic range therefore varies between individual laboratories depending on the APTT reagent used. Dosing algorithms may be adapted by calibrating the therapeutic APTT with plasma-heparin concentrations.[6,7]

A weight-based algorithm for treatment doses of subcutaneous heparin in deep-vein thrombosis has also been proposed.[8]

Catheters and cannulas. Solutions of heparin sodium 10 or 100 units/mL in sodium chloride 0.9% are used for the flushing of intravenous catheters, cannulas, and other indwelling intravenous infusion devices used for intermittent dosing (heparin locks). A meta-analysis[1] of controlled studies was, however, unable to show any major advantage of either strength of heparin sodium solution over sodium chloride 0.9% alone in maintaining peripheral cannula patency or reducing the incidence of thrombophlebitis, and sodium chloride 0.9% is therefore recommended for cannulas intended to be in place for 48 hours or less. Less use of heparin flush solutions could minimise the risk of adverse effects such as thrombocytopenia and reduce the risk of incompatibilities with intravenous drugs.

Use of heparin-bonded catheters or the addition of heparin to intravenous fluids such as total parenteral nutrition solutions has also been tried in an attempt to maintain indwelling intravenous infusion devices (but see Catheters and Cannulas under Precautions, above). Continuous infusion of heparin-containing fluids may prolong the patency of peripheral arterial catheters.[1] To maintain the patency of umbilical artery catheters in neonates, US guidelines[2] suggest continuous infusion of heparin at a concentration of 0.25 to 1 unit/mL.

Central venous catheters are also subject to thrombus formation and their use may be complicated by vascular thrombosis and systemic infection. A meta-analysis[3] of prophylactic heparin used with central venous and pulmonary artery catheters suggested that heparin reduces catheter-related vascular thrombosis and may reduce catheter-related infection. This analysis included a range of heparin doses and methods of administration, as well as heparin-bonded catheters, and the authors suggested that further study was needed. More specific systematic reviews have found that continuous infusion of heparin reduces the incidence of catheter occlusion in neonates with peripherally-placed central venous catheters,[4] and that heparin-bonded catheters may reduce the risk of catheter occlusion in children with central venous catheters.[5] Further evidence that heparin infusion reduces the risk of catheter-related infection has also been reported.[6] Very low doses of warfarin (1 mg daily) may protect against thrombosis in patients with central venous catheters.[7]

Disseminated intravascular coagulation. Heparin has been used with some success in disseminated intravascular coagulation (p.1048) associated with a variety of conditions. However, this use is considered by some to be controversial and should be reserved for specific situations where the risk of bleeding is relatively minor in comparison with the possible beneficial effect on formation of microthromboses. A suggested intravenous dose is 500 units/hour, adjusted if necessary according to clinical response.[1] The maximum dose given intravenously is usually 1000 units/hour because of the risk of bleeding.

1. Baglin T, *et al.* for the British Committee for Standards in Haematology. Guidelines on the use and monitoring of heparin. *Br J Haematol* 2006; **133:** 19–34. Also available at: http://www.bcshguidelines.com/pdf/heparin_220506.pdf (accessed 01/06/06)

Extracorporeal circulation. Anticoagulation with heparin is necessary during procedures such as cardiopulmonary bypass and haemodialysis and haemofiltration. In the case of bypass, heparin is added to the crystalloid solution and any stored blood used for priming the bypass machine and is given intravenously before cannulation of the heart and major blood vessels. Activated clotting time (ACT) is monitored throughout. After bypass is stopped, anticoagulation can be reversed with protamine but caution is advised because of potential toxicity on the cardiopulmonary circulation.

At the start of haemodialysis sessions patients generally get a loading dose of heparin followed by continuous infusion into the exit line of the extracorporeal circuit until about one hour before the end of dialysis. The dose of heparin varies widely depending on body-weight, volume of the extracorporeal circulation, dialysis membrane biocompatibility, and pump speed.

Idiopathic thrombocytopenic purpura. Subcutaneous injection of a low dose of heparin improved platelet counts in a small number of patients with idiopathic thrombocytopenic purpura (p.1505) that was resistant to standard corticosteroid therapy.[1] However, heparin may itself cause thrombocytopenia, even at very low doses (see Effects on the Blood under Adverse Effects, above).

1. Shen ZX, *et al.* Thrombocytopoietic effect of heparin given in chronic immune thrombocytopenic purpura. *Lancet* 1995; **346:** 220–1.

Malignant neoplasms. Cancer is a risk factor for thromboembolism and anticoagulants are often used in patients with malignant neoplasms. There is some evidence that outcomes are improved in patients treated with heparin, and both unfractionated and low-molecular-weight heparins have therefore been studied in patients with malignant neoplasms but no other indication for anticoagulation. Systematic reviews[1,2] have found that there is a clinically significant improvement in survival, although the risk of bleeding is also increased.

1. Akl EA, *et al.* Parenteral anticoagulation for prolonging survival in patients with cancer who have no other indication for anticoagulation. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2007 (accessed 23/05/08).
2. Lazo-Langner A, *et al.* The effect of low-molecular-weight heparin on cancer survival. A systematic review and meta-analysis of randomized trials. *J Thromb Haemost* 2007; **5:** 729–37.

Pregnancy. Heparin or low-molecular-weight heparins are the anticoagulants of choice for use in pregnancy although they are not without risk for the fetus (see Pregnancy, under Precautions, above), and for the mother.

Guidelines on thrombosis associated with pregnancy have been published.[1-3] Pregnant women may require anticoagulation for the treatment or prophylaxis of venous thromboembolism (p.1189), or for the prevention of systemic thromboembolism associated with prosthetic heart valves (p.1187). Patients with a history of thromboembolism or a thrombophilic abnormality such as inherited deficiencies of antithrombin III, protein C, or protein S or acquired antiphospholipid antibodies may be at particular risk. Women with antiphospholipid antibodies may also be at increased risk of fetal loss (see Systemic Lupus Erythematosus, p.1513) and treatment with low-dose aspirin is usually recommended.[2] Addition of heparin has been reported to further reduce the risk,[4,5] and treatment with heparin or low-molecular-weight heparin, in addition to aspirin, has therefore also been recommended.[3]

Reperfusion and revascularisation procedures. Heparin has an established role as an adjunct to percutaneous vascular interventions and bypass surgery, to prevent perioperative thrombosis of the target artery, and is usually given with aspirin or other antiplatelet drugs (see Reperfusion and Revascularisation Procedures, p.1181). High doses are used, particularly in patients undergoing bypass surgery with extracorporeal circulation, and bleeding is a common problem. Although heparin may have an antiproliferative effect, treatment with systemic heparin (unfractionated or low-molecular-weight) appears to have no effect on restenosis;[1] however, a study using local application of enoxaparin suggested that restenosis was reduced.[2] Heparin-coated intracoronary stents have also been used; they improve outcomes compared with balloon angioplasty,[3] but have not been shown to be superior to bare-metal stents[4] or to have any additional effect on restenosis.[5,6] Heparin-coated stents have also been used successfully in cerebrovascular interventions.[7]

Heparinoids

Heparinoides.

Profile

The term heparinoid includes heparin derivatives and has also been used more loosely to include naturally occurring and synthetic highly-sulfated polysaccharides of similar structure. Such compounds have been described in many ways; some of the terms used include sulfated glucosaminoglycans; glycosaminoglycan polysulfate compounds; or sulfated mucopolysaccharides.

The following anticoagulants may be described as heparinoids:

- Danaparoid Sodium, p.1255
- Dermatan Sulfate, p.1256
- Pentosan Polysulfate Sodium, p.1367
- Sodium Apolate, p.1397
- Suleparoid, p.1406
- Sulodexide, p.1406

Heparinoid preparations are available with uses ranging from anticoagulation to the alleviation of inflammation (applied topically); some are claimed to have hypolipidaemic properties.

The proprietary names listed in this monograph refer to preparations containing undefined or less readily defined heparinoids that are used in a range of conditions including musculoskeletal and joint disorders, haemorrhoids, lipid disorders, and thromboembolic disorders.

Hexobendine *(BAN, USAN, rINN)*

Hexobendina; Hexobendinum.

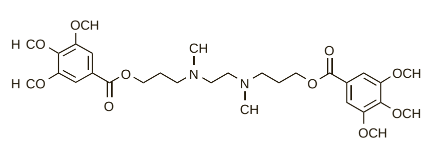
Гексобендин

$C_{30}H_{44}N_2O_{10}$ = 592.7.

CAS — 54-03-5.

ATC — C01DX06.

ATC Vet — QC01DX06.



Hexobendine Hydrochloride *(BANM, rINNM)*

Hexobendine, Chlorhydrate d'; Hexobendini Hydrochloridum; Hidrocloruro de hexobendina; ST-7090. *NN'*-Ethylenebis(3-methylaminopropyl 3,4,5-trimethoxybenzoate) dihydrochloride.

Гексобендина Гидрохлорид

$C_{30}H_{44}N_2O_{10}$,2HCl = 665.6.

CAS — 50-62-4.

ATC — C01DX06.

ATC Vet — QC01DX06.

Profile

Hexobendine hydrochloride is a vasodilator that has been used in ischaemic heart disease. It is also included in multi-ingredient preparations used in cerebrovascular disorders.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Ustimon.

Multi-ingredient: ***Austria:*** Instenon; ***Hong Kong:*** Instenon; ***Rus.:*** Instenon (Инстенон); ***Thai.:*** Instenon†.

Hirudin

Hirudina; Hirudine.

Profile

Hirudin is a 65-amino-acid protein that is a direct inhibitor of thrombin (see Lepirudin, p.1323). It has been extracted from leeches (p.1323) and this form is used in various topical preparations for peripheral vascular disorders. Recombinant hirudins, such as desirudin (p.1257) and lepirudin (p.1323) and analogues of hirudin, such as bivalirudin (p.1234), are used as anticoagulants.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Exhirud; ***Fr.:*** Hirucreme; ***Ger.:*** Exhirud†.

Multi-ingredient: ***Ger.:*** Haemo-Exhirud†; ***Ital.:*** Hirudex†.

Hydralazine Hydrochloride

(BANM, rINNM)

Apressinum; Hidralazin-hidroklorid; Hidralazino hidrochloridas; Hidrocloruro de hidralazina; Hydralatsiinihydrokloridi; Hydralazin hydrochlorid; Hydralazin Hydrochloridum; Hydralazine, chlorhydrate d'; Hydralazinhydroklorid; Hydralazini hydrochloridum; Hydrallazine Hydrochloride; Idralazina. 1-Hydrazinophthalazine hydrochloride.

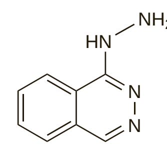
Гидралазина Гидрохлорид

$C_8H_8N_4$,HCl = 196.6.

CAS — 86-54-4 (hydralazine); 304-20-1 (hydralazine hydrochloride).

ATC — C02DB02.

ATC Vet — QC02DB02.



(hydralazine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Hydralazine Hydrochloride). A white or almost white, crystalline powder. Soluble in water; slightly soluble in alcohol; very slightly soluble in dichloromethane. A 2% solution in water has a pH of 3.5 to 4.2. Protect from light.

USP 31 (Hydralazine Hydrochloride). A white to off-white, odourless, crystalline powder. Soluble 1 in 25 of water and 1 in 500 of alcohol; very slightly soluble in ether. A 2% solution in water has a pH of 3.5 to 4.2. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Stability. Discoloration of hydralazine injection was observed on several occasions after storage in a syringe for up to 12 hours.[1] Hydralazine reacts with metals and therefore the injection should be prepared using a nonmetallic filter and should be used as quickly as possible after being drawn through a needle into a syringe.

A study of the rate of degradation of hydralazine hydrochloride, 1 mg/mL in sweetened, aqueous oral liquids showed that glucose, fructose, lactose, and maltose reduced the stability of the drug.[2] In solutions containing mannitol or sorbitol, there was less than 10% degradation of hydralazine after 3 weeks. UK licensed product information states that contact with glucose causes hydralazine to be rapidly broken down and that hydralazine injection is therefore not compatible with glucose solutions.

Adverse Effects

Adverse effects are common with hydralazine, particularly tachycardia, palpitations, angina pectoris, severe headache, and gastrointestinal disturbances such as anorexia, nausea, vomiting, and diarrhoea. These adverse effects, and flushing, dizziness, and nasal congestion, which occur less often, may be seen at the start of treatment, especially if the dose is increased quickly. They generally subside with continued treatment. Other less common adverse effects include orthostatic hypotension, fluid retention with oedema and weight gain, conjunctivitis, lachrymation, tremor, and muscle cramps.

Hydralazine may deplete pyridoxine in the body, and can produce peripheral neuropathy with numbness and tingling of the extremities. Occasionally, hepatotoxicity, blood dyscrasias, haemolytic anaemia, difficulty in urinating, glomerulonephritis, constipation, paralytic ileus, depression, and anxiety occur.

Hypersensitivity reactions including fever, chills, pruritus, and rashes have been reported, and eosinophilia may occur.

Antinuclear antibodies may develop after prolonged use of large doses, and a condition resembling SLE may occur. The incidence is greater in slow acetylators, patients with renal impairment, women, and patients taking more than 100 mg of hydralazine daily. The symptoms usually disappear when the drug is withdrawn; some patients may require treatment with corticosteroids.

Acute overdosage may produce hypotension, tachycardia, myocardial ischaemia, arrhythmias, shock, and coma.

Carcinogenicity. Although earlier reports suggested that hydralazine might be carcinogenic, there was no evidence from a survey of 1978 patients with lung or colorectal cancer and 6807 controls that there was an increased risk of these neoplasms.[1]

1. Kaufman DW, *et al.* Hydralazine use in relation to cancers of the lung, colon, and rectum. *Eur J Clin Pharmacol* 1989; **36:** 259–64.

Effects on the blood. Three cases of thrombocytopenia were reported[1] in neonates whose mothers had been treated with hydralazine for some months before delivery. The thrombocytopenia and bleeding was transient with full recovery occurring within a few weeks. No adverse effects were noticed in the mothers.

1. Widerlöv E, *et al.* Hydralazine-induced neonatal thrombocytopenia. *N Engl J Med* 1980; **303:** 1235.

Effects on the cardiovascular system. Paradoxical severe hypertension developed after oral or intramuscular hydralazine on 3 occasions in a patient with renal artery stenosis.[1]

1. Webb DB, White JP. Hypertension after taking hydrallazine. *BMJ* 1980; **280:** 1582.

Effects on the kidneys. Rapidly progressive glomerulonephritis with focal and segmental lesions, usually accompanied by necrosis and crescent formation, has been reported in patients given hydralazine.[1-3] The condition is reported to be associated with the presence of antinuclear antibodies[3] and slow acetylator status,[2] factors associated with the development of hydralazine-induced lupus erythematosus.[4] However, renal involvement is much less common in drug-induced lupus,[4] and in a report of 15 such cases men and women and fast and slow acetylators were equally affected;[3] in addition the criteria for SLE were not usually fulfilled in these patients and it was suggested that the condition should be distinguished from lupus nephritis. Immediate withdrawal of hydralazine generally results in some improvement in renal function but complete recovery is uncommon; severe cases may require immunosuppressive therapy.[3]

4. Hughes GRV. Recent developments in drug-associated systemic lupus erythematosus. *Adverse Drug React Bull* 1987; (Apr.): 460–3.

Effects on the skin. Pruritus and skin rashes have been reported with hydralazine use.

A 59-year-old woman who had been taking hydralazine 25 mg three times daily for 6 months developed symptoms of Sweet's syndrome (erythematous plaques and nodules and haemorrhagic blisters).[1] Symptoms began to subside on withdrawal of the drug but recurred on rechallenge. The condition resolved on discontinuation of hydralazine and treatment with prednisolone.

1. Gilmour E, *et al.* Drug-induced Sweet's syndrome (acute febrile neutrophilic dermatosis) associated with hydralazine. *Br J Dermatol* 1995; **133:** 490–1.

Lupus erythematosus. Lupus erythematosus is a well-documented adverse effect of hydralazine. Onset is typically delayed from 1 month to 5 years from the start of treatment, and the most common symptoms are arthralgia or arthritis, usually non-deforming, in up to 95% of patients, fever and myalgia in about 50%, and pleuropulmonary involvement, manifesting as pleurisy, pleural effusions, or pulmonary infiltrates in up to 30%.[1-3] Renal involvement is reported to be less common than in idiopathic SLE and there is some uncertainty as to whether the glomerulonephritis sometimes seen in patients receiving hydralazine should be considered lupus nephritis (see Effects on the Kidneys, above). Nonetheless, a 20% incidence of renal involvement has been reported.[1] Other complications and symptoms associated with lupus erythematosus in patients taking hydralazine include cutaneous vasculitis,[4-6] orogenital and cutaneous ulceration,[7] bilateral retinal vasculitis,[8] reactive hypoglycaemia (although the attribution is uncertain),[9] life-threatening cardiac tamponade,[10] and hoarseness and stridor secondary to vocal cord palsy, which progressed to respiratory arrest.[11] Skin rashes are reported to be less prominent than with the idiopathic form of the disease.[1] Fatalities have occurred,[12] but appear to be rare.

Estimates of the overall incidence of hydralazine-associated lupus erythematosus vary from about 1.2 to 5% or more.[13-16] The syndrome appears to occur only in patients who develop antinuclear antibodies while receiving hydralazine, but the incidence of positive antinuclear antibody tests is much higher than that of lupus, at up to 60%, so the presence of antinuclear antibodies alone is not diagnostic.[15] There is a strong relationship with drug dose,[14,16] acetylator status,[13,15,16] and patient gender,[16] the syndrome being more common in slow acetylators and women, and in patients receiving 100 mg daily or more.

Although it has been reported that hydralazine-associated lupus was more frequent in patients with the HLA-DR4 antigen[17] this was not confirmed by others[18] and subsequent work has suggested that the association is rather with the non-expressing or null forms of the adjacent complement C4 gene.[19] Hydralazine can inactivate complement C4 *in vitro*[20] and might exacerbate complement deficiency (which is known to be associated with idiopathic SLE) in patients with an already low level of C4 due to a null allele.[19]

Treatment of Adverse Effects

Withdrawal of hydralazine or dosage reduction reverses many of the adverse effects. Peripheral neuropathy has been reported to be alleviated by pyridoxine.

If overdosage occurs the benefit of gastric decontamination is uncertain, but activated charcoal may be given if the patient presents within 1 hour of ingestion. Symptomatic and supportive treatment, including plasma expanders for shock and a beta blocker for tachycardia, should be given as necessary. Hypotension may respond to placing the patient in the supine position with the feet raised. If possible, pressor drugs should be avoided. If a pressor is necessary, one should be chosen that will not cause tachycardia or exacerbate arrhythmias; adrenaline should not be used.

Precautions

Hydralazine is contra-indicated in patients with severe tachycardia, dissecting aortic aneurysm, heart failure with high cardiac output, cor pulmonale, or myocardial insufficiency due to mechanical obstruction, for example aortic or mitral stenosis or constrictive pericarditis. Hydralazine is also contra-indicated in patients with idiopathic SLE and related disorders.

Hydralazine-induced vasodilatation produces myocardial stimulation. It should therefore be used with caution in patients with ischaemic heart disease since it can increase angina and it should not be given after myocardial infarction until the patient's condition has stabilised. Patients with suspected or confirmed ischaemic heart disease should be given hydralazine under cover of a beta blocker, which should be started a few days before hydralazine, in order to prevent myocardial stimulation. If given to patients with heart failure they should be monitored for orthostatic hypotension and tachycardia during the initial stages of therapy, preferably in hospital. If treatment with hydralazine is to be stopped in patients with heart failure it should generally be withdrawn gradually. Hydralazine should be used with caution in patients with cerebrovascular disorders.

The dose of hydralazine should be reduced or the dosage interval prolonged in patients with hepatic or renal impairment. Complete blood counts and antinuclear antibody determinations should be carried out about every 6 months during long-term therapy. Urine analysis (for microhaematuria and proteinuria) is also recommended.

Hydralazine is teratogenic in some species of *animals* and should therefore be avoided during the first two trimesters of pregnancy.

Patients may experience impaired reactions, especially at the start of therapy, and should not drive or operate machinery if affected.

Breast feeding. Hydralazine is distributed into breast milk in small amounts (see Pregnancy, below) but no adverse effects have been seen in infants and the American Academy of Pediatrics therefore considers[1] hydralazine to be usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 26/09/05)

Porphyria. Hydralazine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Hydralazine should be avoided during the first two trimesters of pregnancy.

Hydralazine concentrations were found to be similar in maternal and umbilical-cord blood in a study of 6 women being treated with hydralazine for pronounced hypertension during pregnancy.[1] Hydralazine was determined in the breast milk of 1 mother, but amounts detected were unlikely to produce clinically relevant concentrations in the infant.

For a report of thrombocytopenia occurring in neonates following maternal treatment with hydralazine during pregnancy, see Effects on the Blood under Adverse Effects, above.

1. Liedholm H, *et al.* Transplacental passage and breast milk concentrations of hydralazine. *Eur J Clin Pharmacol* 1982; **21:** 417–19.

Interactions

The hypotensive effect of hydralazine may be enhanced by other drugs with a hypotensive action. Severe hypotension may occur if hydralazine and diazoxide are given together. However, some interactions with antihypertensives may be beneficial: thiazide diuretics also counteract the fluid retention caused by hydralazine, and beta blockers diminish the cardiac-accelerating effects.

Indometacin. A study[1] in 9 healthy subjects found that indometacin 100 mg daily did not lessen the hypotensive effect of hydralazine. However, another study[2] showed that indometacin 200 mg daily, while having no effect on heart rate, renal or limb blood flow, or plasma-catecholamine concentration, did reduce the hypotensive effect of hydralazine.

Pharmacokinetics

Hydralazine given orally is rapidly absorbed from the gastrointestinal tract but undergoes considerable first-pass metabolism by acetylation in the gastrointestinal mucosa and liver. The rate of metabolism is genetically determined and depends upon the acetylator status of the individual. The bioavailability of hydralazine has been reported to be about 35% in slow acetylators and less in fast acetylators; thus plasma concentrations after a given dose are higher in slow acetylators.

Peak plasma concentrations have been reported to occur after about one hour. Hydralazine is chiefly present in plasma as a hydrazone conjugate with pyruvic acid. Plasma protein binding is about 90%. The drug is widely distributed, notably into arterial walls.

Systemic metabolism in the liver is by hydroxylation of the ring system and conjugation with glucuronic acid; most sources suggest that *N*-acetylation is not of major importance in systemic clearance and that therefore acetylator status does not affect elimination. Hydralazine is excreted mainly in urine as metabolites.

The apparent average half-life for hydralazine has been reported to vary from about 45 minutes to about 8 hours, with a number of sources giving the average as about 2 to 4 hours. Some of the variation may be due to problems with the analytical procedures—see below. The half-life is prolonged in renal impairment and may be up to 16 hours in patients with a creatinine clearance of less than 20 mL/minute.

Hydralazine crosses the placenta and is distributed into breast milk.

◊ Attempts to describe the pharmacokinetics of hydralazine have been complicated by the instability of the drug itself in plasma and in alkaline solutions, and the instability of its circulating metabolites during analysis. This has meant that many techniques for the measurement of hydralazine have proved non-selective and yield overestimates of unchanged drug.[1] Studies using less selective methods have yielded an apparent bioavailability for oral hydralazine of 38 to 69% in slow acetylators and 22 to 32% in fast acetylators; in contrast, more selective assays have yielded values of 31 to 35% and 10 to 16% for slow and rapid acetylators respectively. Similarly, hydralazine plasma clearance is lower and the half-life longer when based upon the results of non-selective assay procedures; mean elimination half-life has ranged from 2.2 to 3.6 hours based upon these methods compared with 0.67 to 0.96 hours using a more selective assay. Improved pharmacokinetic data has indicated that while the first-pass effect is dependent upon acetylator phenotype, systemic clearance is only minimally dependent upon acetylation. The formation of the pyruvic acid hydrazone, which is without significant vasodilator activity, contributes to extrahepatic phenotype-independent clearance.

Although some workers have correlated the hypotensive effect of hydralazine with concentrations,[2] others have been unable to do so.[3] Moreover, the duration of hypotensive effect has been shown to exceed considerably that predicted from the rate of elimination.[4,5] Possible explanations are the accumulation of hydralazine at its sites of action in the arterial walls[6] or the existence of active metabolites.[7-9]

Concurrent intake of food has been found to enhance considerably the bioavailability of hydralazine[10] but food-related reductions in plasma-hydralazine concentrations with reduced vasodilator effect have also been reported.[11] The discrepancy was thought to be due to the greater specificity of the assay used in the latter study and to differences in the timing of food and hydralazine administration in the two studies.[12,13]

Uses and Administration

Hydralazine is a direct-acting vasodilator that acts mainly on the arterioles. It reduces blood pressure and peripheral resistance but produces fluid retention. Tachycardia and an increase in cardiac output occur mainly as a reflex response to the reduction in peripheral resistance. Hydralazine tends to improve renal and cerebral blood flow and its effect on diastolic pressure is more marked than on systolic pressure.

Hydralazine hydrochloride is given orally for the treatment of hypertension (p.1171), usually with a beta blocker and a thiazide diuretic. In addition to an additive antihypertensive effect, this combination reduces the reflex tachycardia and fluid retention caused by hydralazine. Hydralazine may be given intravenously in hypertensive crises. It is also used with isosorbide dinitrate in the management of heart failure (but see Precautions, above). For further discussion of this use of hydralazine, see below.

The dose of hydralazine should be reduced or the dosage interval prolonged in patients with hepatic or renal impairment.

In **hypertension**, the usual initial oral dose of hydralazine hydrochloride is 40 to 50 mg daily in divided doses, increased according to response. In the UK it is recommended that the dose should not be increased above 100 mg daily without checking acetylator status, although the recommended maximum dose for hypertension is 200 mg daily; doses above 100 mg daily are associated with an increased incidence of lupus erythematosus, particularly in women and in slow acetylators.

In hypertensive crises, hydralazine hydrochloride is given in doses of 5 to 10 mg by slow intravenous injection, repeated if necessary after 20 to 30 minutes. Alternatively, it may be given by continuous intravenous infusion in an initial dose of 200 to 300 micrograms/minute; the usual maintenance dose range is 50 to 150 micrograms/minute. Hydralazine hydrochloride has also been given by intramuscular injection.

For **heart failure** in self-identified black patients, hydralazine may be given as an oral combination preparation with isosorbide dinitrate; the dose is 37.5 mg of hydralazine with 20 mg of isosorbide dinitrate three times daily, and may be doubled if necessary.

Heart failure. Hydralazine with isosorbide dinitrate may have a role in the management of patients with heart failure (p.1165) who remain symptomatic despite standard therapy or in whom standard therapy is contra-indicated or not tolerated. Although a meta-analysis of a number of studies[1] of vasodilator therapy for heart failure failed to show a benefit in terms of improved functional status or reduced mortality in patients given hydralazine alone, there is evidence from the Veterans Administration Cooperative Study[2] of reduced mortality from the use of hydralazine with nitrates. This has been confirmed in a second study (V-HeFTII),[3] although hydralazine with isosorbide dinitrate was less effective than enalapril. Subgroup analysis suggested that the effect might be greater in black patients, and a later study[4] in black patients found that addition of isosorbide dinitrate and hydralazine to standard therapy improved both morbidity and mortality.

Hydralazine has also been tried in children with heart failure,[5,6] but experience is limited.

Hydrochlorothiazide *(BAN, rINN)* ⊗

Hidrochlorotiazidas; Hidroclorotiazida; Hidroklorotiazid; Hydrochlorothiazid; Hydrochlorothiazidum; Hydrochlorotiazyd; Hydroklooritiatsidi; Hydroklortiazid. 6-Chloro-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

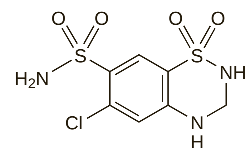
Гидрохлоротиазид

$C_7H_8ClN_3O_4S_2$ = 297.7.

CAS — 58-93-5.

ATC — C03AA03.

ATC Vet — QC03AA03.



NOTE. Compounded preparations of hydrochlorothiazide may be represented by the following names:

- Co-amilozide (*BAN*)—hydrochlorothiazide 10 parts and amiloride hydrochloride 1 part (w/w)
- Co-amilozide (*PEN*)—amiloride hydrochloride and hydrochlorothiazide
- Co-spironozide (*PEN*)—spironolactone and hydrochlorothiazide
- Co-triamterzide (*BAN*)—triamterene 2 parts and hydrochlorothiazide 1 part (w/w)
- Co-triamterzide (*PEN*)—triamterene and hydrochlorothiazide
- Co-zidocapt (*BAN*)—hydrochlorothiazide 1 part and captopril 2 parts (w/w).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Hydrochlorothiazide). A white or almost white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; soluble in acetone. It dissolves in dilute solutions of alkali hydroxides.

USP 31 (Hydrochlorothiazide). A white or practically white, practically odourless crystalline powder. Slightly soluble in water; insoluble in chloroform, in ether, and in dilute mineral acids; freely soluble in dimethylformamide, in *n*-butylamine, and in sodium hydroxide solution; sparingly soluble in methyl alcohol.

Adverse Effects

Hydrochlorothiazide and other thiazide diuretics may cause a number of metabolic disturbances especially at high doses. They may provoke hyperglycaemia and glycosuria in diabetic and other susceptible patients. They may cause hyperuricaemia and precipitate attacks of gout in some patients. Thiazide diuretics may be associated with electrolyte imbalances including hypochloraemic alkalosis, hyponatraemia, and hypokalaemia. Hypokalaemia intensifies the effect of digitalis on cardiac muscle and treatment with digitalis or its glycosides may have to be temporarily suspended. Patients with cirrhosis of the liver are particularly at risk from hypokalaemia. Hyponatraemia may occur in patients with severe heart failure who are very oedematous, particularly with large doses in conjunction with restricted salt in the diet. The urinary excretion of calcium is reduced. Hypomagnesaemia has also occurred. Adverse changes in plasma lipids have also been noted but their clinical significance is unclear.

Signs of electrolyte imbalance include dry mouth, thirst, weakness, lethargy, drowsiness, restlessness, muscle pain and cramps, seizures, oliguria, hypotension, and gastrointestinal disturbances.

Other adverse effects include anorexia, gastric irritation, nausea, vomiting, constipation, diarrhoea, sialadenitis, headache, dizziness, photosensitivity reactions, orthostatic hypotension, paraesthesia, impotence, and yellow vision. Hypersensitivity reactions include skin rashes, fever, pulmonary oedema, pneumonitis, anaphylaxis, and toxic epidermal necrolysis. Cholestatic jaundice, pancreatitis, and blood dyscrasias including thrombocytopenia and, more rarely, granulocytopenia, leucopenia, and aplastic and haemolytic anaemia have been reported.

Intestinal ulceration has occurred after the use of tablets containing thiazides with an enteric-coated core of potassium chloride (see also under Potassium, p.1684).

Carcinogenicity. Several studies have suggested that long-term diuretic therapy may be associated with the development of cancer. A meta-analysis[1] of 9 case control studies and 3 cohort studies found an increased risk of renal cell carcinoma in patients receiving diuretics, and a further retrospective study[2] found that the risk of colon cancer was also increased. While the risk is probably not significant in most patients, it was suggested[1,2] that it should be taken into consideration when choosing long-term therapy for younger patients.

Effects on the blood. There have been case reports of intravascular immune haemolysis in patients taking hydrochlorothiazide and methyldopa.[1-3] In each of these 3 cases the hydrochlorothiazide was identified as the probable cause of haemolysis on serological data, although methyldopa could have been a contributory factor. One of these patients died[3] during the haemolytic episode although post-mortem examination failed to reveal a cause of death.

Effects on electrolyte balance. *MAGNESIUM AND POTASSIUM.* The clinical consequences of diuretic-induced hypokalaemia have been controversial.[1-3] Of major concern has been the possibility that diuretic-induced hypokalaemia could predispose to cardiac arrhythmias and sudden cardiac death in some patients, and it has been suggested that this could explain the lower than expected reduction in deaths due to ischaemic heart disease found in some hypertension trials. Indeed, some case-control studies[4,5] have suggested an association between an increased risk of sudden cardiac death and the use of thiazides or other non-potassium-sparing diuretics; the addition of a potassium supplement had little effect on this risk, whereas addition of a potassium-sparing diuretic to the thiazide lowered the risk.[4] However, no reduction in cardiac arrhythmias after the correction of hypokalaemia has been seen[6] nor any evidence of increased arrhythmias associated with diuretic-induced hypokalaemia.[7] Several reviews[8,9] have argued that there is no proof of a causal relationship between hypokalaemia and serious dysrhythmias and this was endorsed by a randomised study.[10]

It is generally agreed that routine potassium supplementation in patients taking diuretics is unnecessary; however, supplementation will be required if the serum-potassium concentration falls below 3.0 mmol/litre. Potassium replacement or conservation is also likely to be necessary in patients at risk from the cardiac effects of hypokalaemia[11] such as those with severe heart disease, those taking digitalis preparations or high doses of diuretics, and in patients with severe liver disease.

The amount of potassium in fixed combination diuretic and potassium preparations has long been considered insufficient to correct hypokalaemia and the effectiveness of oral potassium supplements in increasing body stores of potassium has been questioned.[12-14] Hypokalaemia may be overcome by adding a potassium-sparing diuretic such as amiloride or triamterene[15] to the regimen, but there is a danger of hyperkalaemia if they are used indiscriminately. The *routine* use of fixed-dose combination preparations of a thiazide or loop diuretic with a potassium-sparing diuretic is considered unnecessary.[16] Potassium-sparing diuretics will not correct the potassium deficit unrelated to diuretic therapy in patients with severe heart failure.[17] When thiazides are given with drugs that may induce hyperkalaemia, such as beta blockers, ACE inhibitors, or angiotensin II receptor antagonists, the diuretic-induced hypokalaemia may be ameliorated, but not necessarily corrected completely. Hypokalaemia has been reported[18-20] in patients taking fixed-dose combinations of thiazides and beta blockers.

Potassium supplementation alone may not be sufficient to correct hypokalaemia in patients who are also deficient in magnesium,[21] although it is unlikely to be of clinical significance.[22] Magnesium depletion has also been implicated as a risk factor for arrhythmias.[9,23]

SODIUM. Diuretics are a common cause of hyponatraemia.[1-5] Dilutional hyponatraemia may occur in patients with heart failure, but hyponatraemia may also result from sodium depletion[1] or inappropriate antidiuretic hormone secretion.[6] Other suggested mechanisms include decreased renal clearance of free water, hypomagnesaemia, and intracellular potassium depletion.[3,7] There have been a number of reports suggesting that hyponatraemia may be a particular problem with combinations of hydrochlorothiazide and potassium-sparing diuretics,[8-10] especially in elderly patients. The effect may be exacerbated by the relatively high doses of thiazide present in some fixed-dose preparations.[11] The symptoms of hyponatraemia may be non-specific and include nausea, lethargy, weakness, mental confusion, and anorexia,[1,2] but it may be an important cause of morbidity.[2,7] Severe sequelae of hyponatraemia include tonic-clonic seizures[12] and clinical features resembling subarachnoid haemorrhage.[13,14] Some patients, especially the elderly, may be particularly susceptible to the hyponatraemic effects of thiazides, possibly as a result of inappropriate secretion of antidiuretic hormone.[6] Plasma electrolyte concentrations should be monitored in patients taking long-term diuretic therapy.[3,12] Measurement of serum-sodium concentration and body-weight after a single dose of thiazide could be useful in identifying patients at increased risk of developing hyponatraemia.[7]

Effects on the gallbladder. There is an increased risk of cholecystitis in patients taking thiazides, with some indication that risk increases with the duration of use;[1,2] some workers concluded that this increased risk was confined to patients with pre-existing gallstones.[2] In a study in 10 healthy subjects,[3] hydrochlorothiazide was found to induce modest changes in biliary lipid concentrations although it was not associated with supersaturation of the bile. These changes could not wholly explain any increase in gallbladder disease in patients taking thiazides. However, evidence is conflicting; other studies[4,5] have found no association between thiazides and cholecystitis, except possibly in women who are not overweight.[5]

Effects on glucose metabolism. The adverse effects of thiazides on glucose metabolism, such as insulin resistance, impaired glucose tolerance, precipitation of overt diabetes, and worsening of diabetic control, are well established but appear to be dose-related and may not be significant at lower doses (for example, hydrochlorothiazide 6.25 or 12.5 mg).[1] A study[2] in 16 non-diabetic hypertensive patients found that bendroflumethiazide, in a dose of 1.25 mg daily, had no effect on insulin sensitivity whereas a daily dose of 5 mg produced hepatic insulin resistance. Similarly, the high doses, for example bendroflumethiazide 5 mg twice daily, used in the Medical Research Council Study on Mild to Moderate Hypertension[3] resulted in an incidence of glucose intolerance that led to withdrawal from the study of 9.38 per 1000 patient-years in men and 6.01 per 1000 patient-years in women compared with 2.51 and 0.82 per 1000 patient-years respectively in patients taking placebo. A later prospective study[4] in non-diabetic hypertensive patients found that those taking thiazides [doses not specified] were at no greater risk for developing diabetes than those not receiving antihypertensive therapy. However, a prospective cohort study[5] in men aged between 50 and 60 found that those taking antihypertensive treatment (mainly thiazides, beta blockers, or both) showed an increase in blood-glucose concentrations which was an independent risk factor for myocardial infarction, even when baseline insulin resistance was accounted for. Another prospective study[6] of 3 cohorts of men or women also found that use of thiazides was independently associated with a higher risk of diabetes.

It has been suggested[7] that the effect of thiazides on glucose metabolism is related to their effect on potassium and that control of hypokalaemia may prevent the development of diabetes, but this remains to be confirmed.

Effects on the kidneys. Thiazides can produce acute renal failure either from over-enthusiastic use producing sodium depletion and hypovolaemia or, occasionally, as a result of a hypersensitivity reaction.[1] Acute interstitial nephritis has been reported.[2,3] They can occasionally cause the formation of non-opaque urate calculi.[4]

Effects on lipid metabolism. Thiazides have been reported to adversely affect the plasma-lipid profile in the short term by increasing concentrations of low-density and very-low-density lipoprotein cholesterol, as well as of triglycerides, but not of high-density lipoprotein cholesterol.[1] These effects are probably dose-related[2] and it has been argued that changes in plasma lipids are likely to be slight at the relatively low doses now used in hypertension. There is some evidence to suggest that these lipid changes may not persist long-term.[3] In the Treatment of Mild Hypertension Study (TOMHS),[4] plasma total cholesterol concentrations were increased after 12 months in patients receiving chlortalidone but this effect was no longer present after 24 months. Although there has been concern that any hyperlipidaemic effect might offset the benefits of treating hypertension in patients at risk of ischaemic heart disease, studies such as ALLHAT[5] have shown that thiazide-like diuretics (in this case chlortalidone) are as effective as other antihypertensives in reducing the incidence of cardiovascular events in patients with hypertension and at least one other risk factor for ischaemic heart disease.

Correction. *ibid.* 2003; **289:** 178.

Effects on the nervous system. A 40-year old woman appeared sleepy and confused 1 week after starting hydrochlorothiazide.[1] Although her plasma-potassium concentrations had fallen they were still in the normal range, and it was concluded that her symptoms were due to an adverse reaction to the drug itself.

1. Daugherty KK, Subramanian J. Cognitive and neurologic impairment with hydrochlorothiazide. *Am J Health-Syst Pharm* 2005; **62:** 2630–3.

Effects on respiratory function. Acute interstitial pneumonitis and acute pulmonary oedema are rare but potentially dangerous complications of thiazides and may be due to a hypersensitivity reaction. Several cases have been reported,[1-7] frequently after a single dose of hydrochlorothiazide or chlorothiazide. The presenting symptoms could be mistakenly attributed to myocardial infarction.

Effects on sexual function. Adverse effects on sexual function have been reported in hypertensive patients given thiazides and other antihypertensives but it is not clear how much this is due to the underlying disease and how much is due to the drugs. In the Treatment of Mild Hypertension Study (TOMHS),[1] a double-blind randomised controlled trial that allocated patients to treatment with one of five groups of antihypertensives, the incidence of erectile dysfunction in men was relatively low but was highest in the diuretic group (chlortalidone treatment). The incidence was significantly higher in chlortalidone recipients than in placebo recipients at 24 months (17.1 and 8.1% respectively), but the difference was no longer significant at 48 months (18.3 and 16.7% respectively).

1. Grimm RH, *et al.* Long-term effects on sexual function of five antihypertensive drugs and nutritional hygienic treatment in hypertensive men and women: Treatment of Mild Hypertension Study (TOMHS). *Hypertension* 1997; **29:** 8–14.

Effects on the skin. Rashes and skin reactions have been reported in patients taking thiazides. *Photosensitivity* reactions are among the most frequently reported skin reactions. In Australia[1] co-amilozide was the preparation most commonly implicated in photosensitivity reactions in reports to the Australian Drug Reactions Advisory Committee, although this may reflect the high usage of this preparation. The most likely mechanism is thought to be phototoxicity[1,2] involving mainly UVA radiation although UVB may be involved in some cases.[2] Chronic photosensitivity does not usually occur after stopping the drug[2] although photosensitivity may persist for longer in some patients than in others.[2,3] Eruptions resembling *lichen planus*[4] and *subacute cutaneous lupus erythematosus*[5-7] may be due to photosensitivity reactions.

Other reported skin reactions include *vasculitis*,[8,9] *erythema multiforme*,[9] and *pseudoporphyria*.[10]

10. Motley RS. Pseudoporphyria due to Dyazide in a patient with vitiligo. *BMJ* 1990; **300:** 1468.

Gout. Thiazides have been associated with hyperuricaemia and gout in some patients. In the Medical Research Council Study on Mild to Moderate Hypertension,[1] a single-blinded trial, men taking bendroflumethiazide had higher incidences of gout than those receiving placebo (12.23 and 1.03 per 1000 patient-years, respectively). The risk appears to be dose-related; in a retrospective study[2] in patients aged 65 or older receiving antihypertensive therapy, there was a significantly increased risk of starting anti-gout therapy in patients taking the equivalent of 25 mg hydrochlorothiazide or more daily, but not in those on lower doses.

Withdrawal. For a report of oedema after abrupt withdrawal of thiazides, see under Precautions, below.

