Ixabepilone is an analogue of the epothilone compound patupilone (p.761) that is used for the treatment of patients with metastatic or locally advanced breast cancer. It is given as monotherapy in those whose tumours are resistant or refractory to anthracyclines, taxanes, and capecitabine. Ixabepilone is also used with capecitabine in those whose tumours are resistant to anthracycline and taxanes, or in those with cancer resistant to taxanes, and for whom further anthracycline therapy is contra-indicated.

The recommended dose of ixabepilone is 40 mg/m^2 given by intravenous infusion over 3 hours every 3 weeks. Patients with a body-surface greater than 2.2 m^2 should be dosed as calculated for 2.2 m^2. Ixabepilone is diluted with lactated Ringer's solution to a final concentration of 200 to 600 micrograms/mL before infusion.

Doses are adjusted for toxicity. If moderate or severe neuropathy, or any severe toxicity (other than neuropathy) occurs, the dose should be decreased by 20%. If severe neuropathy lasts 7 days or more, or any disabling toxicity occurs, therapy should be stopped. If the neutrophil count falls below 500 cells/mm^3 for 7 days or more, if platelets fall below 25 000 cells/mm^3 (or below 50 000 cells/mm^3 with bleeding), or if febrile neutropenia occurs, the dose should be decreased by 20%. If toxicities recur, an additional 20% dose reduction should be made. Patients should not begin a new cycle of treatment unless the neutrophil count is at least 1500 cells/mm^3, the platelet count is at least 100 000 cells/mm^3, and non-haematological toxicities have improved to grade 1 (mild) or resolved.

Doses are also adjusted in hepatic impairment (see Administration in Hepatic Impairment, below).

Use of strong inhibitors of CYP3A4 should be avoided with ixabepilone. If no alternative is available, a dose reduction of ixabepilone to 20 mg/m^2 should be considered. Once the inhibitor is stopped, a washout period of about 1 week should be allowed before the dose of ixabepilone is increased back to the original dose.

◊ References.

3. Thomas ES, *et al.* Ixabepilone plus capecitabine for metastatic breast cancer progressing after anthracycline and taxane treatment. *J Clin Oncol* 2007; **25:** 5210–17.

Administration in hepatic impairment. Therapy with ixabepilone and capecitabine *combination therapy* is contra-indicated in patients with aspartate aminotransferase (AST) or alanine aminotransferase (ALT) greater than 2.5 times the upper limit of normal (ULN), or in those with bilirubin greater than the ULN. Patients with values equal to or below these figures may be given the standard dose of ixabepilone.

In *monotherapy*, the following doses of ixabepilone may be given:

- mild; AST and ALT equal to or less than 2.5 times the ULN, and bilirubin equal to or less than the ULN: 40 mg/m^2 *or* AST or ALT equal to or less than 10 times the ULN and bilirubin equal to or less than 1.5 times the ULN: 32 mg/m^2
- moderate; AST and ALT equal to or less than 10 times the ULN and bilirubin greater than 1.5 times the ULN, but equal to or less than 3 times the ULN: patients should be started at 20 mg/m^2, and the dosage in subsequent cycles escalated up to, but not exceeding, 30 mg/m^2 if tolerated
- severe; AST or ALT greater than 10 times the ULN or bilirubin greater than 3 times the ULN: not recommended

Data are limited for patients with a baseline AST or ALT greater than 5 times the ULN.

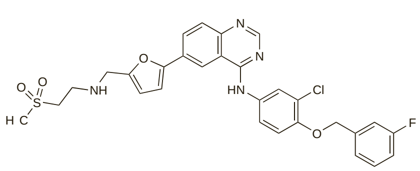
Lapatinib Tosilate *(rINNM)*

GW-572016F; Lapatinib Ditosylate *(USAN)*; Lapatinib, Tosilate de; Lapatinibi Tosilas; Tosilato de lapatinib. *N*-{3-Chloro-4-[(3-fluorobenzyl)oxy]phenyl}-6-[5-({[2-(methylsulfonyl)ethyl]amino}methyl)furan-2-yl]quinazolin-4-amine bis(4-methylbenzenesulfonate) monohydrate.

Лапатиниба Тозилат

$C_{29}H_{26}ClFN_4O_4S,2C_7H_8O_3S,H_2O$ = 943.5.

CAS — 231277-92-2 (lapatinib); 388082-78-8 (lapatinib tosilate).



(lapatinib)

Adverse Effects, Treatment, and Precautions

The most common adverse effects of lapatinib tosilate are gastrointestinal disturbances, dermatological reactions such as palmar-plantar erythrodysesthesia and rash, and fatigue. Diarrhoea may be severe and dose-limiting. Decreases in left ventricular ejection fraction (LVEF) have been reported with lapatinib, usually within the first 9 weeks of treatment. LVEF should be evaluated in all patients before therapy is started, and periodically evaluated during treatment. Prolongation of the QT interval has also been reported, and lapatinib should be given with caution to those patients with relevant risk factors such as hypokalaemia or hypomagnesaemia, congenital QT prolongation, use of antiarrhythmics, or cumulative high-dose anthracycline therapy. Other reported adverse effects include stomatitis, mucosal inflammation, pain in extremities, back pain, dyspnoea, and insomnia. Lapatinib should be given with caution in severe hepatic impairment; doses may need to be reduced.

Interactions

Lapatinib tosilate undergoes extensive metabolism by cytochrome P450 isoenzyme CYP3A4. Inhibitors of CYP3A4, such as ketoconazole, can increase exposure to lapatinib. Conversely, CYP3A4 inducers, such as carbamazepine, can reduce exposure to lapatinib. Use of lapatinib with strong inhibitors or inducers of CYP3A4 should be avoided; if they are to be given together, dose adjustments may be required (see Uses and Administration, below). Grapefruit juice may also increase plasma concentrations of lapatinib and should be avoided. *In vitro* studies indicate that lapatinib itself inhibits CYP3A4 and CYP2C8; it should be used cautiously with substrates of these isoenzymes that have a narrow therapeutic index.

Lapatinib is a substrate of P-glycoprotein and P-glycoprotein inhibitors can increase plasma concentrations of lapatinib. Lapatinib itself also inhibits human P-glycoprotein and may in turn increase plasma concentrations of drugs that are substrates of P-glycoprotein.

Pharmacokinetics

Absorption after an oral dose of lapatinib tosilate is variable and incomplete. Peak plasma concentrations occur after about 4 hours. Systemic exposure to lapatinib is increased when it is given with food. It is highly protein bound. Lapatinib undergoes extensive metabolism, mainly by cytochrome P450 isoenzymes CYP3A4 and CYP3A5; CYP2C19 and CYP2C8 account for some minor metabolism. The terminal half-life after a single dose has been reported to be about 14 hours; accumulation with repeated dosing indicates an effective half-life of 24 hours. About 27% and 14% of an oral dose is recovered in the faeces, as parent lapatinib and metabolites, respectively; renal excretion is negligible.

Uses and Administration

Lapatinib tosilate is a dual tyrosine kinase inhibitor directed against two members of the human epidermal growth factor receptor family, namely epidermal growth factor receptor (EGFR; ErbB1) and human epidermal receptor type 2 (HER2; ErbB2). Lapatinib is used with capecitabine (p.691) for the treatment of patients with advanced or metastatic breast cancer (p.661) whose tumours overexpress HER2, and who have had previous therapy including an anthracycline, a taxane, and trastuzumab.

Doses of lapatinib tosilate are expressed in terms of the base; lapatinib tosilate 405 mg is equivalent to about 250 mg of lapatinib.

The recommended dose of lapatinib is 1.25 g given orally once daily on days 1 to 21 of a 21-day cycle. Capecitabine is given at a dose of 2 g/m^2 daily (given orally in 2 doses about 12 hours apart) on days 1 to 14 of the cycle. Treatment may be continued until disease progression or unacceptable toxicity occurs. If a daily dose is missed, the next day's dose should not be doubled. Lapatinib is given at least one hour before or one hour after food.

Dosage should be reduced in patients with severe hepatic impairment (see Administration in Hepatic Impairment, below). Treatment with lapatinib should be stopped in patients who develop a decreased left ventricular ejection fraction (LVEF); however, patients may be restarted at a reduced dose of lapatinib 1 g daily after a minimum of 2 weeks if the LVEF recovers to normal and if the patient is asymptomatic. Lapatinib may need to be stopped or treatment interrupted if other severe toxicities develop. Patients can be restarted at the recommended dose when the toxicity improves. However, if toxicity recurs, lapatinib should be restarted at the lower dose of 1 g daily.

If use with potent inhibitors or inducers of cytochrome P450 isoenzyme CYP3A4 cannot be avoided, dose adjustments of lapatinib are considered necessary, based on pharmacokinetic studies. Lapatinib should be given at a dose of 500 mg daily when given with a potent CYP3A4 inhibitor; if the inhibitor is stopped, a washout period of about 1 week should be allowed before the lapatinib dose is increased to the usual recommended dose. When given with a potent inducer of this isoenzyme, the dose of lapatinib should be titrated gradually from 1.25 g daily up to 4.5 g daily, based on tolerability; if the inducer is stopped, the dose of lapatinib should be reduced to the usual recommended dose.

Lapatinib is also under investigation for the treatment of head and neck squamous cell carcinoma.

6. Dhillon S, Wagstaff AJ. Lapatinib. *Drugs* 2007; **67:** 2101–8.

Administration in hepatic impairment. Systemic exposure to lapatinib after a single 100-mg oral dose increased by about 14% and 63% in subjects with moderate (Child-Pugh Class B) and severe (Child-Pugh Class C) hepatic impairment, when compared with healthy control subjects. Caution is advised when lapatinib is given to patients with severe hepatic impairment. Oral doses should be reduced to 750 mg daily. However, licensed product information warns that there are no clinical data with this dose adjustment in patients with severe hepatic impairment.

Lenalidomide *(BAN, USAN, rINN)*

CC-5013; CDC-501; Lénalidomide; Lenalidomidum. 3-(4-Amino-1-oxo-1,3-dihydro-2*H*-isoindol-2-yl)piperidine-2,6-dione.

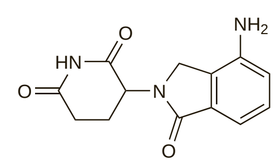
Леналидомид

$C_{13}H_{13}N_3O_3$ = 259.3.

CAS — 191732-72-6.

ATC — L04AX04.

ATC Vet — QL04AX04.



Adverse Effects, Treatment, and Precautions

Lenalidomide is associated with significant neutropenia and thrombocytopenia. Anaemia is also common. Patients may require dose reduction or therapy may need to be delayed or stopped. Full blood counts should be monitored weekly for the first 8 weeks of therapy, and monthly thereafter. There is also an increased risk of deep-vein thrombosis and pulmonary embolism with lenalidomide. Other adverse effects include gastrointestinal disturbances, pruritus, rash, and fatigue. Dyspnoea, muscle cramps, hypotension, tremor, hypoaesthesia, and infections such as pneumonia are common. Peripheral neuropathy has been reported, as have cases of hypothyroidism; thyroid function should be monitored. Cardiac disorders and hepatotoxicity have also been reported. Caution is advised in patients with renal impairment as lenalidomide is excreted via the kidneys.

The symbol † denotes a preparation no longer actively marketed

Because of potential teratogenicity lenalidomide use is restricted in women of child-bearing potential, see also under Thalidomide, p.2397.

Interactions

Lenalidomide may increase peak plasma concentrations of digoxin. Epoetins or other drugs that increase the risk of thrombosis should be used with caution in patients taking lenalidomide.

Pharmacokinetics

Lenalidomide is rapidly absorbed with maximum plasma concentrations occurring between about 0.6 and 1.5 hours after an oral dose. Giving lenalidomide with food may reduce plasma concentrations but not the extent of absorption. Binding to plasma proteins is about 30%. About two-thirds of a dose is eliminated unchanged through the kidneys. The elimination half-life is about 3 hours after a 5 mg-dose; half-life increases with dose. Clearance decreases proportionally with renal function.

Uses and Administration

Lenalidomide is an analogue of thalidomide (p.2397) that has immunomodulatory and antiangiogenic properties. It is given orally for the treatment of patients with transfusion-dependent anaemia due to myelodysplastic syndromes (p.654) associated with certain abnormalities of chromosome 5 (deletion 5q abnormalities). The recommended initial dose is 10 mg daily. Lenalidomide is also used orally with dexamethasone for the treatment of patients with multiple myeloma (p.658) who have received at least one prior therapy. The recommended starting dose of lenalidomide is 25 mg daily, given for 21 days of a 28-day cycle. The recommended oral dose of dexamethasone is 40 mg daily on days 1 to 4, days 9 to 12, and days 17 to 20 of each 28-day cycle, for the first 4 cycles, and then 40 mg daily on days 1 to 4 of each 28-day cycle thereafter.

Lenalidomide is associated with significant neutropenia and thrombocytopenia, and dosage is adjusted according to haematological toxicity.

9. Weber DM, *et al.* Multiple Myeloma (009) Study Investigators. Lenalidomide plus dexamethasone for relapsed multiple myeloma in North America. *N Engl J Med* 2007; **357:** 2133–42.
10. Chanan-Khan AA, Cheson BD. Lenalidomide for the treatment of B-cell malignancies. *J Clin Oncol* 2008; **26:** 1544–52.

Administration in renal impairment. Lenalidomide is eliminated mainly via the kidneys as unchanged drug. Clearance decreases as renal function decreases, prolonging the elimination half-life and increasing exposure to the drug. A study recommended that dose adjustments be made for patients with creatinine clearance (CC) less than 50 mL/minute; a 40% reduction to 60% of the starting dose was recommended for these patients. For those with CC less than 30 mL/minute, the reduced dose should be given at extended dosing intervals. About 30% of circulating lenalidomide was removed by a 4-hour session of haemodialysis.[1]

UK licensed product information makes the following recommendations at the start of oral therapy for patients with multiple myeloma and renal impairment:

- mild renal impairment (CC greater than or equal to 50 mL/minute): 25 mg once daily (full dose)
- moderate renal impairment (CC from 30 mL/minute to less than 50 mL/minute): 10 mg once daily. This dose may be increased to 15 mg once daily after 2 cycles if the patient is not responding to treatment, but is tolerating lenalidomide
- severe renal impairment (CC less than 30 mL/minute, not requiring dialysis): 15 mg every other day
- end-stage renal disease (CC less than 30 mL/minute, requiring dialysis): 15 mg, three times weekly, after dialysis

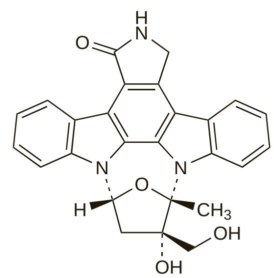
Lestaurtinib *(USAN, rINN)*

A-154475.0; CEP-701; KT-5555; Lestaurtinibum; SP-924. (9*S*,10*S*,12*R*)-10-Hydroxy-10-(hydroxymethyl)-9-methyl-2,3,9,-10,11,12-hexahydro-1*H*-9,12-epoxydiindolo[1,2,3-*fg*:3′,2′,1′-*kl*]-pyrrolo[3,4-*i*][1,6]benzodiazocin-1-one.

Лестауртиниб

$C_{26}H_{21}N_3O_4$ = 439.5.
CAS — 111358-88-4.



Profile

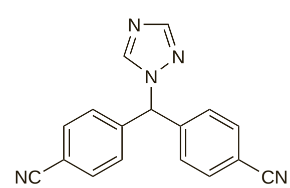
Lestaurtinib is a tyrosine kinase inhibitor that is under investigation for the treatment of acute myeloid leukaemia.

Letrozole *(BAN, USAN, rINN)* ⊗

CGS-20267; Letrotsoli; Letrozol; Létrozole; Letrozolum. 4,4′-(1*H*-1,2,4-Triazol-1-ylmethylene)dibenzonitrile.

Летрозол

$C_{17}H_{11}N_5$ = 285.3.
CAS — 112809-51-5.
ATC — L02BG04.
ATC Vet — QL02BG04.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Letrozole). A white or yellowish, crystalline powder. Practically insoluble in water; sparingly soluble in methyl alcohol; freely soluble in dichloromethane.

USP 31 (Letrozole). A white to yellowish, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; freely soluble in dichloromethane. Store in airtight containers.

Adverse Effects and Precautions

As for Anastrozole, p.681.

Effects on the musculoskeletal system. Postmenopausal women with primary breast cancer were reported to have significant decreases in bone mineral density at the hip and lumbar spine after 24 months of letrozole therapy.[1]

1. Perez EA, *et al.* Effect of letrozole versus placebo on bone mineral density in women with primary breast cancer completing 5 or more years of adjuvant tamoxifen: a companion study to NCIC CTG MA.17. *J Clin Oncol* 2006; **24:** 3629–35.

Effects on the skin. Toxic epidermal necrolysis, attributed to letrozole, has been reported in a patient with breast cancer who was also receiving dexamethasone and omeprazole.[1] She had been switched from tamoxifen to letrozole a few weeks before the reaction occurred.

1. Chia WK, *et al.* Toxic epidermal necrolysis in patient with breast cancer receiving letrozole. *Lancet Oncol* 2006; **7:** 184–5.

Interactions

Tamoxifen. In a study[1] of postmenopausal women with breast cancer, the addition of tamoxifen reduced letrozole plasma concentrations by a mean of about 38%, but the effect of letrozole on hormone concentrations was unchanged. The mechanism and possible clinical effect of this interaction are unknown.

1. Dowsett M, *et al.* Impact of tamoxifen on the pharmacokinetics and endocrine effects of the aromatase inhibitor letrozole in postmenopausal women with breast cancer. *Clin Cancer Res* 1999; **5:** 2338–43.

Pharmacokinetics

Letrozole is rapidly and completely absorbed from the gastrointestinal tract. About 60% of letrozole in the circulation is bound to plasma protein, mainly albumin. Most of an oral dose is slowly metabolised to an inactive carbinol metabolite, which is then excreted as the glucuronide in the urine. Letrozole has a terminal elimination half-life of about 2 days.

Uses and Administration

Letrozole is a selective nonsteroidal inhibitor of the aromatase (oestrogen synthetase) system, similar to anastrozole (p.681). It is used in the treatment of advanced or locally advanced breast cancer (p.661) in postmenopausal women. It may be given as neoadjuvant (pre-operative) therapy to those with localised hormone-receptor positive disease, to allow subsequent breast-conserving surgery. Letrozole is also used for the adjuvant treatment of postmenopausal women with hormone receptor-positive early breast cancer; treatment is generally given for 5 years or until tumour relapse occurs, although optimal duration of therapy is unknown. In postmenopausal women given 5 years of adjuvant tamoxifen for early breast cancer, letrozole may be used as extended adjuvant therapy; treatment should continue for 4 years or until tumour relapse occurs, although optimal duration of therapy is unknown. The usual dose is 2.5 mg daily by mouth.

Administration in hepatic impairment. Licensed product information in the UK and USA states that no dosage adjustment of letrozole is required for patients with mild to moderate hepatic impairment (Child-Pugh category A and B). While letrozole is contra-indicated in the UK in severe hepatic impairment (Child-Pugh category C), in the USA, it is recommended that the dose of letrozole be reduced by 50% in those patients with cirrhosis and severe hepatic impairment; the recommended dose for these patients is 2.5 mg given every other day.

Infertility. Letrozole has been investigated[1-4] as an adjunct to assisted reproduction technologies in the management of infertility (p.2080). However, concerns about this unlicensed use have been raised by the Canadian manufacturer (*Novartis, Canad.*) because of the potential for maternal and fetal toxicity, and fetal malformations:[5] licensed product information contra-indicates the use of letrozole in premenopausal women, and there have been reports of congenital anomalies in the infants of women treated with letrozole for infertility.

Lomustine *(BAN, USAN, rINN)*

CCNU; Lomustiini; Lomustin; Lomustina; Lomustinas; Lomustinum; Lomustyna; Lomusztin; NSC-79037; RB-1509; WR-139017. 1-(2-Chloroethyl)-3-cyclohexyl-1-nitrosourea.

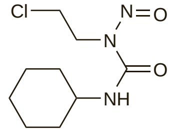
Ломустин

$C_9H_{16}ClN_3O_2$ = 233.7.

CAS — 13010-47-4.

ATC — L01AD02.

ATC Vet — QL01AD02.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Lomustine). A yellow, crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in acetone and in dichloromethane. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Carmustine, p.694. Neurological reactions such as confusion and lethargy have been reported.

Handling and disposal. A method for the destruction of lomustine *waste* by reaction with hydrobromic acid in glacial acetic acid has been described.[1] The residue produced by the degradation of lomustine by this method showed no mutagenicity. This method is not suitable for the degradation of carmustine or semustine.

1. Castegnaro M, *et al.*, eds. Laboratory decontamination and destruction of carcinogens in laboratory wastes: some antineoplastic agents. *IARC Scientific Publications 73*. Lyon: WHO/International Agency for Research on Cancer, 1985.

Overdosage. A patient who inadvertently received 200 mg of lomustine for 7 days instead of a single 200-mg dose developed pancytopenia and subsequent multiorgan dysfunction including liver dysfunction, abdominal pain, pulmonary toxicity with tachypnoea and hypoxaemia, and CNS toxicity leading to confusion and disorientation.[1] Although the white cell count recovered other signs of toxicity did not and the patient developed fever and hypotension and died 59 days after the initial dose of lomustine. In another case of accidental overdose, a 30-year old female received a cumulative dose of 28 mg/kg over 7 days.[2] Severe myelosuppression developed soon after the overdose and lasted for 50 days. The patient was treated with granulocyte colony-stimulating factor and antibacterial cover, norethisterone (to prevent menstruation), and acetylcysteine (to protect against organ toxicity). Gastrointestinal necrosis occurred, and liver enzymes remained elevated even after recovery from the overdose, but the patient survived and her tumour regressed without further chemotherapy.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Cimetidine. For a report of a possible interaction between lomustine and cimetidine, see under Carmustine, p.695.

Theophylline. Leucopenia and thrombocytopenia in a 45-year-old woman were believed to have been secondary to an interaction between theophylline and lomustine.[1]

1. Zeltzer PM, Feig SA. Theophylline-induced lomustine toxicity. *Lancet* 1979; **ii:** 960–1.

Pharmacokinetics

Lomustine is absorbed from the gastrointestinal tract and is rapidly metabolised, with peak plasma concentrations of metabolites occurring within 4 hours of an oral dose. Metabolites have a prolonged plasma half-life reported to range from 16 to 48 hours. Active metabolites readily cross the blood-brain barrier and appear in the CSF in concentrations higher than those in plasma. About half a dose is excreted as metabolites in the urine within 24 hours and about 75% is excreted within 4 days.

Uses and Administration

Lomustine is a nitrosourea with actions and uses similar to those of carmustine (p.695). It has been used in the treatment of brain tumours (p.660) and resistant or relapsed Hodgkin's disease and other lymphomas (p.655), and also lung cancer (p.668), malignant melanoma (p.673), and various solid tumours.

When given as a single agent, lomustine is licensed for oral use in adults and children as a single dose of 120 to 130 mg/m²; division of the dose over 3 consecutive days may reduce gastrointestinal effects. A dose of 100 mg/m² should be given to patients with compromised bone-marrow function. Doses are also generally reduced when lomustine is given as part of a combination regimen. Providing blood counts have returned to acceptable levels, doses may be repeated every 6 to 8 weeks, and should be adjusted according to the haematological response (see also Bone-marrow Depression, p.639).

Preparations

BP 2008: Lomustine Capsules.

Proprietary Preparations (details are given in Part 3)

Lonidamine *(BAN, rINN)*

AF-1890; Diclondazolic Acid; Lonidamina; Lonidaminum; TH-070. 1-(2,4-Dichlorobenzyl)indazole-3-carboxylic acid.

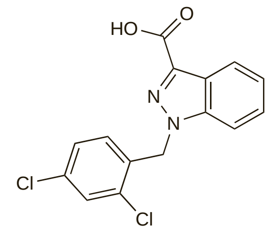
Лонидамин

$C_{15}H_{10}Cl_2N_2O_2$ = 321.2.

CAS — 50264-69-2.

ATC — L01XX07.

ATC Vet — QL01XX07.



Profile

Lonidamine is an antineoplastic that is thought to act by inhibiting mitochondrial function in tumour cells. It has been given orally in the treatment of various solid neoplasms, including those of the lung, breast, prostate, and brain.

Preparations

Proprietary Preparations (details are given in Part 3)

Ital.: Doridamina†.

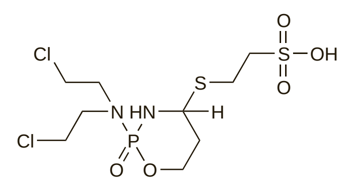
Mafosfamide *(rINN)*

Mafosfamid; Mafosfamida; Mafosfamidi; Mafosfamidum. (±)-2-({2-[Bis(2-chloroethyl)amino]tetrahydro-2*H*-1,3,2-oxazaphosphorin-4-yl}thio)ethanesulphonic acid *P-cis* oxide.

Мафосфамид

$C_9H_{19}Cl_2N_2O_5PS_2$ = 401.3.

CAS — 88859-04-5.



Profile

Mafosfamide is a derivative of cyclophosphamide (p.702) that has been used to treat bone marrow for transplantation. It is also under investigation in the treatment of neoplastic meningitis.

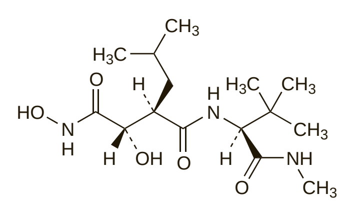
Marimastat *(BAN, USAN, rINN)*

BB-2516; Marimastatum. (2*S*,3*R*)-3-{(*S*)-[2,2-Dimethyl-1-(methylcarbamoyl)propyl]carbamoyl}-2-hydroxy-5-methylhexanohydroxamic acid.

Маримастат

$C_{15}H_{29}N_3O_5$ = 331.4.

CAS — 154039-60-8.



Profile

Marimastat is an oral inhibitor of matrix metalloproteinases, enzymes which are thought to play a role in the metastasis of cancer cells. It has been investigated in various malignant disorders.

Masoprocol *(USAN, rINN)*

CHX-10; CHX-100; Masoprocolum; Mesonordihydroguaiaretic Acid; *meso*-NDGA. *meso*-4,4′-(2,3-Dimethyltetramethylene)-dipyrocatechol.

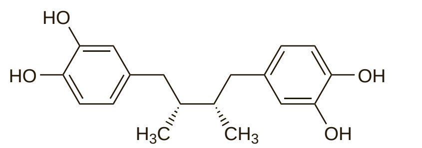
Мазопрокол

$C_{18}H_{22}O_4$ = 302.4.

CAS — 27686-84-6.

ATC — L01XX10.

ATC Vet — QL01XX10.



Profile

Masoprocol is a 5-lipoxygenase inhibitor isolated from the chaparral or creosote bush, *Larrea tridentata* (p.2280). It is reported to have antineoplastic activity. It has been used in the topical treatment of actinic (solar) keratoses. Local irritation and contact dermatitis have occurred.

Melanoma Vaccines

ATC — L03AX12.

Profile

A number of therapeutic vaccines designed to stimulate an antibody response are being developed for the treatment of melanoma (p.673).

One available preparation contains melanoma lysate (*Melacine*; *Schering, Canada*). It is used intramuscularly in a regimen with cyclophosphamide for the treatment of metastatic disease. Patients who show a clinical response may continue the melanoma vaccine as maintenance therapy. Adverse effects include injection site reactions such as granuloma formation, gastrointestinal disturbances, flu-like syndrome, and hypersensitivity reactions.

Other potential melanoma vaccines may be based on whole cells, GM2 ganglioside, heat shock proteins, or autologous tumour cells conjugated to an immunogenic hapten.

Melphalan *(BAN, USAN, rINN)*

CB-3025; Melfalaani; Melfalán; Melfalan; Melphalanum; NSC-8806 (melphalan hydrochloride); PAM; Phenylalanine Mustard; Phenylalanine Nitrogen Mustard; L-Sarcolysine; WR-19813. 4-Bis(2-chloroethyl)amino-L-phenylalanine.

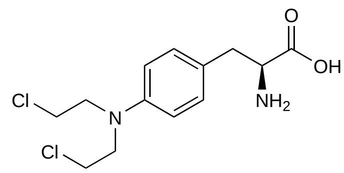
Мелфалан

$C_{13}H_{18}Cl_2N_2O_2$ = 305.2.

CAS — 148-82-3 (melphalan); 3223-07-2 (melphalan hydrochloride).

ATC — L01AA03.

ATC Vet — QL01AA03.



NOTE. Merphalan (CB-3007; NSC-14210; sarcolysine) is the racemic form of melphalan; Medphalan (CB-3026; NSC-35051) is the D-isomer of melphalan.

Pharmacopoeias. In *Br., Jpn,* and *US.*

BP 2008 (Melphalan). A white or almost white powder. Practically insoluble in water, in chloroform, and in ether; slightly soluble in methyl alcohol; dissolves in dilute mineral acids. Protect from light.

USP 31 (Melphalan). An off-white to buff powder with a faint odour. Practically insoluble in water, in chloroform, and in ether; slightly soluble in alcohol and in methyl alcohol; soluble in dilute mineral acids. Store in airtight, glass containers. Protect from light.

Stability. A study of the stability of melphalan 40 and 400 micrograms/mL in infusion fluids reported that the time for a 10% loss of drug at 20° in sodium chloride 0.9% injection was 4.5 hours, compared with 2.9 hours in lactated Ringer's injection, which has a considerably lower chloride ion content, and only 1.5 hours in glucose 5% injection.[1] At 25° the corresponding figures were 2.4, 1.5, and 0.6 hours, and at 37° they were 0.6, 0.4, and 0.3 hours. It was concluded that melphalan is sufficiently stable at 20° in sodium chloride injection to permit infusion, but that increased temperature and decreased chloride ion concentration were associated with faster degradation rates.[1] Another study recommended that solutions of melphalan be handled at temperatures above 5° for the minimum time but found that a solution containing 20 micrograms/mL in sodium chloride 0.9% could be stored for at least 6 months at –20° without significant deterioration.[2] A more recent study, while recommending storage at 4° between preparation and use of the infusion, considered that giving it at a room temperature of 20° or below, and use of hypertonic (3%) saline as a diluent, would be sufficient to allow prolonged infusion.[3] The practicalities of such a procedure were not addressed.

Adverse Effects and Treatment

For general discussions see Antineoplastics, p.635 and p.639.

The onset of neutropenia and thrombocytopenia is variable; the nadir of bone-marrow depression usually occurs at 2 to 3 weeks after starting treatment with melphalan, with recovery after 4 to 5 weeks.

Skin rashes and hypersensitivity reactions, including anaphylaxis, may occur. Cardiac arrest has been reported in association with such effects. Gastrointestinal disturbances may sometimes occur, particularly at high doses where diarrhoea, vomiting, and stomatitis may become dose-limiting. Haemolytic anaemia, vasculitis, pulmonary fibrosis, and hepatic disorders including hepatitis and jaundice have been reported. Suppression of ovarian function is common in premenopausal women; temporary or permanent sterility may occur in male patients. Extravasation of melphalan injection can cause skin ulceration and necrosis. As with other alkylating agents, melphalan also has carcinogenic, mutagenic, and teratogenic potential.

Mucositis. Amifostine has been shown to reduce the frequency and severity of melphalan-induced oral mucositis.[1]

1. Spencer A, *et al.* Prospective randomised trial of amifostine cytoprotection in myeloma patients undergoing high-dose melphalan conditioned autologous stem cell transplantation. *Bone Marrow Transplant* 2005; **35:** 971–7.

Overdosage. A 12-month old child given melphalan 140 mg intravenously (a tenfold overdose) developed pronounced lymphopenia within 24 hours but had no other significant adverse effects until the seventh day, when neutropenia, thrombocytopenia, oral ulceration, and diarrhoea developed.[1] Bone marrow recovered within 40 days. Treatment was by vigorous hyperalimentation and close surveillance during this period and the patient subsequently remained well 9 months afterwards, without complications. Cases of intravenous melphalan overdose have also been reported in adults,[2] resulting in bone-marrow depression, haemorrhagic diarrhoea, and electrolyte disturbances. Bone-marrow depression has also been reported after cumulative oral doses of 360 mg over 3 weeks,[3] and 560 mg over 2 weeks.[4] Filgrastim was used in one of these cases to stimulate bone-marrow recovery.[4]

1. Coates TD. Survival from melphalan overdose. *Lancet* 1984; **ii:** 1048.
2. Jost LM. Überdosierung von Melphalan (Alkeran): Symptome und Behandlung: eine Übersicht. *Onkologie* 1990; **13:** 96–101.
3. Grimes DJ, *et al.* Complete remission of paraproteinaemia and neuropathy following iatrogenic oral melphalan overdose. *Br J Haematol* 1993; **83:** 675–7.
4. Jirillo A, *et al.* Accidental overdose of melphalan per os in a 69-year-old woman treated for advanced endometrial carcinoma. *Tumori* 1998; **84:** 611.

Precautions

For general discussions see Antineoplastics, p.641.

Care is required in patients with impaired renal function.

Handling and disposal. *Urine and faeces* produced for up to 48 hours and 7 days respectively after a dose of melphalan by mouth should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Interactions

Use of nalidixic acid with high-dose intravenous melphalan in children has resulted in fatal haemorrhagic enterocolitis.

Ciclosporin. For reference to enhanced toxicity when melphalan was given with ciclosporin, see under Ciclosporin, p.1826.

Food. The bioavailability of oral melphalan is significantly reduced, by up to 45%, by food. Some recommend that melphalan should not be taken with food, and that if dosage is switched from after to before food patients should be monitored for increased toxicity.[1]

1. Nathan C, Betmouni R. Melphalan: avoid with food. *Pharm J* 1996; **257:** 264.

Interferons. The fever induced by interferon alfa resulted in a reduction in the area under the plasma concentration-time curve for melphalan in a study of 10 patients, although the peak plasma concentration and time to peak concentration were not affected.[1] The effect was thought to represent increased chemical reactivity of melphalan at the elevated temperature.

1. Ehrsson H, *et al.* Oral melphalan pharmacokinetics: influence of interferon-induced fever. *Clin Pharmacol Ther* 1990; **47:** 86–90.

Pharmacokinetics

Absorption of melphalan from the gastrointestinal tract is variable; the mean bioavailability is reported to be 56% but it may range from 25 to 89%. Absorption is reduced by the presence of food (see above). On absorption it is rapidly distributed throughout body water with a volume of distribution of about 0.5 litres/kg, and has been reported to be inactivated mainly by spontaneous hydrolysis. About 60 to 90% is bound to plasma proteins, mainly albumin. The terminal plasma half-life of melphalan has been reported to be of the order of 30 to 150 minutes. Melphalan is excreted in the urine, about 10% as unchanged drug.

Uses and Administration

Melphalan is an antineoplastic that acts as a bifunctional alkylating agent. It is used mainly in the treatment of multiple myeloma. Melphalan has also been given to patients with carcinoma of the breast and ovary, neuroblastoma, Hodgkin's disease, and in polycythaemia vera, and has been given by intra-arterial regional perfusion for malignant melanoma and soft-tissue sarcomas. See also the cross-references given below. Melphalan is also used in the treatment of amyloidosis, see below.

Melphalan is usually given orally as a single daily dose or in divided doses; it is also given intravenously as the hydrochloride. Doses are calculated in terms of the base; 1.12 mg of melphalan hydrochloride is equivalent to about 1 mg of melphalan. Frequent blood counts are essential and dosage should be adjusted according to haematological response. Therapy should be interrupted if the platelet or white cell count fall below acceptable levels (see also Bone-marrow Depression, p.639). It should be given with great caution if the neutrophil count has recently been depressed by chemotherapy or radiotherapy.

Numerous conventional-dose regimens have been tried for the treatment of multiple myeloma and there is still uncertainty as to the best schedule. Licensed **oral** dosage regimens include:

- 150 micrograms/kg daily in divided doses for 4 to 7 days
- 250 micrograms/kg daily for 4 days
- 6 mg daily for 2 to 3 weeks

Melphalan is usually combined with corticosteroids. Courses are followed by a rest period of up to 6 weeks to allow recovery of haematological function and are then repeated, or maintenance therapy may be instituted, usually with a daily dose of 1 to 3 mg, or up to 50 micrograms/kg. For optimum effect, therapy is usually adjusted to produce a moderate leucopenia, with white cell counts in the range 3000 to 3500 cells/mm^3.

In the treatment of breast cancer, licensed doses are 150 micrograms/kg daily or 6 mg/m^2 daily for 5 days, repeated every 6 weeks. Doses of 200 micrograms/kg daily for 5 days every 4 to 8 weeks have been given to patients with ovarian carcinoma.

In patients with polycythaemia vera, doses of 6 to 10 mg daily for 5 to 7 days, and then 2 to 4 mg daily, have been used for remission induction; a dose of 2 to 6 mg weekly has been used for maintenance.

Melphalan is also given **intravenously**; a single dose of 1 mg/kg, repeated in 4 weeks if the platelet and neutrophil counts permit, has been licensed in ovarian adenocarcinoma. It may be infused in sodium chloride 0.9% or injected into the tubing of a fast-running drip; when given by infusion the time from reconstitution of the solution to completion of infusion should not exceed 1.5 hours and prolonged infusions should be carried out with several batches of solution, each freshly prepared. In multiple myeloma, the licensed dose for use as a single agent is an intravenous dose of 400 micrograms/kg or 16 mg/m^2, infused over 15 to 20 minutes; the first 4 doses may be given at 2-week intervals, but further doses should be given at 4-week intervals depending on toxicity.

High-dose melphalan has been given intravenously in some malignancies: doses of 100 to 240 mg/m^2 have been licensed in neuroblastoma, and 100 to 200 mg/m^2 in multiple myeloma, generally followed by autologous stem cell rescue, which becomes essential where doses exceed 140 mg/m^2. High doses should be given through a central venous catheter.

Melphalan may be given by **local arterial perfusion** in the management of melanoma and soft-tissue sarcomas. A typical dosage range for upper extremity perfusions is 0.6 to 1 mg/kg, whereas for lower extremity perfusions doses of 0.8 to 1.5 mg/kg (in melanoma) or 1 to 1.4 mg/kg (in sarcoma) are typically used.

The dose of melphalan should be reduced in patients with **renal impairment** (see below).

Administration in renal impairment. The initial dose of intravenous melphalan should be reduced by about 50% in patients with renal impairment and dosage reduction should be considered when giving it by mouth. High-dose regimens are not recommended in patients with moderate to severe renal impairment.

Amyloidosis. Amyloidosis refers to a group of conditions characterised by accumulation of a waxy proteinaceous infiltrate within body tissues. Various forms are known,[1-3] including:

- primary or AL amyloidosis, in which the amyloid is derived from immunoglobulin light chains
- ATTR amyloidosis (a familial form), in which amyloid is derived from transthyretin
- AA amyloidosis, which is most often secondary to chronic inflammation, such as that associated with rheumatoid arthritis, tuberculosis, or familial Mediterranean fever (p.557)

Symptoms vary, depending on where the amyloid is deposited. The organs most commonly affected are the heart and kidneys. Renal amyloidosis can present as proteinuria, leading to nephrotic syndrome and renal failure. While renal disease is common in the AA and AL forms, it is less prevalent in ATTR amyloidosis, which commonly presents with neuropathy. Cardiac involvement, rare in AA amyloidosis, is variable in the ATTR form, and common in the AL form; it manifests as restrictive cardiomyopathy, leading to congestive heart failure. Painful peripheral sensory neuropathy and carpal tunnel syndrome also occur frequently. Amyloid deposition in the gastrointestinal tract can lead to malabsorption. Hepatomegaly is common. Macroglossia, due to deposition of amyloid in the tongue, occurs only in the AL form.[1,2]

Management depends to some extent upon the type of amyloidosis involved, and the site, but no drug or combination of drugs is unequivocally effective. Treatment for AA amyloidosis secondary to chronic inflammation is aimed at the underlying disease; immunosuppressants such as chlorambucil, cyclophosphamide, and methotrexate have been used, as well as inhibitors of tumour necrosis factor and interleukin-1 receptor antagonists.[4] Colchicine is effective in the treatment of AA amyloidosis complicating familial Mediterranean fever, but is not considered to be of benefit in other forms of amyloidosis.[1,5] Melphalan plus prednisone or prednisolone has been shown to increase median survival in primary amyloidosis patients.[6] It is considered the treatment of choice in AL amyloidosis for patients in whom more intensive chemotherapy is not appropriate; evidence of benefit from the addition of a corticosteroid has not been evaluated and in some patients, it may be reasonable not to include a corticosteroid.[5] Melphalan, prednisone, and colchicine was found to be more effective than colchicine alone in the treatment of AL amyloidosis,[7] but a later trial[8] found no benefit in adding colchicine to the standard therapy. Addition of multiple alkylating agents such as vincristine, carmustine, and cyclophosphamide to the standard therapy[9] did not improve survival or response. Evidence to support the use of alkylating-based combination chemotherapy for primary amyloidosis is lacking.[5] Alternatively, cycles of vincristine, doxorubicin, and dexamethasone (VAD) may be effective, but patients with cardiac amyloidosis may be at increased risk of anthracycline toxicity.[10] In the UK, VAD is considered as first-line therapy in patients under the age of 70 years who do not have cardiac failure, autonomic neuropathy, or peripheral neuropathy.[5] High-dose intravenous melphalan with autologous haematopoietic stem cell transplantation (HSCT) has been used;[11] it may result in complete remission of primary amyloidosis,[12-14] and some[1] consider it the treatment of choice. While this may improve renal disease,[12] the therapy remains very toxic, and patient selection on the basis of limited organ disease and no significant cardiac involvement, may reduce morbidity and mortality.[5,13] The outcome of treatment with high-dose intravenous melphalan with autologous HSCT was not superior to standard-dose oral melphalan plus oral dexamethasone in patients with newly diagnosed AL amyloidosis.[15] High-dose dexamethasone or thalidomide may be considered in patients in whom other regimens may not be feasible due to expected toxicity or in those refractory to chemotherapy;[5] good results have been reported in patients with AL amyloidosis given a regimen combining cyclophosphamide with dexamethasone and thalidomide.[16] Local application or oral dosage of dimethyl sulfoxide, and 4′-iodo-4′-deoxydoxorubicin has been investigated.[1,10]

Symptomatic management is also important. Care must be taken to avoid digitalis toxicity when cardiac amyloid is present, as well as to avoid salt and water depletion through injudicious use of diuretics. Calcium-channel blockers and beta blockers should be avoided.[1] Renal transplantation may be considered in end-stage renal failure due to amyloidosis, but unless amyloid production has been stopped disease is likely to recur in the new kidney. Cardiac transplantation, and subsequent chemotherapy with epirubicin, carmustine, and cyclophosphamide to suppress the underlying disease and control amyloid deposition in the graft has also been described.[17] Liver transplantation is the definitive therapy for patients with ATTR amyloidosis.[1,18] Because amyloid deposits contain a plasma glycoprotein serum amyloid P component (SAP) that contributes to the stability of the deposits, and thus contributes to the pathogenesis of amyloidosis, future therapeutic approaches include the targeting of SAP to deplete it from the tissues and clear it from the plasma. Ro-63-8695 (CPHPC) is being investigated.[3,19] Eprodisate disodium is under investigation for AA amyloidosis.[20]

Bone disorders, non-malignant. Fibrogenesis imperfecta ossium is a rare progressive bone disease in which disorders of bone collagen and mineralisation, and subsequent abnormal bone structure, result in bone pain and fractures. A patient responded to treatment with melphalan 10 mg and prednisolone 20 or 30 mg daily, in 7-day courses every 2 months.[1,2] Another showed some improvement with intermittent 5-day courses of melphalan 10 mg daily and prednisolone 40 mg daily.[3] However, melphalan alone was reported to be ineffective in 2 other patients; both experienced bone-marrow depression.[3,4]

Mepolizumab *(USAN, rINN)*

Mépolizumab; Mepolizumabum; SB-240563. Immunoglobulin G1, anti-(human interleukin 5) (human-mouse monoclonal SB-240563 γ1-chain), disulfide with human-mouse monoclonal SB-240563 κ-chain, dimer.

Меполизумаб

CAS — 196078-29-2.

Profile

Mepolizumab is an anti-interleukin-5 monoclonal antibody. It is under investigation in the treatment of hypereosinophilic syndrome (chronic eosinophilic leukaemia), as well as eosinophilic oesophagitis, and asthma.

Mercaptopurine *(BAN, rINN)*

Mercaptopurina; Mercaptopurinum; Mercaptopurinum Monohydricum; Merkaptopuriini; Merkaptopürin; Merkaptopurin; Merkaptopurin monohydrát; Merkaptopurinas; Merkaptopuryna; NSC-755; 6MP; Purinethiol; WR-2785. 6-Mercaptopurine monohydrate; Purine-6-thiol monohydrate; 1,7-Dihydro-6*H*-purine-6-thione monohydrate.

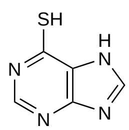
Меркаптопурин

$C_5H_4N_4S,H_2O$ = 170.2.

CAS — 50-44-2 (anhydrous mercaptopurine); 6112-76-1 (mercaptopurine monohydrate).

ATC — L01BB02.

ATC Vet — QL01BB02.



NOTE. In the UK, the CSM noted in October 2004 that confusion had arisen between mercaptopurine and mercaptamine (formerly cysteamine, p.2340) after the switch from prescribing by British Approved Name to prescribing by International Nonproprietary Name. Particular care should be taken to distinguish the two, since they are available in oral dosage forms of similar strength.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Mercaptopurine). A yellow, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; dissolves in solutions of alkali hydroxides. Protect from light.

USP 31 (Mercaptopurine). A yellow, odourless or practically odourless, crystalline powder. Insoluble in water, in acetone, and in ether; soluble in hot alcohol and in dilute alkali solutions; slightly soluble in 2N sulfuric acid.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow depression with mercaptopurine, manifesting as leucopenia, thrombocytopenia, and anaemia, may be delayed; hypoplasia may occur. Mercaptopurine is less toxic to the gastrointestinal tract than the folic acid antagonists or fluorouracil but gastrointestinal disturbances may occur. Hepatotoxicity has been reported, with cholestatic jaundice and necrosis, sometimes fatal. Gastrointestinal and hepatic toxicity are reported to be more frequent in adults than in children, and are more likely at higher doses. Crystalluria with haematuria has been observed rarely as have skin disorders including hyperpigmentation. Fever may occur.

Mercaptopurine is potentially carcinogenic and mutagenic; an increased incidence of abortion has occurred in women given mercaptopurine during the first trimester of pregnancy.

Mercaptopurine should be used with care in patients with impaired hepatic or renal function. Hepatic function should be monitored periodically.

Effects on the blood. Measurement of the activity of thiopurine methyltransferase (TPMT) or the concentration of its substrate, tioguanine nucleotide, has been suggested as a way of predicting those individuals likely to have severe myelotoxicity with mercaptopurine and related drugs (see Azathioprine, p.1819). Patients with an inherited deficiency of the TPMT enzyme may be at increased risk of myelosuppression from mercaptopurine. US licensed product information suggests TPMT testing in patients with evidence of toxicity, and state that reductions in the dose of mercaptopurine may be necessary in those with TPMT deficiency, although optimal initial doses have not been established for these patients. The UK licensed information states that tests for TPMT deficiency have not been shown to identify all patients at risk of severe toxicity, and that close monitoring of blood counts should still be performed.

Effects on the pancreas. Pancreatitis occurred in 13 of 396 patients given mercaptopurine for inflammatory bowel disease.[1] Symptoms resolved on withdrawal but recurred in 7 who were re-challenged with mercaptopurine or azathioprine. Acute pancreatitis has also been reported in 2 children given mercaptopurine during maintenance chemotherapy for acute lymphoblastic leukaemia.[2] They had also suffered pancreatitis from asparaginase during earlier therapy, and the authors suggested that subclinical damage to the pancreas by asparaginase may have been exacerbated by mercaptopurine, but also noted that most patients who develop asparaginase-induced pancreatitis receive mercaptopurine without developing this complication.

1. Present DH, *et al.* 6-Mercaptopurine in the management of inflammatory bowel disease: short- and long-term toxicity. *Ann Intern Med* 1989; **111:** 641–9.
2. Willert JR, *et al.* Recurrent mercaptopurine-induced acute pancreatitis: a rare complication of chemotherapy for acute lymphoblastic leukemia in children. *Med Pediatr Oncol* 2002; **38:** 73–4.

Handling and disposal. A method for the destruction of mercaptopurine or tioguanine in *wastes* by oxidation with potassium permanganate in sulfuric acid.[1] Residues produced by this method had no mutagenic activity. *Urine and faeces* produced for up to 48 hours and 5 days, respectively after a dose of mercaptopurine should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Overdosage. Despite substantial overdose, no acute renal or hepatic toxicity occurred in 2 children. In one case, in which no specific detoxification measures were implemented, neutrophils reached a nadir on day 11 followed by a gradual recovery to normal by day 46. In the other case, gastric lavage was performed and activated charcoal was given; no evidence of neutropenia was seen. The authors recommended that management of acute accidental ingestion should include gastric lavage if the patient presents within 1 hour or if the amount ingested is large. Haemodialysis may be considered if the patient presents within 3 hours of ingestion. Liver function should be monitored. Severe myelosuppression may be managed with granulocyte colony-stimulating factor and a bone-marrow harvest may be of benefit if performed within several hours of the overdose.[1]

1. Chow LML, *et al.* Toxic ingestion of 6-mercaptopurine by young siblings of pediatric oncology patients. *J Pediatr* 2004; **144:** 669–71.

Porphyria. Mercaptopurine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

Mercaptopurine should be given with particular caution with other hepatotoxic drugs. Its effects are enhanced by allopurinol and the dose of mercaptopurine should be reduced to one-third to one-quarter of the usual dose when allopurinol is also given.

Allopurinol. Mercaptopurine plasma concentrations were markedly increased by allopurinol when mercaptopurine was given by mouth but not when it was given intravenously.[1] The results appear to indicate that allopurinol inhibits the first-pass metabolism of mercaptopurine.

1. Zimm S, *et al.* Inhibition of first-pass metabolism in cancer chemotherapy: interaction of 6-mercaptopurine and allopurinol. *Clin Pharmacol Ther* 1983; **34:** 810–17.

Anticoagulants. For reference to mercaptopurine diminishing the activity of *warfarin*, see p.1429.

Antineoplastics. For a suggestion that *doxorubicin* might enhance the hepatotoxicity of mercaptopurine, see under Daunorubicin Hydrochloride, p.709.

Giving mercaptopurine with low-dose oral *methotrexate* increased mean peak plasma concentrations of mercaptopurine by 26% compared with the same dose of mercaptopurine alone in a study in 14 patients with acute lymphoblastic leukaemia.[1] The effect was probably due to inhibition of the first-pass metabolism of mercaptopurine by methotrexate, which is a potent inhibitor of xanthine oxidase. In another study[2] of 10 children with acute lymphoblastic leukaemia, high-dose intravenous methotrexate (2 or 5 g/m^2) increased the peak plasma concentrations of mercaptopurine by 108 and 121% respectively. However, the clinical effect of this pharmacokinetic interaction is probably only minor because of the low, and highly variable, mercaptopurine bioavailability and the lack of correlation between mercaptopurine plasma concentrations and effect.[3] Mercaptopurine and methotrexate have been widely used in combination chemotherapy regimens for acute lymphoblastic leukaemia for their synergistic pharmacodynamic interaction.

Azathioprine. For a report of a fatality when a patient was prescribed mercaptopurine and azathioprine by separate practitioners, see Interactions, under Azathioprine, p.1819.

Gastrointestinal drugs. The enzyme thiopurine methyltransferase is inhibited *in vitro* by *sulfasalazine* and *mesalazine*, raising the possibility of an interaction in patients treated simultaneously with an aminosalicylate and a thiopurine such as mercaptopurine or azathioprine.[1] Myelotoxicity has been reported in a patient receiving mercaptopurine and *olsalazine*.[2] Similarly, severe pancytopenia has occurred in a 13-year-old boy when azathioprine was added to mesalazine therapy.[3] In a study[4] of 34 patients with Crohn's disease in which *balsalazide*, mesalazine, or sulfasalazine was added to established azathioprine or mercaptopurine therapy, mild leucopenia was common in patients given mesalazine or sulfasalazine, and whole blood concentrations of tioguanine nucleotide were found to be increased, probably due to thiopurine methyltransferase inhibition. These effects were not statistically significant in patients given balsalazide.

Pharmacokinetics

Mercaptopurine is variably and incompletely absorbed from the gastrointestinal tract; about 50% of an oral dose has been reported to be absorbed, but the absolute bioavailability is somewhat lower, probably due to gastrointestinal or first-pass metabolism, and is also subject to wide interindividual variation. Once absorbed it is widely distributed throughout body water and tissues. Plasma half-lives ranging from about 20 to 90 minutes have been reported after intravenous injection and the drug is not found in plasma after about 8 hours but this is of limited significance since mercaptopurine is activated intracellularly by conversion to nucleotide derivatives which persist for much longer. It is rapidly and extensively metabolised in the liver, by methylation and oxidation as well as by the formation of inorganic sulfates. Thiol methylation is catalysed by the enzyme thiopurine methyltransferase (TPMT). TPMT activity is highly variable in patients because of a genetic polymorphism in the TPMT gene. Patients with little or no detectable enzyme activity may accumulate excessive cellular concentrations of active tioguanine nucleotides, predisposing them to mercaptopurine toxicity. Considerable amounts of mercaptopurine are also oxidised to thiouric acid by the enzyme xanthine oxidase. Mercaptopurine is excreted in urine as metabolites and some unchanged drug; about half an oral dose has been recovered in 24 hours. A small proportion is excreted over several weeks.

Mercaptopurine crosses the blood-brain barrier to some extent and is found in the CSF, but only in subtherapeutic concentrations.

Therapeutic drug monitoring. For a discussion of therapeutic drug monitoring for mercaptopurine, see under Azathioprine, p.1819.

Uses and Administration

Mercaptopurine is an antineoplastic that acts as an antimetabolite. It is an analogue of the natural purines hypoxanthine and adenine. After the intracellular conversion of mercaptopurine to active nucleotides, including thioinosinic acid, it appears to exhibit a variety of actions including interfering with nucleic acid synthesis. It also has immunosuppressant properties. Its actions are specific for cells in S phase.

Mercaptopurine is used, usually with other agents, in the treatment of leukaemia. It induces remissions in acute lymphoblastic and myeloid leukaemias (p.651 and p.652, respectively) but other agents are generally preferred and mercaptopurine is chiefly employed in maintenance programmes, commonly with methotrexate. It may also be effective in chronic myeloid leukaemia (p.653). There is cross-resistance between mercaptopurine and tioguanine (p.779).

Mercaptopurine has been used for its immunosuppressant properties in the treatment of auto-immune disorders such as inflammatory bowel disease but has been largely replaced by azathioprine.

Mercaptopurine is given orally. The usual initial antineoplastic dose for children and adults is 2.5 mg/kg or 50 to 75 mg/m^2 daily but dosage varies according to individual response and tolerance. If there is no clinical improvement and no evidence of white-cell depression after 4 weeks, the dose may be cautiously increased up to 5 mg/kg daily. In maintenance schedules the dose may vary from 1.5 to 2.5 mg/kg daily. Blood counts should be taken at least once a week and if there is a steep fall in the white cell count or severe bone-marrow depression the drug should be withdrawn immediately. Therapy may be resumed carefully if the white cell count remains constant for 2 or 3 days or rises.

It has been used intravenously as mercaptopurine sodium. Thioinosine (mercaptopurine riboside) has also been used.

Administration. There is evidence[1] that the maintenance dosage of mercaptopurine should be tailored individually to achieve an appropriate systemic exposure in children with acute lymphoblastic leukaemia (although this would involve determining mercaptopurine pharmacokinetics in each child). Improvements in survival since 1980 may be associated with changes in the prescribing of mercaptopurine which have resulted in greater cumulative doses being given;[2] some children may have been undertreated in the past because of variations in the pharmacokinetics of mercaptopurine (particularly boys, who tolerate mercaptopurine better than girls,[3] but who have a poorer prognosis).[2] The concentration of tioguanine nucleotide metabolites in the erythrocytes has been shown to be directly related to the risk of relapse in children with acute lymphoblastic leukaemia.[4] Thiopurine methyltransferase (TPMT) activity (which results in methylation and inactivation of mercaptopurine rather than the formation of active nucleotides) may play a substantial role in this variation,[5] but titration of the dose of mercaptopurine until myelotoxicity occurs may prevent the problem:[2] despite gaps in therapy caused by more frequent drug withdrawal, it appears to result in greater accumulation of tioguanine nucleotides in the cells.[6]

6. Lennard L, *et al.* Mercaptopurine in childhood leukaemia: the effects of dose escalation on thioguanine nucleotide metabolites. *Br J Clin Pharmacol* 1996; **42:** 525–7.

Inflammatory bowel disease. Mercaptopurine has been reported to be of benefit in ulcerative colitis[1,2] and Crohn's disease,[3-5] although azathioprine has generally been preferred (see p.1820). The *BNF* considers that in resistant or frequently relapsing cases mercaptopurine 1 to 1.5 mg/kg given daily may be of use.

Polymyositis. Mercaptopurine has been tried in a few patients with polymyositis but has not been formally assessed.

Preparations

BP 2008: Mercaptopurine Oral Suspension; Mercaptopurine Tablets;
USP 31: Mercaptopurine Tablets.

Proprietary Preparations (details are given in Part 3)

Arg.: Puri-Nethol; Varimer; ***Austral.:*** Puri-Nethol; ***Austria:*** Puri-Nethol; ***Belg.:*** Puri-Nethol; ***Braz.:*** Puri-Nethol; ***Canad.:*** Purinethol; ***Chile:*** Puri-Nethol; ***Cz.:*** Puri-Nethol; ***Fr.:*** Puri-Nethol; ***Ger.:*** Puri-Nethol; ***Gr.:*** Puri-Nethol; ***Hong Kong:*** Puri-Nethol; ***India:*** Puri-Nethol; ***Irl.:*** Puri-Nethol; ***Israel:*** Puri-Nethol; ***Ital.:*** Puri-Nethol; ***Mex.:*** Puri-Nethol; ***Neth.:*** Puri-Nethol; ***Norw.:*** Puri-Nethol; ***NZ:*** Puri-Nethol; ***Philipp.:*** Capmerin; Empurine; Puri-Nethol; ***Rus.:*** Puri-Nethol (Пури-нетол); ***S.Afr.:*** Puri-Nethol; ***Singapore:*** Puri-Nethol; ***Swed.:*** Puri-Nethol; ***Switz.:*** Puri-Nethol; ***Thai.:*** Empurine; Puri-Nethol; ***Turk.:*** Puri-Nethol; ***UK:*** Puri-Nethol; ***USA:*** Purinethol.

Methotrexate *(BAN, USAN, rINN)*

Amethopterin; 4-Amino-4-deoxy-10-methylpteroyl-L-glutamic Acid; 4-Amino-10-methylfolic Acid; CL-14377; α-Methopterin; Methotrexát; Méthotrexate; Methotrexatum; Metotreksaatti; Metotreksatas; Metotrexát; Metotrexat; Metotrexato; MTX; NSC-740; WR-19039. *N*-{4-[(2,4-Diamino-6-pteridinylmethyl)methylamino]benzoyl}-L-glutamic acid.

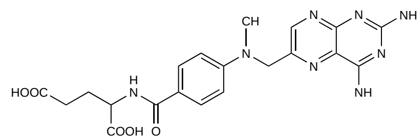
Метотрексат

$C_{20}H_{22}N_8O_5$ = 454.4.

CAS — 59-05-2.

ATC — L01BA01; L04AX03.

ATC Vet — QL01BA01; QL04AX03.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Methotrexate). A yellow or orange, hygroscopic, crystalline powder. It contains not more than 13% of water. Practically insoluble in water, in alcohol, and in dichloromethane; dissolves in dilute solutions of mineral acids and of alkali hydroxides and carbonates. Store in airtight containers. Protect from light.

USP 31 (Methotrexate). It is a mixture of 4-amino-10-methylfolic acid and closely related substances; it contains not less than 98% and not more than 102% of $C_{20}H_{22}N_8O_5$, calculated on the anhydrous basis. A yellow or orange-brown crystalline powder. It contains not more than 12% of water. Practically insoluble in water, in alcohol, in chloroform, and in ether; freely soluble in dilute solutions of alkali hydroxides and carbonates; slightly soluble in 6N hydrochloric acid. Store in airtight containers. Protect from light.

Methotrexate Sodium *(BANM, rINNM)*

Méthotrexate de Sodium; Methotrexate Disodium; Metotreksat Sodyum; Metotrexato sodium; Natrii Methotrexatum.

Натрий Метотрексат

$C_{20}H_{20}N_8Na_2O_5$ = 498.4.

CAS — 7413-34-5 (methotrexate disodium); 15475-56-6 (methotrexate sodium, xNa).

ATC — L01BA01; L04AX03.

ATC Vet — QL01BA01; QL04AX03.

Incompatibility. Methotrexate sodium has been reported to be incompatible with cytarabine, fluorouracil, and prednisolone sodium phosphate;[1] however, another study suggests it is compatible with fluorouracil.[2] Furthermore a mixture of methotrexate sodium with cytarabine and hydrocortisone sodium succinate in various infusion fluids has been reported to be visually compatible for at least 8 hours at 25°, although precipitation did occur on storage for several days.[3]

1. McRae MP, King JC. Compatibility of antineoplastic, antibiotic and corticosteroid drugs in intravenous admixtures. *Am J Hosp Pharm* 1976; **33:** 1010–13.
2. Vincké BJ, *et al.* Extended stability of 5-fluorouracil and methotrexate solutions in PVC containers. *Int J Pharmaceutics* 1989; **54:** 181–9.
3. Cheung Y-W, *et al.* Stability of cytarabine, methotrexate sodium, and hydrocortisone sodium succinate admixtures. *Am J Hosp Pharm* 1984; **41:** 1802–6.

Stability to light. Methotrexate undergoes photodegradation when stored in the light in diluted solutions, although undiluted commercial preparations are reported to show negligible photodegradation.[1] The bicarbonate ion catalyses this reaction and such admixtures should be avoided if possible, although they may be stable in light for 12 hours. Storage of solutions diluted in sodium chloride 0.9% injection in PVC bags was reported to protect against photodegradation although the length of the study was only 4 hours.[2] Photodegradation can take place under normal lighting, but is more rapid in direct sunlight, with about 11% drug loss from a 1 mg/mL solution after 7 hours; storage under normal lighting resulted in little change in drug concentration over 24 hours with a decrease of up to 12% by 48 hours.[3] Loss was greatest from unprotected polybutadiene tubing, with almost 80% drug loss in 48 hours.

Adverse Effects

For general discussions see Antineoplastics, p.635.

The most common dose-related toxic effects of methotrexate are on the bone marrow and gastrointestinal tract. Bone-marrow depression can occur abruptly, and leucopenia, thrombocytopenia, and anaemia may all occur. The nadir of the platelet and white-blood cell counts is usually around 5 to 10 days after a bolus dose, with recovery between about 14 to 28 days, but some sources suggest that leucocytes may exhibit an early fall and rise, followed by a second nadir and recovery, within this period. Ulceration of the mouth and gastrointestinal disturbances are also early signs of toxicity: stomatitis and diarrhoea during treatment indicate that it may need to be interrupted, otherwise haemorrhagic enteritis, intestinal perforation, and death may follow.

Methotrexate is associated with liver damage, both acute (notably after high doses) and, more seriously, chronic (generally after long-term use). Hepatic fibrosis and cirrhosis may develop without obvious signs of hepatotoxicity, and have led to eventual death.

Other adverse effects include renal failure and tubular necrosis after high doses, pulmonary reactions including life-threatening interstitial lung disease, skin reactions (sometimes severe), alopecia, and ocular irritation. Neurotoxicity may be seen: leukoencephalopathy, paresis, demyelination are associated particularly with intrathecal use and are more likely when cranial irradiation is also given. Intrathecal use may also produce arachnoiditis, an acute syndrome of headache, nuchal rigidity, back pain, and fever. Other rarer reactions may include megaloblastic anaemia, osteoporosis, precipitation of diabetes, arthralgias, necrosis of soft tissue and bone, and anaphylaxis.

Methotrexate may cause defective oogenesis and spermatogenesis, and fertility may be impaired (this may be reversible). Like other folate inhibitors it is teratogenic, and it has been associated with fetal deaths. Lymphomas (generally reversible on withdrawal of treatment) have occasionally been reported with methotrexate therapy, although the association has been questioned (see Carcinogenicity, below).

Carcinogenicity. There are reports of lymphomas associated with low-dose methotrexate therapy for rheumatic disorders,[1-4] which in some cases have been associated with concomitant Epstein-Barr virus infection.[2] Transitional cell bladder cancer has also been associated with such therapy.[5] However, a retrospective analysis involving 16 263 patients with rheumatoid arthritis found no evidence of a relationship between the use of methotrexate as an antirheumatic and the development of haematological malignancy.[6] Nonetheless, the spontaneous remission of lymphoma after withdrawal of methotrexate in some patients seems to support an association[7] A later prospective study[8] of all new cases of lymphoma, detected over 3 years in patients treated with methotrexate for rheumatoid arthritis, also found a higher incidence of Hodgkin's disease compared with the general population. The carcinogenic risk with antimetabolites such as methotrexate has generally been considered less than with alkylating agents (p.635).

Effects on the blood. Although serious and sometimes fatal blood dyscrasias are a well-known consequence of high-dose methotrexate therapy the UK CSM[1] stated in September 1997 that it was also aware of 83 reports of blood dyscrasias associated with low-dose methotrexate used to treat psoriasis or rheumatoid arthritis; there were 36 fatalities. Many of the cases had contributing factors such as advanced age, renal impairment, or use with interacting drugs.

Megaloblastic anaemia. Megaloblastic anaemia, usually with marked macrocytosis, has been reported in mainly elderly patients given long-term weekly methotrexate therapy.[1-3] It has been suggested that therapy should be withdrawn if the mean corpuscular volume exceeds 106 femtolitres.[1] Symptoms appear to be associated with folate depletion by methotrexate,[2,4,5] probably due to increased excretion,[6] and in one case megaloblastic anaemia developed after starting a weight-reducing diet poor in folate.[4] Folate supplementation, conversely, may permit continuation of methotrexate therapy with resolution of the anaemia.[5]

Effects on the gastrointestinal tract. Although gastrointestinal toxicity is well recognised as an effect of high-dose regimens, oral ulceration has also been reported after low-dose (weekly) methotrexate use.[1,2] In some instances it was related to overdosage; symptoms resolved upon correction of the dose and with folate supplementation.[1] Folate deficiency may increase the oral toxicity of methotrexate, and folate supplementation may also avoid the need to stop low-dose methotrexate.[2]

Effects on the kidneys. High-dose methotrexate therapy can result in supersaturation of the urine with methotrexate and its metabolites leading to crystal formation.[1] These crystals can cause intrarenal obstruction and are a factor in the development of acute renal failure. Risk factors for crystal formation are acid urine, volume depletion, and renal impairment. Adequate hydration, and urinary alkalinisation with sodium bicarbonate or acetazolamide play an important role in minimising nephrotoxicity in high-dose methotrexate regimens. A study found that the incidence of severe toxicity was reduced in patients given greater hydration and alkalinisation. However, this more intensive hydration regimen also significantly lowered methotrexate plasma concentrations.[2] More recently glucarpidase (p.1447), a recombinant glutamate carboxypeptidase, has been developed and may be useful in the management of methotrexate-induced renal dysfunction when methotrexate concentrations are very high.[3]

Effects on the liver. Methotrexate is well established as a cause of hepatotoxicity, including periportal fibrosis, when given in relatively high doses as an antineoplastic, and it has become clear that its long-term use in lower doses for disorders such as psoriasis and rheumatoid arthritis can also be associated with liver toxicity.[1] There has been some difficulty in these patients in distinguishing the effects of the drug from the effects of the disease, but there is good evidence that the risk is increased in patients given doses on a daily rather than a weekly regimen, and in those with a high alcohol intake.[1] Pre-existing liver disease, obesity (especially if associated with diabetes mellitus), renal impairment, and increasing total cumulative dose may also increase the risk of hepatotoxicity.[1] A lower incidence of hepatotoxicity in patients with rheumatoid arthritis (compared with older studies in patients with psoriasis) may be due to improved dosage regimens and greater awareness of the risks.[1]

In order to minimise the risks of serious liver damage various guidelines and recommendations have been issued for the use of methotrexate in psoriasis and rheumatoid arthritis, and the appropriate monitoring.

- For patients with *psoriasis*, US guidelines[2] recommend a liver biopsy at the beginning of treatment and after each cumulative dose of 1 to 1.5 g, together with monitoring of alanine aminotransferase (ALT), aspartate aminotransferase (AST), alkaline phosphatase, bilirubin, and albumin. The need to repeat routine liver biopsies has been questioned.[3] Some[4] recommend omitting the baseline biopsy in patients with no risk factors. Practice in the UK has been similar but monitoring of the aminoterminal peptide of type III procollagen (PIIINP), a serological marker of hepatic fibrosis,[5] is now recommended by the British Association of Dermatologists[6] as a safer alternative to liver biopsy. PIIINP values should be determined before starting methotrexate and then every 2 to 3 months during treatment. A liver biopsy may then be considered in those with persistently abnormal values. However, some[5] have said that larger studies of the value of PIIINP assays should be undertaken before definitive recommendations can be made.
- In patients with *rheumatoid arthritis* US guidelines[7] suggest an initial biopsy only in patients with a history of excessive alcohol consumption, persistently abnormal AST values or chronic hepatitis B or C infection. All patients should undergo monitoring of liver enzyme values (AST and ALT) and albumin every 4 to 8 weeks, and a biopsy should be performed if 5 of 9 or 6 of 12 measurements of AST are elevated in a 12-month interval; if liver changes are moderate to severe, methotrexate should be discontinued. However, some rheumatologists[8,9] consider that less stringent monitoring may be warranted, especially in those with no risk factors for hepatotoxicity. Similarly, although these guidelines have been widely adopted for use in children with juvenile idiopathic arthritis, some[10] consider that routine blood tests every 4 to 8 weeks are unnecessarily frequent.

The UK CSM advised in 1997 that liver-function tests (together with blood count and renal-function testing) should be performed before beginning long-term low-dose methotrexate therapy and repeated weekly until therapy was stabilised, and thereafter every 2 to 3 months.[11]

Effects on the lungs. Pulmonary toxicity due to methotrexate has been well described.[1,2] A review[1] of over 120 reports of methotrexate pneumonitis found that onset usually occurred during treatment, presenting as dyspnoea, cough, and fever. Examination often found tachypnoea and crackles, eosinophilia, reduced pulmonary function, interstitial and alveolar infiltrates on chest radiography, and interstitial inflammation and fibrosis. The majority of cases were managed with cessation of methotrexate with or without corticosteroid therapy; most patients improved, but there were 16 deaths caused by respiratory disease. Methotrexate was restarted in 16 patients, and pneumonitis recurred in 4 of these.

Up to 25 April 2003, the UK CSM had received 90 reports of parenchymal lung disorders, including 52 reports of pneumonitis, 21 of pulmonary fibrosis, 5 of interstitial lung disease, and 3 of interstitial pneumonitis. The CSM has suggested that patients should seek medical attention if symptoms such as dyspnoea, dry, nonproductive cough, or fever develop; methotrexate should be stopped and corticosteroids given in the event of suspected pneumonitis.[3]

A multicentre case-control study[4] which examined 29 cases of methotrexate-induced lung injury among rheumatoid arthritis patients reported a number of risk factors. These included age over 60 years, pleuropulmonary disease (or to a lesser extent other extra-articular disease), previous use of other disease-modifying antirheumatic drugs, and low serum-albumin; an association with smoking, nonsedentary occupations, and diabetes mellitus was also noted.

Effects on mental function. Children who had received intrathecal methotrexate with cranial irradiation for the prophylaxis of CNS leukaemia, had a significant intellectual deficit compared with their siblings.[1] There was no corresponding significant reduction in IQ in a group of children who had received systemic chemotherapy and radiotherapy when compared with their sibling controls. The results suggest that intrathecal methotrexate and cranial irradiation cause intellectual problems, particularly on the higher, more complex and integrated intellectual functions, and that the repercussions are greater in younger children. Subsequent results in these patients indicated that although the lowering of IQ had persisted, it had not progressed since the original study.[2] A further study confirmed the adverse neurological effects of leukaemia treatment, and its effects on IQ, and did not find a reduced radiation dose to be any less toxic.[3] Neurotoxicity appeared to be greater when systemic therapy with intramuscular rather than oral methotrexate was given with CNS prophylaxis. A study[4] of children who underwent surgery, chemotherapy, and craniospinal radiotherapy for medulloblastoma also found that those patients who received intrathecal methotrexate had significantly worse cognitive deficits than those who did not, and all patients performed worse than a control group of cousins and siblings.

In a small study[5] of children treated for leukaemia with chemotherapy that included intrathecal methotrexate, but without irradiation, there were lower cognitive scores in some measures compared with a group of healthy controls, but overall no major cognitive impairment was found.

A study in 20 patients receiving intermittent oral methotrexate for psoriasis found no evidence of psychological impairment.[6]

Effects on the nervous system. Methotrexate has a cumulative toxic effect on the nervous system, and generalised and focal neurotoxic reactions are associated with intrathecal and high-dose intravenous use.[1] An immediate, usually transient, effect occurring within a day of high intravenous doses can cause nausea and vomiting, headache, somnolence, lethargy, confusion, disorientation, seizures, and increased intracranial pressure. Reversible acute meningitis can follow intrathecal use, with similar results.[1] Aseptic meningitis has also been reported after intramuscular methotrexate.[2] Spinal cord myelopathy resulting in transient or permanent paraplegia has also followed intrathecal methotrexate use, especially if other neurotoxic treatments have also been used. A subacute form of toxic reaction can occur up to several weeks after treatment. It is usually transient and characterised by seizures, varying degrees of paresis, aphasia, anaesthesia, blurred vision, and pseudobulbar palsy. A more delayed syndrome occurs weeks to months after treatment and is of variable severity, but can progress to lethargy, seizures, spasticity, paresis, drooling, and dementia. This condition is characterised by leukoencephalopathy and chronic calcification of brain tissue. It is dose-related, and more severe if the patient has also received radiotherapy.[1]

Effects on the skin. There are rare reports[1,2] of painful erythema of the hands and feet, particularly the fingertips, with progression to blistering and desquamation (palmar-plantar erythrodysesthesia syndrome, p.639) after the use of high-dose intravenous methotrexate. Purpuric skin lesions due to vasculitis have occurred after both high-dose[3] and low-dose[4,5] methotrexate. Accelerated rheumatoid nodulosis has been reported[6,7] after the use of methotrexate in patients with rheumatoid arthritis. Erosion of psoriatic plaques, accompanied by pain and erythema, has been seen[8,9] after low-dose methotrexate therapy; blistering and necrosis consistent with toxic epidermal necrolysis has occurred.[8] Possible exacerbation of a photosensitivity reaction to ciprofloxacin has been described,[10] and reactivation of sunburn has also been reported[11] in a number of cases where methotrexate was given within 2 to 5 days after the initial sunburn.

Hypersensitivity. There are rare reports of anaphylactic reactions in patients given methotrexate. Reactions have usually occurred in patients who had previous exposure to methotrexate, but there are also reports of reaction during initial exposure to high-dose intravenous therapy.[1] Serious reactions have also been described after low-dose intravenous[2] and intrathecal[3] use.

Treatment of Adverse Effects

For general guidelines, see p.639.

Folinic acid neutralises the immediate toxic effects of methotrexate on the bone marrow. It is given as sodium or calcium folinate orally, intramuscularly, by intravenous bolus injection, or by infusion. When overdosage is suspected the dose of folinate should be at least as high as that of methotrexate and should be given as soon as possible; further doses are given as required preferably based on serum-methotrexate concentrations. Folinate should be continued until serum-methotrexate concentrations fall below 0.05 to 0.1 micromol/litre, which may necessitate prolonged treatment in patients with delayed elimination. Other dosage regimens, given intramuscularly or orally, may be appropriate for more modest toxicity associated with conventional doses of methotrexate. For details, see under Folinic Acid, p.1944. After intrathecal overdose, the drainage of 30 mL of CSF within 15 minutes removes about 95% of methotrexate; but methotrexate rapidly enters the systemic circulation and folinic acid treatment should be based on serum-methotrexate concentrations.

Folinic acid is usually given with high-dose methotrexate regimens to prevent damage to normal tissue ('folinic acid rescue') and this is discussed in Uses and Administration, below.