Treatment of Adverse Effects

Hypokalaemia in patients treated with thiazides may be avoided or treated by use with potassium or a potassium-sparing diuretic (but see the discussion on potassium supplements, under Effects on Electrolyte Balance in Adverse Effects, above). Hypokalaemia can also be reduced by moderate sodium restriction. With the exception of patients with conditions such as hepatic failure or renal disease, chloride deficiency is usually mild and does not require specific treatment. Apart from the rare occasions when it is life-threatening, dilutional hyponatraemia is best treated with water restriction rather than salt therapy; in true hyponatraemia, appropriate replacement is the treatment of choice (see p.1670).

In massive overdosage, treatment should be symptomatic and directed at fluid and electrolyte replacement. Use of activated charcoal should be considered if the patient presents within 1 hour of ingestion.

Precautions

All diuretics produce changes in fluid and electrolyte balance (see Adverse Effects, above). They should be used with caution in patients with existing fluid and electrolyte disturbances or who are at risk from changes in fluid and electrolyte balance, such as the elderly. They should be avoided in patients with severe hepatic impairment, in whom encephalopathy may be precipitated. Patients with hepatic cirrhosis are also more likely to develop hypokalaemia. Hyponatraemia may occur in patients with severe heart failure who are very oedematous, particularly with large doses of thiazides and restricted salt intake. All patients should be carefully observed for signs of fluid and electrolyte imbalance, especially in the presence of vomiting or during parenteral fluid therapy. Thiazides should not be given to patients with Addison's disease.

Diuretics should also be given with caution in renal impairment since they can further reduce renal function. Most thiazides are not effective in patients with a creatinine clearance of less than 30 mL/minute. They should not be used in patients with severe renal impairment or anuria.

Thiazides may precipitate attacks of gout in susceptible patients. They may cause hyperglycaemia and aggravate or unmask diabetes mellitus. Blood-glucose concentrations should be monitored in patients taking antidiabetics, since requirements may change. Thiazides can reduce urinary excretion of calcium, sometimes resulting in mild hypercalcaemia; they should not be given to patients with pre-existing hypercalcaemia. There is a possibility that thiazides may exacerbate or activate systemic lupus erythematosus in susceptible patients. For a suggestion that thiazides may increase the risk of developing gallstones, see Effects on the Gallbladder, above.

Thiazides cross the placenta and there have been reports of neonatal jaundice, thrombocytopenia, and electrolyte imbalances after maternal use. Reductions in maternal blood volume could also adversely affect placental perfusion. Treatment with large doses can inhibit lactation.

Breast feeding. Hydrochlorothiazide has been shown to pass into breast milk. In a woman taking 50 mg hydrochlorothiazide daily, peak milk concentrations were found[1] 5 to 10 hours after a dose and were about 25% of peak blood concentrations. No drug could be detected in the infant's blood, and his serum electrolytes, blood glucose, and blood urea nitrogen were normal. The American Academy of Pediatrics considers[2] that hydrochlorothiazide is usually compatible with breast feeding.

1. Miller ME, *et al.* Hydrochlorothiazide disposition in a mother and her breast-fed infant. *J Pediatr* 1982; **101:** 789–91.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 06/07/04)

Hyperparathyroidism. Hypertension is a complication of primary hyperparathyroidism but thiazides have often been withheld for fear of exacerbating hypercalcaemia. However, no differences in plasma-calcium concentrations were found in 13 patients given thiazides intermittently for up to 18 months. It was therefore concluded that thiazides are not contra-indicated in such patients.[1] They should, however, be stopped before parathyroid function is tested.

1. Farquhar CW, *et al.* Failure of thiazide diuretics to increase plasma calcium in mild primary hyperparathyroidism. *Postgrad Med J* 1990; **66:** 714–16.

Porphyria. Hydrochlorothiazide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Withdrawal. In patients with mild hypertension whose blood pressure is consistently controlled, reduction in dosage or withdrawal of antihypertensive drugs may be possible. Serious oedema occurred in 8 patients with controlled hypertension within 2 weeks of abrupt withdrawal of thiazide diuretics.[1] Thiazides were resumed and gradually tapered without recurrence of oedema.

1. Brandspigel K. Diuretic-withdrawal edema. *N Engl J Med* 1986; **314:** 515.

Interactions

Many of the interactions of hydrochlorothiazide and other thiazides are due to their effects on fluid and electrolyte balance. Diuretic-induced hypokalaemia may enhance the toxicity of digitalis glycosides and may also increase the risk of arrhythmias with drugs that prolong the QT interval, such as astemizole, terfenadine, halofantrine, pimozide, and sotalol. Thiazides may enhance the neuromuscular blocking action of competitive neuromuscular blockers, such as atracurium, probably by their hypokalaemic effect. The potassium-depleting effect of diuretics may be enhanced by corticosteroids, corticotropin, $beta_2$ agonists such as salbutamol, carbenoxolone, amphotericin B, or reboxetine.

Diuretics may enhance the effect of other antihypertensives, particularly the first-dose hypotension that occurs with alpha blockers or ACE inhibitors. Orthostatic hypotension associated with diuretics may be enhanced by alcohol, barbiturates, or opioids. The antihypertensive effects of diuretics may be antagonised by drugs that cause fluid retention, such as corticosteroids, NSAIDs, or carbenoxolone; diuretics may enhance the nephrotoxicity of NSAIDs. Thiazides have been reported to diminish the response to pressor amines, such as noradrenaline, but the clinical significance of this effect is uncertain.

Thiazides should not usually be used with lithium since the association may lead to toxic blood concentrations of lithium. Other drugs for which increased toxicity has been reported when given with thiazides include allopurinol and tetracyclines. Thiazides may alter the requirements for hypoglycaemics in diabetic patients.

Antibacterials. Severe hyponatraemia has been reported in patients taking *trimethoprim* with co-amilozide[1] and hydrochlorothiazide.[2]

1. Eastell R, Edmonds CJ. Hyponatraemia associated with trimethoprim and a diuretic. *BMJ* 1984; **289:** 1658–9.
2. Hart TL, *et al.* Hyponatremia secondary to thiazide-trimethoprim interaction. *Can J Hosp Pharm* 1989; **42:** 243–6.

Antiepileptics. There has been a report of symptomatic hyponatraemia associated with the use of hydrochlorothiazide or furosemide and *carbamazepine*.[1]

1. Yassa R, *et al.* Carbamazepine, diuretics, and hyponatremia: a possible interaction. *J Clin Psychiatry* 1987; **48:** 281–3.

Bile-acid binding resins. Gastrointestinal absorption of both chlorothiazide and hydrochlorothiazide has been reported to be reduced by *colestipol* and *colestyramine*.[1-3] In a study in healthy subjects[2] colestyramine had the greatest effect on hydrochlorothiazide, decreasing absorption by 85% compared with a decrease of 43% with colestipol. Even when colestyramine was given 4 hours after hydrochlorothiazide[3] reductions of absorption of at least 30 to 35% could be expected.

1. Kauffman RE, Azarnoff DL. Effect of colestipol on gastrointestinal absorption of chlorothiazide in man. *Clin Pharmacol Ther* 1973; **14:** 886–90.

3. Hunninghake DB, Hibbard DM. Influence of time intervals for cholestyramine dosing on the absorption of hydrochlorothiazide. *Clin Pharmacol Ther* 1986; **39:** 329–34.

Calcium salts. The milk-alkali syndrome, characterised by hypercalcaemia, metabolic alkalosis, and renal failure, developed in a patient taking chlorothiazide and moderately large doses of calcium carbonate.[1] Patients taking thiazides may be at increased risk of developing the syndrome because of their reduced ability to excrete excess calcium. Hypercalcaemia may also occur in patients taking thiazides with drugs that increase calcium levels, such as vitamin D.

1. Gora ML, *et al.* Milk-alkali syndrome associated with use of chlorothiazide and calcium carbonate. *Clin Pharm* 1989; **8:** 227–9.

Dopaminergics. For a report of increased *amantadine* toxicity associated with hydrochlorothiazide and triamterene, see p.793.

NSAIDs. NSAIDs cause fluid retention and may antagonise the diuretic actions of thiazides.[1]

1. Webster J. Interactions of NSAIDs with diuretics and β-blockers: mechanisms and clinical implications. *Drugs* 1985; **30:** 32–41.

Pharmacokinetics

Hydrochlorothiazide is fairly rapidly absorbed from the gastrointestinal tract. It is reported to have a bioavailability of about 65 to 70%. It has been estimated to have a plasma half-life of between about 5 and 15 hours and appears to be preferentially bound to red blood cells. It is excreted mainly unchanged in the urine. Hydrochlorothiazide crosses the placental barrier and is distributed into breast milk.

Uses and Administration

Hydrochlorothiazide and the other thiazide diuretics are used in the treatment of hypertension (p.1171), either alone or with other antihypertensives such as ACE inhibitors and beta blockers. They are also used to treat oedema associated with heart failure (p.1165) and with renal and hepatic disorders. Other indications have included the treatment of oedema accompanying the premenstrual syndrome (p.2099), the prevention of water retention associated with corticosteroids and oestrogens, the treatment of diabetes insipidus (below), and the prevention of renal calculus formation in patients with hypercalciuria (below).

Thiazides are moderately potent diuretics and exert their diuretic effect by reducing the reabsorption of electrolytes from the renal tubules, thereby increasing the excretion of sodium and chloride ions, and consequently of water. They act mainly at the beginning of the distal tubules. The excretion of other electrolytes, notably potassium and magnesium, is also increased. The excretion of calcium is reduced. They also reduce carbonic-anhydrase activity so that bicarbonate excretion is increased, but this effect is generally small compared with the effect on chloride excretion and does not appreciably alter the pH of the urine. They may also reduce the glomerular filtration rate.

Their hypotensive effect is probably partly due to a reduction in peripheral resistance; they also enhance the effects of other antihypertensives. Paradoxically, thiazides have an antidiuretic effect in patients with diabetes insipidus.

Administration and dosage. Thiazides are usually given in the morning so that sleep is not interrupted by diuresis. Diuresis starts in about 2 hours after oral doses of hydrochlorothiazide, reaches a maximum in about 4 hours, and lasts for 6 to 12 hours.

The dosage of thiazides should be adjusted to the minimum effective dose. In general lower doses are required for the treatment of hypertension than for oedema, although the maximum therapeutic effect may not be seen for several weeks.

They may be given to patients with mild renal impairment, but thiazides are generally not effective at a creatinine clearance of less than 30 mL/minute.

Hydrochlorothiazide is given orally.

In the treatment of **hypertension** an initial dose of 12.5 mg may be sufficient, increasing to 25 to 50 mg daily if necessary, either alone or with other antihypertensives. Doses of up to 100 mg have been suggested but are rarely necessary.

In the treatment of **oedema** the usual dose is 25 to 100 mg daily, reduced to a dose of 25 to 50 mg daily or intermittently; in severe cases initial doses of up to 200 mg daily have been suggested, but the more powerful loop diuretics (see Furosemide, p.1292) are preferred in such patients.

In the treatment of nephrogenic **diabetes insipidus** an initial dose of up to 100 mg daily may be used.

An initial dose for children has been 1 to 2 mg/kg daily in single or 2 divided doses. Infants under 6 months may need doses of up to 3 mg/kg daily.

For discussion of potassium supplementation in patients taking thiazide diuretics see Effects on Electrolyte Balance, under Adverse Effects, above.

Bronchopulmonary dysplasia. Bronchopulmonary dysplasia (p.1500) is a major cause of chronic lung disease in infants. Treatment often involves the use of corticosteroids. Additional supportive therapy has included the use of diuretics such as furosemide (p.1294); results with hydrochlorothiazide or spironolactone have been more ambiguous. No beneficial effects on lung function or oxygenation were found in a study of 12 infants after 1 week of treatment with hydrochlorothiazide and spironolactone.[1] However, hydrochlorothiazide and spironolactone therapy was found to improve total respiratory system compliance with decreased lung damage and increased survival rate in 34 premature infants with bronchopulmonary dysplasia after 8 weeks of therapy.[2] In the latter study furosemide was also given if clinically indicated.

1. Engelhardt B, *et al.* Effect of spironolactone-hydrochlorothiazide on lung function in infants with chronic bronchopulmonary dysplasia. *J Pediatr* 1989; **114:** 619–24.
2. Albersheim SG, *et al.* Randomized, double-blind, controlled trial of long-term diuretic therapy for bronchopulmonary dysplasia. *J Pediatr* 1989; **115:** 615–20.

Diabetes insipidus. Thiazide diuretics are used in nephrogenic diabetes insipidus (p.2179), sometimes with potassium-sparing diuretics. For instance, hydrochlorothiazide with amiloride was effective in controlling nephrogenic diabetes insipidus in 5 boys and compared favourably with treatment with hydrochlorothiazide and indometacin.[1] Treatment was well tolerated in 4 patients. Abdominal pain and anorexia necessitated withdrawal of amiloride in the fifth patient after 6 months. The use of hydrochlorothiazide with amiloride avoided the need for potassium supplements, which were required with hydrochlorothiazide and indometacin. The use of hydrochlorothiazide with amiloride was also effective and well tolerated in a group of 4 children with nephrogenic diabetes insipidus who were treated for up to 5 years.[2]

1. Knoers N, Monnens LAH. Amiloride-hydrochlorothiazide versus indomethacin-hydrochlorothiazide in the treatment of nephrogenic diabetes insipidus. *J Pediatr* 1990; **117:** 499–502.
2. Kirchlechner V, *et al.* Treatment of nephrogenic diabetes insipidus with hydrochlorothiazide and amiloride. *Arch Dis Child* 1999; **80:** 548–52.

Hypoparathyroidism. In hypoparathyroidism (p.1087), treatment is usually with oral vitamin D compounds to correct the hypocalcaemia. Thiazides may be useful in some patients. Beneficial effects on serum-calcium concentrations in patients with hypoparathyroidism have been reported after chlortalidone plus dietary salt restriction,[1] and with bendroflumethiazide.[2] However, chlortalidone has not been found to be effective in all patients,[3] and the reduction in urinary calcium excretion by thiazides has been shown to be diminished in patients with hypoparathyroidism,[4] suggesting that this effect may be dependent on the presence of active parathyroid hormone. Care should be taken when giving diuretics to hypoparathyroid patients with co-existing adrenal insufficiency[3] or metabolic alkalosis.[5]

5. Barzel US. Chlorthalidone for hypoparathyroidism. *N Engl J Med* 1978; **289:** 1478.

Ménière's disease. In Ménière's disease (p.564) there is an excess of endolymph fluid in the ear and diuretics such as hydrochlorothiazide have been used in attempts to relieve symptoms by reducing the amount of fluid.

Osteoporosis. Although some epidemiological studies have indicated beneficial effects of thiazides on bone (reduced rates of bone loss[1] and a reduced risk of hip fracture[2-5]) a comprehensive analysis involving 9704 women over the age of 65 years[6] showed only a small effect on bone mass, no effect on the risk for falls, and no overall protective effect against fractures. A further prospective study[7] reported a reduction in forearm fracture, but hip fracture was only reduced in postmenopausal women. Randomised, controlled studies[8,9] have confirmed that hydrochlorothiazide reduces bone loss, but again the effects were small. Thus, thiazides have no established role in the prevention or treatment of osteoporosis (p.1084). They might, however, be useful to reduce hypercalciuria in patients taking glucocorticoids[10] but serum-potassium concentrations should be monitored closely.

Preparations

BP 2008: Co-amilozide Oral Solution; Co-amilozide Tablets; Co-triamterzide Tablets; Hydrochlorothiazide Tablets;

USP 31: Amiloride Hydrochloride and Hydrochlorothiazide Tablets; Bisoprolol Fumarate and Hydrochlorothiazide Tablets; Captopril and Hydrochlorothiazide Tablets; Enalapril Maleate and Hydrochlorothiazide Tablets; Fosinopril Sodium and Hydrochlorothiazide Tablets; Hydrochlorothiazide Tablets; Irbesartan and Hydrochlorothiazide Tablets; Methyldopa and Hydrochlorothiazide Tablets; Metoprolol Tartrate and Hydrochlorothiazide Tablets; Propranolol Hydrochloride and Hydrochlorothiazide Extended-release Capsules; Propranolol Hydrochloride and Hydrochlorothiazide Tablets; Reserpine and Hydrochlorothiazide Tablets; Reserpine, Hydralazine Hydrochloride, and Hydrochlorothiazide Tablets; Spironolactone and Hydrochlorothiazide Tablets; Timolol Maleate and Hydrochlorothiazide Tablets; Triamterene and Hydrochlorothiazide Capsules; Triamterene and Hydrochlorothiazide Tablets; Valsartan and Hydrochlorothiazide Tablets.

Proprietary Preparations (details are given in Part 3)

Hydroflumethiazide *(BAN, rINN)* ⊗

Hidroflumetiazida; Hydrofluméthiazide; Hydroflumethiazidum; Hydroflumetiatsidi; Hydroflumetiazid; Trifluoromethylhydrothiazide. 3,4-Dihydro-6-trifluoromethyl-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

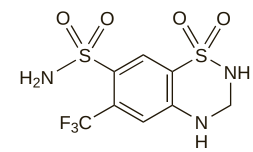
Гидрофлуметиазид

$C_8H_8F_3N_3O_4S_2$ = 331.3.

CAS — 135-09-1.

ATC — C03AA02.

ATC Vet — QC03AA02.



NOTE. Compounded preparations of hydroflumethiazide may be represented by the following names:

- Co-flumactone (*BAN*)—hydroflumethiazide and spironolactone in equal parts (w/w).

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Hydroflumethiazide). White or almost white, odourless or almost odourless, glistening crystals or crystalline powder. Practically insoluble in water; soluble in alcohol; practically insoluble in chloroform and in ether.

USP 31 (Hydroflumethiazide). A white to cream-coloured, odourless, finely divided crystalline powder. Very slightly soluble in water and in chloroform; soluble 1 in 39 of alcohol and 1 in 2500 of ether; freely soluble in acetone. A 1% dispersion in water has a pH of 4.5 to 7.5. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Hydroflumethiazide is incompletely but fairly rapidly absorbed from the gastrointestinal tract. It is reported to have a beta-phase biological half-life of about 17 hours and a metabolite with a longer half-life that is extensively bound to red blood cells. Hydroflumethiazide is excreted in the urine; its metabolite has also been detected in the urine.

◊ References.

1. Brørs O, *et al.* Pharmacokinetics of a single dose of hydroflumethiazide in health and in cardiac failure. *Eur J Clin Pharmacol* 1978; **14:** 29–37.

Uses and Administration

Hydroflumethiazide is a thiazide diuretic with actions and uses similar to those of hydrochlorothiazide (p.1310). It is given orally for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Diuresis begins about 2 hours after an oral dose and has been reported to last for up to 24 hours.

In the treatment of **oedema** the usual initial dose is 50 to 100 mg daily, in one or two divided doses, reduced to a dose of 25 to 50 mg on alternate days or intermittently. Doses of up to 200 mg daily may be required by some patients. In the treatment of **hypertension** the usual dose is 25 to 50 mg daily either alone, or with other antihypertensives. An initial dose of 12.5 mg has been used.

An initial dose for children is 1 mg/kg daily, reduced for maintenance.

Pharmacopoeias. In *Fr.*

Profile

Hydroquinidine is a class Ia antiarrhythmic with actions and uses similar to those of quinidine (p.1383). It is given orally as the hydrochloride in a usual maintenance dose of 600 mg daily in divided doses.

Hydroquinidine alginate and quinalbital (the hydroquinidine salt of amobarbital) have also been used in the treatment of cardiac arrhythmias.

Adverse Effects and Precautions

As for Sympathomimetics, p.1407. Ibopamine should not be used in patients with severe heart failure in whom, similarly to xamoterol (p.1433), it has been reported to increase the risk of death.

Effects on the cardiovascular system. A multicentre study (PRIME II) of the use of ibopamine in patients with severe (NYHA class III or IV) heart failure was stopped early when it was found that the drug was associated with an increased risk of death.[1] Subgroup analysis found that use of an antiarrhythmic drug was independently predictive of an adverse effect in ibopamine-treated patients. Excess mortality in heart failure has also been reported with dobutamine and xamoterol, and with flosequinan and the phosphodiesterase inhibitors amrinone, enoximone, milrinone, and vesnarinone, all of which produce positive inotropic effects through catecholamine-receptor stimulation or post-receptor pathway stimulation.[2] The association with antiarrhythmic therapy in the ibopamine study might reflect an interaction with amiodarone, the most commonly used antiarrhythmic in this study, or might simply be a marker for patients at risk of ibopamine-induced tachyarrhythmias.

1. Hampton JR, *et al.* Randomised study of effect of ibopamine on survival in patients with advanced severe heart failure. *Lancet* 1997; **349:** 971–7.
2. Niebauer J, Coats AJS. Treating chronic heart failure: time to take stock. *Lancet* 1997; **349:** 966–7.

Interactions

As for Sympathomimetics, p.1407. It has been recommended that ibopamine should not be given to patients taking amiodarone in the light of the increased mortality seen in the PRIME II study in patients given both drugs (see above), although it is not clear that this represents a genuine interaction.

Uses and Administration

Ibopamine is a prodrug and is rapidly converted to its active metabolite, epinine, which is a peripheral dopamine agonist and sympathomimetic (p.1408). At low doses its dopaminergic effects predominate, leading to vasodilatation and a weak positive inotropic effect; at high concentrations it has a stimulant action on alpha and beta adrenoceptors.

Ibopamine is used in the management of mild heart failure (p.1165). It is given as the hydrochloride but doses are often expressed in terms of the base; 111.9 mg of hydrochloride is equivalent to about 100 mg of base. Doses of 100 to 200 mg orally two or three times daily have been used.

Ibopamine is also used topically as a mydriatic (p.1874) in the form of eye drops containing ibopamine hydrochloride 2%.

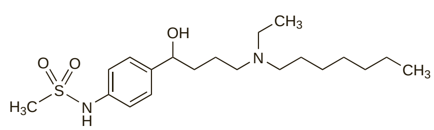
ATC — C01BD05.

ATC Vet — QC01BD05.



(ibutilide)

Adverse Effects

Adverse cardiovascular effects associated with ibutilide include heart block, hypotension, hypertension, and bradycardia. It prolongs the QT interval and, like other antiarrhythmics, can cause arrhythmias, including torsade de pointes. Other adverse effects include nausea and vomiting.

Effects on the heart. Ibutilide prolongs the QT interval and has been associated with torsade de pointes, particularly in women.[1] A small study[2] suggested that this effect could be prevented by magnesium sulfate (p.1679), which might therefore be suitable for use as prophylaxis. Although magnesium could theoretically reduce the antiarrhythmic effect of ibutilide as well as the proarrhythmic effect, a retrospective study[3] found that the rate of cardioversion was higher in patients given both ibutilide and magnesium than in those given ibutilide alone, an effect confirmed in a later study.[4]

1. Gowda RM, *et al.* Female preponderance in ibutilide-induced torsade de pointes. *Int J Cardiol* 2004; **95:** 219–22.
2. Caron MF, *et al.* Effects of intravenous magnesium sulfate on the QT interval in patients receiving ibutilide. *Pharmacotherapy* 2003; **23:** 296–300.
3. Kalus JS, *et al.* Impact of prophylactic i.v. magnesium on the efficacy of ibutilide for conversion of atrial fibrillation or flutter. *Am J Health-Syst Pharm* 2003; **60:** 2308–12.
4. Tercius AJ, *et al.* Intravenous magnesium sulfate enhances the ability of intravenous ibutilide to successfully convert atrial fibrillation or flutter. *Pacing Clin Electrophysiol* 2007; **30:** 1331–5.

Effects on the kidneys. Acute renal failure with biopsy evidence of acute tubular necrosis developed in a 52-year-old man shortly after he received 2 doses of ibutilide for an episode of atrial flutter.[1] Renal function returned to normal after 4 sessions of haemodialysis.

1. Franz M, *et al.* Acute renal failure after ibutilide. *Lancet* 1999; **353:** 467.

Precautions

ECG monitoring should be carried out during, and for at least 4 hours after, ibutilide infusion, and the infusion should be stopped if the QT interval becomes markedly prolonged. Electrolyte abnormalities should be corrected before treatment is started.

Interactions

Use of ibutilide with other antiarrhythmics or drugs that prolong the QT interval should be avoided.

Magnesium. For the synergistic effect of magnesium and ibutilide in producing cardioversion, see Effects on the Heart, above.

Pharmacokinetics

Ibutilide is widely distributed in the body after intravenous infusion. It has low plasma protein binding (about 40%) and undergoes extensive metabolism in the liver to form several metabolites. Ibutilide is excreted mainly in the urine, as metabolites and a small amount of unchanged drug (about 7%), with about 19% being excreted in the faeces. The elimination half-life is reported to range from 2 to 12 hours.

Uses and Administration

Ibutilide is a class III antiarrhythmic (p.1153) used for the acute treatment of atrial fibrillation or flutter (p.1160).

Ibutilide is given intravenously as the fumarate. For the termination of atrial fibrillation or flutter, ibutilide fumarate is given as a single dose of 1 mg in patients weighing 60 kg and over, or 10 micrograms/kg in patients weighing less than 60 kg, infused over 10 minutes; the infusion should be stopped as soon as the arrhythmia is terminated. If the arrhythmia persists 10 minutes after completion of the infusion, a second infusion of the same dose may be given.

Adverse Effects and Precautions

As for Epoprostenol, p.1279. Inhaled iloprost may cause cough.

Effects on the cardiovascular system. Hypotension was observed[1] in 2 of 6 patients given iloprost. Both patients recovered rapidly when iloprost was stopped, although one required intravenous atropine to correct sinus bradycardia.

Evidence of myocardial ischaemia was reported in 4 of 33 patients with coronary artery disease during iloprost infusion.[2] The same authors[3] noted a similar effect in 4 of 28 patients with stable angina in a subsequent study. According to one study,[4] there might be an increased risk of thromboembolism in some patients given iloprost, due to platelet activation and enhanced coagulation.

4. Kovacs IB, *et al.* Infusion of a stable prostacyclin analogue, iloprost, to patients with peripheral vascular disease: lack of antiplatelet effect but risk of thromboembolism. *Am J Med* 1991; **90:** 41–6.

Pregnancy. For reference to the successful use of iloprost in pregnancy see Pulmonary Hypertension, under Uses and Administration, below.

Interactions

Iloprost may increase the effect of other vasodilators and antihypertensives. The use of iloprost with other inhibitors of platelet aggregation may increase the risk of bleeding.

Pharmacokinetics

On intravenous infusion iloprost is rapidly cleared from the plasma by oxidation. About 80% of the metabolites are excreted in urine and 20% in the bile.

Uses and Administration

Iloprost, a vasodilator and platelet aggregation inhibitor, is a stable analogue of the prostaglandin epoprostenol (prostacyclin). It is given as the trometamol salt in the treatment of peripheral vascular disease and pulmonary hypertension but doses are described in terms of iloprost; 1.3 nanograms of iloprost trometamol is equivalent to about 1 nanogram of iloprost.

The usual dose for peripheral vascular disease is the equivalent of iloprost 0.5 to 2 nanograms/kg per minute for 6 hours daily by intravenous infusion. The course of treatment may be up to 4 weeks. For pulmonary hypertension, the dose is 1 to 8 nanograms/kg per minute for 6 hours daily; alternatively, iloprost may be given by nebulised solution at a dose of 2.5 or 5 micrograms inhaled 6 to 9 times daily. Doses should be reduced in patients with hepatic or renal impairment (see below).

Oral iloprost is under investigation.

◊ Reviews.

1. Grant SM, Goa KL. Iloprost: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic potential in peripheral vascular disease, myocardial ischaemia and extracorporeal circulation procedures. *Drugs* 1992; **43:** 889–924.

Administration in hepatic or renal impairment. The dose of intravenous iloprost should be reduced, and may need to be halved, in patients with liver cirrhosis or renal impairment requiring dialysis. In hepatic impairment, the initial dose of inhaled iloprost should be 2.5 micrograms given at intervals of at least 3 hours to a maximum of 6 times daily; the dose may be cautiously increased or given more frequently according to patient response.

Peripheral vascular disease. Prostaglandins, including iloprost,[1-10] have been used in the treatment of peripheral vascular disease (p.1178), particularly in severe Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188), but do not constitute mainline therapy. Systematic review[10] suggests that intravenous iloprost produces prolonged benefit in Raynaud's phenomenon secondary to scleroderma. The benefits of oral iloprost are less clear. It is also unclear whether iloprost infusion is of benefit in occlusive peripheral arterial disease due to atherosclerosis: although a meta-analysis of (conflicting) controlled trials did suggest an effect,[6] firm conclusions are difficult.

Pulmonary hypertension. Epoprostenol is an accepted part of the management of pulmonary hypertension (p.1179) and the use of iloprost, a stable analogue, has been studied. Inhaled iloprost may have a role;[1] it was found[2] to improve walking-test distances, reduce severity of heart failure, and stabilise haemodynamic measures in a 12-week study of patients with severe pulmonary hypertension, while long-term treatment of at least 1 year has been reported to have sustained beneficial effects.[3] Iloprost has also been used successfully in a few cases to manage pulmonary hypertension in pregnant women.[4] There are also reports of effective combination therapy using inhaled iloprost with intravenous epoprostenol,[5] oral sildenafil,[6] or oral bosentan.[7] Continuous intravenous infusion[8] has also been tried with beneficial results over several weeks, and short-term intravenous infusion for 7 days[9] has been successfully used for pulmonary hypertension after pulmonary thromboendarterectomy.

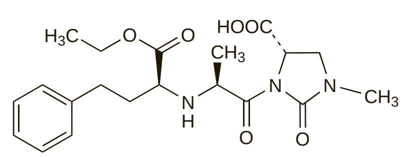
ATC — C09AA16.

ATC Vet — QC09AA16.



(imidapril)

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Imidapril acts as a prodrug of the diacid imidaprilat, its active metabolite. After oral doses, imidapril is rapidly but incompletely absorbed; absorption is about 70% and is reduced in the presence of food. Imidapril is metabolised in the liver to imidaprilat. The bioavailability of imidaprilat is about 42% after oral doses of imidapril, and peak plasma concentrations of imidaprilat are reached in about 7 hours. Both imidapril and imidaprilat are moderately bound to plasma proteins. About 40% of an oral dose is excreted in the urine, the rest in the faeces. The terminal half-life of imidaprilat is more than 24 hours. Imidapril and imidaprilat are removed by haemodialysis.

Uses and Administration

Imidapril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171). Imidapril owes its activity to imidaprilat, to which it is converted after oral doses. The maximum haemodynamic effect occurs 6 to 8 hours after a dose, although the full effect may not develop for several weeks during chronic dosing. Imidapril is given orally as the hydrochloride.

In the treatment of hypertension, the usual initial dose of imidapril hydrochloride is 5 mg once daily, before food. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. An initial dose of 2.5 mg daily should be used in the elderly, in patients with renal or hepatic impairment, or in those receiving a *diuretic*; if possible, the diuretic should be withdrawn 2 or 3 days before imidapril is started and resumed later if necessary. The usual maintenance dose is 10 mg daily, although up to 20 mg daily may be given if required. The maximum dose for elderly patients is 10 mg daily.

Indapamide *(BAN, USAN, rINN)* ⊗

Indapamid; Indapamida; Indapamidi; Indapamidum; SE-1520. 4-Chloro-*N*-(2-methylindolin-1-yl)-3-sulphamoylbenzamide.

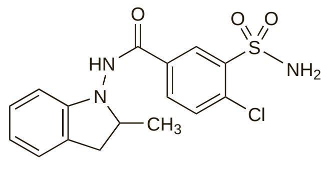
Индапамид

$C_{16}H_{16}ClN_3O_3S$ = 365.8.

CAS — 26807-65-8 (anhydrous indapamide).

ATC — C03BA11.

ATC Vet — QC03BA11.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Indapamide). A white or almost white powder. Practically insoluble in water; soluble in alcohol. Protect from light.

USP 31 (Indapamide). A white to off-white crystalline powder. Practically insoluble in water; soluble in alcohol, in glacial acetic acid, in acetonitrile, in ethyl acetate, and in methyl alcohol; very slightly soluble in chloroform and in ether.

Adverse Effects, Treatment, and Precautions

As for Hydrochlorothiazide, p.1307.

Effects on the blood. A 58-year-old woman[1] had bleeding from the mucous membrane of the tongue 18 months after starting treatment with a modified-release form of indapamide; she was found to have mild thrombocytopenia, and petechiae were observed. After withdrawal of the drug, bleeding stopped immediately; the platelet count returned to normal within 10 days and the skin lesions faded quickly.

1. Hasanova EA, Agasiyeva NE. Bleeding associated with indapamide SR therapy. *Ann Pharmacother* 2005; **39:** 199–200.

Effects on carbohydrate and lipid metabolism. Several studies have reported no changes in blood-glucose concentrations during indapamide treatment,[1-3] although elevated concentrations have been reported in individual patients.[4,5] There have been reports of increases in total cholesterol[2] and of no change.[3] No adverse biochemical changes were found in studies[6] of a modified-release preparation.

Effects on electrolyte balance. It has been claimed that indapamide produces few adverse biochemical effects at the usual dose of 2.5 mg daily. However, by 2002, 164 cases of hyponatraemia had been reported to the Australian Adverse Drug Reactions Advisory Committee (ADRAC)[1], of which 68 also described hypokalaemia. Most patients were elderly women. A review[2] of some of these cases suggested that hyponatraemia was more commonly reported with indapamide than with chlorothiazide, although it was pointed out[3] that the true incidence cannot be determined from spontaneous reports. ADRAC recommends that indapamide should be used cautiously. It may be that indapamide has no clinical advantage over low-dose thiazide diuretics.

1. Australian Adverse Drug Reactions Advisory Committee (ADRAC). Indapamide and hyponatraemia. *Aust Adverse Drug React Bull* 2002; **21:** 11. Also available at: http://www.tga.health.gov.au/adr/aadrb/aadr0208.htm (accessed 06/07/04)

Effects on the kidneys. Acute interstitial nephritis was associated with indapamide treatment in a 74-year-old patient.[1]

1. Newstead CG, *et al.* Interstitial nephritis associated with indapamide. *BMJ* 1990; **300:** 1344.

Effects on the skin. Sixteen cases of skin rash attributed to indapamide had been reported to the Netherlands Centre for Monitoring of Adverse Reactions to Drugs.[1] All patients had taken indapamide 2.5 mg daily for hypertension. The skin rash was accompanied by fever in 5 cases. In all cases the rash subsided within 14 days of withdrawal, and 11 patients subsequently took thiazides, furosemide, or clopamide without recurrence. Among 188 cases of skin rash attributed to indapamide reported to the WHO Collaborating Centre for International Drug Monitoring were 4 cases of erythema multiforme and 2 of epidermal necrolysis. A further case of toxic epidermal necrolysis was reported by independent authors.[2]

1. Stricker BHC, Biriell C. Skin reactions and fever with indapamide. *BMJ* 1987; **295:** 1313–14.
2. Black RJ, *et al.* Toxic epidermal necrolysis associated with indapamide. *BMJ* 1990; **301:** 1280–1.

Interactions

As for Hydrochlorothiazide, p.1309.

Pharmacokinetics

Indapamide is rapidly and completely absorbed from the gastrointestinal tract. Elimination is biphasic with a half-life in whole blood of about 14 hours. Indapamide is strongly bound to red blood cells. It is extensively metabolised. About 60 to 70% of the dose has been reported to be excreted in the urine; only about 5 to 7% is excreted unchanged. About 16 to 23% of dose is excreted in the faeces. Indapamide is not removed by haemodialysis but does not accumulate in patients with renal impairment.

◊ References.

1. Beermann B, Grind M. Clinical pharmacokinetics of some newer diuretics. *Clin Pharmacokinet* 1987; **13:** 254–66.

Uses and Administration

Indapamide is a diuretic with actions and uses similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1310) even though it does not contain a thiazide ring system. It is used for hypertension (p.1171), and also for oedema, including that associated with heart failure (p.1165).

In some countries indapamide is described as the hemihydrate. In the treatment of **hypertension** the usual oral dose is 1.25 to 2.5 mg once daily, either alone, or with other antihypertensives; a modified-release preparation may be given in a dose of 1.5 mg daily. At higher doses the diuretic effect may become apparent without appreciable additional antihypertensive effect although US licensed product information suggests that the dose may be increased to 5 mg after 4 weeks. In the treatment of **oedema** the usual dose is 2.5 mg once daily increasing to 5 mg daily after 1 week if necessary.

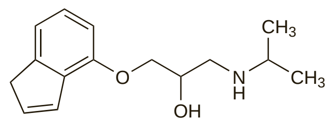
Indenolol Hydrochloride *(BANM, rINNM)* ⊗

Hidrocloruro de indenolol; Indénolol, Chlorhydrate d'; Indenololi Hydrochloridum; Sch-28316Z (indenolol); YB-2.

Инденолола Гидрохлорид

$C_{15}H_{21}NO_2$,HCl = 283.8.

CAS — 60607-68-3 (indenolol); 68906-88-7 (indenolol hydrochloride).



(indenolol)

Description. Indenolol hydrochloride is a 2:1 tautomeric mixture of 1-(inden-7-yloxy)-3-isopropylaminopropan-2-ol hydrochloride and 1-(inden-4-yloxy)-3-isopropylaminopropan-2-ol hydrochloride.

Pharmacopoeias. In *Jpn.*

Profile

Indenolol is a non-cardioselective beta blocker (p.1225). It is reported to possess potent membrane-stabilising properties and intrinsic sympathomimetic activity.

Indenolol has been used orally as the hydrochloride in the management of various cardiovascular disorders.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Securpres†.

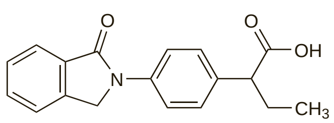
Indobufen *(rINN)*

Indobufén; Indobufène; Indobufenum; K-3920. (±)-2-[4-(1-Oxoisoindolin-2-yl)phenyl]butyric acid.

Индобуфен

$C_{18}H_{17}NO_3$ = 295.3.

CAS — 63610-08-2.
ATC — B01AC10.
ATC Vet — QB01AC10.



Profile

Indobufen is an inhibitor of platelet aggregation used in various thromboembolic disorders (p.1187) in oral doses of 200 to 400 mg daily given in 2 divided doses. For patients over the age of 65, the dose should be reduced to 100 to 200 mg daily. Doses should also be reduced in renal impairment (see below). Indobufen has also been given parenterally as the sodium salt.

◊ References.

Indoramin Hydrochloride

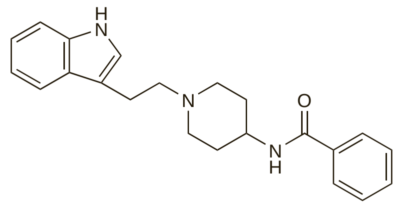
(BANM, USAN, rINNM)

Hidrocloruro de indoramina; Indoramine, Chlorhydrate d'; Indoramini Hydrochloridum; Wy-21901 (indoramin). *N*-[1-(2-Indol-3-ylethyl)-4-piperidyl]benzamide hydrochloride.

Индорамина Гидрохлорид

$C_{22}H_{25}N_3O$,HCl = 383.9.

CAS — 26844-12-2 (indoramin); 33124-53-7 (indoramin hydrochloride); 38821-52-2 (indoramin hydrochloride).
ATC — C02CA02.
ATC Vet — QC02CA02.



(indoramin)

Pharmacopoeias. In *Br.*
BP 2008 (Indoramin Hydrochloride). A white or almost white powder. It exhibits polymorphism. Slightly soluble in water; sparingly soluble in alcohol; very slightly soluble in ether; soluble in methyl alcohol. A 2% suspension in water has a pH of 4.0 to 5.5. Protect from light.

Adverse Effects, Treatment, and Precautions

The most common adverse effects in patients receiving indoramin are sedation and dizziness; dry mouth, nasal congestion, headache, fatigue, depression, weight gain (almost certainly due to fluid retention), and failure of ejaculation may also occur. Tachycardia does not seem to be a problem with therapeutic doses but orthostatic hypotension may occur and may produce syncope. Extrapyramidal disturbances have been reported.

After overdosage, coma, convulsions, and hypotension may occur; hypothermia has been reported in *animals.* In acute poisoning appropriate symptomatic and supportive care should be given; if the patient presents within 1 hour, activated charcoal may be considered.

Indoramin should be avoided in patients with heart failure; it has been recommended that incipient heart failure should be controlled before giving indoramin. Caution should be observed in patients with hepatic or renal impairment, a history of depression, epilepsy, or Parkinson's disease. Elderly patients may respond to lower doses.

Because indoramin can cause drowsiness care should be taken in patients who drive or operate machinery.

Cataract surgery. For a warning about intraoperative floppy iris syndrome during cataract surgery in patients taking alpha blockers, see Surgical Procedures, under Precautions for Tamsulosin Hydrochloride, p.2197.

Effects on mental function. Sleep disturbances and vivid dreams were reported during a study in hypertensive patients when indoramin was added to therapy with a thiazide diuretic and a beta blocker.[1]

1. Marshall AJ, *et al.* Evaluation of indoramin added to oxprenolol and bendrofluazide as a third agent in severe hypertension. *Br J Clin Pharmacol* 1980; **10:** 217–21.

Overdosage. A 43-year-old woman with a long history of heavy alcohol intake died after taking 100 tablets of indoramin 25 mg.[1] The main clinical features were deep sedation, respiratory depression, hypotension, and convulsions. Although the hypotension was satisfactorily controlled the CNS effects were resistant to treatment and proved fatal. Other clinical features included areflexia, metabolic acidosis, tachycardia, and later bradyarrhythmias.

1. Hunter R. Death due to overdose of indoramin. *BMJ* 1982; **285:** 1011.

Interactions

The hypotensive effects of indoramin may be enhanced by diuretics and other antihypertensives. It has been reported that the ingestion of alcohol can increase the rate and extent of absorption and the sedative effects of indoramin (see below) and that indoramin should not be given to patients already receiving MAOIs.

Alcohol. In a study[1] in 9 healthy subjects alcohol 500 mg/kg significantly enhanced plasma-indoramin concentrations after an oral dose of 50 mg. The effect was most marked in the early period, corresponding to the absorptive phase. The mean maximum plasma-indoramin concentration was increased from 15.0 to 23.7 nanograms/mL by alcohol; the area under the concentration/time curve was increased by 25%. Alcohol did not affect the pharmacokinetics of intravenous indoramin. The results suggest that alcohol increases indoramin bioavailability either by enhancing absorption or reducing first-pass metabolism. The combination was more sedative than either drug alone.

1. Abrams SML, *et al.* Pharmacokinetic interaction between indoramin and ethanol. *Hum Toxicol* 1989; **8:** 237–41.

Pharmacokinetics

Indoramin is readily absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism. It is reported to be about 90% bound to plasma proteins. It has a half-life of about 5 hours which is reported to be prolonged in elderly patients. It is extensively metabolised and is excreted mainly as metabolites in the urine and faeces. There is evidence to suggest that some metabolites may have some alpha-adrenoceptor blocking activity.

The elderly. The plasma half-life of indoramin in 5 healthy elderly subjects following a single oral dose ranged from 6.6 to 32.8 hours with a mean of 14.7 hours.[1] The increased half-life may have been caused by reduced clearance in elderly patients.

1. Norbury HM, *et al.* Pharmacokinetics of oral indoramin in elderly and middle-aged female volunteers. *Eur J Clin Pharmacol* 1984; **27:** 247–9.

Uses and Administration

Indoramin is a selective and competitive $alpha_1$-adrenoceptor blocker (p.1153) with actions similar to those of prazosin (p.1376); it is also reported to have membrane-stabilising properties and to be a competitive antagonist at histamine H_1 and 5-hydroxytryptamine receptors. Indoramin is used in the management of hypertension (p.1171), and in benign prostatic hyperplasia (p.2178) to relieve symptoms of urinary obstruction. It has also been used in the prophylactic treatment of migraine.

Indoramin is given orally as the hydrochloride, but doses are usually expressed in terms of the base. Indoramin hydrochloride 11.0 mg is equivalent to about 10 mg of indoramin.

In **hypertension**, the initial dose is 25 mg twice daily, increased in steps of 25 or 50 mg at intervals of 2 weeks to a maximum of 200 mg daily in 2 or 3 divided doses.

In **benign prostatic hyperplasia**, the initial dose is 20 mg twice daily, increased if necessary by 20 mg at 2-week intervals, to a maximum of 100 mg daily in divided doses.

Lower doses may be required in the elderly.

◊ Reviews.

1. Holmes B, Sorkin EM. Indoramin: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic efficacy in hypertension and related vascular, cardiovascular and airway diseases. *Drugs* 1986; **31:** 467–99.

Migraine. Propranolol is probably the most well-established drug for prophylaxis of migraine (p.616). Many other drugs have been used including indoramin. In a double-blind study,[1] indoramin in a dose of 25 mg twice daily was reported to be as effective as dihydroergotamine mesilate in reducing the frequency of migraine attacks.

1. Pradalier A, *et al.* Etude comparative indoramine versus dihydroergotamine dans le traitement préventif de la migraine. *Therapie* 1988; **43:** 293–7.

Irbesartan *(BAN, USAN, rINN)*

BMS-186295; Irbesartaani; Irbésartan; Irbesartán; Irbesartanum; SR-47436. 2-Butyl-3-[*p*-(*o*-1*H*-tetrazol-5-ylphenyl)benzyl]-1,3-diazaspiro[4.4]non-1-en-4-one.

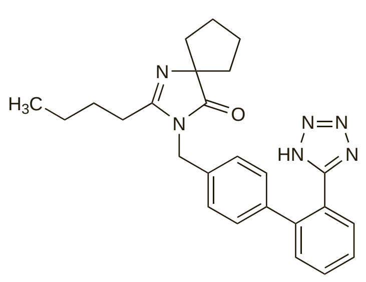
Ирбесартан

$C_{25}H_{28}N_6O$ = 428.5.

CAS — 138402-11-6.

ATC — C09CA04.

ATC Vet — QC09CA04.



Pharmacopoeias. In *US.*

USP 31 (Irbesartan). A white to off-white, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane. Store in airtight containers at a temperature below 30°.

Adverse Effects and Precautions

As for Losartan Potassium, p.1326.

Interactions

As for Losartan Potassium, p.1327.

Pharmacokinetics

Irbesartan is rapidly absorbed from the gastrointestinal tract with an oral bioavailability of 60 to 80%. Peak plasma concentrations of irbesartan occur 1.5 to 2 hours after an oral dose. Irbesartan is about 96% bound to plasma proteins. It undergoes some metabolism in the liver, primarily by the cytochrome P450 isoenzyme CYP2C9, to inactive metabolites. It is excreted as unchanged drug and metabolites in the bile and in urine; about 20% of an oral or intravenous dose is excreted in the urine, with less than 2% as unchanged drug. The terminal elimination half-life is about 11 to 15 hours.

6. Sakarcan A, *et al.* The pharmacokinetics of irbesartan in hypertensive children and adolescents. *J Clin Pharmacol* 2001; **41:** 742–9.

Uses and Administration

Irbesartan is an angiotensin II receptor antagonist with actions similar to those of losartan (p.1327). It is used in the management of hypertension (p.1171) including the treatment of renal disease in hypertensive diabetic patients (see Kidney Disorders, under Uses of Losartan, p.1328). Irbesartan is also under investigation in heart failure.

Irbesartan is given orally. After a dose the hypotensive effect peaks within 3 to 6 hours and persists for at least 24 hours. The maximum hypotensive effect is achieved within 4 to 6 weeks after starting therapy.

In **hypertension**, irbesartan is given in a dose of 150 mg once daily increased, if necessary, to 300 mg once daily. A lower initial dose of 75 mg once daily may be considered in elderly patients over 75 years, for patients with intravascular volume depletion, and for those receiving haemodialysis.

For the treatment of **renal disease** in hypertensive type 2 diabetics, irbesartan should be given in an initial dose of 150 mg once daily, increased to 300 mg once daily for maintenance.

Administration in children. Although irbesartan appears to be well-tolerated in children with hypertension and has been shown to reduce blood pressure in small studies,[1] US licensed product information notes that doses of up to 4.5 mg/kg once daily were ineffective in children aged 6 to 16 years and no longer recommends use in such patients.

In children with chronic kidney diseases, irbesartan has been reported to reduce blood pressure and proteinuria.[2,3] The initial dose was 37.5 mg once daily for children weighing 10 to 20 kg, 75 mg once daily for those weighing 21 to 40 kg, and 150 mg once daily for those weighing more than 40 kg; doses could be doubled if the blood pressure response was inadequate.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Isoprenaline Sulphate). A white or almost white crystalline powder. Freely soluble in water; very slightly soluble in alcohol. A 5% solution in water has a pH of 4.3 to 5.5. Store in airtight containers. Protect from light.

USP 31 (Isoproterenol Sulfate). A white to practically white, odourless, crystalline powder. It gradually darkens on exposure to light and air. Soluble 1 in 4 of water; very slightly soluble in alcohol, in chloroform, in ether, and in benzene. A 1% solution in water has a pH of about 5. Solutions become pink to brownish-pink on standing exposed to air, and almost immediately so when made alkaline. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Sympathomimetics, p.1407. Isoprenaline has almost exclusively beta-agonist properties but also stimulates the CNS; its main adverse effects include tachycardia and cardiac arrhythmias, palpitations, hypotension, tremor, headache, sweating, and facial flushing. Prolonged use of isoprenaline has been associated with swelling of the parotid glands.

Prolonged use of sublingual tablets may also cause severe damage to the teeth due to the acidic nature of the drug. Sublingual use or inhalation may colour the saliva or sputum red.

Increased mortality. For a discussion of the increased mortality and morbidity that has sometimes been observed in asthmatic patients using beta agonists and reference to an early epidemic associated with isoprenaline inhalers, see Fenoterol, p.1121.

Interactions

As for Sympathomimetics, p.1407. Due to the risk of arrhythmias, isoprenaline should not be used with other potent $beta_1$ agonists such as adrenaline.

Theophylline. For reports of increased theophylline clearance following use of isoprenaline, see p.1145.

Pharmacokinetics

As a result of sulfate conjugation in the gut, isoprenaline is considerably less active orally than after parenteral doses. It is absorbed through the oral mucosa and has accordingly been given sublingually, but absorption by this route remains very erratic. Isoprenaline in the body is resistant to metabolism by monoamine oxidase, but is metabolised by catechol-*O*-methyltransferase in the liver, lungs, and other tissues, the metabolite then being conjugated before excretion in the urine. Whereas the sulfate conjugate of isoprenaline is inactive the methylated metabolite exhibits weak activity.

After intravenous injection isoprenaline has a plasma half-life of about one to several minutes according to whether the rate of injection is rapid or slow; it is almost entirely excreted in the urine as unchanged drug and metabolites within 24 hours. A much slower onset of action and a more extended initial half-life has been found after oral dosage. Isoprenaline is reported to have a duration of action of up to about 2 hours after inhalation; it has been shown that a large proportion of an inhaled dose is swallowed.

Uses and Administration

Isoprenaline is a sympathomimetic (p.1408) that acts almost exclusively on beta-adrenergic receptors. It has a powerful stimulating action on the heart and increases cardiac output, excitability, and rate; it also causes peripheral vasodilatation and produces a fall in diastolic blood pressure and usually maintains or slightly increases systolic blood pressure. In addition, isoprenaline has bronchodilating properties. It also stimulates the CNS.

Isoprenaline has been used in a variety of cardiac disorders. It may be used for the temporary prevention or control of Stokes-Adams attacks and in severe bradycardia unresponsive to atropine, but use of a pacemaker is preferred. It has also been advocated as an adjunct for other cardiac disorders including shock (p.1183) and torsade de pointes (see Cardiac Arrhythmias, p.1160). It has been used in the diagnosis of congenital heart defects.

In the management of **cardiac disorders**, isoprenaline is usually given as the hydrochloride by slow intravenous infusion under ECG control. Infusion rates may range from 0.5 to 10 micrograms/minute depending on the clinical condition of the patient; 1 to 4 micrograms/minute may be adequate to correct bradycardia but rates of 4 to 8 micrograms/minute may be required for acute Stokes-Adams attacks. Isoprenaline hydrochloride can be given by intracardiac injection in extreme cases. It has also been given subcutaneously or intramuscularly in initial doses of 200 micrograms (as 1 mL of a 0.02% solution) and by slow intravenous injection in initial doses of 20 to 60 micrograms (as 1 to 3 mL of a 0.002% solution); doses are subsequently adjusted according to ventricular rate. Tablets of isoprenaline hydrochloride have been given orally or sublingually.

Isoprenaline has been used as a bronchodilator in the management of **reversible airways obstruction** but sympathomimetics with a selective action on $beta_2$ receptors, such as salbutamol, are now preferred (see Asthma, p.1108). It has been given as the sulfate or hydrochloride, usually by inhalation; sublingual tablets and intravenous injections have also been used.

US includes Isosorbide Concentrate.

USP 31 (Isosorbide Concentrate). An aqueous solution containing 70.0 to 80.0% w/w of isosorbide. A colourless to slightly yellow liquid. Soluble in water and in alcohol. Store in airtight containers. Protect from light.

Profile

Isosorbide is an osmotic diuretic with properties similar to those of mannitol (p.1330). It is reported to cause less nausea and vomiting than other oral osmotic diuretics.

Isosorbide is used for short-term reduction of intra-ocular pressure in acute glaucoma or prior to surgery (p.1873). The usual oral dose is 1 to 3 g/kg 2 to 4 times daily. The onset of action is usually within 30 minutes and lasts for up to 5 or 6 hours.

Dinitrato de isosorbida; ISDN; Isosorbid dinitrát; Isosorbiddinitrat; Isosorbide, dinitrate d'; Isosorbidi dinitras; Isosorbididinitraatti; Izosorbid Dinitrat; Izosorbido dinitratas; Izosorbidu diazotan; Izoszorbid-dinitrát; Sorbide Nitrate. 1,4:3,6-Dianhydro-D-glucitol 2,5-dinitrate.

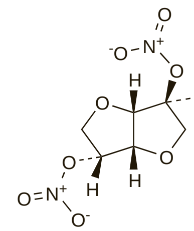
Изосорбида Динитрат

$C_6H_8N_2O_8$ = 236.1.

CAS — 87-33-2.

ATC — C01DA08; C05AE02.

ATC Vet — QC01DA08; QC05AE02.



Pharmacopoeias. In *Chin.* and *Jpn.*

Eur. (see p.vii), *Int.*, and *US* include diluted isosorbide dinitrate.

Ph. Eur. 6.2 (Isosorbide Dinitrate, Diluted). A dry mixture of isosorbide dinitrate and lactose monohydrate or mannitol. The solubility of the diluted product depends on the diluent and its concentration. Protect from light.

Undiluted isosorbide dinitrate is a fine, white or almost white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; very soluble in acetone.

USP 31 (Diluted Isosorbide Dinitrate). A dry mixture of isosorbide dinitrate (usually about 25%) with lactose, mannitol, or other suitable inert excipients, the latter being added to minimise the risk of explosion. It may contain up to 1% of a suitable stabiliser such as ammonium phosphate. It is an ivory-white, odourless powder. Store in airtight containers.

Undiluted isosorbide dinitrate occurs as white crystalline rosettes. Very slightly soluble in water; sparingly soluble in alcohol; very soluble in acetone; freely soluble in chloroform.

Handling. Undiluted isosorbide dinitrate may explode if subjected to percussion or excessive heat.

Stability. The loss of isosorbide dinitrate from solution during infusion was found to be 30% with PVC plastic intravenous infusion sets but negligible when polyolefin or glass delivery systems were used.[1] Another study reported a 23% decrease in isosorbide dinitrate concentration after 24 hours of storage at 21° in PVC containers; most of the loss occurred in the first 6 hours. Loss of potency was not noted when isosorbide dinitrate was stored under similar conditions in glass bottles or polyethylene, nylon, and polypropylene laminated bags.[2]

1. Kowaluk EA, *et al.* Drug loss in polyolefin infusion systems. *Am J Hosp Pharm* 1983; **40:** 118–19.
2. Martens HJ, *et al.* Sorption of various drugs in polyvinyl chloride, glass, and polyethylene-lined infusion containers. *Am J Hosp Pharm* 1990; **47:** 369–73.

Adverse Effects, Treatment, and Precautions

As for Glyceryl Trinitrate, p.1296.

Effects on the blood. Haemolysis occurred in 2 patients with G6PD deficiency during treatment with isosorbide dinitrate.[1]

1. Aderka D, *et al.* Isosorbide dinitrate-induced hemolysis in G6PD-deficient subjects. *Acta Haematol (Basel)* 1983; **69:** 63–4.

Headache. The most common adverse effect of nitrate therapy is headache which usually decreases after a few days. There has been a report[1] of a severe continuous unilateral headache with an oculosympathetic paresis on the same side associated with isosorbide dinitrate therapy.

1. Mueller RA, Meienberg O. Hemicrania with oculosympathetic paresis from isosorbide dinitrate. *N Engl J Med* 1983; **308:** 458–9.

Hypersensitivity. Laryngeal oedema developed on two occasions in a woman after the use of isosorbide dinitrate spray;[1] nifedipine was also given sublingually which on the second occasion caused a noticeable increase in the laryngeal swelling induced by the nitrate.

1. Silfvast T, *et al.* Laryngeal oedema after isosorbide dinitrate spray and sublingual nifedipine. *BMJ* 1995; **311:** 232.

Nitrate tolerance. Continuous use of organic nitrates is associated with tolerance to their haemodynamic effects; for an overview of nitrate tolerance, see under Precautions for Glyceryl Trinitrate, p.1297.

A study in 12 patients with chronic stable angina[1] showed that after treatment for one week with isosorbide dinitrate 30 mg two or three times daily, treadmill-walking time was longer throughout a 5-hour testing period compared with placebo. In contrast, after treatment for one week with isosorbide dinitrate 30 mg four times daily, treadmill-walking time was prolonged at 1 hour but not at 3 or 5 hours. These results support the concept that clinical efficacy of isosorbide dinitrate is maintained if given in a dose schedule which provides a nitrate-free or a low-nitrate period.

The effect of sublingual isosorbide dinitrate in patients receiving chronic therapy with isosorbide dinitrate was evaluated in 24 patients with angina.[2] Sublingual use produced less reduction of aortic systolic pressure and left ventricular end-diastolic pressure and less dilatation of coronary artery diameter in patients who received chronic isosorbide dinitrate therapy compared with patients not receiving chronic therapy.

1. Parker JO, *et al.* Effect of intervals between doses on the development of tolerance to isosorbide dinitrate. *N Engl J Med* 1987; **316:** 1440–4.
2. Naito H, *et al.* Effects of sublingual nitrate in patients receiving sustained therapy of isosorbide dinitrate for coronary artery disease. *Am J Cardiol* 1989; **64:** 565–68.

Oedema. Reports of ankle oedema associated with isosorbide dinitrate therapy in 3 patients with heart failure.[1]

1. Rodger JC. Peripheral oedema in patients treated with isosorbide dinitrate. *BMJ* 1981; **283:** 1365–6.

Interactions

As for Glyceryl Trinitrate, p.1297.

Disopyramide. The effectiveness of sublingual isosorbide dinitrate was reduced in a patient taking disopyramide.[1] The interaction was considered to be due to diminished salivary secretions caused by the antimuscarinic action of disopyramide which inhibited the dissolution of the sublingual isosorbide dinitrate tablet.

1. Barletta MA, Eisen H. Isosorbide dinitrate-disopyramide phosphate interaction. *Drug Intell Clin Pharm* 1985; **19:** 764.

Pharmacokinetics

Like glyceryl trinitrate, isosorbide dinitrate is readily absorbed from the oral mucosa. Isosorbide dinitrate is also readily absorbed when given orally but owing to extensive first-pass metabolism in the liver and presystemic clearance its bioavailability is reduced. Isosorbide dinitrate is also absorbed through the skin from an ointment basis.

After sublingual doses, anti-anginal effect is apparent within 2 to 5 minutes and persists for about 1 to 2 hours. After oral dosage with conventional tablets, anti-anginal activity is present in less than 1 hour and lasts for 4 to 6 hours.

Isosorbide dinitrate is widely distributed with a large apparent volume of distribution. It is taken up by smooth muscle cells of blood vessels and the nitrate group is cleaved to inorganic nitrite and then to nitric oxide. It is also rapidly metabolised in the liver to the major active metabolites isosorbide 2-mononitrate and isosorbide 5-mononitrate (see Isosorbide Mononitrate, below).

After sublingual doses, isosorbide dinitrate has a plasma half-life of 45 to 60 minutes. Plasma half-lives of 20 minutes and 4 hours have been reported after intravenous and oral dosage, respectively. During prolonged use, the half-life is increased due to accumulation of the isosorbide 5-mononitrate metabolite which reduces hepatic isosorbide dinitrate extraction. Both primary metabolites have longer half-lives than the parent compound.

Uses and Administration

Isosorbide dinitrate is a vasodilator with general properties similar to those of glyceryl trinitrate (p.1297). It is used in the management of angina pectoris (p.1157) and of heart failure (below). It has also been investigated in myocardial infarction (p.1175).

Isosorbide dinitrate may be given by the sublingual, oral, transdermal, or intravenous route.

In **angina** isosorbide dinitrate may be given as sublingual tablets or spray for the relief of an acute attack, although glyceryl trinitrate may be preferred because it has a faster onset of action. Isosorbide dinitrate may also be used before an activity or stress which might provoke an attack. The usual dose in acute angina is 2.5 to 10 mg sublingually. As an alternative, one to three sprays (1.25 mg/spray) may be directed under the tongue.

Isosorbide dinitrate is also used in the long-term management of angina in oral doses of 20 to 120 mg daily in divided doses according to the patient's needs. Increases in dosage should be gradual to avoid adverse effects. Up to 240 mg daily in divided doses may be necessary. Modified-release formulations may be used in equivalent doses. Transdermal preparations such as topical sprays or ointments may also be used.

Isosorbide dinitrate is given by intravenous infusion for unstable angina. The dose is titrated according to patient response; doses in the range of 2 to 12 mg/hour are usually suitable but up to 20 mg/hour may be necessary in some patients. The plastic used in the infusion equipment may adsorb isosorbide dinitrate (see Stability, above) and allowance may have to be made for this.

During percutaneous transluminal coronary angioplasty isosorbide dinitrate may be given by the intracoronary route to allow prolonged balloon inflation and to prevent or relieve coronary spasm. Only injections of isosorbide dinitrate which are approved for intracoronary use should be given by this route as preparations intended for normal intravenous use may contain additives that are harmful if injected into diseased coronary vessels. The usual dose is 1 mg as a bolus before balloon inflation. The maximum recommended dose is 5 mg within a 30-minute time period.

Isosorbide dinitrate is also used in the management of **heart failure**. It is given in doses of 5 to 10 mg sublingually every 2 to 3 hours, or in oral doses of 30 to 160 mg daily in divided doses. Oral doses of up to 240 mg daily may be required. It may also be given intravenously using the intravenous doses given above for angina. An oral combination preparation with hydralazine is also available for use in self-identified black patients. It is given in a dose of 20 mg of isosorbide dinitrate with 37.5 mg of hydralazine three times daily; the dose may be doubled if necessary.

Heart failure. Although direct-acting vasodilators do not have a major role in the management of chronic heart failure (p.1165) there is some evidence that use of hydralazine with isosorbide dinitrate may be of benefit,[1] although the effect on mortality is less than that seen with ACE inhibitors.[2] Subgroup analysis suggested that the effect might be greater in black patients, and a later study[3] in black patients found that addition of isosorbide dinitrate and hydralazine to standard therapy improved both morbidity and mortality.

1. Cohn JN, *et al.* Effect of vasodilator therapy on mortality in chronic congestive heart failure: results of a Veterans Administration Cooperative Study. *N Engl J Med* 1986; **314:** 1547–52.
2. Cohn JN, *et al.* A comparison of enalapril with hydralazine-isosorbide dinitrate in the treatment of chronic congestive heart failure. *N Engl J Med* 1991; **325:** 303–10.
3. Taylor AL, *et al.* African-American Heart Failure Trial Investigators. Combination of isosorbide dinitrate and hydralazine in blacks with heart failure. *N Engl J Med* 2004; **351:** 2049–57. Correction. *ibid.* 2005; **352:** 1276.

Non-cardiovascular disorders. Nitrates such as isosorbide dinitrate have been tried in conditions including anal fissure, erectile dysfunction, obstetric and gynaecological disorders, oesophageal motility disorders such as achalasia and spasm, and pain. Further details of these uses are given under Glyceryl Trinitrate (p.1298).

Isosorbide Mononitrate *(BAN, USAN, rINN)*

AHR-4698; BM-22145; IS-5-MN; Isosorbid mononitrát; Isosorbide, mononitrate d'; Isosorbide-5-mononitrate; Isosorbidi mononitras; Izosorbid Mononitrat; Izosorbido mononitratas; Izoszorbid-mononitrát; Mononitrato de isosorbida. 1,4:3,6-Dianhydro-D-glucitol 5-nitrate.

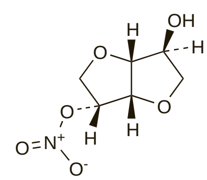
Изозорбида Мононитрат

$C_6H_9NO_6$ = 191.1.

CAS — 16051-77-7.

ATC — C01DA14.

ATC Vet — QC01DA14.



Pharmacopoeias. *Eur.* (see p.vii) and *US* include diluted isosorbide mononitrate.

Ph. Eur. 6.2 (Isosorbide Mononitrate, Diluted). A dry mixture of isosorbide mononitrate and lactose monohydrate or mannitol. The solubility of the diluted product depends on the diluent and its concentration. Protect from light.

Undiluted isosorbide mononitrate is a white or almost white, crystalline powder. Freely soluble in water, in alcohol, in acetone, and in dichloromethane.

USP 31 (Diluted Isosorbide Mononitrate). A dry mixture of isosorbide mononitrate with lactose or other suitable excipients to permit safe handling. Store in airtight containers between 20° and 30°.

Adverse Effects, Treatment, and Precautions

As for Glyceryl Trinitrate, p.1296.

Myalgia has been reported very rarely.

Interactions

As for Glyceryl Trinitrate, p.1297.

Pharmacokinetics

Isosorbide mononitrate is readily absorbed from the gastrointestinal tract. After oral doses of conventional tablets, peak plasma levels are reached in 30 minutes to 1 hour; onset of action occurs within 20 minutes and lasts for about 8 to 10 hours. Unlike isosorbide dinitrate, isosorbide mononitrate does not undergo first-pass hepatic metabolism and bioavailability is nearly 100%. Isosorbide mononitrate is widely distributed with a large apparent volume of distribution. It is taken up by smooth muscle cells of blood vessels and the nitrate group is cleaved to inorganic nitrite and then to nitric oxide. Isosorbide mononitrate is metabolised to inactive metabolites, including isosorbide and isosorbide glucuronide. Only about 2% of isosorbide mononitrate is excreted unchanged in the urine. An elimination half-life of about 4 to 5 hours has been reported.

Uses and Administration

Isosorbide mononitrate is an active metabolite of the vasodilator isosorbide dinitrate and is used in the long-term management of angina pectoris (p.1157) and heart failure (p.1165). It has also been investigated in myocardial infarction (below).

The usual oral dose is 20 mg two or three times daily, although doses ranging from 20 to 120 mg daily have been given. Modified-release oral preparations have been developed for use in angina.

Myocardial infarction. Long-term management of myocardial infarction (p.1175) can involve numerous drug therapies and some patients, for example those with myocardial ischaemia or poor left ventricular function, may require the long-term use of nitrates, although recent studies have thrown doubt on their routine use. In the GISSI-3 study[1] there was no significant benefit from the use of transdermal glyceryl trinitrate when assessed 6 weeks post-infarction and in the ISIS-4 study[2] oral isosorbide mononitrate apparently had no effect on 35-day mortality.

Isradipine *(BAN, USAN, rINN)*

Isradipiini; Isradipin; Isradipinas; Isradipino; Isradipinum; Izradypina; PN-200-110. Isopropyl methyl 4-(2,1,3-benzoxadiazol-4-yl)-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate.

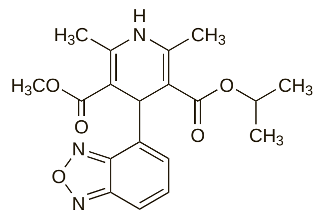
Исрадипин

$C_{19}H_{21}N_3O_5$ = 371.4.

CAS — 75695-93-1.

ATC — C08CA03.

ATC Vet — QC08CA03.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Isradipine). A yellow crystalline powder. Practically insoluble in water; freely soluble in acetone; soluble in methyl alcohol. Protect from light.

USP 31 (Isradipine). A yellow fine crystalline powder. Protect from light.

Stability. An oral preparation of isradipine 1 mg/mL, prepared using the powder from capsules of isradipine suspended in syrup,[1] was stable when stored at 4° for up to 35 days after preparation.

1. MacDonald JL, *et al.* Stability of isradipine in an extemporaneously compounded oral liquid. *Am J Hosp Pharm* 1994; **51:** 2409–11.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

◊ In a multicentre study[1] involving 74 patients allocated to antihypertensive therapy with isradipine 2.5 to 10 mg twice daily, and 72 allocated to treatment with hydrochlorothiazide, adverse effects were reported in 44 of the isradipine group but only 29 of the thiazide group. Flushing, palpitation, and oedema were more common in patients receiving isradipine, while headache, dizziness, and dyspnoea were reported in both groups with similar frequency. In another study,[2] spontaneously reported adverse effects occurred less frequently in patients taking isradipine (18.4% of 103 patients) than in those taking amlodipine (33.3% of 102 patients). In particular, ankle oedema was less frequent, severe, and prolonged with isradipine than with amlodipine. A multicentre study[3] comparing isradipine and enalapril antihypertensive therapy reported adverse effects in 51% of 71 patients taking isradipine and 45% of 64 patients taking enalapril. The commonest side-effects with isradipine were dizziness (14%), oedema (10%), fatigue (9%), headache (9%), and pruritus (7%).

2. Hermans L, *et al.* At equipotent doses, isradipine is better tolerated than amlodipine in patients with mild-to-moderate hypertension: a double-blind, randomized, parallel-group study. *Br J Clin Pharmacol* 1994; **38:** 335–40.
3. Johnson BF, *et al.* A multicenter comparison of adverse reaction profiles of isradipine and enalapril at equipotent doses in patients with essential hypertension. *J Clin Pharmacol* 1995; **35:** 484–92.

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Cimetidine increases the bioavailability of isradipine and the dose of isradipine should be reduced by 50% in patients receiving both drugs.

Pharmacokinetics

Isradipine is almost completely absorbed from the gastrointestinal tract after oral doses but undergoes extensive first-pass metabolism; the bioavailability is reported to be 15 to 24%. Peak plasma concentrations occur about 2 hours after oral dosage. It is about 95% bound to plasma proteins. Isradipine is extensively metabolised in the liver, at least partly by the cytochrome P450 isoenzyme CYP3A4. About 70% of an oral dose is reported to be excreted as metabolites in urine, the remainder in faeces. The terminal elimination half-life is often stated to be about 8 hours although a value of less than 4 hours has also been reported.

◊ In single-dose and steady-state studies of the pharmacokinetics of isradipine in 9 hypertensive subjects using a specific high performance liquid chromatographic assay, isradipine was found to be rapidly absorbed with peak concentrations occurring 1.2 (steady state) to 1.5 (single dose) hours after dosing.[1] The mean terminal elimination half-life at steady state was 3.8 hours, suggesting that duration of action is likely to be short and that isradipine would need to be given at least twice daily. There was considerable interindividual variation in the pharmacokinetics. In an earlier study[2] in healthy subjects the effective half-life of isradipine was calculated to be 8.8 hours, but radiolabelled isradipine was used and the assay method might have been less specific for unchanged drug.

1. Shenfield GM, *et al.* The pharmacokinetics of isradipine in hypertensive subjects. *Eur J Clin Pharmacol* 1990; **38:** 209–11.
2. Tse FLS, Jaffe JM. Pharmacokinetics of PN 200-110 (isradipine), a new calcium antagonist, after oral administration in man. *Eur J Clin Pharmacol* 1987; **32:** 361–5.

Hepatic impairment. Systemic availability after a radiolabelled oral dose of isradipine 5 mg was no different at 15.6% in 7 patients with non-cirrhotic chronic liver disease from the value of 16.5% in 8 healthy subjects.[1] However, in 8 patients with cirrhosis of the liver availability was markedly increased to a mean of 36.9%; this was associated with decreased clearance (1.6 litres/minute, compared with 9.9 in controls). Terminal half-life, as measured after intravenous dosage, was greater at 11.9 hours in cirrhotic patients than the 5.1 hours seen in controls.

1. Cotting J, *et al.* Pharmacokinetics of isradipine in patients with chronic liver disease. *Eur J Clin Pharmacol* 1990; **38:** 599–603.

Uses and Administration

Isradipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the treatment of hypertension (p.1171).

The usual initial dose of isradipine is 2.5 mg by mouth twice daily increased if necessary after 3 to 4 weeks to 5 mg twice daily. Some patients may require 10 mg twice daily. In elderly patients an initial dose of 1.25 mg twice daily may be preferable; a maintenance dose of 2.5 or 5 mg once daily may sometimes be sufficient. A reduced dose should also be considered in patients with hepatic or renal impairment (see below).

The dose of isradipine should be reduced in patients who are also taking cimetidine (see Interactions, above).

A modified-release preparation allowing once-daily dosing is available in some countries.

◊ Reviews.

2. Walton T, Symes LR. Felodipine and isradipine: new calcium-channel blocking agents for the treatment of hypertension. *Clin Pharm* 1993; **12:** 261–75.
3. Brogden RN, Sorkin EM. Isradipine: an update of its pharmacodynamic and pharmacokinetic properties and therapeutic efficacy in the treatment of mild to moderate hypertension. *Drugs* 1995; **49:** 618–49.

Administration in hepatic or renal impairment. In patients with hepatic or renal impairment UK licensed product information recommends an initial dose of isradipine of 1.25 mg twice daily. The dose may be increased as required, but a maintenance dose of 2.5 or 5 mg once daily may be sufficient in some patients.

Ivabradine *(rINN)*

Ivabradina; Ivabradinum; S-16257; S-16257-2 (ivabradine hydrochloride). 3-[3-({[(7*S*)-3,4-Dimethoxybicyclo[4.2.0]octa-1,3,5-trien-7-yl]methyl}methylamino)propyl]-1,3,4,5-tetrahydro-7,8-dimethoxy-2*H*-3-benzazepin-2-one.

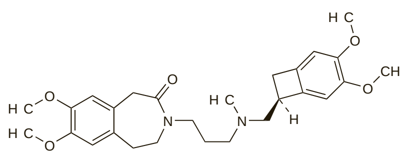
Ивабрадин

$C_{27}H_{36}N_2O_5$ = 468.6.

CAS — 155974-00-8 (ivabradine); 148849-67-6 (ivabradine hydrochloride).

ATC — C01EB17.

ATC Vet — QC01EB17.



Adverse Effects

The most common adverse effects seen with ivabradine are luminous phenomena in the visual field (phosphenes). Other adverse effects include blurred vision, bradycardia, which may be severe, and other cardiac arrhythmias, nausea, constipation, diarrhoea, headache, dizziness, dyspnoea, and muscle cramps. Hyperuricaemia, eosinophilia, and elevated blood-creatinine concentrations have been reported.

◊ Reviews.

1. Savelieva I, Camm AJ. I inhibition with ivabradine: electrophysiological effects and safety. *Drug Safety* 2008; **31:** 95–107.

Precautions

Ivabradine should not be given to patients with resting heart rate below 60 beats/minute, or to patients with cardiogenic shock, severe conduction defects, acute myocardial infarction, or unstable angina. Heart failure should be controlled before ivabradine is started; it has not been studied in severe heart failure. Ivabradine should not be used in patients with congenital QT prolongation. Ivabradine is not recommended in atrial fibrillation or other cardiac arrhythmias that interfere with sinus node function, and regular monitoring for such arrhythmias should be performed. If resting heart rate falls below 50 beats/minute the dose should be reduced; treatment should be stopped if this rate persists.

Ivabradine is contra-indicated in severe hypotension and severe hepatic impairment, and should be used with caution in severe renal impairment.

If unexpected deterioration in visual function occurs, stopping treatment may be considered. Caution should be observed in patients with retinitis pigmentosa.

Studies in *animals* have shown that ivabradine is embryotoxic and teratogenic, and is distributed into breast milk.

Interactions

Ivabradine should not generally be used with drugs that prolong the QT interval.

Ivabradine is metabolised by the cytochrome P450 isoenzyme CYP3A4, and should not be used with potent inhibitors of this enzyme, including azole antifungals such as ketoconazole and itraconazole, macrolide antibacterials such as clarithromycin, HIV-protease inhibitors such as nelfinavir and ritonavir, and nefazodone. Use with the moderate CYP3A4 inhibitors diltiazem and verapamil is also not recommended as the increase in exposure to ivabradine may cause an additional reduction in heart rate. Ivabradine may be used cautiously with other moderate inhibitors, such as fluconazole, at a lower starting dose of 2.5 mg twice daily, with monitoring of the heart rate. Consumption of grapefruit juice should be restricted.

Use with CYP3A4 inducers, such as rifampicin and phenytoin, may require an increase in the dose of ivabradine. St John's wort reduces the exposure to ivabradine by half and its use should be restricted.

Pharmacokinetics

Ivabradine is almost completely absorbed after oral doses but bioavailability is about 40% because of first-pass metabolism. Peak plasma concentrations are achieved after about 1 hour in the fasting state but this is delayed by 1 hour by food and the extent of absorption increased by 20 to 30%. Ivabradine is about 70% bound to plasma proteins.

Ivabradine undergoes extensive metabolism in the liver and gut via the cytochrome P450 isoenzyme CYP3A4 to its main active metabolite *N*-desmethylivabradine (S-18982). This is further metabolised to some degree by CYP3A4. Ivabradine has an elimination half-life of 2 hours. Its metabolites are excreted to a similar extent in the urine and faeces. About 4% of a dose appears in the urine as the parent drug. *Animal* studies indicate that ivabradine is distributed into breast milk.

Uses and Administration

Ivabradine is a selective sinus node I_f inhibitor used in the treatment of angina pectoris in patients unable to take beta blockers. It is given as the hydrochloride, but doses are described in terms of the base; 5.4 mg of ivabradine hydrochloride is equivalent to about 5 mg of ivabradine. It is given orally with food in a usual initial dose of 5 mg twice daily, increased after 3 or 4 weeks if necessary to 7.5 mg twice daily. If the heart rate falls persistently below 50 beats/minute or there are symptoms of bradycardia the dose should be titrated downwards, to as low as 2.5 mg twice daily if necessary. Treatment should be stopped if this low rate or symptoms of bradycardia persist.

In the elderly (75 years or above), a lower initial dose of 2.5 mg twice daily should be considered, before increasing if necessary.

Ketanserin *(BAN, USAN, rINN)*

Ketanseriini; Ketanserina; Kétansérine; Ketanserinum; R-41468. 3-{2-[4-(4-Fluorobenzoyl)piperidino]ethyl}quinazoline-2,4(1*H*,3*H*)-dione.

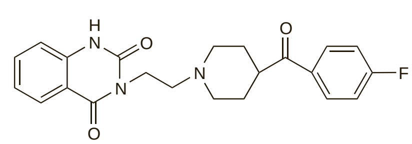
Кетансерин

$C_{22}H_{22}FN_3O_3$ = 395.4.

CAS — 74050-98-9.

ATC — C02KD01.

ATC Vet — QC02KD01; QD03AX90.



Ketanserin Tartrate *(BANM, rINNM)*

Kétansérine, Tartrate de; Ketanserini Tartras; R-49945; Tartrato de ketanserina.

Кетансерина Тартрат

$C_{22}H_{22}FN_3O_3,C_4H_6O_6$ = 545.5.

CAS — 83846-83-7.

ATC — C02KD01.

ATC Vet — QC02KD01.

Adverse Effects and Precautions

Ketanserin has been reported to cause sedation, fatigue, light-headedness, dizziness, headache, dry mouth, and gastrointestinal disturbances. Oedema has been reported rarely. In patients with predisposing factors such as QT prolongation, chronic use of ketanserin has been associated with ventricular arrhythmias including torsade de pointes; ketanserin should be used with caution in patients taking antiarrhythmics and should not be used in second- or third-degree AV block. Care should be taken to avoid the development of hypokalaemia in patients taking ketanserin, for example if diuretics are also given.

Because ketanserin may cause drowsiness care should be taken in patients who drive or operate machinery.

Ketanserin is reported to be better tolerated in elderly than in younger patients.

Interactions

The hypotensive effects of ketanserin may be enhanced by diuretics and other antihypertensives. Ketanserin should be used with caution in patients taking antiarrhythmics or drugs that cause hypokalaemia since the risk of arrhythmias is increased.

Beta blockers. Profound hypotension occurred in 2 patients one hour after taking ketanserin 40 mg orally.[1] Both patients were also taking a beta blocker which may have exacerbated the reaction.

1. Waller PC, *et al.* Profound hypotension after the first dose of ketanserin. *Postgrad Med J* 1987; **63:** 305–7.

Pharmacokinetics

Ketanserin is rapidly absorbed from the gastrointestinal tract but has a bioavailability of about 50% due to first-pass hepatic metabolism. Peak plasma concentrations occur between 30 and 120 minutes after an oral dose. Ketanserin is about 95% bound to plasma proteins. The terminal half-life is stated to be between 13 and 18 hours but some studies report that following multiple doses the half-life is 19 to 29 hours. The metabolite ketanserinol has a terminal half-life of 31 to 35 hours after multiple doses, and it has been suggested that reconversion of ketanserinol to ketanserin may be responsible for the prolonged half-life of the parent compound during chronic use.

About 68% of an oral dose is excreted in urine, and 24% in faeces, mainly as metabolites. Studies in *animals* suggest that ketanserin may cross the placenta and that some is present, with metabolites, in breast milk.

Uses and Administration

Ketanserin is a serotonin antagonist with a high affinity for peripheral serotonin-2 ($5\text{-}HT_2$) receptors and thus inhibits serotonin-induced vasoconstriction, bronchoconstriction, and platelet aggregation. It also has some $alpha_1$-antagonist and histamine H_1-antagonist properties, but the clinical significance of these is controversial.

Ketanserin is used in the management of hypertension (p.1171) and has also been tried in other conditions (see below).

Ketanserin is given as the tartrate, but doses are usually expressed in terms of the base. Ketanserin tartrate 27.6 mg is equivalent to about 20 mg of ketanserin.

Ketanserin produces a gradual hypotensive effect when given orally, and 2 or 3 months of therapy may be required to produce the maximum reduction in blood pressure. After intravenous injection a fall in blood pressure is generally produced in 1 or 2 minutes and lasts for 30 to 60 minutes.

In **hypertension** the usual initial oral dose is 20 mg twice daily, increasing, if necessary, after 2 to 4 weeks, to 40 mg twice daily. It has also been given by intravenous or intramuscular injection. The dose of ketanserin may need to be reduced, or the dosage intervals increased, in patients with hepatic impairment (see below).

◊ Reviews.

1. Brogden RN, Sorkin EM. Ketanserin: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic potential in hypertension and peripheral vascular disease. *Drugs* 1990; **40:** 903–49.

Administration in hepatic impairment. A study[1] in patients with cirrhosis found that the half-life and volume of distribution of ketanserin were decreased but the area under the concentration-time curve was markedly increased; the rate of metabolism was reduced. The results suggested that the dosage should be reduced or the dosage interval increased when ketanserin is given to patients with cirrhosis.

Licensed product information recommends a maximum oral dose of 20 mg twice daily for patients with severe hepatic impairment.

1. Lebrec D, *et al.* Pharmacokinetics of ketanserin in patients with cirrhosis. *Clin Pharmacokinet* 1990; **19:** 160–6.

Administration in renal impairment. Results from a study in 12 patients with chronic renal impairment, of whom 6 required haemodialysis, suggested that no adjustment of a dose of ketanserin 20 mg twice daily was required in patients with renal impairment.[1]

1. Barendregt JNM, *et al.* Ketanserin pharmacokinetics in patients with renal failure. *Br J Clin Pharmacol* 1990; **29:** 715–23.