An adequate flow of alkaline urine should be maintained after high doses of methotrexate to prevent precipitation of methotrexate or its metabolites in the renal tubules; in addition to adequate hydration, the use of acetazolamide or sodium bicarbonate is recommended.

The recombinant glutamate carboxypeptidase glucarpidase (p.1447) rapidly hydrolyses methotrexate to inactive metabolites, and is under investigation in the management of methotrexate toxicity.

Folate supplementation. A discussion of the selection of the appropriate route for folinic acid rescue with *high-dose methotrexate* regimens.[1] The general objective is to give folinic acid (as folinate) at doses that maintain plasma concentrations of reduced folates at a level equivalent to or greater than the plasma-methotrexate concentration. In any clinical situation suggesting impaired gastrointestinal function calcium folinate should be given by injection. Although absorption of intramuscular doses is relatively complete and rapid the intravenous route is usually preferable for other reasons, such as a reduced risk of bleeding at injection sites. In the absence of impaired gastrointestinal function, and where there are no concomitant risk factors for methotrexate toxicity, the oral route may be used provided that methotrexate concentrations are expected to be less than 1 micromol/litre. For very high dose methotrexate regimens it is generally appropriate to begin folinic acid rescue intravenously to ensure adequate initial therapy, but the majority of the dosage regimen can generally be given orally.

There is no consensus on the use of folate supplementation in patients taking *low-dose methotrexate*,[2] although reviews have concluded that supplementation with either folic or folinic acid reduces adverse effects related to the liver function tests, gastrointestinal tract and oral mucosa.[2,3] However, a study found that while folate supplementation reduced the incidence of methotrexate-related liver enzyme elevations, it had no effect on incidence, severity, or duration of other adverse effects.[4] Effects of folate supplementation on the efficacy of methotrexate have been inconclusive;[3] some consider the effect to be small.[4,5] There is some suggestion that folinic acid, but not folic acid, may reduce the efficacy of methotrexate.[2] However, an analysis[6] of two studies found a reduction in efficacy with folic acid supplementation. The issue of supplementation remains controversial, with some recommending routine folic acid,[2,5,7] and others suggesting that folate only be added when demand for folate increases, such as during infection or with antibacterial use.[8]

Other drugs. Pretreatment with fluorouracil is reported to reduce the toxicity of methotrexate sufficiently to permit high-dose methotrexate without the need for folinic acid rescue.[1] Methotrexate has also been given before fluorouracil to modulate its activity (see Administration, in Fluorouracil, p.724).

The acute neurotoxic effects of methotrexate have been reported to be relieved by intravenous aminophylline or oral theophylline in some children.[2]

For reference to the ineffectiveness of diltiazem in preventing the nephrotoxicity due to high-dose methotrexate, see Kidney Disorders, under Diltiazem p.1267.

For evidence that colestyramine might decrease serum-methotrexate concentrations, see Interactions, below. For reference to the use of glucarpidase to manage methotrexate-induced renal toxicity see Effects on the Kidneys, above.

Precautions

For general discussions see p.641.

Methotrexate should be used with great care in patients with bone-marrow, hepatic, or renal impairment. It should also be used cautiously in ulcerative disorders of the gastrointestinal tract, and in the elderly and the very young. Pleural or ascitic effusions may act as a depot for methotrexate and produce enhanced toxicity, and should be drained before treatment.

Regular monitoring of haematological, renal, and hepatic function, and gastrointestinal toxicity is advisable. Treatment should be interrupted if myelosuppression, diarrhoea, or stomatitis occur. Dyspnoea or cough may be a sign of pulmonary toxicity and patients should be advised to contact their doctor if they develop these symptoms. Treatment should be withdrawn and the patient investigated to exclude infection. If methotrexate-induced lung disease is suspected corticosteroid therapy may be started and further treatment with methotrexate should not be given. Patients or their carers should report any symptoms or signs suggestive of infection, especially sore throat.

In patients receiving **low-dose methotrexate for psoriasis or rheumatoid arthritis** full blood counts and renal and liver function tests should be performed before starting treatment and repeated regularly thereafter (for discussion of guidelines for monitoring in these patients see Effects on the Liver, above). Treatment should be interrupted if myelosuppression, stomatitis, or any abnormality of liver function is detected. Methotrexate should not be used to treat rheumatoid arthritis or psoriasis in patients with alcoholism, liver disease or persistent abnormal liver function tests, or in those with significant renal impairment, immunodeficiency, or blood disorders. A test dose has been recommended. Severe or fatal toxicity has resulted from overdosage when doses intended for a low-dose weekly regimen were mistakenly taken daily, and particular care should be taken to avoid confusion about dosage frequency.

With **high-dose regimens**, serum concentrations of methotrexate should be monitored. Maintenance of an adequate flow of alkaline urine is essential (see Treatment of Adverse Effects, above).

Methotrexate is a potent teratogen and should be avoided in **pregnancy**. Some manufacturers advise that conception should be avoided for at least 6 months after therapy but others consider 3 months adequate.

Blood products. Enhanced toxicity was seen in 2 of 14 patients receiving methotrexate by 24-hour infusion when packed red cells were transfused immediately after the methotrexate infusion.[1] Erythrocytes act as reservoirs for methotrexate and probably resulted in the prolonged high serum-methotrexate concentrations seen in these patients. Great care should be exercised whenever packed red blood cells and methotrexate are given concurrently.

1. Yap AKL, *et al.* Methotrexate toxicity coincident with packed red cell transfusions. *Lancet* 1986; **ii:** 641.

Breast feeding. Methotrexate has been detected in breast milk in low concentrations.[1] The American Academy of Pediatrics considers[2] that methotrexate may interfere with cellular metabolism, causing neutropenia and possibly immune suppression in the nursing infant, and has unknown effects on growth, and an association with carcinogenesis.

1. Johns DG, *et al.* Secretion of methotrexate into human milk. *Am J Obstet Gynecol* 1972; **112:** 978–80.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 30/06/04)

Handling and disposal. Care should be taken to avoid inhalation of methotrexate or contact with skin and mucous membranes. It may cause irritation of the eyes.

Methods have been published for the oxidative destruction of methotrexate *wastes* using potassium permanganate and sulfuric acid, aqueous alkaline potassium permanganate, or sodium hypochlorite.[1] The first method may also be used for dichloromethotrexate. Residues produced by the degradation of methotrexate by these methods showed no mutagenicity *in vitro*.

Urine and faeces produced for up to 72 hours and 7 days respectively after a dose of methotrexate should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Hepatitis. Reactivation of hepatitis B infection, with the development of hepatocellular necrosis and fulminant hepatic failure requiring liver transplantation, developed on stopping low-dose methotrexate therapy in a patient with rheumatoid arthritis who was also an asymptomatic chronic hepatitis B carrier.[1] It was suggested that all patients being considered for low-dose methotrexate therapy should be screened for the presence of serum HBsAg before beginning therapy.

1. Flowers MA, *et al.* Fulminant hepatitis as a consequence of reactivation of hepatitis B virus infection after discontinuation of low-dose methotrexate therapy. *Ann Intern Med* 1990; **112:** 381–2.

Porphyria. Methotrexate is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

PUVA. Of a total of 94 patients with psoriasis and 38 with mycosis fungoides treated with PUVA therapy (methoxsalen and ultraviolet light) 2 of the former also given methotrexate developed skin cancers.[1] It was suggested that the combination of methotrexate and PUVA may be synergistic in inducing cutaneous malignancy. However, in a cohort study[2] of patients with severe psoriasis, exposure to methotrexate for at least 4 years was associated with an increase in risk of squamous cell carcinoma but not basal cell carcinoma, and no interaction was found between methotrexate and PUVA.

1. Fitzsimons CP, *et al.* Synergistic carcinogenic potential of methotrexate and PUVA in psoriasis. *Lancet* 1983; **i:** 235–6.
2. Stern RS, Laird N. The carcinogenic risk of treatments for severe psoriasis. *Cancer* 1994; **73:** 2759–64.

Radiation. Analysis of neutrophil counts for 18 months in children with acute lymphoblastic leukaemia showed that methotrexate-induced neutropenia was significantly greater in patients given CNS irradiation and was considered to have contributed to 3 of 5 deaths during remission.[1]

For the effect of cranial irradiation and intrathecal methotrexate on intellectual development, see Effects on Mental Function, above.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. The effects of methotrexate may be enhanced by drugs that decrease its renal excretion, such as NSAIDs and salicylates, probenecid, and some penicillins. Fatal toxicity has occurred in patients given NSAIDs with methotrexate (see below). Severe toxicity has occurred rarely when co-trimoxazole or trimethoprim was given with methotrexate. Use with other myelotoxic, hepatotoxic, or nephrotoxic agents may increase the risk of toxicity. Folic acid and its derivatives may decrease the effectiveness of methotrexate, although they are often used together to reduce methotrexate toxicity (see Treatment of Adverse Effects, above).

Animal studies suggested methotrexate toxicity may be increased by chloramphenicol, para-aminobenzoic acid, and hypoglycaemics, but there does not appear to be any evidence of this clinically.

Antibacterials. The oral *aminoglycosides* neomycin[1] and paromomycin[2] have been reported to reduce the gastrointestinal absorption of methotrexate. Various *penicillins* have been reported to markedly decrease the clearance of methotrexate given intravenously for treatment of neoplasms,[3-6] although *ceftazidime* may not.[4] There have also been a few reports of penicillins possibly exacerbating the toxicity of low-dose methotrexate in patients being treated for psoriasis or rheumatoid arthritis, but a small study found that although flucloxacillin decreased methotrexate clearance slightly, this was not clinically significant.[7] Methotrexate toxicity has been reported in a patient receiving low-dose methotrexate after a course of *tetracycline*.[8] In a patient receiving high-dose methotrexate, giving *doxycycline* before the eleventh cycle was believed to be responsible for an exacerbation of methotrexate toxicity, with raised plasma concentrations and reduced clearance of methotrexate.[9] *Sulfonamides* such as sulfafurazole and sulfamethoxazole may displace methotrexate from binding sites[10] and reduce renal clearance.[11] Megaloblastic pancytopenia has been reported on a number of occasions when methotrexate was given with *co-trimoxazole*[12-14] or *trimethoprim*;[13,15,16] possible mechanisms involved include an additive antifolate effect, in addition to the effect of the sulfamethoxazole component in the case of co-trimoxazole.

Antiepileptics. For mention of the reduction in serum-*valproate* concentration produced by methotrexate see p.511.

Antineoplastics. Enhanced methotrexate toxicity might be expected with nephrotoxic agents (such as *cisplatin*) that can reduce methotrexate excretion by impairing renal function. Sequential use of methotrexate and *fluorouracil* may result in synergistic enhancement of effect (see Administration, in Fluorouracil, p.724), and equally, fluorouracil before methotrexate may reduce its toxicity (see Other Drugs, under Treatment of Adverse Effects, above), but if *asparaginase* (p.682) is given before methotrexate the cytotoxic effect of methotrexate may be reduced.

Methotrexate may increase the bioavailability of *mercaptopurine*, probably by interference with first-pass metabolism (see p.744).

Colestyramine. Serum-methotrexate concentrations were markedly reduced in 3 patients given colestyramine to treat methotrexate toxicity.[1,2] Colestyramine appears to bind methotrexate and reduce its enterohepatic recirculation.

2. Shinozaki T, *et al.* Successful rescue by oral cholestyramine of a patient with methotrexate nephrotoxicity: nonrenal excretion of serum methotrexate. *Med Pediatr Oncol* 2000; **34:** 226–8.

Dantrolene. Dantrolene was considered to have caused methotrexate toxicity in a patient given high-dose methotrexate.[1]

1. André N, *et al.* Can dantrolene contribute to methotrexate toxicity? *Ann Pharmacother* 2006; **40:** 1695–6.

Gastrointestinal drugs. Elevated serum concentrations of methotrexate were reported when it was given to 2 patients also receiving *omeprazole*.[1,2] The effect was not seen with subsequent cycles of methotrexate therapy once omeprazole had been stopped. In another case[3] however, raised methotrexate concentrations were thought to be due to an interaction with omeprazole, but were identical during a second cycle after omeprazole had been withdrawn. Severe generalised myalgia and bone pain were reported in a patient who received methotrexate and *pantoprazole*.[4] The same reaction occurred on rechallenge with the combination, but not with methotrexate alone. Although methotrexate concentrations were unchanged, concentrations of the metabolite 7-hydroxymethotrexate were raised suggesting an interaction with its renal elimination. *Lansoprazole* has been reported not to affect the pharmacokinetics of methotrexate.[5]

Immunosuppressants. For reports of enhanced toxicity with *ciclosporin* in patients who have received methotrexate see p.1826.

Leflunomide. For a report of the effect of methotrexate in patients receiving leflunomide, see p.76.

Nitrous oxide. Severe unpredictable myelosuppression and stomatitis have been attributed to the use of nitrous oxide anaesthesia in patients receiving methotrexate, potentiating the effects of methotrexate on folate metabolism.[1] The effect could be reduced by the use of folinic acid rescue.

1. Goldhirsch A, *et al.* Methotrexate/nitrous-oxide toxic interaction in perioperative chemotherapy for early breast cancer. *Lancet* 1987; **ii:** 151.

NSAIDs. Severe, and in some cases fatal, aggravation of methotrexate toxicity has been reported when it was given with various NSAIDs including *aspirin* and other *salicylates*,[1,2] *azapropazone*,[3] *diclofenac*,[4] *indometacin*,[4,5] and *ketoprofen*.[6] The mechanism is uncertain but may include both displacement of methotrexate from protein-binding sites or an effect of NSAIDs on the kidney resulting in reduced methotrexate excretion.[6,7] *Naproxen* has been reported not to affect the pharmacokinetics of methotrexate,[8,9] but a fatal interaction has nonetheless been reported.[10] Despite the risks, some commentators have pointed out that methotrexate and NSAIDs are frequently used together in the treatment of rheumatoid arthritis,[11,12] and that provided this is done with caution, in low doses, and patients are appropriately monitored and cautioned to avoid additional 'over-the-counter' analgesics, such combinations need not be contra-indicated. A study in patients receiving low-dose methotrexate for rheumatoid arthritis suggested that *flurbiprofen*, *ketoprofen*, or *piroxicam* did not influence methotrexate clearance.[13] A case of methotrexate toxicity has nevertheless been described[14] in an elderly woman when flurbiprofen was added to low-dose methotrexate therapy.

Manufacturers of methotrexate generally contra-indicate the use of NSAIDs with high-dose methotrexate.

13. Tracy TS, *et al.* Methotrexate disposition following concomitant administration of ketoprofen, piroxicam and flurbiprofen in patients with rheumatoid arthritis. *Br J Clin Pharmacol* 1994; **37:** 453–6.
14. Frenia ML, Long KS. Methotrexate and nonsteroidal antiinflammatory drug interactions. *Ann Pharmacother* 1992; **26:** 234–7.

Probenecid. Probenecid can produce two- to fourfold increases in serum-methotrexate concentrations,[1-3] presumably by inhibiting renal excretion of methotrexate. Although probenecid has been shown to reduce protein binding of methotrexate,[4] usual doses of probenecid are unlikely to significantly affect methotrexate elimination by this mechanism. A woman receiving low-dose weekly methotrexate for rheumatoid arthritis developed severe pancytopenia when probenecid was given for asymptomatic hyperuricaemia.[5]

5. Basin KS, *et al.* Severe pancytopenia in a patient taking low dose methotrexate and probenecid. *J Rheumatol* 1991; **18:** 609–10.

Retinoids. An increased risk of hepatotoxicity has been reported when methotrexate and *etretinate* are given together,[1] possibly due to increased plasma concentrations of methotrexate.[2,3]

3. Larsen FG, *et al.* Interaction of etretinate with methotrexate pharmacokinetics in psoriatic patients. *J Clin Pharmacol* 1990; **30:** 802–7.

Xanthines. For mention of the effect of methotrexate on the clearance of theophylline, see Antineoplastics, under Interactions of Theophylline, p.1144.

Pharmacokinetics

When given in low doses, methotrexate is rapidly absorbed from the gastrointestinal tract, but higher doses are less well absorbed. It is also rapidly and completely absorbed after intramuscular doses. Peak serum concentrations are achieved in 1 to 2 hours after an oral dose, and 30 to 60 minutes after an intramuscular one.

Methotrexate is distributed to tissues and extracellular fluid with a steady-state volume of distribution of 0.4 to 0.8 litres/kg; it penetrates ascitic fluid and effusions, which may act as a depot and thus enhance toxicity. Clearance from plasma is reported to be triphasic, with a terminal elimination half-life of between 3 and 10 hours after doses less than 30 mg/m^2 or 8 to 15 hours after high-dose parenteral therapy. It is about 50% bound to plasma protein. Methotrexate enters the cells in part by an active transport mechanism and is bound as polyglutamate conjugates: bound drug may remain in the body for several months, particularly in the liver.

Only small or insignificant amounts cross the blood-brain barrier and enter the CSF after oral or parenteral doses although this may be increased by giving higher doses; however, after intrathecal doses there is significant passage into the systemic circulation.

Methotrexate has been detected in very small amounts in saliva and breast milk. It crosses the placenta.

Methotrexate does not appear to undergo significant metabolism at low doses; after high-dose therapy the 7-hydroxy metabolite has been detected. Methotrexate may be partly metabolised by the intestinal flora after oral doses. It is excreted primarily in the urine, by glomerular filtration and active tubular secretion. Small amounts are excreted in bile and found in faeces; there is some evidence for enterohepatic recirculation.

Considerable interindividual variation exists in the pharmacokinetics of methotrexate: those patients in whom clearance is delayed are at increased risk of toxicity.

Uses and Administration

Methotrexate is an antineoplastic that acts as an antimetabolite of folic acid. It also has immunosuppressant properties. Within the cell, folic acid is reduced to dihydrofolic and then tetrahydrofolic acid. Methotrexate competitively inhibits the enzyme dihydrofolate reductase and prevents the formation of tetrahydrofolate which is necessary for purine and pyrimidine synthesis and consequently the formation of DNA and RNA. It is most active against cells in the S phase of the cell cycle. Folinic acid (the 5-formyl derivative of tetrahydrofolic acid) has been given after high doses to bypass the block in tetrahydrofolate production in normal cells and prevent the adverse effects of methotrexate. A suggested schedule for *folinic acid rescue* is described under Folinic Acid, p.1944. (See also Treatment of Adverse Effects, above). Methotrexate, in very high doses, followed by folinic acid rescue, is used in treating some malignant diseases.

Methotrexate is used in the management of acute lymphoblastic leukaemia. It is seldom used for the induction of remission but is employed in maintenance programmes and in the prophylaxis and treatment of meningeal leukaemia. It may be used for Burkitt's and other non-Hodgkin's lymphomas. In the solid neoplasms it is an important part of curative regimens for choriocarcinoma and other gestational trophoblastic tumours, and for the adjuvant therapy of osteosarcoma and breast cancer. It may also be used in malignant neoplasms of the bladder and head and neck, and some other neoplasms, as indicated by the cross references given below.

Methotrexate is of value in the treatment of psoriasis but because of the risks associated with this use, it should only be given when the disease is severe and has not responded to other forms of treatment. It is widely used as a disease-modifying antirheumatic drug in rheumatoid arthritis. Methotrexate may be used to prevent graft-versus-host disease after bone marrow transplantation and may be used as a cytotoxic immunosuppressant and corticosteroid-sparing agent in non-malignant diseases.

Methotrexate has a role in the management of ectopic pregnancy and in the termination of early pregnancy (see below).

Methotrexate may be given orally as the base or the sodium salt, or by injection as the sodium salt. Doses are calculated in terms of methotrexate. Methotrexate sodium 16.5 mg is equivalent to about 15 mg of methotrexate. The doses and regimens used vary enormously, and may need to be adjusted according to bone marrow or other toxicity (see also under Bone-marrow Depression, p.639). Doses larger than 100 mg are usually given partly or wholly by intravenous infusion over not more than 24 hours.

A common dose for maintenance therapy of acute lymphoblastic **leukaemia** is 15 mg/m^2 once or twice weekly, orally or intramuscularly, with other agents such as mercaptopurine; 20 to 30 mg/m^2 twice weekly has also been given. Alternatively, 2.5 mg/kg may be given intravenously every 14 days. Meningeal leukaemia may be treated by the intrathecal injection of 12 mg/m^2 (maximum 15 mg) once weekly for 2 to 3 weeks, then once monthly; an alternative is 200 to 500 micrograms/kg at intervals of 2 to 5 days until the cell count of the CSF returns to normal. Another regimen has been recommended for children based on age, with children under the age of 1 year receiving 6 mg, 8 mg for those 1 year of age, 10 mg in 2-year-olds, and 12 mg in those 3 years of age or older. Intrathecal doses have also sometimes been given prophylactically to patients with lymphoblastic leukaemia in association with intrathecal cytarabine and hydrocortisone. Methotrexate in intravenous doses of about 500 mg/m^2, followed by folinic acid rescue, may also produce effective concentrations in the CSF and has been used for meningeal leukaemia.

Choriocarcinoma has been treated with doses of 15 to 30 mg daily orally or intramuscularly for 5 days repeated after an interval of 1 week or more, for 3 to 5 courses. Alternatively 0.25 to 1 mg/kg up to a maximum of 60 mg has been given intramuscularly every 48 hours for 4 doses, followed by folinic acid rescue, and repeated at intervals of 7 days for 4 or more courses. Combination chemotherapy may be necessary in patients with metastases.

Doses of 10 to 60 mg/m^2 are given intravenously in the treatment of **breast cancer**, often with cyclophosphamide and fluorouracil.

In advanced **lymphosarcoma** doses of 0.625 to 2.5 mg/kg daily have been suggested with other antineoplastics. Alternatively, higher doses of up to 30 mg/kg have been given intravenously, followed by folinic acid rescue. For Burkitt's lymphoma 10 to 25 mg of oral methotrexate has been given daily for 4 to 8 days, repeated after an interval of 7 to 10 days, while patients with mycosis fungoides may be given an oral dose of 2.5 to 10 mg daily to induce remission; alternatively 50 mg may be given weekly as a single dose or two divided doses, by intramuscular injection.

Very high doses, in the range 12 to 15 g/m^2 have been given by intravenous infusion, followed by folinic acid, as part of combined adjuvant therapy in patients with **osteosarcoma**. High-dose regimens have been tried in other malignancies, including carcinoma of the lung and of the head and neck.

Single weekly doses of 10 to 25 mg may be given orally or by intramuscular or intravenous injection in the treatment of **psoriasis** and adjusted by response. Other, more frequent, regimens have been used but a weekly dosage regimen appears to be less hepatotoxic than a daily one. In the treatment of **rheumatoid arthritis** doses of 7.5 mg orally once weekly are used, adjusted by response and not exceeding 20 mg/week.

It is essential that blood counts and tests of renal and liver function should be made before, during, and after each course of treatment with methotrexate (see Precautions, above).

Asthma. Various immunosuppressants, including methotrexate, have been tried for their anti-inflammatory and corticosteroid-sparing properties in chronic asthma (p.1108), but because of fears about toxicity are largely reserved for certain patients dependent upon systemic corticosteroids. Results of individual studies with methotrexate have been conflicting, but it appears that some patients may benefit from the corticosteroid-sparing effects of methotrexate.[1,2] However, other reviewers considered that the reduction in corticosteroid dose was insufficient to offset the adverse effects of methotrexate.[3] Methotrexate therapy must be given for at least 3 months for an adequate assessment of efficacy.

Connective tissue and muscular disorders. Reports in a limited number of patients indicate that methotrexate given once weekly in low to moderate doses may be of benefit in patients with SLE (p.1513), with benefit reported particularly for joint and mucocutaneous symptoms.[1] In a retrospective analysis of patients with cutaneous lupus erythematosus, low doses of methotrexate significantly decreased disease activity.[2]

Methotrexate therapy has been investigated for its potential corticosteroid-sparing properties in polymyalgia rheumatica (p.1510). Different regimens have been tried and although one study[3] reported benefit, others[4,5] found no evidence of clinical efficacy or a corticosteroid-sparing effect.

Methotrexate is widely used in rheumatoid arthritis (see below) and in polymyositis (p.1510), and has been tried in Cogan's syndrome (p.1502).

Ectopic pregnancy. Ectopic pregnancy occurs when the fertilised ovum implants outside the uterus, usually in the fallopian tube itself (tubal pregnancy). Earlier detection has become possible due to improved diagnostic techniques. In many countries, there has been a rise in the rate of ectopic pregnancies followed by a decline; this may be partly due to increasing rates of infection with *Chlamydia*, followed by the effect of prevention, and changes in the popularity of intra-uterine devices.[1] Although ectopic pregnancies may spontaneously abort early, without clinical sequelae, the potential adverse effects are serious, ranging from pelvic pain and bleeding at 5 to 6 weeks of gestation (indistinguishable from spontaneous abortion), to potentially fatal intra-abdominal haemorrhage later in the course of an otherwise asymptomatic pregnancy.

Laparoscopic surgery remains the standard treatment.[1-3] In some countries non-surgical methods are increasing in popularity because of earlier diagnosis.[1,4] Perhaps the most experience of the latter has been with methotrexate. Management with intramuscular methotrexate may be appropriate for selected women with small unruptured tubal pregnancies who are haemodynamically stable, have low serum-chorionic gonadotrophin concentrations, and lack contra-indications to methotrexate use.[2-6] Surgery is preferred where there is cardiac activity in the conceptus, since a living embryo increases resistance to methotrexate.[5,6] Two regimens of intramuscular methotrexate have been described. A multiple-dose regimen of 1 mg/kg on 4 alternate days, with folinic acid rescue,[1] has similar efficacy to surgery.[3] A single dose of 50 mg/m^2 can be used instead[1,4] but systematic reviews have indicated that it has a higher failure rate than surgery[3,7] and about 20% of patients will require more than one cycle of treatment.[4] The addition of an oral dose of mifepristone to single-dose methotrexate has been investigated[1,8,9] and may reduce treatment failure rates.

Methotrexate has been given by local injection directly into the ectopic (salpingocentesis). Doses of 1 mg/kg or 50 mg have been used[10] but this technique is significantly less successful than surgery.[3] Systemic methotrexate (with folinic acid rescue) has also been reported to be effective in resolving persistent ectopic pregnancy unsuccessfully treated with surgery.

The role of other agents in the management of ectopic pregnancy is less well established. Local instillation of glucose 50% by salpingocentesis has also been used in the treatment of ectopic pregnancy,[10,11] but one study was stopped because of a higher failure rate with glucose treatment compared with local methotrexate.[12]

Methotrexate may also be used in the termination of early uterine pregnancy (see below).

Inflammatory bowel disease. Methotrexate (given intramuscularly once weekly in a dose of 25 mg) was reported to improve symptoms and reduce corticosteroid requirements in a large controlled study in patients with chronic active Crohn's disease.[1] Those patients who were in remission after 16 weeks of methotrexate treatment were entered into a further placebo-controlled trial[2] of methotrexate 15 mg weekly by intramuscular injection. During 40 weeks of follow-up, a higher proportion of patients receiving methotrexate remained in remission, and had fewer relapses. Smaller studies have also reported modest benefit for oral methotrexate 12.5 to 22.5 mg/week in chronic active disease.[3,4] Subcutaneous methotrexate has also been used.[5] A review[6] concluded that low-dose methotrexate could be recommended for induction of remission and for its corticosteroid-sparing effect in refractory and corticosteroid-dependent Crohn's disease, although the precise indications, dose, and route for its use were still unclear. The value of methotrexate in ulcerative colitis is doubtful: although benefits have been seen in some patients,[5,7] a study in active ulcerative colitis found no significant differences between oral methotrexate 12.5 mg/week and placebo.[8] For a discussion of inflammatory bowel disease, see p.1697.

Malignant neoplasms. Methotrexate is extensively used in the management of malignant disease. In acute lymphoblastic leukaemia it is used for maintenance therapy, and intrathecally for prophylaxis of CNS relapse, as discussed on p.651, while it also forms part of a number of regimens used for Burkitt's and other aggressive, intermediate- to high-grade non-Hodgkin's lymphomas (see p.657 and p.656), including mycosis fungoides (p.657) and those associated with AIDS (p.657). In the solid neoplasms it is an important part of curative regimens for gestational trophoblastic tumours (p.650), the adjuvant therapy of osteosarcoma (p.675) and is used in regimens for tumours of the bladder (p.659), brain (p.660), breast (p.661), stomach (p.664), and head and neck (p.666).

Multiple sclerosis. Results suggest that methotrexate 7.5 mg by mouth weekly may be of benefit[1] in slowing the progression of multiple sclerosis (p.892). Although the results of studies of immunosuppressant therapy in this condition have tended to be disappointing, it has been pointed out that benefit was assessed differently in the methotrexate study,[2] which may have a bearing on its more favourable conclusions.

1. Goodkin DE, *et al.* Low-dose (7.5 mg) oral methotrexate reduces the rate of progression in chronic progressive multiple sclerosis. *Ann Neurol* 1995; **37:** 30–40.
2. Whitaker JN, *et al.* Clinical outcomes and documentation of partial beneficial effects of immunotherapy for multiple sclerosis. *Ann Neurol* 1995; **37:** 5–6.

Myasthenia gravis. Methotrexate has been tried in the management of myasthenia gravis (p.629) in patients who require immunosuppression but are intolerant of or unresponsive to corticosteroids and azathioprine.

Organ and tissue transplantation. For reference to the use of methotrexate (usually with ciclosporin) in bone marrow transplantation, see Haematopoietic Stem Cell Transplantation, p.1811.

Primary biliary cirrhosis. Like other drugs used for primary biliary cirrhosis (p.2408) methotrexate has been associated with biochemical improvement but evidence of clinical and in particular histological improvement is harder to demonstrate, and the toxicity of immunosuppressants such as methotrexate is problematic. A randomised study comparing methotrexate with colchicine found a slightly lower survival with methotrexate after 10 years of treatment;[1] a systematic review[2] concluded that methotrexate increased mortality in patients with primary biliary cirrhosis and that its use could not be recommended.

1. Kaplan MM, *et al.* A randomized controlled trial of colchicine plus ursodiol versus methotrexate plus ursodiol in primary biliary cirrhosis: ten-year results. *Hepatology* 2004; **39:** 915–23.
2. Gong Y, Gluud C. Methotrexate for primary biliary cirrhosis. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2005 (accessed 08/02/06).

Psoriatic arthritis. Methotrexate may be useful for severe or progressive cases of psoriatic arthritis (see under Spondyloarthropathies, p.13) when the arthritis is not controlled by physical therapy and NSAIDs, although toxicity may limit long-term use in some patients.

Rheumatoid arthritis. Therapy of rheumatoid arthritis (p.11) is conventionally begun with an analgesic and an NSAID for symptomatic relief, to which a disease-modifying antirheumatic drug (DMARD) is subsequently added in an attempt to retard the disease process. It is now clear that irreversible joint damage commonly occurs in early disease and rheumatologists now generally add the DMARD shortly after rheumatoid arthritis has been diagnosed. Methotrexate is widely used,[1] and is the DMARD of first choice in many patients. Systematic review has confirmed that methotrexate has significant benefit in the short-term treatment of the disease.[2] Methotrexate has also been tried with ciclosporin, hydroxychloroquine and sulfasalazine, leflunomide, etanercept, and infliximab. Studies have shown improved responses to these combinations compared with methotrexate alone, but long-term efficacy and safety has not been studied.[3]

Methotrexate may be of benefit in juvenile idiopathic arthritis (p.10).[4-6]

Methotrexate may also be of value in the management of associated uveitis (see below).

Sarcoidosis. Where therapy is required for sarcoidosis (p.1512) corticosteroids are the first choice of drug; methotrexate is one of the preferred second-line immunosuppressants.

Skin disorders, non-malignant. Methotrexate is widely used in the treatment of severe refractory psoriasis. As discussed on p.1583 the aim of such therapy is to bring the disease under control, enabling a return to other therapy. For use in psoriatic arthritis see above. Methotrexate is also used with corticosteroids in the management of pemphigus and pemphigoid (p.1582).

Termination of pregnancy. Methotrexate has been investigated as an alternative to mifepristone for use with misoprostol for the termination of early pregnancy (p.2004). Intramuscular methotrexate followed 3 days later by intravaginal misoprostol was more effective than misoprostol alone for termination at 56 days or less;[1] the combination was reported to be less successful after 57 to 63 days of gestation.[2] Later studies[3,4] however found the combination to be safe and effective in terminating pregnancies up to 63 days of gestation; in these the misoprostol was given up to 7 days after the methotrexate. Oral methotrexate is also effective.[5-7] However, the efficacy of methotrexate followed by misoprostol does appear to diminish with increasing gestational age,[8] and the time to complete abortion generally takes longer with regimens using methotrexate compared with mifepristone.[9] The American College of Obstetricians and Gynecologists[10] recommends that methotrexate with misoprostol may be used in pregnancies of up to 49 days of gestation, the usual regimen being methotrexate, either 50 mg/m^2 intramuscularly or 50 mg orally, followed 3 to 7 days later by misoprostol 800 micrograms vaginally. The College also advises that it may take up to 4 weeks for complete abortion to occur in about 15 to 25% of women given such regimens.

Vasculitic syndromes. In giant cell arteritis (p.1503), improved clinical response and a corticosteroid-sparing effect have been reported with the addition of methotrexate to corticosteroid therapy,[1] but other studies using different designs and dosages[2,3] have failed to find any benefit. For the use of methotrexate in Takayasu's arteritis and Wegener's granulomatosis see p.1514 and p.1515, respectively.

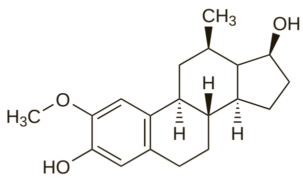
2-Methoxyoestradiol

2-ME2; 2-Methoxyestradiol; NSC-659853. (17β)-2-Methoxyestra-1,3,5(10)-triene-3,17-diol.

$C_{19}H_{26}O_3$ = 302.4.

CAS — 362-07-2.



Profile

2-Methoxyoestradiol is a metabolite of oestradiol (p.2097). It does not exhibit direct oestrogenic activity, but works through multiple cellular pathways to produce antineoplastic effects, including inhibition of angiogenesis and induction of apoptosis. 2-Methoxyoestradiol is under investigation in the treatment of various diseases, including glioblastoma, multiple myeloma, carcinoid tumours, as well as ovarian, prostate, breast, and renal cell cancers. It is also under investigation for pulmonary arterial hypertension.

Mifamurtide *(rINN)*

Mifamurtida; Mifamurtidum; MTP-PE; Muramyl Tripeptide Phosphatidyl Ethanolamine; Muramyl Tripeptide Phosphatidyl Monoethanolamine. 2-[(N-{(2R)-2-[(2-Acetamido-2,3-dideoxy-D-glucopyranos-3-yl)oxy]propanoyl}-L-alanyl-D-isoglutaminyl-L-alanyl)amino]ethyl (2R)-2,3-bis(hexadecanoyloxy)propyl hydrogen phosphate.

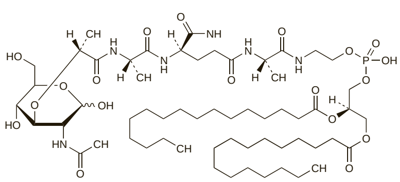
Мифамуртид

$C_{59}H_{109}N_6O_{19}P$ = 1237.5.

CAS — 83461-56-7.

ATC — L03AX15.

ATC Vet — QL03AX15.



NOTE. The name Mifamurtide has been used for both the base and the sodium salt.

Mifamurtide Sodium *(rINNM)*

CGP-19835A; L-MTP-PE (liposomal mifamurtide sodium); Mifamurtida sódica; Mifamurtide *(USAN)*; Mifamurtide Sodique; Mifamurtidum Natricum. 2-[(N-{(2R)-2-[(3R,4R,5S,6R)-3-(Acetylamino)-2,5-dihydroxy-6-(hydroxymethyl)tetrahydro-2H-pyran-4-yloxy]propanoyl}-L-alanyl-D-isoglutaminyl-L-alanyl)amino]ethyl (2R)-2,3-bis(hexanoyloxy)propyl sodium phosphate hydrate.

Мифамуртид Натрий

$C_{59}H_{108}N_6NaO_{19}P,xH_2O$.

CAS — 838853-48-8.

NOTE. The name Mifamurtide has been used for both the base and the sodium salt.

Profile

Mifamurtide is an immunomodulator that activates macrophages to increase their capacity to destroy cancer cells. It is under investigation for the treatment of osteosarcoma.

Miltefosine *(BAN, rINN)*

D-18506; HDPC; Hexadecylphosphocholine; Miltefosiini; Miltefosin; Miltefosina; Miltéfosine; Miltefosinum. [2-(Trimethylammonio)ethyl][hexadecyloxyphosphonate].

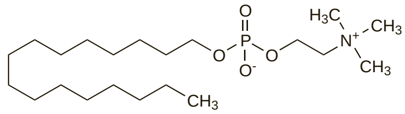
Мильтефозин

$C_{21}H_{46}NO_4P$ = 407.6.

CAS — 58066-85-6.

ATC — L01XX09.

ATC Vet — QL01XX09.



Profile

Miltefosine is a phospholipid derivative which is structurally related to the phospholipid components of the cell membrane and is thought to exert its antineoplastic actions by disruption of cell-membrane function. A 6% solution is applied once or twice daily as a topical antineoplastic agent for skin metastases of breast cancer. Miltefosine has also been tried orally for various malignant neoplasms. It is used for the treatment of visceral and cutaneous leishmaniasis in an oral dose of 1.5 to 2.5 mg/kg daily (maximum daily dose 150 mg) for 28 days.

Leishmaniasis. Miltefosine, given orally in doses of 50 to 150 mg daily, or about 2.5 mg/kg daily, for 28 days, appears to be of benefit[1-7] in the treatment of visceral leishmaniasis (p.824), and has been licensed for this purpose in India and Germany. Benefit has also been reported in patients given similar doses for New World cutaneous leishmaniasis,[8] and it has also been licensed in some South American countries, but success may depend on the infecting *Leishmania* species.[9] The use of longer courses of miltefosine in the treatment of patients with both leishmaniasis and HIV infection has been reported.[10]

Mitobronitol *(BAN, rINN)*

DBM; Dibromomannitol; Mitobronitolum; NSC-94100; R-54; WR-220057. 1,6-Dibromo-1,6-dideoxy-D-mannitol.

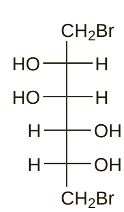
Митобронитол

$C_6H_{12}Br_2O_4$ = 308.0.

CAS — 488-41-5.

ATC — L01AX01.

ATC Vet — QL01AX01.



Pharmacopoeias. In *Br.*

BP 2008 (Mitobronitol). A white or almost white crystalline solid. Slightly soluble in water, in alcohol, and in acetone; practically insoluble in chloroform. Protect from light.

Profile

Mitobronitol is an antineoplastic which appears to act as an alkylating agent, perhaps by epoxide formation. It has been used in the management of thrombocythaemia, both primary, and secondary to chronic myeloid leukaemia or polycythaemia vera.

The usual oral dose is 250 mg daily until the platelet count falls to acceptable levels. Intermittent dosage has been given for maintenance therapy, adjusted according to the blood count. Frequent examination of the blood should be performed during treatment.

Mitobronitol is well absorbed from the gastrointestinal tract and is excreted through the liver into the bile, with reabsorption from the small intestine. It is eliminated as unchanged drug and some bromine-containing metabolites in the urine over several days.

Carcinogenicity. Long-term follow-up of a cooperative study[1] involving 350 patients with polycythaemia vera and treated with mitobronitol was thought to indicate that mitobronitol was less likely than phosphorus-32 or busulfan to induce acute myeloid leukaemia.

For a discussion of the usual management of polycythaemia vera, see p.654.

Mitoguazone Dihydrochloride *(rINNM)*

Dihidrocloruro de mitoguazona; Methyl-GAG; Methylglyoxal Bisguanylhydrazone (mitoguazone); MGBG; Mitoguazone, Dichlorhydrate de; Mitoguazoni Dihydrochloridum; NSC-32946. 1,1′-[(Methylethanediylidene)dinitrilo]diguanidine dihydrochloride.

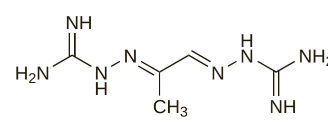
Митогуазона Дигидрохлорид

$C_5H_{12}N_8,2HCl$ = 257.1.

CAS — 459-86-9 (mitoguazone); 7059-23-6 (mitoguazone dihydrochloride).

ATC — L01XX16.

ATC Vet — QL01XX16.



(mitoguazone)

Profile

Mitoguazone is an antineoplastic that may exert its cytotoxic effects by its ability to inhibit polyamine biosynthesis. It has been tried as the dihydrochloride monohydrate or the acetate, in the treatment of leukaemias, lymphomas, and some solid tumours.

Mitoguazone may produce hypoglycaemia and should be given dissolved in glucose-containing infusion fluids; sugar may be taken orally if hypoglycaemia develops during infusion. Granulocytopenia and thrombocytopenia are generally mild and reversible on stopping treatment. Gastrointestinal effects frequently occur.

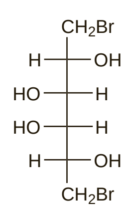
Mitolactol *(rINN)*

DBD; Dibromodulcitol; Mitolactolum; NSC-104800; WR-138743. 1,6-Dibromo-1,6-dideoxy-D-galactitol.

Митолактол

$C_6H_{12}Br_2O_4$ = 308.0.

CAS — 10318-26-0.



Profile

Mitolactol is an antineoplastic that may act by alkylation, probably as epoxide metabolites including dianhydrogalactitol. It has been given orally in the treatment of metastatic breast and cervical carcinoma, although other drugs are usually preferred, and has also been tried in other malignant neoplasms, notably those of the brain.

In addition to myelosuppression, which is usually dose-limiting, and manifests chiefly as leucopenia and thrombocytopenia, adverse effects include gastrointestinal disturbances, skin rashes, grey pigmentation of the skin, transient disturbances of hepatic function, elevated blood-urea nitrogen (BUN), and hypersensitivity reactions. Blood counts should be taken regularly during treatment and mitolactol withdrawn if bone-marrow depression occurs.

Mitomycin *(BAN, USAN, rINN)*

Mitomicina; Mitomicinas; Mitomicinum; Mitomisin; Mitomycin C; Mitomycine; Mitomycine C; Mitomycinum; Mitomysiini; NSC-26980. 6-Amino-1,1a,2,8,8a,8b-hexahydro-8-hydroxymethyl-8a-methoxy-5-methylazirino[2′,3′:3,4]pyrrolo[1,2-*a*]indole-4,7-dione carbamate; (1*S*,2*S*,9*S*,9a*R*)-7-Amino-2,3,5,8,9,9a-hexahydro-9a-methoxy-6-methyl-5,8-dioxo-1,2-epimino-1-*H*-pyrrolo[1,2-*a*]indol-9-ylmethyl carbamate.

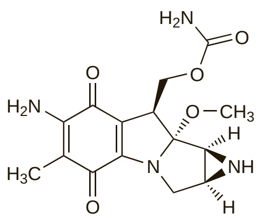
Митомицин

$C_{15}H_{18}N_4O_5$ = 334.3.

CAS — 50-07-7.

ATC — L01DC03.

ATC Vet — QL01DC03.



Description. Mitomycin is an antineoplastic antibiotic produced by the growth of *Streptomyces caespitosus*.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Mitomycin). A substance produced by a strain of *Streptomyces caespitotus.* Blue-violet crystals or crystalline powder. Slightly soluble in water and in acetone; freely soluble in dimethylacetamide; sparingly soluble in methyl alcohol. A 0.1% solution in water has a pH of 5.5 to 7.5. Protect from light.

USP 31 (Mitomycin). A blue-violet crystalline powder. It has a potency of not less than 970 micrograms/mg. Slightly soluble in water; soluble in acetone, in butyl acetate, in cyclohexanone, and in methyl alcohol. A 0.5% suspension in water has a pH of 6.0 to 7.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Mitomycin may be incompatible with drugs that are acid in solution—for a report of incompatibility with topotecan, see p.780.

Stability. Mitomycin undergoes degradation in acid solution,[1] and two studies[2,3] suggested that mitomycin was much less stable in glucose 5% injection than in sodium chloride 0.9%. These findings were queried by a manufacturer (*Bristol, USA*) whose own results suggested[4] that mitomycin was stable for 48 hours in glucose injection 5% at 25°, and it is uncertain whether different manufacturers' formulations differ in stability, or, as has been suggested, that an unsuitable assay was used by the manufacturer to measure stability.[5]

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The main adverse effect of mitomycin is delayed cumulative bone-marrow suppression. Profound leucopenia and thrombocytopenia occurs after about 4 weeks with recovery in about 8 to 10 weeks after a dose. Blood counts may not recover in about one-quarter of patients. Other serious adverse effects include renal damage and pulmonary reactions; a potentially fatal haemolytic-uraemic syndrome has been reported in some patients. US licensed product information states that the degree of renal impairment does not appear to be related to dose or duration of therapy although it has been suggested that the incidence of renal toxicity is greatly increased if the total cumulative dose exceeds 120 mg (see also Effects on the Kidneys, below). Gastrointestinal toxicity, dermatitis, alopecia, fever, malaise, and rarely cardiotoxicity may also occur. Local tissue necrosis, ulceration, and cellulitis may follow extravasation.

Mitomycin is contra-indicated in patients with impaired renal function or coagulation disorders. Renal function should be tested before beginning treatment and after each course.

Effects on the bladder. Intravesical instillation of mitomycin after resection of superficial bladder tumours has led to the development of indolent asymptomatic ulcers at the resection site which may persist for months, and must be distinguished from persistent infiltrating bladder cancer.[1,2] Persistent ulceration, inflammation, necrosis, and pain has also occurred, possibly because of mitomycin extravasation at the resection site.[3] There are also a few reports[4] of eosinophilic cystitis, in which eosinophilic infiltration of the mucosa and muscle were accompanied by oedema, inflammation, muscle necrosis and fibrosis. Severe bladder contracture is a rare, and often irreversible, complication of intravesical mitomycin;[5] urinary diversion may be required in cases of intolerable urinary frequency.[6] Formation of papillary-like calcifications at the resection site,[7] and calcification of the bladder wall have also been described after the use of mitomycin for superficial transitional cell carcinoma of the bladder.

Effects on the eyes. Early complications after the topical use of mitomycin with glaucoma filtering surgery (see Glaucoma, below) include hypotony, shallow anterior chamber, cataract formation, choroidal effusions, hypotonous maculopathy, and suprachoroidal haemorrhage.[1] Late complications include bleb leak, blebitis, and endophthalmitis.[2] Complications from the topical use of mitomycin with or after pterygium surgery (see Pterygium, below) commonly include irritation and photophobia. Other effects include delayed epithelial healing, avascularity of the sclera and cornea, scleral calcification and ulceration, necrotising scleritis, corneal or scleral perforation, iridocyclitis, cataract formation, glaucoma, and symblepharon.[1] Some of these effects may be severe and sight-threatening, and require further surgery.[3] Complications most commonly reported after the use of topical mitomycin in ocular surface neoplasia were hypersensitivity reactions and epiphora (an overflow of tears) secondary to stenosis of the lachrymal punctum.[4]

Effects on the kidneys. A syndrome of thrombotic microangiopathy resembling the haemolytic-uraemic syndrome has been seen in patients receiving mitomycin, either alone[1] or more often with other drugs, particularly fluorouracil[2] or tamoxifen.[3,4] The syndrome is characterised by haemolytic anaemia, thrombocytopenia, and progressive renal failure, and may be accompanied by hypertension, pulmonary oedema, and neurological effects including confusion, headache, and seizures.[1,2] Onset is usually delayed, sometimes occurring several months after the end of a course of mitomycin.[1,2]

There is some uncertainty as to whether mitomycin dose is significant, but one study[1] found that all of 25 cases they reported had received total doses of 70 mg or more, and another[2] reported that 74 of 83 cases had received 60 mg or more.

Symptoms may be exacerbated by blood transfusions.[2] The use of erythropoietin allowed the cessation of blood transfusion, with subsequent haematological improvement and slower progression of chronic renal failure in one case report.[5] Plasma exchange has been suggested as possibly helpful,[1] although only a minority of patients may benefit from this treatment.[2] Captopril therapy may also be useful.[6]

6. Schiebe ME, *et al.* Mitomycin C-related hemolytic uremic syndrome in cancer patients. *Anticancer Drugs* 1998; **9:** 433–5.

Effects on the liver. Hepatic veno-occlusive disease developed in 6 of 29 patients given intensive mitomycin therapy and autologous bone marrow transplantation.[1] The effect was manifest as abdominal pain, hepatomegaly, and ascites, and liver failure was progressive and fatal in 3. A further patient, who had no symptoms, was found to have veno-occlusive disease at post mortem.

1. Lazarus HM, *et al.* Veno-occlusive disease of the liver after high-dose mitomycin C therapy and autologous bone marrow transplantation. *Cancer* 1982; **49:** 1789–95.

Effects on respiratory function. Mitomycin-induced pulmonary toxicity has been reviewed.[1,2] There have been reports of toxicity at total dosages as low as 20 mg/m^2 of mitomycin,[2] although others report[1] that the average cumulative dose associated with toxicity is 78 mg. Premedication with corticosteroids may reduce the incidence of lung toxicity.[2]

See also Effects on the Lungs, p.638. For reference to the respiratory effects of mitomycin used with a vinca alkaloid see Interactions, Antineoplastics, under Vinblastine Sulfate, p.786.

2. Okuno SH, Frytak S. Mitomycin lung toxicity: acute and chronic phases. *Am J Clin Oncol* 1997; **20:** 282–4.

Effects on the skin. Severe eczema of the hands and feet and generalised rash have been reported in patients receiving intravesical mitomycin.[1,2] These symptoms appear to be due to a delayed hypersensitivity (type IV) reaction,[1,2] which is probably also responsible for the bladder irritation and cystitis that may follow intravesical mitomycin[1] (see above). Leucocytoclastic vasculitis caused by an immune-complex mediated (type III) reaction and presenting as purpuric papules has also been described.[2]

1. Colver GB, *et al.* Dermatitis due to intravesical mitomycin C: a delayed-type hypersensitivity reaction? *Br J Dermatol* 1990; **122:** 217–24.
2. Kunkeler L, *et al.* Type III and type IV hypersensitivity reactions due to mitomycin C. *Contact Dermatitis* 2000; **42:** 74–6.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Antineoplastics. Cardiotoxicity developed in 14 of 91 patients who received mitomycin therapy as second-line treatment for breast cancer after the failure of *doxorubicin*-containing regimens, compared with 3 of 89 similar patients whose second-line treatment did not include mitomycin.[1]

For reports of acute bronchospasm after injection of a *vinca alkaloid* in patients pretreated with mitomycin see Vinblastine Sulfate, p.786. For the increased risk of haemolytic-uraemic syndrome that may occur if mitomycin is given with *fluorouracil* or *tamoxifen* see under Effects on the Kidneys, above.

1. Buzdar AU, *et al.* Adriamycin and mitomycin C: possible synergistic cardiotoxicity. *Cancer Treat Rep* 1978; **62:** 1005–8.

Pharmacokinetics

Mitomycin disappears rapidly from the blood after intravenous injection with an initial (distribution) half-life of 17 minutes. It is widely distributed but does not appear to cross the blood-brain barrier. Mitomycin is metabolised mainly but not exclusively in the liver. The terminal half-life is about 50 minutes. After normal doses about 10% of a dose is excreted unchanged in the urine; small amounts are also present in bile and faeces. With increasing doses metabolic pathways are saturated, and more drug is excreted unchanged in the urine.

Uses and Administration

Mitomycin is a highly toxic antibiotic with antineoplastic properties. It acts as an alkylating agent after activation *in vivo* and suppresses the synthesis of nucleic acids. It is a cell-cycle non-specific agent, but is most active in the late G_1 and early S phases.

Mitomycin is used, with other antineoplastic agents, in the treatment of many solid tumours including those of the bladder, breast, cervix, eye, liver, lung, stomach, and prostate as indicated by the cross-references given below. Mitomycin has been tried in other neoplasms including those of the gastrointestinal tract, head and neck, pancreas, in melanoma, sarcomas, and in leukaemias.

Dosage regimens include an initial dose of 10 to 20 mg/m^2 intravenously; subsequent doses are repeated at intervals of 6 to 8 weeks if blood counts permit, and should be reduced according to the previous haematological response. Another suggested regimen is 2 mg/m^2 daily for 5 days, repeated after 2 days. Other regimens may be used, particularly in combination.

Doses are adjusted according to the effect on bone marrow and treatment should not be repeated until the leucocyte and platelet counts are above acceptable levels (see also Bone-marrow Depression, p.639).

Mitomycin is also used as a bladder instillation: 10 to 40 mg is instilled once weekly or three times a week for a total of 20 doses in the treatment of superficial bladder tumours. For the prevention of recurrent bladder tumours 20 mg may be instilled every 2 weeks, or 40 mg monthly or 3-monthly. Alternatively 4 to 10 mg may be instilled once weekly or three times a week. These doses are usually given in 10 to 40 mL of water for injection. The solution should be retained in the bladder for at least 1 hour.

Mitomycin has been given by the intra-arterial route in the treatment of liver tumours, sometimes as an infusion of microcapsules designed to produce localised embolisation.

Mitomycin is used for its effect on fibroblasts to improve outcomes and reduce scarring in certain types of surgery, notably in glaucoma (see below).

Glaucoma. Mitomycin, like fluorouracil, is effective in improving the outcome of glaucoma filtering surgery in selected patients when used as an adjunct to prevent the formation of scar tissue (see p.1873). Fluorouracil is usually given as a regimen of multiple injections but mitomycin given as a single intra-operative topical application in usual concentrations ranging from 0.2 to 0.5 mg/mL appears to be of similar efficacy.[1,2] A systematic review of 11 studies concluded that intra-operative mitomycin reduced the chances of failure in high-risk patients, and in those having their first trabeculectomy.[3] However it was noted that the nature of the data might have led to overestimation of the effect and that there was some evidence of an increased risk of cataract with mitomycin. Late hypotony is also a problem.[4] For other potential complications see Effects on the Eye, above.

Malignant neoplasms. Mitomycin is used in the prevention of recurrent bladder cancer (p.659), in the palliative therapy of advanced breast cancer (p.661), in malignancies of the cervix (p.663), eye (p.664), stomach and anus (p.664 and p.666), liver (p.667), and non-small cell lung cancer (p.668), and has been tried in advanced prostatic cancer (see p.671).

Pterygium. Pterygium is a degenerative condition of subconjunctival tissues that results in a vascularised overgrowth of the conjunctiva and cornea. It is cosmetically unappealing but does not usually require treatment. However, if it affects the pupillary area it can be treated surgically. Pterygium often recurs after removal and methods used to prevent recurrence include radiotherapy or the topical application of mitomycin or thiotepa.[1]

Thiotepa has been applied postoperatively as 0.05% eye drops for several weeks, but pterygium may still recur[2] and adverse effects include conjunctival injection, granuloma, hypertrophic conjunctiva, and black deposits in the conjunctival fornix.[1] Depigmentation of the eyelids may also be a problem, so patients should avoid direct sunlight during thiotepa use.[1]

Mitomycin has been applied topically to the surgical site, or given as eye drops postoperatively.[1] The optimal intra-operative exposure time and concentration are uncertain: concentrations of 0.02 or 0.04% have been applied for up to 5 minutes,[1,3] and low-dose treatment with mitomycin 0.02% for 30 seconds has been reported to be effective with few complications.[4] Postoperative treatment has generally been given as 0.02, 0.04, or 0.1% eye drops for up to 2 weeks, but the higher concentrations and longer treatment periods have been associated with more adverse effects,[1] some of which may be severe and sight-threatening (see also Effects on the Eyes, above). Comparisons of intra-operative with postoperative use suggest that pterygium recurrence rates are similar.[1,5]

A range of β-irradiation doses and fractionation methods have been used. Long-term complications include posterior subcapsular changes of the lens, atrophy and ulceration of the sclera, and scleral necrosis leading to endophthalmitis.[1] In one retrospective study,[6] intra-operative use of 0.04% mitomycin was more effective than β-irradiation in preventing recurrence after surgery. In another study,[7] postoperative mitomycin 0.02% for one week was less effective than radiation therapy.

Mitotane *(USAN, rINN)*

CB-313; *o,p′*DDD; Mitotaani; Mitotan; Mitotano; Mitotanum; NSC-38721; WR-13045. 1,1-Dichloro-2-(2-chlorophenyl)-2-(4-chlorophenyl)ethane.

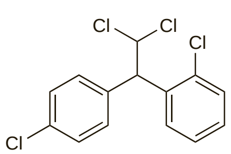
Митотан

$C_{14}H_{10}Cl_4$ = 320.0.

CAS — 53-19-0.

ATC — L01XX23.

ATC Vet — QL01XX23.



Pharmacopoeias. In *US.*

USP 31 (Mitotane). A white crystalline powder with a slight aromatic odour. M.p. is between 75° and 81°. Practically insoluble in water; soluble in alcohol, in ether, in petroleum spirit, and in fixed oils and fats. Store in airtight containers. Protect from light.

Adverse Effects

Almost all patients given mitotane have anorexia, nausea and vomiting, and sometimes diarrhoea, and about 40% suffer some central toxicity with dizziness, vertigo, sedation, lethargy, and depression. Permanent brain damage may develop with prolonged dosage. Bleeding time may be prolonged. Other common adverse effects include leucopenia, thrombocytopenia, anaemia, hypercholesterolaemia, hypertriglyceridaemia, mucositis, gynaecomastia, and headache. Ocular adverse effects may occur including blurred vision, diplopia, lenticular opacities, and retinopathy. Other adverse effects include hypersensitivity reactions, haematuria, albuminuria, skin rashes, fever, myalgia, haemorrhagic cystitis, flushing, hypertension, and orthostatic hypotension.

Precautions

Mitotane inhibits the adrenal cortex and adrenocortical insufficiency may develop during treatment; corticosteroid therapy is often required. In trauma, infection, or shock the drug should be temporarily withdrawn and corticosteroids should be given systemically. Mitotane should be given with care to patients with renal or hepatic impairment. Before mitotane therapy is begun, all possible tumour tissue from large metastases should be surgically removed, in order to minimise possible infarction or haemorrhage in the tumour. Patients should not drive or operate machinery. Behavioural and neurological assessments should be carried out regularly in patients who have been receiving treatment for 2 years or more. Plasma concentrations should be monitored to guide dosage; the therapeutic window lies between 14 and 20 micrograms/mL (see also Therapeutic Drug Monitoring, below).

Interactions

Mitotane may induce hepatic microsomal enzymes and enhance the metabolism of some other drugs, including coumarin anticoagulants.

Spironolactone. Mitotane in a dose of up to 3 g daily in a 65-year-old patient with Cushing's syndrome appeared to be ineffective and did not produce the usual adverse effects associated with mitotane while the patient was also receiving spironolactone.[1]

1. Wortsman J, Soler NG. Mitotane: spironolactone antagonism in Cushing's syndrome. *JAMA* 1977; **238:** 2527.

Pharmacokinetics

Up to 40% of a dose of mitotane is absorbed from the gastrointestinal tract; absorption increases with food. After daily doses of 5 to 15 g, concentrations in the blood of 7 to 90 micrograms/mL of unchanged drug and 29 to 54 micrograms/mL of metabolite have been reported. Mitotane has been detected in the blood for about 6 to 9 weeks after stopping treatment. It is widely distributed and appears to be stored mainly in fatty tissues. It is metabolised in the liver and other tissues and excreted as metabolites in urine and bile. From 10 to 25% of a dose has been recovered in the urine as a water-soluble metabolite.

Therapeutic drug monitoring. Monitoring of mitotane and its major metabolite *o,p′*-DDE in 2 patients receiving mitotane in low doses for Cushing's disease demonstrated that there is a prolonged lag time in the plasma concentration changes in response to alterations in dosage,[1] presumably because of the lipophilicity of both compounds which leads to accumulation in adipose tissue. A study[2] in adrenal carcinoma found that mitotane is preferentially distributed into the very-low-density lipoprotein (VLDL) fraction of the serum of patients with hypertriglyceridaemia, whereas under normolipidaemic conditions, it is bound to high-density lipoproteins and albumin. Because VLDL is not incorporated into the human adrenal cells, mitotane's lipophilicity has implications for treatment and monitoring in patients with hypertriglyceridaemia. In some studies[3,4] tumour responses were seen only in those patients achieving a serum concentration of mitotane above 14 micrograms/mL, and a small prospective study[5] found that therapeutic concentrations (defined as between 14 and 20 micrograms/mL) could be reached by sustained low doses (1 to 3 g daily), thus limiting side-effects.

The symbol † denotes a preparation no longer actively marketed

Uses and Administration

Mitotane is an antineoplastic with a selective inhibitory action on adrenal cortex activity. It may also modify peripheral steroid metabolism. It is given in the treatment of inoperable adrenocortical tumours and has also been used in patients with Cushing's syndrome (p.2344). Dosing schedules vary. In the UK, mitotane is started at a dose of 2 to 3 g daily in patients with adrenocortical tumours, given orally in 2 or 3 divided doses, and preferably with meals. Doses may be reduced to 1 to 2 g daily after 2 months of treatment, or until a cumulative dose of 200 g, or in event of toxicity. If plasma monitoring is available, initial doses may be as high as 4 to 6 g daily in divided doses until a cumulative dose of 75 g is reached (over about 15 days). Children or adolescents may be given starting doses of 1.5 to 3.5 g/m^2 daily, in 2 or 3 divided doses, with meals; this is reduced after 2 to 3 months according to mitotane plasma concentrations. In the USA, the usual initial oral dosage is 2 to 6 g daily in 3 or 4 divided doses. Doses are usually increased to 9 to 10 g daily, unless adverse effects necessitate dose reduction. The maximum tolerated dose ranges from about 2 to 16 g daily. In some countries, mitotane may also be started at 9 to 10 g daily in 3 or 4 divided doses.

◊ A retrospective study involving 105 patients with adrenocortical carcinoma found the prognosis to be generally poor with a 5-year survival of 22% among 88 patients followed up.[1] Surgical resection was the treatment of choice; mitotane treatment had no effect on survival although 8 patients had transient tumour regression and it was of some benefit in controlling adrenal hypersecretion. However, others have previously reported improved survival in patients with adrenocortical carcinoma in whom mitotane serum concentrations were above 14 micrograms/mL, and some[2] have suggested that the poor results with mitotane in the retrospective study may have been due to low serum-mitotane concentrations (see Therapeutic Drug Monitoring, above). A further study[3] found mitotane to be of benefit only in patients with adrenocortical carcinoma undergoing palliative surgery, but of no additional benefit as an adjuvant therapy for survival amongst patients receiving curative surgical resection. However, a retrospective analysis[4] of adjuvant mitotane therapy after radical resection found that it significantly prolonged recurrence-free survival. A review[5] concluded that, although mitotane is recommended for patients with unresectable tumours, only about 35% of such tumours respond.

(mitoxantrone)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Mitoxantrone Hydrochloride). A dark-blue, electrostatic, hygroscopic powder. Sparingly soluble in water; practically insoluble in acetone; slightly soluble in methyl alcohol. Store in airtight containers.

USP 31 (Mitoxantrone Hydrochloride). A dark-blue powder. Sparingly soluble in water; practically insoluble in acetone, in acetonitrile, and in chloroform; slightly soluble in methyl alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Doxorubicin, p.712. Mitoxantrone is reported to be better tolerated than doxorubicin. The nadir of the white cell count usually occurs about 10 days after a dose, with recovery by day 21. Elevation in liver enzyme values may occur; there are occasional reports of severe hepatic impairment in patients with leukaemia, in whom doses are generally higher and adverse effects of mitoxantrone may be more frequent and severe.

Transient blue-green coloration of the urine, and occasionally the sclerae, may occur. Tissue necrosis is rare after extravasation.

Severe neurotoxicity has resulted from erroneous intrathecal dosage; local or regional neuropathy has followed intra-arterial injection. Care is required in patients with pre-existing heart disease, or who have had prior anthracycline treatment or radiotherapy to the chest, as they are at increased risk of cardiotoxicity; regular cardiac examinations should be performed in such patients and in those who receive a total cumulative dose of mitoxantrone in excess of 160 mg/m^2. Care is also required in patients with hepatic impairment. Regular blood counts should be performed during treatment.

Alopecia. Two patients receiving therapy with mitoxantrone developed selective alopecia of white but not of dark hair.[1]

1. Arlin ZA, *et al.* Selective alopecia with mitoxantrone. *N Engl J Med* 1984; **310:** 1464.

Breast feeding. Mitoxantrone was detected in the breast milk of a woman with acute promyelocytic leukaemia in remission who was given consolidation chemotherapy that included mitoxantrone 6 mg/m^2 on days 1 to 3. Concentrations were 120 nanograms/mL just after the third dose and 18 nanograms/mL 28 days after treatment. Although the breast fed her neonate from 3 weeks after the completion of the course of treatment and no adverse effects were seen, the authors recommended that women treated with mitoxantrone should not breast feed.[1]

1. Azuno Y, *et al.* Mitoxantrone and etoposide in breast milk. *Am J Hematol* 1995; **48:** 131–2.

Effects on the heart. Data from over 4000 patients treated with mitoxantrone included 172 reports of cardiac events, including 42 cases of congestive heart failure and 66 of decreased ejection fraction.[1] Previous anthracycline therapy increased the risk, and congestive heart failure seemed to be more likely in patients exposed to a cumulative mitoxantrone dose of 160 mg/m^2, or 100 mg/m^2 in those already given anthracyclines. In a further 78 patients,[2] clinical heart failure developed in 2 after cumulative doses of 174 and 243 mg/m^2. Four of 9 other patients given mitoxantrone in doses above 100 mg/m^2 showed signs of cardiotoxicity, and a further patient previously given doxorubicin 313 mg/m^2 had a fall in stress ejection fraction after only 47 mg/m^2 of mitoxantrone. However, sinus bradycardia has also been reported[3] in 2 previously untreated patients after starting continuous infusions of mitoxantrone 10 mg/m^2. For information on the cardiotoxicity of anthracyclines, to which mitoxantrone is structurally related, see under Adverse Effects and Treatment of Doxorubicin, p.713.

3. Benekli M, *et al.* Mitoxantrone-induced bradycardia. *Ann Intern Med* 1997; **126:** 409.

Handling and disposal. *Urine and faeces* produced for up to 7 days after a dose of mitoxantrone should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Hypersensitivity. In a report of 3 patients, allergic-type reactions to mitoxantrone included vasculitis, facial oedema and skin rashes, and in one, breathlessness, tachypnoea, cyanosis, and unrecordable pulse and blood pressure.[1] Allergic reactions to the drug appear to be rare.

1. Taylor WB, *et al.* Allergic reactions to mitoxantrone. *Lancet* 1986; **i:** 1439.

Interactions

For a report of the effect of ciclosporin in patients receiving mitoxantrone and etoposide, see p.719.

Pharmacokinetics

After intravenous doses mitoxantrone is rapidly and extensively distributed to body tissues, and slowly excreted in urine and bile as unchanged drug and metabolites. The elimination half-life is reported to range from 5 to 18 days. Between 6 and 11% of a dose has been recovered from urine, and 13 to 25% in faeces, within 5 days. It does not appear to cross the blood-brain barrier, but it is distributed into breast milk.

◊ References.

Uses and Administration

Mitoxantrone is an antineoplastic structurally related to doxorubicin (p.712). Its mode of action has not been fully established but it inhibits topoisomerase II and causes DNA strand breakage, as well as intercalating with DNA. It is cell-cycle non-specific but is most active against cells in the late S phase.

It is used in the treatment of metastatic breast cancer (p.661), and of non-Hodgkin's lymphomas (p.656), alone or with other agents. It may also be given to treat adult acute myeloid leukaemias (p.652). Mitoxantrone has also been used in patients with hormone-refractory prostate cancer (p.671), liver cancer (p.667), and ovarian cancer (p.670).

In addition, mitoxantrone is used in the management of secondary progressive or relapsing multiple sclerosis (see below), to reduce neurological disability or the frequency of relapses.

Mitoxantrone is given as the hydrochloride, but doses are expressed in terms of the base; 1.2 mg of the hydrochloride is equivalent to about 1 mg of mitoxantrone. In the treatment of breast cancer, prostate cancer, liver cancer, and lymphomas, a dose equivalent to mitoxantrone 14 mg/m^2 is given initially, then repeated every 3 weeks. It is diluted to at least 50 mL in sodium chloride 0.9% or glucose 5% and injected over at least 3 minutes into a freely-running intravenous infusion of either. Subsequent doses may be adjusted according to the degree of myelosuppression produced. Initial dosage may need to be reduced to 12 mg/m^2 in debilitated patients or those who have had previous chemotherapy. Doses should also probably be reduced when mitoxantrone is given as part of a combination regimen: an initial dose of 10 to 12 mg/m^2 has been suggested.

In the treatment of patients with acute myeloid leukaemia a dose of 12 mg/m^2 daily for 5 days may be given to induce remission; alternatively a similar dose may be given for 3 days with cytarabine.

Cardiac examinations are recommended in all patients who receive a cumulative dose of mitoxantrone greater than 160 mg/m^2; left ventricular ejection fraction (LVEF) should be determined before each dose in patients who have received a cumulative dose in excess of 100 mg/m^2. Regular blood counts should be performed during treatment and courses should not be repeated until blood counts have recovered (see also Bone-marrow Depression, p.639).

In the management of multiple sclerosis, the recommended dose is the equivalent of mitoxantrone 12 mg/m^2 by intravenous infusion over 5 to 15 minutes. This dose may be given once every 3 months initially provided that neutrophil counts are above 1500 cells/mm^3 and that LVEF is greater than 50%. Blood counts should be monitored before each dose. LVEF should be evaluated before beginning mitoxantrone therapy and before all subsequent doses; a total cumulative lifetime dose in excess of 140 mg/m^2 should be avoided. LVEF should also be measured if signs or symptoms of heart failure develop.

Multiple sclerosis. Mitoxantrone has produced clinical benefit[1-4] in terms of reduced relapse rate and a slowing of disease progression in patients with multiple sclerosis (p.892). It has been given intravenously in doses of 5 or 12 mg/m^2 every 3 months, or 8 mg/m^2 every month. Patients with progressive relapsing disease may benefit from rapid induction with 12 mg/m^2 monthly for 3 months.[5] Benefit has also been shown in combination with corticosteroids,[6] although the combination was not compared with mitoxantrone alone. However, cardiotoxicity limits the dose that can be given.[7,8] Because of this and other adverse effects, such as possible secondary malignancy or potentially permanent amenorrhoea, some consider the use of mitoxantrone in multiple sclerosis to be unproven[9] and others have cautioned[10] that it should not be used before other immunomodulators. A systematic review[11] concluded that mitoxantrone was moderately effective in the short-term treatment of multiple sclerosis, but that information on its long-term effects was lacking; use should be limited to patients with worsening relapsing-remitting or secondary progressive disease with evidence of worsening disability.

Multialchilpeptide

Multialquilpéptido.

CAS — 9076-25-9.

Profile

Multialchilpeptide is a complex of metamelfalan, an analogue of melphalan (p.742), with peptides. It has been used in the treatment of malignant neoplasms of the blood and lymphatic systems.

Naptumomab Estafenatox *(rINN)*

ABR-217620; Naptumomab Estafénatox; Naptumomabum Estafenatoxum. Immunoglobulin fragment, anti-[trophoblast glycoprotein (TPBG, 5T4)] monoclonal 5T4 gamma1 heavy chain fragment fusion protein [*Mus musculus* VH (5T4V14: H41>P, S44>G, I69>T, V113>G)-IGHG1_CH1] - [Glycyl-Glycyl-Prolyl] - superantigen SEA/E-120 (synthetic), non-disulfide linked with monoclonal 5T4 kappa light chain [*Mus musculus* V-KAPPA (5T4V18: F10>S, T45>K, I63>S, F73>L, T77>S, L78>V, L83>A)-IGKC].

Наптумомаб Эстафенатокс

CAS — 676258-98-3.

Profile

Naptumomab estafenatox is a murine monoclonal antibody conjugated with a bacterial superantigen, a modified variant of Staphylococcal enterotoxin A that acts as a target for T-cell activation. The antibody is directed against a tumour-specific antigen 5T4. Naptumomab estafenatox is under investigation for the treatment of renal cell carcinoma.

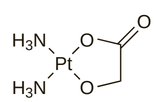
Nedaplatin *(rINN)*

Nédaplatine; Nedaplatino; Nedaplatinum. *cis*-Diammine(glycolato-*O*^{1},*O*^{2})platinum.

Недаплатин

$C_2H_8N_2O_3Pt$ = 303.2.

CAS — 95734-82-0.



Profile

Nedaplatin is a platinum derivative with general properties similar to those of cisplatin (p.698) although it may be associated with less nephrotoxicity. It is used in the treatment of a variety of malignant neoplasms. It is given by intravenous infusion over 1 hour or more, dissolved in at least 300 mL of an appropriate infusion solution, in doses of 80 to 100 mg/m^2. The infusion should be followed by infusion of at least 1 litre of fluid to ensure adequate hydration and reduce the risk of renal damage.

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Aqupla.

Nelarabine *(BAN, USAN, rINN)*

GW-506U; GW-506U78; MAY; Nelarabina; Nélarabine; Nelarabinum; Nelzarabine; 506U; 506U78. 2-Amino-9-β-D-arabinofuranosyl-6-methoxy-9*H*-purine.

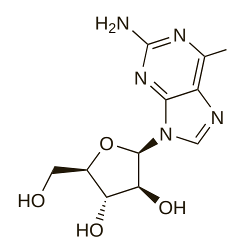
Неларабин

$C_{11}H_{15}N_5O_5$ = 297.3.

CAS — 121032-29-9.

ATC — L01BB07.

ATC Vet — QL01BB07.



Adverse Effects, Treatment, and Precautions

Neurotoxicity is common with nelarabine and may be dose-limiting. Signs and symptoms include somnolence, confusion, convulsions, ataxia, paraesthesias, and hypoaesthesia. Severe toxicity can manifest as coma, status epilepticus (which may be fatal), craniospinal demyelination, or ascending neuropathy. Risk of neurotoxicity is increased by previous or current intrathecal chemotherapy or previous radiation to the spine or brain. Leucopenia, thrombocytopenia, anaemia, and neutropenia are common, especially in children. Full blood counts should be regularly monitored. Other common adverse events include fatigue, gastrointestinal disorders, respiratory disorders, pyrexia, headache, hypokalaemia, hypoalbuminaemia, hyperbilirubinaemia, and increased liver enzyme values. Fatal cerebral haemorrhage has been reported. Appropriate measures to avoid hyperuricaemia (especially in patients considered at risk for tumour lysis syndrome) include adequate hydration, urinary alkalinisation, and possible prophylaxis with allopurinol.

Pharmacokinetics

In adult patients with leukaemia or lymphoma, nelarabine is rapidly eliminated from the plasma, with a half-life of about 30 minutes; no data are available for paediatric patients although the mean clearance is reported to be about 30% higher in children. Nelarabine is rapidly and extensively converted by demethylation to the active metabolite 9-β-D-arabinofuranosylguanine (ara-G; arabinosylguanine; arabinofuranosylguanine; guanine arabinoside); both nelarabine and ara-G are widely distributed throughout the body. Ara-G has an elimination half-life from plasma of about 3 hours. Plasma protein binding is not significant. Nelarabine also undergoes hydrolysis to form methylguanine. Both methylguanine and ara-G undergo further metabolism to guanine, which is deaminated to form xanthine, itself further oxidised to uric acid. Nelarabine and ara-G are partially eliminated by the kidneys; mean apparent clearance is lower in patients with mild to moderate renal impairment.

◊ References.

Uses and Administration

Nelarabine is a prodrug of ara-G, a purine nucleoside analogue that is used as an antimetabolite antineoplastic in the treatment of relapsed or refractory T-cell acute lymphoblastic leukaemia and lymphoma. A dose of 1.5 g/m^2 is given undiluted by intravenous infusion over 2 hours in adults, on days 1, 3, and 5 of a 21-day cycle. In children, nelarabine is given undiluted by intravenous infusion over 1 hour, at a dose of 650 mg/m^2 daily for 5 days, and repeated every 21 days.

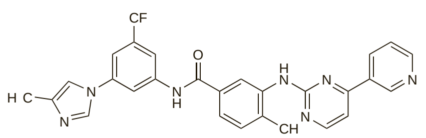
Nilotinib *(USAN, rINN)*

AMN-107; Nilotinibum. 4-Methyl-*N*-[3-(4-methyl-1*H*-imidazol-1-yl)-5-(trifluoromethyl)phenyl]-3-{[4-(pyridin-3-yl)pyrimidin-2-yl]-amino}benzamide.