Peripheral vascular disease. Ketanserin is one of many drugs that have been tried in the management of peripheral vascular disease (p.1178) but results have been contradictory. Subgroup analysis of the multicentre Prevention of Atherosclerotic Complications with Ketanserin Trial (PACK),[1] involving 3899 patients with intermittent claudication, suggested that ketanserin might be of benefit in preventing limb amputation in some patients. Conflicting results have also been reported in patients with Raynaud's syndrome (see Vasospastic Arterial Disorders, p.1188). A systematic review[2] found that ketanserin led to a small improvement in Raynaud's syndrome in patients with systemic sclerosis but that adverse effects increased; the authors concluded that ketanserin was not clinically beneficial in such patients.

Ketanserin has also been tried in other conditions associated with impaired peripheral blood flow: see Wounds and Ulcers, below.

1. Prevention of Atherosclerotic Complications with Ketanserin Trial Group. Prevention of atherosclerotic complications: controlled trial of ketanserin. *BMJ* 1989; **298:** 424–30. Correction. *ibid.*: 644.
2. Pope JE, *et al.* Ketanserin for Raynaud's phenomenon in progressive systemic sclerosis. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 1998 (accessed 26/09/05).

Shivering. Numerous drugs, including ketanserin, have been tried for the treatment of postoperative shivering (p.1779). Ketanserin 10 mg given intravenously has stopped shivering after general anaesthesia.[1,2]

1. Joris J, *et al.* Clonidine and ketanserin both are effective treatment for postanesthetic shivering. *Anesthesiology* 1993; **79:** 532–9.
2. Crisinel D, *et al.* Efficacité de la kétansérine sur le frisson postanesthésique. *Ann Fr Anesth Reanim* 1997; **16:** 120–5.

Wounds and ulcers. Several controlled studies[1-5] have noted improved healing of decubitus, venous, and ischaemic ulcers (see Wounds and Ulcers, p.1585) after topical use of ketanserin 2%. However, when applied topically to surgical wounds no improvement was found and it was suggested that ketanserin is only of benefit where blood supply is compromised.[6]

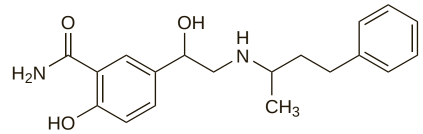
ATC — C07AG01.

ATC Vet — QC07AG01.



(labetalol)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Labetalol Hydrochloride). A white or almost white powder. Sparingly soluble in water and in alcohol; practically insoluble in dichloromethane. A 1% solution in water has a pH of 4.0 to 5.0.

USP 31 (Labetalol Hydrochloride). A white to off-white powder. Soluble in water and in alcohol; insoluble in chloroform and in ether. A 1% solution in water has a pH of 4.0 to 5.0. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Labetalol hydrochloride is compatible with standard intravenous solutions such as glucose 5% and sodium chloride 0.9%. However, precipitation has been reported when labetalol hydrochloride is added to sodium bicarbonate injection 5%.[1] The precipitate is probably labetalol base.[2]

Immediate formation of a precipitate has also been reported when labetalol (generally 5 mg/mL in glucose 5%) was mixed with other drugs including ceftriaxone,[3] furosemide,[4] heparin,[5] insulin,[5] proton pump inhibitors such as pantoprazole,[6] and thiopental.[4] There has also been a report of immediate haze after admixture of labetalol hydrochloride (800 micrograms/mL) with warfarin sodium.[7]

Adverse Effects

The adverse effects associated with beta blockers are described on p.1226. Labetalol also has alpha-blocking activity, which contributes to its adverse effects and these effects may predominate. Orthostatic hypotension may be a problem with high doses or at the start of treatment. Other effects associated with alpha blockade include dizziness, scalp tingling, and nasal congestion. Male sexual function may be impaired to a greater extent than with beta blockade alone. Muscle weakness, tremor, urinary retention, hepatitis, and jaundice have also been reported.

Effects on the liver. By 1990, the FDA had received 11 reports of hepatocellular damage associated with labetalol therapy.[1] Three patients died. Liver function should be monitored and labetalol stopped in patients who develop liver function abnormalities. The *R,R*-isomer of labetalol, dilevalol, was withdrawn from the market because of hepatotoxicity.[2]

2. Harvengt C. Labetalol hepatotoxicity. *Ann Intern Med* 1991; **114:** 341.

Hypersensitivity. Hypersensitivity reactions associated with labetalol may manifest as fever.[1,2] Anaphylactoid reaction to labetalol has also been reported.[3]

1. D'Arcy PF. Drug reactions and interactions: drug fever with labetalol. *Int Pharm J* 1987; **1:** 43–4.
2. Stricker BH, *et al.* Fever induced by labetalol. *JAMA* 1986; **256:** 619–20.
3. Ferree CE. Apparent anaphylaxis from labetalol. *Ann Intern Med* 1986; **104:** 729–30.

Overdosage. Acute oliguric renal failure developed after a short period of moderate hypotension in a patient who ingested labetalol 16 g. Renal function subsequently recovered.[1] Renal failure has also been reported[2] after ingestion of labetalol 6 g. The patient recovered after treatment with glucagon, isoprenaline, and dialysis. Another patient[3] developed circulatory collapse and impaired consciousness after being given labetalol 800 mg orally for hypertensive crisis; glucagon and sympathomimetics were given to restore blood pressure, but amrinone infusion was also needed to improve cardiac output and mental state.

3. Kollef MH. Labetalol overdose successfully treated with amrinone and alpha-adrenergic receptor agonists. *Chest* 1994; **105:** 626–7.

Precautions

As for Beta Blockers, p.1227.

Because labetalol causes orthostatic hypotension it is recommended that injections are given to patients when they are lying down and that patients should remain lying down for the next 3 hours.

Labetalol should be withdrawn from patients who develop signs of hepatic impairment.

Breast feeding. Labetalol is distributed into breast milk, although it has been suggested[1] that the proportion of a maternal dose likely to be ingested by the infant is very low. In a study[2] in 25 patients, the mean concentration of labetalol in breast milk was less than in maternal plasma in patients given doses between 330 and 800 mg daily, although in 1 patient given 1200 mg daily a higher concentration was found in breast milk. In another study,[3] the concentration of drug in milk exceeded maternal plasma concentration in 2 of 3 mothers, and in 1 infant the plasma-labetalol concentration was similar to that of the mother. However, no adverse effects have been seen in breast-feeding infants whose mothers were given labetalol, and the American Academy of Pediatrics considers[4] that it is therefore usually compatible with breast feeding.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Labetalol is readily absorbed from the gastrointestinal tract, but is subject to considerable first-pass metabolism. Bioavailability varies widely between patients and may be increased in the presence of food. Peak plasma concentrations occur about 1 to 2 hours after an oral dose. Labetalol has low lipid solubility and only very small amounts appear to cross the blood-brain barrier in *animals*. It is about 50% protein bound. Labetalol crosses the placenta and is distributed into breast milk (see above). Labetalol is metabolised mainly in the liver, the metabolites being excreted in the urine with only small amounts of unchanged labetalol; its major metabolite has not been found to have significant alpha- or beta-blocking effects. Excretion also occurs in the faeces via the bile. The elimination half-life at steady state is reported to be about 6 to 8 hours. On intravenous infusion, the elimination half-life is about 5.5 hours. Labetalol is not removed by dialysis.

The elderly. Analysis[1] of data from 4 single-dose studies and 3 multidose studies indicated that age did not appear to be a significant factor in oral clearance in elderly patients receiving labetalol for long-term management of hypertension.

1. Rocci ML, *et al.* Effects of age on the elimination of labetalol. *Clin Pharmacokinet* 1989; **17:** 452–7.

Pregnancy. The concentration of labetalol has been found to be lower in amniotic fluid[1] and fetal plasma[2] than in maternal plasma. A ratio of infant to maternal drug concentration of 0.2 to 0.8 has been reported[2] based on concentration in infant cord blood at delivery [time since last maternal dose not stated]. In another study,[3] however, higher concentrations were found in cord plasma than in maternal plasma at delivery when infants were delivered 12 to 24 hours after the last maternal dose.

The half-life of labetalol was reported as 24 hours in a neonate of 37 weeks' gestation whose mother had received labetalol 600 mg daily for 11 weeks prior to delivery.[4]

4. Haraldsson A, Geven W. Half-life of maternal labetalol in a premature infant. *Pharm Weekbl (Sci)* 1989; **11:** 229–31.

Uses and Administration

Labetalol is a non-cardioselective beta blocker (p.1225). It is reported to possess some intrinsic sympathomimetic and membrane-stabilising activity. In addition, it has selective $alpha_1$-blocking properties which decrease peripheral vascular resistance. The ratio of alpha- to beta-blocking activity has been estimated to be about 1:3 after oral doses and 1:7 after intravenous doses.

Labetalol is used as the hydrochloride in the management of hypertension (p.1171). It is also used to induce hypotension during surgery. Labetalol decreases blood pressure more rapidly than other beta blockers; the full antihypertensive effect may be seen within 1 to 3 hours of an oral dose.

In **hypertension** labetalol hydrochloride is usually given in an initial oral dose of 100 mg twice daily with food, gradually increased if necessary according to response and standing blood pressure, to 200 to 400 mg twice daily; total daily doses of 2.4 g, in two to four divided doses, have occasionally been required. Lower doses may be adequate in elderly patients; an initial dose of 50 to 100 mg twice daily has been recommended, and the usual maintenance dose is 100 to 200 mg twice daily.

For the emergency treatment of hypertension labetalol hydrochloride may be given by slow intravenous injection. In the UK a dose of 50 mg is recommended, given over a period of at least 1 minute; if necessary this dose may be repeated at intervals of 5 minutes until a total of 200 mg has been given. In the USA an initial dose of 20 mg is recommended, given over 2 minutes; subsequent doses of 40 to 80 mg may be given every 10 minutes, if necessary, up to a maximum of 300 mg. Blood pressure should be monitored, and the patient should remain supine during the injection and for 3 hours afterwards, to avoid excessive orthostatic hypotension. After bolus intravenous injection a maximum effect is usually obtained within 5 minutes and usually lasts up to 6 hours, although it may extend as long as 18 hours.

Labetalol hydrochloride has also been given by intravenous infusion in usual doses of 2 mg/minute. Suggested concentrations for intravenous infusions are 1 mg/mL or 2 mg/3 mL of suitable diluent. In hypertension in pregnancy, labetalol infusion may be started at the rate of 20 mg/hour, then doubled every 30 minutes until a satisfactory response is obtained or a dose of 160 mg/hour is reached. In hypertension after myocardial infarction, labetalol infusion may be started at the rate of 15 mg/hour and gradually increased until a satisfactory response is obtained or a dose of 120 mg/hour is reached.

The initial dose in **hypotensive anaesthesia** is 10 to 20 mg intravenously, with increments of 5 to 10 mg if satisfactory hypotension is not achieved after 5 minutes. A higher initial dose may be required in patients who do not receive halothane anaesthesia.

For the use of labetalol in children, see below.

Action. Labetalol has 2 optical centres; it is used as the racemic mixture of the 4 stereoisomers. The *R,R*- isomer is responsible for the beta-blocking activity and has limited alpha-blocking activity; it also has beta-adrenergic mediated peripheral vasodilating activity. The *S,R*-isomer has the most potent alpha-blocking activity. The *S,S*-isomer has some alpha-blocking activity and the *R,S*-isomer does not appear to have either alpha- or beta-adrenergic blocking effect.[1] The pure *R,R*-isomer, dilevalol, was withdrawn from the market because of hepatotoxicity.

1. Gold EH, *et al.* Synthesis and comparison of some cardiovascular properties of the stereoisomers of labetalol. *J Med Chem* 1982; **25:** 1363–70.

Administration in children. Labetalol has been used in the management of hypertension in children,[1] although experience is limited. The *BNFC* suggests the following doses:

for **hypertensive emergencies**, labetalol hydrochloride may be given by intravenous infusion as follows:

- neonates: 500 micrograms/kg per hour adjusted at intervals of at least 15 minutes according to response, to a maximum of 4 mg/kg per hour
- 1 month to 12 years: 0.5 to 1 mg/kg per hour adjusted at intervals of at least 15 minutes according to response, to a maximum of 3 mg/kg per hour
- 12 to 18 years: 30 to 120 mg/hour adjusted at intervals of at least 15 minutes according to response

for **hypertension**, labetalol hydrochloride may be given as follows:

- 1 month to 12 years: 1 to 2 mg/kg three or four times daily by mouth or a single intravenous injection in a dose of 250 to 500 micrograms/kg to a maximum of 20 mg
- 12 to 18 years: similar doses to adults (see above) although a lower initial oral dose of 50 to 100 mg twice daily is recommended

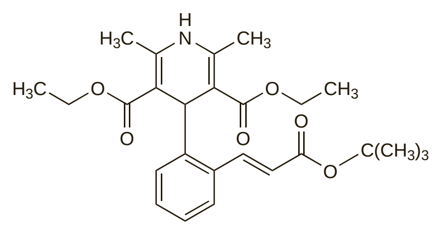
Lacidipine *(BAN, USAN, rINN)*

GR-43659X; GX-1048; Lacidipin; Lacidipino; Lacidipinum; Lasidipiini; Lasidipin. Diethyl 4-{2-[(*tert*-butoxycarbonyl)vinyl]phenyl}-1,4-dihydro-2,6-dimethylpyridine-3,5-dicarboxylate.

Лацидипин

$C_{26}H_{33}NO_6$ = 455.5.
CAS — 103890-78-4.
ATC — C08CA09.
ATC Vet — QC08CA09.



Pharmacopoeias. In *Br.*
BP 2008 (Lacidipine). A white to pale yellow crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in acetone and in dichloromethane.

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Lacidipine is rapidly but poorly absorbed from the gastrointestinal tract after oral doses and undergoes extensive first-pass metabolism; the bioavailability has been reported to be 2 to 9%, or 18.5% (range 4 to 52%) using a more sensitive assay method. It is more than 95% bound to plasma proteins. Lacidipine is eliminated by metabolism in the liver and metabolites are excreted mainly by the biliary route. About 70% of an oral dose is eliminated in the faeces, the remainder in the urine. The average steady-state terminal elimination half-life of lacidipine is 13 to 19 hours.

Uses and Administration

Lacidipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the treatment of hypertension (p.1171).

The usual initial dose of lacidipine is 2 mg once daily by mouth increased if necessary after 3 to 4 weeks or more to 4 mg daily; a further increase in dose to 6 mg daily may be necessary in some patients.

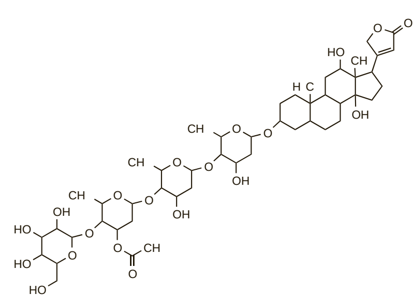
Ланатозид C

$C_{49}H_{76}O_{20}$ = 985.1.
CAS — 17575-22-3.
ATC — C01AA06.
ATC Vet — QC01AA06.



Pharmacopoeias. In *Jpn* and *Pol.*

Profile

Lanatoside C is a cardiac glycoside with positive inotropic activity. It is obtained from digitalis lanata leaf (p.1258). It has general properties similar to those of digoxin (p.1259) and has been used in the treatment of some cardiac arrhythmias and in heart failure.

Mixtures of lanatosides A, B, and C have also been used.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Develanid†; ***Mex.:*** Cedilanid.

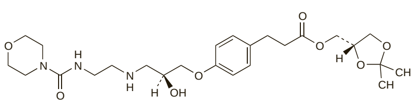
Landiolol Hydrochloride *(rINNM)* ⊗

Hidrocloruro de landiolol; Landiolol, Chlorhydrate de; Landiololi Hydrochloridum; ONO-1101. (−)-[(*S*)-2,2-Dimethyl-1,3-dioxolan-4-yl]methyl *p*-((*S*)-2-hydroxy-3-{[2-(4-morpholinecarboxamido)ethyl]amino}propoxy)hydrocinnamate hydrochloride.

Ландиолола Гидрохлорид

$C_{25}H_{39}N_3O_8$,HCl = 546.1.

CAS — 133242-30-5 (landiolol); 144481-98-1 (landiolol hydrochloride).



(landiolol)

Profile

Landiolol is a short-acting, cardioselective beta blocker given intravenously as the hydrochloride in the management of intra- and postoperative cardiac arrhythmias.

CAS — 32854-75-4 (lappaconitine); 97792-45-5 (lappaconitine hydrobromide).

Profile

Lappaconitine hydrobromide is an antiarrhythmic drug given orally in a usual dose of 25 mg three times daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Rus.: Allapinin (Аллапинин).

Leech

Blutegel; Hirudo; Sangsue; Sanguessugas; Sanguijuela; Sanguisuga.

Description. *Hirudo medicinalis* is the leech commonly used in medicine and is a fresh-water annelid.

NOTE. The substance described in the *Chin. P.* as Hirudo (Leech) is the dried body of *Whitmania pigra, Hirudo nipponica*, or *Whitmania acranulata.*

Profile

Leeches are used for withdrawing blood from congested areas and have been found to be of value in plastic surgery. The buccal secretion of the leech contains the anticoagulant hirudin (p.1305). Once used a leech should not be applied to another patient.

There have been reports of wound infection from *Aeromonas hydrophila* transmitted by leeches. Prolonged bleeding for up to 10 hours may occur from the site of attachment after removal of the leech.

◊ Leeches are commonly used in plastic surgery and this has been reviewed.[1]

Wound infection by *Aeromonas hydrophila*, an organism normally found in the gut of the leech, is a recognised complication of the use of leeches for decongestion after plastic surgery. Other infecting organisms include *Aeromonas sobria* and *Serratia marcescens.* Infections have caused minor wound drainage, cellulitis, abscess, tissue loss, and sepsis, and a case of meningitis secondary to *Aeromonas* infection has been reported.[2] The following protocol has been suggested:[1] the site of application should first be cleaned with heparinised saline, and antibacterial prophylaxis with a quinolone and an aminoglycoside given for the duration of application. Patients discharged with open wounds should continue with oral antibacterials until wound closure.

In addition to its anticoagulant properties the buccal secretion of the leech contains anti-inflammatory substances, and leeches have been reported to provide subjective relief of symptoms[3,4] in osteoarthritis.

Lepirudin *(BAN, rINN)*

HBW-023; Lepirudiini; Lepirudina; Lépirudine; Lepirudinum. 1-L-Leucine-2-L-threonine-63-desulfohirudin (*Hirudo medicinalis* isoform HV1).

Лепирудин

$C_{287}H_{440}N_{80}O_{111}S_6$ = 6979.4.

CAS — 138068-37-8.

ATC — B01AE02.

ATC Vet — QB01AE02.

Adverse Effects and Precautions

The most frequent adverse effect of the direct thrombin inhibitors is bleeding. Hypersensitivity reactions have been reported. There have been reports of severe anaphylactic reactions, including death, with many occurring on re-exposure. There may be cross-reactivity with other hirudins or hirudin analogues.

Intramuscular injection should be avoided as it may cause local haematoma.

Direct thrombin inhibitors should be used with caution or avoided in patients with hepatic or renal impairment, and in those who are bleeding or at serious risk of bleeding, including those with haemorrhagic blood disorders, recent major bleeding, cerebrovascular disorders, bacterial endocarditis, severe hypertension, or patients who have recently undergone major surgery or puncture of large vessels or organ biopsy.

Hypersensitivity. The EMEA reported[1] in October 2002 that they were aware of 7 cases of severe anaphylactic reactions in patients given lepirudin; in 6 cases this followed re-exposure to the drug, and in 5 cases the patient died. A review[2] of the manufacturer's safety database identified 9 patients with severe anaphylactic reactions associated with lepirudin; 4 patients died, all of whom had received lepirudin within the previous 1 to 12 weeks. Although the risk of severe anaphylaxis was estimated to be low (0.015% on first exposure and 0.16% on re-exposure),[2] alternative treatment should be considered before re-exposure to lepirudin and it should only be used where treatment for an anaphylactic reaction is available.[1,2]

1. EMEA. EMEA public statement on Refludan (lepirudin)—fatal anaphylactic reactions (issued October 2002). Available at: http://www.emea.europa.eu/pdfs/human/press/pus/2771702en.pdf (accessed 16/05/08)
2. Greinacher A, *et al.* Anaphylactic and anaphylactoid reactions associated with lepirudin in patients with heparin-induced thrombocytopenia. *Circulation* 2003; **108:** 2062–5.

Interactions

Use of direct thrombin inhibitors with thrombolytics, oral anticoagulants, or drugs that affect platelet function may increase the risk of bleeding.

Pharmacokinetics

Lepirudin is metabolised and excreted by the kidney. About 45% of an intravenous dose is detected in the urine and about 35% is excreted unchanged. The terminal elimination half-life of lepirudin is about 1.3 hours. In patients with severe renal impairment the half-life may be prolonged to about 2 days.

Breast feeding. Three hours after injection, plasma concentrations of hirudin in a woman receiving lepirudin 50 mg subcutaneously twice daily were 0.5 to 1 microgram/mL, but no hirudin was detected in the breast milk.

1. Lindhoff-Last E, *et al.* Hirudin treatment in a breastfeeding woman. *Lancet* 2000; **355:** 467–8.

Uses and Administration

Lepirudin is a recombinant hirudin (p.1305) that is a direct inhibitor of thrombin. It is used as an anticoagulant in the management of thromboembolic disorders (p.1187) in patients with heparin-induced thrombocytopenia. It has been investigated in arterial thromboembolic disorders such as myocardial infarction and unstable angina.

In the management of thromboembolism in patients with heparin-induced thrombocytopenia lepirudin is given in an initial dose of 400 micrograms/kg by slow intravenous injection. This is followed by a maintenance dose of 150 micrograms/kg per hour by continuous intravenous infusion, adjusted according to response, usually for 2 to 10 days. Response should be monitored according to the activated partial thromboplastin time (APTT) ratio to achieve a target of 1.5 to 2.5. Doses must not exceed those based on a patient weight of 110 kg and in general an infusion rate of 210 micrograms/kg per hour should not be exceeded.

Doses of lepirudin should be reduced in patients with renal impairment, and infusions should be avoided in those on haemodialysis (see below).

Administration in renal impairment. Doses of lepirudin should be reduced in patients with renal impairment. The initial dose is reduced to 200 micrograms/kg, and the maintenance infusion rate is reduced according to creatinine clearance (CC):

- CC 45 to 60 mL/minute: infusion rate 50% of normal rate
- CC 30 to 44 mL/minute: 30% of normal rate
- CC 15 to 29 mL/minute: 15% of normal rate
- CC below 15 mL/minute: infusion of lepirudin should be avoided, although in haemodialysis patients or cases of acute renal failure further intravenous bolus doses of 100 micrograms/kg may be used on alternate days, according to response

Heparin-induced thrombocytopenia. Lepirudin is effective for the management of thromboembolism in patients with heparin-induced thrombocytopenia[1] (see Effects on the Blood under Adverse Effects of Heparin p.1302). Bleeding is the main complication during treatment, particularly with usual doses (see Uses and Administration, above) and in patients with renal impairment,[2] and use of lower doses has been suggested.[1,2]

1. Lubenow N, *et al.* HIT Investigators Group. Lepirudin in patients with heparin-induced thrombocytopenia—results of the third prospective study (HAT-3) and a combined analysis of HAT-1, HAT-2, and HAT-3. *J Thromb Haemost* 2005; **3:** 2428–36.
2. Tardy B, *et al.* GEHT-HIT Study Group. Predictive factors for thrombosis and major bleeding in an observational study in 181 patients with heparin-induced thrombocytopenia treated with lepirudin. *Blood* 2006; **108:** 1492–6.

Ischaemic heart disease. Recombinant hirudins have been investigated as alternatives to heparin in the management of acute ST-elevation myocardial infarction (p.1175) and in non-ST elevation myocardial infarction and unstable angina (see Angina Pectoris, p.1157), and have been used as adjuncts to medical or interventional treatment. Overall they appear to have some benefit over heparin,[1] but their precise role in each situation remains to be confirmed.

Initial studies comparing heparin with the recombinant hirudins desirudin[2,3] (p.1257) or lepirudin[4] in patients with acute ST-elevation **myocardial infarction** treated with thrombolytics had to be stopped because of higher than expected haemorrhagic stroke rates,[5,6] and subsequent studies using lower doses of desirudin[7,8] or lepirudin[9] failed to show a clear benefit over heparin. A study[10] with bivalirudin, a synthetic analogue of hirudin, in similar patients also found no mortality benefit; there were fewer reinfarctions in the bivalirudin group, but the risk of bleeding was increased. The role of hirudins is therefore not established, although they may be useful in patients with heparin-induced thrombocytopenia.

Studies in patients with **acute coronary syndromes** (non-ST elevation myocardial infarction and unstable angina) suggest that lepirudin is superior to heparin in preventing cardiovascular death, myocardial infarction, and refractory angina.[11,12] A study[13] comparing desirudin with heparin in unstable angina found that angiographic outcomes were better with desirudin, but another study[7] found little benefit in terms of mortality or recurrent ischaemia. Bivalirudin appears to be as effective as heparin in patients with acute coronary syndromes, but unlike the other hirudins the risk of major bleeding may be reduced.[14,15]

Hirudins have also been studied in patients undergoing **percutaneous coronary interventions** (see Reperfusion and Revascularisation Procedures, p.1181). Desirudin has been used in patients undergoing angioplasty[16,17] and appears to be safe, although no benefit has been shown over heparin. Lepirudin has been used as an alternative to heparin in patients with heparin-induced thrombocytopenia.[18-20] Bivalirudin is effective in patients with stable coronary artery disease[21,22] or acute coronary syndromes[21-23] undergoing percutaneous coronary interventions, and may reduce the need for adjunctive glycoprotein IIb/IIIa inhibitors.[21-23]

In patients undergoing **coronary artery bypass grafting**, hirudins may be an alternative to unfractionated heparin, and positive results have been reported with bivalirudin[24] and with lepirudin;[25] however, postoperative bleeding is increased and it was suggested[25] that hirudins should be reserved for patients with contra-indications to heparin, such as those with heparin-induced thrombocytopenia.

Lercanidipine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de lercanidipino; Lercanidipine, Chlorhydrate de; Lercanidipini Hydrochloridum; Lerkanidipin Hidroklorür; Masnidipine Hydrochloride; R-75; Rec-15-2375. (±)-2-[(3,3-Diphenylpropyl)methylamino]-1,1-dimethylethyl methyl 1,4-dihydro-2,6-dimethyl-4-(*m*-nitrophenyl)-3,5-pyridinedicarboxylate hydrochloride.

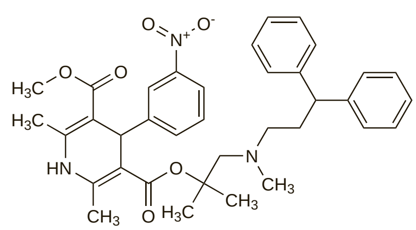
Лерканидипина Гидрохлорид

$C_{36}H_{41}N_3O_6,HCl = 648.2.$

CAS — 100427-26-7 (lercanidipine); 132866-11-6 (lercanidipine hydrochloride).

ATC — C08CA13.

ATC Vet — QC08CA13.



(lercanidipine)

Adverse Effects, Treatment, and Precautions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1350).

Interactions

As for dihydropyridine calcium-channel blockers (see Nifedipine, p.1352).

Pharmacokinetics

Lercanidipine is completely absorbed from the gastrointestinal tract after oral doses but undergoes extensive saturable first-pass metabolism. Bioavailability is low but is increased in the presence of food. Peak plasma concentrations occur about 1.5 to 3 hours after oral dosage. Lercanidipine is rapidly and widely distributed. It is more than 98% bound to plasma proteins. Lercanidipine is extensively metabolised, primarily by the cytochrome P450 isoenzyme CYP3A4, mainly to inactive metabolites; about 50% of an oral dose is excreted in the urine. A terminal elimination half-life of about 2 to 5 hours has been reported, but studies using a more sensitive assay have suggested a value of 8 to 10 hours.

Uses and Administration

Lercanidipine is a dihydropyridine calcium-channel blocker with actions similar to those of nifedipine (p.1354). It is used in the treatment of hypertension (p.1171).

Lercanidipine is given by mouth as the hydrochloride in a usual initial dose of 10 mg once daily before food, increased if necessary, after at least 2 weeks, to 20 mg daily.

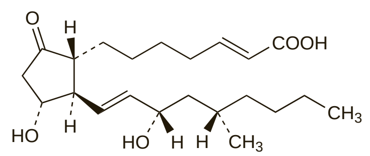
Limaprost (rINN)

Limaprostum; ONO-1206; OP-1206. (*E*)-7-{(1*R*,2*R*,3*R*)-3-Hydroxy-2-[(*E*)-(3*S*,5*S*)-3-hydroxy-5-methyl-1-nonenyl]-5-oxocyclopentyl}-2-heptenoic acid.

Лимапрост

$C_{22}H_{36}O_5$ = 380.5.
CAS — 74397-12-9 (limaprost); 88852-12-4 (limaprost alfadex).



Pharmacopoeias. *Jpn* includes limaprost alfadex.

Profile

Limaprost is a synthetic analogue of alprostadil (prostaglandin E_1) used in the management of peripheral vascular disease (p.1178). It is given orally as limaprost alfadex, in a dose equivalent to limaprost 15 to 30 micrograms daily in three divided doses.

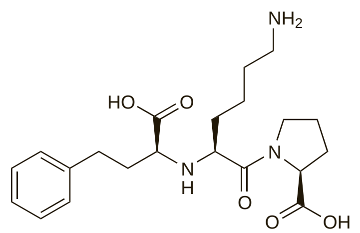
Lisinopril (BAN, USAN, rINN)

L-154826; Lisinopriili; Lisinoprilum; Lizinopril; Lizinoprilis; MK-521. *N*-{*N*-[(*S*)-1-Carboxy-3-phenylpropyl]-L-lysyl}-L-proline dihydrate.

Лизиноприл

$C_{21}H_{31}N_3O_5,2H_2O$ = 441.5.
CAS — 76547-98-3 (anhydrous lisinopril); 83915-83-7 (lisinopril dihydrate).
ATC — C09AA03.
ATC Vet — QC09AA03.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Lisinopril Dihydrate). A white or almost white crystalline powder. Soluble in water; practically insoluble in dehydrated alcohol and in acetone; sparingly soluble in methyl alcohol.

USP 31 (Lisinopril). A white crystalline powder. Soluble 1 in 10 of water and 1 in 70 of methyl alcohol; practically insoluble in alcohol, in acetone, in acetonitrile, in chloroform, and in ether.

Suspension. The US licensed prescribing information provides the following method for making 200 mL of a suspension containing lisinopril 1 mg/mL. Add 10 mL of purified water to a polyethylene terephthalate bottle containing ten 20-mg tablets (*Prinivil, Merck* or *Zestril, AstraZeneca*) and shake for at least 1 minute. Add 30 mL of *Bicitra* (*Alza, USA*) and 160 mL of *Ora-Sweet SF* (*Paddock, USA*) to the bottle and gently shake for several seconds. The suspension should be stored at or below 25° and can be stored for up to 4 weeks. Studies of the characteristics of this and other liquid dosage forms of lisinopril have been published.[1,2]

1. Thompson KC, *et al.* Characterization of an extemporaneous liquid formulation of lisinopril. *Am J Health-Syst Pharm* 2003; **60:** 69–74.
2. Nahata MC, Morosco RS. Stability of lisinopril in two liquid dosage forms. *Ann Pharmacother* 2004; **38:** 396–9.

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Porphyria. Lisinopril has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Lisinopril is slowly and incompletely absorbed after oral doses. About 25% of a dose is absorbed on average, but the absorption varies considerably between individuals, ranging from about 6 to 60%. It is already an active diacid and does not need to be metabolised *in vivo*. Peak concentrations in plasma are reported to occur after about 7 hours. Lisinopril is reported not to be significantly bound to plasma proteins. It is excreted unchanged in the urine. The effective half-life for accumulation after multiple doses is 12 hours in patients with normal renal function. Lisinopril is removed by haemodialysis.

Uses and Administration

Lisinopril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171) and heart failure (p.1165), prophylactically after myocardial infarction (p.1175), and in diabetic nephropathy (see Kidney Disorders, p.1199).

The haemodynamic effects of lisinopril are seen within 1 to 2 hours of a single oral dose and the maximum effect occurs after about 6 hours, although the full effect may not develop for several weeks during chronic dosing. The haemodynamic action lasts for about 24 hours after once-daily dosing. Lisinopril is given orally as the dihydrate, but doses are expressed in terms of the anhydrous substance. Lisinopril 2.72 mg as the dihydrate is equivalent to about 2.5 mg of anhydrous lisinopril. The dose of lisinopril should be reduced in patients with renal impairment (see below).

In the treatment of **hypertension**, the usual initial dose is 10 mg daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. Hypotension is particularly likely in patients with renovascular hypertension, volume depletion, heart failure, or severe hypertension and such patients should be given a lower initial dose of 2.5 to 5 mg once daily. Patients taking diuretics should have the diuretic withdrawn 2 or 3 days before lisinopril is started and resumed later if required; if this is not possible, an initial dose of 5 mg once daily should be given. The usual maintenance dose is 20 mg given once daily, though up to 80 mg daily may be given if necessary.

In the management of **heart failure**, severe first-dose hypotension on introduction of an ACE inhibitor is common in patients on loop diuretics, but their temporary withdrawal may cause rebound pulmonary oedema. Thus treatment should be started with a low dose under close medical supervision. Lisinopril is given in an initial dose of 2.5 mg daily. In the USA an initial dose of 5 mg daily is suggested. Usual maintenance doses range from 5 to 40 mg daily.

After **myocardial infarction**, treatment with lisinopril may be started within 24 hours of the onset of symptoms in an initial dose of 5 mg once daily for two days, then increased to 10 mg once daily. An initial dose of 2.5 mg once daily is recommended for patients with a low systolic blood pressure.

In the management of **diabetic nephropathy**, hypertensive type 2 diabetics with microalbuminuria may be given a dose of 10 mg once daily, increased if necessary to 20 mg once daily to achieve a sitting diastolic blood pressure below 90 mmHg.

Administration in children. Lisinopril has been reported to be an effective and well-tolerated antihypertensive in children 6 years of age and older,[1] although it has been used successfully in younger children.[2] US licensed product information recommends an oral starting dose for lisinopril of 70 micrograms/kg (up to 5 mg) once daily for children 6 years of age and older (but see also Administration in Renal Impairment, below). The *BNFC* recommends similar doses for children aged 6 to 12 years and states that this dose may be increased at intervals of 1 to 2 weeks to a maximum of 600 micrograms/kg or 40 mg once daily. For children between 12 and 18 years of age the *BNFC* recommends an initial dose of 2.5 mg daily increased as necessary to a maximum of 40 mg daily.

In the treatment of heart failure in children between 12 and 18 years of age the *BNFC* recommends an initial dose of 2.5 mg daily increased as necessary to a usual maintenance dose of 5 to 20 mg daily.

2. Raes A, *et al.* Lisinopril in paediatric medicine: a retrospective chart review of long-term treatment in children. *J Renin Angiotensin Aldosterone Syst* 2007; **8:** 3–12.

Administration in renal impairment. In *adult* patients with renal impairment, the initial dose of lisinopril should be reduced depending on the creatinine clearance (CC) as follows:

- CC 31 to 80 mL/minute: 5 to 10 mg once daily
- CC 10 to 30 mL/minute: 2.5 to 5 mg once daily
- CC less than 10 mL/minute or on dialysis: 2.5 mg once daily

The dose should be adjusted according to response, to a maximum of 40 mg once daily.

US licensed prescribing information states that lisinopril should not be given to *children* with a glomerular filtration rate of less than 30 mL/minute per 1.73 m^2 but gives no guidance on dosage in other children with renal impairment.

DuP-753; E-3340; Kalii Losartanum; Losartaanikalium; Losartán potásico; Losartan potassique; Losartan Potasyum; Losartankalium; Losartanum kalicum; MK-0954. 2-Butyl-4-chloro-1-[*p*-(*o*-1*H*-tetrazol-5-ylphenyl)benzyl]imidazole-5-methanol potassium.

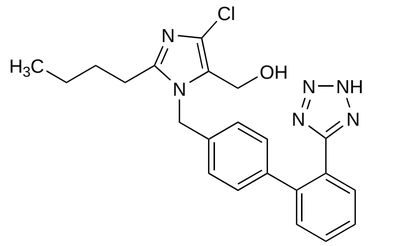
Калия Лозартан

$C_{22}H_{22}ClKN_6O$ = 461.0.

CAS — 114798-26-4 (losartan); 124750-99-8 (losartan potassium).

ATC — C09CA01.

ATC Vet — QC09CA01.



(losartan)

Pharmacopoeias. In *US.*

USP 31 (Losartan Potassium). A white to off-white powder. Freely soluble in water; slightly soluble in acetonitrile; soluble in isopropyl alcohol.

Adverse Effects

Adverse effects of losartan have been reported to be usually mild and transient, and include dizziness, headache, and dose-related orthostatic hypotension. Hypotension may occur particularly in patients with volume depletion (for example those who have received high-dose diuretics). Impaired renal function and, rarely, rash, urticaria, pruritus, angioedema, and raised liver enzyme values may occur. Hyperkalaemia, myalgia, and arthralgia have been reported. Losartan appears less likely than ACE inhibitors to cause cough. Other adverse effects that have been reported with angiotensin II receptor antagonists include respiratory-tract disorders, back pain, gastrointestinal disturbances, fatigue, and neutropenia. Rhabdomyolysis has been reported rarely.

◊ Reviews.

1. Mazzolai L, Burnier M. Comparative safety and tolerability of angiotensin II receptor antagonists. *Drug Safety* 1999; **21:** 23–33.

Angioedema. Angioedema is a recognised adverse effect of ACE inhibitors and is thought to be due to accumulation of bradykinins. Although angiotensin II receptor antagonists were thought to lack effects on bradykinin, several have been associated with reports[1-6] of angioedema, and increased levels of bradykinin have been shown[7] with losartan. In some cases patients had previously experienced angioedema with ACE inhibitors and caution is advised when using angiotensin II receptor antagonists in such patients.[4,8]

Effects on the blood. Symptomatic anaemia occurred[1] in a patient with a renal transplant 6 weeks after starting therapy with losartan. Decreased haemoglobin concentrations have also been reported[2] in patients with severe renal impairment undergoing haemodialysis.

Immune thrombocytopenia has been reported[3] in a patient shortly after starting losartan.

1. Horn S, *et al.* Losartan and renal transplantation. *Lancet* 1998; **351:** 111.
2. Schwarzbeck A, *et al.* Anaemia in dialysis patients as a side-effect of sartanes. *Lancet* 1998; **352:** 286.
3. Ada S, *et al.* Immune thrombocytopenia after losartan therapy. *Ann Intern Med* 2002; **137:** 704.

Effects on the liver. Raised liver enzyme values have occurred rarely in patients receiving losartan. Severe, acute hepatotoxicity developed in a patient 1 month after losartan was substituted for enalapril because of ACE inhibitor-induced cough.[1] The patient recovered when losartan was withdrawn but symptoms and raised liver enzyme concentrations recurred following rechallenge. Acute, reversible hepatotoxicity also occurred in a patient who had been taking losartan 150 mg daily for 6 weeks.[2] A case of cholestatic jaundice associated with irbesartan therapy has also been reported;[3] the jaundice resolved slowly once irbesartan was withdrawn.

3. Hariraj R, *et al.* Prolonged cholestasis associated with irbesartan. *BMJ* 2000; **321:** 547.

Effects on the skin. Atypical cutaneous lymphoid infiltrates developed in 2 patients receiving losartan for hypertension.[1] In both cases the lesions disappeared within a few weeks of stopping the drug.

Henoch-Schönlein purpura has been reported[2,3] in patients taking losartan; in 1 case[2] the reaction recurred on rechallenge. A purpuric rash with evidence of vasculitis has been reported with candesartan;[4] the patient also developed acute nephritis.

A polycyclic rash associated with systemic illness developed in a patient who had been taking irbesartan for 2 years;[5] improvement occurred within 2 days of stopping the drug.

There has also been a report[6] of a number of patients in whom psoriasis either developed or was exacerbated following treatment with an angiotensin II receptor antagonist; the drugs involved included candesartan, irbesartan, losartan, and valsartan. In most cases the lesions regressed after the drug was withdrawn.

6. Marquart-Elbaz C, *et al.* Sartans, angiotensin II receptor antagonists, can induce psoriasis. *Br J Dermatol* 2002; **147:** 617–8.

Effects on taste. Taste disturbances, in some cases progressing to complete taste loss, have occurred[1,2] in patients receiving losartan for hypertension. In each case taste returned to normal after stopping losartan therapy. Taste impairment has also been reported with both candesartan[3,4] and valsartan[4] in healthy subjects.

1. Schlienger RG, *et al.* Reversible ageusia associated with losartan. *Lancet* 1996; **347:** 471–2.

4. Tsuruoka S, *et al.* Angiotensin II receptor blocker-induces blunted taste sensitivity: comparison of candesartan and valsartan. *Br J Clin Pharmacol* 2005; **60:** 204–7.

Hypersensitivity. See Angioedema,and Effects on the Skin, above.

Migraine. Severe migraine has been reported[1] in a patient after use of losartan. The patient had no history of migraine and symptoms recurred on rechallenge. However, angiotensin II receptor antagonists have also been reported to reduce the incidence of migraine (see under Uses and Administration, below).

1. Ahmad S. Losartan and severe migraine. *JAMA* 1995; **274:** 1266–7.

Pancreatitis. Acute pancreatitis has been reported[1,2] in 2 patients receiving losartan. However, 1 of the patients subsequently developed pancreatitis unrelated to losartan.[3] The other patient[2] had also developed acute pancreatitis during enalapril therapy. Acute pancreatitis has also been reported[4] with irbesartan; the patient was also taking hydrochlorothiazide but in a dose lower than that usually associated with thiazide-induced pancreatitis. Biochemical alterations suggestive of acute pancreatitis have been reported after telmisartan overdosage.[5]

1. Bosch X. Losartan-induced acute pancreatitis. *Ann Intern Med* 1997; **127:** 1043–4.

5. Baffoni L, *et al.* Acute pancreatitis induced by telmisartan overdose. *Ann Pharmacother* 2004; **38:** 1088.

Vasculitis. For mention of the development of Henoch-Schönlein purpura and other vasculitic disorders in patients receiving angiotensin II receptor antagonists see Effects on the Skin, above.