Нильотиниб

$C_{28}H_{22}F_3N_7O$ = 529.5.
CAS — 641571-10-0.
ATC — L01XE08.
ATC Vet — QL01XE08.



Nilotinib Hydrochloride *(rINNM)*

Hidrocloruro de nilotinib; Nilotinib, Chlorhydrate d'; Nilotinibi Hydrochloridum. Nilotinib Hydrochloride Monohydrate.

Нильотиниба Гидрохлорид

$C_{28}H_{22}F_3N_7O,HCl,H_2O$ = 584.0.
CAS — 923288-90-8.
ATC — L01XE08.
ATC Vet — QL01XE08.

Adverse Effects, Treatment, and Precautions

The most common adverse effects of nilotinib are rash, pruritus, nausea, fatigue, headache, and gastrointestinal disturbances. Myelosuppression occurs, but is generally reversible and can be managed by temporary cessation of therapy or dose reduction. Complete blood counts should be performed every fortnight for the first 2 months and monthly thereafter. Nilotinib can prolong the QT interval, which may result in ventricular tachycardia (torsade de pointes), causing syncope, seizures, and/or death; nilotinib should not be used in patients with hypokalaemia or hypomagnesaemia or long QT syndrome. Electrolyte abnormalities including hypophosphataemia, hypokalaemia, hyperkalaemia, hypocalcaemia, and hyponatraemia can occur, and should be monitored during therapy. Hepatotoxicity has been reported. Serum lipase should be monitored as increases can occur, and caution is recommended in patients with a history of pancreatitis.

Interactions

Nilotinib is a competitive inhibitor of several cytochrome P450 isoenzymes, particularly CYP3A4, which plays an important role in its metabolism. Use of nilotinib with strong inhibitors or inducers of CYP3A4 should be avoided. If they are used, dose adjustments may be required (see Uses and Administration, below). Grapefruit juice may also increase plasma concentrations of nilotinib and should be avoided. St John's wort should also be avoided. Nilotinib should not be given with drugs that prolong the QT interval.

Pharmacokinetics

Peak plasma concentrations occur about 3 hours after an oral dose of nilotinib; bioavailability is increased almost twofold when given with food, especially a high-fat meal. Plasma protein binding is about 98%. The apparent elimination half-life is about 17 hours. It is metabolised in the liver via oxidation and hydroxylation, in which cytochrome P450 isoenzyme CYP3A4 plays an important role.

Uses and Administration

Nilotinib is a tyrosine kinase inhibitor that is used for the treatment of chronic myeloid leukaemia. In patients who are resistant or intolerant to prior treatment that included imatinib, nilotinib hydrochloride is given in an oral dose equivalent to nilotinib 400 mg every 12 hours, at least 1 hour before or 2 hours after food. Therapy is interrupted if toxicity occurs; treatment may be re-started at a lower dose of 400 mg once daily.

Nilotinib is a competitive inhibitor of cytochrome P450 isoenzymes, including CYP3A4. Use with strong CYP3A4 inhibitors or inducers should be avoided. If no alternative is available, a dose reduction to nilotinib 400 mg once daily should be considered if it is given with a strong CYP3A4 inhibitor. Once the inhibitor is stopped, a washout period should be allowed before nilotinib is increased to the original dose. A dose increase of nilotinib may be needed if a strong CYP3A4 inducer is given; this depends on patient tolerability, and the nilotinib dose will need to be decreased once the inducer is stopped.

Nilotinib is also under investigation for the treatment of gastrointestinal stromal tumours.

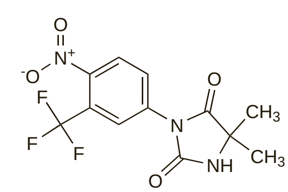
Nilutamide *(BAN, USAN, rINN)*

Nilutamid; Nilutamida; Nilutamidi; Nilutamidum; RU-23908. 5,5-Dimethyl-3-(α,α,α-trifluoro-4-nitro-*m*-tolyl)-imidazolidine-2,4-dione.

Нилутамид

$C_{12}H_{10}F_3N_3O_4$ = 317.2.
CAS — 63612-50-0.
ATC — L02BB02.
ATC Vet — QL02BB02.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Nilutamide). A white or almost white powder. Very slightly soluble in water; freely soluble in acetone; soluble in anhydrous ethanol. Protect from light.

Adverse Effects and Precautions

As for Flutamide, p.725. Interstitial pneumonitis has occurred in patients receiving nilutamide, and the drug is contra-indicated in those with severe respiratory insufficiency.

Effects on the eyes. Reversible visual disturbances, particularly delayed dark adaptation, have been associated with nilutamide.[1,2] Although some consider such visual disturbances to be mild and generally well tolerated,[3] others suggest that these, together with alcohol intolerance and, more seriously, effects on the lung, mean that other nonsteroidal anti-androgens should be preferred.[4]

1. Harnois C, *et al.* Ocular toxicity of Anandron in patients treated for prostatic cancer. *Br J Ophthalmol* 1986; **70:** 471–3.
2. Brisset JM, *et al.* Ocular toxicity of Anandron. *Br J Ophthalmol* 1987; **71:** 639.
3. Dijkman GA, *et al.* Comment: clinical experiences of visual disturbances with nilutamide. *Ann Pharmacother* 1997; **31:** 1550–1.
4. Dole EJ, Holdsworth MT. Comment: clinical experiences of visual disturbances with nilutamide. *Ann Pharmacother* 1997; **31:** 1551–2.

Interactions

Patients receiving nilutamide may exhibit intolerance to alcohol.

Pharmacokinetics

Nilutamide is rapidly and completely absorbed from the gastrointestinal tract. It is extensively metabolised although it may inhibit its own metabolism to some extent after multiple doses. About 60% of an oral dose of nilutamide is eliminated in the urine and less than 10% in the faeces, with an elimination half-life of 41 to 49 hours.

Uses and Administration

Nilutamide is a nonsteroidal anti-androgen that is used similarly to flutamide (p.725) in the treatment of prostatic carcinoma (p.671). It is given orally in a dose of 300 mg daily, usually starting on the same day that the patient undergoes orchidectomy or receives treatment with a gonadorelin analogue. Dosage may be reduced to 150 mg daily after 1 month.

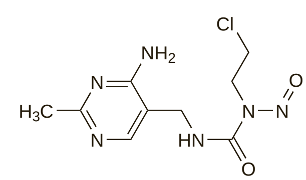
CAS — 42471-28-3 (nimustine); 55661-38-6 (nimustine hydrochloride).
ATC — L01AD06.
ATC Vet — QL01AD06.



(nimustine)

Profile

Nimustine is a nitrosourea antineoplastic with actions and uses similar to those of carmustine (p.694). It is licensed for use in the treatment of malignant glioma. Nimustine hydrochloride is given in doses of 2 to 3 mg/kg or 90 to 100 mg/m^2 as a single dose by slow intravenous injection, repeated at intervals of 6 weeks depending on haematological response.

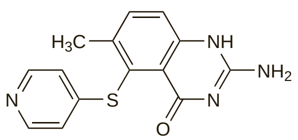
Nolatrexed *(rINN)*

AG-337 (nolatrexed dihydrochloride); Nolatrexedum. 2-Amino-6-methyl-5-(4-pyridylthio)-4(3*H*)-quinazolinone.

Нолатрексед

$C_{14}H_{12}N_4OS = 284.3.$
CAS — 147149-76-6 (nolatrexed); 152946-68-4 (nolatrexed dihydrochloride).



Profile

Nolatrexed is, like raltitrexed (p.766), a selective inhibitor of thymidylate synthase. It has been investigated as an antimetabolite antineoplastic for the treatment of hepatocellular carcinoma, although results of single-agent studies have been disappointing. It is also under investigation in combination therapy for other solid tumours.

Oblimersen Sodium *(USAN, rINNM)*

G-3139; Natrii Oblimersenum; Oblimersén sódico; Oblimersen Sodique.

Натрий Облимерсен

$C_{172}H_{204}N_{62}\text{-}Na_{17}O_{91}P_{17}S_{17} = 6058.3.$
CAS — 190977-41-4.

Profile

Oblimersen sodium is an antisense oligonucleotide that blocks the production of BCL-2, a mitochondrial protein that prevents apoptosis. It is under investigation for the treatment of various malignant neoplasms, including leukaemias, lung cancer, and malignant melanoma.

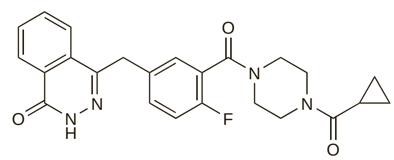
Olaparibum. 4-[(3-{[4-(Cyclopropylcarbonyl)piperazin-1-yl]carbonyl}-4-fluorophenyl)methyl]phthalazin-1(2*H*)-one.

Олапариб

$C_{24}H_{23}FN_4O_3 = 434.5.$
CAS — 763113-22-0.



Profile

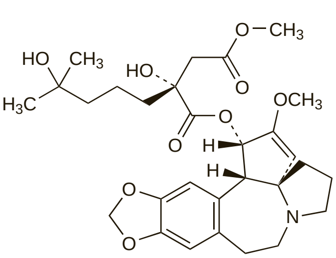
Olaparib is an antineoplastic that is under investigation for the treatment of ovarian cancer.

Omacetaxine Mepesuccinate *(pINN)*

CGX-635; HHT; Homoharringtonine; Mepesuccinato de omacetaxina; NSC-141633; Omacétaxine, Mépésuccinate d'; Omacetaxini mepesuccinas. 1-[(1*S*,3a*R*,14b*S*)-2-Methoxy-1,5,6,8,9,14b-hexahydro-4*H*-cyclopenta[*a*][1,3]dioxolo[4,5-*h*]pyrrolo[2,1-*b*][3]benzazepin-1-yl] 4-methyl (2*R*)-2-hydroxy-2-(4-hydroxy-4-methylpentyl)butanedioate.

Омацетаксин Мепесукцинат

$C_{29}H_{39}NO_9 = 545.6.$
CAS — 26833-87-4.



Pharmacopoeias. In *Chin.*

Profile

Omacetaxine mepesuccinate is a semisynthetic formulation of homoharringtonine, which is an alkaloid derived from the tree *Cephalotaxus harringtonia*, and related species. It is thought to induce apoptosis by inhibition of protein synthesis. It is under investigation for the treatment of chronic myeloid leukaemia (p.653). It has also been tried in the treatment of acute leukaemias and other neoplastic disorders.

The related compounds harringtonine, isoharringtonine, and deoxyharringtonine have also been investigated.

Adverse effects of omacetaxine mepesuccinate may include severe hypotension, cardiac arrhythmias, myelosuppression, gastrointestinal disturbances, chest pain, headache, fatigue, alopecia, rashes, and hyperglycaemia.

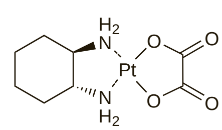
Оксалиплатин

$C_8H_{14}N_2O_4Pt = 397.3.$
CAS — 61825-94-3.
ATC — L01XA03.
ATC Vet — QL01XA03.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Oxaliplatin). A white or almost white, crystalline powder. Slightly soluble in water; practically insoluble in dehydrated alcohol; very slightly soluble in methyl alcohol.

Incompatibility. Licensed product information states that oxaliplatin should not be mixed with chloride-containing solutions (including sodium chloride) or alkaline drugs or solutions. In particular, oxaliplatin should not be mixed with fluorouracil or any trometamol salts. While oxaliplatin may be infused through a Y-site with folinic acid (in glucose 5% solution), they may not be mixed in the same infusion bag, and folinic acid must not contain trometamol as an excipient. The infusion line should be flushed with glucose 5% before giving any other medication. Oxaliplatin may degrade on contact with aluminium, and injection equipment containing aluminium should not be used.

Stability. UK licensed product information states that oxaliplatin must be diluted in glucose 5% to give a concentration not less than 200 micrograms/mL. From a microbiological point of view, the infusion preparation should be used immediately; the infusion should not be stored for longer than 24 hours at 2° to 8° unless it has been prepared in controlled and validated aseptic conditions. Chemical and physical stability has been shown for 48 hours at 2° to 8°, and for 24 hours at 25°. US licensed product information states that, after dilution in 250 to 500 mL of glucose

5%, oxaliplatin infusion solutions have a shelf-life of 6 hours at room temperature (20° to 25°) and up to 24 hours when refrigerated (2° to 8°), and that protection from light is not required.

A study[1] found that oxaliplatin solutions at 700 micrograms/mL in polyolefin infusion bags of glucose 5% were chemically stable for at least 30 days at both 3° to 7° and 20° to 24° without regard to light.

Adverse Effects and Precautions

The adverse affects of oxaliplatin are similar to those of cisplatin (p.698) but nausea and vomiting, nephrotoxicity, and myelosuppression, seem to be less marked. Raised liver enzyme values may occur. Neurotoxicity can be dose-limiting. Peripheral neuropathy occurs in 85 to 95% of patients given oxaliplatin; pain, functional impairment, and loss of tendon reflexes may develop. Pulmonary fibrosis, potentially fatal, has also been reported. Extravasation of oxaliplatin can cause local pain and inflammation; complications may sometimes be severe, including necrosis.

Neurological examinations should be carried out at regular intervals during treatment and the dose should be reduced if symptoms are prolonged or severe. Regular blood counts should be performed during treatment and courses should not be repeated until blood counts have recovered (see also Bone-marrow Depression, p.639). Oxaliplatin should not be given to patients with pre-existing sensory neuropathies or myelosuppression, nor to those with severe renal impairment. Renal function and toxicity should be carefully monitored in those with more moderate degrees of renal impairment.

Patients are recommended to use appropriate contraceptive measures during treatment and for 6 months after stopping treatment for men and for 4 months for women.

Effects on the blood. Acute haemolysis, with[1-4] and without[5] anaemia, has been reported with the use of oxaliplatin. The reactions were considered to be immune-mediated. Evan's syndrome (immune-mediated thrombocytopenia and haemolytic anaemia) has also been reported.[6]

1. Desrame J, *et al.* Oxaliplatin-induced haemolytic anaemia. *Lancet* 1999; **354:** 1179–80.

6. Earle CC, *et al.* Oxaliplatin-induced Evan's syndrome. *Br J Cancer* 2001; **84:** 441.

Effects on the liver. The development of ascites, portal hypertension, and hepatic lesions in a patient with colorectal cancer was considered to be due to oxaliplatin; metastatic or recurrent cancer had been originally suspected.[1]

1. Tisman G, *et al.* Oxaliplatin toxicity masquerading as recurrent colon cancer. *J Clin Oncol* 2004; **22:** 3202–4.

Effects on the nervous system. Neurological toxicity is the principal dose-limiting adverse effect with oxaliplatin.[1-3] The toxicity is biphasic:

- acute paraesthesias or dysaesthesias of the extremities, triggered or exacerbated by cold, are seen in 85 to 95% of patients within hours of infusion, but are normally mild and resolve within hours or days. Some patients also have distressing laryngopharyngeal symptoms, such as difficulty in breathing or swallowing.
- with increasing cumulative dose, peripheral sensory symptoms increase in duration and intensity. Symptoms are sometimes associated with pain and cramps, and may progress to functional impairment (loss of fine sensorimotor coordination). Dosage reduction may be required, but in clinical practice the onset of functional impairment often occurs after the maximum response to therapy has been attained. Cumulative neurotoxicity is reversible in most cases, and about 80% of patients exhibit symptom regression within 4 to 6 months.

The incidence of neurotoxicity may be higher when oxaliplatin is given with fluorouracil. There is some evidence that more prolonged infusion of oxaliplatin can reduce acute toxicity, particularly laryngopharyngeal symptoms. Antiepileptics such as carbamazepine (see Neuropathic Pain, p.477) or gabapentin have been investigated in the management of oxaliplatin-induced neurotoxicity and glutathione has been tried for prevention. Intravenous calcium gluconate and magnesium chloride infusions have been used to prevent acute oxaliplatin neuropathy with good initial results; similarly, intravenous calcium gluconate and magnesium sulfate have been reported to dramatically improve oxaliplatin-associated neuropathy.[4-6] However, a study designed to evaluate potential reduction of cumulative neurotoxicity associated with oxaliplatin, using calcium and magnesium salts, was terminated after those patients receiving calcium and magnesium reported a significantly lower response to chemotherapy (which consisted of oxaliplatin, folinic acid, fluorouracil, and bevacizumab). Although these results need confirmation, the possibility that calcium and magnesium may reduce the activity of certain drugs in the treatment of colorectal cancer should be considered.[7]

GUILLAIN-BARRÉ SYNDROME. A patient with metastatic colon cancer developed Guillain-Barré syndrome after weekly treatment with oxaliplatin-based chemotherapy;[1] he recovered after treatment with intravenous immunoglobulin.

1. Christodoulou C, *et al.* Guillain-Barré syndrome in a patient with metastatic colon cancer receiving oxaliplatin-based chemotherapy. *Anticancer Drugs* 2004; **15:** 997–9.

REVERSIBLE POSTERIOR LEUKOENCEPHALOPATHY SYNDROME. Reversible posterior leukoencephalopathy syndrome (RPLS) was diagnosed in a woman given oxaliplatin with bevacizumab, and capecitabine. She tolerated further therapy with bevacizumab and irinotecan with no complications. The authors attributed the RPLS to oxaliplatin.[1]

1. Pinedo DM, *et al.* Reversible posterior leukoencephalopathy syndrome associated with oxaliplatin. *J Clin Oncol* 2007; **25:** 5320–1.

Extravasation. Although oxaliplatin was originally considered to be non-vesicant, there have been reports of extravasation causing inflammation, sclerosis, or, in some cases, severe necrosis.[1-4] Some consider it to be a vesicant drug,[1,2] although others state oxaliplatin extravasation to be less harmful than that of more classic vesicants.[4]

For discussion of the management of extravasation, see under Treatment of the Adverse Effects of Antineoplastics, p.640.

4. Kretzschmar A, *et al.* Extravasations of oxaliplatin. *J Clin Oncol* 2003; **21:** 4068–9.

Hypersensitivity. Hypersensitivity reactions, including anaphylaxis, have been reported with oxaliplatin,[1-13] usually after several cycles of treatment. Symptoms include hypotension, tachycardia, dyspnoea, burning sensations, pruritus, erythema, sweating, and dizziness.[1,2,7,8] Rashes have also been reported[5,6,12] as have fever and chills.[9,10] While the mechanism of hypersensitivity to oxaliplatin is not clear, it has been suggested that reactions are characterised by development of symptoms during or shortly after the infusion, and are possibly due to a type I IgE-mediated reaction.[7,10] Idiosyncratic or infusional reactions, which are delayed until hours after the infusion,[6,10] are considered to be associated with cytokine release.[7,10] Cases have generally resolved on stopping oxaliplatin and giving appropriate treatment.

Prophylaxis before further oxaliplatin therapy, with corticosteroids and/or antihistamines, has shown variable efficacy.[4-7,9,10] Desensitisation protocols using dilute solutions and longer infusion times have been reported to be successful.[10,11,13]

Intradermal skin testing has been used to identify patients with suspected hypersensitivity to oxaliplatin; however, in some patients with negative skin tests, reactions have occurred upon rechallenge.[6,8]

Interactions

For reference to the effect of oxaliplatin on fluorouracil, see Antineoplastics, p.723.

Pharmacokinetics

After intravenous doses, oxaliplatin is widely distributed throughout the body. It binds irreversibly to red blood cells, which can prolong the half-life of the drug. The mean terminal half-life has been variously stated to be 273 hours and 391 hours.

Oxaliplatin is extensively metabolised to both inactive and active compounds and is predominantly excreted in the urine.

Uses and Administration

Oxaliplatin is a platinum-containing complex similar to cisplatin (see p.698). It is given with fluorouracil and folinic acid in the treatment of metastatic colorectal cancer and in the adjuvant treatment of stage III (Dukes C) colon cancer (p.665). The recommended dose is 85 mg/m^2 by intravenous infusion over 2 to 6 hours, dissolved in 250 to 500 mL of glucose 5%. The dose may be repeated at intervals of 2 weeks if toxicity permits, reduced according to tolerance. In the adjuvant setting, oxaliplatin is given for 12 cycles. After persistent neurotoxicity or recovery from severe adverse effects licensed product information recommends an initial reduction to 65 mg/m^2 in metastatic colorectal cancer, and to 75 mg/m^2 when given as adjuvant treatment. Oxaliplatin should always be given before fluoropyrimidines.

Oxaliplatin is under investigation for the treatment of ovarian and lung cancer. A liposomal formulation of oxaliplatin is in development.

Administration in renal impairment. The primary route of platinum elimination is renal, and clearance of platinum is decreased in patients with renal impairment. However, a study determined that increased platinum exposure in patients with renal impairment was not associated with increased oxaliplatin toxicity. Dose reduction was not considered to be necessary in patients with mild to moderate renal impairment (as defined by creatinine clearance of 20 mL/minute or more).[1] UK licensed product information concurs that no dose adjustment is necessary in mild to moderate renal impairment, but contra-indicates the use of oxaliplatin in severe renal impairment (defined as creatinine clearance of less than 30 mL/minute), due to lack of data.

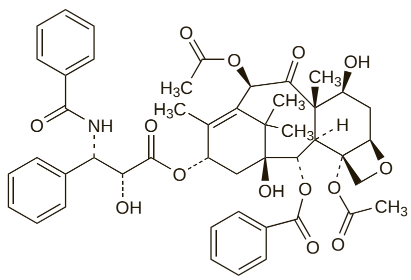
Paclitaxel *(BAN, USAN, rINN)*

BMS-181339-01; NSC-125973; Paclitaxelum; Paklitakselí; Paklitaksel; Paklitaxel; Taxol; Taxol A. (2S,5R,7S,10R,13S)-10,20-Bis(acetoxy)-2-benzoyloxy-1,7-dihydroxy-9-oxo-5,20-epoxytax-11-en-13-yl (3S)-3-benzoylamino-3-phenyl-D-lactate.
Паклитаксел
$C_{47}H_{51}NO_{14}$ = 853.9.
CAS — 33069-62-4.
ATC — L01CD01.
ATC Vet — QL01CD01.



NOTE. Paclitaxel was formerly referred to as taxol, but the use of this name is now limited, as Taxol is a trademark.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Paclitaxel). Isolated from natural sources or produced by fermentation or by a semisynthetic process. A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in dichloromethane; soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Paclitaxel). A white to off-white powder. Insoluble in water; soluble in alcohol. Store in airtight containers at a temperature between 20° and 25°. Protect from light.

Incompatibility. The vehicle for paclitaxel injection, which contains alcohol and polyoxl castor oil, was found to leach the plasticiser diethylhexyl phthalate from some plastic giving sets.[1,2] Consequently, licensed product information recommends the use of non-PVC containers and giving sets.

Paclitaxel was found to be compatible with doxorubicin for at least 24 hours, but microcrystalline precipitation of paclitaxel occurred after 3 to 5 days.[3] For mention of the incompatibility of paclitaxel and cisplatin see p.698.

3. Trissel LA, *et al.* Compatibility and stability of paclitaxel combined with doxorubicin hydrochloride in infusion solutions. *Ann Pharmacother* 1998; **32:** 1013–6.

Adverse Effects, Treatment, and Precautions

For a general outline see Antineoplastics, p.635, p.639, and p.641.

Paclitaxel produces severe dose-limiting bone marrow depression, the nadir of the white cell count usually occurring after about 11 days, with recovery usually by day 15 to 21 after a dose. Myelosuppression may be less frequent and less severe when infusions are given over 3 rather than 24 hours. Peripheral neuropathy can also be severe, and occasionally dose-limiting. Hypersensitivity reactions, with flushing, rash, dyspnoea, hypotension, chest pain, and angioedema may occur, and all patients should be given initial premedication with corticosteroids, antihistamines, and histamine H_2-antagonists. Other adverse effects include alopecia, arthralgia and myalgia, gastrointestinal disturbances, mucositis, bradycardia and ECG changes, nail dystrophies, and elevation of liver enzyme values. Infections are common, as are injection site reactions; extravasation may result in tissue damage. Rare adverse events include hypertension, severe thrombotic events, myocardial infarction, heart failure, severe cardiac conduction abnormalities, seizures, neuroencephalopathy, paralytic ileus, optic nerve disturbances, severe skin reactions, hepatic necrosis, and hepatic encephalopathy. There are rare reports of interstitial pneumonia and other lung disorders.

Paclitaxel is not recommended in patients with severely impaired hepatic function. The drug is formulated in polyoxyl castor oil and should be avoided in patients hypersensitive to this substance. The formulation also contains alcohol, the CNS effects of which should be considered. Blood counts should be monitored frequently. Continuous cardiac monitoring is needed in patients who have had previous significant conduction abnormalities when given paclitaxel.

Alcohol intoxication. Acute alcohol intoxication resulting from high-dose paclitaxel infusion has been reported;[1] it was calculated that the dose used (348 mg/m²) supplied 50 mL of alcohol, or the equivalent of about 3 drinks (half a bottle of wine).

1. Wilson DB, *et al.* Paclitaxel formulation as a cause of ethanol intoxication. *Ann Pharmacother* 1997; **31:** 873–5.

Effects on the eyes. Optic neuritis has occurred with paclitaxel. There is a report of glaucoma possibly related to the use of docetaxel and paclitaxel in a patient also receiving corticosteroids.[1]

1. Fabre-Guillevin E, *et al.* Taxane-induced glaucoma. *Lancet* 1999; **354:** 1181–2.

Effects on the heart. Infusion of paclitaxel has been associated with sinus bradycardia, atrial arrhythmias, ventricular tachycardia, heart block, myocardial infarction, and sudden death.[1,2] Symptoms of heart failure have been reported.[3] In another report sudden death 7 days after paclitaxel treatment raised the question of whether paclitaxel might have had a delayed effect.[4] There is some evidence of cellular damage to the myocardium of a patient with paclitaxel-associated cardiac symptoms.[3] Licensed product information notes that severe cardiovascular events have been seen more frequently after the use of paclitaxel in patients with non-small cell lung cancer than in those with breast or ovarian carcinoma.

4. Alagaratnam TT. Sudden death 7 days after paclitaxel infusion for breast cancer. *Lancet* 1993; **342:** 1232–3.

Effects on the musculoskeletal system. Gabapentin has been reported to be of benefit in the management of taxane-induced arthralgia and myalgia.[1,2]

1. van Deventer H, Bernard S. Use of gabapentin to treat taxane-induced myalgias. *J Clin Oncol* 1999; **17:** 434–5.
2. Nguyen VH, Lawrence HJ. Use of gabapentin in the prevention of taxane-induced arthralgias and myalgias. *J Clin Oncol* 2004; **22:** 1767–9.

Effects on the respiratory system. Acute bilateral interstitial pneumonitis has been reported rarely in patients receiving paclitaxel, despite premedication with corticosteroids and histamine antagonists.[1] Symptoms resolved on treatment with parenteral corticosteroids.

1. Khan A, *et al.* Paclitaxel-induced acute bilateral pneumonitis. *Ann Pharmacother* 1997; **31:** 1471–4.

Effects on the skin and nails. Nail changes, noted as pigmentation or discoloration of the nail-bed, may occur with paclitaxel. Onycholysis (separation of the nail from the nail-bed) has also been reported.[1] Discoloration and onycholysis can also occur after docetaxel use, and there are reports of subungual hyperkeratosis and haemorrhage.[2-4]

Localised oedema evolving into skin sclerosis, mimicking systemic sclerosis, has been reported after taxane use. In most patients, the sclerosis developed mainly on the extremities, and especially the lower extremities. Joint contracture may occur. The total cumulative dose of the taxane may contribute to the onset.[5]

5. Itoh M, *et al.* Taxane-induced scleroderma. *Br J Dermatol* 2007; **156:** 363–7.

Hypersensitivity. Despite premedication with corticosteroids, antihistamines, and H_2-antagonists, hypersensitivity reactions are common in patients given paclitaxel; up to about 40% of patients may have a mild reaction and about 2% a severe reaction. Fatalities have been reported. There are rare reports of delayed hypersensitivity reactions with paclitaxel; necrotic ulceration has occurred, without evidence of extravasation.[1] Some consider the cause to be the polyoxyl castor oil diluent for paclitaxel, and docetaxel has been suggested as a suitable alternative.[2] However, hypersensitivity reactions have also occurred with docetaxel and taxane cross-reactivity has been reported.[3,4] Although the manufacturers of both drugs consider further use to be contra-indicated after a severe reaction, strategies for continuation of treatment and desensitisation have been described.[5,6]

Hypersensitivity reactions to paclitaxel-eluting stents have also been reported;[7] however, the incidence is low, and some consider the polymer coating of the stent to be the likely cause.[8]

Pregnancy. Paclitaxel has been shown to be fetotoxic in *animal* studies, but although the use of potentially teratogenic drugs would normally be avoided during pregnancy, the risk to the mother of inadequate treatment may outweigh whatever risks exist of abnormality in the fetus. Paclitaxel has been used in the treatment of a patient who presented at 27 weeks of gestation with ovarian cancer. She had cytoreductive surgery and then adjuvant chemotherapy consisting of 3 cycles of paclitaxel and cisplatin given every 3 weeks. A healthy child was delivered by caesarean section at 37 weeks, and showed normal growth and development at 30 months of age.[1]

Anhydramnios has been associated with the use of trastuzumab and paclitaxel, see Pregnancy, under Trastuzumab, p.783.

1. Sood AK, *et al.* Paclitaxel and platinum chemotherapy for ovarian carcinoma during pregnancy. *Gynecol Oncol* 2001; **83:** 599–600.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Pretreatment with cisplatin may reduce the clearance of paclitaxel, resulting in increased toxicity, and when both drugs are given, paclitaxel should be given first.

Antineoplastics. For reference to enhanced cardiotoxicity when paclitaxel was given with *doxorubicin*, see p.714. For the pharmacokinetic changes reported when paclitaxel was given with *gemcitabine*, see p.728.

Pretreatment with *fluorouracil* has been reported to inhibit paclitaxel's cytotoxic action, possibly by preventing tumour cells from entering the G_2-M phases of the cell cycle.[1] The effect also occurred when the 2 drugs were given simultaneously, suggesting that combination therapy might not be appropriate.

Valspodar inhibits P-glycoprotein, and a pharmacokinetic study[2] found that it decreased clearance of paclitaxel and prolonged the terminal half-life, increasing exposure to paclitaxel and myelosuppressive effects. The authors suggested that the dose of paclitaxel may need to be reduced by about 60%.

Antivirals. *HIV-PROTEASE INHIBITORS.* In a patient given various antiretrovirals during paclitaxel treatment for Kaposi's sarcoma, pharmacokinetic parameters of paclitaxel were not significantly different when compared with historical controls.[1] The first course of therapy combined paclitaxel with lamivudine, stavudine, and the HIV-protease inhibitors *ritonavir* and *saquinavir.* In subsequent courses, paclitaxel was given with nevirapine, and the final course consisted of paclitaxel given with ritonavir and *indinavir*. However, licensed product information for paclitaxel states that studies suggest that systemic clearance of paclitaxel was significantly lower in the presence of *nelfinavir* and ritonavir, but not indinavir, and that paclitaxel should be given with caution to patients taking HIV-protease inhibitors. HIV-protease inhibitors are metabolised by the cytochrome P450 isoenzyme CYP3A4, but are also reported to inhibit CYP3A activity. This may lead to increased adverse effects when given with taxanes; the combination of delavirdine and saquinavir has been reported to cause serious mucositis, severe myalgia, alopecia, and leucopenia when given with paclitaxel.[2]

1. Nannan Panday VR, *et al.* Paclitaxel in the treatment of human immunodeficiency virus 1-associated Kaposi's sarcoma—drug-drug interactions with protease inhibitors and a nonnucleoside reverse transcriptase inhibitor: a case report study. *Cancer Chemother Pharmacol* 1999; **43:** 516–19.
2. Schwartz JD, *et al.* Potential interaction of antiretroviral therapy with paclitaxel in patients with AIDS-related Kaposi's sarcoma. *AIDS* 1999; **13:** 283–4.

Immunosuppressants. *Ciclosporin* increased the oral absorption of paclitaxel, possibly by inhibiting the multidrug transporter P-glycoprotein in the gastrointestinal tract.[1]

For the effects of *valspodar* (an analogue of ciclosporin) on paclitaxel, see Antineoplastics, above.

Pharmacokinetics

Intravenous paclitaxel exhibits a biphasic decline in plasma concentrations, with a mean terminal half-life of anywhere between about 3 and 50 hours. The pharmacokinetics are non-linear. The steady-state volume of distribution is reported to range from 200 to 700 litres/m^2, indicating extensive extravascular distribution, tissue binding, or both. Paclitaxel is 89% or more bound to plasma protein *in vitro*. The elimination of paclitaxel has not been fully elucidated; only about 1 to 12% of a dose is reported to be excreted in urine, as unchanged drug, indicating extensive non-renal clearance. Paclitaxel is metabolised in the liver, with the major metabolic pathway apparently mediated by the cytochrome P450 isoenzyme CYP2C8, although CYP3A4 may play a minor role. Metabolites are excreted in the faeces via the bile, the primary metabolite being 6α-hydroxypaclitaxel.

Uses and Administration

Paclitaxel is a taxane originally derived from the bark of the Pacific yew tree *Taxus brevifolia* (Taxaceae), and now obtained semisynthetically from a taxane precursor derived from the needles of the European yew, *Taxus baccata*. Paclitaxel's antineoplastic action arises from induction of microtubule formation and stabilisation of microtubules, thereby disrupting normal cell division in the G_2 and M phases of the cell cycle.

Paclitaxel is used for the primary treatment of advanced ovarian cancer (p.670) with cisplatin or carboplatin, and for secondary treatment. In the treatment of node-positive breast cancer (p.661), paclitaxel is used for primary adjuvant therapy after anthracycline-containing chemotherapy. In locally advanced or metastatic breast cancer, it is used first-line with an anthracycline, or as a second-line single-agent, usually after failure of anthracycline-based therapy. In patients with metastatic disease who overexpress HER2 (human epidermal growth receptor 2) it may be used with trastuzumab as initial therapy. Paclitaxel is used with cisplatin or carboplatin, for the primary treatment of advanced non-small cell lung cancer (p.668). It may be used for the second-line treatment of AIDS-related Kaposi's sarcoma (p.675), and has been tried in other neoplasms including cancers of the head and neck, and relapsed germ-cell tumours.

The recommended dose for the primary treatment of **ovarian cancer** is 135 mg/m^2 infused over 24 hours, followed by cisplatin, and repeated at 3-week intervals. Alternatively 175 mg/m^2 may be infused over 3 hours, followed by cisplatin, every 3 weeks. For the secondary treatment of ovarian cancer, the suggested dose as a single agent is 135 or 175 mg/m^2 infused over 3 hours once every 3 weeks.

For **breast cancer**, a dose of paclitaxel 175 mg/m^2 infused over 3 hours once every 3 weeks is recommended for adjuvant treatment (for 4 courses), for second-line monotherapy, and for first-line treatment with trastuzumab; paclitaxel is given the day after the first dose of trastuzumab, or immediately after subsequent doses if well-tolerated. When used first-line with doxorubicin, paclitaxel 220 mg/m^2 is infused over 3 hours once every 3 weeks; the dose is given 24 hours after doxorubicin.

In **non-small cell lung cancer**, the recommended dose is 135 mg/m^2 over 24 hours or 175 mg/m^2 over 3 hours, followed by cisplatin, and repeated at 3-week intervals.

A dose of 135 mg/m^2 over 3 hours once every 3 weeks has been suggested for AIDS-related **Kaposi's sarcoma**. Alternatively, 100 mg/m^2 over 3 hours every 2 weeks may be given, especially in patients with poor performance status.

Regular blood counts should be performed, and dosage should not be repeated until the neutrophil and platelet counts are at acceptable levels; the neutrophil count should be above 1000 cells/mm^3 in patients with AIDS (see also Bone-marrow Depression, p.639). The dose should be reduced by 20% in subsequent courses in patients who have severe neutropenia or peripheral neuropathy. Patients should be pretreated with corticosteroids, antihistamines, and histamine H_2-antagonists. The dose of paclitaxel may need to be reduced in patients with hepatic impairment (see below).

Various formulations have been developed to avoid the use of polyoxyl castor oil and improve the efficacy and safety of paclitaxel. An injectable suspension of albumin-bound paclitaxel nanoparticles (*Abraxane; Abraxis, USA*; ABI-007) is available for the treatment of refractory or relapsed breast cancer. The dose is 260 mg/m^2 given intravenously over 30 minutes every 3 weeks. Other formulations in development include paclitaxel linked to docosahexaenoic acid or biodegradable polymers (such as paclitaxel poliglumex), micellar and liposomal formulations, and an oral dosage form. An injectable vitamin E-based emulsion of paclitaxel has been investigated for the treatment of urothelial cancer and metastatic breast cancer.

Paclitaxel-releasing stents may be used to reduce restenosis after coronary artery stent placement.

Administration. Although many of the original studies of paclitaxel employed a 24-hour infusion regimen, the use of *3-hour infusions* has subsequently become widespread. A systematic review[1] noted that although it was difficult to compare efficacy in studies of unlike malignancies there was no conclusive evidence of a difference in effectiveness with differing length of infusion; however, there were differences in the adverse effect profile, neutropenia being much less marked with the shorter infusion, although neurotoxic effects were reduced with 24-hour administration.

There has also been considerable interest in evaluating the use of paclitaxel in reduced-dose *weekly* schedules.[2-12] Various dosage regimens have been tried: most have found that doses of between 50 and about 100 mg/m^2 weekly, usually by infusion over 1 hour rather than a conventional 3-hour infusion, can be given with relatively modest toxicity. Although higher doses have been tried, neurotoxicity and myelosuppression become problematic and tend to limit dose intensity. A number of studies have addressed the combination of weekly paclitaxel with other antineoplastics, for example with trastuzumab in breast cancer, estramustine in prostate cancer, and with platinum compounds or gemcitabine in other solid tumours such as those of the ovary or lung. Weekly paclitaxel is also under investigation in combination with radiotherapy in the management of lung cancer and glioblastoma multiforme.

Administration in hepatic impairment. The US licensed product information makes recommendations for initial dosage adjustment of some paclitaxel regimens in patients with hepatic impairment, according to transaminase and bilirubin concentrations. They suggest paclitaxel should not be given if transaminase values are more than 10 times normal upper limits, or if bilirubin is more than 75 micrograms/mL or 5 times the normal upper limit.

Reperfusion and revascularisation procedures. Restenosis is a particular problem after percutaneous coronary revascularisation procedures (p.1181) and various drugs have been tried for its prevention. Coronary stents that elute paclitaxel effectively reduce restenosis and have been widely used, although there is some suggestion that sirolimus-eluting stents may be superior to paclitaxel-eluting stents in terms of clinical outcome and rates of restenosis.[1-3] In a study compared with bare metal stents, paclitaxel-releasing stents reduced the risk of restenosis and the need for repeat revascularisation procedures, although the follow-up rates of death from cardiac causes or myocardial infarction were not significantly reduced at 9 months[4] and 1 year.[5] However, between 9 months and 1 year, major cardiac adverse events were significantly reduced in the paclitaxel-releasing stent group compared to controls.[5] A review[6] of various stent designs concluded that safety of paclitaxel-releasing stents was independent of design, dose-density, or presence or absence of a polymer carrier system; however, those without a polymer carrier were unable to show a positive effect on clinical outcome in patients with de novo coronary lesions. However, in a paclitaxel-releasing stent system, failure of the stent-delivery balloon to deflate has been associated with serious injuries and 1 fatality.[7] The risk of late stent thrombosis may also be increased with drug eluting stents,[8] although the evidence is controversial,[9] and their role in complex interventions is not yet established.[10,11]

Positive effects on restenosis have also been reported[12] with use of a paclitaxel-coated angioplasty balloon.

Panitumumab *(USAN, rINN)*

ABX-EGF; E7.6.3; Panitumumabum. Immunoglobulin, anti-(human epidermal growth factor receptor) (human monoclonal ABX-EGF heavy chain), disulfide with human monoclonal ABX-EGF light chain, dimer.

Панитумумаб

CAS — 339177-26-3.

ATC — L01XC08.

ATC Vet — QL01XC08.

Adverse Effects, Treatment, and Precautions

As for Cetuximab, p.695, although the use of premedication for prevention of infusion reactions with panitumumab has not been standardised. The infusion rate should be reduced by 50% in patients who have mild to moderate infusion reactions; if a severe reaction occurs, immediate and permanent discontinuation is recommended. In patients who developed skin reactions, infectious complications including abscesses and sepsis, in some cases fatal, have been reported.

Interactions

Use of panitumumab with combination chemotherapy is not recommended. A high incidence of severe diarrhoea occurred in patients given panitumumab with fluorouracil, folinic acid, and irinotecan. Increased risk of death occurred when panitumumab was given with bevacizumab.

Pharmacokinetics

The pharmacokinetics of panitumumab are reported to be non-linear. Steady-state concentrations were reached by the third infusion with the recommended dose regimen. The elimination half-life was about 7.5 days.

Uses and Administration

Panitumumab is a recombinant human monoclonal antibody that binds to the epidermal growth factor receptor (EGFR). It is used in the treatment of EGFR-expressing metastatic colorectal cancer (p.665) in patients with disease progression after fluoropyrimidine-, oxaliplatin-, or irinotecan-containing regimens. In some countries it is licensed only in patients whose tumour contains a non-mutated *KRAS* gene (Kirsten rat sarcoma 2 viral oncogene homologue), which plays a role in cell growth regulation and angiogenesis; mutations in the *KRAS* gene occur frequently in various human tumours and are implicated in oncogenesis and tumour progression.

The recommended dose is 6 mg/kg given as an intravenous infusion every 14 days. Doses up to and including 1 g are given in 100 mL sodium chloride 0.9% over 60 minutes whereas doses above 1 g are diluted in 150 mL and given over 90 minutes; the final concentration of the infusion should not exceed 10 mg/mL. The infusion should be given via an infusion pump using a low-protein-binding 0.2 or 0.22 micrometre in-line filter. It may be given through a peripheral line or indwelling catheter; the line should be flushed with sodium chloride 0.9% before and after giving panitumumab. The infusion rate should be reduced by 50% in patients who have a mild to moderate infusion reaction, and stopped immediately and permanently if a severe reaction occurs.

Panitumumab should be withheld if severe dermatological toxicity develops, and permanently stopped if toxicity does not improve within 1 month. If toxicity improves after withholding no more than 2 doses of panitumumab, treatment may be restarted at half the original dose. If toxicity recurs, therapy should be permanently stopped. If toxicity does not recur, subsequent doses may be increased in increments of 25% until the recommended dose of 6 mg/kg is reached.

Preparations

Proprietary Preparations (details are given in Part 3)

Cz.: Vectibix; ***Port.:*** Vectibix; ***UK:*** Vectibix; ***USA:*** Vectibix.

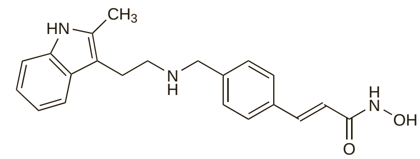
Panobinostat *(rINN)*

Panobinostatum. (2*E*)-*N*-Hydroxy-3-[4-({[2-(2-methyl-1*H*-indol-3-yl)ethyl]amino}methyl)phenyl]prop-2-enamide.

Панобиностат

$C_{21}H_{23}N_3O_2$ = 349.4.

CAS — 404950-80-7.



Profile

Panobinostat is a histone deacetylase inhibitor that is under investigation as an antineoplastic for the treatment of cutaneous T-cell lymphoma.

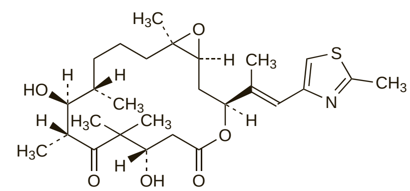
Patupilone *(rINN)*

EPO-906; Epothilone B; Patupilona; Patupilonum. (1*S*,3*S*,7*S*,10*R*,11*S*,12*S*,16*R*)-7,11-Dihydroxy-8,8,10,12,16-pentamethyl-3-[(1*E*)-1-(2-methyl-1,3-thiazol-4-yl)prop-1-en-2-yl]-4,17-dioxabicyclo[14.1.0]heptadecane-5,9-dione.

Патупильон

$C_{27}H_{41}NO_6S$ = 507.7.

CAS — 152044-54-7.



Profile

Patupilone is a metabolite isolated from the bacterium *Sorangium cellulosum*, with microtubule stabilising activity similar to that of the taxanes. It is under investigation as an antineoplastic for the treatment of ovarian cancer.

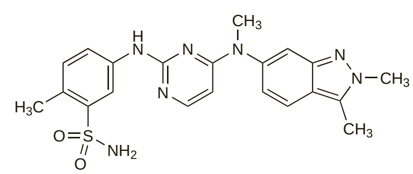
Pazopanib Hydrochloride *(USAN, rINNM)*

GW-786034B; Hidrocloruro de pazopanib; Pazopanib, Chlorhydrate de; Pazopanibi Hydrochloridum. 5-({4-[(2,3-Dimethyl-2*H*-indazol-6-yl)methylamino]pyrimidin-2-yl}amino)-2-methylbenzenesulfonamide hydrochloride.

Пазопаниба Гидрохлорид

$C_{21}H_{23}N_7O_2S,HCl$ = 474.0.

CAS — 444731-52-6 (pazopanib); 635702-64-6 (pazopanib hydrochloride).



(pazopanib)

Profile

Pazopanib hydrochloride is an inhibitor of tyrosine kinase associated with the epidermal growth factor receptor. It is under investigation for the treatment of renal cell carcinoma.

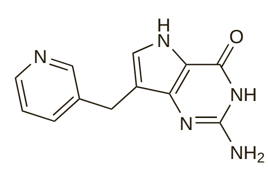
Peldesine *(USAN, pINN)*

BCX-34; Peldesina; Peldésine; Peldesinum. 2-Amino-3,5-dihydro-7-(3-pyridylmethyl)-4*H*-pyrrolo[3,2-*d*]pyrimidin-4-one.

Пельдезин

$C_{12}H_{11}N_5O$ = 241.2.

CAS — 133432-71-0.



Profile

Peldesine is an inhibitor of the enzyme purine nucleoside phosphorylase and is reported to suppress T-cell proliferation. It has been investigated in the management of cutaneous T-cell lymphomas, and has also been tried topically in psoriasis and some T-cell mediated eye disorders.

Pemetrexed Disodium

(BANM, USAN, rINNM)

LY-231514 (pemetrexed or pemetrexed disodium); MTA; Multitargeted Antifolate; Pemetreksed Disodyum; Pemetrexed disódico; Pémétrexed Disodique; Pemetrexedum Dinatricum. Disodium *N*-{*p*-[2-(2-amino-4,7-dihydro-4-oxo-1*H*-pyrrolo[2,3-*d*]pyrimidin-5-yl)ethyl]benzoyl}-L-glutamate.

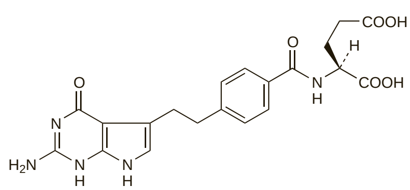
Динатрий Пеметрексед

$C_{20}H_{19}N_5Na_2O_6$ = 471.4.

CAS — 137281-23-3 (pemetrexed); 150399-23-8 (pemetrexed disodium).

ATC — L01BA04.

ATC Vet — QL01BA04.



(pemetrexed)

NOTE. In practice, pemetrexed is given as the disodium heptahydrate ($C_{20}H_{19}N_5Na_2O_6$,$7H_2O$ = 597.5).

Incompatibility. Licensed product information states that pemetrexed is physically incompatible with diluents containing calcium, including Ringer's solution and lactated Ringer's solution. A study[1] found pemetrexed disodium 20 mg/mL to be physically incompatible with 24 drugs resulting in precipitation or colour change during simulated Y-site administration. These drugs include amphotericin B, some cephalosporin and cephamycin antibacterials, chlorpromazine hydrochloride, ciprofloxacin, dobutamine hydrochloride, doxorubicin hydrochloride, doxycycline hyclate, droperidol, gemcitabine hydrochloride, gentamicin sulfate, irinotecan hydrochloride, metronidazole, minocycline hydrochloride, mitoxantrone hydrochloride, nalbuphine hydrochloride, ondansetron hydrochloride, prochlorperazine edisilate, tobramycin sulfate, and topotecan hydrochloride.

1. Trissel LA, *et al.* Physical compatibility of pemetrexed disodium with other drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 2004; **61:** 2289–93.

Stability. Licensed product information states that pemetrexed is chemically and physically stable, once reconstituted and diluted, for 24 hours either refrigerated at 2° to 8° or at 25°; from a microbiological point of view, solutions should be used immediately, unless prepared under controlled and validated aseptic conditions.

Pemetrexed, reconstituted in polypropylene syringes with sodium chloride 0.9% to a concentration of 25 mg/mL, was found to be both chemically and physically stable for 2 days when stored at room temperature, and for 31 days when refrigerated.[1] Although pemetrexed solutions of 2, 10, and 20 mg/mL in glucose 5% and sodium chloride 0.9% in PVC bags were chemically stable for 90 days when frozen at −20°, microparticulates formed, possibly related to the PVC containers. Pemetrexed solutions should therefore not be frozen.[2]

2. Zhang Y, Trissel LA. Physical instability of frozen pemetrexed solutions in PVC bags. *Ann Pharmacother* 2006; **40:** 1289–92.

Adverse Effects, Treatment, and Precautions

As for Raltitrexed, p.766.

Pemetrexed may also cause fatigue, stomatitis, pharyngitis, dyspnoea, chest pain, and neuropathy. Rare cases of hepatitis, colitis, and intestinal pneumonitis have occurred; fatalities have been reported. Serious renal events, including acute renal failure, have been reported with pemetrexed when it was used either alone or with other cytotoxic drugs; most patients had underlying risk factors such as dehydration, hypertension, or diabetes. Cardiovascular events, including myocardial infarction and cerebrovascular events, have occurred rarely, usually when pemetrexed was used with other cytotoxic drugs. Cases of radiation pneumonitis and radiation recall have been reported in patients treated with radiotherapy. Hypersensitivity reactions may occur.

Complete blood cell counts should be monitored, and folate and vitamin B_{12} are given as prophylaxis against haematological and gastrointestinal toxicity during pemetrexed therapy. Pre-treatment with a corticosteroid, such as oral dexamethasone, reduces the incidence and severity of skin reactions.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

High doses of NSAIDs and aspirin may decrease pemetrexed elimination. In patients with mild to moderate renal impairment (creatinine clearance 45 to 79 mL/minute) high doses of NSAIDs and aspirin should be avoided from 2 days before until 2 days after pemetrexed use, and NSAIDs that have longer half-lives, such as piroxicam, should be avoided from 5 days before until 2 days after pemetrexed.

Analgesics. Enteric-coated *aspirin* 325 mg given orally every 6 hours for a total of 9 doses before pemetrexed, did not affect the pharmacokinetic profile of pemetrexed in an interaction study; the authors considered no dose adjustment necessary when moderate doses of aspirin were given with pemetrexed. However, this result could not be extrapolated to high-dose aspirin regimens, as the interaction might be dependent on salicylate concentrations. In contrast, oral *ibuprofen* 400 mg every 6 hours for a total of 9 doses before pemetrexed significantly reduced systemic pemetrexed clearance. Despite an increase in pemetrexed exposure, no increase in toxicity was seen. Dose adjustments were not considered necessary in patients with normal renal function (defined as creatinine clearance of 80 mL/minute or greater). However, in patients with pre-existing reduced pemetrexed clearance due to renal impairment, giving ibuprofen may result in further increases in pemetrexed exposure; the authors advised caution when using these 2 drugs together in patients with a creatinine clearance of less than 80 mL/minute.[1] For licensed drug information regarding the use of aspirin and NSAIDs with pemetrexed, see above.

1. Sweeney CJ, *et al.* Two drug interaction studies evaluating the pharmacokinetics and toxicity of pemetrexed when coadministered with aspirin or ibuprofen in patients with advanced cancer. *Clin Cancer Res* 2006; **12:** 536–42.

Pharmacokinetics

Pemetrexed has a plasma elimination half-life of 3.5 hours in patients with normal renal function. *In-vitro* data indicate that pemetrexed is about 81% bound to plasma proteins. It undergoes limited hepatic metabolism, and about 70 to 90% of a dose is eliminated unchanged in the urine within 24 hours.

Uses and Administration

Pemetrexed is primarily a thymidylate synthase inhibitor like raltitrexed (p.766), but it also inhibits other folate-dependent enzymes involved in purine synthesis such as dihydrofolate reductase and glycinamide ribonucleotide formyltransferase. It is used as second-line monotherapy or first-line with cisplatin in the treatment of locally advanced or metastatic non-small cell lung cancer (p.668). It is also used with cisplatin in the first-line treatment of unresectable malignant pleural mesothelioma (p.669).

Pemetrexed is given as the disodium heptahydrate but doses are expressed in terms of the base: pemetrexed disodium heptahydrate 1.4 g is equivalent to about 1 g of pemetrexed. A dose of pemetrexed 500 mg/m^2 is given by intravenous infusion over 10 minutes. The dose may be repeated in 21-day cycles, and should be adjusted according to toxicity. In combination therapy, cisplatin is given about 30 minutes after the end of pemetrexed infusion.

Pre-treatment with oral dexamethasone 4 mg twice daily for 3 days is recommended, starting the day before pemetrexed. At least 5 doses of oral folic acid (350 micrograms to 1 mg) should be taken during the 7 days before the first dose of pemetrexed; dosing should continue throughout pemetrexed therapy, and for 21 days after the last pemetrexed dose. Patients should also receive an intramuscular injection of vitamin B_{12} 1 mg in the week before the first pemetrexed dose, and once every 3 cycles thereafter; subsequent injections may be given on the same day as pemetrexed.

Pemetrexed is under investigation as an antifolate antimetabolite in the treatment of colon, pancreatic, breast, and head and neck cancer.

Administration in renal impairment. A pharmacokinetic study[1] found that pemetrexed clearance decreased with declining renal function. Although systemic exposure increased in these patients, this was not associated with an increase in drug-related dose-limiting toxicities for patients with a GFR of 40 mL/minute or more and receiving vitamin supplementation (folic acid and vitamin B_{12} supplementation appears to reduce toxicity without altering pemetrexed pharmacokinetics). Patients with a GFR of 80 mL/minute or more tolerated a dose of pemetrexed 600 mg/m^2, given intravenously every 3 weeks, whereas patients with a GFR of 40 to 79 mL/minute tolerated 500 mg/m^2 every 3 weeks. One patient with a GFR of 19 mL/minute died as a result of treatment-related toxicity and accrual into this group was stopped. As a result, no data were available for patients with a GFR below 40 mL/minute.

Licensed product information states that no dose adjustment is necessary in patients with a creatinine clearance (CC) of 45 mL/minute or more. Use in patients with a CC of less than 45 mL/minute is not recommended due to lack of data. Caution is advised when giving pemetrexed with NSAIDs in patients whose CC is less than 80 mL/minute (see Interactions, above).

Pemtumomab

Profile

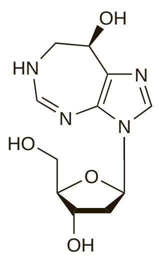
Pemtumomab is a radiolabelled monoclonal antibody of murine origin that binds to muc-1, an epithelial cell surface protein on tumour cells. It has been investigated for the treatment of various cancers, including ovarian and gastric cancers, but results have been disappointing.

Pentostatin *(BAN, USAN, rINN)*

CI-825; Covidarabine; Co-vidarabine; Deoxycoformycin; 2′-Deoxycoformycin; NSC-218321; PD-81565; Pentostatina; Pentostatine; Pentostatinum. (*R*)-3-(2-Deoxy-β-D-*erythro*-pentofuranosyl)-3,6,7,8-tetrahydroimidazo[4,5-*d*][1,3]diazepin-8-ol; 1,2-Dideoxy-1-[(*R*)-3,6,7,8-tetrahydro-8-hydroxyimidazo[4,5-*d*][1,3]-diazepin-3-yl]-D-*erythro*-pentofuranose.

Пентостатин

$C_{11}H_{16}N_4O_4$ = 268.3.
CAS — 53910-25-1.
ATC — L01XX08.
ATC Vet — QL01XX08.



Adverse Effects and Precautions

The most common adverse effects in patients receiving pentostatin include myelosuppression (and in particular suppression of CD4+ lymphocyte subset), headache, abdominal pain, fever and chills, gastrointestinal disturbances (notably diarrhoea and nausea and vomiting), hypersensitivity reactions, and hepatotoxicity. Central neurotoxicity may be manifest as tiredness, anxiety, depression, sleep disturbances, and paraesthesias: treatment should be withheld or stopped in such patients. Impaired renal function and pulmonary toxicity (cough, dyspnoea, and pneumonia) may occur. Severe toxicity in early studies, affecting mainly the CNS, kidneys, liver, and lungs, was associated with the use of doses higher than those currently recommended and produced some fatalities.

Other adverse effects reported with pentostatin include dry skin and rashes (sometimes severe and worsening with continued treatment), pruritus, conjunctivitis, alopecia, arthralgia and myalgia, peripheral oedema, thrombophlebitis, and cardiovascular disorders including arrhythmias, angina pectoris, and heart failure.

Pentostatin should not be given to patients with impaired renal function, or in active infection. It is teratogenic in *animals* and potentially genotoxic: it is therefore contra-indicated in pregnancy and men receiving pentostatin should not father children for 6 months after therapy.

Interactions

Pentostatin should not be given with fludarabine, as the combination may increase pulmonary toxicity. A similar increase in toxicity is expected when pentostatin is used with vidarabine.

Use of pentostatin with carmustine, etoposide and high-dose cyclophosphamide, has produced acute pulmonary oedema and hypotension, leading to death. Pentostatin should therefore not be given with high-dose cyclophosphamide.

Allopurinol. Fatal acute necrotising arteritis developed in a patient given pentostatin and allopurinol.[1] Although the hypersensitivity vasculitis may have been due to allopurinol alone there is circumstantial evidence to suggest that pentostatin may predispose patients to drug hypersensitivity and it may be wise to avoid this combination, and to observe pentostatin-treated patients closely for allergic manifestations.

1. Steinmetz JC, *et al.* Hypersensitivity vasculitis associated with 2-deoxycoformycin and allopurinol therapy. *Am J Med* 1989; **86:** 498–9.

Pharmacokinetics

After intravenous injection, pentostatin has an elimination half-life of about 6 hours. Approximately 90% of a dose is excreted in the urine as unchanged drug and metabolites. Pentostatin crosses the blood-brain barrier and can be measured in the CSF.

Uses and Administration

Pentostatin is a potent inhibitor of the enzyme adenosine deaminase and probably exerts its cytotoxic actions through the interruption of normal purine metabolism and DNA synthesis. Lymphocytes are particularly sensitive to its actions.

Pentostatin is used as a single agent in the treatment of hairy-cell leukaemia (p.654), in usual doses of 4 mg/m^2 every other week. The dose is given as an intravenous bolus injection, or as an infusion over 20 to 30 minutes. Hydration with 500 mL to 1 litre of glucose 5% in sodium chloride 0.18 or 0.9%, or equivalent, is recommended beforehand; a further 500 mL of the hydration solution should be infused once the drug has been given.

Pentostatin has been tried in cutaneous T-cell lymphomas (see Mycosis Fungoides, p.657) and histiocytic syndromes (p.650). It is also under investigation in some other lymphoid malignancies, including chronic lymphocytic leukaemia (p.653) and non-Hodgkin's lymphomas (p.656) and for the management of chronic graft-versus-host disease following haematopoietic stem cell transplantation (p.1811).

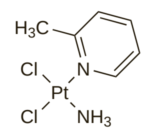
Picoplatin *(BAN, USAN, rINN)*

AMD-473; NX-473; Picoplatine; Picoplatino; Picoplatinum; ZD-0473. *cis*-Amminedichloro(2-methylpyridine)platinum(II).

Пикоплатин

$C_6H_{10}Cl_2N_2Pt$ = 376.1.
CAS — 181630-15-9.



Profile

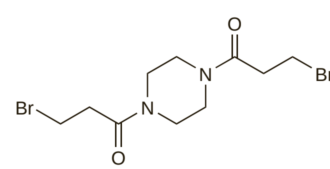
Picoplatin is a platinum derivative that is under investigation as an intravenous antineoplastic for the treatment of small-cell lung cancer. It is also under investigation for the treatment of colorectal cancer and prostate cancer. An oral dosage form is also being developed.

Pipobroman *(USAN, pINN)*

A-8103; NSC-25154; Pipobromán; Pipobromanum. 1,4-Bis(3-bromopropionyl)piperazine.

Пипоброман

$C_{10}H_{16}Br_2N_2O_2$ = 356.1.
CAS — 54-91-1.
ATC — L01AX02.
ATC Vet — QL01AX02.



Profile

Pipobroman is an antineoplastic which appears to act by alkylation. It may be used in the treatment of polycythaemia vera (p.654), in patients requiring myelosuppressive therapy, and in refractory chronic myeloid leukaemia (p.653).

The usual initial dose for polycythaemia vera is 1 mg/kg daily, given orally, and increased to 3 mg/kg, if necessary, according to response. Maintenance dosage is 100 to 200 micrograms/kg daily.

The main adverse effect is moderate bone-marrow depression, which may develop 4 weeks or more from starting treatment. Anaemia may be marked at higher doses and is usually accompanied by leucopenia. Thrombocytopenia and haemolysis have occurred. In the initial stages of treatment, white cell and platelet counts should be determined on alternate days and complete blood counts once or twice weekly. Dosage should be stopped if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p.639).

The symbol † denotes a preparation no longer actively marketed

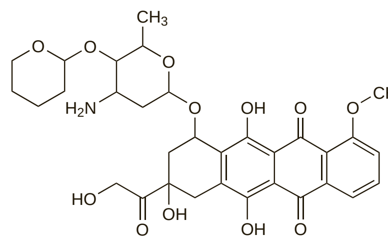
Pirarubicin *(rINN)*

Pirarubicina; Pirarubicine; Pirarubicinum; 1609-RB; Tepirubicin; THP-ADM; THP-doxorubicin. (8*S*,10*S*)-10-{[3-Amino-2,3,6-trideoxy-4-*O*-(2*R*-tetrahydro-2*H*-pyran-2-yl)-α-L-*lyxo*-hexopyranosyl]oxy}-8-glycoloyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxy-5,12-naphthacenedione.

Пирарубицин

$C_{32}H_{37}NO_{12}$ = 627.6.
CAS — 72496-41-4.
ATC — L01DB08.
ATC Vet — QL01DB08.



Pharmacopoeias. In *Jpn.*

Profile

Pirarubicin is an antineoplastic anthracycline antibiotic that is a structural analogue of doxorubicin (p.712), and has similar properties. It is used in the management of breast cancer and has also been tried in other solid neoplasms, acute leukaemias and lymphomas.

Pirarubicin is formulated as the hydrochloride but doses are in terms of the base. A usual dose of 25 to 50 mg/m^2 every 3 to 4 weeks has been recommended in breast cancer, but other dosage regimens have been used. Doses may be given by intravenous injection over 5 to 10 minutes into a rapidly-flowing intravenous infusion of glucose 5%. Patients should undergo regular blood counts and monitoring of cardiac function: at cumulative doses above 600 mg/m^2 ventricular ejection fraction should be checked before each course. Pirarubicin has also been given by the intra-arterial and intravesical routes.

Preparations

Proprietary Preparations (details are given in Part 3)

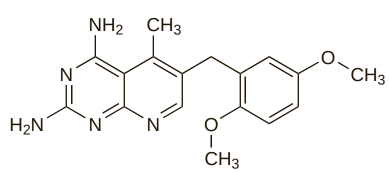
Piritrexim Isetionate *(rINNM)*

BW-301U (piritrexim); Isetionato de piritrexima; NSC-351521; Piritrexim Isethionate *(USAN)*; Piritrexime, Isétionate de; Piritreximi Isetionas. 2,4-Diamino-6-(2,5-dimethoxybenzyl)-5-methylpyrido[2,3-*d*]pyrimidine mono(2-hydroxyethanesulphonate).

Пиритрексима Изетионат

$C_{17}H_{19}N_5O_2,C_2H_6O_4S$ = 451.5.
CAS — 72732-56-0 (piritrexim); 79483-69-5 (piritrexim isetionate).



(piritrexim)

Profile

Piritrexim is a folate antagonist with general properties similar to those of methotrexate (p.745). It has been tried by mouth for its antineoplastic properties, and has also been used (as the isetionate) for the treatment of opportunistic infections in immunosuppressed patients. Myelosuppression, gastrointestinal disturbances, and hepatotoxicity have been reported.

Piritrexim isetionate has also been investigated for severe psoriasis.

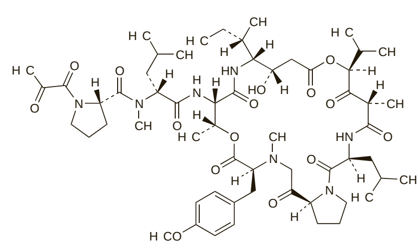
Плитидепсин

$C_{57}H_{87}N_7O_{15}$ = 1110.3.
CAS — 137219-37-5.



Profile

Plitidepsin is an antineoplastic isolated from the marine tunicate *Aplidium albicans*. It is under investigation in the treatment of acute lymphoblastic leukaemia, multiple myeloma, and solid tumours.

Porfimer Sodium *(BAN, USAN, rINN)*

CL-184116; Dihaematoporphyrin Ether; Porfimeerinatrium; Porfimère Sodique; Porfimernatrium; Porfímero sódico; Porfimerum Natricum.

Порфимер Натрий

CAS — 87806-31-3.
ATC — L01XD01.
ATC Vet — QL01XD01.

Adverse Effects and Precautions

Photosensitivity occurs in all patients treated with porfimer sodium. This effect is likely to be prolonged, and patients should avoid sunlight or bright indoor light for at least 30 days. However, exposure to ambient indoor light is encouraged, as it allows gradual inactivation of any remaining drug. Other reported adverse effects include local inflammation, chest pain, respiratory insufficiency or distress (including dyspnoea), abdominal pain, dysphagia, constipation, nausea and vomiting, fever, tachycardia and atrial fibrillation, pleural effusion, mucositis, and anaemia due to tumour bleeding. Pneumonia and bronchitis may occur. Anxiety and insomnia have also been reported. Photodynamic therapy with porfimer sodium is contra-indicated in patients with severe hepatic impairment, oesophageal fistulae, erosion of major blood vessels, or severe acute respiratory distress. Sufficient time should be allowed between photodynamic therapy and radiotherapy to allow inflammatory reactions from either treatment to subside.

Porphyria. The use of porfimer sodium is contra-indicated in patients with porphyria.

Interactions

Use of porfimer sodium with other drugs causing photosensitivity should be avoided as the reaction may be increased.

Pharmacokinetics

Porfimer sodium is distributed and eliminated slowly after intravenous injection, with plasma elimination half-life reported to be between 11 and 28 days. *In vitro* studies indicate that plasma protein binding is about 90%. Excretion occurs primarily via the faeces.

Uses and Administration

Porfimer sodium is a haematoporphyrin derivative that reportedly accumulates in malignant tissue on injection. It is then activated by laser light to release oxygen radicals within malignant cells, producing cytotoxicity. Porfimer sodium is used as a photosensitiser in the photodynamic therapy of non-small cell lung cancer (p.668), oesophageal cancer (p.664), and superficial bladder cancer (p.659). It is also used for the treatment of dysplasia associated with Barrett's oesophagus (see Gastro-oesophageal Reflux Disease, p.1696), and has been investigated in various other neoplasms, including tumours of the gastrointestinal tract and cervix.

Porfimer sodium should be reconstituted with glucose 5% to a final concentration of 2.5 mg/mL. It is given by slow intravenous injection at a dose of 2 mg/kg. This is followed, 40 to 50 hours later, by activation using a laser tuned to a wavelength of 630 nanometres and delivered to the area of the tumour using a fibre optic guide. Residual tumour may subsequently be debrided surgically. A second laser treatment may be given 96 to 120 hours after the original injection. A maximum of 3 courses of photodynamic therapy may be used, with each injection separated by a minimum of 30 days for oesophageal and endobronchial tumours, and a minimum of 90 days for dysplasia in Barrett's oesophagus. However, in the treatment of superficial bladder cancer, only one dose of drug and light is given due to an increased risk of bladder contracture, and no surgical debridement is performed.

Photodynamic therapy. Photodynamic therapy probably has the greatest potential of the various forms of light-activated treatment.[1] Photosensitising drugs are given intravenously, orally, or topically, and are selectively retained by tumour cells. When exposed to the correct wavelength of light the drug produces toxic oxygen radicals that destroy cell membranes and thereby kill the tumour cells. Vascular damage and immune-mediated injury may also occur.[2,3] Tumour cells must have an adequate supply of oxygen to be sensitive to photodynamic therapy,[2] and as light penetration is usually limited, early or superficial malignant lesions respond best to therapy.[1,2] Photodynamic therapy has been tried in skin, gastrointestinal, head and neck, bladder, gynaecological, pancreatic, pulmonary, and various intraperitoneal malignancies[2-11] It is also used for the treatment of Barrett's oesophagus[11-13] and for the treatment of age-related macular degeneration (p.785); it has been tried for other ocular disorders.[14] There is also an interesting report of cytotoxicity against leukaemic cells *in vitro* when exposure to porfimer sodium was combined with ultrasound.[5]

The main adverse effect of photosensitisers such as porfimer is photosensitivity lasting 4 to 8 weeks; patients should be advised to avoid sunlight during this period and therapy is best delayed until the darker winter months if possible.[1] Newer photosensitisers are being developed to show increased tissue penetration and less prolonged photosensitivity.[2] The natural haem precursor 5-aminolevulinic acid (p.679) has the advantage that photosensitivity lasts only a few hours.

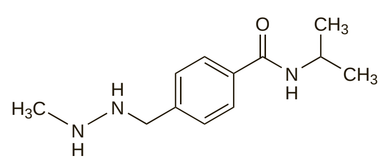
ATC Vet — QL01XB01.



(procarbazine)

Pharmacopoeias. In *Chin.*, *Int.*, *Jpn*, and *US.*

USP 31 (Procarbazine Hydrochloride). Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The most common adverse effects associated with procarbazine are gastrointestinal disturbances such as anorexia, nausea and vomiting (although patients may soon become tolerant), and bone-marrow depression. Leucopenia and thrombocytopenia may be delayed with a nadir at about 4 weeks after a dose, and recovery usually within 6 weeks. Anaemia, haemolysis, and bleeding tendencies have been reported.

Neurotoxicity is also common, with central effects such as somnolence, depression, nervousness or confusion, headache, hallucinations, and dizziness, and peripheral neuropathies including paraesthesias and decreased reflexes. Lethargy, ataxia, and sleep disorders have also occurred, and tremors, convulsions, and coma have been reported.

Other adverse effects reported include fever and myalgia, pulmonary fibrosis or pneumonitis, haematuria, urinary frequency, skin reactions including dermatitis, pruritus, and hyperpigmentation, tachycardia, orthostatic hypotension, ocular defects, infertility, and hepatic impairment.

Procarbazine is a carcinogen, mutagen, and teratogen.

Procarbazine should be used with caution in patients with hepatic or renal impairment, and is contra-indicated if impairment is severe. The haematological status of the patient should be determined at least every 3 or 4 days and hepatic and renal function determined weekly. Care is also advisable in patients with phaeochromocytoma, epilepsy, or cardiovascular or cerebrovascular disease. Treatment should be interrupted if allergic skin reactions occur.

Handling and disposal. *Urine* produced for up to 48 hours after a dose of procarbazine should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Procarbazine is a weak MAOI and the possibility of reactions with other drugs and food, although very rare, must be borne in mind—for details of MAOI reactions see p.417. Procarbazine may enhance the sedative effects of other CNS depressants. A disulfiram-like reaction has been reported with alcohol and the effects of antihypertensive agents may be enhanced.

Antiepileptics. Use with enzyme-inducing antiepileptics is associated with an increased risk of hypersensitivity reactions to procarbazine, possibly through a reactive intermediate generated by induction of the cytochrome P450 isoenzyme CYP3A subfamily.[1] Non-enzyme-inducing antiepileptics might be more appropriate in patients with brain tumours in whom procarbazine therapy is anticipated.

1. Lehmann DF, *et al.* Anticonvulsant usage is associated with an increased risk of procarbazine hypersensitivity reactions in patients with brain tumors. *Clin Pharmacol Ther* 1997; **62:** 225–9.

Pharmacokinetics

Procarbazine is readily absorbed from the gastrointestinal tract. It crosses the blood-brain barrier and diffuses into the CSF. A plasma half-life of about 10 minutes has been reported. Procarbazine is rapidly metabolised (mainly in liver and kidneys) and only about 5% is excreted unchanged in the urine. The remainder is oxidised to *N*-isopropylterephthalamic acid and excreted in the urine, up to about 70% of a dose being excreted in 24 hours. Some of the drug is excreted as carbon dioxide and methane via the lungs. During oxidative breakdown in the body hydrogen peroxide is formed which may account for some of the drug's actions.

Uses and Administration

Procarbazine hydrochloride is a methylhydrazine derivative whose antineoplastic effect, although not fully understood, may resemble that of the alkylating agents; it appears to inhibit protein and nucleic acid synthesis and suppress mitosis. It does not exhibit cross-resistance with other cytotoxic drugs.

Its main use is the treatment of Hodgkin's disease (p.655) when it is usually given with other drugs, as in the MOPP regimen (with chlormethine, vincristine, and prednisone) and its variants. Procarbazine has also been used in the treatment of other lymphomas (p.656) and in some other malignant neoplasms including tumours of the brain (p.660).

Doses of procarbazine hydrochloride are calculated in terms of procarbazine; procarbazine hydrochloride 116 mg is equivalent to about 100 mg of procarbazine. In many of the combination regimens it has been given orally to adults and children in doses of the equivalent of procarbazine 100 mg/m^2 for 10 to 14 days of each 4- or 6-week cycle. If used as a single agent in adults a dose equivalent to 50 mg of procarbazine daily, increased by 50 mg daily to 250 to 300 mg daily in divided doses has been suggested in the UK, while in the USA the recommended regimen is 2 to 4 mg/kg daily for the first week, subsequently increased to 4 to 6 mg/kg daily, doses being given to the nearest 50 mg. These doses are continued until maximum response is achieved or leucopenia, thrombocytopenia, or other signs of toxicity ensue. Maintenance doses are usually 50 to 150 mg daily, or 1 to 2 mg/kg, daily, until a cumulative dose of at least 6 g has been given. In children, initial daily doses of the equivalent of 50 mg/m^2 have been suggested in the USA (UK product information simply suggests a dose of 50 mg), increased to 100 mg/m^2 and then adjusted according to response.

Blood disorders, non-malignant. Chemotherapy with regimens including procarbazine has been used in a few patients with refractory idiopathic thrombocytopenic purpura (p.1505), and has produced prolonged remission although in most cases of the disease such aggressive therapy is difficult to justify.

Raltitrexed *(BAN, USAN, rINN)*

D-1694; ICI-D1694; Raltitreksed; Raltitreksedi; Raltitrexedum; ZD-1694. *N*-{5-[3,4-Dihydro-2-methyl-4-oxoquinazolin-6-ylmethyl(methyl)amino]-2-thenoyl}-L-glutamic acid.

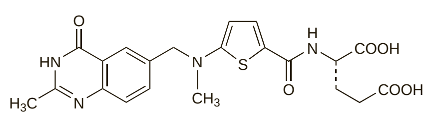
Ралтитрексед

$C_{21}H_{22}N_4O_6S$ = 458.5.

CAS — 112887-68-0.

ATC — L01BA03.

ATC Vet — QL01BA03.



Adverse Effects, Treatment, and Precautions

Raltitrexed produces bone marrow depression, usually mild to moderate, with leucopenia, anaemia, and, less frequently, thrombocytopenia. The nadir of the white cell count usually occurs 7 to 14 days after a dose, with recovery by the third week. Gastrointestinal toxicity is also common, with nausea and vomiting, diarrhoea, and anorexia: mucositis may occur. Reversible increases in liver enzyme values have occurred. Other adverse effects include weakness and malaise, fever, pain, headache, skin rashes, desquamation, arthralgia, muscle cramps, weight loss, dehydration, peripheral oedema, alopecia, increased sweating, taste disturbance, and conjunctivitis. The use of folinic acid 25 mg/m^2 every 6 hours intravenously has been suggested in licensed product information for patients who develop very severe toxicity.