Precautions

Losartan is contra-indicated in pregnancy (see below). It should be used with caution in patients with renal artery stenosis. Losartan is excreted in urine and in bile and reduced doses may therefore be required in patients with renal impairment and should be considered in patients with hepatic impairment. Patients with volume depletion (for example those who have received high-dose diuretic therapy) may experience hypotension; volume depletion should be corrected before starting therapy, or a low initial dose should be used. Since hyperkalaemia may occur, serum-potassium concentrations should be monitored, especially in the elderly and patients with renal impairment, and potassium-sparing diuretics should generally be avoided.

Diabetes mellitus. After reports of reduced awareness of hypoglycaemia in type 1 diabetic patients receiving losartan, a study[1] in healthy subjects found that losartan slightly attenuated the symptomatic and hormonal responses to hypoglycaemia. Although the clinical significance was not established, the authors recommended that losartan should be used with caution in diabetics with reduced awareness of hypoglycaemia. However, losartan and other angiotensin II receptor antagonists may have a role in type 2 diabetics with nephropathy (see Kidney Disorders under Uses, below). There is also some evidence[2-6] that angiotensin II receptor antagonists may prevent the development of diabetes in non-diabetic patients.

Pregnancy. Losartan is contra-indicated in pregnancy since it has been associated with fetal toxicity in *animal* studies and other drugs that act on the renin-angiotensin system, such as ACE inhibitors, have been associated with fetal toxicity in humans (see p.1196). Oligohydramnios with subsequent fetal death occurred in a patient who received losartan during weeks 20 to 31 of pregnancy;[1] the effects on the fetus were similar to those reported with ACE inhibitors. A number of similar cases have subsequently been reported with losartan,[2,3] candesartan,[4] and valsartan.[3,5,6]

Interactions

The antihypertensive effects of losartan may be potentiated by drugs or other agents that lower blood pressure. An additive hyperkalaemic effect is possible with potassium supplements, potassium-sparing diuretics, or other drugs that can cause hyperkalaemia; losartan and potassium-sparing diuretics should not generally be given together. NSAIDs should be used with caution in patients taking losartan as the risk of renal impairment may be increased, particularly in those who are inadequately hydrated; use of NSAIDs may also attenuate the hypotensive effect of losartan. Losartan and some other angiotensin II receptor antagonists are metabolised by cytochrome P450 isoenzymes and interactions may occur with drugs that affect these enzymes.

Lithium. For reference to a possible interaction between lithium and angiotensin II receptor antagonists, see p.404.

Pharmacokinetics

Losartan is readily absorbed from the gastrointestinal tract after oral doses, but undergoes substantial first-pass metabolism resulting in a systemic bioavailability of about 33%. It is metabolised to an active carboxylic acid metabolite E-3174 (EXP-3174), which has greater pharmacological activity than losartan; some inactive metabolites are also formed. Metabolism is primarily by cytochrome P450 isoenzymes CYP2C9 and CYP3A4. Peak plasma concentrations of losartan and E-3174 occur about 1 hour and 3 to 4 hours, respectively, after an oral dose. Both losartan and E-3174 are more than 98% bound to plasma proteins. Losartan is excreted in the urine, and in the faeces via bile, as unchanged drug and metabolites. About 4% of an oral dose is excreted unchanged in urine and about 6% is excreted in urine as the active metabolite. The terminal elimination half-lives of losartan and E-3174 are about 1.5 to 2.5 hours and 3 to 9 hours, respectively.

Uses and Administration

Losartan is an angiotensin II receptor antagonist with antihypertensive activity due mainly to selective blockade of AT_1 receptors and the consequent reduced pressor effect of angiotensin II. It is used in the management of hypertension (p.1171), particularly in patients who develop cough with ACE inhibitors and to reduce the risk of stroke in patients with left ventricular hypertrophy, and in the treatment of diabetic nephropathy (see Kidney Disorders, below). It has also been tried in heart failure (below) and in myocardial infarction (p.1175).

Losartan is given orally as the potassium salt. The maximum hypotensive effect is achieved in about 3 to 6 weeks after starting treatment.

In **hypertension** the usual dose of losartan potassium is 50 mg once daily. The dose may be increased, if necessary, to 100 mg daily as a single dose or in two divided doses. An initial dose of 25 mg once daily should be given to patients with intravascular fluid depletion, and is recommended in the UK in patients over 75 years of age. Similar reductions may be appropriate in patients with hepatic or renal impairment (but see below).

There are limited data on the use of losartan in children with hypertension. In the UK, the recommended initial dose of losartan potassium for children weighing between 20 and 50 kg is 25 mg once daily; this may be increased to a maximum of 50 mg once daily. In the USA, children aged 6 years or over may be given an initial dose of 700 micrograms/kg once daily, with a maximum of 50 mg, adjusted according to response. There are no data to recommend doses for children with glomerular filtration rate below 30 mL/min per 1.73 m^2, and in the UK losartan should not be given to children with hepatic impairment.

In **diabetic nephropathy** losartan potassium is given in an initial dose of 50 mg once daily, increased to 100 mg once daily depending on the blood pressure.

Administration in hepatic or renal impairment. Licensed product information in both the UK and the USA recommend a reduced dose of losartan in patients with hepatic impairment; the suggested initial dose in the USA is 25 mg daily. In the UK an initial dose of 25 mg daily is also recommended in those with moderate to severe renal impairment (creatinine clearance less than 20 mL/minute), but in the USA dosage reduction is considered unnecessary.

Cardiac arrhythmias. See under Heart Failure, below.

Cardiovascular risk reduction. The benefits of ACE inhibitors in patients with high cardiovascular risk are well-established (see Cardiovascular Risk Reduction, p.1164) but whether angiotensin II receptor antagonists have comparable effects is less clear. In the LIFE study,[1] losartan reduced cardiovascular events more than a beta blocker (atenolol), despite a similar effect on blood pressure. In VALUE,[2] there was no difference in the incidence of cardiovascular events between valsartan and a calcium-channel blocker (amlodipine), although the calcium-channel blocker reduced blood pressure to a greater extent. However, in hypertensive stroke patients,[3] eprosartan reduced the risk of cardiovascular and cerebrovascular events more than another calcium-channel blocker (nitrendipine); blood pressure reduction was similar with both drugs. A study[4] comparing telmisartan with the ACE inhibitor ramipril, found that both reduced cardiovascular events to a similar extent; there was no additional benefit in patients given both drugs.

Based on the results of VALUE, there has been concern that angiotensin II receptor antagonists may increase the risk of myocardial infarction, but a systematic review[5] was unable to confirm a significant effect.

Erythrocytosis. For reference to the use of losartan in the management of secondary erythrocytosis, see under ACE inhibitors, p.1198

Heart failure. Diuretics, ACE inhibitors, and beta blockers are the standard drugs used in the management of heart failure (p.1165). Angiotensin II receptor antagonists have been studied as an alternative to ACE inhibitors since they may be better tolerated. In the ELITE study,[1] which compared losartan with captopril, both drugs had similar effects on renal function but other adverse effects were fewer with losartan and there was also a reduction in mortality in patients receiving losartan. However, the larger ELITE II study[2] failed to confirm any survival benefit with losartan, and studies with losartan[3] and valsartan[4] in patients with heart failure following myocardial infarction have also failed to show superiority over ACE inhibitors. ACE inhibitors therefore remain first-line therapy, although angiotensin II receptor antagonists may be used as an alternative, particularly in patients unable to tolerate ACE inhibitors.[5,6] The combination of angiotensin II receptor antagonists with ACE inhibitors has also shown some benefit.[6] In the ValHeFT study,[7] valsartan was added to standard therapy (including ACE inhibitors in most patients) and reduced the combined end-point of death or hospitalisation for heart failure, although the effect on mortality alone was not significant. In the CHARM-Added trial,[8] addition of candesartan to therapy including an ACE inhibitor also led to a reduction in cardiovascular events. However, in the VALIANT study,[4] no additional benefit was found from using valsartan with captopril. There has been some concern that use of triple therapy with angiotensin II receptor antagonists, ACE inhibitors, and beta blockers, might be detrimental, but this has not been confirmed. In ValHeFT,[7] mortality appeared to be increased in patients receiving all three drug classes, but in both CHARM-Added[8] and VALIANT[4] use of beta blockers had no effect on the results. Use of ACE inhibitors and angiotensin II receptor antagonists together may therefore be considered in patients who remain symptomatic despite standard therapy, including patients receiving beta blockers.[9,10]

There is some evidence[11] that angiotensin II receptor antagonists may reduce the incidence of arrhythmias in patients with heart failure.

Kidney disorders. ACE inhibitors have an established role in the management of type 1 and type 2 diabetics with nephropathy, whether or not they are hypertensive, and may also slow the progression of nephropathy in diabetics with microalbuminuria (see p.1199). A number of studies have investigated the effects of angiotensin II receptor antagonists in type 2 diabetics with varying degrees of nephropathy (see Diabetic Complications, p.433). Irbesartan,[1,2] losartan,[3,4] and valsartan[5] have all been reported to reduce the progression of nephropathy independently of their effect on blood pressure. The magnitude of the benefit in retarding progression of nephropathy seems to be similar with angiotensin II receptor antagonists and ACE inhibitors,[6-8] and the American Diabetes Association considers them equal first choices in the management of the condition.[9]

Angiotensin II receptor antagonists have also reduced urinary albumin excretion in non-diabetic patients, including those with hypertension,[10] and those with IgA nephropathy.[11]

A study[12] in diabetics using a combination of candesartan with lisinopril found that blood pressure and microalbuminuria were reduced more with combination therapy than with either drug alone. Benefit has also been reported[13] with a combination of losartan and trandolapril in patients with non-diabetic renal disease.

Migraine. Angiotensin II receptor antagonists may reduce the incidence of headache. A randomised trial[1] in 60 patients with migraine suggested that candesartan might be effective for prophylaxis, and beneficial results have also been reported[2] with olmesartan. However, there has been a report of migraine caused by an angiotensin II receptor antagonist (see under Adverse Effects, above).

Uricosuric action. Losartan has been found to increase urinary uric acid excretion and reduce serum uric acid concentrations in healthy subjects[1] and in hypertensive patients.[2,3] However, the effect is generally small and the clinical significance is not clear. Other angiotensin II receptor antagonists do not appear to have such an effect.[2,3]

Lovastatin *(BAN, USAN, rINN)*

L-154803; Lovastatiini; Lovastatina; Lovastatinas; Lovastatine; Lovastatinum; Lovasztatin; MB-530B; 6α-Methylcompactin; Mevinolin; MK-803; Monacolin K; MSD-803. (3*R*,5*R*)-7-{(1*S*,2*S*,6*R*,8*S*,8a*R*)-1,2,6,7,8,8a-Hexahydro-2,6-dimethyl-8-[(*S*)-2-methylbutyryloxy]-1-naphthyl}-3-hydroxyheptan-5-olide.

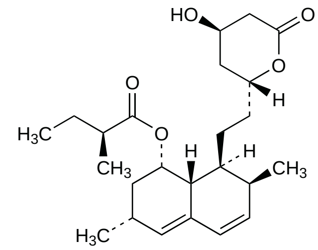
Ловастатин

$C_{24}H_{36}O_5$ = 404.5.

CAS — 75330-75-5.

ATC — C10AA02.

ATC Vet — QC10AA02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Lovastatin). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; soluble in acetone. Store under nitrogen at a temperature of 2° to 8°.

USP 31 (Lovastatin). A white to off-white crystalline powder. Insoluble in water; sparingly soluble in alcohol; practically insoluble in petroleum spirit; freely soluble in chloroform; soluble in acetone, in acetonitrile, and in methyl alcohol. Store under nitrogen in airtight containers at a temperature not exceeding 8°.

Adverse Effects and Precautions

As for Simvastatin, p.1390.

Incidence of adverse effects. Adverse effects led to withdrawal of lovastatin in 21 of 745 patients receiving the drug for about 5 years.[1] They included asymptomatic elevation of hepatic aminotransferases in 10 patients, gastrointestinal symptoms in 3, rash in 2, myopathy in 2, myalgia in 1, arthralgia in 1, insomnia in 1, and weight gain in 1.

1. Lovastatin Study Groups. Lovastatin 5-year safety and efficacy study: Lovastatin Study Groups I through IV. *Arch Intern Med* 1993; **153:** 1079–87.

Interactions

As for Simvastatin, p.1392.

For specific dosage reductions in patients taking lovastatin with interacting drugs, see Uses and Administration, below.

Pharmacokinetics

Lovastatin is absorbed from the gastrointestinal tract and must be hydrolysed to its active β-hydroxyacid form. Three other metabolites have also been isolated. Lovastatin is a substrate for the cytochrome P450 isoenzyme CYP3A4 and undergoes extensive first-pass metabolism in the liver, its primary site of action; less than 5% of an oral dose has been reported to reach the circulation. Peak plasma concentrations occur within 2 to 4 hours, and steady-state concentrations are achieved after 2 to 3 days with daily dosage. Both lovastatin and its β-hydroxyacid metabolite are more than 95% bound to plasma proteins. Lovastatin is mainly excreted in the bile as metabolites; about 85% of a dose has been recovered from the faeces and about 10% from the urine. The half-life of the active metabolite is 1 to 2 hours.

◊ General reviews.

2. Lennernäs H, Fager G. Pharmacodynamics and pharmacokinetics of the HMG-CoA reductase inhibitors: similarities and differences. *Clin Pharmacokinet* 1997; **32:** 403–25.

Uses and Administration

Lovastatin, a 3-hydroxy-3-methylglutaryl coenzyme A (HMG-CoA) reductase inhibitor (a statin), is a lipid regulating drug with actions on plasma lipids similar to those of simvastatin (p.1394).

Lovastatin is used to reduce cholesterol in the treatment of hyperlipidaemias (p.1169), particularly in type IIa and IIb hyperlipoproteinaemias. It is also given for cardiovascular risk reduction (p.1164) in both primary and secondary prevention of ischaemic heart disease.

Lovastatin is given in an initial oral dose of 10 to 20 mg daily in the evening with food, increased, if necessary, at intervals of 4 weeks or more to 80 mg daily as a single dose or in 2 divided doses. Lower doses of lovastatin should be used in patients at risk of myopathy, including patients with severe renal impairment (see below) and those taking drugs that interact with lovastatin; an initial dose of 10 mg daily is recommended in patients taking *ciclosporin* or *danazol*, and the daily dose should not exceed 20 mg in patients taking *ciclosporin, danazol, fibric acid derivatives*, or *nicotinic acid*, or 40 mg in those taking *amiodarone* or *verapamil*.

For the use of lovastatin in children, see below.

◊ General reviews.

1. Curran MP, Goa KL. Lovastatin extended release: a review of its use in the management of hypercholesterolaemia. *Drugs* 2003; **63:** 685–99.

Administration in children. Lovastatin reduces plasma-cholesterol concentrations in children and adolescents with heterozygous familial hypercholesterolaemia[1-3] and has been given safely for up to 48 weeks in boys,[2] and up to 24 weeks in girls.[3] In the USA it is licensed in children aged 10 to 17 years and is given orally in an initial dose of 10 to 20 mg once daily, increased at intervals of 4 weeks or more, if necessary, to a maximum dose of 40 mg once daily.

1. Lambert M, *et al.* Canadian Lovastatin in Children Study Group. Treatment of familial hypercholesterolemia in children and adolescents: effect of lovastatin. *Pediatrics* 1996; **97:** 619–28.
2. Stein EA, *et al.* Efficacy and safety of lovastatin in adolescent males with heterozygous familial hypercholesterolemia: a randomized controlled trial. *JAMA* 1999; **281:** 137–44.
3. Clauss SB, *et al.* Efficacy and safety of lovastatin therapy in adolescent girls with heterozygous familial hypercholesterolemia. *Pediatrics* 2005; **116:** 682–8.

Administration in renal impairment. Patients with renal impairment may be at increased risk of myopathy and US licensed product information states that doses of lovastatin above 20 mg daily should be used cautiously in patients with a creatinine clearance below 30 mL/minute.

Adrenoleucodystrophy. A preliminary study[1] has shown that lovastatin may be useful in the treatment of adrenoleucodystrophy (see under Lorenzo's Oil, p.2334). Lovastatin reduced the plasma levels of very-long-chain fatty acids which are known to be elevated in patients with this rare metabolic disorder.

Low-molecular-weight Heparins

Depolymerised Heparins; Heparina massae molecularis minoris; Heparinas de bajo peso molecular; Hepariner, lågmolekylära; Héparines de basse masse moléculaire; Hepariny nízkomolekulární; LMW Heparins; Low-molecular-mass Heparins; Mažos molekulinės masės heparinai; Pienimolekyyliset hepariinit.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Heparins, Low-molecular Mass; Low-molecular-weight Heparins BP 2008). Salts of sulfated glucosaminoglycans having a mass-average molecular mass less than 8000. They are obtained by fractionation or depolymerisation of heparin of natural origin and display different chemical structures at the reducing or the non-reducing end of the polysaccharide chains.

The potency is not less than 70 units of anti-factor Xa activity per mg with reference to the dried substance and the ratio of anti-factor Xa activity to anti-factor IIa (antithrombin) activity is not less than 1.5.

A white or almost white hygroscopic powder. Freely soluble in water. A 1% solution in water has a pH of 5.5 to 8.0. Store in airtight containers.

Units

The second International Standard for low-molecular-weight heparin was agreed in 2003 and is used to calibrate products for both anti-factor Xa and anti-factor IIa activities. Potency is expressed in terms of units of anti-factor Xa activity per mg and the ratio of anti-factor Xa to anti-factor IIa activity. This ratio differs for individual low-molecular-weight heparins and neither they nor unfractionated heparin can be used interchangeably unit for unit.

Adverse Effects

As for Heparin, p.1301.

Effects on the blood. It was hoped that, because of their higher ratio of anti-factor Xa to anti-thrombin activity compared with heparin, low-molecular-weight heparins might cause less bleeding while maintaining their antithrombotic activity. Some large studies[1,2] have suggested less bleeding with low-molecular-weight heparins than with unfractionated heparin. However, meta-analyses and reviews[3,4] have been unable to confirm a significant reduction in major haemorrhage in patients treated with low-molecular-weight heparins, compared with heparin, for venous thromboembolism, although they confirmed that low-molecular-weight heparins are not associated with an increase in risk. There may be an increased risk of bleeding in patients with renal impairment,[5,6] (see Precautions, below) although the criterion of creatinine clearance 30 mL/minute or less as a guide to selecting patients at increased risk has been questioned;[7] pharmacokinetic response may vary according to the low-molecular-weight heparin used.

Thrombocytopenia has also been reported with low-molecular-weight heparins[8-10] although in one study the incidence was less than with unfractionated heparin.[11]

Thrombocytosis has also been reported.[12,13]

Effects on the skin. Adverse effects of low-molecular-weight heparins on the skin have been reviewed[1] and are estimated to be rare. Most low-molecular-weight heparins have been implicated. Urticarial rash or immediate hypersensitivity has been reported (see below). Delayed hypersensitivity skin reactions have occurred mainly in women. These women were generally postmenopausal, pregnant, or in the postpartum period, suggesting a hormonal influence on pathogenesis. About half of these patients also had a history of allergy to unfractionated heparin.

Skin necrosis reactions are usually localised to the subcutaneous injection site, although distant lesions have also been reported. There has been a report[2] of diffuse skin necrosis leading to fatality in a patient given enoxaparin.

1. Wütschert R, *et al.* Adverse skin reactions to low molecular weight heparins: frequency, management and prevention. *Drug Safety* 1999; **20:** 515–25.
2. Nadir Y, *et al.* A fatal case of enoxaparin induced skin necrosis and thrombophilia. *Eur J Haematol* 2006; **77:** 166–8.

Hypersensitivity. Reports of hypersensitivity reactions associated with low-molecular-weight heparins are rare. However, a patient being treated with enoxaparin 20 mg subcutaneously daily developed a widespread pruritic urticaria and swelling of lips and tongue after 3 days of treatment.[1] Antihistamines and prednisone given with enoxaparin failed to control the reaction and enoxaparin was stopped after a further 3 days. Urticaria and angioedema rapidly resolved on withdrawal.

Delayed hypersensitivity skin reactions have also been reported (see above).

1. Odeh M, Oliven A. Urticaria and angioedema induced by low-molecular-weight heparin. *Lancet* 1992; **340:** 972–3.

Treatment of Adverse Effects

Severe bleeding with low-molecular-weight heparins, usually caused by accidental overdosage, may be reduced by the slow intravenous injection of protamine sulfate (p.1461). The recommended doses of protamine sulfate are given in the individual monographs and should completely neutralise the anti-thrombin effect of the low-molecular-weight heparin but will only partially neutralise the anti-factor-Xa effect. Not more than 50 mg of protamine sulfate should be injected for any one dose.

Precautions

As for Heparin, p.1303.

Low-molecular-weight heparins should not be given to patients who have developed thrombocytopenia with heparin and who have a positive *in-vitro* platelet aggregation test (that is, cross-reactivity) with the particular low-molecular-weight heparin to be used.

Monitoring of plasma-anti-factor-Xa activity may be considered in patients with an increased risk of bleeding, for example the elderly or those with renal impairment or extremes of body-weight, and in patients with active bleeding.

Licensed product information for some low-molecular-weight heparins contra-indicates their use in patients with prosthetic heart valves as they may not provide adequate prophylaxis against thromboembolism even at high doses (but see under Valvular Heart Disease, p.1187, for references to their use).

Spinal anaesthesia. Spinal and epidural haematomas, sometimes leading to paralysis, have occurred in patients receiving low-molecular-weight heparins with spinal or epidural anaesthesia or analgesia (see p.1303).

Interactions

As for Heparin, p.1303.

Pharmacokinetics

Although the precise pharmacokinetic parameters of different low-molecular-weight heparins vary (see individual monographs), they generally have a greater bioavailability after subcutaneous injection and a longer half-life than heparin.

◊ References.

2. Samama MM, Gerotziafas GT. Comparative pharmacokinetics of LMWHs. *Semin Thromb Hemost* 2000; **26** (suppl 1): 31–8.

Uses and Administration

Low-molecular-weight heparins are salts of fragments of heparin produced by chemical or enzymatic depolymerisation of the heparin molecule. Commercially available low-molecular-weight heparins differ in their method of production, molecular-weight range, and degree of sulfation. Those included in *Martindale* are:

- Ardeparin, p.1216
- Bemiparin, p.1223
- Certoparin, p.1242

- Dalteparin, p.1255
- Enoxaparin, p.1277
- Nadroparin, p.1346
- Parnaparin, p.1366
- Reviparin, p.1388
- Tinzaparin, p.1413

Like heparin (p.1303), these compounds enhance the action of antithrombin III but they are characterised by a higher ratio of anti-factor Xa to anti-factor IIa (antithrombin) activity than heparin. Low-molecular-weight heparins have less effect on platelet aggregation than heparin. They have no significant effect on blood coagulation tests such as activated partial thromboplastin time (APTT). Therapy may be monitored by measurement of plasma-anti-factor-Xa activity but monitoring is less frequently required than with heparin since low-molecular-weight heparins have a more predictable effect.

Low-molecular-weight heparins are used in the management of venous thromboembolism (deep-vein thrombosis and pulmonary embolism, p.1189). They are used for prophylaxis, particularly during surgery, and for treatment of established thromboembolism. They are given by subcutaneous injection once or twice daily. They are also used intravenously to prevent coagulation during haemodialysis and other extracorporeal circulatory procedures. They may be given subcutaneously in the management of unstable angina (p.1157) and both intravenously and subcutaneously in acute myocardial infarction (p.1175).

Doses are expressed either in terms of the weight of low-molecular-weight heparin or in terms of units of anti-factor Xa activity. Since low-molecular-weight heparins differ in their relative inhibition of factor Xa and thrombin, doses, even when expressed in terms of anti-factor-Xa activity, cannot be equated. Different preparations of the same low-molecular-weight heparin may appear to have different doses depending on the reference preparation used.

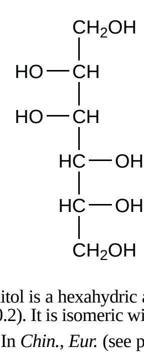
Mannitol ⊗

Cordycepic Acid; E421; Manita; Manitol; Manitolis; Manna Sugar; Mannit; Mannite; Mannitoli; Mannitolum. D-Mannitol.

Маннит; Маннитол

$C_6H_{14}O_6$ = 182.2.
CAS — 69-65-8.
ATC — A06AD16; B05BC01; B05CX04.
ATC Vet — QA06AD16; QB05BC01; QB05CX04.



Description. Mannitol is a hexahydric alcohol related to mannose ($C_6H_{12}O_6$ = 180.2). It is isomeric with sorbitol (p.1965).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Mannitol). A white or almost white crystalline powder or free-flowing granules. It exhibits polymorphism. Freely soluble in water; very slightly soluble in alcohol.

USP 31 (Mannitol). A white odourless crystalline powder or free-flowing granules with a sweet taste. Soluble 1 in 5.5 of water; very slightly soluble in alcohol; practically insoluble in ether; slightly soluble in pyridine; soluble in alkaline solutions.

Incompatibility. Mannitol should never be added to whole blood for transfusion or given through the same set by which blood is being infused. For details of the adverse effects of mannitol on red blood cells, see Effects on the Blood under Adverse Effects, below.

Supersaturated solutions. Supersaturated aqueous solutions are prepared with the aid of heat. Any crystals that form during storage of the injection should be dissolved by warming before use; this may be a particular problem with the 20 and 25% injections which are supersaturated. A 5.07% solution in water is iso-osmotic with serum.

Adverse Effects

The most common adverse effect associated with mannitol therapy is fluid and electrolyte imbalance including circulatory overload and acidosis at high doses. The expansion of extracellular volume can precipitate pulmonary oedema and patients with diminished cardiac reserve are at special risk. The shift of fluid from the intracellular to extracellular compartment can cause tissue dehydration; dehydration of the brain, particularly in patients with renal failure, may give rise to CNS symptoms.

When given orally, mannitol causes diarrhoea. Intravenous infusion of mannitol has been associated with nausea, vomiting, thirst, headache, dizziness, chills, fever, tachycardia, chest pain, hyponatraemia, dehydration, blurred vision, urticaria, and hypotension or hypertension. Large doses have been associated rarely with acute renal failure. Hypersensitivity reactions have occurred.

Extravasation of the solution may cause oedema and skin necrosis; thrombophlebitis may occur.

Effects on the blood. Agglutination and irreversible crenation of erythrocytes occurred when blood was mixed with varying proportions of a 10% mannitol solution.[1] It was suggested that intravenous infusions should be carefully controlled and given at a slow rate. This observation could have particular relevance to patients with sickle-cell disease.[2,3] Although agglutination and crenation had been observed *in vitro*, dilutional effects would make *in-vivo* interaction with blood cells less likely.[4]

1. Roberts BE, Smith PH. Hazards of mannitol infusions. *Lancet* 1966; **ii:** 421–2.
2. Konotey-Ahulu FID. Hazards of mannitol infusions. *Lancet* 1966; **ii:** 591.
3. Roberts BE, Smith PH. Hazards of mannitol infusions. *Lancet* 1966; **ii:** 591.
4. Samson JH. Hazards of mannitol infusions. *Lancet* 1966; **ii:** 1191.

Effects on the gastrointestinal tract. Potentially explosive intracolonic concentrations of hydrogen gas have been measured in patients given mannitol before colonoscopy,[1,2] and cases of colonic explosion, including fatalities, have been reported in patients undergoing colonoscopic electrocautery, who had received mannitol bowel preparation. However, the risk of explosion was considered to be small when air or carbon dioxide insufflation and suction were used during the colonoscopy procedure.[2,3]

Colonic perforation and subsequent death has been attributed to the use of mannitol for the treatment of constipation.[4]

1. La Brooy SJ, *et al.* Potentially explosive colonic concentrations of hydrogen after bowel preparation with mannitol. *Lancet* 1981; **i:** 634–6.
2. Avgerinos A, *et al.* Bowel preparation and the risk of explosion during colonoscopic polypectomy. *Gut* 1984; **25:** 361–4.
3. Trotman I, Walt R. Mannitol and explosions. *Lancet* 1981; **i:** 848.
4. Moses FM. Colonic perforation due to oral mannitol. *JAMA* 1988; **260:** 640.

Effects on the kidneys. Focal osmotic nephrosis occurred in a patient given mannitol 20% intravenously.[1]

Acute oliguric renal failure has been associated with the use of large doses of mannitol in patients with previously normal renal function,[2-4] and acute renal failure developed[5] in a patient with diabetes mellitus complicated by nephropathy after he was given 420 g of mannitol intravenously over 4 days.

1. Goodwin WE, Latta H. Focal osmotic nephrosis due to the therapeutic use of mannitol: a case of perirenal hematoma after renal biopsy. *J Urol (Baltimore)* 1970; **103:** 11–14.
2. Whelan TV, *et al.* Acute renal failure associated with mannitol intoxication. *Arch Intern Med* 1984; **144:** 2053–5.
3. Goldwasser P, Fotino S. Acute renal failure following massive mannitol infusion: appropriate response of tubuloglomerular feedback? *Arch Intern Med* 1984; **144:** 2214–16.
4. Rabetoy GM, *et al.* Where the kidney is concerned, how much mannitol is too much? *Ann Pharmacother* 1993; **27:** 25–8.
5. Matsumura M. Mannitol-induced toxicity in a diabetic patient receiving losartan. *Am J Med* 2001; **110:** 331.

Overdosage. Severe mannitol intoxication was reported in 8 patients with renal failure given large, and sometimes enormous, amounts of mannitol intravenously over 1 to 3 days.[1] These patients had CNS involvement out of proportion to uraemia, severe hyponatraemia, a large osmolality gap, and fluid overload. Six patients were treated with haemodialysis and this was considered to be more effective than peritoneal dialysis, which was used in 1 patient.

1. Borges HF, *et al.* Mannitol intoxication in patients with renal failure. *Arch Intern Med* 1982; **142:** 63–6.

Precautions

Mannitol is contra-indicated in patients with pulmonary congestion or pulmonary oedema, intracranial bleeding (except during craniotomy), heart failure (in patients with diminished cardiac reserve, expansion of the extracellular fluid may lead to fulminating heart failure), and in patients with renal failure unless a test dose has produced a diuretic response (if urine flow is inadequate, expansion of the extracellular fluid may lead to acute water intoxication).

Mannitol should not be given with whole blood.

All patients given mannitol should be carefully observed for signs of fluid and electrolyte imbalance and renal function should be monitored.

Pharmacokinetics

Only small amounts of mannitol are absorbed from the gastrointestinal tract. After intravenous injection mannitol is excreted rapidly by the kidneys before any very significant metabolism can take place in the liver. Mannitol does not cross the blood-brain barrier or penetrate the eye. An elimination half-life of about 100 minutes has been reported.

Uses and Administration

Mannitol is an osmotic agent. Although an isomer of sorbitol, it has little energy value, since it is largely eliminated from the body before any metabolism can take place.

Mannitol is mainly used, with adequate rehydration, to increase urine flow in patients with acute renal failure and to reduce raised intracranial pressure (p.1181) and treat cerebral oedema. It is also used in the short-term management of glaucoma (p.1873), especially to reduce intra-ocular pressure prior to ophthalmic surgery, and to promote the excretion of toxic substances by forced diuresis.

Other indications include bladder irrigation during transurethral resection of the prostate in order to reduce haemolysis and as an oral osmotic laxative for bowel preparation. Mannitol is used as a diluent and excipient in pharmaceutical preparations and as a bulk sweetener. It is under investigation for use in bronchiectasis and cystic fibrosis.

When given parenterally, mannitol raises the osmotic pressure of the plasma thus drawing water out of body tissues and producing an osmotic diuresis. Reduction of CSF and intra-ocular fluid pressure occurs within 15 minutes of the start of a mannitol infusion and lasts for 3 to 8 hours after the infusion is stopped; diuresis occurs after 1 to 3 hours.

When used as an osmotic diuretic, mannitol is given by intravenous infusion. Careful monitoring of fluid balance, electrolytes, renal function, and vital signs is necessary during infusion to prevent fluid and electrolyte imbalance, including circulatory overload and tissue dehydration. Solutions containing more than 15% of mannitol may crystallise during storage, particularly at low temperatures; crystals may be redissolved by warming before use; the giving set should include a filter.

Mannitol may be used to treat patients in the oliguric phase of **renal failure** or those suspected of inadequate renal function after correction of plasma volume, provided a test dose of about 200 mg/kg given by rapid intravenous infusion of a 15 to 25% solution over 3 to 5 minutes produces a diuresis of at least 30 to 50 mL/hour during the next 2 to 3 hours; a second test dose is permitted if the response to the first is inadequate. The usual adult dose of mannitol ranges from 50 to 100 g in a 24 hour period, given by intravenous infusion of a 5 to 25% solution. The rate of infusion is usually adjusted to maintain a urine flow of at least 30 to 50 mL/hour.

For children, a dose of 0.25 to 2 g/kg has been used.

The total dosage, the concentration, and the rate of infusion depend on the fluid requirement, the urinary output, and the nature and severity of the condition being treated. Mannitol infusion has also been used to prevent acute renal failure during cardiovascular and other types of surgery, or after trauma.

To reduce **raised intracranial** or **intra-ocular pressure** mannitol may be given by intravenous infusion as a 15 to 25% solution in a dose of 0.25 to 2 g/kg over 30 to 60 minutes. Rebound increases in intracranial or intra-ocular pressure may occur but are less frequent than with urea.

During **transurethral prostatic resection** a 2.5 to 5% solution of mannitol has been used for irrigating the bladder.

Ciguatera poisoning. Ciguatera poisoning occurs throughout the Caribbean and Indopacific as a result of the consumption of certain fish contaminated with ciguatoxin; it is increasingly seen in Europe, in travellers returning from these areas, or as a result of eating imported fish. Symptoms can be severe, including a bizarre reversal of hot and cold sensation. Some neurological symptoms, pruritus, arthralgia, and fatigue, may persist for years.[1] Treatment is usually symptomatic since there is no specific antidote. Dramatic reversal of neuromuscular symptoms with slower resolution of gastrointestinal upset has been reported after giving mannitol 1 g/kg by intravenous infusion over 30 to 45 minutes in the acute phase of the illness.[2-4] Mannitol may also be beneficial up to a week after poisoning.[5] However, a double-blind study[6] found mannitol to be no better than normal saline at relieving symptoms at 24 hours. Amitriptyline has been found on several occasions[7-9] to relieve neurological symptoms (dysaesthesias and paraesthesias) and pruritus. Gabapentin has also been reported to be of benefit.[10]

Gastrointestinal disorders. BOWEL PREPARATION. Mannitol, 1000 mL of a 10% solution or 500 mL of 10 or 20% solution, given orally, has been used to prepare the bowel for surgical and diagnostic procedures.[1,2] The potential for formation of explosive gas in the bowel should be borne in mind (see Effects on the Gastrointestinal Tract, above).

1. Palmer KR, Khan AN. Oral mannitol: a simple and effective bowel preparation for barium enema. *BMJ* 1979; **2:** 1038.
2. Newstead GL, Morgan BP. Bowel preparation with mannitol. *Med J Aust* 1979; **2:** 582–3.

DIAGNOSIS AND TESTING. Mannitol has been used with lactulose[1,2] and with cellobiose[3,4] in the detection of abnormal small bowel permeability, particularly that occurring in coeliac disease. For further information on the use of differential sugar absorption tests, see Lactulose, p.1739.

4. Hodges S, *et al.* Cellobiose: mannitol differential permeability in small bowel disease. *Arch Dis Child* 1989; **64:** 853–5.

Respiratory disorders. Inhalation of dry powder mannitol improves mucus clearance and small studies have suggested it may be of benefit in bronchiectasis,[1] although further studies are needed to confirm this.

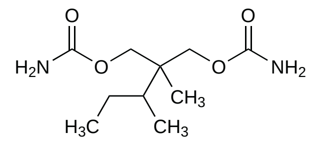
Mebutamate *(BAN, USAN, rINN)*

Mébutamate; Mebutamato; Mebutamatum; W-583. 2-sec-Butyl-2-methyltrimethylene dicarbamate.

Мебутамат

$C_{10}H_{20}N_2O_4$ = 232.3.
CAS — 64-55-1.
ATC — N05BC04.
ATC Vet — QN05BC04.



Profile

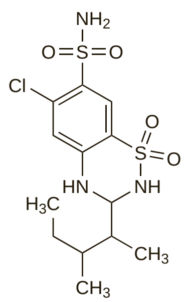
Mebutamate is a carbamate with general properties similar to those of meprobamate (p.1006). It has been given by mouth as an adjunct in the treatment of hypertension.

Mebutizide *(rINN)* ⊗

Mebutizida; Mébutizide; Mebutizidum. 6-Chloro-3-(1,2-dimethylbutyl)-3,4-dihydro-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

Мебутизид

$C_{13}H_{20}ClN_3O_4S_2$ = 381.9.
CAS — 3568-00-1.
ATC — C03AA13.
ATC Vet — QC03AA13.



Profile

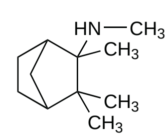
Mebutizide is a thiazide diuretic (see Hydrochlorothiazide, p.1307) that has been used in the treatment of oedema and hypertension.

Mecamylamine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de mecamilamina; Mecamine Hydrochloride; Mécamylamine, Chlorhydrate de; Mecamylamini Hydrochloridum. *N*-Methyl-2,3,3-trimethylbicyclo[2.2.1]hept-2-ylamine hydrochloride.

Мекамиламина Гидрохлорид

$C_{11}H_{21}N,HCl$ = 203.8.
CAS — 60-40-2 (mecamylamine); 826-39-1 (mecamylamine hydrochloride).
ATC — C02BB01.
ATC Vet — QC02BB01.



(mecamylamine)

Pharmacopoeias. In *US.*

USP 31 (Mecamylamine Hydrochloride). Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Trimetaphan Camsilate, p.1419. Mecamylamine may also cause tremor, convulsions, choreiform movements, insomnia, sedation, dysarthria, and mental aberrations.

Pharmacokinetics
Mecamylamine hydrochloride is almost completely absorbed from the gastrointestinal tract. It crosses the placenta and the blood-brain barrier. About 50% of the dose is excreted unchanged in the urine over 24 hours, but the rate is diminished in alkaline urine.

Uses and Administration
Mecamylamine hydrochloride is a ganglion blocker with actions similar to those of trimetaphan (p.1419). It is given orally in the management of hypertension (p.1171), although other antihypertensives with fewer adverse effects are preferred.

The usual initial dosage is 2.5 mg twice daily, gradually increased or decreased, usually in steps of 2.5 mg at intervals of not less than 2 days, until a satisfactory response is obtained. The average maintenance dose is 25 mg daily in three divided doses. Tolerance may develop.

◊ Reviews.

1. Young JM, *et al.* Mecamylamine: new therapeutic uses and toxicity/risk profile. *Clin Ther* 2001; **23:** 532–65.

Smoking cessation. Mecamylamine acts centrally as a nicotinic antagonist and might be of some benefit in assisting withdrawal from smoking. Two studies[1,2] have shown that addition of low-dose oral mecamylamine (2.5 to 5 mg twice daily) appeared to enhance the effectiveness of nicotine skin patches. However, a later controlled study[3] found that a patch containing both mecamylamine and nicotine was not significantly better than transdermal nicotine alone. Smoking cessation is discussed under Nicotine, p.2354.

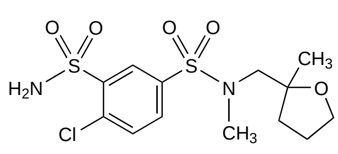
CAS — 7195-27-9.
ATC — C03BA05.
ATC Vet — QC03BA05.



Pharmacopoeias. In *Jpn.*

Profile
Mefruside is a diuretic with properties similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1307) even though it does not contain a thiazide ring system. It is given orally for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Diuresis begins about 2 to 4 hours after an oral dose and reaches a maximum between 6 and 12 hours.

In the treatment of oedema the usual dose is 25 to 50 mg daily, increasing if necessary to 75 to 100 mg. For long-term therapy a dose of 25 to 50 mg every second or third day is preferable.

In the treatment of hypertension the usual dose is 25 mg daily, either alone, or with other antihypertensives; initial doses of 25 to 50 mg daily have been recommended; alternate-day maintenance dosage may be used.

Ксимелагатран

$C_{24}H_{35}N_5O_5$ = 473.6.
CAS — 192939-46-1.
ATC — B01AE05.
ATC Vet — QB01AE05.

Profile
Melagatran is a direct thrombin inhibitor with actions similar to lepirudin, p.1323, that was used as an anticoagulant in the prevention of postoperative venous thromboembolism in patients undergoing hip or knee replacement surgery. It is the active metabolite of ximelagatran and was given subcutaneously; ximelagatran was given orally. It was withdrawn worldwide because of reported liver toxicity.

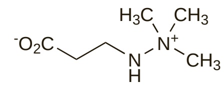
Meldonium *(rINN)*

Meldonio; MET-88; 3-(2,2,2-Trimethylhydrazinium)propionate. 3-(2,2,2-Trimethyldiazaniumyl)propanoate.

Мельдоний

$C_6H_{14}N_2O_2$ = 146.2.
CAS — 76144-81-5 (meldonium); 86426-17-7 (meldonium dihydrate).



Profile
Meldonium is an inhibitor of carnitine synthesis and is reported to have cardioprotective and anti-ischaemic effects. It has been used in a variety of disorders. In the management of ischaemic heart disease and ischaemic cerebrovascular disturbances oral doses have ranged from 500 mg to 1 g daily. A course of 500 mg given four times daily for 7 to 10 days has been used in alcohol abstinence syndrome. Meldonium has also been given intravenously in doses similar to those used orally.

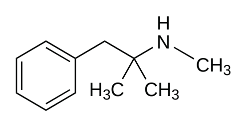
CAS — 100-92-5 (mephentermine); 1212-72-2 (anhydrous mephentermine sulfate); 6190-60-9 (mephentermine sulfate dihydrate).
ATC — C01CA11.
ATC Vet — QC01CA11.



(mephentermine)

Adverse Effects, Treatment, and Precautions
As for Sympathomimetics, p.1407; adverse effects may be related to alpha- or beta-adrenergic stimulation. Mephentermine may produce CNS stimulation, especially in overdosage; anxiety, drowsiness, incoherence, hallucinations, and convulsions have been reported.