Raltitrexed should be given with care to patients with hepatic impairment and should be avoided if impairment is severe. It should also be avoided in severe renal impairment and be given in reduced doses in moderate impairment. Care is also advisable in debilitated or elderly patients or in patients who have had radiotherapy.

Raltitrexed is teratogenic; pregnancy should be avoided while either partner is receiving the drug and for at least 6 months after treatment. It may impair male fertility.

Toxicity. A large multicentre study comparing raltitrexed with fluorouracil plus folinic acid was suspended in 1999 due to an excess of deaths in the raltitrexed arm.[1] This decision has led to some controversy,[1-3] as in 11 of the 17 deaths in patients taking raltitrexed there was evidence that the dose had not been correctly adjusted to take account of renal function. In addition, and further confusing the issue, the incidence of reported serious adverse effects was lower in raltitrexed-treated patients than in controls. A further study[4] reported an increased rate of raltitrexed-related deaths compared with fluorouracil-based regimens. Almost all of the 18 deaths were caused by gastrointestinal and haematological toxicity, and in 3 of these the dose of raltitrexed had not been adjusted for toxicity.

2. Ford HER, Cunningham D. Safety of raltitrexed. *Lancet* 1999; **354:** 1824–5.
3. Kerr D. Safety of raltitrexed. *Lancet* 1999; **354:** 1825.
4. Maughan TS, *et al.* Comparison of survival, palliation, and quality of life with three chemotherapy regimens in metastatic colorectal cancer: a multicentre randomised trial. *Lancet* 2002; **359:** 1555–63.

Interactions

Raltitrexed should not be given with folic or folinic acid, which may impair its cytotoxic action. (For the deliberate use of folinic acid to counteract the effects of raltitrexed in patients with severe toxicity, see above.)

Pharmacokinetics

After intravenous doses raltitrexed exhibits triphasic pharmacokinetics, with an initial rapid decline from peak plasma concentrations followed by a slow terminal elimination phase. Raltitrexed is actively transported into cells and metabolised to active polyglutamate forms. The remainder of a dose is excreted unchanged, about 50% of a dose appearing in the urine, and about 15% in the faeces. The terminal elimination half-life is about 8 days. Clearance is markedly reduced in renal impairment.

◊ References.

1. Clarke SJ, *et al.* Clinical and preclinical pharmacokinetics of raltitrexed. *Clin Pharmacokinet* 2000; **39:** 429–43.

Uses and Administration

Raltitrexed is a folate analogue that is a potent and specific inhibitor of the enzyme thymidylate synthase, which is involved in the synthesis of DNA. It has been used in the treatment of advanced colorectal cancer (p.665) and has also been tried in breast cancer (p.661) and other solid neoplasms.

The recommended initial dose of raltitrexed in patients with normal renal function is 3 mg/m^2 given by intravenous infusion over 15 minutes. Subsequent doses, which should be reduced by up to 50% depending on the severity of initial toxicity, may be given at intervals of 3 weeks provided toxicity has resolved.

A full blood count should be performed before each dose and treatment withheld if the white cell or platelet counts are below acceptable levels (see also Bone-marrow Depression, p.639). Hepatic and renal function should also be tested. It is essential that doses be adjusted in renal impairment (see below).

Administration in renal impairment. It is essential that doses of raltitrexed be adjusted in renal impairment (creatinine clearance less than 65 mL/minute) as fatalities have been associated with the failure to make such adjustments (see Toxicity, under Adverse Effects, above). The dosage interval should be increased from 3 to 4 weeks and the dose adjusted on the basis of creatinine clearance (CC) as follows:

- CC of 55 to 65 mL/minute, 2.25 mg/m^2
- CC of 25 to 54 mL/minute, 1.5 mg/m^2 (in some countries, adjustment of the dose to a percentage of the full dose equivalent to the value of the CC in mL/minute is suggested in this group, e.g. reduction to 30% in those with a CC of 30 mL/minute, or 40% if CC is 40 mL/minute)
- CC less than 25 mL/minute, treatment contra-indicated

Ranpirnase *(USAN, rINN)*

P-30 Protein; Ranpirnasa; Ranpirnasum.

Ранпирназа

CAS — 196488-72-9.

NOTE. P-30 protein has been incorrectly stated to contain ergotamine.

Profile

Ranpirnase is a ribonuclease reported to have antineoplastic properties. It is under investigation in the treatment of malignant mesothelioma. Ranpirnase has also been investigated in the management of solid tumours. It is also reported to have activity *in vitro* against HIV.

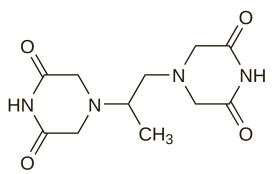
Razoxane *(BAN, rINN)*

ICI-59118; ICRF-159; NSC-129943; Ratsoksaani; Razoxan; Razoxano; Razoxanum. (±)-4,4′-Propylenebis(piperazine-2,6-dione).

Разоксан

$C_{11}H_{16}N_4O_4$ = 268.3.

CAS — 21416-87-5.



Profile

Razoxane is an antineoplastic with inhibitory activity during the pre-mitotic and early mitotic phases of cell growth (G_2-M). It enhances the effects of radiotherapy. It has been used with radiotherapy in the treatment of sarcomas, including Kaposi's sarcoma. Razoxane has also been tried in other malignant diseases including acute leukaemias and non-Hodgkin's lymphomas. However, it is no longer widely used. Razoxane was formerly used in psoriasis, but its carcinogenic properties militate against such use, as discussed below.

In the treatment of sarcomas it has generally been given orally in doses of 125 mg twice daily; higher doses have been given in the management of acute leukaemias and Kaposi's sarcoma. The peripheral blood count should be monitored during treatment.

The principal adverse effects of razoxane include bone-marrow depression, gastrointestinal disturbances, skin reactions, and alopecia. It may enhance the adverse effects of radiotherapy. Razoxane therapy has been associated with the development of secondary malignancies: it is contra-indicated in the treatment of non-malignant conditions.

Dexrazoxane (p.1443) is the (+)-enantiomer of razoxane. It is used to reduce anthracycline-induced cardiotoxicity.

Skin disorders, non-malignant. Razoxane was formerly used in the systemic treatment of psoriasis, and has been found to be extremely effective, with an initial response rate of 97% overall. It was found to be of use in all forms of cutaneous psoriasis and psoriatic arthropathy.[1] However, the development of acute myeloid leukaemias and other malignancies in patients given razoxane[2-5] has led to its being contra-indicated in non-malignant conditions.

Preparations

Proprietary Preparations (details are given in Part 3)
Chile: Cardioxane.

Rituximab *(BAN, USAN, rINN)*

IDEC-102; IDEC-C2B8; Rituksimab; Rituksimabi; Rituximabum. Immunoglobulin G1 (human-mouse monoclonal IDEC-C2B8 γ1-chain anti-human antigen CD 20), disulfide with human-mouse monoclonal IDEC-C2B8 κ-chain, dimer.

Ритуксимаб

CAS — 174722-31-7.

ATC — L01XC02.

ATC Vet — QL01XC02.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Infusion of rituximab has been associated with a cytokine release syndrome of fever, chills, and rigors, usually within 2 hours of beginning therapy (see also below). Other reported symptoms include pruritus, urticaria, rashes, dyspnoea, bronchospasm, angioedema, transient hypotension, and flushing. Asthenia, headache, rhinitis, myalgia, dizziness, and hypertension may also be associated with infusion reactions. Severe cases may be associated with tumour lysis syndrome, acute renal failure, respiratory failure, and death. Hypersensitivity reactions manifest similarly to the cytokine release syndrome, but usually occur within minutes of starting infusion. Mucocutaneous reactions, some fatal, and including Stevens-Johnson syndrome or toxic epidermal necrolysis have also occurred.

Patients with an extensive tumour burden, pulmonary tumour infiltration or pulmonary insufficiency may be at increased risk of severe reactions and should be treated with caution and possibly a decreased initial infusion rate. Therapy should be interrupted in patients who develop severe symptoms and only resumed, at half the previous rate, once all signs and symptoms have resolved. Premedication with analgesics, antihistamines, and possibly corticosteroids is recommended in all patients before receiving rituximab.

Reactivation of hepatitis B virus (HBV) has occurred in some patients; fulminant hepatitis, hepatic failure, and fatalities have been reported. Patients at high risk of HBV infection should be screened before starting rituximab therapy and carriers should be monitored for signs of active infection or hepatitis during and for several months after therapy. Rituximab should be stopped if viral hepatitis develops. Other serious infections, which may be fatal, can occur with rituximab. Cases of progressive multifocal leukoencephalopathy, some fatal, have been reported with rituximab.

Haematological adverse effects including lymphopenia, leucopenia, neutropenia, thrombocytopenia, and anaemia have occurred in some patients; effects are considered mild and reversible. Complete blood and platelet counts should be monitored regularly. Exacerbation of heart failure and angina pectoris has also been reported, and other cardiac events include arrhythmias and tachycardia. Gastrointestinal disturbances may also occur. Abdominal pain, bowel obstruction, and perforation, in some cases fatal, have been reported with rituximab combination chemotherapy.

Effects on the blood. Late-onset neutropenia (defined as neutropenia occurring 30 days after the last dose) has been reported in patients receiving rituximab.[1]

1. Rios-Fernández R, *et al.* Late-onset neutropenia following rituximab treatment in patients with autoimmune diseases. *Br J Dermatol* 2007; **157:** 1271–3.

Effects on the eyes. About 20 minutes after the start of a rituximab infusion, a patient developed bilateral conjunctivitis without pain, lachrymation, or discharge. No other clinical manifestations of a hypersensitivity reaction were apparent, and the conjunctivitis resolved spontaneously, about 30 minutes after the end of the infusion. No recurrence was evident with subsequent rituximab therapy.[1]

1. Marinella MA. Bilateral conjunctivitis due to rituximab. *Ann Pharmacother* 2007; **41:** 1318.

Effects on the gastrointestinal tract. In November 2006 the manufacturer noted that 47 cases of bowel obstruction (9 fatal) and 37 cases of gastrointestinal perforation (4 fatal) had been reported in patients given rituximab.[1] Interpretation of data was difficult due to confounding factors; however, a contributory role of rituximab could not be excluded. The mean time to onset of symptoms was 6 days (range 1 to 77 days) for documented perforation. Complaints of abdominal pain, especially early in a course of rituximab treatment, should prompt thorough diagnostic evaluation and treatment.

Effects on the lungs. Pulmonary reactions have been reported with rituximab use,[1] including reversible interstitial pneumonia[2-4] and interstitial fibrosis.[5] A fatal intra-alveolar haemorrhage in 1 patient was attributed to a hypersensitivity reaction to rituximab.[6]

Effects on the nervous system. As of December 2006, the FDA had received a total of 24 reports of progressive multifocal leukoencephalopathy (PML) in patients given rituximab.[1] PML is a fatal demyelinating disease that follows reactivation of latent JC or PK polyomavirus (also known as papovavirus) in the CNS; the virus is present in about 80% of adults. In the first 12 cases reported to the FDA, 10 patients tested positive for the JC virus and 1 had confirmed BK virus.

Infusion-related reactions. By November 1998 there had been 74 cases of serious infusion-related reactions to rituximab reported worldwide, with 8 fatal cases.[1] An estimated 12 000 to 14 000 patients had been treated.

The reaction usually occurs within the first 2 hours of infusion and the underlying mechanism is believed to be a severe cytokine release syndrome, with some elements of tumour lysis syndrome.[1-3] In one series of cases tumour necrosis factor-α and interleukin-6 levels were found to peak 90 minutes after the onset of the infusion, and these elevated cytokine levels coincided with infusion-related symptoms.[2] The reaction is usually most marked after the first infusion and subsequent infusions are usually tolerated, emphasising that this is not a true hypersensitivity reaction.[4]

Patients with a high tumour burden (lesions over 10 cm in diameter or more than 500 000 circulating malignant cells/mm^3), a history of pulmonary infiltration or insufficiency, or underlying cardiac disease are believed to be at greater risk of severe reactions.[1,2,4] The UK CSM recommends that premedication with an analgesic and an antihistamine should always be given before rituximab, and corticosteroids should be considered.[1] However, serious or fatal reactions have occurred despite such premedication.[3,4] Alternative infusion schedules and/or combination therapy with chemotherapeutic drugs may be required to decrease the tumour burden before rituximab therapy.[2,4]

Pregnancy. Giving 4 cycles of rituximab (with doxorubicin, vincristine, and prednisolone) to a pregnant woman with lymphoma, from 21 weeks of gestation until delivery at 35 weeks, resulted in no adverse effects to either the mother or the infant.[1] In another report, a 31-year-old woman was diagnosed with non-Hodgkin's lymphoma during pregnancy. She received 6 cycles of rituximab with CHOP (cyclophosphamide, doxorubicin, vincristine, and prednisone). Two months after treatment, she spontaneously delivered a premature but healthy infant. Patient and child were clinically assessed every 3 months; the infant's B cells were severely diminished at birth but recovered over 6 to 12 weeks. Rituximab concentrations in both mother and child also decreased as expected. No adverse effects were seen during 16 months of follow-up.[2] In 2 case reports of rituximab use during the first trimester of pregnancy, no significant adverse effects on the neonates were seen; transient granulocytopenia and lymphopenia were reported.[3,4] A 35-year-old woman diagnosed with Burkitt's lymphoma in week 15 of pregnancy received 4 weekly infusions of rituximab starting in week 16, followed by four courses of rituximab with CHOP, and then 2 courses of CHOP alone. In week 41, a healthy infant was delivered by caesarean section. Both the mother and child had very high serum concentrations of rituximab at birth with a complete absence of B cells; rituximab levels in the cord blood serum were three times that in the mother's serum. However, B-cell recovery was reported to be rapid, and no overt infectious complications were seen in the child up to the age of 26 months; growth and developmental status were also normal.[5] Nonetheless, licensed product information advises against rituximab use during pregnancy, given the potential for B-cell depletion in the fetus; women of child-bearing potential should use effective contraceptive methods during treatment and for up to 12 months after therapy.

Pharmacokinetics

The mean maximum plasma concentration of rituximab has been reported to increase with successive infusions; however, considerable interindividual variation is seen. Serum concentrations are negatively correlated with tumour burden and the number of circulating B-cells. The mean terminal half-life is about 20 days. Rituximab is bound to B lymphocytes, and is detectable in the body for 3 to 6 months after treatment.

Uses and Administration

Rituximab is a chimeric monoclonal antibody to CD20 antigen used in the treatment of non-Hodgkin's lymphomas (p.656). It is used as monotherapy in relapsed or refractory low-grade or follicular lymphoma, or as first-line treatment with combination chemotherapy, such as CVP (cyclophosphamide, vincristine, and prednisolone). Rituximab monotherapy may also be used in patients with low-grade stable disease after first-line treatment with CVP chemotherapy. It is also indicated for maintenance therapy in patients with refractory or relapsed follicular lymphoma who respond to induction chemotherapy that may or may not have contained rituximab. Rituximab is also used with CHOP chemotherapy (cyclophosphamide, doxorubicin, vincristine, and prednisone) or other anthracycline-based regimens for CD20-positive diffuse large B-cell non-Hodgkin's lymphoma. Rituximab also forms part of the combination regimen employing ibritumomab tiuxetan (p.730). Rituximab with methotrexate is used in adults with moderate to severely active rheumatoid arthritis (p.11) who have had an inadequate response to DMARDs, including tumour necrosis factor inhibitors.

Rituximab is given by intravenous infusion, diluted in sodium chloride 0.9% or glucose 5% to a final concentration of between 1 and 4 mg/mL. The first infusion is given initially at a rate of 50 mg/hour; subsequently this may be increased in increments of 50 mg/hour every 30 minutes to a maximum of 400 mg/hour, if well tolerated. Subsequent doses may be begun at a rate of 100 mg/hour, and increased in increments of 100 mg/hour every 30 minutes to a maximum of 400 mg/hour.

In the UK for the treatment of refractory or relapsed follicular **lymphoma**, rituximab is given as a single agent in a usual dose of 375 mg/m^2 once weekly for 4 doses; in the USA 8 doses may be given. Patients in either country may be re-treated after relapse for a further 4 doses. When given with combination chemotherapy such as CVP (for follicular lymphoma) or CHOP (for diffuse large B-cell lymphoma), rituximab 375 mg/m^{2}is given on day 1 of the chemotherapy cycle, after the corticosteroid component of the regimen, for a total of 8 cycles. In patients previously treated with 6 to 8 cycles of CVP chemotherapy and who have not progressed, rituximab 375 mg/m^2 may be given once weekly for 4 doses, repeated every 6 months, for up to 16 doses. For maintenance treatment in those who have responded to induction chemotherapy, rituximab 375 mg/m^2 is given once every 3 months until disease progression or for a maximum period of 2 years.

In the regimen with ibritumomab tiuxetan, rituximab is usually given at a dose of 250 mg/m^2.

In the treatment of **rheumatoid arthritis**, rituximab is given in a dose of 1 g, for 2 doses; the infusions are separated by 2 weeks. It is given with methotrexate, and corticosteroids are recommended before each infusion to reduce the incidence and severity of infusion reactions.

Rituximab is also under investigation for the treatment of a number of **other conditions** including chronic lymphocytic leukaemia, multiple sclerosis, ANCA-associated vasculitis, and SLE, including lupus nephritis.

Administration. Rituximab has been used intralesionally in the treatment of cutaneous B-cell lymphoma. There are reports of benefit, with long-term remission in some patients,[1] but rapid recurrence in others.[2] In a study of 8 patients, intralesional rituximab was given to 6 patients, in doses of 10 to 30 mg per lesion, 3 times weekly; if clinical remission was incomplete, another cycle of 3 injections was given 1 month later. Two patients were treated intravenously with weekly infusions for 4 weeks. Complete remission was seen in all 8 patients. No relapse was seen in those given intravenous therapy, but recurrences were seen in 4 of the 6 patients treated intralesionally. Moderate pain was reported during intralesional injection.[3]

Administration in children. Although not licensed in the UK or the USA for use in children, there are reports of benefit in children with various diseases, such as auto-immune haemolytic anaemia, idiopathic thrombocytopenic purpura (see also below), and post-transplantation lymphoproliferative disease,[1] as well as rheumatoid arthritis, and SLE.[2] Standard doses of 375 mg/m^2 weekly have usually been given, in most cases for a median course of 4 doses.

2. El-Hallak M, *et al.* Clinical effects and safety of rituximab for treatment of refractory pediatric autoimmune diseases. *J Pediatr* 2007; **150:** 376–82.

Eye disorders. Orbital pseudolymphomas are uncommon benign tumours which usually affect the lachrymal gland, orbital soft tissue, or extra-ocular muscles. Clinical presentation includes painless onset of ptosis, proptosis, diplopia, or eyelid swelling. There are reports of durable response to rituximab.[1]

1. Witzig TE, *et al.* Treatment of benign orbital pseudolymphomas with the monoclonal anti-CD20 antibody rituximab. *Mayo Clin Proc* 2007; **82:** 692–9.

Glomerular kidney disease. In a report of 5 patients with corticosteroid-resistant nephrotic syndrome, 4 patients had a complete remission and 1 patient had a partial remission after treatment with rituximab in standard doses for 4 weeks. Complete remission was maintained in 3 patients, despite tapering of corticosteroids and calcineurin inhibitors.[1]

1. Bagga A, *et al.* Rituximab in patients with the steroid-resistant nephrotic syndrome. *N Engl J Med* 2007; **356:** 2751–2.

Haemolytic anaemia. Rituximab has been used in the treatment of severe refractory auto-immune haemolytic anaemia (p.1043) of various causes, including warm,[1,2] cold,[3-5] and mixed[6,7] disease.

1. Quartier P, *et al.* Treatment of childhood autoimmune haemolytic anaemia with rituximab. *Lancet* 2001; **358:** 1511–13.

Haemorrhagic disorders. Although data are limited, reports suggest that rituximab may be an effective alternative for the treatment of acquired haemophilia (p.1048) after established therapies have failed.[1,2]

1. Maillard H, *et al.* Rituximab in postpartum-related acquired hemophilia. *Am J Med* 2006; **119:** 86–8.
2. Stachnik JM. Rituximab in the treatment of acquired hemophilia. *Ann Pharmacother* 2006; **40:** 1151–7.

Idiopathic thrombocytopenic purpura. Rituximab has been reported[1-3] to be effective in patients, including children and infants, with idiopathic thrombocytopenic purpura (p.1505) refractory to standard treatments. However, a review[4] cautioned against the indiscriminate use of rituximab in this patient population, given the lack of controlled data.

Pemphigus. Rituximab has been reported to be of benefit in pemphigus vulgaris (p.1582) and 17 cases have been reviewed.[1] It was used in patients with severe and widespread disease that had not responded to usual therapy with corticosteroids and immunosuppressants. A dose of 375 mg/m^2 once weekly was used and most patients were given a course of 4 doses. Most patients showed some improvement from rituximab, including 9 who were free of clinical disease for more than 6 months and 5 who had a partial response. However, although concomitant therapy could be reduced in 8 patients, only 2 were able to stop systemic corticosteroids and immunosuppressants; in 6 cases this information was not reported. Rituximab might therefore be useful for remission induction when corticosteroids have not been effective, but long-term follow-up is needed. Rituximab with normal immunoglobulins has also been reported to be effective in patients with refractory pemphigus vulgaris.[2]

Rituximab has been reported to be of benefit in pemphigus foliaceus,[3,4] a less common variant of pemphigus. A single cycle of 4 weekly infusions of rituximab was reported to achieve complete remission in 12 of 14 patients with pemphigus vulgaris and 6 of 7 patients with pemphigus foliaceus; 2 patients in the former group achieved delayed complete remission. Of these 20 patients, 6 with pemphigus vulgaris and 3 with pemphigus foliaceus had a relapse; 2 of these 9 patients were given a second course of rituximab and again achieved complete remission. After 34 months of follow-up, 18 patients were free of disease, and 8 of these were not receiving any systemic therapy.[5]

Rheumatoid arthritis. Rituximab is of benefit in patients with rheumatoid arthritis (p.11) refractory to standard therapy.[1-3] The ability of rituximab to prevent articular damage, its efficacy for extra-articular manifestations, the efficacy and safety of repeated courses, and long-term effects on the immune system remain to be determined.[4] Radiographic data from a placebo-controlled study showed a trend towards less progression of structural joint damage with a course of rituximab (2 doses); assessment was made at 24 weeks.[5] In a consensus statement, European and Canadian rheumatologists stated that re-treatment with rituximab may be considered after week 24 in those who respond to initial therapy.[6]

In the UK, NICE states that rituximab with methotrexate is a treatment option for adults with severe active rheumatoid arthritis who have had an inadequate response to DMARDs or are intolerant of them; previous therapy should have included at least one tumour necrosis factor α inhibitor. Treatment with rituximab and methotrexate should continue only if patients show an adequate response, and repeat courses should be given no more often than every 6 months; specialist supervision is advised.[7]

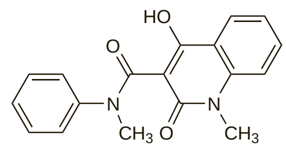
Roquinimex *(USAN, rINN)*

FCF-89; LS-2616; Roquinimexum. 1,2-Dihydro-4-hydroxy-*N*,1-dimethyl-2-oxo-3-quinolinecarboxanilide.

Рохинимекс

$C_{18}H_{16}N_2O_3$ = 308.3.
CAS — 84088-42-6.
ATC — L03AX02.
ATC Vet — QL03AX02.



Profile

Roquinimex is an immunomodulator reported to stimulate various immune functions including macrophage cytotoxicity. It has been investigated for its potential against malignant neoplasms including as adjuvant therapy after bone marrow transplantation in acute leukaemia, to prolong the time to relapse. Roquinimex has also been investigated in immune and auto-immune disorders including multiple sclerosis. However serious cardiovascular toxicity after roquinimex therapy has led to several studies being terminated.

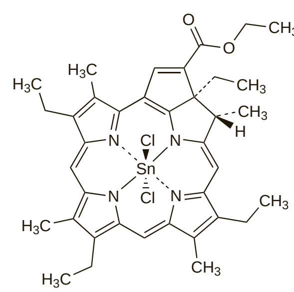
Rostaporfin *(USAN, rINN)*

Rostaporfina; Rostaporfine; Rostaporfinum; SnET2; Tin Ethyl Etiopurpurin; Tin etiopurpurin dichloride. (*OC*-6-13)-Dichloro[ethyl (18*RS*,19*SR*)-3,4,20,21-tetradehydro-4,9,14,19-tetraethyl-18,19-dihydro-3,8,13,18-tetramethyl-20-phorbinecarboxylato (2-)-N^{23},N^{24},N^{25},N^{26}]tin.

Ростапорфин

$C_{37}H_{42}Cl_2N_4O_2Sn$ = 764.4.
CAS — 284041-10-7; 114494-17-6.



and enantiomer

Profile

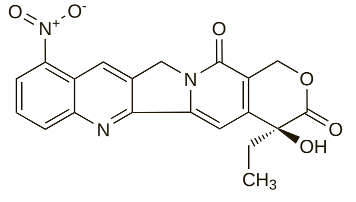
Rostaporfin is a photosensitiser that is under investigation in the photodynamic therapy of neovascular (wet) age-related macular degeneration (p.785). It has also been investigated for photodynamic therapy of malignant neoplasms.

Rubitecan *(USAN, rINN)*

9-NC; 9-Nitrocamptothecin; RFS-2000; Rubitécan; Rubitecán; Rubitecanum. 9-Nitro-20(*S*)-camptothecin.

Рубитекан

$C_{20}H_{15}N_3O_6$ = 393.3.
CAS — 91421-42-0.



Profile

Like irinotecan (p.737), rubitecan is a topoisomerase I inhibitor related to camptothecin. It can be given orally and has been investigated for its antineoplastic properties particularly in the treatment of pancreatic cancer. It is also under investigation for the treatment of paediatric patients infected with HIV.

◊ References.

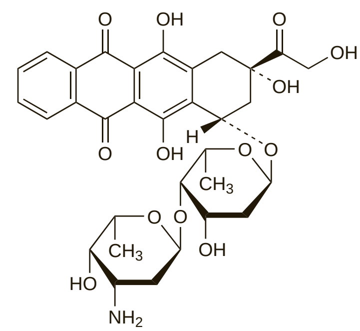
Sabarubicin *(rINN)*

MEN-10755; Sabarubicina; Sabarubicine; Sabarubicinum. (7*S*,9*S*)-7-{[4-*O*-(3-Amino-2,3,6-trideoxy-α-L-*lyxo*-hexopyranosyl)-2,6-dideoxy-α-L-*lyxo*-hexopyranosyl]oxy}-6,9,11-trihydroxy-9-(hydroxyacetyl)-7,8,9,10-tetrahydrotetracene-5,12-dione.

Сабарубицин

$C_{32}H_{37}NO_{13}$ = 643.6.
CAS — 211100-13-9.



Profile

Sabarubicin, an anthracycline, is an analogue of doxorubicin (p.712). It acts as a potent topoisomerase II inhibitor and is under investigation for the treatment of various solid tumours, such as cancers of the lung, ovary, breast, and prostate. Myelosuppression is the main adverse effect.

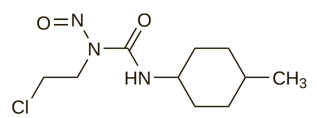
Semustine *(USAN, rINN)*

Methyl Lomustine; Methyl-CCNU; NSC-95441; Semustiini; Semustin; Semustina; Sémustine; Semustinum; WR-220076. 1-(2-Chloroethyl)-3-(4-methylcyclohexyl)-1-nitrosourea.

Семустин

$C_{10}H_{18}ClN_3O_2$ = 247.7.
CAS — 13909-09-6.
ATC — L01AD03.
ATC Vet — QL01AD03.



Pharmacopoeias. In *Chin.*

Adverse Effects, Treatment, and Precautions

As for Carmustine, p.694.

Effects on the kidneys. Nephrotoxicity has been reported in patients receiving high cumulative doses of semustine. Severe renal damage was reported in 6 of 17 children given semustine after radiotherapy for brain tumours; all 6 children had received a total dose above 1.5 g/m^2 in contrast to those not so affected, who had received lower doses.[1] A decrease in kidney size was seen in 2 patients who had received lower cumulative doses. There had been no evidence during treatment that patients were losing renal function. Similarly others have reported an increased risk of renal abnormalities in patients given a cumulative dose of 1.4 g/m^2 or more.[2] Some 25% of patients given higher doses were so affected, while those given lower doses were not. Overall, however, the problem may not be particularly frequent: in one study it was considered that only 4 of 857 patients treated with semustine over 6 years might have had delayed renal insufficiency possibly related to semustine.[3]

1. Harmon WE, *et al.* Chronic renal failure in children treated with methyl-CCNU. *N Engl J Med* 1979; **300:** 1200–3.
2. Micetich KC, *et al.* Nephrotoxicity of semustine (methyl-CCNU) in patients with malignant melanoma receiving adjuvant chemotherapy. *Am J Med* 1981; **71:** 967–72.
3. Nichols WC, Moertel CG. Nephrotoxicity of methyl-CCNU. *N Engl J Med* 1979; **301:** 1181.

Pharmacokinetics

Semustine is well absorbed from the gastrointestinal tract after oral doses, and is rapidly metabolised. The metabolites are reported to possess prolonged plasma half-lives, and cross the blood-brain barrier into the CSF. It is excreted in urine as metabolites: up to 60% of a dose is excreted in this way within 48 hours. Small amounts may be excreted in faeces and via the lungs as carbon dioxide.

Uses and Administration

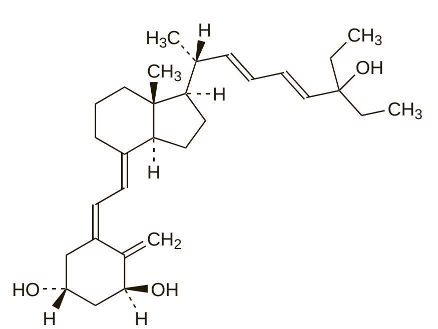
Semustine is a nitrosourea with actions and uses similar to those of carmustine (p.695) and lomustine (p.741).

Seocalcitol *(BAN, rINN)*

EB-1089; Séocalcitol; Seocalcitolum. (5*Z*,7*E*,22*E*,24*E*)-24a,26a,27a-Trihomo-9,10-secocholesta-5,7,10(19),22,24-pentaene-1α,3β,25-triol.

Сеокальцитол

$C_{30}H_{46}O_3$ = 454.7.
CAS — 134404-52-7.



Profile

Seocalcitol is a vitamin D analogue that has been investigated for the treatment of hepatocellular carcinoma.

Sizofiran *(rINN)*

Schizophyllan; Sizofirán; Sizofiranum. Poly[3→-(*O*-β-D-glucopyranosyl-(1→3)-*O*-[β-D-glucopyranosyl-(1→6)]-*O*-β-D-glucopyranosyl-(1→3)-*O*-β-D-glucopyranosyl)→1].

Сизофиран

$(C_{24}H_{40}O_{20})_n$.
CAS — 9050-67-3.

Profile

Sizofiran is a polysaccharide obtained from cultures of the basidiomycete fungus *Schizophyllum commune*. It is reported to have antineoplastic and immunomodulating activity and is given with radiotherapy in malignant neoplasms of the cervix (p.663). It is given by intramuscular injection in usual doses of 40 mg weekly. It has also been tried with chemotherapy or radiotherapy in other malignant neoplasms. Hypersensitivity reactions, including anaphylactoid shock, may occur.

Preparations

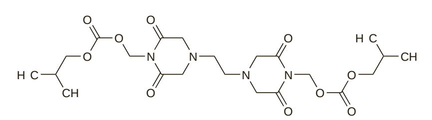
Proprietary Preparations (details are given in Part 3)
Jpn: Sonifilan.

Sobuzoxane *(rINN)*

MST-16; Sobuzoxano; Sobuzoxanum. 4,4′-Ethylenebis[1-(hydroxymethyl)-2,6-piperazinedione] bis(isobutyl carbonate).

Собузоксан

$C_{22}H_{34}N_4O_{10}$ = 514.5.
CAS — 98631-95-9.



Profile

Sobuzoxane is an orally active inhibitor of topoisomerase II that has been used for its antineoplastic properties in the treatment of non-Hodgkin's lymphomas and adult T-cell leukaemia/lymphoma. Adverse effects include myelosuppression, bleeding tendency, renal and hepatic dysfunction, gastrointestinal disturbances, alopecia, headache, and fever.

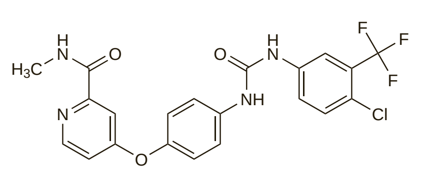
Sorafenib *(USAN, rINN)*

BAY-43-9006; Sorafénib; Sorafenibum. 4-(4-{3-[4-Chloro-3-(trifluoromethyl)phenyl]ureido}phenoxy)-*N*^{2}-methylpyridine-2-carboxamide.

Сорафениб

$C_{21}H_{16}ClF_3N_4O_3$ = 464.8.
CAS — 284461-73-0.
ATC — L01XE05.
ATC Vet — QL01XE05.



Sorafenib Tosilate *(rINNM)*

BAY-54-9085; Sorafénib, Tosilate de; Sorafenib, tosilato de; Sorafenib Tosylate *(USAN)*; Sorafenibi Tosilas. 4-(4-{3-[4-Chloro-3-(trifluoromethyl)phenyl]ureido}phenoxy)-*N*^{2}-methylpyridine-2-carboxamide 4-methylbenzenesulfonate.

Сорафениба Тозилат

$C_{21}H_{16}ClF_3N_4O_3,C_7H_8O_3S$ = 637.0.
CAS — 475207-59-1.
ATC — L01XE05.
ATC Vet — QL01XE05.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641. Dermatological toxicities such as palmar-plantar syndrome and rash are the most common adverse effects with sorafenib. Treatment may include topical therapies, or dose adjustment, or temporary interruption of sorafenib. Mild to moderate hypertension can occur, which may be manageable with antihypertensive therapy, but severe or persistent hypertension or hypertensive crisis despite treatment, may force sorafenib to be stopped. Blood pressure should be regularly monitored. There is an increased risk of bleeding with sorafenib and fatalities have been reported; if severe enough to need intervention, the drug should be permanently stopped. Leucopenia, lymphopenia, anaemia, neutropenia, and thrombocytopenia are common. Hypophosphataemia and transient disturbances in liver function tests can occur. Elevations in lipase and amylase concentrations are very common. Pancreatitis has been reported. Other adverse effects include alopecia, pruritus, dry skin, erythema, acne, flushing, exfoliative dermatitis, hoarseness, gastrointestinal disturbances, arthralgia, myalgia, asthenia, pain, and peripheral neuropathy. Tinnitus, depression, and erectile dysfunction are often reported, as are pyrexia, flu-like illness, and weight decrease. Gastrointestinal perforation has been reported rarely; therapy should be stopped if it occurs. Reversible posterior leukoencephalopathy has also occurred rarely. Sorafenib therapy should be interrupted or stopped in patients who develop cardiac ischaemia and/or infarction.

Effects on the cardiovascular system. A meta-analysis[1] of data involving 4599 patients indicated that 23.4% of those given sorafenib developed hypertension; about 5% of sorafenib-treated patients developed severe (grade 3 or 4) hypertension. This represented a relative risk of developing high blood pressure 6.1 times that of patients not given sorafenib. Hypertension may also develop with other angiogenesis inhibitors; relative risk has been shown to be similar with high-dose bevacizumab, and there is evidence of a slightly smaller risk (incidence of hypertension 22.5%, relative risk 3.89) with sunitinib.

1. Wu S, *et al.* Incidence and risk of hypertension with sorafenib in patients with cancer: a systematic review and meta-analysis. *Lancet Oncol* 2008; **9:** 117–23.

Interactions

For a general discussion of antineoplastic drug interactions, see p.642. Sorafenib is metabolised by the cytochrome P450 isoenzyme CYP3A4. Rifampicin can reduce exposure to sorafenib. Other inducers of this enzyme (such as carbamazepine, dexamethasone, St John's wort, phenobarbital, and phenytoin) may also reduce blood concentrations of sorafenib. However, ketoconazole did not alter exposure to sorafenib and other drugs that inhibit CYP3A4 are considered unlikely to alter the metabolism of sorafenib.

In vitro studies have indicated that sorafenib itself inhibits the cytochrome P450 isoenzymes CYP3A4, CYP2C19, and CYP2D6, but use of sorafenib with midazolam, or omeprazole, or dextromethorphan did not alter the exposure to any of these drugs; interactions with drugs that are substrates of these enzymes are considered unlikely.

Sorafenib inhibits the cytochrome P450 isoenzyme CYP2C9 *in vitro*, and may increase concentrations of its substrates. The effect of warfarin on mean PT-INR was not altered by sorafenib; however, patients taking warfarin or phenprocoumon with sorafenib should have their INR regularly checked.

Sorafenib also inhibits the isoenzymes CYP2B6 and CYP2C8 *in vitro*, and drug interactions with substrates of these may occur.

Sorafenib may increase exposure to docetaxel, doxorubicin, and irinotecan; variable effects on fluorouracil have been reported.

Pharmacokinetics

Sorafenib reaches peak plasma concentrations about 3 hours after an oral dose. Absorption is reduced by about 30% after a high-fat meal. Plasma protein binding is about 99.5%. Sorafenib is metabolised primarily in the liver via the cytochrome P450 isoenzyme CYP3A4. It also undergoes glucuronidation. The elimination half-life of sorafenib is about 25 to 48 hours. About 96% of a dose is excreted within 14 days, with 77%, mostly as unchanged drug, recovered in the faeces, and 19% in the urine as glucuronidated metabolites.

◊ References.

1. Clark JW, *et al.* Safety and pharmacokinetics of the dual action Raf kinase and vascular endothelial growth factor receptor inhibitor, BAY 43-9006, in patients with advanced, refractory solid tumors. *Clin Cancer Res* 2005; **11:** 5472–80.

Uses and Administration

Sorafenib is an inhibitor of multiple intracellular and cell surface kinases thought to be involved in angiogenesis. It is given as the tosilate but doses are expressed in terms of the base; sorafenib tosilate 274 mg is equivalent to about 200 mg of sorafenib. Sorafenib is used in the treatment of advanced renal cell carcinoma and hepatocellular carcinoma. The recommended oral dose is 400 mg twice daily, given at least 1 hour before or 2 hours after food. Treatment is continued until no clinical benefit is seen or until unacceptable toxicity occurs. Doses are reduced to 400 mg once daily if toxicity occurs; further reduction to a single dose of 400 mg every other day may be necessary.

Sorafenib is under investigation for the treatment of locally unresectable and metastatic melanoma.

7. Simpson D, Keating GM. Sorafenib: in hepatocellular carcinoma. *Drugs* 2008; **68:** 251–8.

Administration in hepatic or renal impairment. Sorafenib is primarily metabolised in the liver. Hepatic impairment may reduce exposure to sorafenib, compared with patients with normal hepatic function. In patients with hepatocellular carcinoma, exposure is comparable in patients with mild and moderate (Child-Pugh A and B) impairment. Licensed product information states that no dose adjustment is needed in patients with mild to moderate impairment. No data are available on patients with severe (Child-Pugh C) hepatic impairment.

Licensed product information states that no dose adjustment is needed in patients with mild, moderate, or severe renal impairment, but that no data are available for patients on dialysis.

Preparations

Proprietary Preparations (details are given in Part 3)

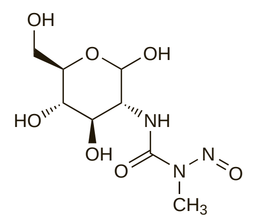
Streptozocin *(USAN, rINN)*

Estreptozocina; NSC-85998; Streptotsosiini; Streptozocine; Streptozocinum; Streptozosin; Streptozotocin; U-9889. 2-Deoxy-2-(3-methyl-3-nitrosoureido)-D-glucopyranose.

Стрептозоцин

$C_8H_{15}N_3O_7$ = 265.2.
CAS — 18883-66-4.
ATC — L01AD04.
ATC Vet — QL01AD04.



Storage. Licensed product information recommends that the freeze-dried streptozocin preparation be stored at 2° to 8° and protected from light.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Cumulative nephrotoxicity is common with streptozocin and may be severe and irreversible. Intra-arterial use may be associated with increased risk of nephrotoxicity.

Other adverse effects include severe nausea and vomiting and alterations in liver function or occasionally severe hepatotoxicity. Myelosuppression may occur but is rarely severe. Streptozocin may affect glucose metabolism. A diabetogenic effect has been reported; hypoglycaemia attributed to the release of insulin from damaged cells has also occurred.

Streptozocin is irritant to tissues and extravasation may lead to local ulceration and necrosis.

Streptozocin should be used with extreme care in patients with pre-existing renal impairment.

Handling and disposal. Methods for the destruction of streptozocin *waste* by reaction with hydrobromic acid in glacial acetic acid or by oxidation with a solution of potassium permanganate in sulfuric acid.[1] Residues produced by either method were free of mutagenic activity.

1. Castegnaro M, *et al.*, eds. Laboratory decontamination and destruction of carcinogens in laboratory wastes: some antineoplastic agents. *IARC Scientific Publications 73*. Lyon: WHO/International Agency for Research on Cancer, 1985.

Interactions

Streptozocin should not be given with other potentially nephrotoxic drugs. For increased doxorubicin toxicity when given with streptozocin see p.714.

Phenytoin. It has been suggested that because phenytoin appeared to protect the beta cells of the pancreas from the cytotoxic effects of streptozocin, its use with streptozocin should be avoided in patients being treated for pancreatic tumours.[1]

1. Koranyi L, Gero L. Influence of diphenylhydantoin on the effect of streptozotocin. *BMJ* 1979; **1:** 127.

Pharmacokinetics

After intravenous doses streptozocin is rapidly cleared from the blood and distributed to body tissues, particularly the liver, kidneys, intestines, and pancreas. It is extensively metabolised, mainly in the liver and perhaps the kidney, and excreted principally in the urine as metabolites and a small amount of unchanged drug. About 60 to 70% of an intravenous dose is excreted in urine within 24 hours. Some is also excreted via the lungs. Streptozocin itself does not cross the blood-brain barrier but its metabolites are found in the CSF.

Uses and Administration

Streptozocin is an antibiotic antineoplastic belonging to the nitrosoureas (see Carmustine, p.695) and is used, alone or with other antineoplastics, mainly in the treatment of pancreatic endocrine (islet-cell) tumours (p.643). It has been tried in other tumours including exocrine pancreatic cancer and prostate cancer. It is licensed for intravenous injection or infusion in doses of 1 g/m^2 weekly, increased if necessary after 2 weeks to up to 1.5 g/m^2. Alternatively doses of 500 mg/m^2 may be given daily for 5 days and repeated every 6 weeks.

Streptozocin has also been given by intra-arterial infusion (but see Adverse Effects above).

Full blood counts, and renal and hepatic function tests should be performed routinely during treatment; doses should be reduced or treatment withdrawn if renal toxicity occurs.

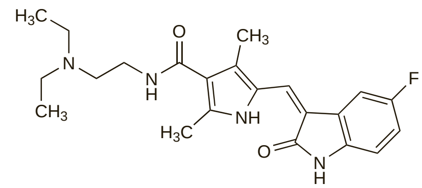
Sunitinib Malate *(USAN, rINNM)*

Malato de sunitinib; PHA-290940AD; SU-010398; SU-011248 (sunitinib); Sunitinib, Malate de; Sunitinibi Malas. *N*-[2-(Diethylamino)ethyl]-5-[(*Z*)-(5-fluoro-2-oxo-1,2-dihydro-3*H*-indol-3-ylidene)methyl]-2,4-dimethyl-1*H*-pyrrole-3-carboxamide hydrogen (2*S*)-2-hydroxybutanedioate.

Сунитиниба Малат

$C_{22}H_{27}FN_4O_2,C_4H_6O_5$ = 532.6.
CAS — 557795-19-4 (sunitinib); 341031-54-7 (sunitinib malate).
ATC — L01XE04.
ATC Vet — QL01XE04.



(sunitinib)

Adverse Effects, Treatment, and Precautions

Common adverse effects of sunitinib include gastrointestinal disturbances, anorexia, headache, fatigue, fever, hypertension, hypothyroidism, mouth pain or irritation, dry mouth, mucosal inflammation, oedema, taste disturbances, arthralgia, and myalgia. Myelosuppression is common, and complete blood counts should be performed at the beginning of each treatment cycle. Other effects include dizziness, paraesthesia, dyspnoea, alopecia, Yellow skin discoloration and chromaturia can occur. Other dermatological effects include depigmentation of the hair or skin, dryness, rash, exfoliative dermatitis, or palmar-planter syndrome. Gastrointestinal perforation has been reported rarely; fatalities have been reported in patients with intra-abdominal malignancies.

Decreases in left ventricular ejection fraction (LVEF) have occurred with sunitinib; baseline and periodic evaluations of LVEF should be taken. Patients should be monitored for signs of congestive cardiac failure and therapy interrupted or stopped if they occur. Dose reductions may be necessary in patients who show no signs of heart failure but who show decreases in LVEF. Sunitinib may prolong the QT interval and should be used with caution in patients with a history of this, who are taking antiarrhythmics, or who have pre-existing cardiac disease, bradycardia, or electrolyte disturbances.

There is an increased risk of bleeding at all sites; epistaxis is the most common treatment-related bleeding event but fatal pulmonary haemorrhage has occurred in patients with lung cancer. Pulmonary embolism or venous thromboembolic events may occur. Patients under stresses such as surgery, trauma, or severe infection should be monitored for adrenal insufficiency. Increases in serum amylase and lipase concentrations have been seen and there are rare reports of pancreatitis and hepatic failure. There are also rare reports of seizures and reversible posterior leukoencephalopathy syndrome.

Effects on the cardiovascular system. A retrospective review in 75 patients given repeating cycles of sunitinib in phase I/II studies of its efficacy for gastrointestinal stromal tumours found that cardiovascular events occurred in 8, of whom 6 developed congestive heart failure.[1] Of 36 patients given the subsequently approved dose, 10 had reductions in left ventricular ejection fraction of at least 10%. Hypertension developed in 35 of the 75 patients, and it was suggested that left ventricular dysfunction might be due to a combination of hypertension and a direct toxic effect on heart muscle.

For the relative risk of developing hypertension with sunitinib, and the view that this may be an effect common to angiogenesis inhibitors, see under Sorafenib, p.770.

1. Chu TF, *et al.* Cardiotoxicity associated with tyrosine kinase inhibitor sunitinib. *Lancet* 2007; **370:** 2011–19.

Effects on the kidneys. For a report of haemolytic-uraemic syndrome after the use of bevacizumab and sunitinib, see Effects on the Kidneys, under Bevacizumab, p.685.

Effects on the nervous system. Coma has been reported with sunitinib; therapy was immediately stopped and the patient regained consciousness within 24 hours.[1]

1. Arnaud L, *et al.* Transient sunitinib-induced coma in a patient with fibromyxoid sarcoma. *J Clin Oncol* 2008; **26:** 1569–71.

Effects on the skin. A patient developed palmar-plantar syndrome and rashes resembling seborrhoeic dermatitis while taking sunitinib. Therapy was stopped and the rash was treated with a topical corticosteroid; blisters on the palms and soles resolved with desquamation.[1]

1. Tsai K-Y, *et al.* Hand-foot syndrome and seborrheic dermatitis-like rash induced by sunitinib in a patient with advanced renal cell carcinoma. *J Clin Oncol* 2006; **24:** 5786–8.

Effects on thyroid function. Hypothyroidism is common after sunitinib therapy. A cohort study found that 36% of patients developed hypothyroidism after an average of 50 weeks of therapy. The incidence of hypothyroidism increased with the duration of therapy, and the effect was not transient; patients needed replacement therapy with levothyroxine. Mild thyrotoxicosis may precede the onset of hypothyroidism. Although the mechanism is not clear, the drug may cause destructive thyroiditis. Patients should be screened for hypothyroidism and serum concentrations of thyroid-stimulating hormone (TSH) measured at suggested intervals of 2 to 3 months.[1]

1. Desai J, *et al.* Hypothyroidism after sunitinib treatment for patients with gastrointestinal stromal tumors. *Ann Intern Med* 2006; **145:** 660–4.

Tumour lysis syndrome. Tumour lysis syndrome has been reported after treatment with sunitinib; electrolytes and renal function should be closely monitored.[1,2]

1. Nicholaou T, *et al.* Tumour lysis syndrome in a patient with renal-cell carcinoma treated with sunitinib malate. *Lancet* 2007; **369:** 1923–4.
2. Saylor PJ, Reid TR. Tumor lysis syndrome after treatment of a gastrointestinal stromal tumor with the oral tyrosine kinase inhibitor sunitinib. *J Clin Oncol* 2007; **25:** 3544–6.

Interactions

Sunitinib is metabolised primarily by the cytochrome P450 isoenzyme CYP3A4 to produce an active metabolite, which is further metabolised by CYP3A4. Ketoconazole increased exposure to sunitinib, and use with other potent inhibitors of CYP3A4 (such as other azole antifungals, macrolide antibacterials, HIV-protease inhibitors, or grapefruit juice) may also increase sunitinib concentrations. Conversely, use with rifampicin decreased exposure to sunitinib, and inducers of CYP3A4 (such as dexamethasone, phenytoin, carbamazepine, phenobarbital, or St John's wort) may decrease plasma sunitinib concentrations. If the use of alternative drugs is not feasible, dose adjustments of sunitinib may be necessary (see Uses and Administration, below).

◊ The US manufacturer of *bevacizumab* has recommended that it should not be used with sunitinib after several patients receiving the combination had developed microangiopathic haemolytic anaemia.[1]

1. Genentech, USA. Important drug warning subject: microangiopathic hemolytic anemia (MAHA) in patients treated with Avastin (bevacizumab) and sunitinib malate (issued July 2008). Available at: http://www.fda.gov/medwatch/safety/2008/MAHA_DHCP.pdf (accessed 30/07/08)

Pharmacokinetics

Maximum plasma concentrations occur 6 to 12 hours after an oral dose of sunitinib. Bioavailability is unaffected by food. Sunitinib is metabolised mainly via the cytochrome P450 isoenzyme CYP3A4 to its primary active metabolite, which itself is then further metabolised via CYP3A4. Plasma protein binding of sunitinib and its metabolite is about 95% and 90%, respectively; plasma elimination half-lives are 40 to 60 hours, and 80 to 110 hours, respectively. Sunitinib is excreted mainly in faeces; about 16% is found in urine, as unchanged drug and metabolites.

Uses and Administration

Sunitinib malate is an inhibitor of several receptor tyrosine kinases. It is used for the treatment of gastrointestinal stromal tumours (see Soft-tissue Sarcoma, p.676) after disease progression during imatinib treatment, or in patients intolerant to imatinib. It is also used for the treatment of advanced and/or metastatic renal cell carcinoma (p.667).

Sunitinib is given orally as the malate, but doses are expressed in terms of the base; sunitinib malate 66.8 mg is equal to about 50 mg of sunitinib. The recommended dose is 50 mg once daily, for 4 weeks of a 6-week treatment cycle. Doses may be increased or decreased in steps of 12.5 mg, based on individual tolerability. UK licensed product information recommends that the daily dose should not normally exceed 75 mg nor be decreased below 25 mg.

Use of inhibitors or inducers of CYP3A4 may increase or decrease sunitinib plasma concentrations. If no alternative is available, a dose reduction of sunitinib to a minimum of 37.5 mg daily should be considered if it is given with a strong CYP3A4 inhibitor. Doses can be increased to a maximum of 87.5 mg daily if sunitinib is given with a CYP3A4 inducer; the patient should be closely monitored for toxicity.

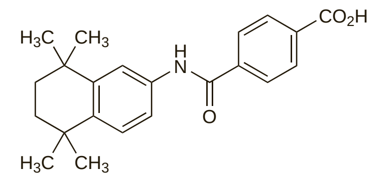
CAS — 94497-51-5.



Profile

Tamibarotene is a synthetic retinoid that is given orally for the treatment of relapsed or refractory acute promyelocytic leukaemia.

Malignant neoplasms. Tamibarotene has been used to induce remission in patients with acute promyelocytic leukaemia (see Acute Myeloid Leukaemias, p.652) who relapsed after successful remission induction with tretinoin.[1,2] Twenty-four patients received tamibarotene at a daily oral dose of 6 mg/m^2; 14 patients obtained complete remission after a median of 41 days.[1] Reported adverse effects include hypercholesterolaemia, hypertriglyceridaemia,[1,3] cheilitis, xerosis, gastrointestinal disturbances, bone pain, headache, dermatitis, liver damage, and leucocytosis; in one case, retinoic acid syndrome occurred.[1]

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*
Ph. Eur. 6.2 (Tamoxifen Citrate). A white or almost white, polymorphic, crystalline powder. Slightly soluble in water and in acetone; soluble in methyl alcohol.
USP 31 (Tamoxifen Citrate). A white, fine, crystalline powder. Very slightly soluble in water, in alcohol, in acetone, and in chloroform; soluble in methyl alcohol. Protect from light.

Adverse Effects

The most frequent adverse effects of tamoxifen are hot flushes. Other adverse effects include fluid retention, nausea, gastrointestinal intolerance, vaginal bleeding or discharge, pruritus vulvae, rashes, dry skin, and alopecia. There have also been reports of dizziness, headache, depression, confusion, fatigue, and muscle cramps. There may be an increased tendency to thromboembolism, and pulmonary embolism has occurred. Tumour pain and flare may be a sign of response, but hypercalcaemia, sometimes severe, has developed in patients with bony metastases. Transient thrombocytopenia and leucopenia have been reported. Blurred vision and loss of visual acuity, corneal opacities, retinopathies, and cataracts have occurred rarely. Tamoxifen has been associated with increased liver enzymes, and rarely with cholestasis and hepatitis. Hypertriglyceridaemia has occurred. Uterine fibroids and endometrial changes including hyperplasia and polyps may occur, and an increased incidence of endometrial carcinoma, and rarely uterine sarcoma, has been reported. Suppression of menstruation may occur in premenopausal women and cystic ovarian swellings have occasionally occurred. Very rare cases of interstitial pneumonitis have been reported.

Carcinogenicity. Tamoxifen has a stimulant effect on the endometrium (probably by acting as a partial oestrogen agonist) and its use has been associated with the development of endometrial polyps[1,2] and endometriosis,[3] and an increased risk of endometrial cancer.[4-6] The risk, which increases with duration of therapy, is generally agreed to be modest, and the clinical benefit in women with breast cancer outweighs any increased risk of endometrial neoplasm.[7-10] Women taking tamoxifen to prevent breast cancer have been estimated to have a 2.53-fold greater risk of developing endometrial carcinoma than untreated women.[11] The risk may increase with more prolonged use and a case-control study has reported that long-term (over 2 years) users may have a worse prognosis if endometrial cancer develops, due to less favourable history and stage.[12] Another case-control study showed that the relative risk of endometrial cancer increased with duration of tamoxifen treatment, up to at least 10 years. Risk was not associated with the daily dose of tamoxifen, and was comparable in pre- and postmenopausal women.[13]

It has been recommended that women with breast cancer taking tamoxifen should have annual gynaecological examinations, and any unusual symptoms, including abnormal bleeding or spotting should be investigated promptly.[14] Women taking tamoxifen for prophylaxis of breast cancer should be monitored carefully for endometrial hyperplasia. If atypical hyperplasia develops, tamoxifen should be stopped while the condition is treated and a hysterectomy should be considered before tamoxifen is re-started.[14] However, up to 39% of postmenopausal women taking tamoxifen show endometrial changes and as these seldom progress to cancer, the value of routine endometrial biopsies has been questioned.[8,9,14,15] Transvaginal ultrasonography has been used as a noninvasive method of endometrial screening, but has a high rate of false-positive results.[16] It has been suggested that colour doppler ultrasonography, which distinguishes vascularised lesions such as polyps and carcinomas from avascular atrophic lesions, may be a useful alternative.[17] There is some evidence that a levonorgestrel-releasing intra-uterine device can protect against the uterine changes induced by tamoxifen.[18]

Although rare, there is an increase in the risk of uterine sarcoma in women receiving tamoxifen. Between 1978, when tamoxifen was first marketed in the USA, and April 2001, the FDA was aware of 43 cases in women who had been receiving tamoxifen; there had also been reports in 116 women in other countries.[19] Although less than the expected rate in this population, this was considered to be due to underreporting. An evaluation of data from 39 451 breast cancer patients initially treated with tamoxifen found that the overall risk of uterine corpus cancer was more than doubled with the use of tamoxifen; the risk of rare but aggressive forms of uterine tumours, notably malignant mixed mullerian tumours, was increased more than fourfold.[20]

Tamoxifen has been shown to form DNA adducts in *rat* livers, and there has been speculation that it may cause liver cancer in humans. However, there is considerable interspecies variation in the metabolism of tamoxifen and several large-scale clinical trials did not find an increase in liver carcinogenicity in humans.[10] There is also little evidence of an increased relative risk of other secondary malignancies such as gastrointestinal or ovarian cancers.[10]

Effects on the blood. Pancytopenia developed shortly after beginning tamoxifen therapy in an elderly woman, and persisted for some years;[1] the patient eventually developed very severe leucopenia and died of infection. Thrombocytopenia has also been reported.[2]

2. Nasiroğlu N, *et al.* Tamoxifen induced-thrombocytopenia: it does occur. *Med Oncol* 2007; **24:** 453–4.

Effects on blood lipids. Tamoxifen has been reported to have a generally favourable effect on serum lipid profiles.[1] Patients with breast cancer and subsequent chemotherapy-induced ovarian failure developed marked increases in total cholesterol and low-density lipoprotein levels; adjuvant tamoxifen was found to decrease these serum lipid concentrations to below baseline concentrations. No significant changes in high-density lipoprotein or serum triglyceride concentrations were observed.[2] However, some cases of increased serum triglycerides in women with pre-existing hypertriglyceridaemia have been reported. Pancreatitis has also resulted. It has been suggested that tamoxifen should be used with caution in patients with hypertriglyceridaemia.[3,4]

Effects on the cardiovascular system. ***ISCHAEMIC HEART DISEASE.*** For discussion of whether the effects of tamoxifen on lipid profiles can alter the incidence of ischaemic heart disease, see Cardiovascular Disorders under Uses and Administration, below.

STROKE. An excess risk of stroke was seen in tamoxifen compared with placebo recipients (5 cases versus 1) in a study of adjuvant tamoxifen.[1] A statistically non-significant increase in stroke was also seen in a study on the use of tamoxifen for breast cancer prevention (0.5 excess cases per 1000 women per year).[2] A meta-analysis[3] of 9 trials for prevention or treatment of breast cancer, involved data from 39 601 women, of whom 19 954 received tamoxifen. It concluded that use of tamoxifen increased the risk of ischaemic stroke by 82%, and the risk of any stroke by 29%; however, the absolute increase in risk was small.

In contrast, a case-control study of 11 045 women with breast cancer, found that tamoxifen use was not associated with an increased risk of first stroke.[4]

THROMBOEMBOLISM. A case control study,[1] involving 25 cases of deep-vein thrombosis or pulmonary embolism among more than 10 000 women with breast cancer, suggested that current use of tamoxifen was associated with an estimated relative risk of developing idiopathic venous thromboembolism of 7.1 (95% confidence interval 1.5 to 33). Past use of tamoxifen was not associated with a materially increased risk. In a randomised placebo-controlled study, there was an increase in pulmonary emboli in women receiving tamoxifen for cancer prevention (excess of 0.46 cases per 1000 women per year).[2] The fatality rate from pulmonary emboli in tamoxifen recipients was about 17%. In this study, there was also a trend towards more deep-vein thrombosis in tamoxifen recipients. In another controlled study[3] of breast cancer prevention, tamoxifen approximately doubled the risk of developing a major thromboembolic event such as pulmonary embolism, deep-vein thrombosis, or retinal thrombosis. Cerebral sinus thrombosis has also been reported.[4] An analysis[5] of 4 tamoxifen prevention studies also found that venous thromboembolic events were increased in all studies, with a relative risk of 1.9 for those taking tamoxifen compared with placebo. However, another randomised study[6] found only a borderline significantly higher risk of developing venous thromboembolic events in those women allocated to tamoxifen; most of these events were superficial thrombophlebitis. Furthermore, women already at risk for atherosclerosis had a higher risk of venous thromboembolism. While the authors could not exclude a selection bias for healthier subjects in the study, they commented that the prothrombotic effect of tamoxifen may depend on the patient's existing endocrine status, and may be attenuated in those women taking HRT, especially when it is used transdermally.

Effects on the eyes. Tamoxifen has been reported to be associated with decreased visual acuity, corneal opacities and cataract, and retinopathy. The latter is sometimes progressive although in most cases it has shown improvement once the drug was stopped.[1] A prospective study in 63 patients taking tamoxifen 20 mg daily found evidence of decreased visual acuity, macular oedema, and retinal opacities in 4, occurring after 10 to 35 months of therapy.[2] A small excess risk of developing cataracts (3.1 extra per year per 1000 women) and of requiring cataract surgery (1.7 per year per 1000 women) was found in women taking tamoxifen for up to 5 years to reduce the risk of breast cancer.[3] Studies *in vitro* have suggested that cataract formation may be due to inhibition of chloride channels in the lens by tamoxifen or its hydroxy metabolite.[4] Retinopathy after high-dose tamoxifen treatment may be associated with crystalline deposition of the drug in the retina.[5]

5. Bourla DH, *et al.* Peripheral retinopathy and maculopathy in high-dose tamoxifen therapy. *Am J Ophthalmol* 2007; **144:** 126–8.

Effects on the genito-urinary system. Persistent nocturnal priapism was reported in a man receiving tamoxifen 20 mg daily.[1] Symptoms abated within 24 hours of withdrawing the drug. Impotence has been reported in men receiving tamoxifen, and has been attributed to a paradoxical oestrogenic effect.[2]

1. Fernando IN, Tobias JS. Priapism in patient on tamoxifen. *Lancet* 1989; **i:** 436.
2. Collinson MP, *et al.* Two case reports of tamoxifen as a cause of impotence in male subjects with carcinoma of the breast. *Breast* 1993; **2:** 48–9.

Effects on the liver. Cholestasis and increased liver enzyme values have been reported on use of tamoxifen in a 75-year-old patient.[1] Enzyme activity rose again on rechallenge with tamoxifen. Fatal hepatocellular necrosis and agranulocytosis, possibly exacerbated by continuing to take the drug once jaundice developed, has also been reported;[2] the authors noted that 4 cases of hepatic failure (3 fatal) and 5 cases of hepatitis (1 fatal) had been reported to the UK CSM. Patients taking tamoxifen may also develop steatohepatitis,[3-7] which must be distinguished from alcohol-induced liver disease. Steatohepatitis is reversible on withdrawal of tamoxifen.[3,5,6] A study in healthy women who had had hysterectomies found the risk of steatohepatitis to be particularly high among obese women, moderately high among overweight women, and similar to that with placebo in women of normal weight.[8] Bezafibrate has been tried to prevent progression of steatohepatitis and permit continued use of tamoxifen.[9]

For a report of peliosis hepatis and liver haemorrhage in a patient receiving tamoxifen and warfarin, see under Interactions, below.

For reference to studies in *animals* suggesting that tamoxifen has the potential to cause liver cancer, see Carcinogenicity, above.

Effects on the ovaries. Ovarian cysts are relatively common as an adverse effect in women receiving adjuvant tamoxifen: a study[1] in 95 such women reported the development of ovarian cysts in 6 of 16 (37.5%) who were premenopausal and in 5 of 79 postmenopausal women (6.3%). In 2 of the premenopausal women the cysts were complex. Two women underwent laparotomy for persistent cysts that were found to be benign, and 1 for leiomyoma; the cysts in the other 8 women resolved after withdrawal of tamoxifen. A study of 142 breast cancer patients receiving tamoxifen found ovarian cysts in 24 patients after treatment. Cyst development was more common in pre-menopausal women, patients with high oestrogen levels, and patients who did not receive high-dose chemotherapy.[2] There is little evidence that tamoxifen increases the risk of ovarian cancer (see Carcinogenicity, above).

2. Mourits MJE, *et al.* Ovarian cysts in women receiving tamoxifen for breast cancer. *Br J Cancer* 1999; **79:** 1761–64.

Effects on the skin and hair. Vasculitis has been reported in patients given tamoxifen.[1,2] Withdrawal of the drug resulted in complete clearance of the lesions;[1,2] in one case, on re-introduction, purpura developed again within a few days.[1] The results suggest that tamoxifen can produce immune-mediated vascular damage.

In another report a patient with white hair developed darkening and repigmentation of the hair after about 2½ years of tamoxifen therapy.[3] Alopecia has also been reported in women given tamoxifen,[4,5] and in older patients the follicle may not recover.[4]

Precautions

All patients being considered for treatment with tamoxifen should be assessed for any increased risk of thromboembolism. Tamoxifen should not be used for treatment of infertility or the prophylaxis of breast cancer in women with a history of thromboembolic events. When used to treat breast cancer in such women, the risks and benefits should be considered; in some patients, especially those given cytotoxic drugs, prophylactic anticoagulation may be justified. Care is also needed during or immediately after major surgery or prolonged immobility; all patients should be given prophylaxis against thrombosis. In patients being treated for infertility, tamoxifen should be stopped at least 6 weeks before surgery or long-term immobility and only restarted when the patient is fully mobile. Patients should be made aware of the symptoms of thromboembolism and advised to report sudden breathlessness or any pain in the calf of one leg. Tamoxifen should be withdrawn immediately in any patient developing thromboembolism and appropriate treatment given. Treatment should not usually be restarted for infertility therapy but resumption of tamoxifen with prophylactic anticoagulation may be justified in selected patients with breast cancer.

Women treated with tamoxifen should have routine gynaecological monitoring, and any abnormal symptoms such as menstrual irregularities, abnormal vaginal bleeding or discharge, or pelvic pain should be investigated (see also under Carcinogenicity, above). Periodic complete blood counts and liver function tests have been suggested.

Abuse. Although the supervised use of tamoxifen for the treatment of gynaecomastia resulting from the abuse of anabolic steroids has been reported[1] it also appears to be widely used without medical supervision. Tamoxifen can be used to treat idiopathic gynaecomastia and gynaecomastia resulting as an adverse effect of nonsteroidal anti-androgens used to treat prostate cancer (see under Breast Disorders, Non-malignant, below).

1. de Luis DA, *et al.* Anabolizantes esteroideos y ginecomastia: revisión de la literatura. *An Med Interna* 2001; **18:** 489–91.

Breast feeding. Tamoxifen was shown to inhibit lactation in 60 puerperal women.[1] Licensed product information recommends that it should not be given to lactating women.

1. Masala A, *et al.* Inhibition of lactation and inhibition of prolactin release after mechanical breast stimulation in puerperal women given tamoxifen or placebo. *Br J Obstet Gynaecol* 1978; **85:** 134–7.

Porphyria. Tamoxifen has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Tamoxifen is contra-indicated in pregnancy. Ambiguous genitalia have been reported in an infant exposed to tamoxifen *in utero*, although no causal link was demonstrated.[1] Another infant was born with Goldenhar's syndrome (oculoauriculovertebral dysplasia) after exposure to tamoxifen throughout a 26-week pregnancy.[2] The mother had also taken cocaine and marijuana during the first 6 weeks of pregnancy, and a bone scan using technetium Tc99m medronate had been performed. The US manufacturer of tamoxifen (*Zeneca, USA*) was aware of 50 pregnancies in patients taking tamoxifen, resulting in 19 normal births, 8 terminations, 13 unknown outcomes and 10 infants with fetal or neonatal abnormalities.[2]

Tamoxifen has also been used to stimulate ovulation in women with luteal phase dysfunction. In one study tamoxifen was given to 40 women, resulting in 14 pregnancies. Although 9 infants were born with no congenital abnormalities, there were 5 spontaneous abortions, which the authors felt was unacceptably high.[3] Another study, using lower doses of tamoxifen (in some cases sequentially with clomifene), reported 32 pregnancies and only 3 spontaneous abortions in 65 treated patients.[4]

4. Wu CH. Less miscarriage in pregnancy following tamoxifen treatment of infertile patients with luteal phase dysfunction as compared to clomiphene treatment. *Early Pregnancy* 1997; **3:** 301–5.

Radiotherapy. There are reports of radiation recall, with erythema at the site of previous radiotherapy, in patients receiving tamoxifen.[1,2]

1. Parry BR. Radiation recall induced by tamoxifen. *Lancet* 1992; **340:** 49.
2. Extermann M, *et al.* Radiation recall in a patient with breast cancer treated for tuberculosis. *Eur J Clin Pharmacol* 1995; **48:** 77–8.

Interactions

There is a risk of increased anticoagulant effect if tamoxifen is given with coumarin anticoagulants. Conversely, use with cytotoxic drugs may increase the risk of thromboembolic events; prophylactic anticoagulation should be considered. Tamoxifen increases the dopaminergic effect of bromocriptine. Use with inhibitors of cytochrome P450 isoenzyme CYP2D6 has been shown to reduce plasma concentrations of endoxifen, a tamoxifen metabolite (see Pharmacokinetics, below); the clinical relevance is unclear.

Allopurinol. For reference to exacerbation of hepatotoxicity when tamoxifen was given with allopurinol, see p.553.

Antibacterials. *Rifampicin* was found to decrease plasma concentrations of tamoxifen in 10 healthy subjects. This was thought to be due to induction of cytochrome P450 isoenzyme CYP3A4 by rifampicin.[1]

1. Kivistö KT, *et al.* Tamoxifen and toremifene concentrations in plasma are greatly decreased by rifampin. *Clin Pharmacol Ther* 1998; **64:** 648–54.

Anticoagulants. Cases of a potentially life-threatening interaction between tamoxifen and *warfarin*, with marked prolongation of prothrombin times, haematuria, and haematoma, have been reported.[1-3] It has been suggested that in addition to enhancement of the effects of warfarin, competition for the same metabolic enzyme systems might reduce the activity of tamoxifen against tumours,[2] but this remains speculative.

Peliosis hepatis and fatal liver haemorrhage have been reported in a patient who was receiving tamoxifen with warfarin and a liothyronine-levothyroxine preparation.[4]

1. Lodwick R, *et al.* Life threatening interaction between tamoxifen and warfarin. *BMJ* 1987; **295:** 1141.
2. Tenni P, *et al.* Life threatening interaction between tamoxifen and warfarin. *BMJ* 1989; **298:** 93.
3. Ritchie LD, Grant SMT. Tamoxifen-warfarin interaction: the Aberdeen hospitals drug file. *BMJ* 1989; **298:** 1253.
4. Loomus GN, *et al.* A case of peliosis hepatis in association with tamoxifen therapy. *Am J Clin Pathol* 1983; **80:** 881–3.

Antidepressants. The metabolism of tamoxifen to an active metabolite, 4-hydroxy-*N*-desmethyltamoxifen (endoxifen), may be inhibited by paroxetine, a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6.[1] However, the clinical consequences of this are, as yet, unclear.[1] In addition, a case-control study[2] found that patients taking tamoxifen with known inhibitors of CYP isoenzymes, including CYP2D6, were no more likely to relapse than those not receiving a CYP inhibitor.

1. Stearns V, *et al.* Active tamoxifen metabolite plasma concentrations after coadministration of tamoxifen and the selective serotonin reuptake inhibitor paroxetine. *J Natl Cancer Inst* 2003; **95:** 1758–64.
2. Lehmann D, *et al.* Lack of attenuation in the antitumor effect of tamoxifen by chronic CYP isoform inhibition. *J Clin Pharmacol* 2004; **44:** 861–5.

Antineoplastics. *Aminoglutethimide* reduces serum tamoxifen concentrations, possibly by increasing its metabolism.[1] For mention of an increased risk of haemolytic-uraemic syndrome in patients who received therapy with tamoxifen and *mitomycin* see Effects on the Kidneys, under Mitomycin, p.752. Tamoxifen is reported to reduce plasma concentrations of *letrozole*, see p.740.

1. Lien EA, *et al.* Decreased serum concentrations of tamoxifen and its metabolites induced by aminoglutethimide. *Cancer Res* 1990; **50:** 5851–7.

Immunosuppressants. For the results of a study *in vitro* suggesting that tamoxifen might inhibit the metabolism of *tacrolimus* by inhibiting the cytochrome P450 isoenzyme system, see under Interactions of Tacrolimus, p.1845.

Neuromuscular blockers. For reference to prolonged neuromuscular blockade in a patient given *atracurium* while receiving tamoxifen, see p.1904.

Pharmacokinetics

Peak plasma concentrations of tamoxifen occur 4 to 7 hours after an oral dose. It is extensively protein bound. Plasma clearance is reported to be biphasic and the terminal half-life may be up to 7 days. It is extensively metabolised by the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2D6. The major serum metabolite, *N*-desmethyltamoxifen, has a half-life at steady state of about 14 days. 4-Hydroxytamoxifen is a minor metabolite. *In-vitro* studies suggest that both these metabolites are further metabolised to 4-hydroxy-*N*-desmethyltamoxifen (endoxifen). Several of the metabolites are stated to have similar pharmacological activity to the parent compound. Tamoxifen is excreted slowly in the faeces, mainly as conjugates. Small amounts are excreted in urine. Tamoxifen appears to undergo enterohepatic circulation.

Genetic factors. Tamoxifen is metabolised by the cytochrome P450 isoenzymes, and its metabolites may play a role in its antineoplastic effect. Studies have suggested that patients with low or absent CYP2D6 activity or who are being treated with CYP2D6 inhibitors have lower concentrations of endoxifen. Patients with CYP2D6*3, *4, *5, and *6 alleles are designated as poor metabolisers, those with *9, *10, *17, *29, and *41 as intermediate metabolisers, and those with *1, *2, and *35 as extensive metabolisers.[1,2] Genetic polymorphism in the enzymes responsible for tamoxifen biotransformation has the potential to affect clinical outcomes. While a small study[3] showed a decreased risk of breast cancer recurrence in patients with the CYP2D6*4 allele when treated with tamoxifen, another[4] found that this allele was an independent predictor of a higher risk of disease relapse and a lower incidence of hot flashes in postmenopausal women with breast cancer. A further study[5] found that carriers of CYP2D6 alleles *4 or *5 showed a greater risk for breast cancer relapse. Furthermore, carriers of the CYP2C19*17 genotype had a more favourable clinical outcome. These results prompted the Clinical Pharmacology Subcommittee of the US FDA Advisory Committee for Pharmaceutical Science to advise that availability of genotypic testing be included in licensed product information for tamoxifen.[6,7] Some have commented[7] that it would seem reasonable to confine CYP2D6 testing to situations where it might guide the choice between tamoxifen and an alternative.

Metabolism. Tamoxifen is extensively metabolised by cytochrome P450 isoenzymes, to active metabolites that include *N*-desmethyltamoxifen, 4-hydroxytamoxifen, and 4-hydroxy-*N*-desmethyltamoxifen (endoxifen).[1] *In-vitro* studies suggest that both *N*-desmethyltamoxifen and 4-hydroxytamoxifen are further metabolised to endoxifen.[2] However, the biotransformation of tamoxifen has not been fully elucidated, and there is growing interest in how genetic polymorphism might influence the efficacy and toxicity of tamoxifen and its metabolites (see Genetic Factors, above).

Uses and Administration

Tamoxifen is an oestrogen antagonist with actions similar to those of clomifene citrate (see p.2086). It may also inhibit the production or release of cellular growth factors and induce apoptosis. It is used in the adjuvant endocrine therapy of node-positive breast cancer, in the treatment of metastatic disease, and for prophylaxis in women at increased risk including those with ductal carcinoma in situ. It has been tried in some other malignancies including tumours of the ovary and in malignant melanoma. Tamoxifen is also used to stimulate ovulation in women with anovulatory infertility. See also the cross-references below.

Tamoxifen is given orally as the citrate but doses are calculated in terms of the base; tamoxifen citrate 15.2 mg is equivalent to about 10 mg of tamoxifen. In the treatment of breast cancer, usual doses are tamoxifen 20 mg daily, in 2 divided doses or as a single daily dose. Doses of up to 40 mg daily may be given but no additional benefit has been demonstrated. Adjuvant therapy is normally continued for up to 5 years, although the optimum duration is still uncertain (p.661). To reduce breast cancer incidence in women at high risk of the disease, the licensed dose of tamoxifen is 20 mg daily for 5 years.

In the treatment of anovulatory infertility the usual dose is tamoxifen 20 mg daily on days 2 to 5 of the menstrual cycle, increased if necessary in subsequent cycles up to 80 mg daily. In women with irregular menstruation the initial course may be begun on any day, and a second course begun at a higher dose after 45 days if there has been no response. If the patient responds with menstruation, subsequent courses may begin on day 2 of the cycle.