Interactions
As for Sympathomimetics, p.1407.

Pharmacokinetics
Mephentermine acts in about 5 to 15 minutes after intramuscular injection and has a duration of action of up to about 4 hours; it acts almost immediately after intravenous injection with a duration of action of up to about 30 minutes. It is rapidly metabolised in the body by demethylation; hydroxylation may follow. It is excreted as unchanged drug and metabolites in the urine; excretion is more rapid in acidic urine.

Uses and Administration
Mephentermine is a sympathomimetic (p.1408) with mainly indirect effects on adrenergic receptors. It has alpha- and beta-adrenergic activity, and a slight stimulating effect on the CNS. It has an inotropic effect on the heart.

Mephentermine has been used to maintain blood pressure in hypotensive states, for example after spinal anaesthesia. It is given as the sulfate but doses are expressed in terms of the base; 21 mg of sulfate is equivalent to about 15 mg of base. Typical doses are up to 45 mg by slow intravenous injection, or 15 to 30 mg intramuscularly.

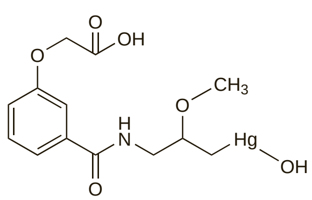
$C_{13}H_{17}HgNO_6$ = 483.9.

CAS — 486-67-9.

ATC — C03BC01.

ATC Vet — QC03BC01.



Mersalyl Sodium ⊗

Mersalyl *(pINN)*; Mersalilo; Mersalylum; Mersalyyli. The sodium salt of mersalyl acid.

Мерсалил

$C_{13}H_{16}HgNNaO_6$ = 505.8.

CAS — 492-18-2.

ATC — C03BC01.

ATC Vet — QC03BC01.

Profile

Mersalyl acid, in the form of its salts, is a powerful diuretic that acts on the renal tubules, increasing the excretion of sodium and chloride, in about equal amounts, and of water. Organic mercurial diuretics were widely used before the introduction of thiazide and other diuretics but have now been almost completely superseded by these orally active drugs, which are both potent and less toxic. The most frequent adverse effects of mersalyl are stomatitis, gastric disturbance, vertigo, febrile reactions, and skin eruptions and irritation. Thrombocytopenia, neutropenia, and agranulocytosis have followed the use of mercurial diuretics. Intravenous injection may cause severe hypotension and cardiac arrhythmias and has been followed by sudden death.

Mersalyl acid was usually given by injection as the sodium salt with theophylline as this lessened the local irritant reaction and increased absorption. It was given by deep intramuscular injection after a test dose for hypersensitivity. Other organic mercurial diuretics include chlormerodrin, meralluride, mercaptomerin sodium, mercurophylline sodium, and merethoxylline procaine. They were mainly given by intramuscular injection or, for those which were less irritant, subcutaneous injection.

Metaraminol Tartrate *(BANM, rINNM)* ⊗

Hydroxynorephedrine Bitartrate; Metaradrine Bitartrate; Metaraminol Acid Tartrate; Metaraminol Bitartrate; Métaraminol, Tartrate de; Metaraminoli Tartras; Tartrato de metaraminol. (−)-2-Amino-1-(3-hydroxyphenyl)propan-1-ol hydrogen tartrate.

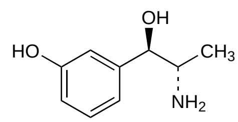
Метараминола Тартрат

$C_9H_{13}NO_2,C_4H_6O_6$ = 317.3.

CAS — 54-49-9 (metaraminol); 33402-03-8 (metaraminol tartrate).

ATC — C01CA09.

ATC Vet — QC01CA09.



(metaraminol)

Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2008 (Metaraminol Tartrate). An odourless or almost odourless, white, crystalline powder. Freely soluble in water; sparingly soluble in alcohol; practically insoluble in chloroform and in ether. A 5% solution in water has a pH of 3.2 to 3.5.

USP 31 (Metaraminol Bitartrate). A 5% solution in water has a pH of between 3.2 and 3.5. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects, Treatment, and Precautions

As for Sympathomimetics, p.1407. The adverse effects of metaraminol primarily relate to its alpha-agonist action. Metaraminol has a longer duration of action than adrenaline or noradrenaline and therefore an excessive vasopressor response may cause a prolonged rise in blood pressure. Tissue necrosis can occur as a result of accidental extravasation during intravenous injection.

Interactions

As for Sympathomimetics, p.1407. The interactions of metaraminol relate to both its direct and indirect actions.

Pharmacokinetics

Metaraminol acts about 10 minutes after intramuscular injection with a duration of action of up to about 1 hour. Effects are seen 1 to 2 minutes after intravenous injection with a duration of action of about 20 minutes.

Uses and Administration

Metaraminol is a sympathomimetic (p.1408) with direct and indirect effects on adrenergic receptors. It has alpha- and beta-adrenergic activity, the former being predominant. Metaraminol has an inotropic effect and acts as a peripheral vasoconstrictor, thus increasing cardiac output, peripheral resistance, and blood pressure. Coronary blood flow is increased and the heart rate slowed.

Metaraminol tartrate is used for its pressor action in **hypotensive states** such as those that may occur after spinal anaesthesia. Doses are expressed in terms of the base; metaraminol tartrate 9.5 mg is equivalent to about 5 mg of metaraminol. An intravenous infusion of 15 to 100 mg of metaraminol in 500 mL of glucose 5% or sodium chloride 0.9% may be used for maintaining the blood pressure, the rate of infusion being adjusted according to blood pressure response. Higher concentrations have been given. As the maximum effects are not immediately apparent, at least 10 minutes should elapse before increasing the dose and the possibility of a cumulative effect should be borne in mind. In an emergency an initial dose of 0.5 to 5 mg may be given by direct intravenous injection followed by an intravenous infusion as above.

Metaraminol tartrate has also been given by intramuscular or subcutaneous injection for the prevention of hypotension in doses equivalent to 2 to 10 mg of metaraminol. Subcutaneous injection increases the risk of local tissue necrosis and sloughing.

Priapism. Priapism[1,2] or prolonged penile erection may occur due to either decreased venous outflow (low-flow priapism) or increased arterial inflow (high-flow priapism). Low-flow priapism is a medical emergency since inflow is also impaired, leading to the development of ischaemia. It may be related to the use of drugs that cause smooth muscle relaxation, such as alpha blockers; intraluminal obstruction, such as in sickle-cell disease, may also be a cause. It is usually treated with corporal aspiration, followed if necessary by irrigation with a low dosage of a dilute solution of an alpha agonist such as metaraminol.

Intracavernosal metaraminol has been used successfully to treat drug-induced priapism,[3] as well as priapism associated with chronic myeloid leukaemia,[4] haemodialysis,[5] spinal block,[6] or fentanyl-induced general anaesthesia.[6] It may also be used to reverse the effects of alprostadil or papaverine given intracavernosally for the management of some types of erectile dysfunction, although this has been associated with fatal hypertensive crisis (see also Alprostadil, p.2184).

Alternative alpha agonists that have been used include intracavernosal phenylephrine,[7] and intracavernosal adrenaline, again in a low dosage and dilute solution. Phenylpropanolamine,[7] or pseudoephedrine,[8] given orally, have also been used. In patients with priapism due to sickle-cell disease, intracavernosal irrigation with a dilute adrenaline solution or intracavernosal injection of etilefrine have been used (see p.1205); oral etilefrine has been given for prophylaxis. Many other drugs have been tried or suggested, including baclofen, gabapentin, terbutaline, and, paradoxically, low doses of phosphodiesterase type-5 inhibitors such as sildenafil or tadalafil.[2] Surgery is usually favoured in low-flow priapism unresponsive to drug therapy.

In high-flow priapism, which is less of an emergency, embolisation of the source of abnormal inflow is the usual treatment.

Methoxamine Hydrochloride *(BANM, rINNM)* ⊗

Hidrocloruro de metoxamina; Methoxamedrine Hydrochloride; Méthoxamine, Chlorhydrate de; Methoxamini Hydrochloridum. 2-Amino-1-(2,5-dimethoxyphenyl)propan-1-ol hydrochloride.

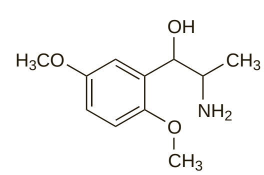
Метоксамина Гидрохлорид

$C_{11}H_{17}NO_3,HCl$ = 247.7.

CAS — 390-28-3 (methoxamine); 61-16-5 (methoxamine hydrochloride).

ATC — C01CA10.

ATC Vet — QC01CA10.



(methoxamine)

Pharmacopoeias. In *Br.* and *Chin.*

BP 2008 (Methoxamine Hydrochloride). Colourless crystals or white plate-like crystals or white crystalline powder; odourless or almost odourless. Freely soluble in water; soluble in alcohol; very slightly soluble in chloroform and in ether. A 2% solution in water has a pH of 4.0 to 6.0.

Profile

Methoxamine is a sympathomimetic (p.1407) with mainly direct effects on adrenergic receptors. It has alpha-adrenergic activity entirely; beta-adrenergic activity is not demonstrable and beta-adrenoceptor blockade may occur at high doses. Methoxamine hydrochloride has been used parenterally for its pressor action in the management of hypotensive states, particularly in anaesthesia, and also in the management of paroxysmal supraventricular tachycardia. It has also been used topically as a vasoconstrictor in the management of nasal congestion.

Preparations

BP 2008: Methoxamine Injection.

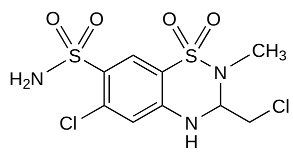
Proprietary Preparations (details are given in Part 3)
Irl.: Vasoxine†.

Methyclothiazide *(BAN, USAN, rINN)* ⊗

Méthyclothiazide; Methyclothiazidum; Meticlotiazida; Metyklotiatsidi; Metyklotiazid; NSC-110431. 6-Chloro-3-chloromethyl-3,4-dihydro-2-methyl-2*H*-1,2,4-benzothiadiazine-7-sulphonamide 1,1-dioxide.

Метиклотиазид

$C_9H_{11}Cl_2N_3O_4S_2$ = 360.2.
CAS — 135-07-9.
ATC — C03AA08.
ATC Vet — QC03AA08.



Pharmacopoeias. In *US.*

USP 31 (Methyclothiazide). A white or practically white crystalline powder, odourless or with a slight odour. Very slightly soluble to practically insoluble in water and in chloroform; soluble 1 in 92.5 of alcohol and 1 in 2700 of ether; freely soluble in acetone and in pyridine; sparingly soluble in methyl alcohol; very slightly soluble in benzene.

Profile

Methyclothiazide is a thiazide diuretic with properties similar to those of hydrochlorothiazide (see p.1307). It is given orally for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Diuresis starts in about 2 hours, reaches a peak at about 6 hours, and lasts for 24 hours or more.

In the treatment of oedema the usual initial dose is 2.5 to 5 mg daily, increasing to a maximum dose of 10 mg daily if necessary. In the treatment of hypertension the usual dose is 2.5 to 5 mg daily, either alone, or with other antihypertensives. Doses of up to 10 mg daily have been suggested, but this may not result in an increased hypotensive effect.

Children have been given a dose of 50 to 200 micrograms/kg daily.

Preparations

USP 31: Methyclothiazide Tablets.

Proprietary Preparations (details are given in Part 3)
Hong Kong: Enduron†; ***USA:*** Aquatensen†; Enduron.

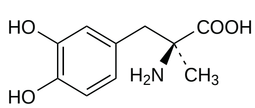
Multi-ingredient: ***Fr.:*** Isobar; ***Hong Kong:*** Enduronyl†; ***USA:*** Diutensen-R†.

Methyldopa *(BAN, USAN, rINN)*

Alpha-methyldopa; Méthyldopa; Methyldopum; Methyldopum Hydratum; Metildopa; Metyldopa; Metyylidopa; MK-351. (−)-3-(3,4-Dihydroxyphenyl)-2-methyl-L-alanine sesquihydrate; (−)-2-Amino-2-(3,4-dihydroxybenzyl)propionic acid sesquihydrate.

Метилдопа

$C_{10}H_{13}NO_4,1\frac{1}{2}H_2O$ = 238.2.
CAS — 555-30-6 (anhydrous methyldopa); 41372-08-1 (methyldopa sesquihydrate).
ATC — C02AB01; C02AB02.
ATC Vet — QC02AB01; QC02AB01 (laevorotary); QC02AB02; QC02AB02 (racemic).



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

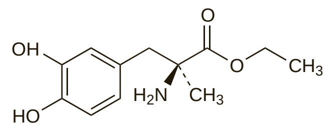
Ph. Eur. 6.2 (Methyldopa). Colourless or almost colourless crystals or a white to yellowish-white crystalline powder. Slightly soluble in water; very slightly soluble in alcohol; freely soluble in dilute mineral acids. Protect from light.

USP 31 (Methyldopa). A white to yellowish-white odourless fine powder which may contain friable lumps. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in ether; very soluble in 3N hydrochloric acid. Protect from light.

Methyldopate Hydrochloride *(BANM, USAN)*

Cloridrato de Metildopato; Metildopato, hidrocloruro de. The hydrochloride of the ethyl ester of anhydrous methyldopa; Ethyl (−)-2-amino-2-(3,4-dihydroxybenzyl)propionate hydrochloride.

$C_{12}H_{17}NO_4,HCl$ = 275.7.
CAS — 2544-09-4 (methyldopate); 2508-79-4 (methyldopate hydrochloride).



(methyldopate)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Methyldopate Hydrochloride). A white or almost white, odourless or almost odourless, crystalline powder. Freely soluble in water, in alcohol, and in methyl alcohol; slightly soluble in chloroform; practically insoluble in ether. A 1% solution in water has a pH of 3.0 to 5.0. Protect from light.

USP 31 (Methyldopate Hydrochloride). A white or almost white, odourless or almost odourless, crystalline powder. Freely soluble in water, in alcohol, and in methyl alcohol; slightly soluble in chloroform; practically insoluble in ether. A 1% solution in water has a pH of between 3.0 and 5.0. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Incompatibility. A haze developed over 3 hours when methyldopate hydrochloride 1 mg/mL was mixed with amphotericin B 200 micrograms/mL in glucose; crystals were produced with methohexital sodium 200 micrograms/mL in sodium chloride, and a haze developed when they were mixed in glucose. A crystalline precipitate occurred with tetracycline hydrochloride 1 mg/mL in glucose, and with sulfadiazine sodium 4 mg/mL in glucose or sodium chloride.[1]

1. Riley BB. Incompatibilities in intravenous solutions. *J Hosp Pharm* 1970; **28:** 228–40.

Adverse Effects

The adverse effects of methyldopa are mostly consequences of its pharmacological action. The incidence of adverse effects overall may be as high as 60% but most are transient or reversible. Drowsiness is common, especially initially and after an increase in dosage. Dizziness and lightheadedness may be associated with orthostatic hypotension; nausea, headache, weakness and fatigue, and decreased libido and impotence have also been reported quite often.

The mental and neurological effects of methyldopa have included impaired concentration and memory, mild psychoses, depression, disturbed sleep and nightmares, paraesthesias, Bell's palsy, involuntary choreoathetotic movements, and parkinsonism.

As well as orthostatic hypotension, methyldopa is often associated with fluid retention and oedema, which responds to diuretics but may rarely progress to heart failure. Angina pectoris may be aggravated. Bradycardia, syncope, and prolonged carotid sinus hypersensitivity have been reported. Intravenous methyldopate has been associated with a paradoxical rise in blood pressure.

Methyldopa may produce gastrointestinal disturbances including nausea and vomiting, diarrhoea, constipation, and rarely pancreatitis and colitis. A black or sore tongue, and inflammation of the salivary glands, have occurred, and dry mouth is quite common.

A positive Coombs' test may occur in 10 to 20% of all patients on prolonged therapy but only a small proportion develop haemolytic anaemia. Thrombocytopenia and leucopenia, notably granulocytopenia, have occurred and warrant prompt withdrawal. Other hypersensitivity effects have included myocarditis, fever, eosinophilia, and disturbances of liver function. Hepatitis may develop, particularly in the first 2 or 3 months of therapy, and is generally reversible on stopping, but fatal hepatic necrosis has occurred. Antinuclear antibodies may develop and cases of a lupus-like syndrome have been reported.

Other adverse effects that have been reported in patients taking methyldopa include rashes, lichenoid and granulomatous eruptions, toxic epidermal necrolysis, a flu-like syndrome (of fever, myalgia, and mild arthralgia), nocturia, uraemia, nasal congestion, and retroperitoneal fibrosis. Hyperprolactinaemia may occur, with breast enlargement or gynaecomastia, galactorrhoea, and amenorrhoea.

Methyldopa may occasionally cause urine to darken on exposure to the air because of the breakdown of the drug or its metabolites.

Effects on the blood. An analysis of drug-induced blood dyscrasias reported to the Swedish Adverse Drug Reaction Committee for the 10-year period 1966 to 1975 showed that haemolytic anaemia attributable to methyldopa had been reported on 69 occasions and had caused 3 deaths. This represented the vast majority of all the reports of drug-induced haemolytic anaemia.[1] However, the actual incidence of haemolytic anaemia in patients receiving methyldopa is quite low; data from the Boston Collaborative Drug Surveillance Program indicated that only 2 of 1067 patients receiving methyldopa developed haemolytic anaemia,[2] an incidence of about 0.2%. The proportion of patients with a positive Coombs' test is much higher, being variously reported[3-5] at 10 to 20%. It has been suggested that the high incidence of autoantibody formation may be due to inhibition of suppressor T-cells by methyldopa[4] while the relatively low incidence of resultant haemolysis may be due to drug-associated impairment of the reticuloendothelial system which would normally clear the antibody-sensitised cells from the circulation.[5]

PANCREATITIS. Increases in serum- and urinary-amylase activity accompanied by fever and suggestive of pancreatitis were associated with methyldopa in 2 patients,[1] one of whom had symptoms of severe pancreatitis. Symptoms reappeared on rechallenge in both patients. A further report of acute pancreatitis in a patient who had recently begun methyldopa therapy (with a diuretic) also confirmed a recurrence of symptoms on rechallenge.[2] In contrast to the acute form, chronic pancreatitis is not generally attributable to drug use.[3] However, a case of florid chronic pancreatitis, with exocrine and endocrine insufficiency and heavy calcification over 30 months, associated with 2 periods of methyldopa treatment, has been reported.[4] Symptoms in this patient, who was also receiving a thiazide, included severe diabetic ketoacidosis.

Effects on the heart. Sudden death in a number of patients receiving methyldopa has been associated with myocarditis (often with hepatitis and pneumonitis).[1,2] The effect is thought to be due to hypersensitivity. Hypersensitivity myocarditis is generally marked by ECG changes, a slight rise in cardiac enzymes, cardiomegaly, and persistent sinus tachycardia, along with peripheral blood eosinophilia, and most patients will recover within days if the drug is withdrawn in time.[3]

3. Anonymous. Myocarditis related to drug hypersensitivity. *Lancet* 1985; **ii:** 1165–6.

Effects on the liver. In a report of 6 cases of hepatitis in patients taking methyldopa, including a review of 77 cases from the literature,[1] most patients presented with symptoms including malaise, fatigue, anorexia, weight loss, nausea, and vomiting, and histopathological changes resembling those of viral hepatitis. Fever occurred in 28 of the 83 patients; rashes and eosinophilia occurred rarely. Symptoms usually began 1 to 4 weeks after the first dose of methyldopa. Clinically apparent jaundice occurred as early as 1 week and as late as 3 years after the start of therapy, although only 6 or 7 patients presented with jaundice later than 3 months. Liver damage was not dose-related and had features suggestive of an immunologically-mediated hypersensitivity reaction. The histological changes included chronic active hepatitis, massive fatal necrosis, and cirrhosis.

In a further analysis of 36 patients with liver damage due to methyldopa, hepatic injury tended to occur in 2 phases—acute and chronic.[2] Acute damage developed within a few months of starting treatment, and was considered to be an allergic reaction to methyldopa metabolites. The chronic form usually occurred at least a year after starting methyldopa, and was characterised by an accumulation of fat in the liver. Recovery after withdrawal of methyldopa was directly related to duration of exposure and degree of liver damage. There was also a suggestion of genetic predisposition, as acute methyldopa-induced liver damage occurred in 4 members of a family. Idiosyncratic metabolism of methyldopa in susceptible patients may be responsible for expression of an antigen on the surface of liver cells with which circulating antibodies react.[3]

3. Neuberger J, *et al*. Antibody mediated hepatocyte injury in methyldopa induced hepatotoxicity. *Gut* 1985; **26:** 1233–9.

Effects on mental function. Anecdotal reports have implicated methyldopa in disturbances of mental acuity including inability to concentrate, impaired calculating ability, and forgetfulness.[1-3] These have been confirmed to some extent by psychometric studies. Impaired verbal but not visual memory has been reported in 10 patients receiving methyldopa with a diuretic.[4] A crossover study in 16 patients also indicated impairment of cognitive function by methyldopa.[5]

1. Adler S. Methyldopa-induced decrease in mental activity. *JAMA* 1974; **230:** 1428–9.
2. Ghosh SK. Methyldopa and forgetfulness. *Lancet* 1976; **i:** 202–3.

5. Johnson B, *et al*. Effects of methyldopa on psychometric performance. *J Clin Pharmacol* 1990; **30:** 1102–5.

DEPRESSION. Depression has been associated with methyldopa therapy, although the exact relationship is unclear.[1] One review[2] reported the incidence to be 3.6% and suggested that depression was more common in patients with a previous history.

1. Patten SB, Love EJ. Drug-induced depression. *Drug Safety* 1994; **10:** 203–19.
2. Paykel ES, *et al*. Psychiatric side effects of antihypertensive drugs other than reserpine. *J Clin Psychopharmacol* 1982; **2:** 14–39.

Effects on the nervous system. Involuntary choreoathetotic movements resembling those of Huntington's chorea began in a 59-year-old man with cerebrovascular disease after an increase of his methyldopa dose from 1 to 1.5 g daily. He recovered when the drug was withdrawn.[1] In another report methyldopa was associated with the development of bilateral choreiform movements in a patient without cerebrovascular disease but with chronic renal failure.[2]

1. Yamadori A, Albert ML. Involuntary movement disorder caused by methyldopa. *N Engl J Med* 1972; **286:** 610.
2. Neil EM, Waters AK. Generalized choreiform movements as a complication of methyldopa therapy in chronic renal failure. *Postgrad Med J* 1981; **57:** 732–3.

Effects on sexual function. Methyldopa has been associated with numerous cases of sexual dysfunction. In males failure to maintain erection, decreased libido, impaired ejaculation, and gynaecomastia have occurred, while in females decreased libido, painful breast enlargement, and delayed or absent orgasm have been reported.[1] The reported incidence varies and there is some evidence[2] that sexual dysfunction may be underreported: while only 2 of 30 men receiving methyldopa spontaneously reported erection failure the actual incidence on questioning was 16 of 30.

1. Stevenson JG, Umstead GS. Sexual dysfunction due to antihypertensive agents. *Drug Intell Clin Pharm* 1984; **18:** 113–21.
2. Alexander WD, Evans JI. Side effects of methyldopa. *BMJ* 1975; **2:** 501.

Fever. In a report of 78 cases of methyldopa-induced fever,[1] fever occurred 5 to 35 days after the first exposure to methyldopa in 77 patients and one day after recommencing methyldopa in the remaining patient. Rigors, headache, and myalgia were common accompanying symptoms, but eosinophilia and skin rashes were not seen. The majority of patients did not appear seriously ill, but 4 patients presented with symptoms of septic shock. Biochemical evidence of liver damage was found in 61% of patients but jaundice was uncommon. In the majority of patients, symptoms were relieved within 48 hours of stopping the drug.

1. Stanley P, Mijch A. Methyldopa: an often overlooked cause of fever and transient hepatocellular dysfunction. *Med J Aust* 1986; **144:** 603–5.

Lupus erythematosus. The incidence of antinuclear antibodies was 13% in 269 hypertensive patients taking methyldopa (irrespective of other medication), compared with 3.8% in 448 hypertensive patients not taking methyldopa.[1] However, methyldopa-induced lupus has been reported[2] only rarely.

1. Wilson JD, *et al*. Antinuclear antibodies in patients receiving non-practolol beta-blockers. *BMJ* 1978; **1:** 14–16.
2. Dupont A, Six R. Lupus-like syndrome induced by methyldopa. *BMJ* 1982; **285:** 693–4.

Overdosage. Ingestion of methyldopa 2.5 g produced coma, hypothermia, hypotension, bradycardia, and dry mouth in a 19-year-old man.[1] His serum-methyldopa concentration 10 hours after ingestion was 19.2 micrograms/mL compared with serum concentrations of about 2 micrograms/mL in patients receiving therapeutic doses of methyldopa. He recovered after treatment with intravenous fluids.

1. Shnaps Y, *et al*. Methyldopa poisoning. *J Toxicol Clin Toxicol* 1982; **19:** 501–3.

Retroperitoneal fibrosis. A 60-year-old patient developed retroperitoneal fibrosis and a positive direct Coombs' test associated with methyldopa given in a daily dose of 750 mg with bendroflumethiazide 2.5 mg for about 5 years.[1]

1. Iversen BM, *et al*. Retroperitoneal fibrosis during treatment with methyldopa. *Lancet* 1975; **ii:** 302–4.

Treatment of Adverse Effects

Withdrawal of methyldopa or reduction in dosage causes the reversal of many adverse effects. If overdosage occurs, the benefit of gastric decontamination is uncertain, but patients who present within 1 hour may be given activated charcoal. Treatment is largely symptomatic, but if necessary, intravenous fluid infusions may be given to promote urinary excretion, and vasopressors given cautiously. Atropine may be given for bradycardia. Severe hypotension may respond to placing the patient in the supine position with the feet raised.

Methyldopa is dialysable.

Precautions

Methyldopa should be used with caution in the elderly, and in patients with hepatic or renal impairment or with a history of haemolytic anaemia, liver disease, or depression. Care is also advisable in patients with parkinsonism. It should not be given to patients with active liver disease or depression and it is not recommended for phaeochromocytoma.

It is advisable to make periodic blood counts and to perform liver function tests at intervals during the first 6 to 12 weeks of treatment or if the patient develops an unexplained fever. Patients taking methyldopa may produce a positive response to a direct Coombs' test; if blood transfusion is required, prior knowledge of a positive direct Coombs' test reaction will aid cross-matching.

Methyldopa may cause sedation; if affected, patients should not drive or operate machinery.

Breast feeding. Methyldopa is distributed into breast milk in small amounts.[1] In a study[2] of 3 breast-feeding women, concentrations of free methyldopa in the breast milk were found to be between 19 and 30% of those in the plasma after a 500-mg dose. Detectable levels were found in the plasma of only 1 infant and adverse effects were seen in none. It was estimated that the amount of methyldopa a breast-fed infant would receive would be about 0.02% of the maternal dose. In another study[3] over a 3-month period no adverse effects were found in a breast-feeding infant whose mother was taking methyldopa, although the drug was detectable in the infant's urine. The American Academy of Pediatrics considers[4] that methyldopa is therefore usually compatible with breast feeding.

4. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 26/09/05)

Porphyria. Methyldopa has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Methyldopa is commonly used in the management of hypertension during pregnancy (p.1171). There is little evidence of adverse effects on fetal development. However, it crosses the placenta[1] and reduced blood pressure has been reported in infants born to mothers receiving the drug.[2] There has also been a report of tremor in 7 infants associated with maternal methyldopa use in pregnancy.[3] Depressed noradrenaline concentrations in the CSF were noted in the 3 infants examined leading to successful treatment of the other 4 infants with atropine: tremor was abolished in 2 and substantially reduced in the other 2.

3. Bódis J, *et al*. Methyldopa in pregnancy hypertension and the newborn. *Lancet* 1982; **ii:** 498–9.

Interactions

The hypotensive effects of methyldopa are potentiated by diuretics, other antihypertensives, and drugs with hypotensive effects. However, there have been reports of paradoxical antagonism of the hypotensive effects by tricyclic antidepressants, antipsychotics, and beta blockers. Sympathomimetics may also antagonise the hypotensive effects.

There may be an interaction between methyldopa and MAOIs and care is required if they are given together. Caution is also needed with catechol-*O*-methyltransferase inhibitors, such as entacapone, since they might reduce the metabolism of methyldopa.

Patients receiving methyldopa may require lower doses of general anaesthetics.

Alpha blockers. Urinary incontinence occurred when methyldopa was given with *phenoxybenzamine* in a patient who had undergone bilateral lumbar sympathectomy.[1]

1. Fernandez PG, *et al*. Urinary incontinence due to interaction of phenoxybenzamine and α-methyldopa. *Can Med Assoc J* 1981; **124:** 174–5.

Antipsychotics. Antipsychotics may enhance the hypotensive effects of methyldopa but a paradoxical increase in blood pressure has also been reported. A woman with SLE taking *trifluoperazine* up to 15 mg daily and prednisone up to 120 mg daily was given methyldopa up to 2 g and triamterene for high blood pressure.[1] Her blood pressure rose further to 200/140 mmHg. After stopping trifluoperazine blood pressure returned to 160/100 mmHg.

In another report, 2 patients with essential hypertension who had been taking methyldopa for 3 years and 18 months respectively developed symptoms of dementia within days of taking *haloperidol* for anxiety.[2] In both patients the symptoms resolved rapidly on stopping haloperidol.

1. Westervelt FB, Atuk NO. Methyldopa-induced hypertension. *JAMA* 1974; **227:** 557.
2. Thornton WE. Dementia induced by methyldopa with haloperidol. *N Engl J Med* 1976; **294:** 1222.

Cephalosporins. A pustular pruritic eruption occurred after use of *cefazolin* by a patient taking methyldopa.[1] A previous similar case involved use of *cefradine* with methyldopa.

1. Stough D, *et al*. Pustular eruptions following administration of cefazolin: a possible interaction with methyldopa. *J Am Acad Dermatol* 1987; **16:** 1051–2.

Digoxin. Syncope associated with carotid sinus hypersensitivity has been reported to be possibly enhanced by methyldopa in a patient taking digoxin and chlortalidone.[1] In another report,[2] sinus bradycardia developed in 2 patients taking methyldopa and digoxin.

1. Bauernfeind R, *et al*. Carotid sinus hypersensitivity with alpha methyldopa. *Ann Intern Med* 1978; **88:** 214–15.
2. Davis JC, *et al*. Sinus node dysfunction caused by methyldopa and digoxin. *JAMA* 1981; **245:** 1241–3.

Iron. After results in healthy subjects indicated that the absorption of methyldopa was reduced by 73% and 61% respectively when taken with a dose of *ferrous sulfate* or *ferrous gluconate*, 5 hypertensive patients taking methyldopa were also given ferrous sulfate 325 mg three times daily for 2 weeks.[1] All patients experienced a rise in systolic pressure, and 4 had a rise in diastolic pressure, amounting to more than 15/10 mmHg in some patients after 2 weeks. Blood pressure fell again when the ferrous sulfate was stopped.

1. Campbell N, *et al*. Alteration of methyldopa absorption, metabolism, and blood pressure control caused by ferrous sulfate and ferrous gluconate. *Clin Pharmacol Ther* 1988; **43:** 381–6.

Levodopa. For reference to a mutual interaction between methyldopa and levodopa, see Antihypertensives, under Levodopa, Interactions, p.807.

Lithium. For reference to the development of lithium toxicity when given with methyldopa, see p.405.

Sympathomimetics. A 31-year-old man whose hypertension was well controlled with methyldopa and oxprenolol suffered a severe hypertensive episode when he took a preparation containing *phenylpropanolamine* for a cold.[1]

1. McLaren EH. Severe hypertension produced by interaction of phenylpropanolamine with methyldopa and oxprenolol. *BMJ* 1976; **2:** 283–4.

Pharmacokinetics

After oral use methyldopa is variably and incompletely absorbed, apparently by an amino-acid active transport system. The mean bioavailability has been reported to be about 50%. It is extensively metabolised and is excreted in urine mainly as unchanged drug and the *O*-sulfate conjugate. It crosses the blood-brain barrier and is decarboxylated in the CNS to active alpha-methylnoradrenaline.

The elimination is biphasic with a half-life of about 1.7 hours in the initial phase; the second phase is more prolonged. Clearance is decreased and half-life prolonged in renal impairment. Plasma protein binding is reported to be minimal. Methyldopa crosses the placenta; small amounts are distributed into breast milk.

Uses and Administration

Methyldopa is an antihypertensive that is thought to have a mainly central action. It is decarboxylated in the CNS to alpha-methylnoradrenaline, which is thought to stimulate $alpha_2$ adrenoceptors resulting in a reduction in sympathetic tone and a fall in blood pressure. It may also act as a false neurotransmitter, and have some inhibitory actions on plasma renin activity. Methyldopa reduces the tissue concentrations of dopamine, noradrenaline, adrenaline, and serotonin.

Methyldopa is used in the management of hypertension (p.1171), although other drugs with fewer adverse effects are generally preferred. Methyldopa may, however, be the treatment of choice for hypertension in pregnancy. Oedema and tolerance sometimes associated with methyldopa therapy may be reduced when it is given with a thiazide diuretic.

Methyldopa is given orally as the sesquihydrate, but doses are usually expressed in terms of anhydrous methyldopa. Methyldopa sesquihydrate 1.13 g is equivalent to about 1 g of anhydrous methyldopa. For hypertensive crises, methyldopa has been given intravenously as methyldopate hydrochloride.

When methyldopa is given orally its effects reach a maximum in 4 to 6 hours after a single dose, although the maximum hypotensive effect may not occur until the second or third day of continuous treatment; some effect is usually apparent for 48 hours after withdrawal of methyldopa. When given intravenously the hypotensive effect may be obtained within 4 to 6 hours and last for 10 to 16 hours. It lowers the standing, and to a lesser extent the supine, blood pressure.

In hypertension, the usual initial adult oral dose is 250 mg of methyldopa two or three times daily for 2 days; this is then adjusted, not more frequently than every 2 days according to response, up to a usual maximum dose of 3 g daily. The usual maintenance dosage is 0.5 to 2 g of methyldopa daily. In the elderly an initial dose of 125 mg twice daily has been used; this dose may be increased gradually if necessary, but should not exceed 2 g daily.

An initial dose for children is 10 mg/kg daily in 2 to 4 divided doses, increased as necessary to a maximum of 65 mg/kg or 3 g daily, whichever is less.

Preparations

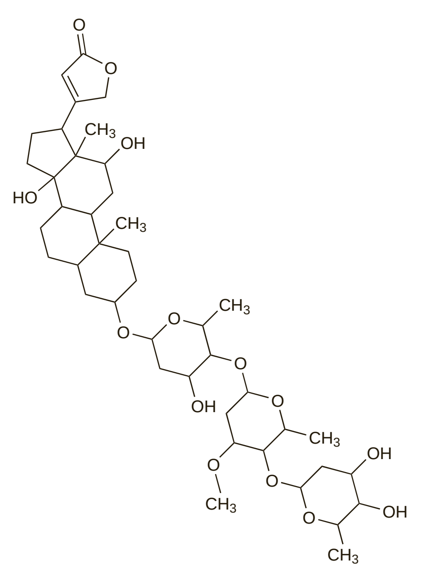
ATC Vet — QC01AA08.



Pharmacopoeias. In *Chin.* In *Jpn.* as $C_{42}H_{66}O_{14}, \frac{1}{3}C_3H_6O$.

Adverse Effects, Treatment, and Precautions

As for Digoxin, p.1259.

Interactions

As for Digoxin, p.1261.

Calcium-channel blockers. For a report of an interaction between metildigoxin and *diltiazem*, see Calcium-channel Blockers, under Interactions of Digoxin, p.1262.

Pharmacokinetics

Metildigoxin is rapidly and almost completely absorbed from the gastrointestinal tract and at steady state has a half-life of 36 to 47.5 hours. Demethylation to digoxin occurs. About 60% of an oral or intravenous dose is excreted in the urine as unchanged drug and metabolites over 7 days.

Hepatic impairment. Hepatic demethylation of metildigoxin was reduced in 12 patients with cirrhosis of the liver compared with 12 healthy subjects. This resulted in a reduction in metildigoxin clearance, a smaller volume of distribution, and a significantly higher serum concentration.[1]

1. Rameis H, *et al.* Changes in metildigoxin pharmacokinetics in cirrhosis of the liver: a comparison with β-acetyldigoxin. *Int J Clin Pharmacol Ther Toxicol* 1984; **22:** 145–51.

Renal impairment. For reference to the pharmacokinetics of metildigoxin in patients with renal impairment, see under Uses and Administration, below.

Uses and Administration

Metildigoxin is a cardiac glycoside with positive inotropic activity. It has actions similar to those of digoxin (p.1263) and may be used in the treatment of some cardiac arrhythmias (p.1160) and in heart failure (p.1165).

The onset of action of metildigoxin is more rapid than that of digoxin. When metildigoxin is given orally an effect may appear within 5 to 20 minutes and a maximum effect on the myocardium may be seen in 15 to 30 minutes. The duration of action is similar to or a little longer than that of digoxin; therapeutic plasma concentrations are also similar. In stabilised patients on oral therapy a dose of 300 micrograms of metildigoxin is as effective as 500 micrograms of digoxin.

Metildigoxin may be given orally or intravenously. Initial oral doses of 100 to 600 micrograms daily may be given depending upon whether rapid or slow digitalisation is desired; digitalisation is usually performed over about 2 to 4 days and the larger doses are given in divided daily doses. Similar doses may also be given intravenously. Oral maintenance therapy is continued with 50 to 300 micrograms daily in divided doses.

Dosage should be reduced in patients with renal impairment (see below).

Administration in renal impairment. Fairly good non-linear correlation was found between creatinine clearance and metildigoxin half-life in a study of 15 patients with chronic renal impairment, including 8 undergoing haemodialysis, and 4 patients with heart failure and unimpaired renal function. The mean elimination half-life was 5.62 days in patients undergoing dialysis (clearance essentially 0 mL/minute) and 3.41 days in the other patients with chronic renal impairment (clearance 15 to 50 mL/minute) compared with 1.49 days in patients with normal renal function (clearance 62 to 96 mL/minute). It was recommended that patients undergoing dialysis should be given 30 to 50% of the usual dose initially.[1] Other studies have suggested[2] that dose reduction may be necessary in renal impairment when creatinine clearance is below 50 mL/minute per 1.48 m^2.

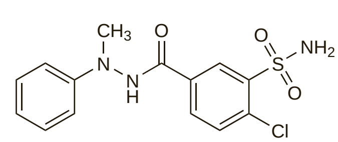
Metipamide ⊗

Metipamid; Metipamidum; VÚFB-14429. 3-(Aminosulfonyl)-4-chlorobenzoic acid 2-methyl-2-phenylhydrazide.

$C_{14}H_{14}ClN_3O_3S$ = 339.8.
CAS — 85683-41-6.



Profile

Metipamide is a diuretic structurally related to indapamide (p.1314); it is used as an antihypertensive.

Preparations

Proprietary Preparations (details are given in Part 3)

Cz.: Hypotylin.

Metirosine *(BAN, rINN)*

L-588357-0; Metirosiini; Metirosin; Metirosina; Métirosine; Metirosinum; Metyrosine *(USAN)*; MK-781. (–)-α-Methyl-L-tyrosine; 4-Hydroxy-α-methylphenylalanine.

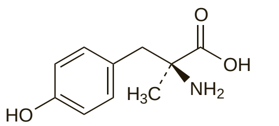
Метирозин

$C_{10}H_{13}NO_3$ = 195.2.

CAS — 672-87-7 (metirosine); 620-30-4 (racemetirosine).

ATC — C02KB01.

ATC Vet — QC02KB01.



NOTE. The term α-methyltyrosine (α-MPT; α-MT; α-methyl-*p*-tyrosine) is used below since although metirosine, the (–)-isomer, is the active form the manufacturers state that some racemate (racemetirosine; (±)-α-methyl-DL-tyrosine) is produced during synthesis but that the material supplied contains mainly (–)-isomer with a small amount of (+)-isomer.
The code name MK-781, applied to earlier investigational material, may have described a racemate or a preparation containing a smaller proportion of (–)-isomer than the product now available commercially.
Potency of the proprietary preparation (*Demser*) is expressed in terms of metirosine.

Pharmacopoeias. In *US.*

Adverse Effects

Sedation occurs in almost all patients receiving α-methyltyrosine. Other adverse effects include extrapyramidal symptoms, such as trismus and frank parkinsonism; anxiety, depression, and psychic disturbances including hallucinations, disorientation, and confusion; and diarrhoea, which may be severe. Crystalluria, transient dysuria, and haematuria have been seen in a few patients. There have also been occasional reports of slight swelling of the breast, galactorrhoea, nasal congestion, decreased salivation, gastrointestinal disturbances, headache, impotence or failure of ejaculation, and hypersensitivity reactions. Eosinophilia, raised serum aspartate aminotransferase, and peripheral oedema have been reported rarely.

Neuroleptic malignant syndrome. Neuroleptic malignant syndrome occurred after the use of the dopamine-depleting drugs tetrabenazine and α-methyltyrosine in a patient with Huntington's chorea.[1]

1. Burke RE, *et al.* Neuroleptic malignant syndrome caused by dopamine-depleting drugs in a patient with Huntington disease. *Neurology* 1981; **31:** 1022–6.

Precautions

To minimise the risk of crystalluria, patients receiving α-methyltyrosine should have a fluid intake sufficient to maintain a urine volume of at least 2 litres daily and their urine should be examined regularly for the presence of crystals.

α-Methyltyrosine has sedative effects and patients should be warned of the hazards of driving a motor vehicle or operating machinery while receiving the drug. Symptoms of psychic stimulation and insomnia may occur when α-methyltyrosine is withdrawn.

When α-methyltyrosine is used pre-operatively in patients with phaeochromocytoma, blood pressure and the ECG should be monitored continuously during surgery as the danger of hypertensive crises and arrhythmias is not eliminated. Concomitant alpha blockade (e.g. with phentolamine) may be required; a beta blocker or lidocaine may be needed for the management of arrhythmias. Blood volume must be maintained during and after surgery, particularly if an alpha blocker is used, to avoid hypotension.

Interactions

The sedative effects of α-methyltyrosine may be potentiated by alcohol and other CNS depressants. Use with phenothiazines or haloperidol may exacerbate extrapyramidal effects.

Pharmacokinetics

α-Methyltyrosine is well absorbed from the gastrointestinal tract and is excreted mainly unchanged by the kidneys. A plasma half-life of 3.4 to 7.2 hours has been reported. Less than 1% of a dose may be excreted as the metabolites α-methyldopa, α-methyldopamine, α-methylnoradrenaline, and α-methyltyramine.

Uses and Administration

α-Methyltyrosine is an inhibitor of the enzyme tyrosine hydroxylase, and consequently of the synthesis of catecholamines. It is used to control the symptoms of excessive sympathetic stimulation in patients with phaeochromocytoma (p.1179) and decreases the frequency and severity of hypertensive attacks and related symptoms in most patients. It may be given for pre-operative preparation, or for long-term management in those for whom surgery is contra-indicated or who have malignant phaeochromocytoma.

In the management of phaeochromocytoma, α-methyltyrosine is given orally in a dose of 250 mg four times daily, increased daily by 250 mg or 500 mg to a maximum of 4 g daily in divided doses. The optimum dose, achieved by monitoring clinical symptoms and catecholamine excretion, is usually in the range of 2 to 3 g daily and when used pre-operatively it should be given for at least 5 to 7 days before surgery. The use of alpha blockers may also be necessary.

α-Methyltyrosine is not effective in controlling essential hypertension.

α-Methyltyrosine has also been tried in patients with schizophrenia.

Preparations

USP 31: Metyrosine Capsules.

Proprietary Preparations (details are given in Part 3)
USA: Demser.

Metolazone *(BAN, USAN, rINN)* ⊗

Metolatsoni; Metolazon; Metolazona; Métolazone; Metolazonum; SR-720-22. 7-Chloro-1,2,3,4-tetrahydro-2-methyl-4-oxo-3-*o*-tolylquinazoline-6-sulphonamide.

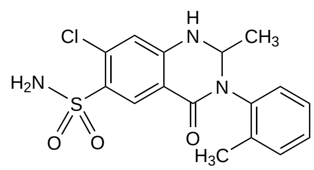
Метолазон

$C_{16}H_{16}ClN_3O_3S$ = 365.8.

CAS — 17560-51-9.

ATC — C03BA08.

ATC Vet — QC03BA08.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Metolazone). A white or slightly yellowish, crystalline powder. It exhibits polymorphism. Very slightly soluble in water and dichloromethane; sparingly soluble in methyl alcohol; slightly soluble in ethyl acetate. Protect from light.

USP 31 (Metolazone). Store in airtight containers. Protect from light.

Adverse Effects and Treatment

As for Hydrochlorothiazide, p.1307. Metolazone has also been reported to cause palpitations, chest pain, and chills.

Effects on the blood. Profound neutropenia was seen in a 58-year-old woman within 10 days of starting treatment with metolazone.[1] Neutropenia persisted for a further 10 days after metolazone was withdrawn. No other haematological abnormalities were seen.

1. Donovan KL. Neutropenia and metolazone. *BMJ* 1989; **299:** 981.

Effects on the nervous system. Two patients had acute muscle cramps with impairment of consciousness and epileptiform movements after taking metolazone 5 mg (single dose) or 2.5 mg daily for 3 days.[1]

1. Fitzgerald MX, Brennan NJ. Muscle cramps, collapse, and seizures in two patients taking metolazone. *BMJ* 1976; **1:** 1381–2.

Precautions

As for Hydrochlorothiazide, p.1309.

Interactions

As for Hydrochlorothiazide, p.1309. Severe electrolyte disturbances may occur when metolazone and furosemide are used together.

ACE inhibitors. Deterioration in renal function occurred in a 65-year-old woman when metolazone 5 mg [daily] was added to *captopril*, furosemide, spironolactone, and digoxin for heart failure.[1] An interaction between captopril and metolazone was suspected and both drugs were stopped with a subsequent return to normal renal function. It was suggested that natriuresis and a fall in blood pressure caused by the diuretic may have compromised an already low renal perfusion pressure when autoregulatory mechanisms were blocked by captopril.

1. Hogg KJ, Hillis WS. Captopril/metolazone induced renal failure. *Lancet* 1986; **i:** 501–2.

Antidiabetics. Hypoglycaemia occurred in a patient with type 2 diabetes mellitus controlled with *glibenclamide* 40 hours after starting therapy with metolazone 5 mg daily.[1] Studies of protein binding *in vitro* did not reveal any evidence of displacement of glibenclamide from binding sites.

1. George S, *et al.* Possible protein binding displacement interaction between glibenclamide and metolazone. *Eur J Clin Pharmacol* 1990; **38:** 93–5.

Ciclosporin. An increase in serum-creatinine concentration in a renal transplant patient was attributed to a toxic drug interaction between metolazone and ciclosporin.[1] Serum-creatinine concentrations returned to pretreatment values when metolazone was stopped.

1. Christensen P, Leski M. Nephrotoxic drug interaction between metolazone and cyclosporin. *BMJ* 1987; **294:** 578.

Pharmacokinetics

Metolazone is slowly and incompletely absorbed from the gastrointestinal tract. An average of about 65% of a dose has been reported to be absorbed after oral doses in healthy subjects, and an average of about 40% in patients with cardiac disease. In some countries a formulation with enhanced bioavailability is available. About 95% of the drug is bound in the circulation: about 50 to 70% to the red blood cells and between 15 and 33% to plasma proteins. The half-life has been reported to be 8 to 10 hours in whole blood, and 4 to 5 hours in plasma, but the diuretic effect persists for up to 24 hours or more. About 70 to 80% of the amount of metolazone absorbed is excreted in the urine, of which 80 to 95% is excreted unchanged. The remainder is excreted in the bile and some enterohepatic circulation has been reported. Metolazone crosses the placenta and is distributed into breast milk.

◊ References.

1. Tilstone WJ, *et al.* Pharmacokinetics of metolazone in normal subjects and in patients with cardiac or renal failure. *Clin Pharmacol Ther* 1974; **16:** 322–9.

Uses and Administration

Metolazone is a diuretic with actions and uses similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1310) even though it does not contain a thiazide ring system. It is given orally for oedema, including that associated with heart failure (p.1165), and for hypertension (p.1171).

Unlike thiazides in general, metolazone is reported to be effective in patients with a glomerular filtration rate of less than 20 mL/minute. Diuresis starts in about 1 hour, reaches a peak in about 2 hours, and lasts for 12 to 24 hours depending on the dose.

A preparation with enhanced bioavailability, which is effective in lower doses than conventional formulations, is available in some countries. Doses given in *Martindale* refer to the conventional tablet formulation unless otherwise stated.

In the treatment of **oedema** the usual dose is 5 to 10 mg daily; in some cases doses of 20 mg or more may be required. No more than 80 mg should be given in any 24-hour period. In refractory cases, metolazone has been used with furosemide or other loop diuretics, but the electrolyte balance should be monitored closely.

In the treatment of **hypertension** the usual dose is 2.5 to 5 mg daily either alone, or with other antihypertensives. An initial dose of 1.25 mg has also been used. The dosage may be adjusted after 3 to 4 weeks according to response. A maintenance dose of 5 mg on alternate days may be used.

Formulations with enhanced bioavailability are given in doses of 0.5 to 1 mg daily in the treatment of hypertension. They are not bioequivalent to the conventional tablet formulation and should not be used interchangeably.

USP 31 (Metoprolol Tartrate). A white crystalline powder. Very soluble in water; freely soluble in alcohol, in chloroform, and in dichloromethane; slightly soluble in acetone; insoluble in ether. A 10% solution in water has a pH of between 6.0 and 7.0. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Stability. Metoprolol tartrate 400 micrograms/mL in glucose 5% or sodium chloride 0.9% was stable for 36 hours when stored at 24° in PVC bags.[1]

1. Belliveau PP, *et al.* Stability of metoprolol tartrate in 5% dextrose injection or 0.9% sodium chloride injection. *Am J Hosp Pharm* 1993; **50:** 950–2.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Metoprolol is distributed into breast milk and studies[1-3] have shown that the concentration in milk is higher than that in plasma. However, the amount ingested by an infant is likely to be small, and the concentration of metoprolol in infant plasma has been found[3] to be undetectable or very low. No adverse effects have been seen in breast-fed infants whose mothers were given metoprolol and the American Academy of Pediatrics considers[4] that it is therefore usually compatible with breast feeding.

4. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/01/08)

Effects on hearing. Loss of hearing in a patient receiving metoprolol appeared to be dose-related;[1] hearing gradually improved over several months once the drug was withdrawn.

1. Fäldt R, *et al.* β Blockers and loss of hearing. *BMJ* 1984; **289:** 1490–2.

Effects on lipid metabolism. Beta blockers may increase serum-triglyceride concentrations. For a report of acute pancreatitis provoked by severe hypertriglyceridaemia in a patient taking atenolol and metoprolol, see p.1227.

Effects on the liver. Acute hepatitis associated with metoprolol has been reported in a 56-year-old woman.[1] The hepatotoxicity could not be explained by deficient oxidation of metoprolol; drug oxidation phenotyping showed she was an extensive metaboliser of debrisoquine and hence metoprolol.

For a discussion of the relationship between polymorphic oxidation of metoprolol and the incidence of adverse effects, see Metabolism, under Pharmacokinetics, below.

1. Larrey D, *et al.* Metoprolol-induced hepatitis: rechallenge and drug oxidation phenotyping. *Ann Intern Med* 1988; **108:** 67–8.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Antivirals. US licensed product information for *ritonavir* warns that ritonavir may increase concentrations of metoprolol and that the dose of metoprolol may need to be reduced if used together.

Pharmacokinetics

Metoprolol is readily and completely absorbed from the gastrointestinal tract but is subject to considerable first-pass metabolism, with a bioavailability of about 50%. Peak plasma concentrations vary widely and occur about 1.5 to 2 hours after a single oral dose. It is moderately lipid-soluble.

Metoprolol is widely distributed; it crosses the blood-brain barrier and the placenta, and is distributed into breast milk. It is about 12% bound to plasma protein. It is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP2D6, and undergoes oxidative deamination, *O*-dealkylation followed by oxidation, and aliphatic hydroxylation. The metabolites are excreted in the urine with only small amounts of unchanged metoprolol. The rate of metabolism by CYP2D6 is determined by genetic polymorphism; the half-life of metoprolol in fast hydroxylators is stated to be 3 to 4 hours, whereas in poor hydroxylators it is about 7 hours.

The elderly. Several studies[1-3] indicate that age-related physiological changes have negligible effects on the pharmacokinetics of metoprolol.

1. Quarterman CP, *et al.* The effect of age on the pharmacokinetics of metoprolol and its metabolites. *Br J Clin Pharmacol* 1981; **11:** 287–94.
2. Regårdh CG, *et al.* Pharmacokinetics of metoprolol and its metabolite α-OH-metoprolol in healthy, non-smoking, elderly individuals. *Eur J Clin Pharmacol* 1983; **24:** 221–6.
3. Larsson M, *et al.* Pharmacokinetics of metoprolol in healthy, elderly, non-smoking individuals after a single dose and two weeks of treatment. *Eur J Clin Pharmacol* 1984; **27:** 217–22.

Metabolism. Metoprolol is metabolised by the cytochrome P450 isoenzyme CYP2D6 and therefore exhibits a debrisoquine-type genetic polymorphism.[1-3] Poor, intermediate, extensive, and ultrarapid metabolisers of metoprolol have been identified, and studies[4-6] have confirmed that plasma-metoprolol concentrations correlate with metaboliser status. However, the clinical relevance of these differences is less clear. A retrospective study[7] found that the proportion of poor metabolisers among patients who had severe adverse effects was higher than expected, but other studies[8,9] have found no correlation between the incidence of adverse effects and metaboliser status. Controlled studies in patients with hypertension[5] and in healthy subjects[4] have found that there is little or no relationship between plasma concentrations or metaboliser status and either the incidence of adverse effects or the response to therapy.

The subject may be further confused by variations in the phenotype between ethnic groups. Although the incidence of the poor metaboliser phenotype in whites of European origin is reported to be about 9%, a study in 138 Nigerians[10] failed to identify evidence of polymorphic metabolism, and the authors caution against extrapolation of data between different racial groups.

Pregnancy. The clearance of metoprolol was increased fourfold in 5 pregnant women during the last trimester, compared with that some months after delivery; this was probably due to enhanced hepatic metabolism in the pregnant state.[1]

The disposition of metoprolol was investigated in neonates of mothers treated with metoprolol 50 to 100 mg twice daily.[2] In 15 of the 17 neonates plasma-metoprolol concentrations increased in the first 2 to 5 hours of the postnatal period, then declined over the next 15 hours; 5 of these infants had no detectable metoprolol concentrations in the umbilical plasma. No infant showed signs of beta blockade.

2. Lundborg P, *et al.* Disposition of metoprolol in the newborn. *Br J Clin Pharmacol* 1981; **12:** 598–600.

Renal impairment. A single dose of a modified-release tablet of metoprolol produced similar plasma-metoprolol concentrations and values for the area under the concentration/time curve in both normal subjects and those with renal impairment.[1] Mean plasma concentrations of the metabolite α-hydroxymetoprolol were increased two to threefold in subjects with renal impairment compared with normal subjects but such a rise was not considered likely to contribute to beta blockade.

Uses and Administration

Metoprolol is a cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic activity and to have little or no membrane-stabilising activity.

It is used in the management of hypertension (p.1171), angina pectoris (p.1157), cardiac arrhythmias (p.1160), myocardial infarction (p.1175), and heart failure (p.1165). It is also used in the management of hyperthyroidism (p.2165) and in the prophylactic treatment of migraine (p.616).

Metoprolol is given orally and intravenously as the tartrate. Modified-release tablets usually contain the tartrate or the succinate, but the fumarate has also been used. Doses are usually expressed in terms of the tartrate; 95 mg of metoprolol fumarate or metoprolol succinate is equivalent to about 100 mg of metoprolol tartrate.

The bioavailability of metoprolol is increased if taken with food and it has been recommended that some preparations are taken with or immediately after a meal.

Reduced doses should be given to patients with hepatic impairment.

In **hypertension** metoprolol tartrate is usually given in an initial oral dose of 100 mg daily, as a single dose or in two divided doses. The dose may be increased weekly, according to response; the usual maintenance dose is 100 to 200 mg daily, but up to 400 mg daily may be given.

The usual oral dose for **angina pectoris** is 50 to 100 mg two or three times daily.

In the treatment of **cardiac arrhythmias** the usual oral dose is 50 mg two or three times daily, increased if necessary up to 300 mg daily in divided doses.

For the emergency treatment of cardiac arrhythmias metoprolol tartrate may be given intravenously in an initial dose of up to 5 mg, at a rate of 1 to 2 mg/minute; this may be repeated, if necessary, at intervals of 5 minutes to a total dose of 10 to 15 mg. When acute arrhythmias have been controlled, maintenance therapy may be started 4 to 6 hours after intravenous therapy, at oral doses not exceeding 50 mg three times daily.

Arrhythmias may be prevented on induction of anaesthesia, or controlled during anaesthesia, by the slow intravenous injection of 2 to 4 mg; further injections of 2 mg may be repeated as necessary to a maximum total dose of 10 mg.

Metoprolol is also used as an adjunct in the early management of acute **myocardial infarction.** Treatment should be given within 12 hours of the onset of chest pain; metoprolol tartrate 5 mg should be given intravenously at 2-minute intervals to a total of 15 mg, where tolerated. After 15 minutes, in patients who have received the full intravenous dose, oral treatment should be started; 50 mg is given every 6 hours for 2 days. In patients who have failed to tolerate the full intravenous dose a reduced oral dose should be given as, and when, their condition permits. Subsequent maintenance dosage is 100 mg given twice daily by mouth. In patients who did not receive metoprolol by intravenous injection as part of the early management of myocardial infarction, metoprolol may be started once the clinical condition of the patient stabilises, in a dose of 200 mg daily in 2 or 4 divided doses.

In the management of stable, symptomatic **heart failure** metoprolol succinate may be given as an oral modified-release preparation. The initial dose is the equivalent of metoprolol tartrate 12.5 to 25 mg once daily, increased as tolerated, at intervals of 2 weeks, with a target dose of 200 mg once daily.

As an adjunct in the treatment of **hyperthyroidism** metoprolol tartrate may be given in oral doses of 50 mg four times daily. Doses of 100 to 200 mg are given daily in divided doses for **migraine** prophylaxis.

Administration in children. Metoprolol has been used in children, although experience is limited. A study[1] in children aged 6 to 16 years with hypertension found that modified-release metoprolol succinate was well tolerated in doses of up to the equivalent of metoprolol tartrate 2 mg/kg daily, although efficacy was not established. US licensed product information nevertheless allows the use of oral doses of metoprolol succinate once daily in children aged 6 to 16 years; the initial dose is the equivalent of metoprolol tartrate 1 mg/kg daily (maximum 50 mg), adjusted according to response to a maximum of 2 mg/kg (not more than 200 mg) daily.

The *BNFC* recommends that for hypertension children aged 1 month to 12 years may be given standard formulations of metoprolol tartrate in an initial dose of 1 mg/kg twice daily orally, increased if necessary to a maximum dose of 8 mg/kg daily in 2 to 4 divided doses. Children over 12 years may be given the adult dose (see above).

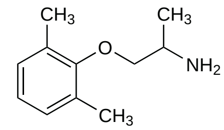
Мексилетина Гидрохлорид

$C_{11}H_{17}NO,HCl$ = 215.7.

CAS — 31828-71-4 (mexiletine); 5370-01-4 (mexiletine hydrochloride).

ATC — C01BB02.

ATC Vet — QC01BB02.



(mexiletine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Mexiletine Hydrochloride). A white or almost white, crystalline powder. It exhibits polymorphism. Freely soluble in water and in methyl alcohol; sparingly soluble in dichloromethane. A 10% solution in water has a pH of 4.0 to 5.5.

USP 31 (Mexiletine Hydrochloride). A white powder. Freely soluble in water and in dehydrated alcohol; practically insoluble in ether; slightly soluble in acetonitrile. A 10% solution in water has a pH of between 3.5 and 5.5. Store in airtight containers.

Adverse Effects and Treatment

Mexiletine has a narrow therapeutic ratio; many adverse effects of mexiletine are dose-related and will respond to dosage reduction but may be severe enough to force mexiletine to be stopped and symptomatic and supportive therapy to be given. Toxicity is common with oral or parenteral loading doses when plasma concentrations are high.

The most common adverse effects involve the gastrointestinal tract and CNS. Effects on the gastrointestinal tract include nausea, vomiting, constipation, and diarrhoea; oesophageal ulceration has also been reported. Effects on the nervous system include tremor, confusion, lightheadedness, dizziness, blurred vision and other visual disturbances, sleep disturbances, and speech difficulties. The most frequent cardiovascular effects are hypotension, sinus bradycardia, heart block and AV dissociation, and atrial fibrillation. As with other antiarrhythmics mexiletine may exacerbate arrhythmias. Other adverse effects that have been reported include skin rashes, abnormal liver function tests, thrombocytopenia, positive antinuclear factor titres, and convulsions. The Stevens-Johnson syndrome has been reported rarely.

Incidence of adverse effects. In a study involving 100 patients with ventricular arrhythmias, mexiletine had to be stopped in 49 patients because of intolerable adverse effects.[1] The most common of these affected the gastrointestinal system (27%) and included nausea (10%), vomiting (6%), heartburn (6%), and oesophageal spasm (3%). Intolerable effects on the CNS occurred in 10% of patients and these were most commonly tremor (4%), ataxia (2%), dyskinesia (1%), and tinnitus (1%). When mexiletine was used with another antiarrhythmic, the incidence of intolerable effects was 56%.

Tolerable adverse effects with mexiletine alone were transient and dose-dependent and occurred in 18% of patients. They most often affected the gastrointestinal tract. No irreversible adverse effects were reported and no proarrhythmic effects were seen.

1. Kerin NZ, *et al.* Mexiletine: long-term efficacy and side effects in patients with chronic drug-resistant potentially lethal ventricular arrhythmias. *Arch Intern Med* 1990; **150:** 381–4.

Effects on the lungs. Pulmonary fibrosis has been reported in an elderly patient receiving mexiletine; the manufacturer was aware of 3 other cases.[1]

1. Bero CJ, Rihn TL. Possible association of pulmonary fibrosis with mexiletine. *DICP Ann Pharmacother* 1991; **25:** 1329–31.

Precautions

Mexiletine is contra-indicated in cardiogenic shock and in second- or third-degree AV block (unless the patient has a pacemaker). It should be used with caution in patients with sinus node dysfunction, other conduction disorders, bradycardia, hypotension, heart failure, or hepatic impairment. ECG and blood pressure monitoring should be carried out during treatment.

Absorption of oral mexiletine may be delayed in situations where gastric emptying is slowed, such as acute myocardial infarction.

Breast feeding. Mexiletine is distributed into human breast milk in higher concentrations than in maternal serum. A woman[1] given 200 mg of mexiletine three times daily during the last trimester of pregnancy (see below), went on to breast feed the infant. Concentrations of mexiletine in the maternal milk and serum were found to be 0.6 and 0.3 micrograms/mL respectively on the second day postpartum, and 0.8 and 0.7 micrograms/mL respectively after 6 weeks. This represented a milk to serum ratio of 2.0 and 1.1 respectively. However, mexiletine was undetectable in the infant's serum on both occasions and no adverse effects were seen. In another report[2] a woman taking a similar dose of mexiletine for the last 5 months of her pregnancy also breast fed her infant. In samples of maternal milk and blood collected between the second and fifth day postpartum the milk to plasma ratio varied between 0.78 and 1.89 with a mean of 1.45. It was considered unlikely that the infant would ingest more than 1.25 mg of mexiletine in any 24-hour period, and this amount was not thought to be enough to cause adverse effects. Failure to feed was noted[3] in the first 17 days in an infant whose mother was taking 750 mg daily of mexiletine and 50 mg daily of atenolol. After maternal education and formula supplementation an acceptable growth curve was established. Breast feeding continued until the infant was 3 months old, and no adverse effects were seen at 10 months. The American Academy of Pediatrics[4] therefore considers that mexiletine is usually compatible with breast feeding.

Pregnancy. Mexiletine crosses the placenta but there have been several reports of its use in pregnant women with no apparent long-term effects on the infants. A normal infant was born to a woman given mexiletine with propranolol for the control of ventricular tachycardia during the third trimester of pregnancy.[1] During the first 6 hours after delivery the infant had a heart rate of only 90 beats/minute, probably due to the propranolol; it was normal thereafter. At delivery the serum concentration of mexiletine in mother and infant was the same. A woman[2] who received mexiletine and atenolol throughout pregnancy also delivered a normal infant; failure to feed was noted at 17 days but at 10 months no adverse effects were seen. In another case[3] where the mother took mexiletine throughout pregnancy, the infant had a low Apgar score at 1 minute and hypoglycaemia was also noted, but the relationship to mexiletine was unclear; cord and maternal blood concentrations at the time of delivery were 400 nanograms/mL and 600 nanograms/mL, respectively.

Interactions

Mexiletine undergoes extensive metabolism in the liver particularly by the cytochrome P450 isoenzymes CYP1A2 and CYP2D6, and possibly CYP3A4, and interactions may occur with other drugs metabolised by the same enzymes. Plasma concentrations of mexiletine may be reduced by hepatic enzyme inducers such as phenytoin and rifampicin; increased plasma concentrations may occur with enzyme inhibitors.

Absorption of mexiletine may be delayed by drugs that slow gastric emptying such as opioid analgesics and atropine. The rate of absorption may be increased by metoclopramide; the extent of absorption is unaffected.

Drugs that acidify or alkalinise the urine enhance or reduce the rate of elimination of mexiletine, respectively.

There may be an increased risk of arrhythmias if mexiletine is used with other antiarrhythmics or with arrhythmogenic drugs.

Mexiletine has been reported to increase theophylline concentrations (p.1142) and to precipitate lidocaine toxicity (p.1863).

Pharmacokinetics

Mexiletine is readily and almost completely absorbed from the gastrointestinal tract, with a bioavailability of about 90%, although absorption may be delayed in situations where gastric emptying is slowed, such as acute myocardial infarction.

Mexiletine is metabolised in the liver to a number of metabolites; metabolism may involve cytochrome P450 isoenzymes CYP1A2, CYP2D6, and CYP3A4, and genetic polymorphism in relation to CYP2D6 has been identified. Mexiletine is excreted in the urine, mainly in the form of its metabolites with about 10% excreted unchanged; clearance is increased in acid urine.

Mexiletine is widely distributed throughout the body and is about 50 to 70% bound to plasma proteins. Mexiletine crosses the placenta and is distributed into breast milk. It has an elimination half-life of about 10 hours in healthy subjects but this may be prolonged in patients with heart disease, hepatic impairment, or severe renal impairment. Its therapeutic effect has been correlated with plasma concentrations of 0.5 to 2 micrograms/mL, but the margin between therapeutic and toxic concentrations is narrow, and severe toxicity may occur within this range.

◊ References.

1. Labbé L, Turgeon J. Clinical pharmacokinetics of mexiletine. *Clin Pharmacokinet* 1999; **37:** 361–84.

Uses and Administration

Mexiletine is a class Ib antiarrhythmic (p.1153) with actions similar to those of lidocaine (p.1864), to which it is structurally related. Unlike lidocaine it undergoes little hepatic first-pass metabolism and can be given orally.

Mexiletine is used for the treatment of ventricular **arrhythmias** (p.1160). It is given orally or intravenously as the hydrochloride.

Mexiletine hydrochloride is given orally in a usual loading dose of 400 mg followed by 200 to 250 mg three or four times daily, starting 2 hours after the loading dose. The usual maintenance dosage is 600 to 900 mg daily in divided doses; doses up to 1.2 g daily may be given. Oral doses should be taken with food and swallowed with plenty of liquid to avoid oesophageal ulceration. Modified-release preparations have been used. Higher loading doses (for example, of 600 mg) may be necessary in patients after myocardial infarction to overcome delayed absorption, especially if they have received an opioid analgesic.

Mexiletine hydrochloride may be given by slow intravenous injection in doses of 100 to 250 mg at a rate of 25 mg/minute, followed by an infusion at a rate of 250 mg over 1 hour, 250 mg over the next 2 hours, and then at about 500 micrograms/minute for maintenance, according to response; when appropriate the patient may be transferred to oral therapy with doses of 200 to 250 mg three or four times daily. Alternatively, an initial intravenous dose of 200 mg at a rate of 25 mg/minute, may be followed by an oral dose of 400 mg on completion of the injection, with subsequent oral therapy as above.

Mexiletine has also been tried in the treatment of refractory neuropathic **pain** (see below).

Administration in children. Mexiletine may be effective for ventricular arrhythmias in children; a study[1] of 42 children and young adults (age range 5 months to 34 years) found that mexiletine, given orally in a dose of 1.4 to 5 mg/kg every 8 hours, was effective in 30 patients (71%), with long-term control reported in 18. Treatment was more effective in children with congenital heart disease than in those with cardiomyopathy or no heart disease. Another report[2] found that young children required higher mg/kg doses than adults; a 2-week-old girl and a 20-month-old boy required oral doses of 25 and 15 mg/kg daily, respectively, to produce therapeutic plasma concentrations and control of tachycardia.

1. Moak JP, *et al*. Mexiletine: an effective antiarrhythmic drug for treatment of ventricular arrhythmias in congenital heart disease. *J Am Coll Cardiol* 1987; **10:** 824–9.
2. Holt DW, *et al*. Paediatric use of mexiletine and disopyramide. *BMJ* 1979; **2:** 1476–7.

Administration in the elderly. The rate of absorption of mexiletine was slower in a group of 7 elderly subjects compared with 8 young subjects given mexiletine 100 mg by mouth, but the extent of absorption was probably not affected.[1] Elimination of mexiletine was not significantly different between the 2 groups and there was no pharmacokinetic basis for dosage modification of mexiletine in the elderly. An observational study[2] in patients receiving mexiletine found a small decrease in clearance with age, but again this was not considered to warrant dosage adjustment.

1. Grech-Bélanger O, *et al*. Pharmacokinetics of mexiletine in the elderly. *J Clin Pharmacol* 1989; **29:** 311–15.
2. Ueno K, *et al*. Pharmacokinetics of mexiletine in middle-aged and elderly patients. *Clin Pharm* 1993; **12:** 768–70.

Administration in renal impairment. The pharmacokinetics of mexiletine do not appear to be affected by renal impairment,[1] although one study[2] found that in patients with creatinine clearance below 10 mL/minute the steady-state plasma concentration and half-life were increased, suggesting that dosage should be adjusted according to plasma concentrations in such patients. Haemodialysis[1] and continuous ambulatory peritoneal dialysis[3] do not appear to affect mexiletine clearance.

Pain. Neuropathic pain (p.8) is often insensitive to opioid analgesics and various drugs, including mexiletine, have been tried. Mexiletine may be of benefit in diabetic neuropathy,[1] although studies have given conflicting results; two of the studies that reported no difference between treatment and placebo found that a subset of patients (those with stabbing or burning pain, heat sensations, and formication) appeared to benefit.[2,3] There have also been reports of improvement in patients with central post-stroke pain (thalamic pain syndrome),[4] and in neuropathic pain associated with cancer,[5-7] and a systematic review[8] concluded that mexiletine was safe and effective in various types of neuropathic pain.

Other painful states in which mexiletine has been reported to be of benefit include: Dercum's disease (a condition involving painful fatty deposits),[9] and erythromelalgia.[10,11]

Mibefradil Hydrochloride *(BANM, rINNM)*

Hidrocloruro de mibefradil; Mibéfradil, Chlorhydrate de; Mibefradil Dihydrochloride *(USAN)*; Mibefradili Hydrochloridum; Ro-40-5967 (mibefradil); Ro-40-5967/001 (mibefradil hydrochloride). (1*S*,2*S*)-(2-{[3-(2-Benzimidazolyl)propyl]methylamino}-ethyl)-6-fluoro-1,2,3,4-tetrahydro-1-isopropyl-2-naphthyl methoxyacetate dihydrochloride.

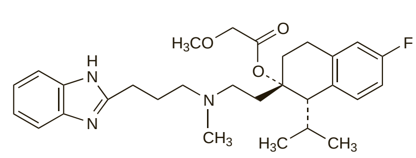
Мибефрадила Гидрохлорид

$C_{29}H_{38}FN_3O_3,2HCl = 568.6.$

CAS — 116644-53-2 (mibefradil); 116666-63-8 (mibefradil hydrochloride).

ATC — C08CX01.

ATC Vet — QC08CX01.



(mibefradil)

Profile

Mibefradil is a calcium-channel blocker that acts principally on fast T-type calcium channels, unlike conventional calcium-channel blockers that act on slow L-type channels (see p.1154). Mibefradil was introduced for the management of hypertension and angina pectoris but was withdrawn worldwide several months later due to increasing reports of serious interactions with a wide range of drugs.

Midodrine Hydrochloride *(BANM, USAN, rINNM)* ⊗

Hidrocloruro de midodrina; Midodrine, Chlorhydrate de; Midodrini Hydrochloridum; ST-1085 (midodrine or midodrine hydrochloride). 2-Amino-*N*-(β-hydroxy-2,5-dimethoxyphenethyl)-acetamide hydrochloride; (*RS*)-N^1-(β-Hydroxy-2,5-dimethoxyphenethyl)glycinamide hydrochloride.

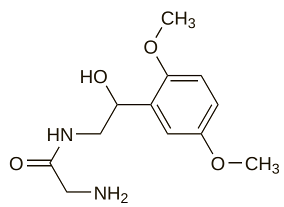
Мидодрина Гидрохлорид

$C_{12}H_{18}N_2O_4$,HCl = 290.7.

CAS — 42794-76-3 (midodrine); 3092-17-9 (midodrine hydrochloride).

ATC — C01CA17.

ATC Vet — QC01CA17.



(midodrine)

Adverse Effects, Treatment, and Precautions

As for Sympathomimetics, p.1407. Midodrine has mainly alpha-agonist properties and the most serious adverse effect of midodrine is supine hypertension. Paraesthesias, dysuria, pilomotor reaction (goose flesh), pruritus and rashes have been reported.

Interactions

As for Sympathomimetics, p.1407.

Pharmacokinetics

Midodrine is well absorbed from the gastrointestinal tract and undergoes enzymatic hydrolysis in the systemic circulation to its active metabolite, deglymidodrine (desglymidodrine; ST-1059). Midodrine itself reaches its peak plasma concentrations about half an hour after an oral dose, and has a plasma half-life of about 25 minutes. The active metabolite reaches its peak plasma concentration about an hour after oral dosage and has a terminal elimination half-life of about 3 hours. Deglymidodrine undergoes some further metabolism in the liver. Midodrine is primarily excreted in the urine as metabolites and a small amount of unchanged drug.

Uses and Administration

Midodrine is a direct-acting sympathomimetic (p.1408) with selective alpha-agonist activity; the main active moiety has been stated to be its major metabolite, deglymidodrine. It acts as a peripheral vasoconstrictor but has no direct cardiac stimulatory effects.

Midodrine hydrochloride is used in the treatment of hypotensive states (p.1174) and in particular of orthostatic hypotension (p.1530). Alpha-agonist drugs such as midodrine have also been used as an adjunct in the management of urinary incontinence (p.2180).

In **hypotensive states**, the usual initial oral dose of midodrine hydrochloride is 2.5 mg two or three times daily, adjusted gradually according to response; up to 10 mg three times daily may be required. The potential for supine hypertension is reduced by taking the last dose of the day at least 4 hours before bedtime.

An oral dose for **urinary incontinence** is 2.5 to 5 mg two or three times daily.

Midodrine hydrochloride can also be given in similar doses by slow intravenous injection. It has also been used orally or by injection in the treatment of **retrograde ejaculation**.

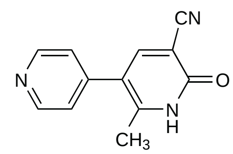
ATC — C01CE02.

ATC Vet — QC01CE02.



Pharmacopoeias. In *US.*

USP 31 (Milrinone). A white to tan, hygroscopic, crystalline solid. Practically insoluble in water and in chloroform; very slightly soluble in methyl alcohol; freely soluble in dimethyl sulfoxide. Store in airtight containers.

Milrinone Lactate *(BANM, rINNM)*

Lactato de milrinona; Milrinone, Lactate de; Milrinoni Lactas.

Мильринона Лактат

$C_{12}H_9N_3O,C_3H_6O_3$ = 301.3.

ATC — C01CE02.

ATC Vet — QC01CE02.

Incompatibility. UK licensed product information states that milrinone lactate injection is incompatible with furosemide and bumetanide, and it should not be diluted with sodium bicarbonate injection. Physical incompatibility with imipenem-cilastatin sodium has also been reported.[1]

1. Veltri MA, Conner KG. Physical compatibility of milrinone lactate injection with intravenous drugs commonly used in the pediatric intensive care unit. *Am J Health-Syst Pharm* 2002; **59:** 452–4.

Adverse Effects and Precautions

Prolonged oral use of milrinone has increased the mortality rate and milrinone is now only used intravenously for short-term use.

Supraventricular and ventricular arrhythmias, hypotension, angina-like chest pain, and headache have been reported. Hypokalaemia, tremor, and thrombocytopenia may occur. The incidence of arrhythmias may be lower in *children* whereas the risk of thrombocytopenia may be higher (see Administration in Children, below).

Milrinone should be used with caution in patients with severe obstructive aortic or pulmonary valvular disease or with hypertrophic cardiomyopathy. Since milrinone may facilitate conduction through the atrioventricular node it can increase the ventricular response rate in patients with atrial flutter or fibrillation. Digitalisation should be considered in these patients before milrinone therapy is started.

Blood pressure, heart rate, ECG, fluid and electrolyte balance, and renal function should be monitored during milrinone therapy.

Milrinone should be given in reduced doses to patients with renal impairment.

Pharmacokinetics

Although milrinone is rapidly and almost completely absorbed from the gastrointestinal tract, it is only given intravenously. It is about 70% bound to plasma proteins. Elimination occurs mainly via the urine; about 83% of a dose is excreted as unchanged drug. The elimination half-life is about 2.3 hours.

◊ General references.

1. Rocci ML, Wilson H. The pharmacokinetics and pharmacodynamics of newer inotropic agents. *Clin Pharmacokinet* 1987; **13:** 91–109. Correction. *ibid.* 1988; **14:** (contents page).

Uses and Administration

Milrinone is a phosphodiesterase inhibitor similar to amrinone (p.1215) with positive inotropic and vasodilator activity. It is, however, reported to have greater positive inotropic activity than amrinone. It is given intravenously, as the lactate, in the short-term management of severe heart failure unresponsive to other forms of therapy and in acute heart failure after cardiac surgery. In some longer-term studies milrinone was given by mouth, but an increased mortality rate was reported.

Doses of milrinone lactate are expressed in terms of the base; milrinone lactate 1.43 mg is equivalent to about 1 mg of milrinone. The initial loading dose is the equivalent of milrinone 50 micrograms/kg given over 10 minutes followed by a continuous maintenance infusion. The maintenance infusion may be titrated between 375 and 750 nanograms/kg per minute but a total daily dose of 1.13 mg/kg should not be exceeded.

Dosage should be reduced in patients with renal impairment (see below).

Administration in children. Milrinone has been used in children with septic shock or heart failure after cardiac surgery. Pharmacokinetic studies[1,2] have suggested that steady-state plasma concentrations of milrinone are lower in children than in adults given similar doses, and that milrinone clearance is faster in children. Higher doses in proportion to body-weight may therefore be necessary in children than in adults. For neonates and children aged 1 month to 18 years with heart failure, low cardiac output after cardiac surgery, or shock, the *BNFC* recommends an initial dose of 50 to 75 micrograms/kg by intravenous infusion over 30 to 60 minutes, followed by continuous intravenous infusion at a dose of 30 to 45 micrograms/kg per hour (500 to 750 nanograms/kg per minute). The infusion may be continued for 2 to 3 days, but is usually given for 12 hours after cardiac surgery.

Milrinone also appears to be effective for the prevention of low cardiac output in children undergoing cardiac surgery.[3] It has been tried for the prevention of low systemic blood flow in premature infants, but further studies are needed to confirm its role.[4]

A study[5] of adverse effects in children given milrinone has suggested that arrhythmias are less common than in adults whereas thrombocytopenia is more common.

5. Watson S, *et al.* Use of milrinone in the pediatric critical care unit. *Pediatrics* 1999; **104** (suppl): 681–2.

Administration in renal impairment. Doses of milrinone should be reduced in patients with renal impairment. The following doses for maintenance infusion are recommended based on creatinine clearance (CC):

- CC 50 mL/minute: 430 nanograms/kg per minute
- CC 40 mL/minute: 380 nanograms/kg per minute
- CC 30 mL/minute: 330 nanograms/kg per minute
- CC 20 mL/minute: 280 nanograms/kg per minute
- CC 10 mL/minute: 230 nanograms/kg per minute
- CC 5 mL/minute: 200 nanograms/kg per minute

Heart failure. Milrinone is one of several drugs that may be used in heart failure (p.1165), but because of an increased mortality rate reported following long-term oral use it is usually only given intravenously for short-term management of heart failure unresponsive to other treatments. The PROMISE (Prospective Randomized Milrinone Survival Evaluation) study[1] showed that oral milrinone increased morbidity and mortality in patients with severe chronic heart failure. However, more recently, longer-term continuous intravenous use for up to 8 weeks has been studied in patients awaiting heart transplantation and appeared to be well tolerated.[2] Intermittent use on several days a week has also been tried.[3]

In patients with acute exacerbation of heart failure, a prospective study[4] found no benefit from the routine use of short-term intravenous milrinone.

Minoxidil *(BAN, USAN, rINN)*

Minoksidiili; Minoksidilis; Minoxidilum; U-10858. 2,6-Diamino-4-piperidinopyrimidine 1-oxide.

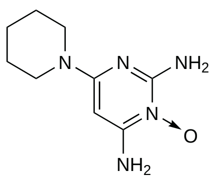
Миноксидил

$C_9H_{15}N_5O$ = 209.2.

CAS — 38304-91-5.

ATC — C02DC01; D11AX01.

ATC Vet — QC02DC01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Minoxidil). A white or almost white crystalline powder. Slightly soluble in water; soluble in methyl alcohol and in propylene glycol. Protect from light.

USP 31 (Minoxidil). A white or off-white crystalline powder. Slightly soluble in water; soluble in alcohol and in propylene glycol; practically insoluble in acetone, in chloroform, in ethyl acetate, and in petroleum spirit; sparingly soluble in methyl alcohol.

Adverse Effects and Treatment

Adverse effects commonly caused by minoxidil include reflex tachycardia, fluid retention accompanied by weight gain, oedema, and sometimes deterioration of existing heart failure and changes in the ECG. Hypertrichosis develops in up to 80% of patients within 3 to 6 weeks of the start of minoxidil therapy but is slowly reversible on discontinuation. Pericardial effusion, sometimes with associated tamponade, has been reported in about 3% of patients. Pericarditis may also occur. Minoxidil may aggravate or uncover angina pectoris. Other less frequent adverse effects include headache, nausea, gynaecomastia and breast tenderness, polymenorrhoea, allergic skin rashes, Stevens-Johnson syndrome, and thrombocytopenia.

Reflex tachycardia can be overcome by the use of a beta blocker, or alternatively methyldopa, and a diuretic (usually a loop diuretic) is used to reduce fluid retention. If excessive hypotension occurs, an intravenous infusion of sodium chloride 0.9% can be given to maintain the blood pressure. If a pressor agent is necessary, drugs such as adrenaline, which can aggravate tachycardia, should be avoided; phenylephrine, angiotensinamide, vasopressin, or dopamine may be given if there is evidence of inadequate perfusion of a vital organ.

Topical application of minoxidil may be associated with contact dermatitis, pruritus, local burning, and flushing; sufficient may be absorbed to produce systemic adverse effects. Changes in hair colour or texture may occur.

Effects on the eyes. Bilateral optic neuritis and retinitis occurred in a patient during treatment with minoxidil for hypertension after a renal transplant.[1] The patient was also taking prednisolone and azathioprine.