A topical formulation of 4-hydroxytamoxifen, a metabolite of tamoxifen, is under investigation for the treatment of cyclic mastalgia.

Breast disorders, non-malignant. *GYNAECOMASTIA.* Tamoxifen, usually in doses of 10 mg twice daily, has been reported to be effective[1-7] in reducing pain, swelling, and breast size in men or pubertal boys with gynaecomastia (p.2092). Tamoxifen has been recommended as a drug of choice in patients requiring drug therapy, given for 3 months to see if a response occurs.[7] It has also been reported to be effective for the prevention and treatment of gynaecomastia and breast pain caused by the nonsteroidal anti-androgen bicalutamide,[8-11] which is used in the treatment of prostate cancer (see Gynaecomastia under Adverse Effects and Precautions of Flutamide, p.725).

MASTALGIA. Tamoxifen 20 mg daily has been shown to be effective in patients with both cyclic and non-cyclic mastalgia,[1] and improvement has also been reported at a lower dose of 10 mg daily.[2] However, there is concern about the use of tamoxifen in otherwise healthy premenopausal women,[3-5] particularly since many patients relapse on withdrawal,[2] and it has been recommended[6,7] that tamoxifen be reserved for patients who fail to respond to other drugs (see p.2092).

A topical formulation of 4-hydroxytamoxifen, a metabolite of tamoxifen, is under investigation in the treatment of cyclic mastalgia.

Cardiovascular disorders. Tamoxifen has been reported to have a generally favourable effect on lipid profiles (see Effects on Blood Lipids, under Adverse Effects, above) suggesting it may have cardiovascular benefits.[1] A cohort study of adjuvant tamoxifen found that the drug reduced the incidence of myocardial infarction,[2] and a randomised study of the same therapy also showed a trend towards a decrease in mortality from coronary heart disease.[3] However, in a much larger breast cancer prevention trial, tamoxifen did not reduce the risk of, and mortality from, ischaemic heart disease, neither of which differed between placebo and tamoxifen recipients.[4,5] This lack of difference was independent of pre-existing cardiovascular disease.[5] A review[6] noted that while the available data suggested an overall benefit, most of them came from studies in women at low absolute risk of myocardial infarction; studies in men at high absolute risk would be needed to determine whether tamoxifen and related drugs were suitable as cardioprotectants.

Disorders related to the menstrual cycle. Apart from cyclic mastalgia (see above) tamoxifen has been used in a number of cases in which disorders were linked to the hormonal changes of the menstrual cycle, including menorrhagia due to myometrial hypertrophy,[1] an auto-immune dermatitis due to post-ovulatory rises in serum progesterone[2,3] (see Effects on the Skin under Progesterone, p.2125), and premenstrual migraine.[4] However, tamoxifen was thought to be a cause of recurrent migraines in another patient, because of its action at oestrogen receptors.[5]

Infertility. Tamoxifen is reported to be as effective as clomifene in the treatment of anovulatory infertility (p.2080) in women,[1,2] and may be useful in women in whom abnormal cervical mucus acts as a barrier to spermatozoa.[3] In infertile men, however, results are reportedly contradictory, with some studies reporting increase in sperm density and improved pregnancy rates while others failed to demonstrate any effect.[4] The addition of testosterone may improve outcomes, however, and a later study of men with idiopathic oligozoospermia reported that tamoxifen with testosterone improved sperm variables and pregnancy rates compared with a placebo group (there was no comparison with tamoxifen alone).[5]

Malignant neoplasms. For reference to the use of tamoxifen in malignant neoplasms of breast, ovary, and in cutaneous melanoma, see p.661, p.670, and p.673. The most common use of tamoxifen is for the endocrine therapy of oestrogen-receptor positive early or advanced breast cancer, where there seems to be a clear benefit. How long such therapy should be continued remains uncertain although continuing therapy beyond 5 years may not increase the overall benefit. However, extending therapy by following 5 years of tamoxifen therapy with several years of an aromatase inhibitor such as letrozole (see, p.740) does seem to provide additional benefit.

Extension of tamoxifen use to the attempted prophylaxis of breast cancer has proved controversial (see p.662). Nonetheless, evidence that tamoxifen can reduce short-term incidence of breast cancer in some women at increased risk has been seen, and tamoxifen has been approved for such use in the USA.

Despite some positive data, tamoxifen does not appear to be effective in the treatment of hepatocellular carcinoma (see p.667).

Osteoporosis. Tamoxifen has been reported to have favourable effects on bone mass,[1-3] but any general role in the prevention of osteoporosis (p.1084) seems unlikely given concerns about the carcinogenicity of tamoxifen. The effects are reported to be comparable in magnitude to those of calcium supplementation, and less than those of oestrogens (see also p.2077) or bisphosphonates. It has been suggested that such an effect on bone would provide an additional benefit in women receiving tamoxifen for the prophylaxis of breast cancer,[4] although others dispute the benefits.[5]

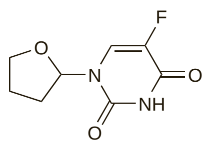
Tegafur *(BAN, USAN, rINN)*

FT-207; Ftorafur; MJF-12264; NSC-148958; Tégafur; Tegafurum; Tegafuuri; WR-220066. 5-Fluoro-1-(tetrahydro-2-furyl)uracil; 5-Fluoro-1-(tetrahydro-2-furyl)pyrimidine-2,4(1*H*,3*H*)-dione.

Тегафур

$C_8H_9FN_2O_3$ = 200.2.
CAS — 17902-23-7.
ATC — L01BC03.
ATC Vet — QL01BC03.



Pharmacopoeias. In *Chin.* and *Jpn.*

Adverse Effects, Treatment, and Precautions

As for Fluorouracil, p.722.

Bone-marrow depression may be less severe with tegafur but gastrointestinal toxicity is often dose-limiting and central neurotoxicity is more common. Peripheral oedema and dyspnoea occur commonly. Increases in liver function test values are common and there are reports of fatal fulminant hepatitis. Liver function should be monitored in patients with hepatic impairment given tegafur; it should not be given in severe hepatic impairment.

Interactions

Tegafur should not be used with drugs that inhibit dihydropyrimidine dehydrogenase; fatalities have occurred in patients given tegafur and sorivudine (see Antivirals under Interactions of Fluorouracil, p.723). Increased plasma concentrations of phenytoin, and symptoms of toxicity during use with tegafur and uracil, have been reported.

Pharmacokinetics

Tegafur is well absorbed from the gastrointestinal tract after oral doses. After an intravenous dose it is reported to have a prolonged plasma half-life of 6 to 16 hours. Tegafur appears to be slowly metabolised in the liver to fluorouracil (p.723), and some intracellular conversion to fluorouracil may also occur. Tegafur crosses the blood-brain barrier and is found in the CSF.

◊ References.

Uses and Administration

Tegafur is considered to be an orally active prodrug of fluorouracil (p.723). It has been used in the management of malignant neoplasms including those of the breast, gallbladder, gastrointestinal tract, head and neck, liver, and pancreas. Tegafur has been given orally in doses up to 1 g/m^2 daily. It is often given with uracil (UFT; p.2407). Tegafur 300 mg/m^2 daily, with uracil 672 mg/m^2 daily, may be given in 3 divided oral doses, together with calcium folinate, in the management of metastatic colorectal cancer. Doses are given for a cycle of 28 days, followed by 7 days without treatment. The drugs should be taken 1 hour before or after meals, and doses modified according to toxicity. Doses of tegafur 1 to 3 g/m^2 daily for 5 days have been given intravenously.

Administration. Tegafur is an orally active prodrug of fluorouracil. Although it has been given as a single agent, it is more often used with drugs that modify its bioavailability and toxicity.[1] These include uracil (p.2407) and gimestat (5-chlorodihydropyrimidine, CDHP), which can increase fluorouracil concentrations by inhibition of dihydropyrimidine dehydrogenase, the enzyme responsible for its further catabolism,[1-3] and oxonic acid (otastat), which inhibits another enzyme, orotate pyrimidine phosphoribosyl transferase, thought to play a role in the gastrointestinal toxicity of fluorouracil and its prodrugs.[2]

UFT consists of tegafur and uracil in the optimal molar ratio 1:4.[1] It is available for the treatment of colorectal cancer (p.665)—for doses, see above. A preliminary analysis of a large study comparing oral UFT and calcium folinate therapy with intravenous fluorouracil and calcium folinate found both regimens to be well tolerated with similar levels of toxicity.[4] Adjuvant therapy with UFT appears to improve survival in patients with adenocarcinoma of the lung[5] and node-negative breast cancer.[6]

S-1 (TS-1, *Taiho Jpn*) is a combination of tegafur, gimestat and the potassium salt of oxonic acid in the molar ratio 10:4:10. It has been tried in gastric and colorectal cancers,[2,3,7,8] and initial results have suggested comparable activity to fluorouracil and calcium folinate in induction regimens, but the incidence of diarrhoea and stomatitis was reduced.

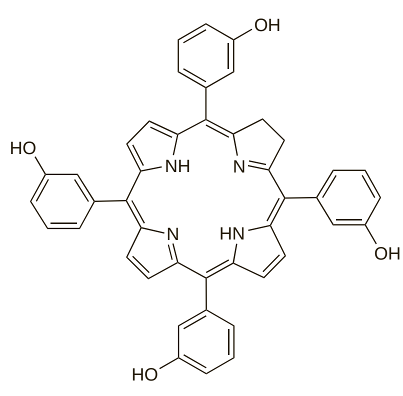
Temoporfin *(BAN, USAN, rINN)*

EF-9; mTHPC; Temoporfiini; Temoporfina; Témoporfine; Temoporfinum; *meso*-Tetrahydroxyphenylchlorin; *meta*-Tetrahydroxyphenylchlorin. 3,3′,3″,3‴-(7,8-Dihydroporphyrin-5,10,15,20-tetrayl)tetraphenol; 7,8-Dihydro-5,10,15,20-tetrakis(3-hydroxyphenyl)porphyrin.

Темопорфин

$C_{44}H_{32}N_4O_4$ = 680.7.
CAS — 122341-38-2.
ATC — L01XD05.
ATC Vet — QL01XD05.



Adverse Effects and Precautions

Adverse effects of temoporfin include photosensitivity, local inflammatory reactions, and gastrointestinal disturbances. Patients should be advised to avoid direct sunlight or bright indoor light for 15 days, and to protect the injection site from light for at least 3 months if extravasation has occurred.

Porphyria. The use of temoporfin is contra-indicated in patients with porphyria.

Interactions

Use of temoporfin with other drugs causing photosensitivity should be avoided as the reaction may be increased; this has been reported with topical fluorouracil.

Pharmacokinetics

Peak plasma concentrations of temoporfin are reached about 2 to 4 hours after intravenous infusion. Thereafter, elimination is biexponential, with a terminal plasma half-life of about 65 hours. Plasma protein binding is about 85%. *Animal* data indicate that temoporfin is metabolised in the liver and excreted in the faeces via the bile.

Uses and Administration

Temoporfin is a porphyrin derivative. It is used palliatively as a photosensitiser in the photodynamic therapy (see under Porfimer Sodium, p.764) of refractory squamous cell carcinoma of the head and neck (p.666), that cannot be treated with radiotherapy, surgery, or systemic chemotherapy. It is also under investigation in the treatment of various other malignant neoplasms. Temoporfin is given by slow intravenous injection over at least 6 minutes, at a dose of 150 micrograms/kg. This is followed 96 hours later by activation using a laser tuned to a wavelength of 652 nanometres for about 200 seconds, sufficient to supply a dose of 20 J/cm^2. Treatment may be repeated once after 4 weeks if necessary.

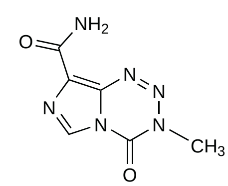
Temozolomide *(BAN, USAN, rINN)*

CCRG-81045; M&B-39831; NSC-362856; Sch-52365; Temotsolomidi; Temozolomid; Temozolomida; Témozolomide; Temozolomidum. 3,4-Dihydro-3-methyl-4-oxoimidazo[5,1-*d*][1,2,3,5]tetrazine-8-carboxamide.

Темозоломид

$C_6H_6N_6O_2$ = 194.2.
CAS — 85622-93-1.
ATC — L01AX03.
ATC Vet — QL01AX03.



Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641. Myelosuppression is common with temozolomide and is dose-limiting. The nadir of cell counts usually occurs 21 to 28 days after treatment, with recovery within the next 1 to 2 weeks. Patients over 70 years of age are thought to be more susceptible to severe myelosuppression. Prolonged pancytopenia may result in aplastic anaemia, and fatalities have been reported. Opportunistic infections can occur; *Pneumocystis jirovecii* pneumonia has been reported in patients also given radiotherapy or corticosteroids, or during a longer dosing regimen of temozolomide. Other common adverse effects include gastrointestinal disturbances, anorexia, alopecia, fatigue, headache, rashes, convulsions, and insomnia or somnolence. Anxiety, depression, confusion, dizziness, hemiparesis, aphasia, dysphagia, peripheral neuropathy, paraesthesia, neurological and/or speech disorders, tremor, and concentration or memory impairment can occur, as can visual field defects, blurred vision, diplopia, hearing impairment, or tinnitus. Deafness has been reported. Vascular disorders such as haemorrhage, deep venous thrombosis, and peripheral oedema can occur; pulmonary embolism has been reported. Other commonly reported adverse effects include dyspnoea, coughing, dry skin, pruritus, arthralgia and/or myalgia, urinary incontinence, fever, pain, and dysgeusia. Liver enzyme values can increase, and hyperglycaemia may occur. Cushingoid disorders have occurred uncommonly. Hypersensitivity reactions, including rare cases of anaphylaxis, have been reported. Toxic epidermal necrolysis, Stevens-Johnson syndrome, and erythema multiforme have been reported rarely. Temozolomide has carcinogenic, mutagenic, and teratogenic potential.

Pharmacokinetics

Temozolomide is rapidly and completely absorbed from the gastrointestinal tract, with peak plasma concentrations occurring 0.5 to 1.5 hours after a dose. Food reduces the rate and extent of absorption. It readily crosses the blood-brain barrier and can be detected in the CSF. The plasma elimination half-life is 1.8 hours. Temozolomide undergoes spontaneous hydrolysis to its active metabolite 5-(3-methyl-1-triazeno)imidazole-4-carboxamide (MTIC), which is then further hydrolysed to active and inactive compounds. It is largely eliminated by the kidneys, about 5 to 10% as unchanged drug.

Uses and Administration

Temozolomide is a prodrug that is converted to MTIC (see Pharmacokinetics, above), the active metabolite of dacarbazine (p.706). MTIC acts as an alkylating agent. Temozolomide is given orally and is licensed for the treatment of malignant gliomas such as glioblastoma multiforme and anaplastic astrocytoma, and malignant melanoma (below).

In adult patients with *newly diagnosed* **glioblastoma multiforme**, temozolomide is given initially with focal radiotherapy (the *concomitant phase*) in an oral dose of 75 mg/m^2 daily for 42 days. Treatment may be interrupted or stopped depending on toxicity. Complete blood counts should be monitored weekly. Four weeks after completing the concomitant phase, temozolomide *monotherapy* is begun at an oral dose of 150 mg/m^2 once daily for 5 days of a 28-day cycle. In cycle 2, the dose is increased to 200 mg/m^2 for 5 days, if toxicity allows. If the dose cannot be increased in cycle 2, it should not be increased in subsequent cycles. The dose used at cycle 2 is then given every 28 days, toxicity allowing. Up to 6 cycles of temozolomide monotherapy may be given.

The usual oral dose for *recurrent or progressive* malignant gliomas in adults and children over 3 years of age (and previously untreated with chemotherapy) is 200 mg/m^2 daily for 5 days, repeated every 28 days. In patients who have received previous courses of chemotherapy the dose should be reduced to 150 mg/m^2 for the first cycle of therapy, but may be increased to 200 mg/m^2 for subsequent courses if there is no haematological toxicity.

A dose of 200 mg/m^2 daily for 5 days every 28 days is also used for metastatic **malignant melanoma**.

Malignant neoplasms. Temozolomide has been studied[1-9] particularly in the management of malignant neoplasms of the brain (p.660). In the UK, guidance has been issued[10] on its use in patients with recurrent progressive malignant glioma who have failed first-line chemotherapy treatment with other agents (either because of lack of efficacy or because of adverse effects).

Melanoma. Temozolomide has been studied[1-3] as a treatment for advanced metastatic melanoma (p.673). A phase III trial compared the overall survival-time in 305 patients treated with either oral temozolomide or intravenous dacarbazine in standard doses for up to 12 cycles of therapy. Temozolomide was found to be at least equivalent to dacarbazine in these patients, and there were no major differences in adverse effects.[2] However, median survival-times were short in both groups (7.7 months and 6.4 months respectively). Another phase III study comparing temozolomide alone or with interferon alfa in 282 patients also found modest median survival-times of 8.4 and 9.7 months respectively.[4] Temozolomide has also been investigated in *animals* for regional therapy of melanoma of the extremities by isolated limb infusion in combination with hyperthermia.[5]

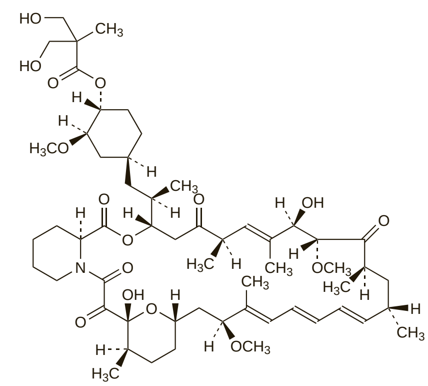
Temsirolimus *(BAN, USAN, rINN)*

CCI-779; Temsirolimusum. (3*S*,6*R*,7*E*,9*R*,10*R*,12*R*,14*S*,15*E*,17*E*,19*E*,21*S*,23*S*,26*R*,27*R*,34a*S*)-9,10,12,13,14,21,22,23,24,25,26,27,32,33,34,34a-Hexadecahydro-9,27-dihydroxy-3-{(1*R*)-2-[(1*S*,3*R*,4*R*)-4-hydroxy-3-methoxycyclohexyl]-1-methylethyl}-10,21-dimethoxy-6,8,12,14,20,26-hexamethyl-23,27-epoxy-3*H*-pyrido[2,1-c][1,4]oxaazacyclohentriacontine-1,5,11,28,29(4*H*,6*H*,31*H*)-pentone 4′[2,2-bis(hydroxymethyl)propionate].

Темсиролимус

$C_{56}H_{87}NO_{16}$ = 1030.3.

CAS — 162635-04-3.



Incompatibility. The formulation of temsirolimus injection contains polysorbate 80, which increases the rate of extraction of the plasticiser di-2-ethylhexylphthalate (DEHP) from PVC. In order to minimise exposure to DEHP, the infusion should be given in glass, polyolefin, or polyethylene containers, through non-DEHP giving sets with an in-line polyethersulfone filter of not greater than 5 microns.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The most frequent adverse effects of temsirolimus include rash, asthenia, mucositis, gastrointestinal disturbances, anaemia, leucopenia, thrombocytopenia, hyperglycaemia, hyperlipidaemia, hypertriglyceridaemia, lymphopenia, and hypophosphataemia. Raised liver transaminase concentrations are common. Hypersensitivity reactions, including anaphylaxis, dyspnoea, flushing, and chest pain have occurred. Antihistamines should be given about 30 minutes before the start of the infusion. If the patient develops a hypersensitivity reaction, the infusion should be stopped and the patient observed for 30 to 60 minutes, after which treatment may be resumed if appropriate, at a slower infusion rate; a further dose of an H_1- or H_2-receptor antagonist may be given. Infections, including urinary-tract infection, pharyngitis, rhinitis, and pneumonia can occur. Acute, and sometimes fatal, renal failure has been reported. Interstitial lung disease has been reported, including some fatalities, although other cases were asymptomatic. Manifestations included dyspnoea, cough, hypoxia, or fever. Cases of fatal bowel perforation have occurred; patients presented with fever, abdominal pain, metabolic acidosis, bloody stools, diarrhoea, and/or acute abdomen. Abnormal wound healing has also been reported. Patients with CNS tumours given anticoagulants may be at increased risk of developing intracranial bleeding, which may be fatal.

Effects on the lungs. Eight out of 22 patients given temsirolimus developed pulmonary abnormalities compatible with drug-induced pneumonitis. Dyspnoea and dry cough were the most common symptoms, although 4 patients were asymptomatic. The risk of developing pulmonary toxicity is increased in those with abnormal pre-treatment pulmonary function, or a history of lung disease.[1]

1. Duran I, *et al.* Characterisation of the lung toxicity of the cell cycle inhibitor temsirolimus. *Eur J Cancer* 2006; **42:** 1875–80.

Interactions

Temsirolimus is metabolised primarily by the cytochrome P450 isoenzyme CYP3A4 to produce sirolimus. Ketoconazole had no effect on exposure to temsirolimus, but increased exposure to the metabolite. Use with other strong inhibitors of CYP3A4 (such as other azole antifungals, macrolide antibacterials, HIV-protease inhibitors, or grapefruit juice) may also increase sirolimus concentrations. Rifampicin had no effect on exposure to temsirolimus, but decreased exposure to sirolimus. Strong inducers of CYP3A4 (such as dexamethasone, phenytoin, carbamazepine, or phenobarbital) may also decrease exposure to sirolimus; St John's wort may decrease temsirolimus plasma concentrations unpredictably. If the use of alternative drugs is not feasible, dose adjustments of temsirolimus may be necessary (see Uses and Administration, below).

◊ References.

1. Boni J, *et al.* Pharmacokinetic profile of temsirolimus with concomitant administration of cytochrome P450-inducing medications. *J Clin Pharmacol* 2007; **47:** 1430–9.

Pharmacokinetics

Temsirolimus is mainly metabolised by cytochrome P450 isoenzyme CYP3A4 to 5 metabolites; sirolimus is the main active metabolite. The mean half-lives of temsirolimus and sirolimus are about 17 hours and 55 hours, respectively. Exposure to sirolimus may be much greater than that of temsirolimus, due principally to the longer half-life of sirolimus. Elimination is mainly in faeces; about 5% is recovered in the urine.

The symbol † denotes a preparation no longer actively marketed

Uses and Administration

Temsirolimus is an ester analogue of sirolimus (p.1841) that is given intravenously for the treatment of advanced renal cell carcinoma in a dose of 25 mg once weekly. Treatment may continue until disease progression or toxicity occurs. Temsirolimus is given in 250 mL sodium chloride 0.9% and infused over 30 to 60 minutes, preferably via an infusion pump.

Treatment should be interrupted if the absolute neutrophil count falls below 1000 cells/mm^3, or the platelet count falls below 75 000 cells/mm^3, or if grade 3 toxicity occurs. Once these have resolved to grade 2 or less, temsirolimus may be restarted with the dose reduced by 5 mg weekly, to a dose no lower than 15 mg weekly.

Use of strong inhibitors or inducers of CYP3A4 may increase or decrease exposure to sirolimus, the active metabolite of temsirolimus. If no alternative is available, a dose reduction of temsirolimus to 12.5 mg weekly should be considered if it is given with a strong CYP3A4 inhibitor. Once the inhibitor is stopped, a washout period of about 1 week should be allowed before the dose of temsirolimus is increased back to the original dose. A dose increase of temsirolimus to 50 mg weekly should be considered if it is given with a strong CYP3A4 inducer; once the inducer is stopped, the dose of temsirolimus should be decreased to the original dose.

Temsirolimus is also under investigation for the treatment of mantle cell lymphoma.

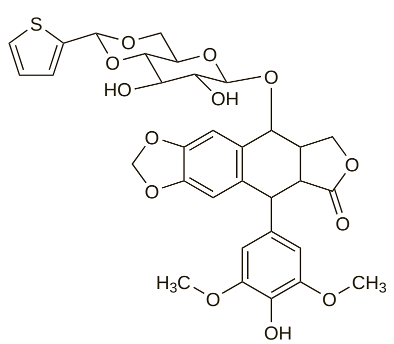
Teniposide *(BAN, USAN, rINN)*

ETP; NSC-122819; Teniposid; Téniposide; Teniposidi; Tenipósido; Teniposidum; VM-26. (5*S*,5a*R*,8a*S*,9*R*)-5,8,8a,9-Tetrahydro-5-(4-hydroxy-3,5-dimethoxyphenyl)-9-(4,6-*O*-thenylidene-β-D-glucopyranosyloxy)isobenzofuro[5,6-*f*][1,3]benzodioxol-6(5a*H*)-one.

Тенипозид

$C_{32}H_{32}O_{13}S$ = 656.7.
CAS — 29767-20-2.
ATC — L01CB02.
ATC Vet — QL01CB02.



Stability. Precipitation occurred repeatedly in preparations for infusion containing teniposide 200 micrograms/mL in either glucose 5% or sodium chloride 0.9% injection, although previously such preparations had been used uneventfully.[1] Dilution of teniposide solutions to 100 micrograms/mL or less reduced the frequency of the problem, which could not be attributed to a change in formulation and remained unexplained.

1. Strong DK, Morris LA. Precipitation of teniposide during infusion. *Am J Hosp Pharm* 1990; **47:** 512,518.

Adverse Effects, Treatment, and Precautions

As for Etoposide, p.718. There is some evidence that teniposide may be a more potent mutagen and carcinogen than etoposide.

Hypersensitivity. Haemolytic anaemia and acute renal failure with tubular necrosis has been reported in a patient who developed an antibody to teniposide.[1] As with etoposide (p.718) hypersensitivity or infusion reactions occur, sometimes with the first dose, and may be severe;[2,3] the frequency may be as high as 13% in neuroblastoma patients.[2] Although it has been suggested that hypersensitivity reactions might be due to the polyoxyl castor oil in the injection vehicle,[2] studies *in vitro* suggest that it is the drug rather than the vehicle that is responsible.[3]

1. Habibi B, *et al.* Immune hemolytic anemia and renal failure due to teniposide. *N Engl J Med* 1982; **306:** 1091–3.
2. Siddall SJ, *et al.* Anaphylactic reactions to teniposide. *Lancet* 1989; **i:** 394.
3. Carstensen H, *et al.* Teniposide-induced hypersensitivity reactions in children. *Lancet* 1989; **ii:** 55.

Interactions

For a general outline of antineoplastic drug interactions, see p.642.

Antiepileptics. Clearance of teniposide was markedly increased by *phenytoin* or *phenobarbital*; the resultant decrease in systemic exposure to the antineoplastic might reduce its efficacy, and increased dosage would be needed in patients receiving these drugs to guarantee equivalent exposure.[1]

1. Baker DK, *et al.* Increased teniposide clearance with concomitant anticonvulsant therapy. *J Clin Oncol* 1992; **10:** 311–15.

Ciclosporin. Use of ciclosporin with teniposide has been reported[1] to produce a decrease in the clearance of the latter, with increased terminal half-life, peak plasma concentrations, and toxicity.

1. Toffoli G, *et al.* Cyclosporin A as a multidrug-resistant modulator in patients with renal cell carcinoma treated with teniposide. *Br J Cancer* 1997; **75:** 715–21.

Uses and Administration

Teniposide is an antineoplastic agent with general properties similar to those of etoposide (p.718). It has been given alone or with other antineoplastic agents in the treatment of refractory acute lymphoblastic leukaemia (p.651). Teniposide has been tried in solid tumours including neuroblastoma (p.674), and retinoblastoma (p.675).

Teniposide is given by slow intravenous infusion over at least 30 to 60 minutes, as a solution of up to 1 mg/mL in sodium chloride 0.9% injection or glucose 5% injection. Dosage regimens have ranged from 30 mg/m^2 every 5 days, to 180 mg/m^2 weekly, as a single agent. Doses of 165 mg/m^2 twice weekly for 8 or 9 doses with cytarabine, or up to 250 mg/m^2 weekly for 4 to 8 weeks with vincristine and prednisone have been given in the treatment of refractory acute lymphoblastic leukaemia.

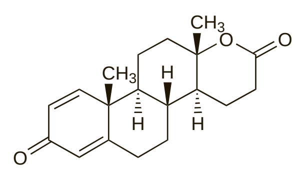
Testolactone *(USAN, rINN)* ⊗

1-Dehydrotestololactone; NSC-23759; SQ-9538; Testolactona; Testolactonum; Testolakton; Testolaktoni. D-Homo-17a-oxaandrosta-1,4-diene-3,17-dione.

Тестолактон

$C_{19}H_{24}O_3$ = 300.4.
CAS — 968-93-4.



Pharmacopoeias. In *US.*

USP 31 (Testolactone). A white to off-white, practically odourless, crystalline powder. Soluble 1 in 4050 of water; soluble in alcohol and in chloroform; slightly soluble in benzyl alcohol; insoluble in ether and in petroleum spirit. Store in airtight containers.

Profile

Testolactone is a derivative of testosterone (see p.2129). It is reported to be an aromatase inhibitor that reduces peripheral oestrogen synthesis but has no significant androgenic activity. It has been used in the palliative treatment of advanced breast cancer in postmenopausal women (p.661).

The usual oral dose is 250 mg four times daily.

It should not be given to men with breast cancer.

Peripheral neuropathies have occurred in patients given testolactone; gastrointestinal disturbances, pain or oedema of the extremities, hypertension, malaise, maculopapular erythema, and glossitis have also been reported.

Congenital adrenal hyperplasia. For mention of the use of testolactone with flutamide to block androgenic effects in congenital adrenal hyperplasia, see p.1502.

Precocious puberty. Encouraging results have been reported using testolactone in the treatment of 5 girls with precocious puberty (p.2081) due to the McCune-Albright syndrome.[1] Testolactone is an aromatase inhibitor and blocks the synthesis of oestrogens from androgens. Long-term therapy (for up to 5 years) was associated with continued benefit in many patients; however, signs of puberty were not always completely suppressed, in some cases perhaps because of difficulties in maintaining the dosage regimen.[2] Encouraging results were also obtained using testolactone with spironolactone in the treatment of familial precocious puberty in boys, although neither agent was successful when used alone.[3] Again, signs of a reduced response to longer-term therapy have occurred; in this case control was restored by addition of a gonadorelin analogue.[4] Another study[5] in 10 boys who were treated for at least 6 years with spironolactone and testolactone, with deslorelin added at the onset of secondary central precocious puberty, found normalisation in growth rate and bone maturation, and improvements in predicted adult height.

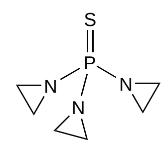
Thiotepa *(BAN, rINN)*

NSC-6396; TESPA; Thiophosphamide; Thiotépa; Thiotepum; Tiotepa; Triethylenethiophosphoramide; TSPA; WR-45312. Phosphorothioic tri(ethyleneamide); Tris(aziridin-1-yl)phosphine sulphide.

Тиотепа

$C_6H_{12}N_3PS$ = 189.2.
CAS — 52-24-4.
ATC — L01AC01.
ATC Vet — QL01AC01.



Pharmacopoeias. In *Br., Chin., Fr., Jpn,* and *US.*

BP 2008 (Thiotepa). Fine white, crystalline flakes. M.p. 52° to 57°. Freely soluble in water, in alcohol, and in chloroform. Store at 2° to 8°. At higher temperatures it polymerises and becomes inactive.

USP 31 (Thiotepa). Fine white, crystalline flakes, having a faint odour. M.p. 52° to 57°. Soluble 1 in 13 of water, 1 in about 8 of alcohol, 1 in about 2 of chloroform, and 1 in about 4 of ether. Store at 2° to 8° in airtight containers. Protect from light.

Incompatibility. Lyophilised thiotepa 1 mg/mL in glucose 5% was incompatible when mixed with solutions of cisplatin or minocycline hydrochloride.[1]

1. Trissel LA, Martinez JF. Compatibility of thiotepa (lyophilized) with selected drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 1996; **53:** 1041–5.

Stability. A solution of a lyophilised thiotepa preparation 0.5 mg/mL in glucose 5% was considered to be stable (less than 10% loss of thiotepa) for 8 hours at both 4° and 23°.[1] After 24 hours losses ranged between about 10 and 17%. A higher thiotepa concentration (5 mg/mL) was stable for 3 days at 23° and 14 days at 4°. Another study found that solutions containing 1 or 3 mg/mL of thiotepa in sodium chloride 0.9% were stable for 24 hours at 25° and 48 hours at 8°, but solutions containing 0.5% thiotepa needed to be used immediately.[2]

1. Xu QA, *et al.* Stability of thiotepa (lyophilized) in 5% dextrose injection at 4 and 23°C. *Am J Health-Syst Pharm* 1996; **53:** 2728–30.
2. Murray KM, *et al.* Stability of thiotepa (lyophilized) in 0.9% sodium chloride injection. *Am J Health-Syst Pharm* 1997; **54:** 2588–91.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow depression may be delayed; the nadir of white cell and platelet counts may occur up to 30 days after therapy has been stopped. Bone-marrow depression has been reported after intravesical as well as parenteral use, and has occasionally been prolonged or fatal.

Gastrointestinal disturbances, fatigue, weakness, headache and dizziness, hypersensitivity reactions, blurred vision and conjunctivitis may occur. Amenorrhoea and impaired fertility have also been reported. Local irritation, and rarely frank chemical or haemorrhagic cystitis may follow intravesical instillation. Depigmentation of periorbital skin has occurred after the use of thiotepa eye drops. As with other alkylating agents, thiotepa is potentially mutagenic, teratogenic, and carcinogenic.

Thiotepa should be given with extreme care, if at all, to patients with pre-existing impairment of hepatic, renal, or bone-marrow function.

Pharmacokinetics

The absorption of thiotepa from the gastrointestinal tract is incomplete and unreliable; variable absorption also occurs from intramuscular injection sites. Absorption through serous membranes such as the bladder and pleura occurs to some extent. After intravenous doses it is rapidly cleared from plasma, with an elimination half-life of about 2.4 hours. It is extensively metabolised: triethylenephosphoramide (TEPA), the primary metabolite, and some of the other metabolites have cytotoxic activity and are eliminated more slowly than the parent compound. It is excreted in the urine: less than 2% of a dose is reported to be present as unchanged drug or its primary metabolite.

Uses and Administration

Thiotepa is an ethyleneimine compound whose antineoplastic effect is related to its alkylating action. It has generally been replaced by cyclophosphamide (p.703) or other drugs. It is not a vesicant and may be given by all parenteral routes, as well as directly into tumour masses.

Instillations of thiotepa may be used in the adjuvant treatment of superficial tumours of the bladder (p.659) and in the control of malignant effusions (p.659). It has been given parenterally in the palliative treatment of various solid tumours, including those of breast and ovary (p.661 and p.670). It has also been given intrathecally to patients with malignant meningeal disease, and has been used, in the form of eye drops, as an adjunct to the surgical removal of pterygium, to prevent recurrence (see p.753).

Thiotepa is given in a variety of dosage schedules. In general, initial doses to suit the individual patient are followed by maintenance doses given at intervals of 1 to 4 weeks. Blood counts are recommended before and during therapy and should continue for at least 3 weeks after stopping. Thiotepa should not be given if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p.639) and treatment should be stopped if the white cell count falls rapidly. Dosage should be reduced in patients with lesser degrees of leucopenia.

In the treatment of bladder cancer thiotepa in doses up to 60 mg may be instilled in 30 to 60 mL of sterile water or sodium chloride 0.9% into the bladder of a patient previously dehydrated for 8 to 12 hours, and retained if possible for 2 hours. The instillation may be repeated weekly for up to 4 weeks. Similar instillations have been given at intervals of 1 to 2 weeks, for up to 8 instillations in the prophylaxis of recurrence after surgical removal of bladder cancer. Single doses of 90 mg in 100 mL of sterile water have also been used prophylactically. For malignant effusions, doses of up to 60 mg of thiotepa in 20 to 60 mL of sterile water may be instilled after aspiration; in the USA the licensed dose is 600 to 800 micrograms/kg, a dose similar to that suggested for injection directly into tumours. Thiotepa for local use may be mixed with solutions of procaine and adrenaline.

Intramuscular and intravenous dosage regimens vary considerably; several regimens have used courses of 15 mg daily for 4 days. In the USA a licensed dose is 300 to 400 micrograms/kg given at 1- to 4-week intervals. A solution containing 1 mg/mL in sterile water has been tried intrathecally in doses of up to 10 mg given on alternate days, for up to 4 doses.

Thiotepa 0.05% in sterile Ringer's solution has been instilled as eye drops every 3 hours for up to 6 weeks after surgical removal of pterygium in order to reduce the likelihood of recurrence.

A dose of 60 mg weekly has been instilled into the urethra for the treatment of condylomata acuminata (genital warts). Topical application of thiotepa has also been used for condylomata.

Thiotepa is under investigation for use as conditioning therapy before haematopoietic stem cell transplantation.

Tioguanine *(BAN, rINN)*

NSC-752; 6-TG; Thioguanine *(USAN)*; 6-Thioguanine; Tioguaniini; Tioguanin; Tioguanina; Tioguaninum; WR-1141. 2-Aminopurine-6(1*H*)-thione; 2-Amino-6-mercaptopurine; 2-Aminopurine-6-thiol.

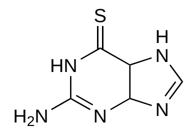
Тиогуанин

$C_5H_5N_5S$ = 167.2.

CAS — 154-42-7 (anhydrous tioguanine); 5580-03-0 (tioguanine hemihydrate).

ATC — L01BB03.

ATC Vet — QL01BB03.



Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2008 (Tioguanine). A pale yellow, crystalline powder. Practically insoluble in water, in alcohol, and in chloroform; dissolves in dilute solutions of alkali hydroxides.

USP 31 (Thioguanine). It is anhydrous or contains one-half molecule of water of hydration. A pale yellow, odourless or practically odourless, crystalline powder. Insoluble in water and in chloroform; soluble 1 in 7700 of alcohol; freely soluble in dilute solutions of alkali hydroxides. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Mercaptopurine, p.744.

In some patients, gastrointestinal reactions are reported to be less frequent than with mercaptopurine.

Effects on the blood. For the view that it may be possible to predict those individuals likely to have severe bone-marrow depression with tioguanine based on measurement of the activity of thiopurine methyltransferase or the concentration of tioguanine nucleotide, see under Azathioprine, p.1819.

Effects on the liver. The use of tioguanine has been limited by reports of hepatic veno-occlusive disease attributed to the drug.[1-4] The manufacturer (*GlaxoSmithKline*) has stated that, in most cases, liver toxicity is reversible upon withdrawal of chemotherapy. A comparison with mercaptopurine in the maintenance treatment of children with acute lymphoblastic leukaemia found that of 95 patients who developed veno-occlusive disease, 82 were receiving tioguanine, representing about 11% of all patients assigned to the drug.[5] In addition, although tioguanine was associated with fewer CNS relapses, patients in the tioguanine arm were more likely to develop fatal infections.

Centrilobular hepatic necrosis has also been reported; reports are confounded by the use of high doses of tioguanine, other antineoplastics, oral contraceptives, and chronic alcohol abuse.

1. Gill RA, *et al.* Hepatic veno-occlusive disease caused by 6-thioguanine. *Ann Intern Med* 1982; **96:** 58–60.
2. Krivoy N, *et al.* Reversible hepatic veno-occlusive disease and 6-thioguanine. *Ann Intern Med* 1982; **96:** 788.

5. Vora A, *et al.* Medical Research Council/National Cancer Research Network Childhood Leukaemia Working Party. Toxicity and efficacy of 6-thioguanine versus 6-mercaptopurine in childhood lymphoblastic leukaemia: a randomised trial. *Lancet* 2006; **368:** 1339–48.

Handling and disposal. For reference to a method for the destruction of tioguanine in wastes, see Mercaptopurine, p.744.

Interactions

Unlike mercaptopurine (p.744), normal doses of tioguanine may be used with allopurinol.

A number of cases of portal hypertension with hepatic nodular regenerative hyperplasia have been reported in patients who received tioguanine with busulfan (see p.691).

It has been suggested that daunorubicin might enhance the hepatotoxicity of tioguanine (see p.709).

Pharmacokinetics

Tioguanine is incompletely and variably absorbed from the gastrointestinal tract; on average about 30% of a dose is absorbed after oral doses. It is rapidly activated in the body by intracellular conversion to its nucleotide, thioguanylic acid and its thioguanosine phosphate derivatives. With repeated doses increasing amounts of the nucleotide are incorporated into DNA. Very little unchanged tioguanine has been detected circulating in the blood but the half-life of the nucleotide in the tissues is prolonged. Tioguanine is inactivated primarily by methylation to aminomethylthiopurine; small amounts are deaminated to thioxanthine, and may go on to be oxidised by xanthine oxidase to thiouric acid, but inactivation is essentially independent of xanthine oxidase and is not affected by inhibition of the enzyme.

It is excreted in the urine almost entirely as metabolites; only negligible amounts of tioguanine have been detected. Tioguanine does not appear to cross the blood-brain barrier to a significant extent; very little is found in CSF after normal clinical doses. It crosses the placenta.

Uses and Administration

Tioguanine is an analogue of the naturally occurring purine, guanine, and is an antineoplastic with actions and uses similar to those of mercaptopurine (p.744). It appears to cause fewer gastrointestinal reactions but cross-resistance exists so that patients who do not respond to one are unlikely to respond to the other.

Tioguanine may be given orally, usually with other antineoplastics, in the induction of remissions in acute myeloid leukaemia (p.652). It has also been used in other malignancies including acute lymphoblastic leukaemia (p.651) and chronic myeloid leukaemia (p.653).

Doses of between 100 and 200 mg/m^2 daily have been given at various stages of treatment for short term cycles; similar doses have been used in children. A dose of 2 mg/kg daily increased after 4 weeks, if there is no response or toxicity allows, to 3 mg/kg daily may be given to adults and children in those rare cases when single agent therapy is considered appropriate.

Blood counts should be made frequently, particularly during induction and when tioguanine is given with other antineoplastics. Therapy should be withdrawn at the first sign of severe bone-marrow depression. Tioguanine is not recommended for long-term continuous therapy because of the high risk of hepatotoxicity (see Effects on the Liver, above).

Tioguanine has been given intravenously as the sodium salt.

Psoriasis. A report of the use of tioguanine, in doses ranging from 20 mg twice weekly to 120 mg daily, in the management of patients with refractory psoriasis.[1] Dramatic improvement occurred in 14 of 18 patients, but a further 2 were unable to tolerate the drug. Myelosuppression was the principal toxic effect and it was suggested that thiopurine methyltransferase activity could be measured as a basis to determine initial dosage and the risk of toxicity. For the conventional management of psoriasis see p.1583.

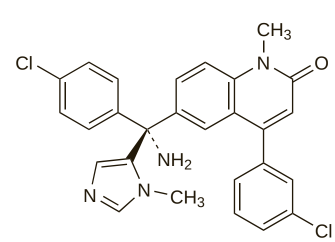
Tipifarnib *(USAN, rINN)*

R-115777; Tipifarnibum. (+)-6-[(*R*)-Amino(4-chlorophenyl)(1-methyl-1*H*-imidazol-5-yl)methyl]-4-(3-chlorophenyl)-1-methyl-2(1*H*)-quinolinone.

Типифарниб

$C_{27}H_{22}Cl_2N_4O$ = 489.4.

CAS — 192185-72-1.



The symbol † denotes a preparation no longer actively marketed

The symbol ⊗ denotes a substance whose use may be restricted in certain sports (see p.vii)

Profile

Tipifarnib is a farnesyl transferase inhibitor that is under investigation for the treatment of acute myeloid leukaemia.

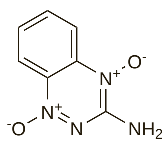
Tirapazamine *(USAN, rINN)*

SR-4233; Tirapazamina; Tirapazaminum; Win-59075. 3-Amino-1,2,4-benzotriazine 1,4-dioxide.

Тирапазамин

$C_7H_6N_4O_2$ = 178.1.

CAS — 27314-97-2.



Profile

Tirapazamine is reported to be reduced in hypoxic cells to an active anion that causes DNA strand breaks. It sensitises hypoxic tumour cells to the cytotoxic activity of other drugs. It is under investigation for its cytotoxic actions, alone or with cisplatin or radiotherapy. Adverse effects reported with tirapazamine include nausea and vomiting, diarrhoea, skin rashes, muscle cramps and fatigue; myelosuppression is said to be rare.

Topotecan Hydrochloride

(BANM, USAN, pINNM)

Hidrocloruro de topotecán; SKF-104864A; SKFS-104864-A; Topotécane, Chlorhydrate de; Topotecani Hydrochloridum; Topotekaanihydrokloridi; Topotekanhydroklorid. (*S*)-10-Dimethylaminomethyl-4-ethyl-4,9-dihydroxy-1*H*-pyrano[3′,4′:6,7]indolizino[1,2*b*]quinoline-3,14(4*H*,12*H*)-dione hydrochloride.

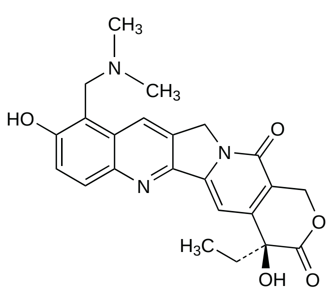
Топотекана Гидрохлорид

$C_{23}H_{23}N_3O_5$,HCl = 457.9.

CAS — 123948-87-8 (topotecan); 119413-54-6 (topotecan hydrochloride).

ATC — L01XX17.

ATC Vet — QL01XX17.



(topotecan)

Incompatibility. Topotecan hydrochloride was found to degrade to 88.7% of its original concentration over 4 hours when mixed with ticarcillin sodium or potassium clavulanate. It was also found to be incompatible with dexamethasone sodium phosphate and fluorouracil.[1] When mixed with mitomycin solution an immediate colour change took place and concentrations of mitomycin fell by 15 to 20% over 4 hours. The pH of the mixtures remained constant at 3.3 to 3.5.

1. Mayron D, Gennaro AR. Stability and compatibility of topotecan hydrochloride with selected drugs. *Am J Health-Syst Pharm* 1999; **56:** 875–81.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641.

Neutropenia is very common with topotecan and is usually dose-limiting. The nadir of white cell count usually occurs about 9 to 12 days after a dose. Febrile neutropenia, sepsis, and neutropenic colitis can occur; fatalities have been reported. Thrombocytopenia, anaemia, and leucopenia also occur commonly. Topotecan should not be given to those patients with pre-existing bone-marrow depression, and blood counts should be monitored regularly. Gastrointestinal disturbances and anorexia are also common with topotecan, and may be severe. Other adverse effects include fatigue and weakness, alopecia, malaise, pruritus, pyrexia, and hyperbilirubinaemia. Hypersensitivity reactions including rashes have been reported; anaphylaxis may occur rarely.

Licensed product information recommends that topotecan should not be given to patients with severe hepatic or renal impairment, due to a lack of data in these patients. Its use in breast feeding is contra-indicated for the same reason. Topotecan has been reported to produce fetal death and malformations in *animals*.

Interactions

For a report of topotecan reducing the clearance of docetaxel, see Antineoplastics, p.711.

Greater myelosuppression is seen when topotecan is used with other cytotoxic drugs, which may require dosage reductions of either drug. However, with platinum drugs, there is a sequence-dependent interaction; giving a platinum drug on the first day of topotecan dosage requires lower doses of each, compared with giving it on the fifth day.

Granulocyte colony-stimulating factor can prolong the duration of neutropenia if given with topotecan, so if used, it should not be started until, 24 hours after topotecan dosage is complete.

Ciclosporin has been reported to increase exposure to topotecan.

Pharmacokinetics

Topotecan is rapidly absorbed after oral doses; peak plasma concentrations occur after about 1 to 2 hours. The oral bioavailability is about 40%. Food does not appreciably affect topotecan pharmacokinetics. Topotecan is widely distributed after intravenous doses. Plasma protein binding is about 35%. The drug undergoes reversible hydrolysis of the lactone ring to the inactive hydroxy acid form; only small amounts are demethylated in the liver. A significant proportion of a dose is excreted in urine. The terminal half-life has been reported to be 2 to 3 hours for the intravenous formulation, and 3 to 6 hours for the oral formulation.

◊ References.

1. Herben VMM, *et al.* Clinical pharmacokinetics of topotecan. *Clin Pharmacokinet* 1996; **31:** 85–102.

Uses and Administration

Like irinotecan (p.738), topotecan is a semisynthetic derivative of the alkaloid camptothecin that exerts its antineoplastic activity by inhibition of topoisomerase I. It is used in the treatment of metastatic carcinoma of the ovary refractory to other therapy (see p.670) and in relapsed small cell lung cancer (p.668) after standard therapy. Topotecan is given with cisplatin in the treatment of metastatic, recurrent, or persistent carcinoma of the cervix (p.663) which is not amenable to curative treatment with surgery and/or radiation therapy. Topotecan is also under investigation in the management of myelodysplastic syndromes.

Topotecan is given as the hydrochloride but doses are calculated in terms of the base. Topotecan hydrochloride 1.09 mg is equivalent to about 1 mg of topotecan.

In **ovarian** and **small cell lung cancer**, topotecan hydrochloride may be given *intravenously* in an initial dose equivalent to topotecan 1.5 mg/m^2, infused over 30 minutes, on days 1 to 5 of a 21-day course. A minimum of 4 courses should be given, in the absence of tumour progression, and provided that blood counts and haemoglobin have recovered adequately (see also Bone-marrow Depression, p.639). If severe neutropenia occurs in any course the dose in the subsequent courses may be reduced by 250 micrograms/m^2, or a granulocyte colony-stimulating factor may be given from day 6 of the course, 24 hours after topotecan dosage is complete. If severe toxicity recurs once the dose has been reduced to 1 mg/m^2 withdrawal of topotecan may be required. Dosage should also be reduced after severe thrombocytopenia and in patients with renal impairment (see below).

Topotecan may also be given *orally* for small cell lung cancer. The recommended dose is 2.3 mg/m^2 once daily for 5 consecutive days, repeated every 21 days. If neutropenia occurs, or if the platelet count falls below 25 000 cells/mm^3, or for patients with severe diarrhoea, the daily dose should be reduced by 400 micrograms/m^2 for subsequent courses.

In **cervical cancer**, topotecan is given in an intravenous dose of 750 micrograms/m^2, infused over 30 minutes, on days 1, 2, and 3 of a 21-day course; cisplatin 50 mg/m^2 is given by intravenous infusion after topotecan on day 1. Dosage adjustments for subsequent courses are specific for each drug; for cisplatin, see p.700. If severe febrile neutropenia occurs, or if the platelet count falls below 10 000 cells/mm^3, the topotecan dose should be reduced to 600 micrograms/m^2. Alternatively, in the event of severe febrile neutropenia, granulocyte colony-stimulating factor may be given from day 4 of the course, 24 hours after completion of the topotecan infusion; if febrile neutropenia recurs despite this, topotecan dosage should be further reduced to 450 micrograms/m^2 for subsequent courses.

Administration in renal impairment. Licensed product information for *intravenous* topotecan recommends the following for patients with **ovarian or small cell lung cancer** according to creatinine clearance (CC):

- mild renal impairment (CC 40 to 60 mL/minute): no dosage adjustment
- moderate renal impairment (CC 20 to 39 mL/minute): 0.75 mg/m^2 daily for 5 consecutive days

For patients with small cell lung cancer given *oral* topotecan, the following is suggested:

- mild renal impairment (CC 50 to 80 mL/minute): no dosage adjustment
- moderate renal impairment (CC 30 to 49 mL/minute): 1.8 mg/m^2 once daily for 5 consecutive days

Data are insufficient to make dose recommendations in patients with severe renal impairment.

In patients with **cervical cancer**, treatment with topotecan and cisplatin should only be started in those with a serum creatinine of 1.5 mg or less per 100 mL.

Toremifene Citrate *(BANM, USAN, rINNM)* ⊗

Citrato de toremifeno; FC-1157a; Toremifen Sitrat; Torémifène, Citrate de; Toremifeni Citras. 2-{*p*-[(*Z*)-4-Chloro-1,2-diphenyl-1-butenyl]phenoxy}-*N*,*N*-dimethylethylamine citrate.

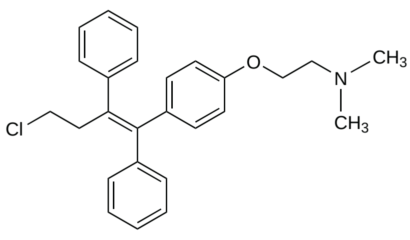
Торемифена Цитрат

$C_{26}H_{28}ClNO,C_6H_8O_7 = 598.1.$

CAS — 89778-26-7 (toremifene); 89778-27-8 (toremifene citrate).

ATC — L02BA02.

ATC Vet — QL02BA02.



(toremifene)

Adverse Effects and Precautions

As for Tamoxifen Citrate, p.772.

Use of toremifene is contra-indicated in patients with pre-existing endometrial hyperplasia, or in those with severe thromboembolic disease or severe hepatic impairment. Toremifene must be used with caution in patients with uncompensated heart failure or severe angina. Patients with bone metastases should be monitored for signs and symptoms of hypercalcaemia.

Interactions

Toremifene is metabolised by cytochrome P450 isoenzyme CYP3A4, and potent enzyme-inducing drugs such as phenytoin, phenobarbital and carbamazepine, might be expected to increase toremifene metabolism, thereby lowering the serum concentration. Conversely, azole antifungals and macrolide antibacterials may inhibit toremifene metabolism by inhibiting the isoenzyme.

Use with drugs that decrease renal calcium excretion, such as thiazide diuretics, may increase the incidence of hypercalcaemia. Use with coumarin anticoagulants should be avoided as there is a risk of increased bleeding time.

Antibacterials. *Rifampicin* was found to decrease plasma concentrations of toremifene in 9 subjects. This was thought to be due to induction of cytochrome P450 isoenzyme CYP3A4 by rifampicin.[1]

1. Kivistö KT, *et al.* Tamoxifen and toremifene concentrations in plasma are greatly decreased by rifampin. *Clin Pharmacol Ther* 1998; **64:** 648–54.

Pharmacokinetics

Toremifene citrate is well absorbed from the gastrointestinal tract, reaching peak plasma concentrations of toremifene within 3 hours. Plasma concentration declines biexponentially; the mean distribution half-life is about 4 hours and the elimination half-life is about 5 days. It is extensively bound to plasma proteins, mainly albumin. Toremifene is metabolised principally by the cytochrome P450 isoenzyme CYP3A4; the main metabolite is N-demethyltoremifene, which is reported to have anti-oestrogenic activity but with weak anti-tumour activity. It undergoes enterohepatic circulation and is eliminated mainly in the faeces as metabolites. About 10% is excreted in the urine.

◊ Reviews.

1. Taras TL, *et al.* Clinical pharmacokinetics of toremifene. *Clin Pharmacokinet* 2000; **39:** 327–34.

Uses and Administration

Toremifene is an anti-oestrogen with properties similar to those of tamoxifen (p.775). It is used in the treatment of metastatic breast cancer (p.661) in postmenopausal women with oestrogen-receptor positive tumours. It is also being investigated for the treatment of lung tumours and for the management of prostate cancer.

Toremifene is given orally as the citrate, but doses are calculated in terms of the base; 88.4 mg of toremifene citrate is equivalent to about 60 mg of toremifene. A dose of toremifene 60 mg once daily is used.

Tositumomab *(rINN)*

B-1; Tositumomabum. Immunoglobulin G2a anti-(human antigen CD 20) (mouse monoclonal clone B1R1 γ2a-chain), disulfide with mouse monoclonal clone B1R1 λ_x-chain, dimer.

Тоситумомаб

CAS — 192391-48-3.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

Infusion reactions suggestive of a cytokine release syndrome, and other hypersensitivity reactions including anaphylaxis, have been reported with tositumomab. Prolonged and severe neutropenia, thrombocytopenia, and anaemia occur commonly; full blood counts should be monitored weekly for up to 12 weeks. Other adverse effects include gastrointestinal disturbances, dehydration, abdominal pain, pleural effusion, and increased susceptibility to infection. Delayed adverse effects such as the development of secondary malignancies, leukaemia, or myelodysplastic syndrome may occur. Patients receiving the radiolabelled regimen may be susceptible to hypothyroidism and pretreatment with thyroid blocking drugs is recommended (see Uses and Administration, below); levels of thyroid-stimulating hormone should be measured before treatment and annually thereafter.

Uses and Administration

Tositumomab is an anti-B1 monoclonal antibody that is directed against the CD20 antigen found on the surface of B lymphocytes. It is radiolabelled with iodine-131 (p.2054) for the treatment of patients with CD20 antigen-expressing, relapsed or refractory, low-grade, follicular, or transformed non-Hodgkin's lymphoma (p.656), and including those patients who have disease refractory to rituximab.

The regimen consists of a dosimetric step, followed 7 to 14 days later by a therapeutic step. The dosimetric step consists of 450 mg of tositumomab given intravenously in 50 mL sodium chloride 0.9% over 60 minutes. Tositumomab 35 mg radiolabelled with iodine-131 is then given intravenously in 30 mL sodium chloride 0.9% over 20 minutes. This is followed by whole body imaging to determine whether biodistribution is acceptable, and to allow calculation of the therapeutic dose of radiolabelled tositumomab. In the therapeutic step, tositumomab 450 mg is given again, and followed by the calculated dose of radiolabelled tositumomab.

The rate of infusion may be halved for mild to moderate infusional toxicity, and stopped if this is severe; the infusions may be restarted at half the rate once toxicity resolves. Patients are pretreated with thyroid protective agents at least 24 hours before the first radiolabelled dose of tositumomab; treatment is continued until 2 weeks after the radiolabelled therapeutic dose. Analgesics and antihistamines are also given by mouth 30 minutes before doses of tositumomab.

Trabectedin *(USAN, rINN)*

Ecteinascidin-743; ET-743; NSC-648766; Trabectedina; Trabectédine; Trabectedinum. (1′*R*,6*R*,6a*R*,7*R*,13*S*,14*S*,16*R*)-6′,8,14-Trihydroxy-7′,9-dimethoxy-4,10,23-trimethyl-19-oxo-3′,4′,6,7,12,13,14,16-octahydrospiro[6,16-(epithiopropanooxymethano)-7,13-imino-6a*H*-1,3-dioxolo[7,8]isoquino[3,2-*b*][3]benzazocine-20,1′(2′*H*)-isoquinolin]-5-yl acetate.

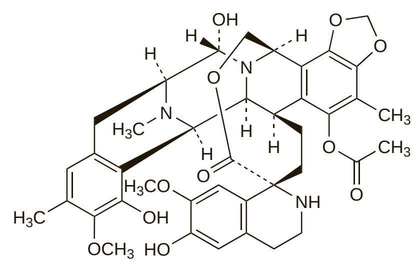
Трабектедин

$C_{39}H_{43}N_3O_{11}S = 761.8.$

CAS — 114899-77-3.

ATC — L01CX01.

ATC Vet — QL01CX01.



Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641. Neutropenia, thrombocytopenia, anaemia, and leucopenia are very common with trabectedin; febrile neutropenia often occurs. Full blood counts should be performed at baseline, weekly for the first 2 cycles, and then once between cycles thereafter. Dose reductions may be needed in those with haematological toxicity. Hepatobiliary disorders are also very common, and include hyperbilirubinaemia and alterations in liver function tests, which are mostly transient. Patients with liver disease should be closely monitored, and trabectedin should not be given to those with hyperbilirubinaemia.

Other very common adverse effects include gastrointestinal disturbances, anorexia, headache, and fatigue. Antiemetic prophylaxis with dexamethasone should be given to all patients. Peripheral sensory neuropathy, paraesthesia, dysgeusia, dizziness, pyrexia, and oedema are common, as are dyspnoea, cough, alopecia, myalgia, arthralgia, dehydration, hypokalaemia, hypotension, and flushing. Injection site reactions can occur, and the use of a central line is recommended.

Deaths associated with trabectedin treatment often involved a combination of adverse events including pancytopenia, febrile neutropenia, and in some cases sepsis, hepatic involvement, renal failure, and rhabdomyolysis.

Trabectedin may cause serious birth defects if given during pregnancy, although data are limited. Women and men of fertile age are advised to use effective contraception during treatment, and for 3 and 5 months, respectively, after stopping treatment. Breast feeding is contra-indicated due to lack of data, and should be avoided for the duration of treatment and for 3 months after therapy is stopped.

Interactions

Trabectedin is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme (such as azole antifungals, macrolide antibacterials, or ritonavir) may increase blood concentrations of trabectedin. Equally, inducers of CYP3A4 (such as rifampicin, phenobarbital, and St John's wort) may decrease systemic exposure to trabectedin. Trabectedin is a substrate of P-glycoprotein, and use with P-glycoprotein inhibitors (such as ciclosporin and verapamil) may alter trabectedin pharmacokinetics, although the clinical significance of this interaction has not been established. Alcohol and other hepatotoxic drugs should be avoided during trabectedin treatment due to possible potentiation of hepatotoxicity. Use with live attenuated vaccines is not recommended, and use with yellow fever vaccine is specifically contra-indicated. For the effect of trabectedin on phenytoin, see p.499.

Pharmacokinetics

Trabectedin is extensively distributed in the tissues. Plasma protein binding is about 94 to 98%. It is metabolised in the liver, mainly by cytochrome P450 isoenzyme CYP3A4. The terminal half-life is about 180 hours. Trabectedin is excreted mainly in the faeces, with a small amount in the urine, of which less than 1% is unchanged drug.

Uses and Administration

Trabectedin is a novel DNA-binding agent derived from the marine tunicate, *Ecteinascidia turbinata*. It is used for the treatment of advanced soft-tissue sarcomas, after failure of anthracyclines or ifosfamide, or in patients for whom these drugs are unsuitable. The recommended dose is 1.5 mg/m^2, given as an intravenous infusion over 24 hours. The dose can be repeated at 3-week intervals as long as clinical benefit persists, provided haematological, hepatic, and renal function parameters are met. If these baseline criteria are not met, treatment must be delayed for up to 3 weeks, until the criteria are met. If haematological toxicity or hepatotoxicity occurs at any time between cycles, the dose for subsequent cycles must be reduced to 1.2 mg/m^2. Once a dose has been reduced, dose escalation for subsequent cycles is not recommended. If any toxicities recur in subsequent cycles, a further dose reduction to 1 mg/m^2 may be made; thereafter, if further toxicity occurs, treatment should be stopped. If trabectedin is given via a central venous line, which is the preferred method, the dose should be diluted in at least 500 mL of sodium chloride 0.9% or glucose 5%. If central access is unfeasible, and it is given peripherally, the dose should be diluted in at least 1 litre of diluent. Dexamethasone 20 mg is given intravenously 30 minutes before treatment with trabectedin, to reduce nausea and hepatotoxicity.

Trabectedin is also under investigation for the treatment of ovarian cancer.

Administration in hepatic impairment. Licensed product information states that there are no studies of trabectedin in hepatic impairment and data are unavailable to recommend doses in these patients. However, since systemic exposure is likely to be increased in these patients, thus increasing the risk of hepatotoxicity, caution is advised and dose adjustments may be needed. Trabectedin should not be given to patients with hyperbilirubinaemia.

Administration in renal impairment. Licensed product information for trabectedin states that no dose adjustments are needed in patients with mild or moderate renal impairment, but that trabectedin should not be used in patients with severe renal impairment (creatinine clearance less than 30 mL/min) as no data are available for this population.

Trastuzumab *(BAN, rINN)*

HER-2 Monoclonal Antibody; rhuMAb HER2; Trastutsumabi; Trastuzumabum. Immunoglobulin G1 (human-mouse monoclonal rhuMab HER2 γ_1-chain anti-human p185$^{c\text{-}erbB2}$ receptor), disulfide with human-mouse monoclonal rhuMab HER2 light chain, dimer.

Трастузумаб

CAS — 180288-69-1.
ATC — L01XC03.
ATC Vet — QL01XC03.

Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639 and p.641.

Trastuzumab has been associated with fatal hypersensitivity reactions, infusion reactions characteristic of a cytokine release syndrome, and pulmonary events including acute respiratory distress syndrome. These usually occur after the first dose of trastuzumab and are more common in patients with reduced lung function. Use of trastuzumab is contra-indicated in patients with severe dyspnoea at rest. Cardiac dysfunction and congestive heart failure may also occur and left ventricular function should be monitored before and during therapy. The risk of cardiotoxicity is increased if trastuzumab is given with anthracyclines or cyclophosphamide (see below).

There is an increase in the incidence of leucopenia, thrombocytopenia, anaemia, and febrile neutropenia when trastuzumab is given with chemotherapy, but it infrequently causes myelosuppression when used alone. Diarrhoea occurs in about 25% of patients given trastuzumab as monotherapy; the incidence increases with combination therapy. Other gastrointestinal disturbances are common, as are chills, fever, headache, arthralgia, myalgia, and rashes. Asthenia, chest pain, and renal or liver disorders have also been reported.

Effects on the heart. Cardiac events related to the use of trastuzumab include asymptomatic decreases in left ventricular ejection fraction, tachycardia, palpitations, dyspnoea, and chest pain. Congestive heart failure may develop.[1]

In a pivotal comparative trial,[2] an increased incidence of cardiac adverse events prompted a retrospective analysis. This independent review identified cardiac dysfunction in 27% of patients receiving trastuzumab, an anthracycline, and cyclophosphamide, compared with only 8% receiving an anthracycline and cyclophosphamide. In patients given trastuzumab and paclitaxel, 13% developed cardiac dysfunction compared with 1% of patients given paclitaxel alone, although all these patients had previously received an anthracycline. The incidence of severe dysfunction was highest in those patients receiving trastuzumab, an anthracycline, and cyclophosphamide.

Further analysis[3] of this and 6 other studies found that, in a total of 1219 patients, 10 heart-related deaths had been reported, and that 9 of these were patients who had received trastuzumab. However, the risk of developing cardiotoxicity was less when trastuzumab was given alone than when given with anthracyclines. Advanced age was found to be a significant risk factor, whereas giving trastuzumab and the anthracycline at different times appeared to decrease the rate of cardiotoxicity.

Licensed product information for trastuzumab warns that patients who have previously received anthracyclines may also be at increased risk of cardiotoxicity with trastuzumab treatment. Furthermore, because the half-life of trastuzumab is about 28.5 days, trastuzumab may persist in the circulation for up to 24 weeks, and patients given anthracyclines after stopping trastuzumab may still be at increased risk of cardiotoxicity. If anthracyclines are used, the patient's cardiac function should be carefully monitored. Patients with pre-existing cardiovascular disease should also be treated with caution.

However, the majority of patients who develop congestive heart failure improve with standard treatment, including the use of ACE inhibitors, beta blockers, cardiac glycosides and diuretics.[1,4,5] Cardiotoxicity may improve even in those patients who continue with trastuzumab therapy.[4,5] A small retrospective study found that cardiotoxicity appeared to be largely reversible once trastuzumab was stopped, and that therapy might even be restarted. Findings from myocardial biopsy suggested that, while the mechanism of cardiotoxicity with trastuzumab remained uncertain, it differed from that with anthracyclines.[6] A retrospective review[7] of 173 patients with metastatic breast cancer who were treated with trastuzumab-based therapy for at least 1 year found that 28% of patients experienced a cardiac event; 10.9% had grade 3 cardiotoxicity, including 1 cardiac-related death. However, cardiotoxicity, whether symptomatic or not, was generally reversible, with or without specific therapy, suggesting that maintenance or re-treatment with trastuzumab may be feasible in those patients for whom no alternative therapeutic options are available.

The pathogenesis of the cardiotoxicity associated with trastuzumab is under investigation. A small study[8] showed specific uptake of a pretreatment tracer dose of radiolabelled trastuzumab into the myocardium of patients who subsequently developed cardiac adverse events. The human epidermal growth factor receptor 2 (HER2) gene appears essential for normal cardiac development; studies in *animals* suggest that trastuzumab may interfere with HER2 signalling and function in cardiomyocytes, and that loss of HER2 increases sensitivity to anthracycline toxicity.[4,5]

Analysis of symptomatic heart failure with trastuzumab suggests a lower incidence than that previously reported with retrospective data; however, this may be due to over-reported events in pivotal trials and the more recent exclusion of patients at risk of cardiotoxicity.[4] More recent analysis from a large study of patients given adjuvant chemotherapy with or without trastuzumab found a cumulative incidence of cardiac events (defined as confirmed New York Heart Association class III or IV cardiac dysfunction, or cardiac death) with trastuzumab of 4.1% at 3 years. The difference in cumulative incidence was 3.3% when compared with the control group.[9] Some have commented[10] that follow-up was relatively short and that long-term data on cardiac risks with trastuzumab are lacking. Reviews[11,12] have concluded that trastuzumab-induced cardiotoxicity is not dose-related and is generally reversible once the drug is stopped. However, others[13] have challenged the concept that cardiotoxicity is reversible, and the need for longer-term follow-up data, especially with respect to asymptomatic left ventricular dysfunction, has been emphasised.[11,13]

Metastatic disease. There is some suggestion that patients treated with trastuzumab for metastatic breast cancer have a higher incidence of cerebral metastases. This may reflect increased survival of patients given trastuzumab, and the lack of CNS penetration by the drug,[1,2] or tumours overexpressing human epidermal growth receptor 2 (HER2) may be more likely to metastasise to the CNS.[2] A comparison[1] of trastuzumab-treated patients with a control group found that, although trastuzumab reduced the incidence of bone metastases, the development of brain metastases was similar in both groups. However, trastuzumab improved overall survival in all patients developing metastases, including those with brain metastases. A retrospective review[2] found an association between the development of cerebral metastases and both hormone-receptor negative status and the presence of visceral disease.

2. Clayton AJ, *et al.* Incidence of cerebral metastases in patients treated with trastuzumab for metastatic breast cancer. *Br J Cancer* 2004; **91:** 639–43.

Peripheral vascular toxicity. A woman developed a painless prominence of the veins in her left arm and hand 3 days after receiving trastuzumab via a left hand vein. The veins were thickened and rope-like on palpation but there was no tenderness, oedema, or skin changes; there was no evidence of thrombus. She had previously received intravenous chemotherapy into left hand veins without sequelae. Biopsy suggested venous wall injury. Cardiac function was preserved, suggesting the mechanism of vascular injury was unrelated to cardiac dysfunction. Trastuzumab therapy was stopped permanently and her symptoms gradually resolved over the course of a year.[1]

1. Pansegrau GK, *et al.* Trastuzumab-associated peripheral vascular toxicity. *J Clin Oncol* 2007; **25:** 1438–40.

Pregnancy. A 28-year-old woman who had been given trastuzumab 6 mg/kg every 3 weeks was found to be pregnant after 5 months of therapy. Trastuzumab was stopped at about 20 weeks of gestation. Ultrasound study of the fetus at 23 weeks indicated no amniotic fluid. On observation, the anhydramnios slowly resolved. No further complications occurred and a healthy female infant was induced at 37⁄ weeks; amniotic fluid was clear at delivery.[1] Similarly, 2 cycles of trastuzumab and paclitaxel were given to a 38-year-old pregnant woman between 26 and 32 weeks of gestation: fetal abdominal circumference stopped increasing and the volume of amniotic fluid decreased to almost total anhydramnios. There was also evidence of fetal renal failure. Fetal lung maturation was induced and a caesarean section done at about 32 weeks of gestation. The infant showed signs of bacterial sepsis with hypotension, transient renal failure, and respiratory failure necessitating mechanical ventilation. After antibacterial therapy, blood pressure normalised, ventilation was ended, and diuresis was deemed adequate. He was discharged at age 6 weeks in healthy condition and development at 12 weeks of age was deemed to be normal.[2] In another report, a 30-year-old patient conceived 3 days after her second cycle of trastuzumab; no further therapy was given. Her pregnancy went successfully to term and a healthy female was born with no sequelae.[3] Low amniotic fluid volume was seen in another case of trastuzumab use during pregnancy; at 5 years of age, the child was reported to have normal growth and development.[4]

Interactions

For reports of trastuzumab enhancing the effect of warfarin, see p.1429.

Pharmacokinetics

The half-life of trastuzumab varies considerably: it has been reported to be 1.7 days after a 10-mg dose, 12 days after a 500-mg dose, and 5.8 days after the recommended dose (4 mg/kg followed by 2 mg/kg weekly); 28.5 days has also been reported after the recommended dose. Detectable concentrations of the cell surface protein of the HER2 receptor (shed antigen) have been found in patients' serum; those patients with higher baseline values for shed antigen had lower serum trough concentrations of trastuzumab, although target trastuzumab concentrations were still achieved after weekly dosing, and no relationship to clinical response was observed.

Uses and Administration

Trastuzumab is a humanised monoclonal antibody directed against a cell surface protein produced by the human epidermal growth factor receptor 2 (HER2) gene. HER2 protein is overexpressed in about one-third of all breast cancers. Trastuzumab is used in the treatment of breast cancer (p.661) with such characteristics.

The recommended dose in **metastatic** breast cancer, alone, with an aromatase inhibitor, or followed by a taxane, is 4 mg/kg initially, by intravenous infusion in 250 mL of sodium chloride 0.9% over 90 minutes. This may be followed by 2 mg/kg over 30 minutes at weekly intervals.

Trastuzumab is also given in **early** breast cancer after surgery, chemotherapy, and radiotherapy. There are 2 recommended schedules, with trastuzumab given either weekly or every 3 weeks.

- The recommended dose for the 3-weekly schedule is 8 mg/kg initially, by intravenous infusion in 250 mL sodium chloride 0.9% over 90 minutes. This may be followed by 6 mg/kg at 3-weekly intervals. Treatment is continued for 1 year or until disease recurrence.

  If the patient misses a dose of trastuzumab by 1 week or less, then the usual dose of 6 mg/kg should be given as soon as possible, without waiting until the next planned cycle. Subsequent cycles are then given according to the previous schedule.

  If the dose is missed by more than 1 week, a re-loading dose of trastuzumab 8 mg/kg should be given, and subsequent maintenance doses of 6 mg/kg should then be given every 3 weeks thereafter.
- In the weekly schedule, trastuzumab is given with paclitaxel after 4 cycles of the AC regimen (doxorubicin and cyclophosphamide). It is given at an initial loading dose of 4 mg/kg followed by 2 mg/kg weekly thereafter for 1 year; paclitaxel is given either weekly or 3-weekly for a total of 12 weeks.

HER2 may also be overexpressed in other epithelial cancers, and trastuzumab is under investigation for use in non-small cell lung cancer, pancreatic, prostate, and ovarian malignancies.

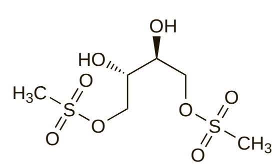
Treosulfan *(BAN, rINN)*

Dihydroxybusulphan; NSC-39069; Treosulfaani; Tréosulfan; Treosulfano; Treosulfanum. L-Threitol 1,4-dimethanesulphonate.

Треосульфан

$C_6H_{14}O_8S_2$ = 278.3.
CAS — 299-75-2.
ATC — L01AB02.
ATC Vet — QL01AB02.



Profile

Treosulfan is an antineoplastic agent related to busulfan (p.690), which is reported to act by alkylation after conversion *in vivo* to epoxide compounds. It is used palliatively or as an adjunct to surgery mainly in the treatment of ovarian cancer (p.670).

Treosulfan 1 g daily is licensed for oral use in 4 divided doses for 2 or 4 weeks followed by the same period without treatment. Alternatively 1.5 g daily in 3 divided doses may be given for 1 week, followed by 3 weeks without therapy. The cycle is then repeated, the dose being adjusted if necessary according to the effect on bone marrow. Doses of 3 to 8 g/m^2 may instead be given intravenously every 1 to 3 weeks. Doses larger than 3 g/m^2 should be given by infusion at a rate of 3 g/m^2 every 5 to 10 minutes. Doses up to 1.5 g/m^2 have been given intraperitoneally. Lower doses should be used if treatment with other antineoplastic drugs or radiotherapy is being given.

Regular blood counts should be made and treatment should be interrupted if the white cell or platelet counts fall below acceptable levels (see also Bone-marrow Depression, p.639). Because bone-marrow depression may be cumulative the interval between blood counts should be reduced after the second course of treatment with treosulfan.

Preparations

Proprietary Preparations (details are given in Part 3)

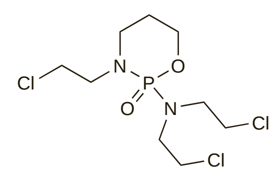
Trofosfamide *(rINN)*

A-4828; NSC-109723; Trilophosphamide; Trofosfamid; Trofosfamida; Trofosfamidi; Trofosfamidum; Trophosphamide; Z-4828. 3-(2-Chloroethyl)-2-[bis(2-chloroethyl)amino]tetrahydro-2*H*-1,3,2-oxazaphosphorine-2-oxide.

Трофосфамид

$C_9H_{18}Cl_3N_2O_2P$ = 323.6.
CAS — 22089-22-1.
ATC — L01AA07.
ATC Vet — QL01AA07.



Profile

Trofosfamide is a derivative of cyclophosphamide (p.702) and has the same general properties. It is used in the treatment of malignant disorders in usual initial oral doses of 300 to 400 mg daily. Doses of 50 to 150 mg daily have been given for maintenance therapy.

Uses. References[1-10] to the use of trofosfamide, including its investigational use with pioglitazone and rofecoxib as antiangiogenic therapy.[4,5,7]

Tasonermin *(BAN, rINN)*

Tasonermiini; Tasonermina; Tasonermine; Tasonerminum; TNFα-1a.

Тасонермин

$C_{778}H_{1225}N_{215}O_{231}S_2$ = 17350.5.
CAS — 94948-59-1.
ATC — L03AX11.
ATC Vet — QL03AX11.

Profile

Tumour necrosis factor is a cytokine of which 2 forms have been identified with similar biological properties: TNFα or cachectin, which is produced mainly by macrophages, and TNFβ or lymphotoxin, which is produced by lymphocytes. Various recombinant forms of TNFα, both human and mouse, are available: the names sonermin and sertenef have been used for such products.

The antitumour effects of tumour necrosis factor *in vitro* and in *animals* have prompted investigation of recombinant TNFα in the treatment of cancer either alone or with other cytokines such as interleukin-2 or the interferons. Tasonermin is a recombinant TNFα used with melphalan (p.742) for soft tissue sarcomas. It is given by mild hyperthermic isolated limb perfusion at a total dose of 3 mg for an upper limb and 4 mg for a lower limb.

Leakage of tasonermin into the systemic circulation should not exceed 10%, as severe toxicity may occur. Local adverse effects include skin reactions, oedema, and pain; less commonly, vascular thrombosis, onycholysis, or severe tissue damage have occurred. Systemic effects include fever, chills, nausea and vomiting, arrhythmias, hepatotoxicity, and infections. Shock or hypotension, neurological disorders, thrombocytopenia, leucopenia, acute renal failure, and hypersensitivity reactions have all been reported.

Units. The first International Standard for human tumour necrosis factor α, which contained 40 000 international units/ampoule, was considered unsuitable for the assay of recombinant *mouse* tumour necrosis factor α, for human tumour necrosis factor β, or for preparations of tumour necrosis factor α of modified structure.[1] The second International Standard for human tumour necrosis factor α has been established as having a potency of 46 500 international units/ampoule.[2]

The first Reference Reagent for tumour necrosis factor β had an assigned potency of 150 000 units/ampoule.[3]

Pharmacopoeias. In *Chin.*

Profile

Ubenimex is a peptide derived from *Streptomyces olivoreticuli*. It is reported to have antineoplastic and immunostimulant properties. It has been used in the adjuvant treatment of acute myeloid leukaemia and is under investigation for the treatment of lung cancer. Adverse effects include gastrointestinal and hepatic function disturbances, skin rashes, headache, and paraesthesias.

Valrubicin *(USAN, rINN)*

AD-32; NSC-246131; *N*-Trifluoroacetyladriamycin-14-valerate; *N*-Trifluoroacetyldoxorubicin-14-valerate; Valrubicina; Valrubicine; Valrubicinum. (8*S*,10*S*)-8-Glycoloyl-7,8,9,10-tetrahydro-6,8,11-trihydroxy-1-methoxy-10-{[2,3,6-trideoxy-3-(2,2,2-trifluoroacetamido)-α-L-*lyxo*-hexopyranosyl]oxy}-5,12-naphthacenedione 8^2-valerate.

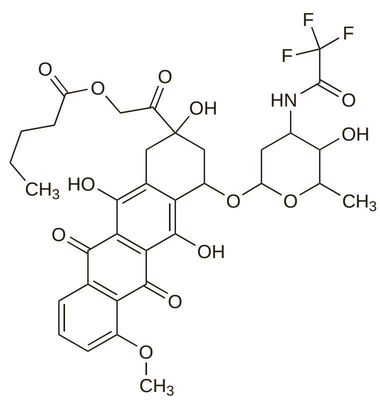
Вальрубицин

$C_{34}H_{36}F_3NO_{13}$ = 723.6.

CAS — 56124-62-0.

ATC — L01DB09.

ATC Vet — QL01DB09.



Pharmacopoeias. In *US.*

USP 31 (Valrubicin). An orange to orange-red crystalline powder. Very slightly soluble in water, in hexane, and in petroleum spirit; soluble in dehydrated alcohol, in acetone, in dichloromethane, and in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

Increased urinary frequency and urgency, dysuria, bladder spasm and pain may follow intravesical use of valrubicin due to local irritation of the bladder, and usually resolve within 1 to 7 days of treatment. Gross haematuria has occurred rarely but should be distinguished from drug-induced red coloration of the urine. Abdominal pain and nausea may occur.

Myelosuppression similar to that seen with other anthracyclines (see Adverse Effects of Doxorubicin, p.712) is possible if significant systemic exposure occurs. Therefore valrubicin should not be given to patients with a perforated bladder or compromised bladder mucosa.

Because of the risk of metastasis, cystectomy should be reconsidered for patients with carcinoma *in situ* who do not respond completely to valrubicin treatment after 3 months.

Pharmacokinetics

On intravesical use valrubicin penetrates the bladder wall but systemic absorption is low in patients who have an intact bladder mucosa. The drug is almost entirely excreted by voiding after the installation period.

Uses and Administration

Valrubicin is a semisynthetic analogue of the anthracycline doxorubicin (p.712). It is used for carcinoma *in situ* of the bladder (p.659) refractory to BCG vaccine, when surgery is contra-indicated, although only about 20% of such patients exhibit a complete response. A dose of 800 mg has been given intravesically once a week for 6 weeks, as 75 mL of a solution diluted with sodium chloride 0.9%. The solution should be retained for 2 hours if possible before voiding.

Verteporfin *(BAN, USAN, rINN)*

Benzoporphyrin Derivative; BPD; CL-318952; Verteporfiini; Verteporfina; Vertéporfine; Verteporfinum. *trans*-18-Ethenyl-4,4a-dihydro-3,4-bis(methoxycarbonyl)-4a,8,14,19-tetramethyl-23*H*,25*H*-benzo[*b*]porphine-9,13-dipropanoic acid monomethyl ester.

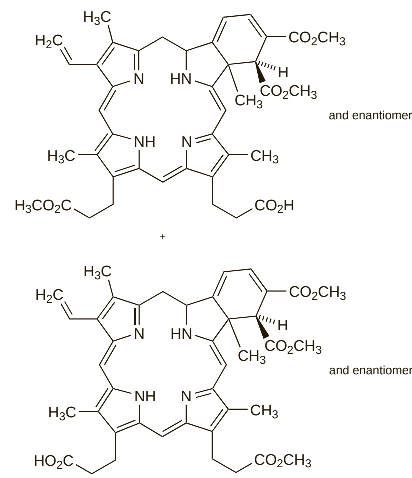
Вертепорфин

$C_{41}H_{42}N_4O_8$ = 718.8.

CAS — 129497-78-5.

ATC — S01LA01.

ATC Vet — QS01LA01.



Pharmacopoeias. In *US.*

USP 31 (Verteporfin). Store at a temperature between −25° and −10° in airtight containers.

Adverse Effects and Precautions

Photosensitivity will occur in all patients treated with verteporfin and patients should not be exposed to direct sunlight for 2 to 5 days after treatment. However, exposure to ambient indoor light is encouraged, as it allows gradual inactivation of any remaining drug. Headaches, injection site reactions, and visual disturbances occur frequently. Extravasation at the injection site may produce severe pain and inflammation and requires interruption of therapy. Patients who experience a severe decrease in vision should not be re-treated until their vision recovers. Other reported adverse effects include hypersensitivity, infusion-related pain (primarily presenting as back pain), chest pain, gastrointestinal disturbances, atrial fibrillation, hypertension, decreased hearing, and anaemia. Verteporfin should be used with care in patients with hepatic impairment and may be contra-indicated if impairment is severe.

Porphyria. The use of verteporfin is contra-indicated in patients with porphyria.

Interactions

Use of verteporfin with other drugs causing photosensitivity should be avoided as the reaction may be increased.

Pharmacokinetics

After intravenous doses, elimination of verteporfin is bi-exponential, with a terminal plasma elimination half-life of about 5 to 6 hours. Protein binding is about 90%. It is metabolised in the liver. It is excreted in faeces via the bile, mostly as unchanged drug, with less than 1% of a dose recovered in the urine.

◊ References.

Uses and Administration

Verteporfin is a photosensitiser used in photodynamic therapy (see under Porfimer Sodium, p.764). It is used to treat neovascular (wet) age-related macular degeneration (see below). After intravenous dosage verteporfin accumulates preferentially in the endothelial cells of actively growing blood vessels, including those in the choroid. When activated by laser light it produces local vascular occlusion and this inhibits neovascularisation and reduces the decline in visual acuity. It is given by intravenous infusion over 10 minutes at a dose of 6 mg/m^2. This is followed 15 minutes after the start of the infusion by activation using a laser tuned to a wavelength of 689 nanometres and delivered to the eye via a fibre optic device and a slit lamp, together with a suitable contact lens. The recommended light dose is 50 J/cm^2, given over 83 seconds. Therapy may be repeated every 3 months for recurrent choroidal neovascular leakage. Verteporfin has also been investigated in the photodynamic therapy of a variety of other disorders including malignant neoplasms.

Age-related macular degeneration. Age-related macular degeneration (AMD) is a degenerative disease usually occurring in people over the age of 50 years.[1-3] The central portion of the retina (the macula) deteriorates[2,4,5] and it is a major cause of severe visual loss in people over 60 years old in North America and Europe.[4,6] There are two main types of AMD.

- In geographic atrophy or *non-neovascular* or *non-exudative (dry) AMD*, which occurs at an early stage of AMD, the retinal pigment epithelium is lost completely in localised areas, causing a gradual loss of central vision in the affected eye(s). It is characterised by retinal hypo- or hyperpigmentation, and yellow deposits of acellular amorphous debris beneath the retina, called drusen. These are usually large, or soft (with indistinct margins); small hard drusen occur naturally with ageing but, unlike drusen in AMD, do not progress.
- In *neovascular* or *exudative (wet) AMD*, new blood vessels develop in the choroidal layer beneath the retina; leaks or haemorrhage from these lead to macular oedema, retinal scarring, and often acute, significant loss of vision.[2,4,5,7-10] This process of *choroidal neovascularisation* (CNV) is defined as classic or occult according to its appearance on fluorescein angiography;[2,5,9,11] the classic form is associated with more rapid progression than the occult form.[2,9] CNV lesions are also classified according to their location relative to the fovea.[1,2,12] Although the neovascular form accounts for only about 20% of all cases of AMD, the risk of severe visual loss with this form is much higher than with dry AMD.[1,9] However, about 10 to 20% of patients with dry AMD can progress to the neovascular form,[1,10] and both forms can occasionally co-exist in the same patient.[11]

Risk factors, besides older age, include a family history of the disorder, the presence of a mutation in the complement factor H (CFH) gene, smoking, white race, and increased body-mass index;[3,8,13] female sex, atherosclerosis, dietary fat or fish intake, alcohol or caffeine consumption, refractive error, iris colour, and increased exposure to sunlight have also been proposed as risk factors but have not consistently been related to development of AMD.[13]

There is currently no **treatment** that effectively prevents visual loss or improves vision in all patients with AMD.[14]

- Laser photocoagulation treatment is of proven efficacy for neovascular AMD, especially for extrafoveal CNV; however, rates of recurrence are high.[1,6,8,13,14]
- Photodynamic therapy (see under Porfimer Sodium, p.764) with verteporfin has been shown to decrease the risk of visual loss in patients with neovascular AMD, including subfoveal CNV.[1,4,8,9,11,12,14-18] Systematic reviews have noted that although photodynamic therapy with verteporfin is probably effective in preventing visual loss in those with classic and occult CNV due to AMD, the size of the effect remains in doubt.[5,19] Furthermore, the therapy can only be effective during the proliferative stage of the disease while the neovascular process is active.[5]

  In the UK, NICE guidelines considered the evidence to show a larger treatment effect in patients with classic CNV, and recommend photodynamic therapy in those patients with neovascular AMD with a confirmed diagnosis of classic, with no occult, subfoveal CNV.[2] However, other guidelines[20] on the use of verteporfin recommend that verteporfin treatment be considered for patients with minimally classic subfoveal CNV who have relatively small lesions, or where the proportion of classic CNV is increasing. For those patients with occult CNV and who are presumed to have recent disease progression, verteporfin may be considered in those with smaller lesions or lower levels of visual acuity; for those with large occult lesions, treatment may be considered if levels of visual acuity are rapidly decreasing. Patients should be followed up at least as often as every 3 months after initial therapy, and re-treated if necessary.[20]

  While photodynamic therapy is considered to have minimal adverse effects and a low complication rate, some have cautioned that patients should be counselled that verteporfin therapy rarely leads to an improvement in vision.[21]
- Vascular endothelial growth factor (VEGF) plays a role in the development of CNV secondary to AMD; pegaptanib and ranibizumab are VEGF inhibitors used in the treatment of neovascular (wet) AMD.[22-24] Systematic reviews[25,26] of randomised controlled studies of these drugs concluded that both show benefit in slowing or stopping the progression of disease. Greater effect was seen with ranibizumab than with pegaptanib, although head-to-head comparative studies are needed to confirm this. Bevacizumab has also been tried, although its use is controversial.[6,22,27] Triamcinolone acetonide, a corticosteroid that may also downregulate VEGF, has been given intravitreally with variable results; combination treatment with photodynamic therapy is under investigation.[10,13,28]
- Angiogenesis inhibitors such as anecortave are under investigation for neovascular AMD.[3,10,13,14,28] Interferon alfa showed encouraging preliminary results, but controlled data showed no benefit.[8,10,13] Thalidomide has been tried, but trials were stopped due to adverse effects.[10,13]
- Vitamin and mineral supplements may be of use in selected patients; the AREDS trial found that antoxidants (vitamin C, vitamin E, and betacarotene) plus zinc modestly benefited those with moderate to severe signs of the disease.[11,14] However, betacarotene should be avoided in smokers.[3,6,10] The carotenoids, lutein and zeaxanthin, have been promoted as retinal protectants, but controlled data are lacking.[10,11,14,29] Some recommend that those at risk of AMD should be encouraged to stop smoking and to consume a diet including vegetables, fish, nuts, and to reduce consumption of fats especially vegetable oil.[7,29] A prospective cohort study found that a high dietary intake of vitamin E and zinc, or an above-median intake of the combination of vitamins C and E, betacarotene, and zinc were associated with a lower risk of incident AMD.[30] However, systematic reviews[31,32] have found no evidence to support the role of antioxidant vitamin and mineral supplements in the primary prevention of AMD.
- Retinal or macular surgery, and transpupillary thermotherapy are under investigation.[1,8,11,13,14,28] Radiotherapy has also been tried with mixed results.[10,13] Retinal transplantation is under investigation.[6,8,11,14] Gene silencing with bevasiranib, a short interfering RNA (siRNA) therapeutic designed to turn off or silence the gene that produces VEGF, is also under investigation for wet AMD.[33]

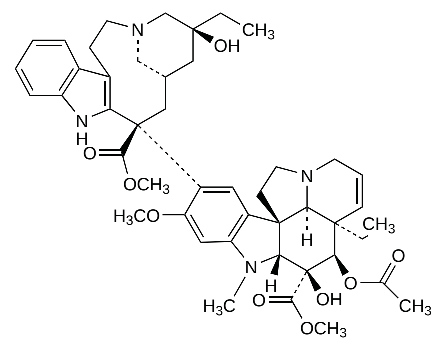
Винбластина Сульфат

$C_{46}H_{58}N_4O_9,H_2SO_4 = 909.1.$

CAS — 865-21-4 (vinblastine); 143-67-9 (vinblastine sulfate).

ATC — L01CA01.

ATC Vet — QL01CA01.



(vinblastine)

Description. Vinblastine sulfate is the sulfate of an alkaloid, vincaleukoblastine, extracted from *Catharanthus roseus* (*Vinca rosea*) (Apocynaceae).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Vinblastine Sulphate). A white or slightly yellowish, very hygroscopic, crystalline powder. It loses not more than 15% of its weight on drying. Freely soluble in water; practically insoluble in alcohol. A 0.15% solution in water has a pH of 3.5 to 5.0. Store at a temperature not exceeding −20° in airtight glass containers. Protect from light.

USP 31 (Vinblastine Sulfate). A white or slightly yellow, odourless, hygroscopic, amorphous or crystalline powder. It loses not more than 15% of its weight on drying. Freely soluble in water. A 0.15% solution in water has a pH of 3.5 to 5.0. Store at a temperature between −25° and −10° in airtight containers. Protect from light.

Stability. Between about 5 and 20% of active drug was lost from solution when a solution of vinblastine sulfate 3 micrograms/mL in glucose 5% injection was stored for 48 hours in a range of intravenous burette giving sets, the highest loss being from cellulose propionate sets and the lowest from one made from methacrylate butadiene styrene.[1] Similarly, storage in PVC tubing led to a 42 to 44% loss from solution whereas only about 6% was lost over the 48 hours in polybutadiene tubing. The losses appeared to be due to drug sorption, and were therefore greater from the tubing which had a greater surface-area-to-volume ratio than the burettes.

1. McElnay JC, *et al.* Stability of methotrexate and vinblastine in burette administration sets. *Int J Pharmaceutics* 1988; **47:** 239–47.

Adverse Effects, Treatment, and Precautions

For general discussions, see Antineoplastics, p.635, p.639, and p.641.

Bone-marrow depression, especially leucopenia, is the most common adverse effect with vinblastine and tends to be dose-limiting. Maximum depression occurs 5 to 10 days after a dose with recovery in a further 7 to 14 days. Leucopenia may be more severe in patients with cachexia or extensive skin ulceration: vinblastine should not be used in elderly patients with these conditions. Stomatitis and gastrointestinal bleeding may occur; nausea and vomiting respond to treatment with antiemetics.

The vinca alkaloids can produce central and peripheral (including autonomic) neurotoxicity, although these effects are less frequent with vinblastine. Symptoms include malaise, weakness, headache, depression, paraesthesia and numbness, loss of deep tendon reflexes, peripheral neuropathies, constipation and adynamic ileus, jaw pain, and convulsions. Damage to the eighth cranial nerve may result in vestibular and auditory toxicity leading to dizziness, nystagmus, vertigo, and partial or total deafness. A routine prophylactic regimen against constipation is recommended in patients receiving high doses of vinblastine. Overdosage has caused permanent damage to the CNS. Intrathecal use of the vinca alkaloids is contra-indicated because of the likelihood of fatal neurotoxicity (see Administration Error, below).

Other reported effects include skin reactions, alopecia, ischaemic cardiac toxicity, hypertension, dyspnoea and bronchospasm, and bone and tumour pain. A syndrome of inappropriate secretion of antidiuretic hormone has occurred at high doses, and may be relieved by fluid restriction and, if necessary, a suitable diuretic. Rare cases of anaphylaxis and anaphylactoid-type reactions have been reported with the vinca alkaloids.

Vinblastine is irritant to the skin and mucous membranes and extravasation may cause necrosis, cellulitis, and sloughing. The application of warmth and local injection of hyaluronidase may be of benefit in relieving the effects of extravasation. By analogy with its use in the management of vincristine overdosage (see p.787), folinic acid has been suggested for use in overdosage with vinblastine.

Vinblastine should not be injected into an extremity with impaired circulation because of an increased risk of thrombosis. It should be given with caution and at reduced dosage to patients with hepatic impairment (see under Uses, below).

Administration error. *Intrathecal doses of vinca alkaloids, including vinblastine, result in ascending paralysis and death.* For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK guidelines on dilution of vinca alkaloids to avoid intrathecal use, see p.787.

Handling and disposal. A method for the destruction of vincristine or vinblastine *wastes* using sulfuric acid and potassium permanganate.[1] Residues produced by degradation of either drug by this method showed no mutagenicity *in vitro*.

Urine and faeces produced for up to 4 and 7 days respectively after a dose of vinblastine should be handled wearing protective clothing.[2]

2. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Porphyria. Vinblastine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems, although there is conflicting evidence of porphyrinogenicity.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Use with drugs that inhibit cytochromes of the CYP3A subfamily may result in decreased metabolism of vinblastine and increased toxicity. For a report of the possible contribution of vinblastine to reduced plasma concentrations of phenytoin, see p.499.

Analgesics. A report of enhanced hepatotoxicity in patients treated with interferon alfa and vinblastine who were given *paracetamol*.[1]

1. Kellokumpu-Lehtinen P, *et al.* Hepatotoxicity of paracetamol in combination with interferon and vinblastine. *Lancet* 1989; **i:** 1143.

Antibacterials. There is a report of severe vinblastine toxicity in 3 patients who received vinblastine and ciclosporin with *erythromycin*.[1] Adverse effects resolved on stopping erythromycin and recurred in 1 patient who was rechallenged with erythromycin.

1. Tobe SW, *et al.* Vinblastine and erythromycin: an unrecognised serious drug interaction. *Cancer Chemother Pharmacol* 1995; **35:** 188–90.

Antineoplastics. Acute bronchospastic reactions after injection of a vinca alkaloid have been reported, usually in patients who have also received *mitomycin*,[1] and presenting as acute respiratory distress, cyanosis, and dyspnoea, often with the development of pulmonary infiltrates and pneumonitis.[2,3] A number of fatalities due to respiratory complications have occurred. For reports of vascular toxicity and Raynauds syndrome associated with the use of vinca alkaloids with *bleomycin* and other drugs, see Effects on the Cardiovascular System, p.636.

2. Konits PH, *et al.* Possible pulmonary toxicity secondary to vinblastine. *Cancer* 1982; **50:** 2771–4.
3. Ozols RF, *et al.* MVP (mitomycin, vinblastine, and progesterone): a second-line regimen in ovarian cancer with a high incidence of pulmonary toxicity. *Cancer Treat Rep* 1983; **67:** 721–2.

Antivirals. Severe myelosuppression has occurred in patients given relatively high doses of vinblastine with *interferon alfa-n1*.

A patient who had been given vinblastine 6 mg/m^2 every 3 weeks had severe gastrointestinal and haematological toxicity and moderate renal failure when *HAART* with zidovudine, lamivudine, abacavir, nevirapine, and lopinavir with ritonavir was reintroduced.[1] The vinblastine dosage was eventually stabilised at 2 mg/m^2 during HAART without toxicity.

1. Kotb R, *et al.* Life-threatening interaction between antiretroviral therapy and vinblastine in HIV-associated multicentric Castleman's disease. *Eur J Haematol* 2006; **76:** 269–71.

Pharmacokinetics

Vinblastine is not reliably absorbed from the gastrointestinal tract. After intravenous use it is rapidly cleared from the blood and distributed to tissues; it is reported to be concentrated in blood platelets. It is extensively protein bound. Vinblastine is metabolised in the liver, by cytochrome P450 isoenzymes of the CYP3A subfamily, to an active metabolite desacetylvinblastine, and is excreted in faeces via the bile, and in urine; some is excreted as unchanged drug. The terminal half-life is reported to be about 25 hours. It does not cross the blood-brain barrier in significant amounts.

Uses and Administration

Vinblastine sulfate is an antineoplastic agent that apparently acts by binding to the microtubular proteins of the spindle and arresting mitosis at the metaphase; it is thus specific for the M phase of the cell cycle. It also interferes with glutamate metabolism and possibly nucleic acid synthesis, and has some immunosuppressant activity. Significant cross-resistance with vincristine has not been reported although pleiotropic resistance may occur.

Vinblastine sulfate is used, usually with other antineoplastics, in the treatment of Hodgkin's disease and other lymphomas, for some inoperable malignant neoplasms including those of the breast, bladder, and kidney, and in non-small cell lung cancer, choriocarcinoma, and Kaposi's sarcoma; vinblastine has also been employed in the management of Langerhans-cell histiocytosis. It was formerly used with bleomycin and cisplatin (PVB) for testicular cancer, but other regimens are now preferred. The management of these conditions is discussed under Choice of Antineoplastic, as indicated by the cross-references given below.

Vinblastine sulfate may be given by intravenous injection as a solution containing 1 mg/mL in sodium chloride 0.9%. However, UK guidelines recommend that for patients over the age of 10 years, solutions of vinblastine should generally be diluted to a volume of at least 20 mL to avoid inadvertent intrathecal use; higher concentrations can be used for children under 10 years of age. Care should be taken to avoid extravasation and the intravenous injection may be given into a freely running infusion of sodium chloride injection if preferred. The usual dose is about 6 mg/m^2, not more often than every 7 days, although doses starting at 3.7 mg/m^2 and increasing to 18.5 mg/m^2 have been given as a single agent. If a maintenance dose is required, it may be given every 7 days provided white cell counts permit (see below), and should be the maximum dose that the patient is able to tolerate without serious leucopenia occurring.

Children may be given vinblastine sulfate in a usual maximum weekly dose of 7.5 mg/m^2. Doses of up to 12.5 mg/m^2 weekly as a single agent have been given.

White cell counts should be made before each injection and some sources suggest a repeat dose should not be given unless the count has risen to at least 4000 cells/mm^3 (but see also Bone-marrow Depression, p.639). A dosage reduction is advised in patients with hepatic impairment (see below).

Administration in hepatic impairment. UK licensed product information recommends that the dose of vinblastine be reduced by 50% in patients having a serum bilirubin value above 3 mg per 100 mL.

Blood disorders, non-malignant. The vinca alkaloids vinblastine and vincristine have been used experimentally in the treatment of auto-immune blood disorders such as idiopathic thrombocytopenic purpura (p.1505). There are also reports of the haemolytic-uraemic syndrome/thrombotic thrombocytopenic purpura responding to treatment with intravenous injection of vincristine.[1-3] For further details on the treatment of thrombotic microangiopathies, see under Plasma, p.1076. Vincristine has been given with normal immunoglobulin in the management of a patient with life-threatening thrombocytopenia due to sarcoidosis.[4] Vincristine has also been used for life-threatening haemangioma (p.1505).

4. Larner AJ. Life threatening thrombocytopenia in sarcoidosis. *BMJ* 1990; **300:** 317–19.

Histiocytic syndromes. The value of systemic chemotherapy in patients with Langerhans-cell histiocytosis (p.650) is uncertain; however, it is certainly widely used in extensive disease, vinblastine being one of the drugs often employed.[1,2]

Malignant neoplasms. Vinblastine plays an important role in the ABVD regimen in patients with Hodgkin's disease (p.655). It also formed part of the effective, if toxic, PVB regimen used to treat germ cell (ovarian or testicular) cancer, p.670 and p.673 respectively, although other regimens tend now to be preferred. The vinca alkaloids are also active in gestational trophoblastic tumours (p.650), and vinblastine is also used in the therapy of invasive bladder cancer (p.659); it may be used in the adjuvant or palliative treatment of non-small-cell lung cancer (p.668) and in the palliative care of advanced breast cancer (p.661) and mycosis fungoides (p.657). It has been used in malignancies of the kidney (p.667). Vinca alkaloids are also used to treat Kaposi's sarcoma (p.675).

Compound 37231; Leurocristine Sulphate; NSC-67574; 22-Oxovincaleukoblastine Sulphate; Sulfato de vincristina; Vincristine, sulfate de; Vincristine Sulphate *(BANM)*; Vincristini sulfas; Vinkristiinisulfaatti; Vinkristin Sülfat; Vinkristino sulfatas; Vinkristinsulfat; Vinkristin-sulfát; Vinkrisztin-szulfát; Winkrystyny siarczan.

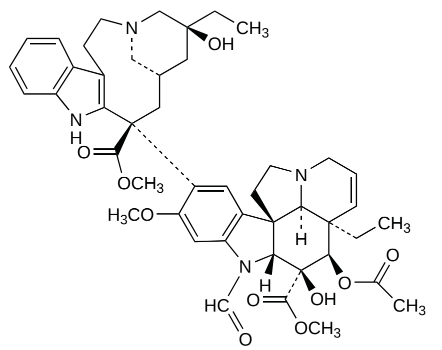
Винкристина Сульфат

$C_{46}H_{56}N_4O_{10},H_2SO_4 = 923.0.$

CAS — 57-22-7 (vincristine); 2068-78-2 (vincristine sulfate).

ATC — L01CA02.

ATC Vet — QL01CA02.



(vincristine)

Description. Vincristine sulfate is the sulfate of an alkaloid, 22-oxovincaleukoblastine, obtained from *Catharanthus roseus* (*Vinca rosea*) (Apocynaceae).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Vincristine Sulphate). A white or slightly yellowish, very hygroscopic, crystalline powder. It loses not more than 12% of its weight on drying. Freely soluble in water; slightly soluble in alcohol. A 0.1% solution in water has a pH of 3.5 to 4.5. Store at a temperature not exceeding −20° in airtight glass containers. Protect from light.

USP 31 (Vincristine Sulfate). A white to slightly yellow, odourless, hygroscopic, amorphous or crystalline powder. It loses not more than 12% of its weight on drying. Freely soluble in water; slightly soluble in alcohol; soluble in methyl alcohol. A 0.1% solution in water has a pH of 3.5 to 4.5. Store at a temperature between −25° and −20° in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p.786.

Bone-marrow depression occurs less commonly than with vinblastine but neurological and neuromuscular effects are more severe with vincristine and are dose-limiting. Walking may be impaired and the neurological effects may not be reversed for several months after the drug is stopped. Convulsions, often with hypertension, have occurred. Constipation is common and there may be abdominal pain. Urinary disturbances have occurred and alopecia is frequent.

Folinic acid has been given for the treatment of overdosage: suggested doses are as much as 100 mg of folinic acid intravenously every 3 hours for 24 hours, then every 6 hours for at least 48 hours. However, this is unlikely to be of benefit in reversing neuromuscular toxicity. For mention of the use of glutamic acid in managing the usually fatal consequences of inadvertent intrathecal dosage, see below.

Because severe constipation and impaction of faeces often occur with vincristine, laxatives or enemas may be necessary to ensure regular bowel function. Vincristine should be given with caution to patients with pre-existing neuromuscular disease and is contra-indicated in patients with the demyelinating form of Charcot-Marie-Tooth syndrome (see under Effects on the Nervous System, below). Doses may need to be adjusted in patients with hepatic impairment. Care should also be taken in elderly patients, who may be more susceptible to neurotoxicity.

Administration error. *Inadvertent intrathecal doses of vincristine result in ascending paralysis and death.*[1,2] However, in one case[1] treatment immediately after the error, and consisting of removal of contaminated spinal fluid and flushing with lactated Ringer's solution and fresh frozen plasma diluted in lactated Ringer's solution, plus intravenous and oral glutamic acid, was reported successful in stabilising neurological dysfunction and preventing death. A similar case of successful treatment has subsequently been reported,[3] in which immediate CSF aspiration and irrigation (with lactated Ringer's solution containing fresh frozen plasma to bind vincristine) for 6 days was combined with intravenous folate, glutamic acid, and pyridoxine. The role of neuroprotectant drugs in these cases is uncertain, although a study involving 84 patients found that glutamic acid 1.5 g daily given orally in divided doses during a 6-week induction chemotherapy course decreased vincristine-induced neurotoxicity.[4] One manufacturer (*Lilly*) has stated that the roles of glutamic acid, folinic acid, and pyridoxine remain unclear.

While early recognition and immediate treatment with cerebrospinal fluid drainage and exchange may improve survival,[5] fatalities still occur despite these measures.[5,6] Recommendations[2,6] have been made in order to prevent further errors occurring, including restrictions on the prescription, administration, and storage of intrathecal drugs. In the UK, recommendations state that vinca alkaloids for intravenous use in adults or children over 10 years should be diluted to a maximum concentration of 100 micrograms/mL (vincristine) or a volume of at least 20 mL (vinblastine, vindesine, or vinorelbine) and labelled with a clear warning of the consequences of use by other routes. Higher concentrations may be used in children under 10 years, and in certain specialised centres.[2]

Effects on the nervous system. In its most typical form, vincristine neurotoxicity[1] manifests as a mixed sensorimotor neuropathy of the distal type. The earliest symptoms are sensory changes in the form of paraesthesias, accompanied by impairment and ultimately loss of deep tendon reflexes. In more severe forms, impairment of motor function occurs with wrist drop and foot drop, ataxia and gait abnormalities, and occasionally progressive quadriparesis.

In contrast to these peripheral neuropathies, which are usually associated with long-term usage, there may be short-term autonomic neuropathy resulting in constipation and occasionally ileus, abdominal pain, atony of the urinary bladder (which may lead to urinary retention), orthostatic hypotension, and rarely, impotence. Effects on the cranial nerves may result in ptosis, hoarseness (due to laryngeal nerve paralysis), or optic neuropathies. Effects on the CNS are rare, probably in part because of poor penetration into CSF, but include excessive release of antidiuretic hormone and consequent hyponatraemia.

Hallucinations have occurred[2] and effects on the special senses have been reported: both bilateral optic atrophy and blindness,[3] and profound neurological deafness (which was largely reversible on drug withdrawal)[4] have occurred. Convulsions associated with hypertension are another feature of vincristine toxicity.[5]

Toxicity is related to both the cumulative and the individual dose.[1] It usually begins in adults after receiving a total of 5 to 6 mg, and is significant by the time a cumulative dose of 15 to 20 mg is reached. If individual doses are low (less than 2 mg) or intervals between doses are longer than the usual week, patients can tolerate higher cumulative doses. Children tolerate vincristine better than adults, but the elderly are particularly prone to neurotoxicity. Patients with existing neurological disorders such as poliomyelitis or the Charcot-Marie-Tooth syndrome may be at increased risk of neurotoxicity.[6-9] It has been suggested that increased neurotoxicity may be associated with the use of ready-to-use solutions rather than reconstituted lyophilised preparations but this has not been proved.[10-14]

There is no good treatment for the effects of vincristine on the nervous system: symptoms are largely reversible once dosage is interrupted, and should be managed with appropriate symptomatic care.[1] However, there is some suggestion that glutamic acid may be of benefit in treating neurotoxicity—see Administration Error, above. For the use of dinoprost to alleviate ileus induced by vinca alkaloids, see p.2007.

14. Gennery BA. Vincristine neurotoxicity. *Lancet* 1985; **ii:** 385.

Handling and disposal. For a method for the destruction of vincristine *wastes*, see under Vinblastine Sulfate, p.786.

Urine and faeces produced for up to 4 and 7 days respectively after a dose of vincristine should be handled wearing protective clothing.[1]

1. Harris J, Dodds LJ. Handling waste from patients receiving cytotoxic drugs. *Pharm J* 1985; **235:** 289–91.

Porphyria. Vincristine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems, although there is conflicting evidence of porphyrinogenicity.

Interactions

For a general outline of antineoplastic drug interactions, see p.642. Use of vincristine with drugs that inhibit cytochromes of the CYP3A subfamily may result in decreased metabolism of vincristine and increased toxicity. If vincristine is used with asparaginase it should be given 12 to 24 hours before the enzyme: giving asparaginase with or before vincristine may reduce vincristine clearance and increase toxicity. For reports of vascular toxicity and Raynaud's syndrome associated with the use of vinca alkaloids with bleomycin and other drugs see Effects on the Cardiovascular System, p.636.

Antibacterials. Severe neurotoxicity has occurred when *isoniazid* was added to the regimen of a patient receiving vincristine.[1]

1. Carrión C, *et al.* Possible vincristine-isoniazid interaction. *Ann Pharmacother* 1995; **29:** 201.

Antiepileptics. A pharmacokinetic study showed that systemic clearance of vincristine was 63% higher when it was given with *phenytoin* or *carbamazepine*, two inducers of the cytochrome P450 isoenzyme CYP3A4. The clinical significance of this finding is unknown.[1]

1. Villikka K, *et al.* Cytochrome P450-inducing antiepileptics increase the clearance of vincristine in patients with brain tumours. *Clin Pharmacol Ther* 1999; **66:** 589–93.

Antifungals. Toxicity has been reported to be increased in children who received *itraconazole* with or without nifedipine during treatment involving vincristine.[1-4] Itraconazole is presumed to potentiate the toxicity of vincristine either by inhibition of cytochrome P450 isoenzymes, thus reducing the clearance of vincristine,[1-4] or by inhibiting the P-glycoprotein efflux pump,[2,3] and increasing intracellular concentrations of vincristine. Nifedipine also decreases the clearance of vincristine, by similar mechanisms,[1,3,4] and can theoretically further potentiate toxicity.

4. Kamaluddin M, *et al.* Potentiation of vincristine toxicity by itraconazole in children with lymphoid malignancies. *Acta Paediatr* 2001; **90:** 1204–7.

Nifedipine. Vincristine toxicity may be potentiated by nifedipine, see Antifungals, above.

Pharmacokinetics

Vincristine is not reliably absorbed from the gastrointestinal tract. After intravenous injection it disappears rapidly from the blood. It is extensively protein bound and is reported to be concentrated in blood platelets. It is metabolised in the liver and excreted primarily in the bile; about 70 to 80% of a dose is found in faeces, as unchanged drug and metabolites, while 10 to 20% appears in the urine. The terminal half-life is reported to be about 85 hours but may range from about 19 to 155 hours. Vincristine does not appear to cross the blood-brain barrier in significant amounts.

Uses and Administration

Vincristine is an antineoplastic agent that may act similarly to vinblastine (p.786) by arresting mitosis at the metaphase. Significant cross-resistance with vinblastine has not been reported although pleiotropic resistance may occur.

Vincristine sulfate is used mainly in combination chemotherapy regimens for acute and chronic leukaemias, lymphomas, including Hodgkin's disease and non-Hodgkin's lymphomas, and multiple myeloma. It is also used for tumours of the breast, lung, head and neck, and soft-tissue sarcomas, as well as for paediatric solid tumours including Ewing's sarcoma, rhabdomyosarcoma, neuroblastoma, Wilms' tumour, retinoblastoma, and medulloblastoma. Vincristine has also been used in idiopathic thrombocytopenic purpura refractory to other agents. See also the cross-references given below.

Vincristine sulfate is given by intravenous injection. It has been given as a solution containing 1 mg/mL. However, UK guidelines recommend that for patients over the age of 10 years, solutions of vincristine should generally be diluted to a maximum concentration of 100 micrograms/mL and to a volume of at least 10 mL, to avoid inadvertent intrathecal use; higher concentrations can be used for children under 10 years of age. Care should be taken to avoid extravasation and the injection may be given over 1 minute into a freely-running intravenous infusion (usually sodium chloride 0.9%) if preferred.

The usual adult intravenous dose of vincristine sulfate is 1.4 to 1.5 mg/m^2 once weekly, up to a maximum weekly dose of 2 mg (see also Administration, below). For children weighing over 10 kg, the suggested dose is 1.4 to 2 mg/m^2 once weekly, up to a maximum weekly dose of 2 mg. For those weighing less than 10 kg, the suggested initial dose is 50 micrograms/kg, once weekly.

Blood counts should be carried out before giving each dose. Dosage reduction is recommended in patients with hepatic impairment (see below).

A liposomal formulation of vincristine is under investigation for the treatment of acute lymphoblastic leukaemia.

Action. Results *in vitro* suggested[1] a selective action of vincristine against lymphocytes of patients with chronic lymphocytic leukaemia; lymphocytes of healthy subjects were not so affected. A further study[2] confirmed these findings, and also found marked variation in vincristine susceptibility among individual chronic lymphocytic leukaemic cells. This suggests that vincristine may have effects other than arrest of mitosis.

1. Vilpo J, Vilpo L. Selective toxicity of vincristine against chronic lymphocytic leukaemia in vitro. *Lancet* 1996; **347:** 1491–2.
2. Vilpo JA, *et al.* Selective toxicity of vincristine against chronic lymphocytic leukemia cells in vitro. *Eur J Haematol* 2000; **65:** 370–8.

Administration. Although a maximum single dose of 2 mg is recommended for vincristine sulfate to reduce neurotoxicity, a review[1] has suggested that this guideline is overly rigid, since it does not take into account interindividual variations in pharmacokinetics and susceptibility to toxicity, which may be considerable. Furthermore the authors considered the evidence for effectiveness of this dosage limitation to be equivocal. They suggested beginning therapy at 1.4 mg/m^2 and adjusting subsequent doses according to toxicity.

For UK recommendations on dilution of intravenous vinca alkaloids see Administration Error, under Adverse Effects, above.

1. McCune JS, Lindley C. Appropriateness of maximum-dose guidelines for vincristine. *Am J Health-Syst Pharm* 1997; **54:** 1755–8.

Administration in hepatic impairment. Licensed product information states that the dose of vincristine should be reduced by 50% in patients having a serum bilirubin value above 3 mg per 100 mL (51 micromoles/litre).

Amyloidosis. For mention of regimens including vincristine used in the management of amyloidosis, see p.743.

Blood disorders, non-malignant. Vincristine may be employed in the treatment of various auto-immune blood disorders, see under Vinblastine, p.786.

Malignant neoplasms. Vincristine is widely used in the treatment of malignant neoplasms. It is a fundamental part of potentially curative regimens for acute lymphoblastic leukaemia, Hodgkin's disease and aggressive non-Hodgkins lymphomas (see p.651, p.655 and p.656). It has also been used in chronic lymphocytic leukaemia (p.653) and in other non-Hodgkin's lymphomas including AIDS-related lymphoma (p.657), Burkitt's lymphoma (p.657) and mycosis fungoides (p.657). Other haematological malignancies in which it may be tried include multiple myeloma (p.658). Among the solid neoplasms, vincristine is used in regimens to treat gestational trophoblastic tumours (p.650), tumours of the brain (p.660), head and neck (p.666), Wilms' tumour (p.667), small-cell lung cancer (p.668), and thymoma (p.674). It is also employed in regimens for neuroblastoma (p.674), retinoblastoma (p.675), and some sarcomas including sarcomas of bone, Kaposi's sarcoma, and rhabdomyosarcoma (see p.675, p.675, and p.676).

Preparations

BP 2008: Vincristine Injection;
USP 31: Vincristine Sulfate for Injection; Vincristine Sulfate Injection.

Proprietary Preparations (details are given in Part 3)

Vindesine Sulfate *(USAN, rINNM)*

Compound 112531 (vindesine); Desacetyl Vinblastine Amide Sulfate; LY-099094; NSC-245467 (vindesine or vindesine sulfate); Sulfato de vindesina; Vindesiinisulfaatti; Vindésine, sulfate de; Vindesine Sulphate *(BANM)*; Vindesini sulfas; Vindesinsulfat; Vindesin-sulfát; Vindezino sulfatas; Vindezin-szulfát. 3-Carbamoyl-4-*O*-deacetyl-3-de(methoxycarbonyl)vincaleukoblastine sulfate.

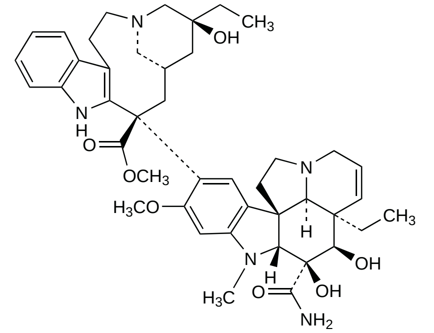
Виндезина Сульфат

$C_{43}H_{55}N_5O_7,H_2SO_4$ = 852.0.

CAS — 53643-48-4 (vindesine); 59917-39-4 (vindesine sulfate).

ATC — L01CA03.

ATC Vet — QL01CA03.



(vindesine)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Vindesine Sulphate). A white or almost white, hygroscopic, amorphous substance. Freely soluble in water and in methyl alcohol; practically insoluble in cyclohexane. The pH of a 0.5% solution in water is 3.5 to 5.5. Store in airtight polypropylene containers with a polypropylene cap, at a temperature not exceeding –50°.

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p.786.

The main dose-limiting effect of vindesine is granulocytopenia, with the nadir of the white cell count usually occurring 3 to 5 days after a dose and recovery after a further 4 to 5 days. Although neurotoxicity occurs it may be less severe than that seen with vincristine (see p.787). Alopecia is the most common adverse effect.

Folinic acid has been suggested for the treatment of overdosage by analogy with vincristine.

Vindesine should not be given by the intrathecal route, as this may produce fatal toxicity. Care should be taken if acute abdominal pain occurs: further doses may result in paralytic ileus.

Administration error. *Inadvertent intrathecal doses of vinca alkaloids result in ascending paralysis and death.* In a 10-year-old child accidentally given an intrathecal injection of vindesine, treatment with folinic acid and dexamethasone produced transient recovery but symptoms subsequently recurred and the patient died of progressive ascending paralysis.[1] The CNS showed changes at necropsy similar to those seen after intrathecal vincristine. Other fatal cases[2] have subsequently been reported. For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK recommendations on dilution of vinca alkaloids to avoid intrathecal use, see p.787.

1. Robbins G. Accidental intrathecal injection of vindesine. *BMJ* 1985; **291:** 1094.
2. Nisse P, *et al.* Administration accidentelle intrathécale de vindésine: à propos de 2 cas mortels. *Therapie* 2007; **62:** 360–1.

Interactions

As for Vinblastine Sulfate, p.786.

Pharmacokinetics

The pharmacokinetics of vindesine are similar to those of the other vinca alkaloids. After intravenous doses elimination from the blood is triphasic; the drug is rapidly distributed to body tissues. The terminal half-life is reported to be about 20 hours. It is metabolised primarily in the liver and excreted in bile and urine.

Uses and Administration

Vindesine sulfate is an antineoplastic agent derived from vinblastine (see p.785); like the other vinca alkaloids it causes mitotic arrest in metaphase by binding to microtubular protein. It is used in the treatment of refractory acute lymphoblastic or chronic myeloid leukaemias, and malignant melanoma. It has also been tried in malignant neoplasms of the breast, and lung. See also the cross references given below.

Vindesine sulfate is given weekly by intravenous injection. It may be given as a solution containing 1 mg/mL in sodium chloride injection 0.9%. However, UK guidelines recommend that for patients over the age of 10 years, solutions of vindesine should generally be diluted to a volume of at least 20 mL to avoid inadvertent intrathecal use; higher concentrations can be used for children under 10 years of age. Care should be taken to avoid extravasation and it may be given into a fast-running infusion of sodium chloride, glucose 5%, or glucose-saline injection. The usual starting dose for adults is 3 mg/m^2 which may be raised by increments of 500 micrograms/m^2 weekly providing that the granulocyte and platelet counts do not fall below acceptable levels (see also Bone-marrow Depression, p.639), and acute abdominal pain is not experienced; weekly doses are usually between 3 and 4 mg/m^2. Children may be given 4 mg/m^2 initially, with weekly doses usually ranging between 4 and 5 mg/m^2. An alternative regimen for children with leukaemia is 2 mg/m^2 daily for 2 consecutive days, repeated after an interval of 5 to 7 days. Blood counts should be made before each injection. It may be necessary to reduce initial doses in patients with significantly impaired hepatic function.

Malignant neoplasms. Vindesine has been tried in refractory metastatic melanoma (p.673), childhood acute lymphoblastic leukaemia (p.651), chronic myeloid leukaemia in blastic crisis (p.653), and neuroblastoma (p.674). It is also under investigation in lung cancer, particularly non-small cell lung cancer (p.668) and responses have been reported in advanced breast cancer (p.661).

Preparations

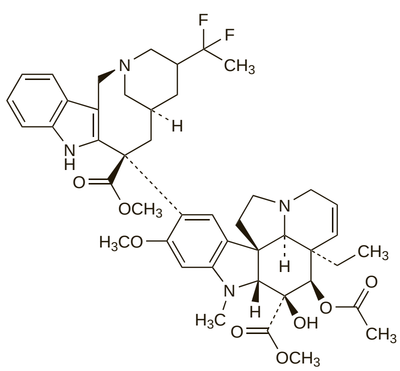
Vinflunine *(rINN)*

F-12158; F-13840; L-0070; Vinflunina; Vinfluninum. 4′-Deoxy-20′,20′-difluoro-8′-norvincaleukoblastine.

Винфлунин

$C_{45}H_{54}F_2N_4O_8$ = 816.9.

CAS — 162652-95-1 (vinflunine); 194468-36-5 (vinflunine tartrate).



Profile

Vinflunine is a vinca alkaloid derived from vinorelbine (p.789) that is under investigation for the treatment of bladder cancer and non-small cell lung cancer.

Vinorelbine Tartrate *(BANM, USAN, rINNM)*

5′-Nor-anhydrovinblastine Tartrate; Tartrato de vinorelbina; Vinorelbiinitartraatti; Vinorelbin Bitartrat; Vinorelbin-ditartarát; Vinorelbine Ditartrate; Vinorelbine, tartrate de; Vinorelbini Ditartras; Vinorelbini tartras; Vinorelbino tartratas; Vinorelbintartrat. 3′,4′-Didehydro-4′-deoxy-8′-norvincaleukoblastine ditartrate.

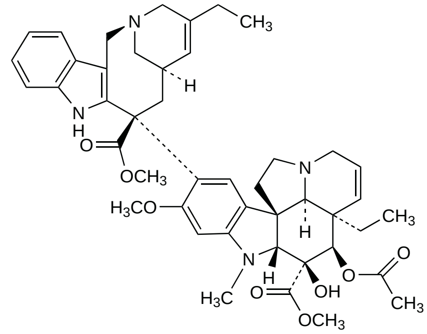
Винорелбина Тартрат

$C_{45}H_{54}N_4O_8,2C_4H_6O_6$ = 1079.1.

CAS — 71486-22-1 (vinorelbine); 125317-39-7 (vinorelbine tartrate).

ATC — L01CA04.

ATC Vet — QL01CA04.



(vinorelbine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Vinorelbine Tartrate). A white or almost white, hygroscopic powder. Freely soluble in water and in methyl alcohol; practically insoluble in hexane. A 1.4% solution in water has a pH of 3.3 to 3.8. Store under an inert gas at a temperature not exceeding −15°. Protect from light.

USP 31 (Vinorelbine Tartrate). A white to yellow or light brown amorphous powder. Freely soluble in water. pH of a 1% solution in water is between 3.3 and 3.8. Store at a temperature between −25° and −10° in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Vinblastine Sulfate, p.786. The main dose-limiting effect of vinorelbine is granulocytopenia. The nadir of the granulocyte count occurs 5 to 10 days after a dose, with recovery usually after a further 7 to 14 days. The drug should be stopped if moderate or severe neurotoxicity develops. Local pain and thrombophlebitis may be seen with repeated injection of vinorelbine. Gastrointestinal effects such as nausea and vomiting are common with the oral formulation.

Administration error. *Inadvertent intrathecal doses of vinca alkaloids result in ascending paralysis and death.* For reference to the successful treatment of inadvertent intrathecal dosage of vincristine, and UK recommendations on dilution of vinca alkaloids to avoid intrathecal use, see p.787.

Effects on the gastrointestinal tract. For reference to a report of vinorelbine possibly exacerbating ischaemic colitis in patients receiving docetaxel, see p.711.

Interactions

As for Vinblastine Sulfate, p.786.

Pharmacokinetics

As with the other vinca alkaloids, vinorelbine exhibits triphasic pharmacokinetics after intravenous injection, and has a terminal half-life of between about 28 and 44 hours. It is rapidly absorbed from the gastrointestinal tract with peak plasma concentrations achieved between 1.5 and 3 hours after oral doses. It is metabolised in the liver; deacetylvinorelbine has antineoplastic activity. Vinorelbine and its metabolites are excreted primarily in faeces via the bile but also in urine.

Uses and Administration

Vinorelbine is a semisynthetic derivative of vinblastine (p.786) with similar general properties. It is used in the treatment of advanced breast cancer and non-small cell lung cancers (see p.661 and p.668 respectively), and has been tried in other malignancies including lymphomas and tumours of ovary and prostate.

Vinorelbine is given as the tartrate but doses are calculated in terms of vinorelbine: vinorelbine tartrate 1.385 mg is equivalent to about 1 mg of vinorelbine. It may be given by intravenous injection over 5 to 10 minutes, as a solution containing the equivalent of vinorelbine 1.5 to 3 mg/mL in glucose 5% or sodium chloride 0.9% injection, directly or into a freely-running intravenous infusion. However, UK guidelines recommend that for patients over the age of 10 years, solutions of vinorelbine should generally be diluted to a volume of at least 20 mL to avoid inadvertent intrathecal use; higher concentrations can be used for children under 10 years of age. It may also be given by intravenous infusion over 20 to 30 minutes after dilution in 125 mL of glucose 5% or sodium chloride 0.9%.

The usual initial intravenous dose in the treatment of breast cancer or non-small cell lung cancer is the equivalent of vinorelbine 25 to 30 mg/m^2 weekly. In the UK, the manufacturers recommend that if the neutrophil count falls below 2000 cells/mm^3 subsequent doses should be delayed until recovery. In the USA it is suggested that subsequent doses should be halved if granulocyte counts fall to between 1000 and 1500 cells/mm^3; treatment should be interrupted if counts are below 1000 cells/mm^3 and stopped if granulocytopenia persists for more than 2 weeks (see also Bone-marrow Depression, p.639). Doses should also be reduced in hepatic impairment and in patients with massive liver metastases (but see also below).

In the treatment of non-small cell lung cancer, vinorelbine is also given orally at a dose of 60 mg/m^2 once weekly for 3 weeks. Subsequent doses may be increased to 80 mg/m^2, unless the neutrophil count falls below 500 cells/mm^3, or to between 500 and 1000 cells/mm^3 on two separate occasions, in which case the dose is kept at 60 mg/m^2 for the next 3 doses.

Administration in hepatic impairment. Clearance of vinorelbine was markedly reduced in patients with diffuse liver metastases and hence severely altered hepatic function: a 50% dose reduction was probably appropriate in such patients even if hyperbilirubinaemia was not marked.[1] However, reduced doses were not necessary in patients with moderate liver involvement in whom liver function, as measured by lidocaine metabolism, was not markedly reduced. Licensed product information in the UK suggests that the intravenous dose be reduced by one-third in patients with massive liver metastases (more than 75% of liver volume replaced by tumour cells).

In the USA, licensed information recommends that the intravenous dose of vinorelbine be reduced by 50% in patients with bilirubin values of 2.1 to 3 mg per 100 mL and by 75% in those with bilirubin greater than 3 mg per 100 mL.

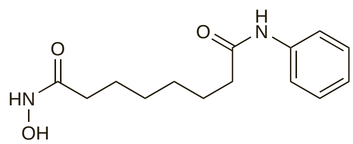
Vorinostat *(USAN, rINN)*

SAHA; Suberoylanilide Hydroxamic Acid; Vorinostatum. *N*-Hydroxy-*N′*-phenyl octanediamide.

Вориностат

$C_{14}H_{20}N_2O_3$ = 264.3.

CAS — 149647-78-9.



Adverse Effects, Treatment, and Precautions

For general discussions see Antineoplastics, p.635, p.639, and p.641.

The most common adverse effects of vorinostat are gastrointestinal disturbances, fatigue, chills, dry mouth and taste disorders. Thrombocytopenia and anaemia also occur commonly, and are dose-related; dose reductions may be necessary and in some instances, therapy may need to be stopped. Pulmonary embolism has occurred. Other adverse effects include muscle spasms, alopecia, dizziness, peripheral oedema, headache, pruritus, cough, upper respiratory-tract infection, and pyrexia. Hypokalaemia and hyperglycaemia have been reported, as has prolongation of the QT interval. Blood cell counts, electrolytes, glucose, and serum creatinine should be monitored every 2 weeks during the first 2 months of therapy and monthly thereafter. Baseline and periodic ECG monitoring should be performed.

Interactions

Severe thrombocytopenia and gastrointestinal bleeding have been reported when vorinostat has been given with other histone deacetylase inhibitors such as valproic acid; platelet counts should be monitored every 2 weeks for the first 2 months of therapy. Vorinostat may prolong prothrombin time and affect the INR in patients receiving coumarin anticoagulants.

Pharmacokinetics

After an oral dose of vorinostat with a high-fat meal, mean time to maximum plasma concentration was about 4 hours; this was reduced to 1.5 hours after fasting. Aside from this decrease in the rate of absorption, a high-fat meal also increased the extent of absorption. While these results were stated not to be clinically significant, licensed product information recommends that vorinostat be taken with food. Plasma protein binding is about 71%. Vorinostat is metabolised by glucuronidation and hydrolysis followed by oxidation; metabolites are pharmacologically inactive. Less than 1% of a dose is recovered in the urine as unchanged drug. The mean terminal half-life is about 2 hours for vorinostat.

◊ References.

1. Rubin EH, *et al.* A study to determine the effects of food and multiple dosing on the pharmacokinetics of vorinostat given orally to patients with advanced cancer. *Clin Cancer Res* 2006; **12:** 7039–45.

Uses and Administration

Vorinostat is a histone deacetylase inhibitor used for the treatment of cutaneous T-cell lymphoma (see Non-Hodgkin's Lymphomas, p.656). The recommended dose is 400 mg orally, given once daily with food. This may be reduced to 300 mg once daily, with a further reduction to 300 mg once daily for 5 consecutive days of each week, if needed. Treatment may be continued as long as there is no evidence of progressive disease or unacceptable toxicity.

Vorinostat is also under investigation for the treatment of multiple myeloma and mesothelioma.

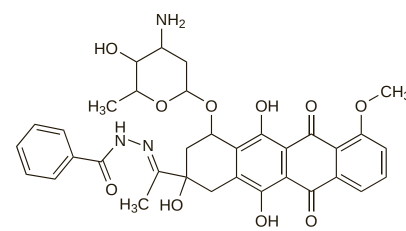
ATC — L01DB05.

ATC Vet — QL01DB05.



(zorubicin)

Profile

Zorubicin is an anthracycline antibiotic with antineoplastic actions similar to those of doxorubicin (see p.712). It has been used as the hydrochloride in the treatment of acute leukaemias.

Antiparkinsonian Drugs

The antiparkinsonian drugs described in this chapter can be broadly divided into 2 groups; the **dopaminergics**, drugs that are used to potentiate the actions of dopamine, and the **antimuscarinics**, drugs that are used to reduce excessive central cholinergic effects.

Dopamine is a key neurotransmitter in the CNS; in particular, striatal dopamine depletion is associated with the clinical condition of parkinsonism. Dopamine also inhibits prolactin release from the pituitary and is believed to be the prolactin-release inhibiting factor (PRIF or PIF); dopamine deficiency in the pituitary is associated with conditions characterised by hyperprolactinaemia. Accordingly, drugs that replenish central dopamine or that can act as stimulants of dopamine receptors (dopamine agonists), may alleviate the symptoms of parkinsonism (see below), hyperprolactinaemia (p.2079), and related disorders.

At least 5 subtypes of dopamine receptor are thought to exist: D_1 receptors appear to stimulate adenylate cyclase activity; D_2 receptors activate various systems and inhibit adenylate cyclase activity. D_3, D_4, and D_5 receptors have been less well studied but D_3 and D_4 are similar to D_2, forming the D_2-like group, whereas D_1 and D_5 form the D_1-like group. D_2 receptors have been implicated in the pathophysiology of parkinsonism and schizophrenia.

Dopaminergics, or drugs that enhance their actions, described in this chapter include:

- levodopa, which is converted by decarboxylation into dopamine in the body, and which, unlike dopamine itself, can penetrate the blood-brain barrier and supply a source of dopamine to the brain
- the peripheral dopa-decarboxylase inhibitors, benserazide and carbidopa, which have no dopaminergic action of their own but increase the availability of levodopa
- apomorphine, which is structurally related to dopamine and acts as a dopamine agonist
- the adamantanamine, amantadine, which may augment dopaminergic activity
- the ergot derivatives, bromocriptine, cabergoline, lisuride, and pergolide, which act as dopamine agonists
- various other non-ergot dopamine agonists, such as piribedil, pramipexole, ropinirole, rotigotine, talipexole, and terguride
- the specific monoamine oxidase type B inhibitors, rasagiline and selegiline, which enhance the action of dopamine and levodopa
- the catechol-*O*-methyltransferase inhibitors (COMT-inhibitors), entacapone and tolcapone, which enhance the action of levodopa

Antimuscarinic drugs are used in Parkinson's disease (idiopathic or primary parkinsonism) and, particularly, drug-induced parkinsonism. They act by reducing the excessive central cholinergic effects of dopamine deficiency. Antimuscarinics described in this chapter include the tertiary amines, such as benzatropine, orphenadrine, procyclidine, and trihexyphenidyl, which are the most commonly used in the treatment of parkinsonism.

Parkinsonism

The syndrome of parkinsonism is characterised by tremor, rigidity, akinesia or bradykinesia, and loss of postural reflexes, associated with reduced dopamine activity in the brain. It may be **classified** as follows:

- primary (idiopathic) parkinsonism, usually referred to as Parkinson's disease (formerly paralysis agitans)
- secondary (acquired) parkinsonism, including postencephalitic parkinsonism, drug-induced parkinsonism, and symptoms associated with manganese poisoning
- 'parkinsonism-plus' syndromes where parkinsonism is a feature of other degenerative diseases of the CNS, such as progressive supranuclear palsy and multiple system atrophy

'Arteriosclerotic parkinsonism' has been used to describe parkinsonism associated with cerebrovascular disease, although this may be confusing since vascular brain damage is not a cause of Parkinson's disease.

The term parkinsonism is often used for the idiopathic form, that is, Parkinson's disease. Parkinson's disease and postencephalitic parkinsonism have been attributed primarily to depletion of striatal dopamine in the basal ganglia as a result of the loss of neurones in the substantia nigra. Striatal dopamine deficiency results in loss of the normal functional balance between dopaminergic and cholinergic activity and the aim of treatment is to increase the former and/or decrease the latter.

The **cause** of *Parkinson's disease* is not established, although environmental and genetic factors are probably superimposed on a background of neuronal loss related to ageing. MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine), a contaminant of an illicitly produced pethidine analogue MPPP (1-methyl-4-phenyl-4-propionoxypiperidine), causes irreversible parkinsonism similar to Parkinson's disease. This effect appears to follow conversion by monoamine oxidase B to the neurotoxic methylphenylpyridinium ion which is selectively concentrated in dopaminergic neurones in the substantia nigra. It has been proposed that free radicals produced during normal metabolism of dopamine in the brain by monoamine oxidase B might be similarly neurotoxic to dopaminergic neurones in the substantia nigra (the oxidant stress hypothesis). This has led to concern that use of levodopa, by increasing the supply of dopamine, might therefore exacerbate neurodegeneration and hasten the progression of Parkinson's disease but compelling evidence of such an effect is lacking.

Drug-induced parkinsonism (see Extrapyramidal Disorders, p.971) can arise from depletion of presynaptic dopamine, as with reserpine and tetrabenazine, or from blockade of postsynaptic dopamine receptors in the striatum, as by antipsychotics and some antiemetics such as metoclopramide. It is generally reversible on drug withdrawal or dose reduction and may sometimes disappear gradually despite continuous drug therapy. Although the use of levodopa to overcome antipsychotic-induced blockade of dopamine receptors might appear rational, it has generally been reported to be ineffective or to increase psychiatric symptoms. Antimuscarinics may provide relief from the extrapyramidal symptoms that occur as adverse effects of antipsychotic therapy; however, they do not relieve the symptoms of tardive dyskinesia and should be withdrawn if it develops.

There is no cure for Parkinson's disease. Although the possibility of using drug therapy to slow neurodegeneration is being investigated, no drug so far has a proven neuroprotective effect. **Treatment** is palliative and symptomatic and consists mainly of drug therapy supplemented when necessary with physical treatment such as physiotherapy and speech therapy. Surgery is occasionally used and there is growing interest in the use of transplantation and in electrical devices for the control of tremor.

Drugs used in Parkinson's disease. Drug therapy consists largely of the use of dopaminergics or antimuscarinics in an attempt to restore the normal balance between dopaminergic and cholinergic activity. Dopaminergics may act by direct replacement of dopamine, by delaying the metabolism of endogenous dopamine, by stimulation of dopamine receptors directly, or by enhancement of release of endogenous dopamine. Drugs with differing actions are often used together to achieve optimum control of symptoms.

- *Levodopa* is the most effective symptomatic treatment. It is converted by decarboxylation into dopamine and, unlike dopamine, can penetrate the blood-brain barrier and supply a source of dopamine to the brain. Levodopa is usually given with a peripheral dopa-decarboxylase inhibitor such as *benserazide* or *carbidopa*. These drugs are unable to penetrate the blood-brain barrier and therefore prevent only extracerebral conversion of levodopa to dopamine. This allows effective concentrations of dopamine to be achieved in the brain with lower doses of levodopa and also reduces nausea and vomiting and other adverse effects associated with peripheral formation of dopamine.

  The majority of patients respond initially to levodopa and its use has improved the quality and duration of life. However, after 2 years or more, benefit is reduced as the disease progresses and late complications emerge. Apart from dyskinesias and psychiatric effects, a major problem with long-term levodopa treatment is the appearance of fluctuations in mobility, the two predominant forms being 'end-of-dose' deterioration ('wearing-off' effect) and the 'on-off' phenomenon (see Complications of Treatment, below). Thus, views differ as to the best time to start treatment and the dosage to use in order to limit the long-term complications.

  Catechol-*O*-methyltransferase (COMT) inhibitors, such as *entacapone* and *tolcapone*, are selective and reversible inhibitors of COMT, with mainly peripheral actions. They are given as adjunctive therapy to patients experiencing fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations; because of the risk of serious hepatotoxicity, tolcapone should be restricted to when other adjunctive therapy is ineffective or contra-indicated. When levodopa is used with a peripheral dopa-decarboxylase inhibitor, *O*-methylation becomes the predominant form of metabolism of levodopa; adding a peripheral COMT inhibitor can thus extend the duration and effect of levodopa in the brain, and allow lower and less frequent doses of levodopa. They therefore can help to stabilise patients, especially those experiencing 'end-of-dose' deterioration.
- *Rasagiline* and *selegiline* are selective inhibitors of monoamine oxidase type B, an enzyme involved in the metabolism of dopamine in the brain. When used with levodopa in severe parkinsonism they have a dose-sparing effect and are of value in patients experiencing fluctuations in mobility. Early treatment with selegiline may delay the need for levodopa and there has been much interest in the possibility that these drugs might have neuroprotective effects, but it is difficult to separate any putative effect on disease progression from symptomatic benefits, and at present there is insufficient evidence to show that any treatment can slow progression of the disease. Used alone, selegiline produces few adverse effects but when used with levodopa it can provoke or worsen dyskinesias or psychiatric symptoms and doubts have been expressed on the safety of long-term use.
- Dopamine agonists such as *bromocriptine, cabergoline, lisuride, pergolide, pramipexole,* and *ropinirole* act by direct stimulation of remaining postsynaptic dopamine receptors. Dopamine agonists are increasingly used in the early treatment of younger patients with parkinsonism in an attempt to delay therapy with levodopa (younger patients are at an increased risk of motor complications with levodopa). However, their efficacy often decreases after a few years. In older patients they may be reserved for adjunctive use when levodopa is no longer effective alone or cannot be tolerated. They are sometimes useful in reducing 'off' periods with levodopa and in ameliorating fluctuations in mobility in the later stages of the disease. *Apomorphine* is a potent dopamine agonist, but must be given parenterally and with an antiemetic. Although this restricts its use, it has a role in stabilising patients who suffer unpredictable 'on-off' effects. It is also used in the differential diagnosis of parkinsonism. Transdermal patches containing *rotigotine*, another dopamine agonist, are available for use as monotherapy in the treatment of early-stage Parkinson's disease and as an adjunct to levodopa therapy in some countries.
- *Antimuscarinics* are considered to have a weak antiparkinsonian effect compared with levodopa. They may reduce tremor but have little effect on bradykinesia. They may be of use alone or with other drugs in the initial treatment of patients with mild symptoms, especially when tremor is pronounced, or later as an adjunct to levodopa, such as in patients with refractory tremor or dystonias. Antimuscarinic adverse effects, particularly cognitive impairment, occur frequently and can limit their use. However, some antimuscarinic effects can ameliorate complications associated with Parkinson's disease; dry mouth may be an advantage in patients with sialor-

rhoea. There appear to be no important differences in the efficacy of antimuscarinics for Parkinson's disease but some patients may tolerate one drug better than another. Those commonly used for Parkinson's disease include *benzatropine, orphenadrine, procyclidine,* and *trihexyphenidyl*.

- *Amantadine* is a weak dopamine agonist with some antimuscarinic activity although its activity as an antagonist of *N*-methyl-D-aspartate may also have a beneficial effect in Parkinson's disease. It has mild antiparkinsonian effects compared with levodopa but is relatively free from adverse effects. It can improve bradykinesia as well as tremor and rigidity but only a small proportion of patients derive much benefit. It is used similarly to antimuscarinics in early disease when symptoms are mild, but tolerance to its effects can occur rapidly.

Choice and implementation of drug treatment. If symptoms are mild, drug therapy may not be required in the early stages of the disease. When symptoms become troublesome but are still relatively mild *amantadine* or an *antimuscarinic* may be started; antimuscarinics are useful when tremor predominates but are generally more suitable for younger patients and in drug-induced rather than idiopathic parkinsonism. Some have begun treatment with *selegiline* immediately, but there have been doubts over whether it has a neuroprotective effect, as postulated, and also over long-term safety. There is no consensus on when to start dopaminergic treatment or whether to begin with *levodopa* or a *dopamine agonist*. For most patients treatment with levodopa eventually becomes necessary, but many neurologists delay initial treatment with levodopa because of the increased risk of motor complications. New patients, especially younger patients, therefore often begin treatment with a dopamine agonist, with levodopa reserved for the elderly, the frail, or those with intercurrent illness or more severe symptoms.

When levodopa does become necessary, the usual practice is to start with small doses, together with a peripheral dopa-decarboxylase inhibitor, and increase slowly to a dose which reduces disability to an acceptable level. Variations in response and diminishing effectiveness over the years necessitate careful adjustment of the size and form of the dose and the dosage schedule.

Complications of treatment. Fluctuations in mobility have been reported in more than half of patients on levodopa after 5 years of therapy. They generally proceed through predictable **'end-of-dose'** deterioration to the **'on-off'** phenomenon with marked very sudden swings from mobility to immobility. The cause of the fluctuations is not known, but multiple factors including desensitisation of dopamine receptors, interference with the response to dopamine by other levodopa metabolites such as 3-*O*-methyldopa, fluctuating plasma concentrations, and erratic transport of levodopa from blood to the brain have been suggested. It appears that as the disease progresses the capacity of the nigrostriatal dopaminergic system to synthesise and store dopamine, and to act as a buffer in maintaining dopamine brain concentrations, declines. Dopamine concentrations therefore become more dependent on levodopa dosage and the pattern of response will come to reflect more closely the rise and fall in levodopa concentrations. Eventually the effect of various factors that produce even small changes in plasma concentrations of levodopa will progressively become more pronounced.

Approaches to the management of 'end-of-dose' fluctuations include more frequent but smaller doses and the use of modified-release preparations. Addition of selegiline or partial replacement of levodopa by a dopamine agonist with a more prolonged action may also be tried.

Various attempts have been made to overcome the 'on-off' phenomenon. Those speculating that long-term treatment results in altered dopamine receptor sensitivity have used controlled withdrawal of levodopa for short periods ('drug holidays') but it is a dangerous procedure of doubtful value and no longer recommended.

Others have linked the 'on-off' phenomenon to variable plasma concentrations although, since transfer of levodopa into the brain involves active transport mechanisms, concentrations in plasma may not necessarily reflect those in the brain. Continuous intraduodenal or intravenous infusion of levodopa has been shown to reduce fluctuations in mobility, which suggests that dopamine receptors are still sensitive, although this is not practical for day-to-day management (but see below). However, there is evidence that some patients may benefit from modified-release formulations of levodopa with a peripheral dopa-decarboxylase or COMT inhibitor. As levodopa competes with amino acids for uptake into the brain, attempts to lessen fluctuations in dopamine brain concentrations have included taking levodopa on an empty stomach and also delaying most of a day's protein consumption until the evening. Addition of entacapone, rasagiline, selegiline, or a dopamine agonist may also help to reduce 'on-off' phenomena. If fluctuations remain a problem subcutaneous apomorphine is often effective. In some countries a gel formulation of levodopa with carbidopa is available for continuous infusion by an ambulatory pump into the duodenum when other available combination therapy has not been satisfactory.

Other complications of treatment with levodopa can include **dyskinesia**, which may respond to dosage adjustment or partial replacement of levodopa with a dopamine agonist. Amantadine may also be considered, although evidence is lacking. Some patients with Parkinson's disease may experience **severe pain** and **dystonia**; measures to increase 'on' periods can help reduce or eliminate pain in most patients.

Patients with Parkinson's disease can suffer from a range of **psychiatric effects**, such as depression, dementia, sleep disturbances, and psychosis, due to the adverse effects of drug therapy and to disease progression. It has been recommended that if patients develop psychotic reactions, an attempt to adjust their antiparkinsonian drugs should be tried before resorting to the use of antipsychotics. Although classical antipsychotics are usually contra-indicated because they can exacerbate parkinsonism, the atypical antipsychotics clozapine and quetiapine may be used in treatment-resistant psychosis—see Disturbed Behaviour, p.954. The cholinesterase inhibitor rivastigmine is licensed in some countries for the symptomatic treatment of mild to moderately severe dementia in Parkinson's disease. **Excessive daytime sleepiness** and **sudden onset of sleep** have been reported with dopamine agonists and patients should be warned of the possible risks (see Effects on Mental Function, under Adverse Effects of Levodopa, p.805). **Fibrotic reactions** resulting in cardiovascular and pulmonary adverse effects have been reported with ergot derivatives and patients should be monitored (see Fibrosis, under Adverse Effects of Bromocriptine, p.799). **Nausea and vomiting** induced by dopaminergics may be minimised by introducing the drug gradually and giving the dose with food, but if this is ineffective or apomorphine is being used these effects can be controlled by the antiemetic domperidone. Domperidone does not readily cross the blood-brain barrier and therefore acts mainly as a peripheral dopamine antagonist. Tolerance to the nausea usually develops after a few weeks and domperidone may then be withdrawn.

ATC Vet — QN04BB01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Amantadine Hydrochloride). A white or almost white crystalline powder. It sublimes on heating. Freely soluble in water and in alcohol.

USP 31 (Amantadine Hydrochloride). A white or practically white crystalline powder. Soluble 1 in 2.5 of water, 1 in 5.1 of alcohol, 1 in 18 of chloroform, and 1 in 70 of macrogol 400. pH of a 20% solution in water is between 3.0 and 5.5.

Amantadine Sulfate *(pINNM)*

Amantadine, Sulfate d'; Amantadine Sulphate; Amantadini Sulfas; Sulfato de amantadina.

Амантадина Сульфат

$(C_{10}H_{17}N)_2,SO_4$ = 398.6.
CAS — 31377-23-8.
ATC — N04BB01.
ATC Vet — QN04BB01.

Adverse Effects

Most adverse effects associated with amantadine therapy appear to be dose-related and relatively mild; some resemble those of antimuscarinic drugs. They may be reversed by withdrawing therapy but many resolve despite continuation.

Livedo reticularis, sometimes associated with ankle oedema, is quite common in patients given very high doses of amantadine or with long-term therapy. CNS effects such as anxiety, inability to concentrate, dizziness, insomnia, nightmares, headache, and changes in mood may occur. Psychotic reactions, hallucinations, and confusion have been reported, especially in the elderly, patients with renal impairment or psychiatric disorders, and those also receiving antimuscarinics.

Other adverse effects reported have included orthostatic hypotension, palpitations, urinary retention, slurred speech, ataxia, lethargy, anorexia, nausea, vomiting, dry mouth, constipation, skin rash, diaphoresis, photosensitisation, and blurred vision. There have been isolated reports of congestive heart failure, leucopenia, neutropenia, dyskinesias, oculogyric episodes, and convulsions.

Effects on the cardiovascular system. Congestive heart failure has been reported with amantadine;[1] the patient had been receiving combined treatment with amantadine, levodopa, and orphenadrine for 4 years. Others have considered that while amantadine sometimes causes ankle oedema, an association between amantadine and heart failure is not proven.[2] Livedo reticularis, a mottled blue discoloration of the skin due to prominence of the normal pattern of venous drainage, has been reported[2] to occur in about 50% of all elderly patients given amantadine 100 to 300 mg daily for 2 to 6 weeks and was associated with oedema in 5 to 10%. Both livedo and oedema have usually been confined to the legs and may result from the catecholamine-releasing action of amantadine in certain vascular beds; the oedema was unlikely to be due to heart failure. Angina, dyspnoea, pulmonary congestion, or distension of neck veins has also been reported[2] in 4 of 89 parkinsonian patients treated with amantadine; only 2 of these 4 had had ankle oedema before heart failure developed. No patient had been seen in whom heart failure seemed due directly to amantadine.