1. Gombos GM. Bilateral optic neuritis following minoxidil administration. *Ann Ophthalmol* 1983; **15:** 259–61.

Effects on the hair. The hypertrichosis frequently associated with oral minoxidil makes it generally unsuitable for women. There have also been reports of changes in hair colour.[1] In addition a case has been reported of increased hair loss, followed by subsequent regrowth of differently-coloured hair.[2] Substantial hair loss occurred in a woman after withdrawal of minoxidil and she had to wear a wig.[3]

Severe hypertrichosis has also been reported in 5 of 56 women applying minoxidil 5% solution topically for androgenetic alopecia.[4] Facial, arm, and leg hypertrichosis were reported 2 to 3 months after starting treatment. Hypertrichosis had disappeared 5 months after discontinuation of minoxidil.

1. Traub YM, *et al.* Treatment of severe hypertension with minoxidil. *Isr J Med Sci* 1975; **11:** 991–8.
2. Ingles RM, Kahn T. Unusual hair changes with minoxidil therapy. *Int J Dermatol* 1983; **22:** 120–2.

4. Peluso AM, *et al.* Diffuse hypertrichosis during treatment with 5% topical minoxidil. *Br J Dermatol* 1997; **136:** 118–20.

Effects on skeletal muscle. A polymyalgia syndrome, manifesting as fatigue, anorexia, weight loss, and severe pain in the shoulders and pelvic girdle, was seen in 4 men using topical minoxidil.[1] All symptoms improved within 2 to 4 weeks of stopping the drug. In 2 of the patients rechallenge produced a recurrence of symptoms.

1. Colamarino R, *et al.* Polymyalgia and minoxidil. *Ann Intern Med* 1990; **113:** 256–7.

Effects on the skin. Although skin reactions to systemic minoxidil do not appear to be common, cases of classic Stevens-Johnson syndrome have been reported.[1,2] The syndrome generally responds to withdrawal and corticosteroid therapy; in one case[1] subsequent rechallenge provoked a recurrence. In another patient an extensive erythematous weeping rash with lesions consistent with actinic keratosis also appeared to be due to minoxidil; bullous lesions recurred on re-exposure.[3] After topical application itching, scaling, flushing, and dermatitis have been the most common adverse effects; allergic contact dermatitis has been reported in rare instances.[4]

For other lesions associated with Kaposi's sarcoma and angioma, see Neoplasms, below, and for effects on the hair, see above.

1. DiSantis DJ, Flanagan J. Minoxidil-induced Stevens-Johnson syndrome. *Arch Intern Med* 1981; **141:** 1515.
2. Callen EC, *et al.* Stevens-Johnson syndrome associated with oral minoxidil: a case report. *J Nephrol* 2007; **20:** 91–3.
3. Ackerman BH, *et al.* Pruritic rash with actinic keratosis and impending exfoliation in a patient with hypertension managed with minoxidil. *Drug Intell Clin Pharm* 1988; **22:** 702–3.
4. Clissold SP, Heel RC. Topical minoxidil: a preliminary review of its pharmacodynamic properties and therapeutic efficacy in alopecia areata and alopecia androgenetica. *Drugs* 1987; **33:** 107–22.

Neoplasms. Two haemorrhagic lesions with Kaposi's features appeared on the forehead, an unusual location for HIV-associated Kaposi's sarcoma, in an HIV-positive patient who had applied topical minoxidil there for 3 months.[1] In a healthy patient an angioma of the scalp developed after 2 months of topical minoxidil therapy. The patient had had a similar lesion as a baby. Minoxidil may induce angiogenesis or may stimulate endothelial cells, fibroblasts, and muscle cells to proliferate. Care should be taken when minoxidil is applied to the skin of people who are predisposed to neo-angiogenesis, or who are HIV-positive.

For other effects of minoxidil on the skin following topical application, see above.

1. Pavlovitch JH, *et al.* Angiogenesis and minoxidil. *Lancet* 1990; **336:** 889.

Precautions

Minoxidil is contra-indicated in phaeochromocytoma. It should be used with caution after a recent myocardial infarction, and in patients with pulmonary hypertension, angina pectoris, chronic heart failure, and significant renal impairment.

Topical application of minoxidil should be restricted to the scalp; it should not be applied to inflamed scalp skin or areas affected by psoriasis, severe sunburn, or severe excoriations, because of the risk of increased absorption. Patients being treated for hypertension should be monitored if topical minoxidil is used concurrently.

AIDS. For recommendations that topical minoxidil should be used with caution in HIV-positive patients, see Neoplasms under Adverse Effects, above.

Breast feeding. Study[1] of a breast-feeding mother showed that minoxidil was rapidly distributed into breast milk, achieving similar concentrations to those in the maternal plasma. No adverse effects were seen in the infant after 2 months and the American Academy of Pediatrics considers[2] that minoxidil is therefore usually compatible with breast feeding.

1. Valdivieso A, *et al.* Minoxidil in breast milk. *Ann Intern Med* 1985; **102:** 135.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 26/09/05)

Porphyria. Minoxidil is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Pregnancy. A patient who took minoxidil, propranolol, and furosemide throughout pregnancy delivered a normal infant at 37 weeks. Pregnancy was uneventful.[1]

1. Valdivieso A, *et al.* Minoxidil in breast milk. *Ann Intern Med* 1985; **102:** 135.

Interactions

The antihypertensive effect of minoxidil may be enhanced by use of other hypotensive drugs. Severe orthostatic hypotension may occur if minoxidil and sympathetic blocking drugs such as guanethidine are given concurrently.

Topical minoxidil should not be used with other topical agents known to enhance absorption, such as corticosteroids, retinoids, or occlusive ointment bases.

Tretinoin. Percutaneous absorption of minoxidil is enhanced by tretinoin as a result of increased stratum corneum permeability.[1]

1. Ferry JJ, *et al.* Influence of tretinoin on the percutaneous absorption of minoxidil from an aqueous topical solution. *Clin Pharmacol Ther* 1990; **47:** 439–46.

Pharmacokinetics

About 90% of an oral dose of minoxidil is absorbed from the gastrointestinal tract. The plasma half-life is about 4.2 hours although the haemodynamic effect may persist for up to 75 hours, presumably due to accumulation at its site of action. Minoxidil is not bound to plasma proteins. It is distributed into breast milk. Minoxidil is extensively metabolised by the liver. It requires sulfation to become active, but the major metabolite is a glucuronide conjugate. Minoxidil is excreted predominantly in the urine mainly in the form of metabolites. Minoxidil and its metabolites are dialysable, although the pharmacological effect is not reversed.

About 0.3 to 4.5% of a topical dose of minoxidil is absorbed from intact scalp.

Uses and Administration

Minoxidil is an antihypertensive that acts mainly by causing direct peripheral vasodilatation of the arterioles. It produces effects on the cardiovascular system similar to those of hydralazine (p.1307). Minoxidil is given orally for the treatment of severe hypertension unresponsive to standard therapy (p.1171). When applied topically to the scalp minoxidil may stimulate hair growth to a limited extent and is used in the treatment of alopecia.

In the treatment of **hypertension** minoxidil is given with a beta blocker, or with methyldopa, to diminish the cardiac-accelerating effects, and with a diuretic, usually a loop diuretic, to control oedema. After a single oral dose, the maximum hypotensive effect usually occurs after 2 to 3 hours, although the full effects may not occur until after 3 to 7 days of continuous treatment. An initial dose of 5 mg of minoxidil daily (or 2.5 mg daily in the elderly) is gradually increased at intervals of not less than 3 days to 40 or 50 mg daily according to response; in exceptional circumstances up to 100 mg daily has been given. If more rapid control of blood pressure is required, dosage changes may be made every 6 hours with careful monitoring. The daily dose may be given as a single dose or in 2 divided doses. For children, the initial dose is 200 micrograms/kg daily, increased in steps of 100 to 200 micrograms/kg at intervals of not less than 3 days, until control of blood pressure has been achieved or a maximum of 1 mg/kg or 50 mg daily has been reached.

Reduced doses may be required in patients with renal impairment (see below).

In the treatment of **alopecia androgenetica** (male-pattern baldness) 1 mL of a 2% or 5% solution of minoxidil is applied twice daily to the scalp. The 5% solution is not recommended for women.

Administration in renal impairment. A study of the pharmacokinetics of minoxidil in patients with varying degrees of renal impairment found that the non-renal clearance was also impaired as renal function worsened.[1] Substantial accumulation of minoxidil might occur in these patients during multiple-dose therapy. It was advised that minoxidil be started with smaller doses or at longer dosage intervals in patients with renal impairment.

1. Halstenson CE, *et al.* Disposition of minoxidil in patients with various degrees of renal function. *J Clin Pharmacol* 1989; **29:** 798–802.

Alopecia. Minoxidil is used topically to stimulate hair growth in alopecia (p.1577), although its mechanism of action is poorly understood.[1] Increases in pigmented non-vellus hair may be due to thickening and pigmentation of existing vellus rather than new growth.[2] Measurement over 96 weeks showed[3] that minoxidil in solutions of 2 or 5% had a greater effect on hair weight than number of hairs in men with androgenetic alopecia (male-pattern baldness) with the 5% solution being more effective; 24 weeks after treatment was stopped both values had returned to baseline. Another study[4] also showed that 5% minoxidil had a greater effect than 2%, and produced an earlier response. However, 5% minoxidil has been found[5] less effective than oral finasteride. Even with continued use there is a waning of effect with minoxidil.[6,7] It may be more effective in retarding the progression of male-pattern baldness than in reversing it,[2] and users are advised to abandon treatment if there is insufficient benefit after a year.[8]

Minoxidil has also been used in women with female pattern hair loss, and as with men the 5% solution has been found[9] more effective than the 2%. In women with no evidence of biochemical hyperandrogenism minoxidil 2% was more effective[10] than oral cyproterone; where there was such evidence, cyproterone was superior.

Topical minoxidil has been shown to be safe in a large prospective study[11] of men and women with androgenetic alopecia.

Minoxidil appeared to have no beneficial effect on alopecia areata,[12] although one study indicated that topical minoxidil with 0.5% dithranol cream was more effective than either treatment alone.[13]

CHEMOTHERAPY-INDUCED ALOPECIA. Minoxidil 2% solution was applied daily to the scalp of a boy with acute lymphoblastic leukaemia whose hair had failed to regrow satisfactorily after intensive chemotherapy.[1] Almost normal hair growth, achieved over a 9-month period, was attributed to the use of minoxidil.

A small study[2] in women undergoing combination chemotherapy including doxorubicin found that topical minoxidil applied throughout therapy and for up to 4 months afterwards reduced the duration of alopecia by an average of 50 days.

Other methods for reducing chemotherapy-induced alopecia are described under the Treatment of Adverse Effects of Antineoplastics, p.639.

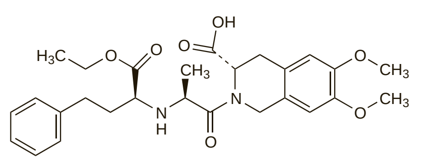
Моэксиприла Гидрохлорид

$C_{27}H_{34}N_2O_7,HCl$ = 535.0.
CAS — 103775-10-6 (moexipril); 82586-52-5 (moexipril hydrochloride).
ATC — C09AA13.
ATC Vet — QC09AA13.



(moexipril)

Adverse Effects, Treatment, and Precautions

As for ACE inhibitors, p.1193.

Interactions

As for ACE inhibitors, p.1196.

Pharmacokinetics

Moexipril acts as a prodrug of the diacid moexiprilat, its active metabolite. After oral doses moexipril is rapidly but incompletely absorbed and is metabolised to moexiprilat in the gastrointestinal mucosa and liver. Absorption is reduced in the presence of food. The bioavailability of moexiprilat is about 13% after oral doses of moexipril, and peak plasma concentrations of moexiprilat are reached in about 1.5 hours. Both moexipril and moexiprilat are moderately bound to plasma proteins. Moexipril is excreted mainly in the urine as moexiprilat, unchanged drug, and other metabolites; some moexiprilat may also be excreted in the faeces. The functional elimination half-life of moexiprilat is about 12 hours.

Uses and Administration

Moexipril is an ACE inhibitor (p.1193). It is used in the treatment of hypertension (p.1171).

Moexipril owes its activity to moexiprilat, to which it is converted after oral doses. The haemodynamic effects are seen about 1 hour after an oral dose and the maximum effect occurs after about 3 to 6 hours, although the full effect may not develop for 2 to 4 weeks during chronic dosing. Moexipril is given orally as the hydrochloride.

In the treatment of hypertension, the usual initial dose of moexipril hydrochloride is 7.5 mg once daily. Since there may be a precipitous fall in blood pressure in some patients when starting therapy with an ACE inhibitor, the first dose should preferably be given at bedtime. An initial dose of 3.75 mg once daily, given under close medical supervision, is suggested for patients who are taking a *diuretic*; if possible the diuretic should be withdrawn 2 or 3 days before moexipril is started and resumed later if necessary. An initial dose of 3.75 mg once daily is also recommended for patients with renal or hepatic impairment and for the elderly.

The usual maintenance dose is 7.5 to 30 mg daily, which may be given in 2 divided doses if control is inadequate with a single dose.

◊ Reviews.

Administration in renal impairment. In patients with renal impairment (creatinine clearance 40 mL/minute or less) an initial dose of moexipril hydrochloride 3.75 mg is given; in the USA it is required that the maximum dose in such patients should not exceed 15 mg daily.

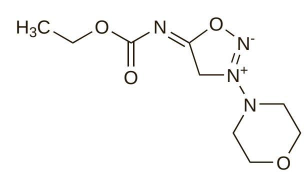
Molsidomine *(BAN, USAN, rINN)*

CAS-276; Molsidomiini; Molsidomin; Molsidomina; Molsidominum; Morsydomine; SIN-10. *N*-Ethoxycarbonyl-3-morpholinosydnonimine.

Молсидомин

$C_9H_{14}N_4O_4$ = 242.2.
CAS — 25717-80-0.
ATC — C01DX12.
ATC Vet — QC01DX12.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Molsidomine). A white or almost white, crystalline powder. Sparingly soluble in water; soluble in anhydrous alcohol and in dichloromethane. A 1% solution in water has a pH of 5.5 to 7.5. Protect from light.

Profile

Molsidomine is a nitrovasodilator used in angina pectoris (p.1157). It may also be used in heart failure (p.1165) and after myocardial infarction (below).

Molsidomine is given in usual oral doses of 1 to 4 mg two to four times daily. Modified-release preparations are also available. It is also given intravenously in single doses of 2 to 4 mg and doses of 2 mg may be repeated at intervals of at least 2 hours if necessary; total doses of up to 40 mg daily have been given. Infusions may be given at a rate of up to 3 mg/hour.

Molsidomine is metabolised to linsidomine (p.1325), an active metabolite.

Carcinogenicity. Molsidomine tends to degrade into morpholine (even when protected from the light), a compound considered potentially carcinogenic. This finding led to the suspension of marketing of one molsidomine formulation;[1] an earlier temporary suspension was related to evidence of carcinogenicity in some *animals*, although this has not been confirmed in humans.

1. Anonymous. Corvaton Tropfen. *Dtsch Apotheker Ztg* 1989; **129** (49): VI.

Myocardial infarction. Although intravenous nitrates (glyceryl trinitrate or sodium nitroprusside) may be used in the management of acute myocardial infarction (p.1175), molsidomine and its active metabolite linsidomine (a nitric oxide donor) had no effect on mortality.[1]

1. European Study of Prevention of Infarct with Molsidomine (ESPRIM) Group. The ESPRIM trial: short-term treatment of acute myocardial infarction with molsidomine. *Lancet* 1994; **344:** 91–7.

Pharmacokinetics. The pharmacokinetics of molsidomine have been reviewed.[1] Molsidomine is metabolised in the liver to linsidomine and other morpholine derivatives. Prolonged elimination half-lives of molsidomine and linsidomine due to reduced plasma clearance have been reported in patients with liver cirrhosis.[2]

Monteplase *(rINN)*

E-6010; Monteplasa; Montéplase; Monteplasum.

Монтеплаза

$C_{2569}H_{3896}N_{746}O_{783}S_{39}$ = 59009.5.
CAS — 156616-23-8.

Profile

Monteplase is a thrombolytic related to alteplase (p.1207) that is used in acute myocardial infarction (p.1175) and venous thromboembolism (p.1189). For acute myocardial infarction, the usual dose is 27 500 units/kg given by intravenous injection as soon as possible after the onset of symptoms. For pulmonary embolism, the usual dose is 13 750 units/kg to 27 500 units/kg.

Морацизина Гидрохлорид

$C_{22}H_{25}N_3O_4S,HCl$ = 464.0.
CAS — 29560-58-5.
ATC — C01BG01.
ATC Vet — QC01BG01.

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Moricizine Hydrochloride). A white to off-white crystalline powder. Soluble in water and in alcohol. Store in airtight containers.

Adverse Effects

The most common adverse effects associated with moracizine affect the CNS and the gastrointestinal tract and include dizziness, headache, fatigue, nausea, and abdominal pain. Other adverse effects include dyspnoea, dry mouth, blurred vision, impotence, and urinary-tract disorders. There have been occasional reports of fever, thrombocytopenia, hepatic dysfunction, hypothermia, and skin rash.

Like other antiarrhythmics moracizine can provoke or worsen arrhythmias. This may range from an increase in the frequency of premature ventricular contractions to induction or worsening of ventricular tachycardia.

An increased mortality rate occurred when moracizine was tested in the control of asymptomatic ventricular arrhythmias in post-infarction patients (see Cardiac Arrhythmias under Uses and Administration, below).

Effects on body temperature. Fever with elevated creatine phosphokinase and hepatic transaminase concentrations was associated with moracizine in 2 patients.[1] The fever abated within 48 hours of stopping moracizine and recurred within 24 hours of rechallenge in both patients. Results suggested a similarity to the neuroleptic malignant syndrome that is associated with other phenothiazine derivatives.

1. Miura DS, *et al.* Ethmozine toxicity: fever of unknown origin. *J Clin Pharmacol* 1986; **26:** 153–5.

Precautions

As for Flecainide Acetate, p.1288.

Interactions

Use of moracizine with other antiarrhythmics or arrhythmogenic drugs may increase the incidence of cardiac arrhythmias. Moracizine undergoes metabolism in the liver and its activity may be influenced by other drugs affecting the enzymes responsible for its metabolism; it is an enzyme inducer and may also affect the activity of other hepatically-metabolised drugs.

Pharmacokinetics

Moracizine is readily and almost completely absorbed from the gastrointestinal tract. It undergoes significant first-pass hepatic metabolism so that the oral bioavailability is about 38%. Moracizine is extensively metabolised and some of the numerous metabolites may be active. It induces its own metabolism; the plasma elimination half-life is about 2 hours after multiple doses. Although plasma concentrations are reduced with multiple dosing, clinical response is not affected. It is about 95% bound to plasma proteins. Moracizine is distributed into breast milk. About 56% of a dose is excreted in the faeces and about 39% in the urine.

◊ References.

1. Benedek IH, *et al.* Enzyme induction by moricizine: time course and extent in healthy subjects. *J Clin Pharmacol* 1994; **34:** 167–75.

Uses and Administration

Moracizine is a phenothiazine compound that has class I antiarrhythmic activity (p.1153) but does not readily fall into the subclasses a, b, or c. It is used as the hydrochloride in the treatment of serious symptomatic ventricular arrhythmias. Moracizine hydrochloride is given orally in a usual dose of 600 to 900 mg daily in 2 or 3 divided doses. Treatment should be started in hospital, and doses should be adjusted at intervals of not less than 3 days. Doses should be reduced in patients with hepatic or renal impairment (see below).

◊ Reviews.

1. Clyne CA, *et al.* Moricizine. *N Engl J Med* 1992; **327:** 255–60.

Administration in hepatic or renal impairment. The initial dose of moracizine hydrochloride in hepatic or renal impairment should be 600 mg or less daily and patients should be monitored closely (including ECG) before any adjustment of dose is made.

Cardiac arrhythmias. Moracizine is effective in various arrhythmias but is usually reserved for life-threatening ventricular arrhythmias; like other class I antiarrhythmics (see Cardiac Arrhythmias under Flecainide, p.1289), it has been associated with increased mortality when used prophylactically after myocardial infarction,[1] and is not recommended in such patients. However, there is limited evidence that it may be useful in some patients with supraventricular arrhythmias.[2,3]

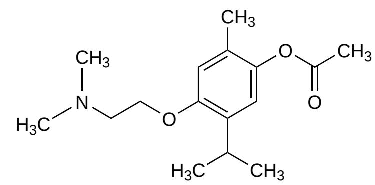
Proprietary Preparations (details are given in Part 3)
USA: Ethmozine†.

Moxisylyte Hydrochloride *(BANM, rINNM)*

Hidrocloruro de moxisilita; Moksisylyyttihydrokloridi; Moxisilita Clorhidrato; Moxisylyte, Chlorhydrate de; Moxisylythydroklorid; Moxisylyti Hydrochloridum; Moxisylytum Hydrochloridum; Thymoxamine Hydrochloride. 4-(2-Dimethylaminoethoxy)-5-isopropyl-2-methylphenyl acetate hydrochloride.

Моксизилита Гидрохлорид

$C_{16}H_{25}NO_3,HCl$ = 315.8.
CAS — 54-32-0 (moxisylyte); 964-52-3 (moxisylyte hydrochloride).
ATC — C04AX10; G04BE06.
ATC Vet — QC04AX10; QG04BE06.



(moxisylyte)

NOTE. MOX, formerly THY, is a code approved by the BP 2008 for use on single unit doses of eye drops containing moxisylyte hydrochloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Br.*

BP 2008 (Moxisylyte Hydrochloride). A white, odourless or almost odourless, crystalline powder. Freely soluble in water and in chloroform; soluble in alcohol; practically insoluble in ether and in petroleum spirit. A 5% solution in water has a pH of 4.5 to 5.5. Protect from light.

Adverse Effects

Moxisylyte hydrochloride may cause nausea, diarrhoea, headache, vertigo, flushing of the skin, dry mouth, and nasal congestion. Hepatotoxicity has been reported. Overdosage may cause hypotension.

Transient ptosis has occurred occasionally after ophthalmic application. Prolonged erections or priapism have occurred rarely after intracavernosal injection and systemic effects may also occur.

Effects on the liver. Hepatic adverse reactions with moxisylyte first appeared in France after its use in benign prostatic hyperplasia, a condition in which relatively high doses were used (up to 480 mg daily compared with up to 320 mg daily for peripheral vascular disease). Since then the UK CSM has received reports associated with lower doses.[1] Thirteen hepatic reactions, accounting for 17% of all reports of suspected adverse reactions to moxisylyte, had been received. These comprised 3 cases of hepatic function abnormalities, 3 of jaundice, 4 of cholestatic jaundice, 2 of hepatitis, and 1 of hepatitis with jaundice. In most cases the reaction occurred within 5 weeks of the start of treatment and resolved on drug withdrawal. In 9 cases the dosage of moxisylyte was known and varied from 80 to 320 mg daily with 7 patients receiving 160 mg or less daily.

1. Committee on Safety of Medicines/Medicines Control Agency. Hepatic reactions with thymoxamine (Opilon). *Current Problems* 1993; **19:** 11–12. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024456&RevisionSelectionMethod=LatestReleased (accessed 10/04/08)

Precautions

Moxisylyte hydrochloride should not be given to patients with active liver disease and should be given with care to patients with diabetes mellitus as it may theoretically decrease insulin requirements. Monitoring of liver function is recommended, especially if therapy is prolonged or if high doses are being used. Intracavernosal injection of moxisylyte is contra-indicated in patients with conditions that predispose to priapism.

Interactions

Moxisylyte may enhance the effects of antihypertensives and the hypotensive effect of moxisylyte may be enhanced by tricyclic antidepressants.

Uses and Administration

Moxisylyte is an alpha-adrenoceptor blocker with vasodilating activity. It is used by mouth in the treatment of peripheral vascular disease (p.1178) and has been self-administered by intracavernosal injection in erectile dysfunction (p.2179).

Moxisylyte is given as the hydrochloride but the dose may be expressed in terms of the base. Moxisylyte hydrochloride 45.2 mg is equivalent to about 40 mg of moxisylyte.

In the management of **peripheral vascular disease**, the usual oral dose is the equivalent of 40 mg of moxisylyte four times daily increased if necessary to 80 mg four times daily. It should be withdrawn if there is no response in 2 weeks.

Moxisylyte has been used locally in the eye to reverse the mydriasis caused by phenylephrine and other sympathomimetics. It has also been used orally in benign prostatic hyperplasia, although such use has been associated with hepatotoxicity; the doses used in prostatic hyperplasia were generally higher than those in peripheral vascular disease.

Moxonidine *(BAN, USAN, rINN)*

BDF-5895; BDF-5896; BE-5895; LY-326869; Moksonidi; Moksonidiini; Moksonidin; Moksonidinas; Moxonid; Moxonidin; Moxonidina; Moxonidinum; Moxonidum. 4-Chloro-5-(2-imidazolin-2-ylamino)-6-methoxy-2-methylpyrimidine.

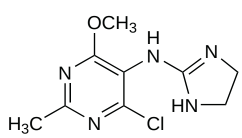
Моксонидин

$C_9H_{12}ClN_5O$ = 241.7.

CAS — 75438-57-2.

ATC — C02AC05.

ATC Vet — QC02AC05.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Moxonidine). A white or almost white powder. Very slightly soluble in water and in acetonitrile; slightly soluble in dichloromethane; sparingly soluble in methyl alcohol.

Adverse Effects and Treatment

Moxonidine has similar adverse effects to clonidine (p.1247) but causes less sedation. The incidence of dry mouth may also be lower.

Precautions

Moxonidine should not be used in patients with conduction disorders, bradycardia, severe arrhythmias, severe heart failure, severe ischaemic heart disease, severe hepatic or renal impairment, or a history of angioedema. Licensed product information suggests that it should also be avoided in patients with intermittent claudication or Raynaud's disease, Parkinson's disease, epilepsy, glaucoma, and depression. Moxonidine is distributed into breast milk and should not be used during breast feeding.

Although rebound hypertension has not been reported after moxonidine withdrawal it should not be stopped abruptly but should be withdrawn gradually over 2 weeks. As for clonidine (p.1247), if patients are also receiving a beta blocker, this should be stopped several days before moxonidine is withdrawn.

Interactions

The hypotensive effect of moxonidine may be enhanced by other antihypertensives and drugs that cause hypotension. The effect of sedatives and hypnotics, including benzodiazepines, may be enhanced by moxonidine.

Pharmacokinetics

Moxonidine is well absorbed when given orally and has a bioavailability of about 88%. Peak plasma concentrations occur 0.5 to 3 hours after an oral dose. It is excreted almost entirely in the urine as unchanged drug and metabolites; about 50 to 75% of an oral dose is excreted as unchanged drug. The mean plasma elimination half-life is 2 to 3 hours and is prolonged in renal impairment. Moxonidine is about 7% bound to plasma proteins. It is distributed into breast milk.

Uses and Administration

Moxonidine is a centrally acting antihypertensive structurally related to clonidine (p.1247). It appears to act through stimulation of central imidazoline receptors to reduce sympathetic tone, and also has alpha$_2$-adrenoceptor agonist activity. It is used in the treatment of hypertension (p.1171) and has also been investigated for heart failure (but see below).

In the treatment of hypertension, moxonidine is given orally in a usual initial dose of 200 micrograms once daily. The dose may be increased if necessary, after 3 weeks, to 400 micrograms daily as a single dose or in 2 divided doses, and after a further 3 weeks, to a maximum dose of 600 micrograms daily in 2 divided doses. The dose should be reduced in patients with renal impairment (see below).

Administration in renal impairment. UK licensed product information states that in patients with moderate renal impairment (GFR 30 to 60 mL/minute) single doses of moxonidine should not exceed 200 micrograms and the daily dose should not exceed 400 micrograms; moxonidine should not be given in severe impairment (GFR less than 30 mL/minute).

Heart failure. Heart failure is usually treated with diuretics, ACE inhibitors, and beta blockers (see p.1165). Beta blockers are thought to act by suppressing the sympathetic nervous system, which is activated in heart failure. Centrally-acting antihypertensives such as moxonidine also suppress sympathetic activation and might therefore have a role in heart failure. A study[1] in patients with heart failure found that moxonidine reduced plasma-noradrenaline concentrations and increased left ventricular ejection fraction, but also led to an increase in adverse effects. A further study[2] was stopped early due to increased mortality in the group receiving moxonidine.

Nadolol *(BAN, USAN, rINN)* ⊗

Nadololi; Nadololis; Nadololum; SQ-11725. (2*R*,3*S*)-5-(3-*tert*-Butylamino-2-hydroxypropoxy)-1,2,3,4-tetrahydronaphthalene-2,3-diol.

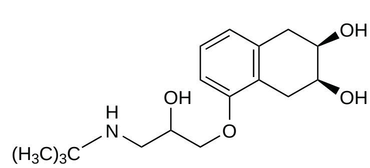
Надолол

$C_{17}H_{27}NO_4$ = 309.4.

CAS — 42200-33-9.

ATC — C07AA12.

ATC Vet — QC07AA12.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Nadolol). A white or almost white crystalline powder. Slightly soluble in water; freely soluble in alcohol; practically insoluble in acetone.

USP 31 (Nadolol). A white or off-white, practically odourless, crystalline powder. Soluble in water at pH 2; slightly soluble in water at pH 7 to 10; freely soluble in alcohol and in methyl alcohol; insoluble in acetone, in ether, in petroleum spirit, in trichloroethane, and in benzene; slightly soluble in chloroform, in dichloromethane, and in isopropyl alcohol.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Breast feeding. Nadolol is distributed into breast milk and concentrations in milk are higher than those in maternal plasma. In a study[1] in 12 normotensive women given nadolol 80 mg daily by mouth for 5 days, the mean nadolol concentration in milk for the 24 hours after the last dose was 357 nanograms/mL; the equivalent mean serum-nadolol concentration was only 77 nanograms/mL. It was calculated that a 5-kg infant would therefore ingest about 2 to 7% of an equivalent adult dose. No adverse effects have been seen in breast-fed infants whose mothers were given nadolol and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 10/01/08)

Hypersensitivity. Hypersensitivity pneumonitis was associated with nadolol in a patient given the drug for migraine.[1] Symptoms improved when nadolol was withdrawn.

1. Levy MB, *et al.* Nadolol and hypersensitivity pneumonitis. *Ann Intern Med* 1986; **105:** 806–7.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Nadolol is incompletely absorbed from the gastrointestinal tract to give peak plasma concentrations about 3 or 4 hours after a dose. It has low lipid solubility. Nadolol is widely distributed and concentrations found in breast milk have been higher than those in serum. It is only about 30% bound to plasma proteins. It does not appear to be metabolised and is excreted mainly in the urine. The plasma half-life has been reported as ranging from about 12 to 24 hours. Nadolol is reported to be dialysable.

◊ In 4 patients with mild hypertension given nadolol 2 mg orally or intravenously, the elimination half-life from plasma was an average of 10 to 12 hours (a range of 5.9 to 12.2 hours after intravenous doses, and a range of 9.6 to 14.2 hours after oral doses). Calculations based on urinary excretion and plasma concentration data suggested that about 33% was absorbed after oral dosage. There was evidence of biliary as well as urinary excretion since after intravenous dosage about 73% was excreted in urine and 23% in faeces. Nadolol did not appear to be metabolised.[1] In a similar study of therapeutic oral doses, terminal half-lives ranging from 14 to 17 hours were reported for nadolol 80 mg given as a single dose and the same dose daily in a multiple dosage regimen.[2]

1. Dreyfuss J, *et al*. Metabolic studies in patients with nadolol: oral and intravenous administration. *J Clin Pharmacol* 1977; **17:** 300–7.
2. Dreyfuss J, *et al.* Pharmacokinetics of nadolol, a beta-receptor antagonist: administration of therapeutic single- and multiple-dosage regimens to hypertensive patients. *J Clin Pharmacol* 1979; **19:** 712–20.

Children. The pharmacokinetics of nadolol given intravenously and orally were studied in six children aged 3 months to 14 years.[1] The elimination half-lives for the two oldest children aged 10 and 14 years were 7.3 and 15.7 hours, respectively. These values are similar to those reported for adults whereas in the children 22 months of age or younger, shorter half-lives of 3.2 to 4.3 hours were found. The shorter half-lives were probably a result of a reduction in the total apparent volume of distribution of nadolol in the youngest children. Elimination rates were similar after either intravenous or oral dosage.

1. Mehta AV, *et al.* Pharmacokinetics of nadolol in children with supraventricular tachycardia. *J Clin Pharmacol* 1992; **32:** 1023–7.

Uses and Administration

Nadolol is a non-cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic and membrane-stabilising activity. Nadolol is given orally in the management of hypertension (p.1171), angina pectoris (p.1157), and cardiac arrhythmias (p.1160). It is also used in the management of hyperthyroidism (p.2165) and in the prophylactic treatment of migraine (p.616).

In the treatment of **hypertension**, nadolol is usually given in an initial dose of 40 to 80 mg once daily, increased weekly according to response to 240 mg or more daily.

In **angina pectoris**, the usual initial dose is 40 mg once daily, increased weekly according to response to usual doses of up to 160 mg daily; some patients may require up to 240 mg daily. Doses of 40 to 160 mg once daily have also been given for **cardiac arrhythmias**.

Doses of 40 to 160 mg once daily are used in **migraine** prophylaxis.

As an adjunct in the treatment of **hyperthyroidism**, doses of 80 to 160 mg once daily have been given; most patients are reported to require the higher dose.

Patients with renal impairment may require a reduction in dose (see below).

Administration in renal impairment. Nadolol is excreted mainly in the urine and doses should be reduced in patients with renal impairment, usually by increasing the dosage interval. For patients with hypertension or angina pectoris, US licensed product information recommends the following dosage intervals, based on creatinine clearance (CC):

- CC between 31 and 50 mL/minute per 1.73 m^2: give every 24 to 36 hours
- CC between 10 and 30 mL/minute per 1.73 m^2: give every 24 to 48 hours
- CC less than 10 mL/minute per 1.73 m^2: give every 40 to 60 hours.

Nadroparin Calcium *(BAN, rINN)*

CY-216; Nadropariinikalsium; Nadroparin Kalsiyum; Nadroparin vápenatá sůl; Nadroparina cálcica; Nadroparine calcique; Nadroparinkalcium; Nadroparin-kalcium; Nadroparino kalcio druska; Nadroparinum calcicum.

Надропарин Кальций

ATC — B01AB06.
ATC Vet — QB01AB06.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Nadroparin Calcium). It is prepared by nitrous acid depolymerisation of heparin obtained from the intestinal mucosa of pigs. The majority of the components have a 2-*O*-sulfo-α-L-idopyranosuronic acid structure at the non-reducing end and a 6-*O*-sulfo-2,5-anhydro-D-mannitol structure at the reducing end of their chain. The mass-average molecular mass ranges between 3600 and 5000, with a characteristic value of 4300. The mass percentage of chains lower than 2000 is not more than 15%. The degree of sulfation is about 2 per disaccharide unit.

The potency is not less than 95 units and not more than 130 units of anti-factor Xa activity per mg with reference to the dried substance, and the ratio of anti-factor Xa activity to anti-factor IIa (antithrombin) activity is between 2.5 and 4.0.

Profile

Nadroparin calcium is a low-molecular-weight heparin (p.1329) with anticoagulant properties. It is used in the treatment and prophylaxis of venous thromboembolism (p.1189) and to prevent clotting during extracorporeal circulation. It is also used in the management of unstable angina (p.1157).

Doses are expressed in terms of anti-factor Xa activity (anti-Xa units) although different values may be encountered in the literature depending upon the reference preparation used. For *prophylaxis* of **venous thromboembolism** during surgery, patients at moderate risk of thrombosis are given 2850 units of nadroparin calcium by subcutaneous injection daily for at least 7 days or until the patient is ambulant; the first dose is given 2 to 4 hours before the procedure. For patients at high risk of thrombosis the dose is adjusted according to body-weight. Usual doses are 38 units/kg 12 hours before surgery, 12 hours postoperatively and then daily until 3 days after the procedure; the dose is then increased by 50% to 57 units/kg daily. The total duration of treatment should be at least 10 days.

For the *treatment* of thromboembolism, nadroparin calcium is given in a dose of 85 units/kg by subcutaneous injection every 12 hours for up to 10 days. Alternatively, a dose of 171 units/kg is given once daily.

For prevention of clotting in the extracorporeal circulation during **haemodialysis** sessions lasting less than 4 hours, nadroparin calcium is given into the arterial line of the circuit at the beginning of the dialysis session. The usual dose is 2850 units for patients weighing less than 50 kg, 3800 units for patients weighing 50 to 69 kg, and 5700 units for patients weighing 70 kg or more. Doses should be reduced in patients at high risk of haemorrhage.

In the management of unstable **angina**, nadroparin calcium is given subcutaneously in a dose of 86 units/kg every 12 hours, for about 6 days. An initial dose of 86 units/kg may be given intravenously. Low-dose aspirin should also be given.

Elimination of nadroparin is prolonged in renal impairment, and doses may need to be reduced in moderate or severe impairment.

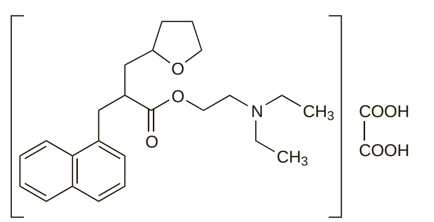
CAS — 31329-57-4 (naftidrofuryl); 3200-06-4 (naftidrofuryl oxalate).
ATC — C04AX21.
ATC Vet — QC04AX21.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Naftidrofuryl Hydrogen Oxalate; Naftidrofuryl Oxalate BP 2008). A white or almost white powder. Freely soluble in water; freely soluble or soluble in alcohol; slightly or sparingly soluble in acetone.

Adverse Effects

Naftidrofuryl oxalate given orally may cause nausea and epigastric pain. Rash has been reported occasionally. Hepatitis or hepatic failure has occurred rarely. Convulsions and depression of cardiac conduction may occur after overdosage. After intravenous use cardiac arrhythmias, hypotension, and convulsions have been reported and intravenous preparations have been withdrawn from the market (see below).

◊ In early 1995 the UK CSM published details of adverse reactions to naftidrofuryl.[1] After parenteral doses of naftidrofuryl 47 reports of 79 reactions had been received, the most serious consequences being 9 cases of cardiac arrhythmias, 3 of convulsions, and 2 of hypotension. It was also noted that 2 fatal cases of cardiac arrest had occurred in Germany after bolus intravenous doses and it was stressed that the drug must not be given as a bolus but as a slow intravenous infusion. Additionally, 16 reports, including one fatality, of hepatitis or hepatic failure associated with oral naftidrofuryl had been received although this appeared to be a rare reaction.

Later in 1995, after a review conducted in the UK and Europe, it was announced by the CSM that intravenous naftidrofuryl was to be withdrawn.[2] It was considered that the risks of cardiac and neurological toxicity outweighed the benefits of intravenous dosage in peripheral vascular disease. The oral form of naftidrofuryl would remain available.

Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2015619&RevisionSelectionMethod=LatestReleased (accessed 08/05/08)

Effects on the kidneys. Calcium oxalate crystals in the renal tubules of 2 patients with acute renal failure[1] were associated with the high amounts of oxalate they had received when naftidrofuryl oxalate was given intravenously.

1. Moesch C, *et al.* Renal intratubular crystallisation of calcium oxalate and naftidrofuryl oxalate. *Lancet* 1991; **338:** 1219–20.

Uses and Administration

Naftidrofuryl oxalate is used as a vasodilator in the treatment of peripheral (p.1178) and cerebral vascular disorders (p.1165). It is also claimed to enhance cellular oxidative capacity thereby protecting cells against the results of ischaemia.

Naftidrofuryl oxalate is given orally in usual doses of 100 to 200 mg three times daily for peripheral vascular disorders and 100 mg three times daily for cerebrovascular disorders.

Naftidrofuryl oxalate has also been given parenterally. However, intravenous use has been associated with serious adverse effects (see above) and intravenous preparations have been withdrawn.

Назаруплаза

CAS — 99821-44-0.

NOTE. The term prourokinase has been used for both nasaruplase and saruplase (p.1390).

Nasaruplase Beta *(USAN, rINN)*

Abbott-74187; ABT-187; Nasaruplasa beta; Nasaruplase Bêta; Nasaruplasum Beta. Prourokinase (enzyme-activating) human (clone pUK4/pUK18 protein moiety), glycosylated (murine cell line SP2/0).

Назаруплаза Бета

CAS — 136653-69-5.

Profile

Nasaruplase is a thrombolytic under investigation in acute ischaemic stroke.

Nateplase *(rINN)*

Nateplasa; Natéplase; Nateplasum. A mixture of *N*-[N^2-(*N*-glycyl-L-alanyl)-L-arginyl]plasminogen activator (human tissue-type 1-chain form, protein moiety), glycoform β (major component) and plasminogen activator (human tissue-type 1-chain form, protein moiety), glycoform β.

Натеплаза

CAS — 159445-63-3.

Profile

Nateplase is a thrombolytic related to alteplase (p.1207) that has been used in acute myocardial infarction (p.1175).

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Milyzer†.

Natriuretic Peptides ⊗

Péptidos natriuréticos.

Profile

Natriuretic peptides are endogenous substances that possess diuretic, natriuretic, and vasodilator properties. Three types are known. *Atrial natriuretic peptide* (ANP), also known as atrial natriuretic factor (ANF), atriopeptin, auriculin, or cardionatrin, is produced mainly in the cardiac atria, although another form, ularitide (urodilatin), is produced in the kidney. *Brain natriuretic peptide* (BNP, B-type natriuretic peptide) was originally isolated from brain tissue but is now known to be mainly produced by the cardiac ventricles. *C-type natriuretic peptide* (CNP) is produced by the endothelium and appears to act locally as a vasodilator but has little natriuretic effect.

Natriuretic peptides have an important physiological role in fluid and electrolyte homoeostasis and in the regulation of blood pressure, and they interact closely with other complex systems such as the renin-angiotensin-aldosterone cascade. Plasma concentrations of atrial natriuretic peptide and brain natriuretic peptide are altered in some pathological states and have been used as indicators of cardiac function. Natriuretic peptides that have been investigated for therapeutic use include anaritide, a synthetic form of atrial natriuretic peptide, and ularitide; both have been studied in acute renal failure, and ularitide has also been studied in heart failure. Recombinant forms of atrial natriuretic peptide (carperitide, p.1241) and brain natriuretic peptide (nesiritide, p.1347) are used in the management of acute heart failure.