2. Parkes JD, *et al.* Amantadine-induced heart-failure. *Lancet* 1977; **i:** 904.

Effects on electrolytes. For a report of a patient who developed hyponatraemia when given amantadine or levodopa, see Effects on Kidney Function under Levodopa, p.805.

Effects on the eyes. Superficial punctate keratitis and corneal abrasion with loss of visual acuity was seen in both eyes of a 64-year-old man about 3 weeks after starting treatment with amantadine 100 mg daily.[1] Symptoms resolved on stopping amantadine but recurred when re-treatment with amantadine was attempted. In another report,[2] a 14-year-old boy developed bilateral corneal oedema with visual loss associated with amantadine treatment. He had been taking amantadine 300 mg daily for several months with numerous other drugs; symptoms resolved when amantadine was stopped.

2. Hughes B, *et al.* Reversible amantadine-induced corneal edema in an adolescent. *Cornea* 2004; **23:** 823–4.

Effects on mental function. It has been suggested[1] that the ability of amantadine and memantine to cause psychotic disturbances in patients with Parkinson's disease might be related to their action as *N*-methyl-D-aspartate antagonists.

1. Riederer P, *et al.* Pharmacotoxic psychosis after memantine in Parkinson's disease. *Lancet* 1991; **338:** 1022–3.

Effects on the nervous system. Peripheral sensory motor neuropathy secondary to long-term (8 years) use of amantadine has been reported[1] in a 48-year-old woman with parkinsonism. Trophic skin ulcers, paraesthesias, and distal weakness resolved on stopping amantadine.

1. Shulman LM, *et al.* Amantadine-induced peripheral neuropathy. *Neurology* 1999; **53:** 1862–5.

Overdosage. A patient with postencephalitic parkinsonism who had taken an estimated 2.8 g of amantadine hydrochloride in a suicide attempt developed acute toxic psychosis with disorientation, visual hallucinations, and aggressive behaviour.[1] Convulsions did not occur, possibly because he had been receiving phenytoin, which was continued. The patient was treated with hydration and chlorpromazine and recovered in 4 days.

A 2-year-old child who had ingested 600 mg of amantadine hydrochloride developed symptoms of acute toxicity, including agitation and dystonic posturing, despite emesis with 'syrup of ipecac'.[2] She responded immediately to a trial of physostigmine 500 micrograms intravenously, repeated after 10 minutes. Her pupils remained moderately dilated until about 20 hours after the ingestion; thereafter she made a full recovery.

Cardiac arrest developed 4 hours after a 37-year-old woman ingested 2.5 g of amantadine hydrochloride and was treated successfully.[3] However, ventricular arrhythmias, including torsade de pointes, continued over the ensuing 48 hours and may have been exacerbated by use of isoprenaline and dopamine. The patient was subsequently stabilised with lidocaine by intravenous infusion, but died of respiratory failure 10 days after admission.

3. Sartori M, *et al*. Torsade de pointe: malignant cardiac arrhythmia induced by amantadine poisoning. *Am J Med* 1984; **77:** 388–91.

Precautions

Amantadine is usually contra-indicated in severe renal disease and in patients with a history of epilepsy or other seizure disorders, or gastric ulceration. It should also not be given to patients with untreated angle-closure glaucoma. Amantadine should be used with caution in patients with cardiovascular or liver disease, renal impairment, recurrent eczema, or psychiatric disorders. Suicide attempts, in some cases fatal, and suicidal ideation have been reported in patients taking amantadine. Care should be taken in all elderly patients, who may be more sensitive to antimuscarinic effects, and in whom renal clearance is likely to be reduced.

In common with other drugs having antimuscarinic properties amantadine may cause blurred vision or impair alertness; patients so affected should not drive or operate machinery.

Treatment with amantadine should not be stopped abruptly in parkinsonian patients since they may experience a sudden marked clinical deterioration. There have been isolated reports of a neuroleptic malignant-like syndrome associated with abrupt withdrawal of amantadine, especially in patients also receiving antipsychotics.

Antiviral resistance. See Influenza under Uses and Administration, below.

Breast feeding. Amantadine is distributed into breast milk and licensed product information states that adverse effects have occurred in infants being breast fed by mothers taking amantadine.

Pregnancy. Amantadine should not be used during pregnancy; embryotoxicity and teratogenicity have been reported in *rats* given high doses.[1]

A complex cardiovascular lesion occurred in an infant whose mother had taken amantadine hydrochloride 100 mg daily during the first 3 months of pregnancy.[1] In another case, tetralogy of Fallot and limb deformities were seen in the neonate of a mother who was given amantadine hydrochloride 100 mg daily for 7 days during the 4th and 6th weeks of gestation.[2] However, a report of the use of amantadine during 2 separate pregnancies by a woman with multiple sclerosis noted no abnormalities in either infant.[3]

2. Pandit PB, *et al.* Tibial hemimelia and tetralogy of Fallot associated with first trimester exposure to amantadine. *Reprod Toxicol* 1994; **8:** 89–92.
3. Levy M, *et al.* Fetal outcome following intrauterine amantadine exposure. *Reprod Toxicol* 1991; **5:** 79–81.

Renal impairment. Evidence of extremely limited excretion of amantadine was found in 12 patients who were either anephric or had negligible renal function after a single 100-mg dose of amantadine hydrochloride.[1] Only small amounts were removed by dialysis. It was suggested that amantadine should be given with caution to patients requiring maintenance haemodialysis; a single dose may provide adequate plasma concentrations for many days.[1]

Dosage regimens based on creatinine clearance[2] or fixed doses at extended intervals[3] have been published. However, both regimens have been criticised and a conservative approach to amantadine dosage in these patients recommended[4] (for the regimens in licensed product information, see Administration in Renal Impairment, below). The need for caution in using amantadine in patients with renal impairment is highlighted by a report of a patient with end-stage renal disease who progressed from delirium to coma after receiving amantadine 100 mg twice daily for 3 days.[5]

4. Aoki FY, Sitar DS. Clinical pharmacokinetics of amantadine hydrochloride. *Clin Pharmacokinet* 1988; **14:** 35–51.
5. Macchio GJ, *et al.* Amantadine-induced coma. *Arch Phys Med Rehabil* 1993; **74:** 1119–20.

Withdrawal. Neuroleptic malignant syndrome occurred in a patient being treated for heat stroke when all his medication, including antipsychotics and amantadine, was withdrawn.[1] It is suggested that dopamine agonists should not be stopped in patients with hyperpyrexia at risk from this syndrome. In another report,[2] a 14-year-old boy being treated with amantadine for influenza A encephalopathy developed neuroleptic malignant syndrome when the drug was stopped after 5 days; the patient improved when amantadine treatment was resumed. The authors recommended a gradual reduction in dosage when stopping amantadine therapy.

Acute delirium developed in 3 elderly patients with Parkinson's disease after gradual withdrawal of long-term amantadine therapy;[3] symptoms resolved when amantadine was restarted.

1. Simpson DM, Davis GC. Case report of neuroleptic malignant syndrome associated with withdrawal from amantadine. *Am J Psychiatry* 1984; **141:** 796–7.
2. Ito T, *et al.* Neuroleptic malignant syndrome following withdrawal of amantadine in a patient with influenza A encephalopathy. *Eur J Pediatr* 2001; **160:** 401.
3. Factor SA, *et al.* Acute delirium after withdrawal of amantadine in Parkinson's disease. *Neurology* 1998; **50:** 1456–8.

Interactions

Amantadine may enhance the adverse effects of antimuscarinics and the dose of these drugs should be reduced when used with amantadine; adverse effects of levodopa may also be exacerbated.

Licensed product information states that amantadine should be used with caution in patients receiving drugs that affect the CNS. The rate of excretion of amantadine may be reduced by drugs that raise urinary pH.

Antiarrhythmics. *Quinine* and *quinidine* have been reported to reduce the renal clearance of amantadine in healthy male, but not female, subjects.[1] Patients taking these drugs together should be observed for signs of amantadine toxicity.

1. Gaudry SE, *et al.* Gender and age as factors in the inhibition of renal clearance of amantadine by quinine and quinidine. *Clin Pharmacol Ther* 1993; **54:** 23–7.

Antimalarials. For the possible effects of the use of *quinine* and *quinidine* with amantadine, see Antiarrhythmics, above.

Diuretics. A patient with Parkinson's disease, previously stabilised on amantadine hydrochloride 300 mg daily, developed symptoms of amantadine toxicity, including ataxia, myoclonus, and confusion, 7 days after starting treatment with a preparation containing *triamterene* and *hydrochlorothiazide* (*Dyazide*).[1] It was postulated that the effect was due to reduction of the tubular secretion of amantadine.

1. Wilson TW, Rajput AH. Amantadine-Dyazide interaction. *Can Med Assoc J* 1983; **129:** 974–5.

MAOIs. Hypertension occurred about 48 hours after starting treatment with *phenelzine sulfate* in a patient already receiving amantadine.[1]

1. Jack RA, Daniel DG. Possible interaction between phenelzine and amantadine. *Arch Gen Psychiatry* 1984; **41:** 726.

Pharmacokinetics

Amantadine hydrochloride is well absorbed from the gastrointestinal tract; peak concentrations in the plasma appear within about 4 hours after oral doses. Plasma protein binding is reported to be about 67%, with a substantial amount bound to erythrocytes; the concentration is about 2.7 times higher in erythrocytes than in plasma. It is mainly excreted unchanged in the urine by glomerular filtration and tubular secretion although small amounts of an acetylated metabolite have also been detected in urine; the plasma elimination half-life is reported to be about 15 hours in patients with normal renal function but is significantly prolonged in the elderly and in patients with renal impairment. The rate of elimination may be increased by acidification of the urine. Amantadine crosses the placenta and the blood-brain barrier. It is also distributed into breast milk.

Uses and Administration

Amantadine is a weak dopamine agonist with some antimuscarinic activity; it is also an antagonist at *N*-methyl-D-aspartate receptors. Amantadine has mild antiparkinsonian activity and is used in the management of parkinsonism, mainly in early disease when symptoms are mild. It may improve bradykinesia, rigidity, and tremor but tolerance can develop.

Amantadine is also an antiviral that inhibits replication of influenza type A virus; it has very little or no activity against influenza type B virus. It is used prophylactically against infection with influenza type A virus and to ameliorate symptoms when given during the early stages of infection.

Amantadine has also been used in the management of herpes zoster.

Amantadine is usually given orally as the hydrochloride and the doses below are expressed in terms of this salt.

In **parkinsonism**, treatment is usually started with 100 mg daily, increasing to 100 mg twice daily after a week or more. Doses up to a maximum of 400 mg daily have occasionally been used. The lowest effective dose should be used in patients over 65 years of age because of the potential for reduced renal clearance in this age group. Withdrawal of amantadine treatment for parkinsonism should be gradual to avoid exacerbating the condition; UK licensed product information suggests decreasing the dose by half at weekly intervals.

The dose of amantadine in the UK for the treatment of **influenza A** is 100 mg daily, usually given for about 5 days. For the prophylaxis of influenza A the same dose is given for as long as protection from infection is required, which may be for about 6 weeks. If amantadine is being given with influenza vaccination then it is usually only given for up to 3 weeks after vaccination. Children aged 10 to 15 years may also be given 100 mg daily for the recommended period. A daily dose of less than 100 mg or 100 mg given at intervals greater than one day has been recommended for patients over 65 years of age.

Doses in the USA are higher than those in the UK: for the treatment of influenza A the daily dose is 200 mg daily as a single dose or in two divided doses, continued for 24 to 48 hours after the disappearance of symptoms. The same dose is given for the prophylaxis of influenza A for at least 10 days following exposure. If given with vaccination then amantadine should be taken for the next 2 to 4 weeks. The dose of amantadine should be reduced to 100 mg daily in patients aged 65 years and over, and in those who show intolerance to the higher dose. Children aged 1 to 9 years may be given 4.4 to 8.8 mg/kg daily to a maximum of 150 mg daily; older children may be given 100 mg twice daily.

In **herpes zoster**, treatment with 100 mg twice daily may be given for 14 days; if pain persists, treatment may be continued for a further 14 days.

The dosage of amantadine should be reduced in patients with renal impairment (see below).

Amantadine sulfate has been used similarly to the hydrochloride; it has been given by mouth or by intravenous infusion.

Administration. Amantadine sulfate has been used successfully in doses of up to 600 mg daily by intravenous infusion in the management of akinetic crisis in patients with Parkinson's disease.[1]

1. Gadoth N, *et al.* I.V. amantadine sulfate for extrapyramidal crisis. *Clin Pharm* 1985; **4:** 146.

Administration in renal impairment. The dose of amantadine should be reduced in patients with renal impairment by either reducing the total daily dose or by increasing the dosage interval in accordance with their creatinine clearance (CC).

In the UK the following doses are recommended:

- CC over 35 mL/min: 100 mg daily
- CC 15 to 35 mL/min: 100 mg every 2 to 3 days
- CC less than 15 mL/min: not recommended

In the USA the following doses are recommended:

- CC 30 to 50 mL/min: 200 mg on the first day followed by 100 mg daily thereafter
- CC 15 to 29 mL/min: 200 mg on the first day followed by 100 mg on alternate days
- CC less than 15 mL/min or those on haemodialysis: 200 mg every 7 days

See also under Precautions, above.

Extrapyramidal disorders. Amantadine has been used as an alternative to antimuscarinics[1] in the short-term management of *drug-induced extrapyramidal symptoms* (p.971). US licensed product information has recommended a usual dose of 200 mg daily in 2 divided doses increased up to 300 mg daily if necessary. However the development of tolerance has limited its usefulness. See also Parkinsonism, below.

Amantadine has been investigated in the management of *chorea* in patients with Huntington's disease.[2,3]

3. Heckmann JM, *et al.* IV amantadine improves chorea in Huntington's disease: an acute randomized, controlled study. *Neurology* 2004; **63:** 597–8.

Hepatitis C. Amantadine has been investigated[1-4] as an addition to interferon-based antiviral regimens in the treatment of chronic hepatitis C infection (p.851). A meta-analysis[1] concluded that it was of no value in treatment-naive patients or relapsers, but that triple therapy with amantadine, ribavirin, and interferon improved sustained responses in patients previously unresponsive to therapy.

Hiccup. Amantadine[1] has been reported to have produced beneficial results in patients with intractable hiccups (p.976).

1. Askenasy JJM, *et al.* Persistent hiccup cured by amantadine. *N Engl J Med* 1988; **318:** 711.

Influenza. Amantadine has been used similarly to rimantadine (p.904) in the prophylaxis and treatment of influenza A (p.859). In adults, the two drugs are equally effective, but amantadine is associated with more adverse effects;[1] further study on their safety and efficacy in children and the elderly is considered warranted.[2] Amantadine reduced the duration of influenza A symptoms when given in a dose of 200 mg daily within 48 hours of the onset of symptoms.[3] Vaccination is usually the method of choice for prophylaxis of influenza but amantadine has been used in addition to vaccination in certain individuals or when vaccination is contra-indicated. Although amantadine is licensed in the UK and USA for the prophylaxis and treatment of influenza A, its use for such purposes is not recommended.[4-6] Resistance to amantadine may occur rapidly.[7] For further information see Resistance, under Rimantadine, p.904.

Multiple sclerosis. Amantadine has been used to alleviate fatigue associated with multiple sclerosis (p.892). However, a systematic review[1] concluded that there was insufficient evidence to support its use in reducing fatigue in patients with multiple sclerosis; further large controlled studies are considered warranted.

1. Pucci E, *et al.* Amantadine for fatigue in multiple sclerosis. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2007 (accessed 29/05/08).

Neuroleptic malignant syndrome. Amantadine has been tried[1-3] in the treatment of the neuroleptic malignant syndrome (p.972).

3. Woo J, *et al.* Neuroleptic malignant syndrome successfully treated with amantadine. *Postgrad Med J* 1986; **62:** 809–10.

Parkinsonism. Amantadine's mechanism of action in parkinsonism (p.791) is unclear but may be due to its antimuscarinic activity and alterations in dopamine release and reuptake. It has also been suggested that amantadine's action as a non-competitive antagonist of *N*-methyl-D-aspartate may have a beneficial effect.[1,2] It has mild antiparkinsonian activity compared with levodopa but is relatively free from adverse effects. It can improve bradykinesia as well as tremor and rigidity and is used in a similar manner to antimuscarinics mainly in the treatment of patients with early Parkinson's disease when symptoms are mild. It may also be useful for dyskinesias in more advanced disease.[3] However, few patients obtain much benefit and tolerance to its effects can occur. Moreover, two systematic reviews[4,5] concluded that there was insufficient evidence from randomised controlled trials on the safety and efficacy of amantadine in the treatment of both Parkinson's disease and levodopa-induced dyskinesias in late disease.

Licensed product information suggests that the effectiveness of amantadine may be prolonged by withdrawing it for 3 to 4 weeks, continuing with existing antiparkinsonian therapy or starting low-dose levodopa treatment if clinically necessary in the meantime.

Apomorphine Hydrochloride *(BANM)*

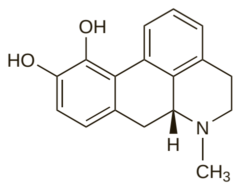
Apomorfiinihydrokloridi; Apomorfin Hidroklorür; Apomorfina, hidrocloruro de; Apomorfin-hidroklorid; Apomorfin-hydrochlorid hemihydrát; Apomorfinhydroklorid; Apomorfino hidrochloridas; Apomorfiny chlorowodorek; Apomorphine, chlorhydrate d'; Apomorphini hydrochloridum; Apomorphini Hydrochloridum Hemihydricum. 6aβ-Aporphine-10,11-diol hydrochloride hemihydrate; (*R*)-10,11-Dihydroxy-6a-aporphine hydrochloride hemihydrate; (6a*R*)-5,6,6a,7-Tetrahydro-6-methyl-4*H*-dibenzo[*de,g*]quinoline-10,11-diol hydrochloride hemihydrate.

$C_{17}H_{17}NO_2,HCl,{}^1\!/_2H_2O$ = 312.8.

CAS — 58-00-4 (apomorphine); 314-19-2 (anhydrous apomorphine hydrochloride); 41372-20-7 (apomorphine hydrochloride, hemihydrate).

ATC — G04BE07; N04BC07.

ATC Vet — QG04BE07; QN04BC07.



(apomorphine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Apomorphine Hydrochloride). White or faintly yellow to green-tinged greyish crystals or crystalline powder, the green tinge becoming more pronounced on exposure to air and light. Sparingly soluble in water and in alcohol. A 1% solution in water has a pH of 4.0 to 5.0. Store in airtight containers. Protect from light.

USP 31 (Apomorphine Hydrochloride). Odourless, minute white or greyish-white, glistening crystals or white powder. It gradually acquires a green colour on exposure to light and air. Soluble 1 in 50 of water and 1 in 20 of water at 80°; soluble 1 in 50 of alcohol; very slightly soluble in ether and in chloroform. Its solutions are neutral to litmus. Store in airtight containers. Protect from light.

Stability. Aqueous solutions of apomorphine hydrochloride decompose on storage and should not be used if they turn green or brown or contain a precipitate.

Adverse Effects

Treatment of parkinsonism. Apomorphine usually produces nausea and vomiting when given in therapeutic doses but these effects can be controlled by treatment with domperidone or trimethobenzamide. Transient sedation can be common during the first few weeks of treatment. Increased salivation and perspiration have also been reported. Apomorphine can produce neuropsychiatric disturbances including increasing cognitive impairment, personality changes, confusion, and hallucinations. Signs of CNS stimulation including euphoria, lightheadedness, restlessness, tremor, tachycardia, and tachypnoea occur less frequently. Apomorphine may induce dyskinesias during 'on' periods in patients with parkinsonism and these may be severe enough to require stopping therapy; postural instability and falls may also be a problem. Transient orthostatic hypotension may also occur infrequently. Eosinophilia has occurred rarely. The use of apomorphine with levodopa may cause haemolytic anaemia and treatment may need to be stopped if this cannot be satisfactorily controlled through dosage adjustment. Induration, nodule formation, and panniculitis, sometimes leading to ulceration, often develops at the site of subcutaneous injection.

Management of erectile dysfunction. The most common adverse effects have been nausea, headache, and dizziness. Other effects reported include yawning, rhinitis, pharyngitis, somnolence, infection, pain, increased cough, flushing, taste disturbances, and sweating. Fainting and syncope (vasovagal syndrome) have also occurred.

Overdosage with apomorphine can produce persistent vomiting, respiratory depression, bradycardia, hypotension, and coma; death may occur.

Akinesia. A 60-year-old man who was being investigated for parkinsonian symptoms became totally immobile and mute 15 minutes after receiving apomorphine 4 mg subcutaneously.[1] He remained conscious but was drowsy and sweating. Similar profound akinesia occurred on rechallenge with 2- and 6-mg doses. A diagnosis of probable nigrostriatal degeneration was made as the patient had previously shown no improvement with levodopa, but the mechanism of the idiosyncratic reaction to apomorphine was unclear.

1. Jenkins JR, Pearce JMS. Paradoxical akinetic response to apomorphine in parkinsonism. *J Neurol Neurosurg Psychiatry* 1992; **55:** 414–15.

Effects on the heart. A 67-year-old man developed palpitations with cold perspiration and chest pain, in addition to asthenia, salivation, nausea and vomiting, 5 minutes after receiving 3 mg apomorphine subcutaneously. An ECG showed atrial fibrillation with a ventricular frequency of 140 beats/minute.[1]

1. Stocchi F, *et al.* Transient atrial fibrillation after subcutaneous apomorphine bolus. *Mov Disord* 1996; **11:** 584–5.

Effects on mental function. Severe confusion, hallucinations, and acute psychosis were reported in 4 of 6 parkinsonian patients given subcutaneous apomorphine.[1] Three of the 4 had previously experienced mental disturbances while receiving lisuride. However, other studies failed to note effects on mental function in parkinsonian patients given apomorphine[2,3] and it has been suggested that the risk of psychosis in patients with no history of confusion or hallucinations is low.[3] UK licensed product information notes that apomorphine has been reported to exacerbate neuropsychiatric disturbances in patients with parkinsonism.

1. Ruggieri S, *et al.* Side-effects of subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; **i:** 566.
2. Stibe CMH, *et al.* Subcutaneous apomorphine in parkinsonian on-off oscillations. *Lancet* 1988; **i:** 403–6.
3. Poewe W, *et al.* Side-effects of subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; **i:** 1084–5.

Hypersensitivity. Allergic reactions including contact dermatitis, severe rhinitis, and respiratory distress have been reported in 2 workers who came into contact with apomorphine powder.[1] Contact allergy has also been reported in a patient who developed a swollen nose and lips after intranasal use of apomorphine.[2] Skin testing in all these cases[1,2] gave a positive reaction to apomorphine. Biopsy of subcutaneous nodules, which develop at the site of injection in most patients using apomorphine subcutaneously, has not been able to clarify what type of reaction was responsible for the development of panniculitis.[3] Although the nodules may slowly resolve the sites are often unsuitable for reuse as absorption from them is unpredictable; concern has been expressed that this may limit long-term use of apomorphine.[3]

1. Dahlquist I. Allergic reactions to apomorphine. *Contact Dermatitis* 1977; **3:** 349–50.
2. van Laar T, *et al.* Nasolabiale allergische reactie op intranasale toediening van apomorfine bij de ziekte van Parkinson. *Ned Tijdschr Geneeskd* 1992; **136** (suppl 47): 26–7.
3. Acland KM, *et al.* Panniculitis in association with apomorphine infusion. *Br J Dermatol* 1998; **138:** 480–2.

Oedema. Severe reversible oedema of the lower limbs developed in a patient receiving subcutaneous apomorphine.[1] Oedema recurred when apomorphine was reintroduced, but to a lesser extent.

1. Vermersch P. Severe oedema after subcutaneous apomorphine in Parkinson's disease. *Lancet* 1989; **ii:** 802.

Stomatitis. Stomatitis, severe enough to warrant stopping treatment, occurred in 4 of 8 patients after 2 to 6 months of therapy with sublingual apomorphine.[1]

1. Montastruc JL, *et al.* Sublingual apomorphine in Parkinson's disease: a clinical and pharmacokinetic study. *Clin Neuropharmacol* 1991; **14:** 432–7.

Treatment of Adverse Effects

In the UK, domperidone is usually given to control nausea and vomiting when apomorphine is used in the management of Parkinson's disease; pretreatment with domperidone for at least 2 days is advised before starting treatment with apomorphine. Usually domperidone can be withdrawn gradually over several weeks or longer although some patients may need to continue treatment indefinitely. In the USA, trimethobenzamide hydrochloride is used similarly, beginning 3 days before starting apomorphine treatment.

In overdosage an opioid antagonist such as naloxone has been given to treat excessive vomiting, and CNS and respiratory depression.

◊ References.

Precautions

Apomorphine should not be given to patients with respiratory or CNS depression, hypersensitivity to opioids, neuropsychiatric problems, or dementia. It should be used with caution in patients prone to nausea and vomiting or when vomiting is likely to pose a risk. Apomorphine should also be used with care in patients with pulmonary, cardiovascular, or endocrine disease or with renal or hepatic impairment. Extra care is needed when starting treatment in elderly or debilitated patients and in those with a history of orthostatic hypotension. Patients who experience dizziness, lightheadedness, or syncope should not drive or operate machinery.

Treatment of parkinsonism. Apomorphine is not suitable for use in patients who have an 'on' response to levodopa marred by severe dyskinesia, hypotonia, or psychiatric effects; it should also not be used in those with hepatic impairment. Periodic monitoring of hepatic, renal, haematopoietic, and cardiovascular function has been advised and the *BNF* recommends that patients receiving apomorphine with levodopa should be screened for haemolytic anaemia on starting treatment and then every 6 months. Patients who develop anaemia, or those who have continuing confusion or hallucinations during treatment with apomorphine require observation and dosage adjustment under specialist supervision; treatment may need to be stopped. Excessive daytime sleepiness and sudden onset of sleep may also occur with apomorphine and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Local subcutaneous reactions can sometimes be reduced by using sodium chloride 0.9% to dilute injection solutions, by rotating injection sites, and possibly by use of ultrasound in areas of nodularity and induration.

Management of erectile dysfunction. UK licensed product information has warned that drugs for erectile dysfunction should be used with caution in patients with anatomical penile deformity.

Interactions

Apomorphine should be used with caution in patients receiving antihypertensives or organic nitrates as it may potentiate their hypotensive effects. Enhanced hypotensive effects may also occur when alcohol is given with apomorphine. The therapeutic effects of apomorphine may be antagonised by antipsychotics and other drugs that act as CNS dopamine inhibitors. The effect of apomorphine is possibly enhanced by entacapone and memantine.

Antiemetics. *Domperidone* (in the UK) and *trimethobenzamide* (in the USA) are used with apomorphine to control nausea and vomiting when it is prescribed for the management of parkinsonism. However, whether other antiemetics may safely be used is less clear. US licensed product information contra-indicates the use of *ondansetron* and related 5-HT_3 antagonists with apomorphine, on the grounds that profound hypotension and loss of consciousness has been reported in patients given this combination. However, UK licensed product information makes no mention of such a contra-indication, and licensed information for lower-dose products used in the management of erectile dysfunction notes that on the basis of interaction studies, ondansetron hydrochloride or *prochlorperazine maleate* may safely be given to patients receiving apomorphine for this indication.

Pharmacokinetics

Apomorphine is well absorbed after subcutaneous injection but undergoes extensive first-pass hepatic metabolism when given by mouth and oral bioavailability is low. However, it is readily absorbed after sublingual doses and peak plasma concentrations are achieved in about 40 to 60 minutes; bioavailability is reported to be about 17 to 18% compared with subcutaneous injection. Apomorphine is about 90% bound to plasma proteins, mainly to albumin.

Apomorphine is extensively metabolised in the liver, primarily by conjugation with glucuronic acid or sulfate; the major metabolite is apomorphine sulfate. It is also demethylated to produce norapomorphine. Most of a dose is excreted in urine, mainly as metabolites.

Uses and Administration

Apomorphine is a morphine derivative with structural similarities to dopamine. It is a potent dopamine D_1- and D_2-receptor agonist used in the management of parkinsonism, especially in the control of the 'on-off' effect. It has also been used in the management of erectile dysfunction. Apomorphine is given as the hydrochloride and doses are expressed in terms of this salt. The regimen for parkinsonism given below applies to the UK preparation and doses are give subcutaneously; a similar preparation is available in the USA although the licensed maximum single and daily doses are less than those in the UK.

The optimal dose of apomorphine in the management of 'off' periods in **parkinsonism** should be established individually under specialist care. At least 2 days of pretreatment with the antiemetic domperidone is advised before starting apomorphine. After withholding antiparkinsonian therapy overnight to provoke an 'off' period, a test dose of 1 mg is given initially, followed by a second dose of 2 mg after 30 minutes, if necessary. Subsequent incremental increases should then be given at intervals of at least 40 minutes, as necessary, to determine the lowest dose producing a satisfactory motor response. Once the patient's normal antiparkinsonian therapy is re-established, the effective dose of apomorphine hydrochloride is given at the first signs of an 'off' period.

The dose and frequency are further adjusted according to response; patients typically require 3 to 30 mg daily in divided doses but individual injections should not be greater than 10 mg. Patients who require more than 10 injections daily or those whose overall control of symptoms remains unsatisfactory with intermittent injections may benefit from continuous subcutaneous infusion. The infusion is started at a rate of 1 mg/hour and this may be increased in steps of up to 0.5 mg/hour at intervals of not less than 4 hours to a maximum rate of 4 mg/hour. It is advised that infusions should only be given during waking hours and that the infusion site should be changed every 12 hours; 24-hour infusions are not advised unless there are severe night-time symptoms. Patients usually need to supplement the infusion with intermittent bolus injections but the recommended maximum total daily dose given by infusion and/or injection is 100 mg.

In the management of **erectile dysfunction** the usual initial dose has been 2 mg taken sublingually about 20 minutes before sexual activity. A dose of 3 mg was used on subsequent occasions if necessary with a minimum of 8 hours between doses. Reduced dosage is needed in patients with renal impairment (see below).

Apomorphine stimulates the chemoreceptor trigger zone in the brain and can produce emesis within a few minutes of a dose. However, the use of apomorphine for the induction of emesis in poisoning is considered dangerous owing to the risk of inducing protracted vomiting and shock, and is not recommended.

Administration in renal impairment. In the management of erectile dysfunction, the maximum dose of apomorphine hydrochloride has been limited to 2 mg sublingually in patients with severe renal impairment.

Erectile dysfunction. Apomorphine is among a wide range of drugs that has been used in the management of erectile dysfunction[1-5] (p.2179) with some beneficial results. It is usually given sublingually although it has also been given subcutaneously.[3] Inhaled apomorphine is also under investigation.

DIAGNOSIS. Test doses of subcutaneous apomorphine have been used in the differential diagnosis of parkinsonian syndromes,[1-4] to distinguish forms responsive to dopaminergics from other parkinsonian syndromes such as Wilson's disease, corticobasal degeneration, and diffuse Lewy-body dementia. Oral challenge with levodopa is still the best test of dopaminergic responsiveness[5,6] but apomorphine has proved of value in re-assessing patients who have become less responsive to levodopa.[1,4]

Parkinsonism. ***TREATMENT.*** Although apomorphine has produced benefit in Parkinson's disease (p.791) when given orally, the high doses required to overcome extensive first-pass hepatic metabolism (up to 1.4 g daily in one study[1]), were associated with uraemia. The use of apomorphine in Parkinson's disease has therefore been limited by the need for parenteral dosage. The current main use of apomorphine in Parkinson's disease is for the stabilisation of patients with 'on-off' fluctuations unresponsive to other dopamine agonists. It is usually given subcutaneously either by injection or infusion but a review[2] of the use of apomorphine in Parkinson's disease also discussed studies of rectal, sublingual, and intranasal use. Inhaled apomorphine is also under investigation.

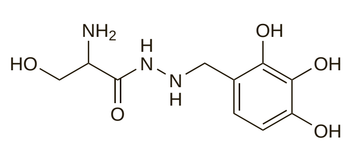
Benserazide *(BAN, USAN, rINN)*

Benseratsidi; Benserazid; Benserazida; Bensérazide; Benserazidum; Ro-4-4602. DL-Serine 2-(2,3,4-trihydroxybenzyl)hydrazide; 2-Amino-3-hydroxy-2′-(2,3,4-trihydroxybenzyl)propionohydrazide.

Бенсеразид

$C_{10}H_{15}N_3O_5$ = 257.2.

CAS — 322-35-0.



Benserazide Hydrochloride *(BANM, rINNM)*

Benseratsidihydrokloridi; Bensérazide, chlorhydrate de; Benserazid-hydrochlorid; Benserazidhydroklorid; Benserazidi hydrochloridum; Benserazido hidrochloridas; Benszerazid-hidroklorid; Hidrocloruro de benserazida; Serazide Hydrochloride.

Бенсеразида Гидрохлорид

$C_{10}H_{15}N_3O_5$,HCl = 293.7.

CAS — 14919-77-8; 14046-64-1.

NOTE. Compounded preparations of benserazide hydrochloride may be represented by the following names:

- Co-beneldopa *(BAN)*—benserazide 1 part and levodopa 4 parts (w/w).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Benserazide Hydrochloride). A white or yellowish-white or orange-white crystalline powder. It shows polymorphism. Freely soluble in water; very slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 1% solution in water has a pH of 4.0 to 5.0. Protect from light.

Solubility. Benserazide is unstable in a neutral, alkaline, or strongly acidic medium.[1]

1. Schwartz DE, Brandt R. Pharmacokinetic and metabolic studies of the decarboxylase inhibitor benserazide in animals and man. *Arzneimittelforschung* 1978; **28:** 302–7.

Adverse Effects and Precautions

◊ Early reports[1] noted developmental abnormalities of the *rat* skeleton, but others found no evidence of any disorder involving bone metabolism in man.[2] Nevertheless licensed product information recommends that benserazide should not be given to patients under 25 years of age, nor to pregnant women or to women of child-bearing potential in the absence of adequate contraception.

1. Theiss E, Schärer K. Toxicity of L-dopa and a decarboxylase inhibitor in animal experiments. In: de Ajuriaguerra J, Gauthier G, eds. *Monoamines Noyaux Gris Centraux et Syndrome de Parkinson*. Geneva: Georg, 1971: 497–504.
2. Ziegler WH, *et al.* Toxicity of L-dopa and a dopa decarboxylase inhibitor in humans. In: de Ajuriaguerra J, Gauthier G, eds. *Monoamines Noyaux Gris Centraux et Syndrome de Parkinson*. Geneva: Georg, 1971: 505–16.

Pharmacokinetics

◊ Pharmacokinetic and metabolic studies[1,2] in *animals* and man have shown that, after oral doses in parkinsonian patients, benserazide was rapidly absorbed to the extent of about 58%; giving it with levodopa tended to increase this slightly. Benserazide was rapidly excreted in the urine in the form of metabolites, mostly within the first 6 hours; 85% of urinary excretion had occurred within 12 hours. It is mainly metabolised in the gut and appears to protect levodopa against decarboxylation primarily in the gut, but also in the rest of the organism, mainly by way of its metabolite trihydroxybenzylhydrazine. Benserazide did not cross the blood-brain barrier in *rats*.

1. Schwartz DE, *et al.* Pharmacokinetics of the decarboxylase benserazide in man: its tissue distribution in the rat. *Eur J Clin Pharmacol* 1974; **7:** 39–45.
2. Schwartz DE, Brandt R. Pharmacokinetic and metabolic studies of the decarboxylase inhibitor benserazide in animals and man. *Arzneimittelforschung* 1978; **28:** 302–7.

Uses and Administration

Benserazide hydrochloride is a peripheral dopa-decarboxylase inhibitor with actions similar to those of carbidopa (p.803) and is used similarly as an adjunct to levodopa in the treatment of parkinsonism (p.791). For details of dosage, see Levodopa, p.808.

Benzatropine Mesilate *(BANM, rINNM)*

Benzatropine, Mésilate de; Benzatropine Methanesulfonate; Benzatropini Mesilas; Benztropine Mesylate; Mesilato de benzatropina. (1*R*,3*r*,5*S*)-3-Benzhydryloxytropane methanesulphonate.

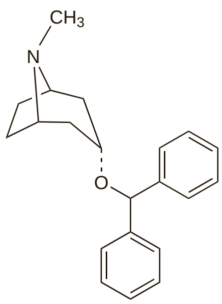
Бензатропина Мезилат

$C_{21}H_{25}NO,CH_4O_3S = 403.5.$

CAS — 86-13-5 (benzatropine); 132-17-2 (benzatropine mesilate).

ATC — N04AC01.

ATC Vet — QN04AC01.



(benzatropine)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Benzatropine Mesilate). A white, odourless or almost odourless, crystalline powder. Very soluble in water; freely soluble in alcohol; practically insoluble in ether.

USP 31 (Benztropine Mesylate). A white, slightly hygroscopic, crystalline powder. Very soluble in water; freely soluble in alcohol; very slightly soluble in ether. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Drowsiness may be severe in some patients and patients so affected should not drive or operate machinery. Mental disturbances and excitement may occur with large doses or in susceptible patients.

Abuse. For mention of abuse of benzatropine see under Trihexyphenidyl Hydrochloride, p.820.

Effects on the heart. Paradoxical sinus bradycardia in a patient with depression and psychotic symptoms was attributed to benzatropine since it persisted despite modification to other treatment and resolved only when benzatropine was withdrawn.[1]

1. Voinov H, *et al.* Sinus bradycardia related to the use of benztropine mesylate. *Am J Psychiatry* 1992; **149:** 711.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Antidepressants. A report[1] of 5 patients who developed delirium while taking an antipsychotic, an *SSRI,* and benzatropine suggested that there might be an interaction between SSRIs and benzatropine.

1. Roth A, *et al.* Delirium associated with the combination of a neuroleptic, an SSRI, and benztropine. *J Clin Psychiatry* 1994; **55:** 492–5.

Antipsychotics. Fatal heat stroke after exposure to an ambient temperature of over 29° has been reported[1,2] in patients receiving benzatropine with antipsychotics. Paralytic ileus, sometimes fatal, has also been seen in patients taking benzatropine with antipsychotics.[3]

1. Stadnyk AN, Glezos JD. Drug-induced heat stroke. *Can Med Assoc J* 1983; **128:** 957–9.
2. Tyndel F, Labonté R. Drug-facilitated heat stroke. *Can Med Assoc J* 1983; **129:** 680.
3. Wade LC, Ellenor GL. Combination mesoridazine- and benztropine mesylate-induced paralytic ileus: two case reports. *Drug Intell Clin Pharm* 1980; **14:** 17–22.

Uses and Administration

Benzatropine mesilate is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820); it also has antihistaminic properties.

Benzatropine is used for the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias (see under Uses and Administration of Levodopa, p.809).

Benzatropine mesilate is given orally or, if necessary, by intramuscular or intravenous injection.

In idiopathic **parkinsonism** benzatropine mesilate is usually given orally in an initial daily dose of 0.5 to 1 mg at bedtime. Its actions are cumulative, and may not be manifest for several days after beginning therapy. Patients with post-encephalitic parkinsonism often tolerate an initial daily dose of 2 mg. The dose may be gradually increased by 500 micrograms every 5 to 6 days to a maximum of 6 mg daily until the optimum dose is reached. Maintenance therapy may be given as a single daily dose at bedtime or in divided doses 2 to 4 times daily.

In the management of **drug-induced extrapyramidal symptoms** doses of 1 to 4 mg once or twice daily have been given orally or parenterally. Therapy may be withdrawn after 1 to 2 weeks to assess whether it is still necessary.

In an emergency, benzatropine mesilate may be injected intramuscularly or intravenously in a dose of 1 to 2 mg; intramuscular injection is reported to produce an effect as quickly as intravenous dosage so the latter is rarely necessary.

For management of **dystonias in children**, the *BNFC* suggests that in an emergency, single doses of 20 to 100 micrograms/kg (maximum of 2 mg) may be given by intravenous or intramuscular injection to children aged 3 to 12 years, and 1 to 2 mg to those aged 12 to 18 years.

Benzatropine has also been given as the hydrochloride.

CAS — 7085-45-2.

ATC — N04AA02.

ATC Vet — QN04AA02.

Pharmacopoeias. *US* includes Biperiden Lactate Injection.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

Parenteral use may be followed by slight transient hypotension.

Abuse. Abuse of biperiden has been reported in psychiatric patients.[1]

1. Pullen GP, *et al.* Anticholinergic drug abuse: a common problem? *BMJ* 1984; **289:** 612–13.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Pharmacokinetics

Biperiden is readily absorbed from the gastrointestinal tract, but bioavailability is only about 30% suggesting that it undergoes extensive first-pass metabolism. Biperiden has an elimination half-life of about 20 hours.

◊ References.

1. Hollmann M, *et al.* Biperiden effects and plasma levels in volunteers. *Eur J Clin Pharmacol* 1984; **27:** 619–21.
2. Grimaldi R, *et al.* Pharmacokinetic and pharmacodynamic studies following the intravenous and oral administration of the antiparkinsonian drug biperiden to normal subjects. *Eur J Clin Pharmacol* 1986; **29:** 735–7.

Uses and Administration

Biperiden is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820) but with more potent antinicotinic properties.

Biperiden is used in the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias.

Biperiden is given orally as the hydrochloride and by injection as the lactate; doses are expressed in terms of the relevant salt. The initial oral dose for **Parkinson's disease** is 2 mg of the hydrochloride three or four times daily increased according to response to a maximum of 16 mg daily. The dose for **drug-induced extrapyramidal symptoms** is 2 mg of the hydrochloride orally one to three times daily; alternatively, 2 mg of biperiden lactate may be given by intramuscular or slow intravenous injection and repeated every 30 minutes if needed up to a maximum of 4 doses in 24 hours.

Preparations

USP 31: Biperiden Hydrochloride Tablets; Biperiden Lactate Injection.

Bornaprine Hydrochloride *(BANM, rINNM)*

Bornaprin Hidroklorür; Bornaprine, Chlorhydrate de; Bornaprini Hydrochloridum; Hidrocloruro de bornaprina. 3-Diethylaminopropyl 2-phenylbicyclo[2.2.1]heptane-2-carboxylate hydrochloride.

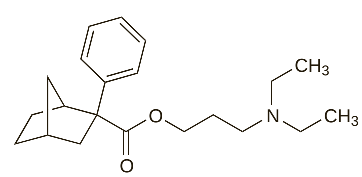
Борнаприна Гидрохлорид

$C_{21}H_{31}NO_2,HCl = 365.9.$

CAS — 20448-86-6 (bornaprine); 26908-91-8 (bornaprine hydrochloride).

ATC — N04AA11.

ATC Vet — QN04AA11.



(bornaprine)

Profile

Bornaprine hydrochloride is a quaternary ammonium antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820). It is used in the symptomatic treatment of **parkinsonism** (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias; it is claimed to be mainly effective against tremor. Bornaprine hydrochloride is given orally in initial doses of 2 mg daily gradually increased to 6 to 12 mg daily according to response. It is also used in the treatment of **hyperhidrosis** (p.1580) in a dose of 4 to 8 mg daily.

Bromocriptine Mesilate *(BANM, rINNM)*

Bromocriptine, mésilate de; Bromocriptine Mesylate *(USAN)*; Bromocriptine Methanesulphonate; Bromocriptini mesilas; Bromocryptine Mesylate; 2-Bromo-α-ergocryptine Mesylate; 2-Bromoergocryptine Monomethanesulfonate; Bromokriptiinimesilaatti; Bromokriptin Mesilat; Bromokriptinmesilat; Bromokriptin-mesylát; Brómokriptin-mezilát; Bromokriptino mesilatas; CB-154 (bromocriptine); Mesilato de bromocriptina. (5′S)-2-Bromo-12′-hydroxy-2′-(1-methylethyl)-5′-(2-methylpropyl)-ergotaman-3′,6′,18-trione methanesulphonate.

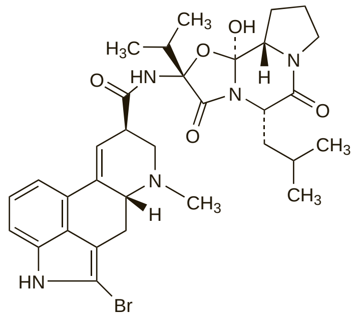
Бромокриптина Мезилат

$C_{32}H_{40}BrN_5O_5,CH_4O_3S$ = 750.7.

CAS — 25614-03-3 (bromocriptine); 22260-51-1 (bromocriptine mesilate).

ATC — G02CB01; N04BC01.

ATC Vet — QG02CB01; QN04BC01.



(bromocriptine)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Bromocriptine Mesilate). A white or slightly coloured fine crystalline powder. Practically insoluble in water; soluble in alcohol; sparingly soluble in dichloromethane; freely soluble in methyl alcohol. A 1% solution in a mixture of 2 parts methyl alcohol to 8 of water has a pH of 3.1 to 3.8. Store in airtight containers at a temperature not exceeding −15°. Protect from light.

USP 31 (Bromocriptine Mesylate). A white or slightly coloured fine crystalline powder; odourless or having a weak characteristic odour. Store in airtight containers at a temperature not exceeding 8°. Protect from light.

Adverse Effects

Nausea is the most common adverse effect at the beginning of treatment with bromocriptine, but vomiting, dizziness, and orthostatic hypotension may also occur. Syncope has followed initial doses.

Adverse effects are generally dose-related and may therefore be more frequent with the higher doses that have been used in the treatment of parkinsonism and acromegaly. Reduction of the dosage, followed in a few days by a more gradual increase, may alleviate many adverse effects. Nausea may be reduced by taking bromocriptine with food; domperidone may also be given at least 1 hour before bromocriptine, for the first few days of therapy.

Bromocriptine and similar drugs are vasoconstrictors; Raynaud's syndrome or digital vasospasm, induced by cold, and leg cramps have been reported. Other cardiovascular effects have included erythromelalgia, prolonged severe hypotension, arrhythmias, and exacerbation of angina. Very rarely hypertension, myocardial infarction, seizures or stroke (both sometimes preceded by severe headache or visual disturbances), and psychiatric disorders have been reported in postpartum women given bromocriptine.

The use of ergot derivatives such as bromocriptine has been associated with retroperitoneal fibrosis, pleural thickening and effusions, and pericarditis and pericardial effusions.

Other adverse effects reported include headache, nasal congestion, drowsiness, dry mouth, constipation, diarrhoea, and altered liver-function tests. Dyskinesias and psychomotor excitation have occurred in patients suffering from parkinsonism. Gastrointestinal bleeding has been reported in acromegalic patients. Psychosis, with hallucinations, delusions, and confusion, occurs particularly when high doses are used to treat parkinsonism, but has also been reported with low doses. A neuroleptic malignant-like syndrome associated with abrupt withdrawal of bromocriptine has been reported very rarely.

Incidence of adverse effects. In 27 published studies of the treatment of Parkinson's disease, 217 of the 790 patients given bromocriptine had adverse effects.[1] Mental changes were noted in 90 patients, dyskinesia in 20, orthostatic hypotension in 40, and gastrointestinal effects in 40. The fewest adverse effects (9%) occurred with low-dose bromocriptine, more occurred with high-dose bromocriptine (27%) or with low-dose bromocriptine with levodopa (26%), and the most occurred with high-dose bromocriptine and levodopa (32%). However, those on high doses had more advanced disease and might have been more susceptible to mental changes and dyskinesias.

An analysis by the manufacturer of published reports on patients treated with bromocriptine for 1 to 10 years concluded that in general, adverse effects noted were no different from those associated with short-term treatment.[2]

1. Lieberman AN, Goldstein M. Bromocriptine in Parkinson disease. *Pharmacol Rev* 1985; **37:** 217–27.
2. Weil C. The safety of bromocriptine in long-term use: a review of the literature. *Curr Med Res Opin* 1986; **10:** 25–51.

Effects on the blood. Severe leucopenia and mild thrombocytopenia developed in a 23-year-old woman after treatment with bromocriptine 7.5 to 10 mg daily for about 3 months.[1]

1. Giampietro O, *et al*. Severe leukopenia and mild thrombocytopenia after chronic bromocriptine (CB-154) administration. *Am J Med Sci* 1981; **281:** 169–72.

Effects on the cardiovascular system. An early review noted that asymptomatic **hypotension** occurred in many subjects given bromocriptine.[1] However, faintness and dizziness, sometimes accompanied by *nausea* and *vomiting*, were common at the start of treatment with bromocriptine and these symptoms rather than an anaphylactic type of reaction were likely to account for the collapse that occurred in a few sensitive patients. Two of 53 patients with Parkinson's disease fainted after an initial dose of 1.25 or 2.5 mg, but the exact incidence of shock-like syndromes was difficult to assess; the manufacturers had stated that 22 of over 10 000 subjects given bromocriptine had had hypotension and collapse, mainly at the start of treatment.

- All patients starting treatment should be warned of the possibility of fainting. The initial dose should not exceed 1.25 to 2.5 mg and should be taken with food and in bed.

If fainting does occur recovery is usually rapid and spontaneous. Tolerance to adverse effects such as hypotension and nausea may develop rapidly.

Hypertension, seizures, stroke, and *myocardial infarction* have been associated with bromocriptine therapy, notably in postpartum women.[2-4] A study involving 1813 women suggested that the risk of **postpartum hypertension** was increased in women who had pregnancy-induced hypertension and that this risk was further increased in those who took bromocriptine for suppression of lactation.[5] A case-controlled study[6] involving 43 of the women who had had postpartum seizures while taking bromocriptine found that while the initial risk of seizures appeared to be lower in patients taking bromocriptine there was a small positive association with seizures occurring more than 72 hours after delivery.

- Although a causal relationship between the use of bromocriptine and these adverse effects in postpartum women has not been established, licensed product information recommends that bromocriptine should not be used post partum or in the puerperium in women with high blood pressure, coronary artery disease or other severe cardiovascular disorders, or symptoms or history of serious psychiatric disorders.
- It is also recommended that when bromocriptine is used in postpartum women blood pressure should be carefully monitored, especially during the first few days and if hypertension, unremitting headache, or signs of CNS toxicity develop, treatment should be discontinued immediately.

Severe dilated **cardiomyopathy** has been reported in a patient being treated with bromocriptine for microprolactinoma.[7]

For details of **fibrotic reactions** resulting in cardiovascular adverse effects, see Fibrosis, below.

2. Damase-Michel C, *et al*. Hyponatraemia in a patient treated with bromocriptine. *Drug Invest* 1993; **5:** 285–7.

Effects on the eyes. Blurred vision and diplopia has been reported in several patients receiving bromocriptine.[1] Reversible myopia also developed in a patient with hyperprolactinaemia given bromocriptine.[2]

Licensed product information states that visual field impairment associated with macroprolactinoma usually resolves with bromocriptine treatment. However, in a patient with progressive visual loss due to compression of the optic chiasm by a large pituitary tumour, bromocriptine caused total visual loss within hours.[3] Vision slowly returned to normal when the patient was placed in the supine position; the most likely cause of the visual loss was thought to be orthostatic hypotension with resultant decrease in perfusion pressure to the visual system. Monitoring of visual fields is recommended in patients with macroprolactinoma.

Bromocriptine has been reported to cause visual cortical disturbances.[4] In some cases blurred vision and transient cortical blindness have preceded seizures and strokes.

Effects on mental function. High doses of bromocriptine are well known to cause **psychotic reactions** in patients with parkinsonism.[1] However, mania has also been associated with the use of bromocriptine post partum[2,3] and it has been stated that psychological symptoms can occur with doses of only 2.5 to 5 mg daily.[4] It was also noted that, unlike the relatively mild and transient symptoms associated with levodopa, bromocriptine produces a severe psychosis in which the patient is violent and aggressive, suffering from intense delusions which are often hostile and violent; complete withdrawal of bromocriptine may still leave a residue of severe psychotic illness persisting for 1 to 3 weeks. Psychosis associated with low doses of bromocriptine has often occurred in patients with a history of psychotic illness or disturbances in behaviour and mood prior to treatment.[5-7] Drug-related psychotic reactions have also been reported in patients with no psychiatric history;[8,9] of 600 patients given bromocriptine or lisuride for the treatment of acromegaly or prolactinoma, 8 developed symptoms including anxiety, depression, auditory hallucinations, delusions, hyperactivity, disinhibition, euphoria, and insomnia and 4 had received doses only previously associated with psychosis in susceptible patients.[9]

Effects on the nervous system. CSF rhinorrhoea has been associated with bromocriptine therapy in patients with invasive prolactinomas. A report of 3 cases found 13 further cases on reviewing the literature;[1] of these, 7 patients had developed rhinorrhoea within 1 month of starting bromocriptine and 2 cases developed after 12 months.

Effects on the respiratory system. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including bromocriptine, see Fibrosis, below.

Effects on sexual function. For reports of the effects of dopamine agonists on sexual function, see under Levodopa, p.806.

Effects on the urinary tract. Constant dribbling urinary incontinence developed in a woman receiving bromocriptine 2.5 mg daily for a recurrent pituitary growth; symptoms resolved on stopping the drug and recurred on rechallenge.[1] Bromocriptine has been shown to have two effects, one on the bladder outflow tract and one on the detrusor muscle, that could predispose to urinary incontinence.[2]

Fibrosis. Fibrosis has been associated with the long-term use of ergot derivatives (see under Methysergide, p.623). Fibrotic reactions such as cardiac valvulopathy and pleuropulmonary effusion have been reported with bromocriptine, cabergoline, lisuride, and pergolide therapy in patients with Parkinson's disease.

Constrictive pericarditis[1] was reported in 2 patients who had received *bromocriptine* for 2 and 4 years, respectively; the latter still had slight pleural effusion 13 months after the drug was stopped. Valvular heart disease[2] developed in another patient who had received bromocriptine for 5 years; symptoms resolved 6 months after stopping the drug. Interstitial lung disease, with dyspnoea, chest pain, cough, and pulmonary fibrosis was reported[3] in a patient after use of relatively high doses of bromocriptine (62 mg daily). Respiratory symptoms largely resolved on withdrawal of the drug, although functional respiratory changes and moderate dyspnoea persisted after 6 months. A review of the literature revealed several other reports of pleuropulmonary fibrosis associated with relatively high doses of bromocriptine which occurred after between 15 days and up to 3 years of treatment. Although the incidence of this effect did not seem to be high, similar cases have continued to be reported.[4-6] In June 2008 the EMEA recommended that for long-term use in conditions such as Parkinson's disease, the maximum dose should be 30 mg daily.[7]

A patient developed pleuropulmonary disease 16 months after starting treatment with *cabergoline*;[8] he had previously received bromocriptine for 10 years and had had a normal chest X-ray at the time of transfer to cabergoline treatment. In another report, 2 cases of pleural effusion/pulmonary fibrosis, occurring after 10 to 11 months of treatment, were described.[9] One patient had modest pretreatment lung alterations attributed to previous bromocriptine therapy. Withdrawal was associated with improvement in both cases. Congestive heart failure secondary to constrictive pericarditis, and severe pleuropulmonary fibrosis that resulted in dyspnoea, persistent in one case,[10] have also been reported in 2 patients receiving long-term cabergoline.[10,11] Another patient developed cardiac valvulopathy after taking cabergoline for a total of 20 months;[12] her dosage was 4 mg daily for the last 7 months. Cardiac symptoms slowly improved on withdrawal of the drug, although some evidence of valvular defects was still present 23 months later. Valvular heart disease has also been reported in a 74-year-old man after 4 months of therapy with cabergoline [dosage not stated].[13] By December 2005, 86 cases of suspected adverse reactions to cabergoline had been reported to the Australian Drug Reactions Advisory Committee (ADRAC),[14] of which 15 described pleural or pulmonary fibrosis/effusion, or pneumonitis; time to onset ranged from a few days to over 3 years with a median of 4 months. There had been no reports of fibrotic complications associated with low-dose cabergoline in the treatment of lactation suppression and hyperprolactinaemia. The UK MHRA considers the risk of cardiac valvulopathy to be high and UK labelling for cabergoline has been amended accordingly (see p.802) with the EMEA in June 2008 recommending a maximum dose of 3 mg daily.[7]

A woman developed bilateral pleural effusions after taking *lisuride* 4 mg daily for about 17 months.[8] Her condition improved on stopping lisuride.

The UK CSM[15] reported in 2003 that *pergolide* had been associated with cases of cardiac valvulopathy; since 1989, valvulopathy had been reported in fewer than 5 in 100 000 patients. The CSM also referred to a published case series[16] which reported on 3 patients with severe tricuspid regurgitation after long-term pergolide treatment. The authors of this case series and the CSM both considered that, based on the available evidence, there was a potential association between pergolide and cardiac valvulopathy. Subsequently, the FDA[17] stated that, up to the end of 2002, it was aware of 15 cases of valvular heart disease with pergolide treatment; this figure included the 3 cases reported in the above series and 4 cases from the UK. A later study[18] that examined 78 patients taking pergolide for Parkinson's disease found evidence of restrictive valvular heart disease in 15 of 52 (29%) patients taking doses less than 5 mg daily and in 11 of 26 (42%) receiving doses of 5 mg or more daily. Pulmonary fibrosis and retroperitoneal fibrosis have also been associated with pergolide treatment;[19-21] in most cases, symptoms improved when the drug was stopped. Duration of exposure to pergolide ranged from 6 months[20] to 11 years.[21]

In April 2002 the CSM[22] calculated crude reporting rates of fibrotic reactions associated with the ergot derivative dopamine agonists (bromocriptine, cabergoline, lisuride, and pergolide), based on data submitted to its Yellow Card scheme and estimated drug exposure. Pergolide was found to be associated with a higher reporting rate of fibrotic reactions compared with the other ergot derivatives; however, this result needed further investigation to see if it reflected a true increase in risk or was due to factors such as reporting biases. There is some evidence that the incidence of reactions to pergolide are dose-related, and doses are restricted in many countries (see p.812) and in June 2008 the EMEA recommended a maximum dose of 3 mg daily.[7] Pergolide was withdrawn from the market in the USA and Canada. It is recommended that baseline investigations such as erythrocyte sedimentation rate, urea and electrolyte concentrations, and a chest x-ray should be performed before starting treatment with this class of drugs.

Hypersensitivity. An allergic reaction developed in a 26-year-old woman being treated with bromocriptine for a prolactin-secreting microadenoma.[1] The patient reacted similarly to lisuride and treatment was continued with quinagolide.

1. Merola B, *et al.* Allergy to ergot-derived dopamine agonists. *Lancet* 1992; **339:** 620.

Oedema. Oedema poorly responsive to diuretics has been reported[1] in a patient given bromocriptine as part of treatment for prolactinoma. The oedema improved on substitution of pergolide but worsened with higher doses. Oedema resolved when treatment was changed to quinagolide. The reaction was considered to be idiosyncratic since enquiries by the author of the report had revealed only one similar case. In a subsequent report[2] a patient with Parkinson's disease who had been receiving bromocriptine for 5 years developed marked lower leg oedema, and subsequently cough, dyspnoea, and chest pain associated with an exudative pleural effusion; there was no evidence of fibrosis. Both oedema and effusion had largely resolved within 4 weeks of stopping bromocriptine.

2. Messiaen T, *et al.* Épanchement pleural et importants œdèmes des membres inférieurs induits par la bromocriptine. *Rev Med Interne* 1996; **17:** 680–3.

Overdosage. The most striking symptom in two children aged 2 and 2½ years who accidentally ingested an estimated 25 and 7.5 mg of bromocriptine, respectively, was lethargy with altered mental status.[1] The first child vomited and became sleepy. On admission he was markedly lethargic, but combative when disturbed, and also had hypotension, shallow breathing, dilated pupils, and hyperreflexic lower extremities. Nasogastric lavage was promptly performed, and activated charcoal and then magnesium citrate given. Blood pressure and ECG were monitored, and glucose and sodium chloride solution infused. The other child vomited, became lethargic, and had dilated pupils. Ipecacuanha was given, and activated charcoal followed by magnesium citrate given by nasogastric tube. Both children recovered completely.

1. Vermund SH, *et al.* Accidental bromocriptine ingestion in childhood. *J Pediatr* 1984; **105:** 838–40.

Withdrawal syndromes. Transient galactorrhoea and hyperprolactinaemia occurred in a young woman after withdrawal of bromocriptine therapy for Parkinson's disease.[1] It was suggested the effects were due to a rebound phenomenon. For discussion of a syndrome resembling neuroleptic malignant syndrome that has developed on withdrawal of bromocriptine and other antiparkinsonian drugs, see under Levodopa, p.806.

1. Pentland B, Sawers JSA. Galactorrhoea after withdrawal of bromocriptine. *BMJ* 1980; **281:** 716.

Precautions

Patients with hyperprolactinaemia should be investigated for the possibility of a pituitary tumour before treatment with bromocriptine. Malignancy must be excluded in patients with cyclical benign breast disorders such as mastalgia. Annual gynaecological examinations (or every 6 months for postmenopausal women) are recommended. Treatment of women with hyperprolactinaemic amenorrhoea results in ovulation; patients not wishing to conceive should be advised to use contraceptive measures although oral contraceptives should be avoided because they may increase prolactin levels. Acromegalic patients should be checked for symptoms of peptic ulceration before therapy and should immediately report symptoms of gastrointestinal discomfort during therapy.

In general, bromocriptine should be given with caution to patients with cardiovascular disease, Raynaud's syndrome, or a history of psychosis. It is contra-indicated in patients with hypersensitivity to bromocriptine or other ergot alkaloids, and in those with uncontrolled hypertension.

Bromocriptine is contra-indicated in the toxaemia of pregnancy. It should also not be used postpartum or in the puerperium in women with hypertension, coronary artery disease, or symptoms or a history of serious psychiatric disorders. When used, blood pressure should be monitored carefully, especially during the first few days in postpartum women. Particular caution is necessary in patients who are receiving or who have recently received drugs that can alter blood pressure; use with ergot alkaloids during the puerperium is not recommended. Treatment in postpartum women should be stopped immediately if hypertension, unremitting headache, or signs of CNS toxicity develop.

Hypotensive reactions may be disturbing in some patients during the first few days of treatment and those who drive or operate machinery should be warned of the possibility of dizziness and fainting during this period. Excessive daytime sleepiness and sudden onset of sleep may also occur with bromocriptine and other dopaminergic agonists, and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring. A reduction in dosage or withdrawal of the drug may be appropriate. Because of the risk of fibrosis bromocriptine is contra-indicated in patients with pre-existing valve problems.

Patients on long-term, high-dose therapy should be monitored for signs of progressive fibrotic disorders such as retroperitoneal fibrosis and bromocriptine withdrawn if fibrotic changes are diagnosed or suspected. It is recommended that baseline investigations such as erythrocyte sedimentation rate, urea and electrolyte concentrations, and a chest x-ray should be performed before starting treatment with bromocriptine. Periodic monitoring of cardiovascular, haematopoietic, hepatic, and renal function is also recommended. Monitoring of visual fields is recommended in patients with macroprolactinoma.

Breast feeding. The American Academy of Pediatrics[1] considers that bromocriptine should be given with caution to breast-feeding mothers, since it suppresses lactation and may be hazardous to the mother.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 16/02/06)

Porphyria. Bromocriptine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Pregnancy. Details of various surveys of the effect of the use of bromocriptine during pregnancy have been published by the manufacturer.[1,2] The first survey was based on spontaneous reporting of all pregnancies between 1973 and 1980 in women who had taken bromocriptine after conception.[1] Information was obtained on 1410 pregnancies in 1335 women, the majority of whom had been treated for hyperprolactinaemic conditions, while in 256 pregnancies pituitary tumours and acromegaly were the primary diagnosis. Bromocriptine was generally taken at some time in the first 8 weeks after conception, the mean duration of treatment being 21 days. In 4 patients bromocriptine was not prescribed until late in pregnancy and in 9 with acromegaly and pituitary microadenoma it was taken continuously throughout gestation. There were 157 (11.1%) spontaneous abortions, 12 (0.9%) extrauterine pregnancies, 2 patients with 3 hydatidiform moles (0.2%), and an incidence of twin pregnancies of 1.8%. Major congenital abnormalities were detected in 12 (1%) infants at birth and minor abnormalities in 31 (2.5%). A second survey,[2] which consisted of formal monitoring of the use of bromocriptine at 33 clinics between 1979 and 1980, collected data on a further 743 pregnancies in 668 women and had similar findings. The incidence rates reported in these surveys were comparable with those quoted for normal populations and the data indicate that the use of bromocriptine in the treatment of women with infertility is not associated with an increased risk of abortion, multiple pregnancy, or congenital abnormalities. Furthermore, follow-up, for up to 9 years, of 546 children exposed to bromocriptine *in utero* found no evidence that bromocriptine had any adverse effect on postnatal development.[2] Nevertheless, since the risk of abortion is not increased by interruption of treatment, licensed drug information recommends that bromocriptine therapy be stopped as soon as pregnancy is confirmed unless there is a definite indication for its continuation.

Interactions

Dopamine antagonists such as the phenothiazines, butyrophenones, thioxanthenes, and metoclopramide (but see below) might be expected to reduce the prolactin-lowering and the antiparkinsonian effects of bromocriptine and domperidone might reduce its prolactin-lowering effect. Memantine may enhance the effects of bromocriptine. Stimulants of gastrointestinal motility such as macrolide antibacterials or octreotide can increase the bioavailability of bromocriptine.

Alcohol. Alcohol intolerance was noted in 5 of 73 patients receiving bromocriptine 10 to 60 mg daily for the treatment of acromegaly.[1] Two patients who had gastrointestinal adverse effects while taking low doses of bromocriptine had a marked reduction in their symptoms and were able to tolerate higher doses when they refrained completely from alcohol.[2]

1. Wass JAH, *et al.* Long-term treatment of acromegaly with bromocriptine. *BMJ* 1977; **1:** 875–8.
2. Ayres J, Maisey MN. Alcohol increases bromocriptine's side effects. *N Engl J Med* 1980; **302:** 806.

Antibacterials. Drowsiness, dystonia, choreoathetoid dyskinesias, and visual hallucinations occurred when *josamycin* was given to a patient receiving bromocriptine.[1]

The systemic bioavailability of a single oral dose of bromocriptine 5 mg was markedly increased in 5 healthy subjects after treatment with *erythromycin estolate* 250 mg four times daily for 4 days;[2] clearance of bromocriptine was decreased and peak plasma concentrations of bromocriptine were more than 4 times higher than when given alone.

2. Nelson MV, *et al.* Pharmacokinetic evaluation of erythromycin and caffeine administered with bromocriptine. *Clin Pharmacol Ther* 1990; **47:** 694–7.

Antifungals. The response to bromocriptine was blocked in a patient who was also receiving *griseofulvin.*[1]

1. Schwinn G, *et al.* Metabolic and clinical studies on patients with acromegaly treated with bromocriptine over 22 months. *Eur J Clin Invest* 1977; **7:** 101–7.

Antipsychotics. Serum concentrations of prolactin rose and visual fields deteriorated when *thioridazine* was given to a 40-year-old man receiving bromocriptine therapy for a large prolactinoma.[1]

For a discussion of the effect of bromocriptine on patients receiving antipsychotics, see Antiparkinsonian Drugs under Chlorpromazine on p.974.

1. Robbins RJ, *et al.* Interactions between thioridazine and bromocriptine in a patient with a prolactin-secreting pituitary adenoma. *Am J Med* 1984; **76:** 921–3.

Metoclopramide. As noted in Interactions, above, there are theoretical reasons to suppose that dopamine antagonists such as metoclopramide might reduce the effects of bromocriptine. However, an early study[1] in 10 patients with Parkinson's disease given single doses of bromocriptine 12.5 to 100 mg found that pretreatment with metoclopramide 60 mg had no consistent effect upon plasma concentrations of bromocriptine or growth hormone and no consistent effect upon clinical response.

1. Price P, *et al.* Plasma bromocriptine levels, clinical and growth hormone responses in parkinsonism. *Br J Clin Pharmacol* 1978; **6:** 303–9.

Sympathomimetics. There have been isolated reports[1,2] of severe hypertension, with headache and life-threatening complications, in patients taking bromocriptine with *isometheptene mucate* or *phenylpropanolamine*.

1. Kulig K, *et al.* Bromocriptine-associated headache: possible life-threatening sympathomimetic interaction. *Obstet Gynecol* 1991; **78:** 941–3.
2. Chan JCN, *et al.* Postpartum hypertension, bromocriptine and phenylpropanolamine. *Drug Invest* 1994; **8:** 254–6.

Pharmacokinetics

Bromocriptine is rapidly absorbed from the gastrointestinal tract and peak plasma concentrations are achieved within 1 to 3 hours after oral doses. However, only about 30% of an oral dose is absorbed and, owing to extensive first-pass metabolism, the bioavailability is only about 6%. It has been reported to be 90 to 96% bound to serum albumin *in vitro*. It is metabolised in the liver, mainly by hydrolysis to lysergic acid and peptides. The elimination of bromocriptine is biphasic; half-lives of about 4 to 4.5 hours and 15 hours, respectively have been reported for the 2 phases. It is excreted mainly in faeces via the bile, with small amounts in urine.

◊ In a study involving 10 patients with Parkinson's disease, single oral doses of bromocriptine 12.5, 25, 50, and 100 mg resulted in very variable peak plasma concentrations ranging from 1.3 to 5.3, 1.4 to 3.5, 2.6 to 19.7, and 6.5 to 24.6 nanograms/mL, respectively, 30 to 210 minutes (mean 102 minutes) after dosage.[1] After 4 hours plasma concentrations were about 75% of the peak values. Clinical improvement was evident within 30 to 90 minutes of a dose with peak effect at about 130 minutes and in most patients improvement persisted throughout the 4-hour study period. Peak clinical response, peak fall in blood pressure, and peak rise in plasma concentrations of growth hormone occurred about 30, 60, and 70 minutes, respectively after peak plasma-bromocriptine concentrations but there was no significant relationship between them. However, there was a significant relationship between plasma concentrations and concurrent changes in clinical response compared with pretreatment scores. Dyskinesias occurred within 90 to 180 minutes of dosage in 5 of 10 patients.

Bromocriptine is well absorbed from standard oral tablets placed in the vagina and plasma concentrations sufficient to lower plasma prolactin concentrations have been achieved using this route.[2,3]

Uses and Administration

Bromocriptine, an ergot derivative (p.2010), is a dopamine D_2-agonist. It inhibits the secretion of prolactin (p.2017) from the anterior pituitary and is used in the treatment of prolactinoma and endocrinological disorders associated with hyperprolactinaemia, including amenorrhoea, galactorrhoea, hypogonadism, and infertility in both men and women. Bromocriptine is also used to suppress puerperal lactation for medical reasons; it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support. Growth hormone secretion may be suppressed by bromocriptine in some patients with acromegaly. Because of its dopaminergic activity bromocriptine is also used in the management of Parkinson's disease.

Bromocriptine is usually given orally as the mesilate; doses are expressed in terms of the base. Bromocriptine mesilate 2.87 mg is equivalent to about 2.5 mg of bromocriptine. Oral doses should be taken with food. Bromocriptine mesilate has also been given intramuscularly as a depot injection for disorders associated with hyperprolactinaemia.

For the **prevention of puerperal lactation** bromocriptine 2.5 mg is given on the day of delivery followed by 2.5 mg twice daily for 14 days. The risk of hypotension and, more rarely, hypertension must be borne in mind and it has been recommended that bromocriptine should not be given until at least 4 hours after delivery. For the **suppression of established lactation** it is given in a dose of 2.5 mg daily for 2 to 3 days subsequently increased to 2.5 mg twice daily for 14 days.

For the treatment of other conditions (see below) the dose of bromocriptine is usually increased gradually. In the UK, typically, an initial dose of 1 to 1.25 mg at night is given, increased to 2 to 2.5 mg at night after 2 to 3 days, and subsequently increased by 1 mg every 2 to 3 days to a dose of 2.5 mg twice daily, or more if necessary. In the USA, a usual starting dose is 1.25 to 2.5 mg daily increased by 2.5 mg every 2 to 7 days.

In the **treatment of hypogonadism and galactorrhoea syndromes and infertility** bromocriptine is introduced gradually as described above. Most patients with hyperprolactinaemia respond to 7.5 mg daily but up to 30 mg daily may be required. Infertile patients without raised serum concentrations of prolactin are usually given 2.5 mg twice daily. In patients known to have **prolactinomas** the dose is also introduced gradually as described above and may then be increased further by 2.5 mg every 2 to 3 days to a dose of 5 mg every 6 hours but occasionally patients may require up to 30 mg daily. Although unlicensed in the UK and USA, bromocriptine is used in some countries for **cyclical benign breast and menstrual disorders**. In benign breast disease bromocriptine is introduced gradually up to a daily dosage of 5 to 7.5 mg if necessary. In the treatment of premenstrual symptoms therapy should begin on day 14 of the cycle and introduced gradually up to a usual dosage of 2.5 mg twice daily until menstruation begins.

Bromocriptine may be used as an adjunct to surgery and radiotherapy to reduce plasma-growth hormone concentrations in **acromegalic patients**. In the UK, it is introduced gradually as described above and may then be increased further by 2.5 mg every 2 to 3 days if necessary up to 5 mg every 6 hours, according to response. In the USA, the usual starting dose (see above) may be increased by 1.25 to 2.5 mg every 3 to 7 days to a maximum daily dose of 100 mg if necessary; the usual dosage range is 20 to 30 mg daily.

In **Parkinson's disease** bromocriptine has been used alone, although it is usually given as an adjunct to levodopa treatment. It should be introduced even more gradually than the regimen above, and during this period patients already receiving levodopa can have their levodopa dosage decreased gradually until an optimal response is achieved. In the UK, a suggested initial dose is the equivalent of 1 to 1.25 mg of bromocriptine at night during week 1, increased to 2 to 2.5 mg at night for week 2, 2.5 mg twice daily for week 3, and for week 4, 2.5 mg three times daily; the dose may be increased thereafter by 2.5 mg every 3 to 14 days according to response. The EMEA has recommended a maximum dose of 30 mg daily. In the USA, a usual starting dose is 1.25 to 2.5 mg twice daily increased by 2.5 mg every 14 to 28 days to a maximum dose of 100 mg daily if necessary.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and bromocriptine has been used in acromegaly (p.1798) as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels. While it is less effective than somatostatin analogues, it can be given orally and is therefore more convenient to administer.

Cushing's syndrome. There have been occasional reports of benefit with the use of bromocriptine in the treatment of Cushing's syndrome (p.2344). Remission of ACTH-dependent Cushing's syndrome was maintained for 6 years by bromocriptine 2.5 mg twice daily in a patient who had initially received pituitary irradiation.[1] However, the same group subsequently reported that they had found that bromocriptine did not effectively reduce ACTH secretion following bilateral adrenalectomy.[2]

2. Atkinson AB. The treatment of Cushing's syndrome. *Clin Endocrinol (Oxf)* 1991; **34:** 507–13.

Hepatic encephalopathy. For the view that the evidence does not support the use of dopaminergics such as bromocriptine in the management of hepatic encephalopathy see p.1697.

Hyperprolactinaemia and prolactinomas. Prolactinomas (prolactin-secreting pituitary adenomas) are among the commonest causes of hyperprolactinaemia. Raised serum-prolactin concentrations can result in reduced gonadotrophin production, which in turn may suppress gonadal function. Consequences may include oligomenorrhoea or amenorrhoea, and infertility in either sex. Galactorrhoea may also result from high prolactin levels and can occur in men as well as women.

Dopamine is the major inhibitory factor in the hypothalamus and directly inhibits the secretion of prolactin. Bromocriptine, a dopamine agonist, has been the first choice of treatment in many centres for the treatment of hyperprolactinaemia secondary to a prolactinoma although cabergoline is now preferred by some. Bromocriptine is extremely effective in controlling elevated circulating prolactin concentrations and restoring gonadal function; although it is rarely curative, it may produce considerable shrinkage of the adenoma.[1]

The sensitivity of hyperprolactinaemia to bromocriptine therapy can vary considerably between patients and this is reflected in the wide range of oral doses required to reduce prolactin concentrations to normal levels. Although beginning therapy with gradually increasing doses can minimise adverse effects it has been reported that about 5 to 10% of patients are unable to tolerate oral bromocriptine;[2] other dosage routes have therefore been investigated. Bromocriptine is well absorbed from standard oral tablets placed in the vagina and appears to be both effective in lowering prolactin concentrations and well tolerated when given by this route.[3] However, limitations are considered to be the relatively short duration of action and the relatively low dose that can be given.[2] A depot preparation given intramuscularly in a dose of 50 to 250 mg monthly has been found to be effective and well tolerated in long-term studies;[4,5] it is reported to be used in some centres to begin treatment for macroprolactinomas.[2]

For discussions of the management of hyperprolactinaemia and associated disorders see p.2079 (hyperprolactinaemia), p.2078 (amenorrhoea), p.2079 (hypogonadism), p.2179 (erectile dysfunction), and p.2080 (infertility).

PREGNANCY. References to the management of prolactinoma during pregnancy.[1-3] Bromocriptine has been successfully used for management in pregnant women, particularly if there is symptomatic enlargement of the tumour, although there continues to be debate on the appropriateness of continuous therapy in less high-risk individuals.

3. Chiodini I, Liuzzi A. PRL-secreting pituitary adenomas in pregnancy. *J Endocrinol Invest* 2003; **26:** 96–9.

Lactation inhibition. Because of its effects on prolactin, bromocriptine is a potent suppressor of lactation and has been widely used for the prevention of lactation in women who choose not to breast feed post partum. However, bromocriptine has been associated with severe adverse effects in some women, and its use to suppress a physiological state has been criticised (see p.2003). Consequently, licensed product information from a number of countries recommends that bromocriptine should only be used to suppress puerperal lactation for medical reasons; it is also not recommended for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support.

Mastalgia. Since mastalgia (p.2092) can improve spontaneously, treatment should rarely be considered unless pain has been present for about 6 months. Bromocriptine is one of the drugs that may be used to treat mastalgia.[1,2] It may improve symptoms in up to about 50% of patients with cyclical mastalgia, but is less effective in the non-cyclical form.[3,4] Adverse effects can be severe in some patients.

Neuroleptic malignant syndrome. Bromocriptine has been used in doses of up to 30 mg daily,[1-6] usually alone or with dantrolene, in the treatment of neuroleptic malignant syndrome (p.972) although some workers have not found it to be of use.[7]

7. Rosebush PI, *et al.* The treatment of neuroleptic malignant syndrome: are dantrolene and bromocriptine useful adjuncts to supportive care? *Br J Psychiatry* 1991; **159:** 709–12.

Parkinsonism. Dopamine agonists such as bromocriptine are often used to begin treatment of parkinsonism (p.791), particularly in younger patients, in an attempt to delay therapy with levodopa. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stage of the disease. However, in early disease, there is no evidence that adjunctive bromocriptine prevents or delays the onset of motor complications associated with levodopa monotherapy.

Polycystic ovary syndrome. Bromocriptine has been tried in women with the polycystic ovary syndrome (p.2080) who have mild basal hyperprolactinaemia without evidence of a pituitary tumour.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p.958) is obscure and treatment has largely been empirical but dopaminergic therapy has emerged as a common first-line choice. Bromocriptine showed some benefit in a small study.[1]

Withdrawal syndromes. ***ALCOHOL.*** Studies of the efficacy of bromocriptine as an aid in the maintenance of abstinence from alcohol (p.1626) have yielded conflicting results.[1-4] However, it has been suggested[3] that response to bromocriptine might be linked to a specific genotype of the D_2 dopamine receptor.

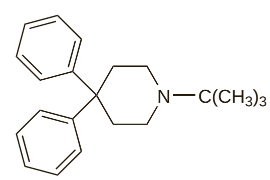
Budipine *(rINN)*

Budipino; Budipinum. 1-*tert*-Butyl-4,4-diphenylpiperidine.

Будипин

$C_{21}H_{27}N$ = 293.4.
CAS — 57982-78-2.
ATC — N04BX03.
ATC Vet — QN04BX03.



Profile

Budipine is a phenylpiperidine derivative used as an adjunct in the treatment of parkinsonism (p.791). It is given orally as the hydrochloride in daily doses of up to 60 mg.

Ger.: Parkinsan.

Cabergoline *(BAN, USAN, rINN)*

Cabergolina; Cabergolinum; FCE-21336; Kabergoliini; Kabergolin; Kabergolina. 1-[(6-Allylergolin-8β-yl)carbonyl]-1-[3-(dimethylamino)propyl]-3-ethylurea; (8*R*)-6-Allyl-*N*-[3-(dimethylamino)-propyl]-*N*-(ethylcarbamoyl)ergoline-8-carboxamide.

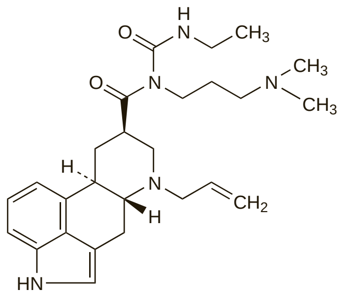
Каберголин

$C_{26}H_{37}N_5O_2$ = 451.6.

CAS — 81409-90-7.

ATC — G02CB03; N04BC06.

ATC Vet — QG02CB03; QN04BC06.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Cabergoline). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; freely soluble in alcohol; very slightly soluble in *n*-hexane. It is slightly soluble in 0.1M hydrochloric acid. Protect from light.

Adverse Effects and Precautions

As for Bromocriptine, p.798, although patients unable to tolerate bromocriptine may tolerate cabergoline (and *vice versa*).

Licensed product information states that conception should be avoided for at least one month after treatment.

Effects on mental function. For reports of **daytime somnolence** occurring in patients receiving dopamine agonists including cabergoline, see under Levodopa, p.805.

For reference to **pathological gambling** reported in patients with Parkinson's disease receiving dopamine agonists including cabergoline, see under Levodopa, p.805.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including cabergoline, see under Bromocriptine, p.799.

In 2007, based on further evidence from 3 studies,[1-3] the UK MHRA[4] considered the risk of cardiac valvulopathy to be high and clinically significant with cabergoline and pergolide, and the risks of treatment with these 2 drugs to be similar. This resulted in the following changes to UK labelling for cabergoline products in Parkinson's disease:

- restricted to second-line treatment in patients intolerant of, or who do not respond to, non-ergot drug treatment
- contra-indicated in patients with a history of pulmonary, pericardial, and retroperitoneal fibrotic disorders, or in those with anatomical evidence of cardiac valvulopathy
- monitoring for development of valvular disease or fibrosis recommended: echocardiography should be performed within 3 to 6 months of starting treatment and every 6 to 12 months thereafter

In June 2008 the EMEA further recommended that the maximum dose should be 3 mg daily.[5]

5. EMEA. EMEA recommends new warnings and contraindications for ergot-derived dopamine agonists (issued 26th June, 2008). Available at: http://www.emea.europa.eu/pdfs/human/press/pr/32239508en.pdf (accessed 08/08/08)

Oedema. Three cases of lower limb oedema after chronic treatment with cabergoline have been reported.[1] In one case the oedema was severe enough to necessitate withdrawal of therapy.

1. Geminiani G, *et al.* Cabergoline in Parkinson's disease complicated by motor fluctuations. *Mov Disord* 1996; **11:** 495–500.

Interactions

As for Bromocriptine, p.800.

Pharmacokinetics

Cabergoline is absorbed from the gastrointestinal tract and mean peak plasma concentrations are achieved within 2 to 3 hours. It is subject to first-pass metabolism and is extensively metabolised to several metabolites that do not appear to contribute to its pharmacological activity. Plasma protein binding has been estimated to be about 40%. Cabergoline is mainly eliminated via the faeces; a small proportion is excreted in the urine. In *rats*, cabergoline has been reported to cross the placenta and to be distributed into breast milk.

◊ General references.

1. Del Dotto P, Bonuccelli U. Clinical pharmacokinetics of cabergoline. *Clin Pharmacokinet* 2003; **42:** 633–45.

Half-life. Pharmacokinetic studies of cabergoline have been hampered by lack of an assay method sensitive enough to detect plasma concentrations of cabergoline after therapeutic doses. However, the plasma elimination half-life of cabergoline has been estimated indirectly to be 63 to 68 hours in healthy subjects and 79 to 115 hours in patients with hyperprolactinaemia.[1]

1. Rains CP, *et al.* Cabergoline: a review of its pharmacological properties and therapeutic potential in the treatment of hyperprolactinaemia and inhibition of lactation. *Drugs* 1995; **49:** 255–79.

Uses and Administration

Cabergoline, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p.800). It is a potent and long-lasting inhibitor of prolactin secretion used in the management of disorders associated with hyperprolactinaemia. It is also used to suppress puerperal lactation for medical reasons; it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that may be adequately relieved with simple analgesics and breast support. Cabergoline is also used in the management of Parkinson's disease as monotherapy, or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response; in the UK cabergoline is restricted to patients who are intolerant of, or who do not respond to, non-ergot drug treatment.

Cabergoline is given orally and should be taken with food.

To **inhibit physiological lactation**, cabergoline is given as a single 1-mg dose on the first day post partum. For **suppression of established lactation**, the dose is 250 micrograms every 12 hours for 2 days.

In the treatment of **disorders associated with hyperprolactinaemia**, the initial dose of cabergoline is 500 micrograms weekly. The dose is then increased at monthly intervals in increments of 500 micrograms weekly according to response. The weekly dose may be given on a single occasion or divided into 2 or more doses on separate days; doses over 1 mg should be given as divided doses. The usual dose is 1 mg weekly but up to 4.5 mg weekly has been used.

In **Parkinson's disease**, cabergoline should be introduced gradually and during this period the dose of levodopa may be reduced gradually until an optimal response is achieved. A suggested initial dose of cabergoline given as a single daily dose is 0.5 mg in monotherapy or 1 mg in adjunctive therapy. The dose may be increased in increments of 0.5 or 1 mg at intervals of 7 or 14 days. The EMEA has recommended a maximum dose of 3 mg daily.

Doses of cabergoline may need to be reduced in patients with severe hepatic impairment (see below).

Administration in hepatic impairment. Licensed drug information recommends caution in patients with severe hepatic impairment (Child-Pugh category C), and doses of cabergoline should be adjusted accordingly.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone concentrations, although they are less effective than somatostatin analogues (p.1798). Although a small study comparing cabergoline with depot bromocriptine and quinagolide failed to find evidence of its effectiveness (see p.2377), in a later open study[1] there was a good response in about 40% of patients treated with cabergoline, which is better than the response usually reported for bromocriptine. The addition of cabergoline has also been beneficial in acromegaly that is resistant to somatostatin analogue therapy.[2]

Hyperprolactinaemia and prolactinomas. Dopamine agonists are widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (see p.2079). Although bromocriptine has been the first choice for this indication, some now prefer cabergoline,[1] which appears to be more effective and better tolerated.[2,3]

Lactation inhibition. A single 1-mg dose of cabergoline was found to be as effective as bromocriptine 2.5 mg given twice daily for 14 days for preventing puerperal lactation in a double-blind multicentre study involving 272 women.[1] It has been suggested that cabergoline would be a better choice than bromocriptine for lactation inhibition.[2] However, as discussed on p.2003, the routine use of dopaminergics such as bromocriptine or cabergoline is not recommended for the suppression of physiological lactation.

2. Webster J. A comparative review of the tolerability profiles of dopamine agonists in the treatment of hyperprolactinaemia and inhibition of lactation. *Drug Safety* 1996; **14:** 228–38. Correction. *ibid.*; 342.

Parkinsonism. Cabergoline is used as a long-acting dopamine agonist in Parkinson's disease (p.791). Dopamine agonists are often used to begin treatment in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stages of the disease.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p.958) is obscure and treatment has been largely empirical but dopaminergic therapy has emerged as a common first-line choice. Long-acting drugs such as cabergoline may be preferred in order to avoid the complications associated with levodopa therapy. Results from a 12-week open-label pilot study[1] in 9 patients with idiopathic RLS given cabergoline after insufficient response to levodopa therapy were promising; doses of cabergoline ranged from 1 to 4 mg. A later randomised multicentre study[2] in 85 patients concluded that a single evening dose of cabergoline for 5 weeks markedly reduced symptoms during the night and the next day compared with placebo. Results from the follow-up analysis of 66 patients after 1 year of treatment suggested that cabergoline at a median dose of 2 mg daily has a high rate of remission and is well tolerated. The authors recommended an initial dose of cabergoline 500 micrograms in the evening increased in increments of 500 micrograms weekly according to response.

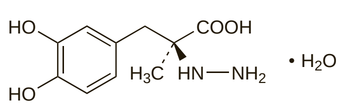
Carbidopa *(BAN, USAN, rINN)*

Carbidopum; Carbidopum Monohydricum; Karbidopa; Karbidopa monohydrát; α-Methyldopa Hydrazine; MK-486. (+)-2-(3,4-Dihydroxybenzyl)-2-hydrazinopropionic acid monohydrate; (−)-L-α-Hydrazino-3,4-dihydroxy-α-methylhydrocinnamic acid monohydrate.

Карбидопа

$C_{10}H_{14}N_2O_4,H_2O$ = 244.2.

CAS — 28860-95-9 (anhydrous); 38821-49-7 (monohydrate).



NOTE. The synonym MK-485 has been used for the racemic mixture.

Compounded preparations of carbidopa and levodopa may be represented by the following names:

- Co-careldopa *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of carbidopa and levodopa respectively
- Co-careldopa (*PEN*)—carbidopa and levodopa

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Carbidopa). A white or yellowish-white powder. Slightly soluble in water; very slightly soluble in alcohol; practically insoluble in dichloromethane; dissolves in dilute solutions of mineral acids. Protect from light.

USP 31 (Carbidopa). A white to creamy-white, odourless or practically odourless powder. Slightly soluble in water and in methyl alcohol; practically insoluble in alcohol, in acetone, in chloroform, and in ether; freely soluble in 3N hydrochloric acid. Protect from light.

Adverse Effects

Hypersensitivity. Henoch-Schönlein purpura that developed in a 68-year-old patient being treated for Parkinson's disease appeared to be due to either carbidopa or an excipient of the carbidopa preparation (*Sinemet*).[1]

1. Niedermaier G, Briner V. Henoch-Schönlein syndrome induced by carbidopa/levodopa. *Lancet* 1997; **349:** 1071–2.

Pharmacokinetics

Carbidopa is rapidly but incompletely absorbed from the gastrointestinal tract. It is rapidly excreted in the urine both unchanged and in the form of metabolites. It does not cross the blood-brain barrier. In *rats*, carbidopa has been reported to cross the placenta and to be distributed into breast milk.

Uses and Administration

Carbidopa is a peripheral dopa-decarboxylase inhibitor with little or no pharmacological activity when given alone in usual doses. It inhibits the peripheral decarboxylation of levodopa to dopamine and as, unlike levodopa, it does not cross the blood-brain barrier, effective brain concentrations of dopamine are produced with lower doses of levodopa. At the same time reduced peripheral formation of dopamine reduces peripheral adverse effects, notably nausea and vomiting, and cardiac arrhythmias, although the dyskinesias and adverse mental effects associated with levodopa therapy tend to develop earlier. Contrary to its effect in patients on levodopa alone, pyridoxine does not inhibit the response to levodopa in patients also receiving a peripheral dopa-decarboxylase inhibitor.

In the treatment of parkinsonism (p.791) carbidopa is given with levodopa to enable a lower dosage of the latter to be used, a more rapid response to be obtained, and to decrease adverse effects. For details of administration and dosage, see Levodopa, p.808.

Carbidopa also inhibits the peripheral decarboxylation of the serotonin precursor oxitriptan (p.414).

Dexetimide *(BAN, USAN, rINN)*

Dexetimida; Dexétimide; Dexetimidum. (*S*)-2-(1-Benzyl-4-piperidyl)-2-phenylglutarimide; (*S*)-3-Phenyl-1′-(phenylmethyl)-(3,4′-bipiperidine)-2,6-dione.

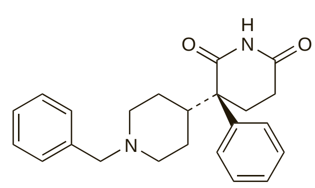
Дексэтимид

$C_{23}H_{26}N_2O_2$ = 362.5.

CAS — 21888-98-2.

ATC — N04AA08.

ATC Vet — QN04AA08.



Dexetimide Hydrochloride *(BANM, rINNM)*

Dexbenzetimide Hydrochloride; Dexétimide, Chlorhydrate de; Dexetimidi Hydrochloridum; Hidrocloruro de dexetimida; R-16470.

Дексэтимида Гидрохлорид

$C_{23}H_{26}N_2O_2,HCl$ = 398.9.

CAS — 21888-96-0.

ATC — N04AA08.

ATC Vet — QN04AA08.

Profile

Dexetimide is a tertiary antimuscarinic with actions similar to those of trihexyphenidyl (p.820). It has been used to alleviate drug-induced extrapyramidal symptoms (see under Chlorpromazine, p.971), but, like other antimuscarinics, is of no value against tardive dyskinesias. Dexetimide is given as the hydrochloride although doses are expressed in terms of the base; dexetimide hydrochloride 1.1 mg is equivalent to about 1 mg of dexetimide. A usual oral dose is 0.5 to 1 mg once daily; it has also been given by intramuscular injection.

Preparations

Proprietary Preparations (details are given in Part 3)

Belg.: Tremblex; ***Neth.:*** Tremblex.

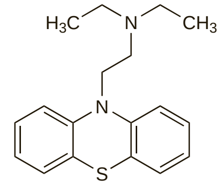
Diethazine Hydrochloride *(BANM, rINNM)*

Diaethazinium Chloratum; Diéthazine, Chlorhydrate de; Diethazini Hydrochloridum; Eazamine Hydrochloride; Hidrocloruro de dietazina; RP-2987. 10-(2-Diethylaminoethyl)phenothiazine hydrochloride.

Диэтазина Гидрохлорид

$C_{18}H_{22}N_2S,HCl$ = 334.9.

CAS — 60-91-3 (diethazine); 341-70-8 (diethazine hydrochloride).



(diethazine)

Profile

Diethazine hydrochloride is an antimuscarinic with actions similar to those of profenamine hydrochloride (p.815), but it is more toxic and bone-marrow depression may occur. It has been used in the treatment of parkinsonism.

Preparations

Proprietary Preparations (details are given in Part 3)

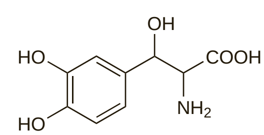
Droxidopa *(USAN, rINN)*

L-*threo*-3,4-Dihydroxyphenylserine; DOPS; Droxidopum; L-DOPS; L-*threo*-DOPS. (−)-*threo*-3-(3,4-Dihydroxyphenyl)-L-serine.

Дроксидопа

$C_9H_{11}NO_5$ = 213.2.

CAS — 23651-95-8.



Profile

Droxidopa is a precursor of noradrenaline that is used in the treatment of parkinsonism (p.791) and some forms of orthostatic hypotension (p.1530). The usual oral maintenance dose is 600 mg daily for the treatment of parkinsonism and 300 to 600 mg daily in orthostatic hypotension; daily doses should be divided.

The racemic form (DL-*threo*-3,4-dihydroxyphenylserine) has also been studied for orthostatic hypotension.

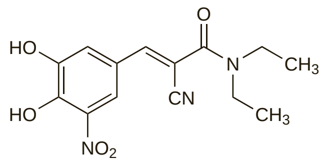
Энтакапон

$C_{14}H_{15}N_3O_5$ = 305.3.

CAS — 130929-57-6.

ATC — N04BX02.

ATC Vet — QN04BX02.



Adverse Effects

The most frequent adverse effects produced by entacapone relate to increased dopaminergic activity and occur most commonly at the start of treatment; reduction of the levodopa dosage may reduce the severity and frequency of such effects. Adverse effects may include nausea, vomiting, abdominal pain, constipation, diarrhoea, colitis, dry mouth, and dyskinesias. Other commonly reported adverse effects include dizziness, insomnia, nightmares, hallucinations, confusion, fatigue, and increased sweating. There have been rare reports of agitation, urticaria, erythematous or maculopapular rash, anorexia, and weight decrease. Increases in liver enzyme values have been reported rarely; there have also been isolated cases of cholestatic hepatitis. Isolated cases of neuroleptic malignant syndrome have been reported after abrupt reduction or withdrawal of entacapone; there have also been isolated cases of rhabdomyolysis. It may produce a harmless reddish-brown discoloration of the urine. Skin, hair, beard, and nail discolorations have been reported.

Precautions

Entacapone is contra-indicated in patients with phaeochromocytoma and in patients with a history of neuroleptic malignant syndrome or nontraumatic rhabdomyolysis. It should be avoided in patients with hepatic impairment, and given with caution to patients with biliary obstruction. A general medical evaluation, including liver function, should be considered in those who experience progressive anorexia, asthenia, and weight decrease within a relatively short period of time.Use with levodopa may cause dizziness and orthostatic hypotension; if affected patients should not drive or operate machinery. Excessive daytime sleepiness and sudden onset of sleep may also occur with combination use (see Effects on Mental Function, in Levodopa, p.805) and again, caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Treatment with entacapone should not be stopped abruptly; when necessary withdrawal should be made gradually, increasing the dose of levodopa as required.

Genetic polymorphism. For reference to slow metabolisers being more susceptible to COMT-inhibitor induced hepatotoxicity, see under Tolcapone, p.820.

Interactions

Use of entacapone with a non-selective MAOI is contra-indicated. Entacapone should be used with caution in patients receiving drugs metabolised by catechol-*O*-methyltransferase (COMT) including adrenaline, apomorphine, dobutamine, dopamine, isoprenaline, methyldopa, noradrenaline, paroxetine, and rimiterol. Caution is also advised when used with certain antidepressants including the tricyclics, reversible inhibitors of monoamine oxidase type A, and noradrenaline reuptake inhibitors such as venlafaxine.

Entacapone may aggravate levodopa-induced orthostatic hypotension and should be used cautiously in patients who are taking other drugs which may cause orthostatic hypotension.

Entacapone may form chelates with iron preparations in the gastrointestinal tract; the two drugs should be taken at least 2 to 3 hours apart.

Pharmacokinetics

There are large intra- and interindividual variations in the absorption of entacapone. Peak plasma concentrations are achieved about one hour after oral doses. Entacapone undergoes extensive first-pass metabolism and oral bioavailability is about 35%. Absorption is not affected significantly by food. Entacapone is about 98% bound to plasma proteins. It is eliminated mainly in the faeces with about 10 to 20% being excreted in the urine, mainly as glucuronide conjugates. Entacapone is thought to be distributed into breast milk on the basis of studies in *rats*.

◊ Entacapone is rapidly absorbed from the gastrointestinal tract and bioavailability after oral doses has been reported to range from 29 to 46%. It does not cross the blood-brain barrier. Over half of a dose appears in the faeces with smaller amounts being excreted in the urine as glucuronides of entacapone and its (*Z*)-isomer. Elimination half-lives of about 1.6 to 3.4 hours have been reported for entacapone.

Uses and Administration

Entacapone is a selective, reversible, peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of dopamine and levodopa. It is used as an adjunct to combination preparations of levodopa and dopa-decarboxylase inhibitors, in patients with Parkinson's disease and 'end-of-dose' motor fluctuations who cannot be stabilised on levodopa combinations alone. Entacapone is given orally in a dosage of 200 mg at the same time as each dose of levodopa with dopa-decarboxylase inhibitor, up to a maximum of 200 mg ten times daily. It is often necessary to gradually reduce the dosage of levodopa by about 10 to 30% within the first few weeks after starting treatment with entacapone; this effect may be more marked in the presence of benserazide than of carbidopa.

Entacapone may also be given as a combination preparation with carbidopa and levodopa; for dosage details, see Levodopa, p.808.

Parkinsonism. Entacapone is a selective and reversible inhibitor of catechol-*O*-methyltransferase (COMT), with mainly peripheral actions. It is given as adjunctive therapy to patients with Parkinson's disease (p.791) experiencing fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations. When levodopa is given with a peripheral dopa-decarboxylase inhibitor, *O*-methylation then becomes the predominant form of metabolism of levodopa; therefore adding a peripheral COMT inhibitor such as entacapone potentially extends the duration and effect of levodopa in the brain, and thus allows levodopa to be given less often and in lower doses.

Levodopa *(BAN, USAN, rINN)*

Dihydroxyphenylalanine; L-Dopa; 3-Hydroxy-L-tyrosine; Laevodopa; Lévodopa; Levodopum. (−)-3-(3,4-Dihydroxyphenyl)-L-alanine.

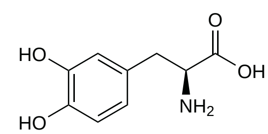
Леводопа

$C_9H_{11}NO_4$ = 197.2.

CAS — 59-92-7.

ATC — N04BA01.

ATC Vet — QN04BA01.



NOTE. Compounded preparations of levodopa may be represented by the following names:

- Co-beneldopa (*BAN*)—benserazide 1 part and levodopa 4 parts (w/w)
- Co-careldopa *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of carbidopa and levodopa, respectively
- Co-careldopa (*PEN*)—carbidopa and levodopa

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 6.2 (Levodopa). A white or slightly cream-coloured, crystalline powder. Slightly soluble in water; freely soluble in 1M hydrochloric acid but sparingly soluble in 0.1M hydrochloric acid; practically insoluble in alcohol. A 1% suspension in water has a pH of 4.5 to 7.0. Protect from light.

USP 31 (Levodopa). A white to off-white, odourless, crystalline powder. In the presence of moisture, it is rapidly oxidised by atmospheric oxygen and darkens. Slightly soluble in water; freely soluble in 3N hydrochloric acid; insoluble in alcohol. Store in a dry place in airtight containers at a temperature not exceeding 40°. Protect from light.

Stability. Extemporaneously prepared oral liquid dosage forms may be unstable and manufacturers' formulations should be used where possible.[1] Water dispersible formulations of levodopa with benserazide are available in some countries but a method that can be used by patients to prepare daily solutions of levodopa with carbidopa has been suggested:[2] one litre of a solution in potable water may be prepared with ten crushed standard tablets of levodopa 100 mg with carbidopa 25 mg and 2 g of ascorbic acid added to stabilise the levodopa.

Adverse Effects

Gastrointestinal effects, notably nausea, vomiting, and anorexia are common early in treatment with levodopa, particularly if the dosage is increased too rapidly. Gastrointestinal bleeding has been reported in patients with a history of peptic ulcer disease.

The commonest cardiovascular effect is orthostatic hypotension, which is usually asymptomatic, but may be associated with faintness and dizziness. Cardiac arrhythmias have been reported and hypertension has occasionally occurred.

Psychiatric symptoms occur in a high proportion of patients, especially the elderly, and include agitation, anxiety, euphoria, nightmares, insomnia or sometimes drowsiness, and depression. More serious effects, usually requiring a reduction in dosage or withdrawal of levodopa, include aggression, paranoid delusions, hallucinations, delirium, severe depression, with or without suicidal behaviour, and unmasking of psychoses. Psychotic reactions are more likely in patients with postencephalitic parkinsonism or a history of mental disorders. Excessive daytime sleepiness and sudden onset of sleep have been reported very rarely.

Abnormal involuntary movements or dyskinesias are the most serious dose-limiting adverse effects of levodopa and are very common at the optimum dose required to control parkinsonism; their frequency increases with duration of treatment. Involuntary movements of the face, tongue, lips, and jaw often appear first and those of the trunk and extremities later. Severe generalised choreoathetoid and dystonic movements may occur after prolonged use. Muscle twitching and blepharospasm may be early signs of excessive dosage. Exaggerated respiratory movements and exacerbated oculogyric crises have been reported in patients with postencephalitic parkinsonism. Bradykinesia and akinesia, in the form of 'end-of-dose' deterioration and the 'on-off' phenomenon, may re-emerge in patients with parkinsonism as a complication of long-term treatment, but may be due to progression of the disease rather than to levodopa (see also Parkinsonism, p.791).

A positive response to the direct Coombs' test may occur, usually without evidence of haemolysis although auto-immune haemolytic anaemia has occasionally been reported. Transient leucopenia and thrombocytopenia have occurred rarely. The effects of levodopa on liver and kidney function are generally slight; transient increases in liver enzymes, and in blood-urea nitrogen and serum-uric acid concentrations, have been reported. Levodopa may cause discoloration of the urine; reddish at first then darkening on standing. Other body fluids may also be discoloured.

Some of the adverse effects reported may not be attributable directly to levodopa, but rather to the use of antimuscarinics, to increased mobility, or to the unmasking of underlying conditions as parkinsonism improves. Use with a peripheral dopa-decarboxylase inhibitor may reduce the severity of peripheral symptoms such as gastrointestinal and cardiovascular effects, but central effects such as dyskinesias and mental disturbances may occur earlier in treatment.

Incidence of adverse effects. The major adverse effects of levodopa are dyskinesia in 75% of patients and psychiatric disturbances in 25%.[1] Nausea and vomiting in 40 to 50% gradually regress and hypotension in 25 to 30% is generally asymptomatic. Less common adverse effects include cardiac arrhythmias, particularly atrial and ventricular ectopic beats and less commonly atrial flutter and fibrillation; palpitations and flushing often accompanied by excessive sweating; hypertension; polyuria, incontinence, and urinary retention, although antimuscarinic drugs often contribute to problems with micturition; and dark coloration of the urine and saliva. Rare adverse effects include abdominal pain, constipation, and diarrhoea; mydriasis, blurred vision, diplopia, and precipitation of glaucoma; headache; stridor; tachypnoea; and paraesthesias.

Abnormal coloration. Black pigmentation of rib cartilage has been noted at necropsy in patients treated with levodopa.[1,2] Abnormal pigmentation is generally not seen at other sites[2] but there have been isolated reports[2,3] of patients who also had pigmentation of the intervertebral discs. Although the pigmentation appears to be irreversible it was considered to be probably harmless.[2] It has been suggested that the pigmentation was due to deposition of dihydroxyphenylalanine (DOPA) in the cartilage.[1] It is known that DOPA will readily auto-oxidise *in vitro* in the presence of oxygen to a black pigment and this can also happen *in vivo* since black urine is a well known adverse effect of levodopa. Dark sweat and pigmentation of the skin and teeth are also known adverse effects.

Dysgeusia. A change in taste sensation was reported[1] in 23 of 514 patients treated with levodopa and a peripheral dopa-decarboxylase inhibitor; 2 of the 23 had total loss of taste initially. The altered taste, often described as insipid, metallic, or plastic, was first observed 3 to 32 weeks after beginning treatment, and lasted for 2 to 40 weeks. In an earlier report, 22 of 100 patients receiving levodopa alone had experienced changes in taste.[2]

Effects on the blood. Reports of effects of levodopa on the blood are mostly confined to individual case reports. A study in 365 patients, receiving levodopa in a mean daily dosage of 4.04 g, found that 32 developed a positive direct Coombs' test, the majority after between 3 and 12 months of therapy, but none developed haemolytic anaemia.[1] However, occasional cases of auto-immune haemolytic anaemia have been reported;[2-4] in one case, dosage reduction and addition of a peripheral dopa-decarboxylase inhibitor largely abolished haemolysis,[3] but in another, haemolysis recurred on re-institution of levodopa with carbidopa and required corticosteroid treatment.[4] A case of severe acute non-haemolytic anaemia related to levodopa therapy has also been reported.[5]

Although levodopa is widely stated to produce leucopenia in some patients, there are few published reports. However transient minor decreases in total leucocyte counts were reported in 3 of a group of 80 patients receiving levodopa.[6]

Severe thrombocytopenia has been reported in 2 patients who had received levodopa for 3 and 2 years respectively;[7,8] the condition was apparently an auto-immune response and responded to prednisone therapy and withdrawal of levodopa.

Effects on the cardiovascular system. There have been conflicting reports on the effects of peripheral dopa-decarboxylase inhibitors on orthostatic hypotension attributed to levodopa therapy. In a study,[1] supine and erect systolic blood pressure was found to be significantly higher in parkinsonian patients given levodopa with carbidopa than in those receiving levodopa alone, suggesting that the peripheral actions of dopamine contribute to levodopa-induced hypotension. However, another study[2] found no change in the incidence and degree of orthostatic hypotension after giving levodopa with carbidopa and, similarly, no difference in the frequency of ventricular arrhythmias.

Effects on electrolytes. See Effects on Kidney Function, below.

Effects on the endocrine system. Single doses of levodopa given to healthy subjects cause an increase in plasma concentrations of glucose, insulin, and glucagon, as well as of growth hormone[1] and there has been concern over the potential endocrine effects of levodopa therapy in patients with Parkinson's disease.[2] A study of carbohydrate metabolism in 24 patients with Parkinson's disease indicated that these patients had abnormally low rates of **glucose utilisation** when untreated, apparently due to impaired insulin release, and this was not altered when levodopa therapy was given.[3] However, a similar study completed by 19 patients[2] noted increased impairment of glucose utilisation after levodopa therapy for 1 year with a delayed hypersecretion of insulin in response to a glucose load similar to the metabolic changes of acromegaly. It was considered that patients given levodopa for parkinsonism should be monitored for evidence of diabetes mellitus or frank acromegaly.[2]

Postmenopausal bleeding occurred in varying degrees in 12 of 47 women treated with levodopa.[4] In one case bleeding was severe enough to warrant interrupting treatment and subsequent dosage reduction.

2. Weintraub MI, *et al.* Pupillary effects of levodopa therapy: development of anisocoria in latent Horner's syndrome. *N Engl J Med* 1970; **283:** 120–3.

Effects on the gastrointestinal tract. Although gastrointestinal bleeding has more commonly been reported in patients with a history of peptic ulceration, there is a rare report[1] of acute melaena and non-specific gastritis associated with levodopa therapy in a 56-year-old man without any previous evidence of a gastric disorder.

See also Dysgeusia, above.

1. Riddoch D. Gastritis and -dopa. *BMJ* 1972; **1:** 53–4.

Effects on kidney function. Levodopa 1 to 2 g given to 7 patients with idiopathic or postencephalitic Parkinson's disease produced significant increases in renal plasma flow, glomerular filtration rate, and sodium and potassium excretion.[1] It was considered that the natriuretic effects could contribute to the orthostatic hypotension commonly seen in patients receiving levodopa. There is a report of a patient who developed hyponatraemia when given levodopa with carbidopa.[2] The patient had previously had a similar reaction with amantadine. On each occasion symptoms disappeared when dopaminergic medication was withdrawn and recurred on rechallenge. Inappropriate secretion of antidiuretic hormone was suggested as a possible mechanism.

Levodopa has also been reported to have a kaliuretic effect, resulting in hypokalaemia, in some parkinsonian patients;[3] the effect could be prevented by also giving a peripheral dopa-decarboxylase inhibitor.

3. Granérus A-K, *et al.* Kaliuretic effect of -dopa treatment in parkinsonian patients. *Acta Med Scand* 1977; **201:** 291–7.

Effects on mental function. Psychiatric complications were the single commonest reason for stopping levodopa treatment in a follow-up study of 178 patients with idiopathic Parkinson's disease, 81 of whom were still taking levodopa after 6 years.[1] Within 2 years, levodopa was withdrawn because of toxic confusional states (21 patients), paranoid psychosis (6), unipolar depression (2), and mania (1). The incidence of visual hallucinations increased as treatment continued but, as with toxic confusional states, patients generally improved when levodopa was withdrawn. Before treatment, 40 patients had suffered severe depression and levodopa produced sustained improvement in only 2. After 6 years, 20 of the 81 patients remaining were moderately or severely depressed and were rarely improved by withdrawal or reduction in dosage of levodopa. Increasing dementia affected 26 of the 81 patients after 6 years; withdrawal of levodopa in 5 failed to improve cognitive disabilities, but increased parkinsonism.

Another study[2] reported that 141 of 400 patients being treated for Parkinson's disease developed mental disorders. In this study certain acute states, particularly anxiety, on-off hallucinations, and fits of delirium were linked to treatment with levodopa, whereas dementia and depression were not.

Long-term use of levodopa and dopamine agonists has been associated with a number of **behavioural disturbances**, including hypersexuality (see Effects on Sexual Function, below), punding (purposeless repetitive acts), excessive gambling or shopping (see below), and other obsessive behaviour such as compulsive eating.[3] Reduction in dopaminergic therapy can lead to cessation or improvement in symptoms. Some patients may develop dopamine dysregulation syndrome (see Abuse, under Precautions, below).

A 12-month study of 1281 patients in the USA treated with dopamine agonists for Parkinson's disease found that 9 were suffering from **excessive gambling**.[4] All patients had received levodopa, 8 pramipexole, and the remaining patient pergolide. The rate of pathological gambling was 1.5% in the 529 patients taking pramipexole. The authors considered that this was not unexpected given the general availability of casinos in the local area and an incidence in the general US population of 0.3 to 1.3%. An analysis[5] of 11 patients who began pathological gambling after starting therapy with pramipexole (9 cases) or ropinirole (2 cases) found that in 8 patients such behaviour resolved when the drug was tapered or stopped; follow-up was not available in the other 3. In 7 patients the symptoms had developed within 1 to 3 months of achieving maintenance dose or after dose increases of dopamine agonist therapy. Of the 11 patients, 3 had not received levodopa. Cabergoline therapy has also been associated with pathological gambling.[6] Similar behaviour described as being markedly increased in "on" periods has been reported in other patients treated with levodopa.[7] Pathological gambling has also been associated with misuse of dopaminergics.[8]

Sleep-related complaints have occurred and were reported by 74 of 100 patients with Parkinson's disease.[9] All 74 were on levodopa and the prevalence of symptoms increased with the duration of treatment. Symptoms included insomnia, excessive daytime somnolence, altered dream phenomena, nocturnal vocalisation, involuntary myoclonic movements, and rarely, sleepwalking. Sleep fragmentation, which includes insomnia and somnolence, was the most common symptom overall. It has been suggested[10] that in patients with mild to moderate disease levodopa and dopamine agonists could cause sleep disruption. However, these drugs produce beneficial effects on nocturnal disabilities in patients with more severe disease. Reports[11-17] of daytime somnolence or sudden onset of sleep with various other dopamine agonists, including apomorphine, bromocriptine, cabergoline, lisuride, pergolide, piribedil, pramipexole, quinagolide, and ropinirole, suggest that this is a class effect of dopaminergic antiparkinsonian therapy, and patients should be warned of the possible risks (see Precautions, below). The risk of somnolence may be increased in those patients taking combinations of dopaminergics.[15,18]

Effects on respiration. Respiratory crises, including attacks of gasping, panting, sniffing, puffing, and breath-holding, occurred in 12 of 25 patients with postencephalitic parkinsonism during treatment with levodopa.[1] A further 8 developed respiratory and phonatory tics, including sudden deep breaths, yawns, coughs, giggles, sighing, grunting, and moaning. All 20 patients also suffered tachypnoea, bradypnoea, and asymmetrical movement of both sides of the chest, paradoxical diaphragmatic movements, and reversal of inspiratory and expiratory phases. The induction of respiratory crises may be prompt or greatly delayed; 3 patients only developed crises after more than 9 months of treatment with levodopa. Crises were readily precipitated by psychophysiological arousals such as rage and exertion. Most of the patients who developed marked respiratory disorders had shown slight irregularities of respiratory rhythm, rate, and force before receiving levodopa.

In another report a distressing dose-related irregularity in the rate and depth of breathing occurred when a patient with Parkinson's disease was given levodopa with benserazide.[2] The respiratory abnormality was completely suppressed by use of tiapride, with no reduction in the efficacy of levodopa.

2. De Keyser J, Vincken W. -Dopa-induced respiratory disturbance in Parkinson's disease suppressed by tiapride. *Neurology* 1985; **35:** 235–7.

Effects on sexual function. An increase in libido, over and above the effects of improved mobility and well-being, has been reported in parkinsonian patients receiving levodopa or dopamine agonists. One report noted increased libido but no improvement in sexual performance in 4 of 80 patients receiving levodopa[1] while another reported a moderate increase in sexual interest in 4 of 7 male patients.[2] There have also been reports of hypersexuality and deviant sexual behaviour in patients with Parkinson's disease receiving levodopa or dopamine agonists.[3-6] In some cases this was associated with increased dosage and possibly abuse of the drugs. Symptoms often improved on dosage reduction or withdrawal. Hypersexual behaviour and hypergenitalism have also been reported in a pre-pubertal boy given levodopa for behavioural disturbances.[7]

Some workers[8] have commented that dopaminergics such as cabergoline are being promoted illegally on the Internet for male sexual enhancement and warn of the potential for abuse and serious adverse effects.

Clitoral tumescence and increased libido has been noted in a woman receiving bromocriptine to suppress lactation[9] but there has been a report of sexual dissatisfaction and decreased libido in 3 women receiving bromocriptine for hyperprolactinaemia.[10]

Effects on the skin and hair. Two women who were given levodopa, up to 3 g daily, developed diffuse alopecia in addition to other adverse effects.[1] Repigmentation of hair has occurred in a white-bearded man after being treated with levodopa 1.5 g daily for 8 months.[2] Vitiligo has been reported[3] in a patient with Parkinson's disease following addition of tolcapone to his levodopa/carbidopa regimen. The development of vitiligo was attributed to the increase in plasma-levodopa concentrations brought about by concomitant use of tolcapone.

3. Sabaté M, *et al.* Vitiligo associated with tolcapone and levodopa in a patient with Parkinson's disease. *Ann Pharmacother* 1999; **33:** 1228–9.

Extrapyramidal effects. Choreiform movements were the major dose-limiting complication of long-term treatment with levodopa in a follow-up study of 178 patients with idiopathic Parkinson's disease, 81 of whom were still taking levodopa after 6 years.[1] Dyskinesias usually appeared in the first year and became more severe and generalised with time. Certain distinctive patterns of involuntary movements occurred as follows:

- peak-dose movements affected 65 of the 81 patients and were dose-related. Movements were usually choreic, affecting the face and limbs, but dystonic and ballistic movements were also seen; characteristically they began 20 to 90 minutes after an oral dose and lasted from 10 minutes to 4 hours with a tendency to be more severe mid-way through the interdose period
- biphasic movements presenting as 2 distinct episodes of chorea or dystonia within each interdose period occurred in only 3 patients
- early morning and 'end-of-dose' dystonia was present in 15 patients after 6 years of treatment with levodopa, but rarely developed during the first 3 years
- nocturnal myoclonus occurred in 12 patients

The frequency, intensity, and complexity of spontaneous fluctuations in performance were greatly enhanced by long-term levodopa therapy. Two clinically distinct types of fluctuation, 'end-of-dose' deterioration and the 'on-off' phenomenon, were related to treatment. 'End-of-dose' deterioration or the 'wearing-off' effect affected 52 patients after 6 years of treatment and was characterised by progressive reduction in the duration of benefit from each dose with a gradual return of nocturnal and early morning disability in some patients. The 'on-off' phenomenon affected 14 patients who experienced completely unpredictable swings from relative mobility, usually accompanied by involuntary movements, to periods of profound bradykinesia and hypotonia. In addition, 'freezing episodes' and abrupt falls became increasingly common and affected 50 patients after 6 years compared with 33 before therapy.

1. Shaw KM, *et al*. The impact of treatment with levodopa on Parkinson's disease. *Q J Med* 1980; **49:** 283–93.

OCULOGYRIC CRISIS. After initial remission, oculogyric crises in 5 of 25 patients with postencephalitic parkinsonism recurred and were subsequently severely exacerbated during treatment with levodopa.[1] One patient, who previously had not had oculogyric crises, developed severe crises in the fourth month of therapy with levodopa. During these crises forced gaze deviation was always accompanied by severe neurological and mental symptoms, some of which were scarcely tolerable.

1. Sacks OW, Kohl M. -Dopa and oculogyric crises. *Lancet* 1970; **ii:** 215–16.

Gout. There have been reports of elevated serum uric acid concentrations in patients receiving levodopa, but some of these are of doubtful significance since levodopa has been shown to give falsely-elevated uric acid concentrations by colorimetric methods.[1] However, hyperuricaemia as measured by more specific methods,[2,3] with a few cases of overt gout,[2,3] has also been reported.

1. Cawein MJ, Hewins J. False rise in serum uric acid after -dopa. *N Engl J Med* 1969; **281:** 1489–90.

3. Calne DB, Fermaglich J. Gout induced by -dopa and decarboxylase inhibitors. *Postgrad Med J* 1976; **52:** 232–3.

Hypersensitivity. Reports of hypersensitivity reactions to levodopa have included a vasculitis characterised by neuromyopathy, periarteriolitis with eosinophilia,[1] and a lupus-like auto-immune syndrome.[2]

1. Wolf S, *et al.* Neuromyopathy and periarteriolitis in a patient receiving levodopa. *Arch Intern Med* 1976; **136:** 1055–7.
2. Massarotti G, *et al.* Lupus-like autoimmune syndrome after levodopa and benserazide. *BMJ* 1979; **2:** 553.

Overdosage. Adverse effects after ingestion of 80 to 100 g of levodopa over a 12-hour period by a parkinsonian patient included hypertension initially, followed by hypotension of a few hours' duration, sinus tachycardia, and symptomatic orthostatic hypotension for more than a week.[1] Marked confusion, agitation, insomnia, and restlessness were the most prominent clinical symptoms and did not disappear completely for over a week; severe anorexia and insomnia persisted for 2 to 3 weeks. After the overdose the patient had virtually no signs of parkinsonism and received no levodopa or antimuscarinic medication for 6 days; rigidity and akinesia began to recur on the fourth day.

1. Hoehn MM, Rutledge CO. Acute overdose with levodopa: clinical and biochemical consequences. *Neurology* 1975; **25:** 792–4.

Withdrawal syndromes. Withdrawal of antiparkinsonian drugs, particularly levodopa, has been implicated in the development of a syndrome resembling the neuroleptic malignant syndrome,[1-6] characterised by fever, muscle rigidity, profuse sweating, tachycardia, tachypnoea, and elevated muscle enzyme values.[1] Several fatalities have occurred.[1,2] It has been suggested that the neuroleptic malignant syndrome is associated with blockade of dopamine receptors in the striatum, leading to increased rigidity and heat production, and in the hypothalamus, resulting in impaired thermoregulation[7] and it seems reasonable that withdrawal of levodopa might have a similar effect in patients with depleted central dopamine concentrations. Thus, the use of a 'drug holiday' to manage fluctuations in response to levodopa (see Parkinsonism, p.791) is no longer recommended.

Fever, extrapyramidal symptoms and raised creatine kinase concentrations, resembling a very mild form of the neuroleptic malignant syndrome, have also been reported in parkinsonian patients exposed to stress such as dehydration or infection but without any change in medication.[8]

Treatment of Adverse Effects

Reduction in dosage reverses most of the adverse effects of levodopa. Nausea and vomiting may be diminished by increasing the dose of levodopa gradually, and/or by taking with or after meals, although taking levodopa on a full stomach may lead to lower plasma concentrations. Gastrointestinal effects may also be reduced by giving an antiemetic such as cyclizine or domperidone but not a phenothiazine (see Antipsychotics, under Interactions, below). Use with a peripheral dopa-decarboxylase inhibitor reduces peripheral but not central adverse effects. Orthostatic hypotension may respond to the use of elastic stockings.

The benefits of gastric decontamination are uncertain. However, activated charcoal should be considered in adults who have ingested more than 2 g (or more than the total daily dose, whichever is greater), and in children who have taken more than 200 mg, if they present within 1 hour of ingestion. Supportive measures should also be instituted. Pyridoxine may increase the metabolism of levodopa (see Nutritional Agents, under Interactions, below) but its value in overdosage has not been established; it does not reduce the effects of levodopa given with a peripheral dopa-decarboxylase inhibitor.

Nausea and vomiting. For reference to the use of domperidone in the management of nausea and vomiting associated with levodopa in patients with Parkinson's disease, see under Uses and Administration of Domperidone, p.1727.

Psychosis. Atypical antipsychotics such as clozapine (p.985) have been tried in the management of psychosis occurring as a complication of parkinsonism and of drugs such as levodopa used in its treatment.

Precautions

Levodopa is contra-indicated in patients with angle-closure glaucoma and should be used with caution in open-angle glaucoma. Caution is also required in patients with cardiovascular disease, pulmonary disease, endocrine disorders, psychiatric disturbances, osteomalacia, hepatic or renal disease, or a history of peptic ulceration. Periodic evaluations of hepatic, psychiatric, haematological, renal, and cardiovascular functions have been advised.

Since an association between levodopa and activation of malignant melanoma has been suspected (although not confirmed), it is generally recommended that levodopa should not be given to patients with (or with a history of) the disease or with skin disorders suggestive of it.

Parkinsonian patients who benefit from levodopa therapy should be warned to resume normal activities gradually to avoid the risk of injury. Treatment with levodopa should not be stopped abruptly.

Excessive daytime sleepiness and sudden onset of sleep may occur with levodopa and caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Levodopa inhibits prolactin secretion and may therefore interfere with lactation.

Food interferes with the absorption of levodopa, though levodopa is usually given with or immediately after meals to reduce nausea and vomiting. However, patients experiencing the 'on-off' phenomenon may benefit from dosage on an empty stomach (see Parkinsonism, p.791).

Abuse. Abuse of levodopa and dopamine agonists in patients with Parkinson's disease has been reported.[1-6] The term dopamine dysregulation syndrome, has been used to describe a condition where there is a compulsive and dysregulated use of dopaminergic drugs beyond that needed to achieve relief of motor symptoms and which is harmful to the patient.[7] Patients have progressively increased the dosage of levodopa to obtain psychotropic effects such as euphoria despite accompanying dystonia and other extrapyramidal adverse effects. Withdrawal often led to craving, drug-seeking behaviour, and mood disturbances such as depression, features resembling a psychological dependence syndrome. Abuse in patients without parkinsonism has also occurred.[8]

See also Effects on Sexual Function under Adverse Effects, above.

8. Steiner I, Wirguin I. Levodopa addiction in non-parkinsonian patients. *Neurology* 2003; **61:** 1451.

Cardiovascular disorders. A high incidence of cardiovascular adverse effects was reported in early studies of levodopa, but both Parkinson's disease and heart disease are common in the elderly and adverse cardiac effects of levodopa may be less prevalent than was first thought. A study in 40 patients[1] concluded that, apart from those with severe orthostatic hypotension or unstable coronary disease, levodopa may be used safely in parkinsonian patients with heart disease. Others[2] noted that levodopa and bromocriptine cause cardiac arrhythmias in less than 1% of all patients, the incidence for levodopa with a peripheral dopa-decarboxylase inhibitor being lower still. Nevertheless, caution is advised in patients with cardiovascular disease.

1. Jenkins RB, *et al.* Levodopa therapy of patients with parkinsonism and heart disease. *BMJ* 1972; **3:** 512–14.
2. Parkes JD, *et al.* Amantadine-induced heart failure. *Lancet* 1977; **i:** 904.

Diabetes mellitus. For reference to concern over the potential of levodopa to impair glucose utilisation, see Effects on the Endocrine System under Adverse Effects, above.

Melanoma. There has been concern over the effects of levodopa on melanoma in view of the ability of malignant melanoma cells to convert levodopa to melanin and isolated reports of melanoma developing or being exacerbated during levodopa therapy continue to appear. However, in a survey of 1099 patients with primary cutaneous malignant melanoma only one had taken levodopa.[1] It was concluded that levodopa therapy is not an important factor in the induction of malignant melanoma. Furthermore, use of levodopa in daily doses of up to 4 g with carbidopa in 17 patients with metastatic melanoma failed to provide any evidence that levodopa accelerated the progression of the disease.[2] Reviews[3,4] of these and later reports concluded that the purported link between levodopa and malignant melanoma was tenuous.

For a report of antineoplastic chemotherapy used for the treatment of melanoma reducing the efficacy of levodopa, see under Interactions, below.

1. Sober AJ, Wick MM. Levodopa therapy and malignant melanoma. *JAMA* 1978; **240:** 554–5.
2. Gurney H, *et al.* The use of L-dopa and carbidopa in metastatic malignant melanoma. *J Invest Dermatol* 1991; **96:** 85–7.
3. Siple JF, *et al.* Levodopa therapy and the risk of malignant melanoma. *Ann Pharmacother* 2000; **34:** 382–5.
4. Fiala KH, *et al.* Malignant melanoma and levodopa in Parkinson's disease: causality or coincidence? *Parkinsonism Relat Disord* 2003; **9:** 321–7.

Pregnancy. Levodopa alone and with carbidopa has been associated with fetal abnormalities in *animals* given high doses; no teratogenic effect has been noted with carbidopa alone. However, 2 women with parkinsonism who received levodopa with carbidopa or levodopa alone throughout their pregnancies gave birth to normal infants.[1]

1. Cook DG, Klawans HL. Levodopa during pregnancy. *Clin Neuropharmacol* 1985; **8:** 93–5.

Withdrawal. For adverse effects associated with withdrawal of levodopa, see under Adverse Effects, above.

Interactions

The therapeutic or adverse effects of levodopa may be affected by interactions with a variety of drugs. Mechanisms may include effects on catecholamine metabolising enzymes, neurotransmitters, or receptor sites, effects on the endocrine system, and effects on gastrointestinal absorption. Drugs that modify gastric emptying may affect the absorption of levodopa.

Antibacterials. A study[1] in 7 healthy subjects showed that use of *spiramycin* with levodopa and carbidopa resulted in reduced plasma-levodopa concentrations and an increase in its peripheral metabolism.

A hypertensive reaction and severe tremor occurred when *isoniazid* was given to a patient receiving levodopa;[2] it was not certain whether isoniazid was acting as an MAOI.

1. Brion N, *et al.* Effect of a macrolide (spiramycin) on the pharmacokinetics of -dopa and carbidopa in healthy volunteers. *Clin Neuropharmacol* 1992; **15:** 229–35.
2. Morgan JP. Isoniazid and levodopa. *Ann Intern Med* 1980; **92:** 434.

Antidementia drugs. Increasing the dose of *tacrine* worsened parkinsonian symptoms in an elderly woman with Alzheimer's disease and mild parkinsonism; symptoms responded to levodopa with carbidopa, but recurred when the dose of tacrine was again increased.[1]

1. Ott BR, Lannon MC. Exacerbation of parkinsonism by tacrine. *Clin Neuropharmacol* 1992; **15:** 322–5.

Antidepressants. ***BUPROPION.*** Caution has been advised with bupropion because of reports of a higher incidence of adverse effects during use with levodopa.

MAOIS. Giving levodopa with non-specific MAOIs such as *phenelzine*, *pargyline*, *nialamide*, or *tranylcypromine* may cause dangerous hypertension;[1-4] it is recommended that levodopa should not be given with, or within at least 14 days of stopping, an MAOI. Hypertensive reactions to levodopa with tranylcypromine were inhibited by carbidopa,[5] but licensed product information for preparations containing levodopa with carbidopa or benserazide still contra-indicates their use with MAOIs. The incidence of adverse effects may be increased if levodopa is used with *moclobemide*, a monoamine oxidase type A inhibitor (see Dopaminergics, p.411). *Selegiline*, a monoamine oxidase type B inhibitor, is used to enhance the antiparkinsonian effect of levodopa, see p.818.

4. Sharpe J, *et al.* Idiopathic orthostatic hypotension treated with levodopa and MAO inhibitor: a preliminary report. *Can Med Assoc J* 1972; **107:** 296–300.
5. Teychenne PF, *et al.* Interactions of levodopa with inhibitors of monoamine oxidase and -aromatic amino acid decarboxylase. *Clin Pharmacol Ther* 1975; **18:** 273–7.

SSRIS. There was some evidence from a prescribing study that SSRIs might exacerbate parkinsonism resulting in increased doses of levodopa or addition of adjunctive drugs.[1]

1. van de Vijver DAMC, *et al.* Start of a selective serotonin reuptake inhibitor (SSRI) and increase of antiparkinsonian drug treatment in patients on levodopa. *Br J Clin Pharmacol* 2002; **54:** 168–70.

TRICYCLIC ANTIDEPRESSANTS. Although tricyclic antidepressants have generally been used safely with levodopa,[1] hypertensive crises have occurred in some rare cases. Such events have been reported in patients receiving *amitriptyline* or *imipramine* and levodopa with carbidopa.[2,3] Imipramine has been reported to impair the rate of levodopa absorption,[4] presumably due to its antimuscarinic properties (for the effect of antimuscarinics on the absorption of levodopa, see below).

1. Hunter KR, *et al.* Use of levodopa with other drugs. *Lancet* 1970; **ii:** 1283–5.
2. Rampton DS. Hypertensive crisis in a patient given Sinemet, metoclopramide, and amitriptyline. *BMJ* 1977; **2:** 607–8.
3. Edwards M. Adverse interaction of levodopa with tricyclic antidepressants. *Practitioner* 1982; **226:** 1447–8.
4. Morgan JP, *et al.* Imipramine-mediated interference with levodopa absorption from the gastrointestinal tract in man. *Neurology* 1975; **25:** 1029–34.

TRYPTOPHAN. See Amino Acids under Nutritional Agents, below.

Antiepileptics. *Phenytoin* has been shown to diminish the therapeutic effect of levodopa in patients with parkinsonism or chronic manganese poisoning.[1] The mechanism of the interaction was considered uncertain.

1. Mendez JS. Diphenylhydantoin: blocking of levodopa effects. *Arch Neurol* 1975; **32:** 44–6.

Antihypertensives. Use of levodopa with *guanethidine* may cause increased hypotension.[1] *Clonidine* has been reported to inhibit the therapeutic effect of levodopa, possibly by stimulating central alpha-adrenoceptors.[2] *Methyldopa* and levodopa may enhance each other's therapeutic or adverse effects, although there has been mention of the inhibitory effect of methyldopa on the therapeutic response to levodopa.[3,4] *Reserpine and other rauwolfia alkaloids* may oppose the antiparkinsonian effects of levodopa by central depletion of dopamine; UK licensed product information advises that use together should be avoided.

1. Hunter KR, *et al.* Use of levodopa with other drugs. *Lancet* 1970; **ii:** 1283–5.
2. Shoulson I, Chase TN. Clonidine and the anti-parkinsonian response to -dopa or piribedil. *Neuropharmacology* 1976; **15:** 25–7.
3. Cotzias GC, *et al.* -Dopa in Parkinson's syndrome. *N Engl J Med* 1969; **281:** 272.
4. Kofman O. Treatment of Parkinson's disease with -dopa: a current appraisal. *Can Med Assoc J* 1971; **104:** 483–7.

Antimuscarinics. Antimuscarinic antiparkinsonian drugs may enhance the therapeutic effects of levodopa but by delaying gastric emptying they may also reduce its absorption.[1]

1. Algeri S, *et al.* Effect of anticholinergic drugs on gastro-intestinal absorption of L-dopa in rats and in man. *Eur J Pharmacol* 1976; **35:** 293–9.

Antineoplastics. A patient with Parkinson's disease noted[1] that the efficacy of levodopa was reduced each time he received *dacarbazine* for the treatment of melanoma. As serum-dopamine concentrations were unchanged it was suggested[1] that dacarbazine might compete with levodopa at the blood-brain barrier.

1. Merello M, *et al.* Impaired levodopa response in Parkinson's disease during melanoma therapy. *Clin Neuropharmacol* 1992; **15:** 69–74.

Antipsychotics. The therapeutic effects of levodopa may be diminished by CNS dopamine inhibitors including phenothiazine derivatives[1] such as *prochlorperazine.*[2] Butyrophenones such as *haloperidol* and thioxanthenes such as *flupentixol* might be expected to have a similar effect due to their antidopaminergic properties.

1. Yahr MD, Duvoisin RC. Drug therapy of parkinsonism. *N Engl J Med* 1972; **287:** 20–4.
2. Duvoisin RC. Diphenidol for levodopa induced nausea and vomiting. *JAMA* 1972; **221:** 1408.

Anxiolytics. Reversible deterioration of parkinsonism has been reported in patients receiving levodopa who were also given *benzodiazepines* such as *diazepam*,[1,2] *nitrazepam*[1] (although the evidence was equivocal), or *chlordiazepoxide.*[3] In one case parkinsonian symptoms resolved without alteration in the medication.[1]

3. Yosselson-Superstine S, Lipman AG. Chlordiazepoxide interaction with levodopa. *Ann Intern Med* 1982; **96:** 259–60.

Baclofen. Adverse effects including hallucinations, confusion, headache, and nausea and worsening of symptoms have been reported[1,2] in patients with Parkinson's disease taking levodopa when also given baclofen.

Gastrointestinal drugs. *ANTACIDS.* Some studies have suggested that taking an antacid before a dose of levodopa enhances the absorption of levodopa, apparently by enhancing gastric emptying and reducing metabolism of levodopa in the stomach.[1,2] This was particularly marked in a case report in a patient with prolonged gastric emptying time.[1] However, another study in 8 patients with presumably normal gastric motility, only 3 of whom had Parkinson's disease, found no significant increase in overall absorption of levodopa when given with an antacid although there was some evidence of increased absorption in some of the patients.[3] UK licensed product information (*Madopar CR; Roche*) states that antacids reduce the absorption of levodopa from the modified-release preparation by 32%.

3. Leon AS, Spiegel HE. The effect of antacid administration on the absorption and metabolism of levodopa. *J Clin Pharmacol* 1972; **12:** 263–7.

ANTIEMETICS. *Metoclopramide* is a dopamine antagonist and may cause extrapyramidal symptoms including parkinsonism; however, it accelerates gastric emptying and has been reported[1] to increase the rate of levodopa absorption. The importance of timing has been noted[2] since levodopa delays gastric emptying and metoclopramide antagonises this effect. Licensed product information advises caution when using metoclopramide with levodopa. *Domperidone* has been reported to increase the bioavailability of levodopa slightly.[3]

1. Neira WD, *et al.* The effects of cisapride on plasma -dopa levels and the clinical response in Parkinson's disease. *Mov Disord* 1995; **10:** 66–70.

General anaesthetics. The general anaesthetics *cyclopropane* and *halothane* lower the threshold for ventricular arrhythmias to sympathomimetic amines, including dopamine, and should probably not be used within 6 to 8 hours of levodopa.[1,2] Although other general anaesthetics are now usually preferred, it was suggested that, in any case, levodopa could safely be taken before surgery when given with a peripheral dopa-decarboxylase inhibitor.[3]

Nutritional agents. *AMINO ACIDS.* The transport of levodopa into the brain is subject to competition from chemically related L-amino acids, especially the other aromatic amino acids *phenylalanine*, *tyrosine*, *tryptophan*, and *histidine*.[1] A high-protein diet or the large neutral amino acids phenylalanine, *leucine*, or *isoleucine* have been shown to reduce the therapeutic effect of levodopa given by intravenous infusion to parkinsonian patients; such alterations in the absorption and transport of levodopa may contribute to the fluctuating responses seen in Parkinson's disease, the so-called 'on-off' phenomenon[2] (see also Parkinsonism, p.791). In contrast, a study in healthy subjects[3] found that while a low-protein meal appeared to cause a small reduction in levodopa absorption, a high-protein meal had no such effect. Other reported interactions with amino acids include *methionine*-antagonism of the therapeutic effect of levodopa in parkinsonism[4] and *tryptophan*-reduced blood concentrations of levodopa.[5]

IRON SALTS. Levodopa forms complexes with iron salts and ferrous sulfate has reduced bioavailability of levodopa by about 50% in healthy subjects.[1] Giving *ferrous sulfate* to 9 patients with Parkinson's disease receiving levodopa with carbidopa reduced the area under the curve for levodopa by 30%; the reduction was greater than 75% for carbidopa. Although this was associated with deterioration in some patients' disability, the average reduction in efficacy of therapy did not achieve statistical significance.[2]

2. Campbell NRC, *et al.* Sinemet-ferrous sulphate interaction in patients with Parkinson's disease. *Br J Clin Pharmacol* 1990; **30:** 599–605.

PYRIDOXINE. The enzyme responsible for the decarboxylation of levodopa, L-amino acid decarboxylase, is dependent on pyridoxine and pyridoxine supplements have been reported to enhance the peripheral metabolism of levodopa to dopamine leaving less available to cross the blood-brain barrier for central conversion to dopamine;[1-4] pyridoxine therefore inhibits the action of levodopa but this can be stopped by use of a peripheral dopa-decarboxylase inhibitor.[3,4]

Papaverine. Antagonism of the beneficial effects of levodopa in parkinsonism has been reported when patients were also given papaverine,[1,2] and it was recommended that the combination should be avoided. However, a later study[3] in 9 patients receiving levodopa with a peripheral dopa-decarboxylase inhibitor found no changes in the control of Parkinson's disease when they were also given papaverine for 3 weeks.

3. Montastruc JL, *et al.* Does papaverine interact with levodopa in Parkinson's disease? *Ann Neurol* 1987; **22:** 558–9.

Penicillamine. Isolated case reports suggest that penicillamine increases plasma-levodopa concentrations.[1]

1. Mizuta E, *et al.* Effect of -penicillamine on pharmacokinetics of levodopa in Parkinson's disease. *Clin Neuropharmacol* 1993; **16:** 448–50.

Sympathomimetics. It has been suggested that sympathomimetics such as *adrenaline* or *isoprenaline* may enhance the cardiac adverse effects of levodopa.[1]

1. Goldberg LI, Whitsett TL. Cardiovascular effects of levodopa. *Clin Pharmacol Ther* 1971; **12:** 376–82.

Pharmacokinetics

Levodopa is rapidly absorbed from the gastrointestinal tract by an active transport system. Most absorption takes place in the small intestine; absorption is very limited from the stomach, and since decarboxylation may take place in the stomach wall, delays in gastric emptying may reduce the amount of levodopa available for absorption. Peak plasma concentrations are achieved within 2 hours of oral doses. Levodopa is about 10 to 30% bound to plasma proteins.

Levodopa is rapidly decarboxylated by the enzyme aromatic L-amino acid decarboxylase, mostly in the gut, liver, and kidney, to dopamine, which is metabolised in turn, principally to dihydroxyphenylacetic acid (DOPAC) and homovanillic acid (HVA). Other routes of metabolism include *O*-methylation, transamination, and oxidation, producing a variety of minor metabolites including noradrenaline and 3-*O*-methyldopa; the latter may accumulate in the CNS due to its relatively long half-life. The elimination half-life of levodopa itself is reported to be about 30 to 60 minutes.

Unlike dopamine, levodopa is actively transported across the blood-brain barrier, but because of the extent of peripheral decarboxylation very little is available to enter the CNS unless it is given with a peripheral dopa-decarboxylase inhibitor. In the presence of a peripheral dopa-decarboxylase inhibitor the major route of metabolism of levodopa becomes the formation of 3-*O*-methyldopa by the enzyme catechol-*O*-methyltransferase.

About 80% of an oral dose of levodopa is excreted in the urine within 24 hours, mainly as dihydroxyphenylacetic and homovanillic acids. Only small amounts of levodopa are excreted unchanged in the faeces.

Levodopa crosses the placenta and is distributed into breast milk.

Uses and Administration

Levodopa, a naturally occurring amino acid, is the immediate precursor of the neurotransmitter dopamine. The actions of levodopa are mainly those of dopamine (p.1273).

Unlike dopamine, levodopa readily enters the CNS and is used in the treatment of conditions, such as Parkinson's disease, that are associated with depletion of dopamine in the brain. Levodopa is rapidly decarboxylated by peripheral enzymes so that very little unchanged drug is available to cross the blood-brain barrier for central conversion into dopamine. Consequently, levodopa is usually given with a peripheral dopa-decarboxylase inhibitor such as benserazide (p.796) or carbidopa (p.803) to increase the proportion of levodopa that can enter the brain. This enables the dosage of levodopa to be reduced and may diminish peripheral adverse effects, such as nausea and vomiting and cardiac arrhythmias, by blocking the peripheral production of dopamine. It may also provide a more rapid response at the start of therapy.

The majority of patients with Parkinson's disease benefit from levodopa therapy, but after 2 years or more, improvement in disability is gradually lost as the disease progresses and fluctuations in mobility emerge. Postencephalitic parkinsonism responds to levodopa, but a higher incidence of adverse effects has been reported than in the idiopathic form so smaller doses are generally used. Levodopa has also been used to control the neurological symptoms of chronic manganese poisoning, which resemble those of parkinsonism. It should not be used in antipsychotic-induced parkinsonism.

Levodopa has an effect on pituitary function as a result of its conversion to dopamine. It may enhance growth hormone secretion and has been used diagnostically as a provocative test for growth hormone deficiency. Levodopa also inhibits prolactin secretion.

Response to levodopa varies considerably between patients. **Treatment of parkinsonism** should begin with small doses increased gradually, ideally to a dose that improves mobility without producing adverse effects. Levodopa should be taken with or after meals, although in later disease, it may be preferable to take it on an empty stomach (see Precautions, above). Once established, maintenance doses may need to be reduced as the patient ages. When given **without a peripheral dopa-decarboxylase inhibitor** (which is rare) a suggested initial oral dose is 125 mg twice daily increased gradually every 3 to 7 days, according to response, to up to 8 g daily in divided doses. The intervals between doses should be adjusted to meet individual needs; many patients find 4 or 5 divided doses daily to be satisfactory although some may require smaller, more frequent doses in order to control fluctuations in mobility. Maximum improvement may take up to 6 months or longer to occur.

When given **with a peripheral dopa-decarboxylase inhibitor** lower doses of levodopa are used. As high central dopamine concentrations can be achieved more quickly, both beneficial and adverse effects tend to occur more rapidly than with levodopa alone and patients should be monitored carefully. In those already receiving levodopa the drug should be stopped and benserazide or carbidopa with levodopa started on the next day or after 24 hours if the patient was receiving a modified-release preparation of levodopa.

Benserazide is given as the hydrochloride but doses are expressed in terms of the base. Benserazide hydrochloride 28.5 mg is equivalent to about 25 mg of benserazide. Benserazide is usually given with levodopa in the ratio of 1 part of benserazide base to 4 parts of levodopa (co-beneldopa) and the doses for co-beneldopa that follow are expressed in terms of the levodopa component.

- An initial oral dose for *patients not previously treated with levodopa* is levodopa 50 mg three or four times daily increased gradually in increments of levodopa 100 mg once or twice weekly, according to response. If the disease is at an advanced stage, the initial starting dose may be increased to levodopa 100 mg three times daily. For some elderly patients, an initial dose of levodopa 50 mg once or twice daily, increased by 50 mg every third or fourth day, may be suitable. Maintenance doses usually lie within the range of levodopa 400 to 800 mg daily in divided doses, although most patients require no more than 600 mg daily. If optimal improvement has not been achieved after several weeks at the average dose, further increases may be made with caution; it is rarely necessary to give more than 1 g of levodopa daily.
- The initial dose of levodopa given with benserazide in *patients previously treated with levodopa alone* should be about 10 to 15% of the dose previously being taken, thus levodopa 300 mg would be appropriate for a patient previously taking levodopa 2 g daily. For *patients previously treated with other levodopa/dopa-decarboxylase inhibitor combinations* an initial dose is levodopa 50 mg given three or four times daily. In either situation, the dose may then be adjusted in a similar manner as described for previously untreated patients.
- Modified-release capsules containing the equivalent of benserazide 25 mg with levodopa 100 mg are available to reduce fluctuations in response to immediate-release preparations. For *patients not already receiving levodopa* the initial dose is one capsule three times daily adjusted every 2 to 3 days according to response; it is recommended that initial dosages should not exceed 600 mg of levodopa daily. For *patients already receiving an immediate-release preparation* of levodopa with benserazide, initially one capsule should be substituted for every 100 mg of levodopa and should be given at the same dosage frequency as before; increases in dosage can then be made every 2 to 3 days according to response. An average of 50% more levodopa may be required compared with previous therapy and titration may take up to 4 weeks. *Supplementary doses* of an immediate-release preparation of benserazide with levodopa may also be required with the first morning dose.

Carbidopa is usually given with levodopa (co-careldopa) as tablets in the ratio of 1 to 4 or 1 to 10, which allows dosage adjustments of either drug for individual patients. Carbidopa is given as the hydrous base although doses are expressed in terms of the anhydrous base; hydrous carbidopa 10.8 mg is equivalent to about 10 mg of anhydrous carbidopa. Full inhibition of peripheral dopa-decarboxylase is reported to be achieved with 70 to 100 mg of carbidopa daily.

- A suggested initial oral dose for *patients not previously treated with levodopa* is carbidopa 25 mg with levodopa 100 mg three times daily, increased gradually, in increments of carbidopa 12.5 mg with levodopa 50 mg or carbidopa 25 mg with levodopa 100 mg every day or on alternate days, as necessary. The usual maintenance dosage range is carbidopa 75 to 200 mg with levodopa 750 mg to 2 g daily in divided doses. Carbidopa doses greater than 200 mg daily are not generally exceeded.
- The initial dose of levodopa with carbidopa in *patients previously treated with levodopa alone* should be about 20 to 25% of the dose previously being taken, thus for patients taking less than 1.5 g of levodopa daily a suggested initial dose is carbidopa 25 mg with levodopa 100 mg given three or four times daily; a suggested initial dose for patients taking more than 1.5 g of levodopa daily is carbidopa 25 mg with levodopa 250 mg given three or four times daily. For *patients previously treated with other levodopa/dopa-decarboxylase inhibitor combinations* an initial dose should provide a similar daily amount of levodopa.
- Modified-release tablets containing carbidopa with levodopa in the ratio of 1 to 4 are available to reduce fluctuations in response to immediate-release preparations. For *patients not already receiving levodopa* therapy, or for *those currently receiving levodopa alone*, the initial dose is carbidopa 50 mg with levodopa 200 mg twice daily, adjusted according to response, at intervals of not less than 3 days. It is recommended that for patients who are not already receiving levodopa initial dosages should not exceed 600 mg of levodopa daily. For *patients already receiving an immediate-release preparation* of carbidopa with levodopa, the initial dose of the modified-release preparation should provide a similar daily amount of levodopa, but the dosing intervals should be prolonged and are normally between 4 to 12 hours. The initial substitution dose of the modified-release preparation should provide no greater than 10% more levodopa than was previously given for doses of levodopa exceeding 900 mg daily. Doses and intervals may then be altered according to clinical response, allowing at least 3 days between adjustments. Up to 30% more levodopa may be required in the modified-release preparation than was previously given in the immediate-release preparation. Average maintenance doses of modified-release preparations lie within the range of carbidopa 100 mg with levodopa 400 mg to carbidopa 400 mg with levodopa 1.6 g daily in divided doses. *Supplementary doses* of an immediate-release preparation of carbidopa with levodopa may be required in some patients.

Combination preparations of levodopa with carbidopa and the catechol-*O*-methyltransferase (COMT) inhibitor **entacapone** are also available; each tablet contains levodopa and carbidopa in a ratio of 4 to 1 with entacapone 200 mg. Such preparations are indicated for patients with end-of-dose motor fluctuations not stabilised on levodopa/peripheral dopa-decarboxylase inhibitor treatment. Patients should only take one combination tablet for each dose.

- *Patients previously treated with an immediate-release preparation of levodopa with a peripheral dopa-decarboxylase inhibitor and separate entacapone* should be transferred to the combination preparation at a dose that provides similar or slightly higher amounts of levodopa.
- For *patients not currently taking entacapone*, the dose of the combination preparation should normally provide a similar or slightly lower dose of levodopa to that previously taken. However, patients with *dyskinesia* or taking *levodopa in doses above 800 mg daily* should start entacapone as a separate medication before being transferred to the combination preparation, as a 10 to 30% reduction in their levodopa dose may be needed when starting combination therapy, especially if levodopa is being given with benserazide.

In some countries a gel formulation of levodopa 20 mg/mL with carbidopa 5 mg/mL is available for continuous infusion by an ambulatory pump into the duodenum. It is indicated for the treatment of advanced levodopa-responsive Parkinson's disease with severe motor fluctuations when other available combination therapy has not been satisfactory. A positive test of the clinical response via a temporary nasoduodenal tube is required before a permanent tube is inserted into the duodenum or upper jejunum. The total daily dose comprises of 3 individually-adjusted doses, which are expressed in terms of the levodopa component as follows:

- the *morning bolus dose*, based on the patient's previous morning intake of levodopa, is usually 100 to 200 mg infused over 10 to 30 minutes and should not exceed 300 mg
- the *continuous maintenance dose*, based on the patient's previous daily intake of levodopa, is usually 40 to 120 mg/hour infused over 16 hours, adjustable in steps of 2 mg/hour to within a range of 20 to 200 mg/hour; higher doses may be needed in exceptional cases
- *extra bolus doses*, given when required, are usually between 10 to 40 mg/hour although higher doses may be needed in exceptional cases; the maintenance dose should be increased if more than 5 bolus doses are needed daily

After the initial dose setting, further dose adjustments should be made over a few weeks. If medically justified, it may be administered during the night.

Melevodopa, the methyl ester of levodopa, has been used orally as the hydrochloride with carbidopa in some countries for parkinsonism. The ethyl ester of levodopa, etilevodopa, is under study.

Administration. A small crossover study involving 24 patients with severe Parkinson's disease found that intraduodenal infusion of a levodopa and carbidopa gel preparation for 3 weeks was clinically superior to individually optimised conventional regimens.[1] Long-term experience (up to 7 years) in a limited number of patients has suggested that intraduodenal infusion is a good alternative for those with advanced disease and disabling motor fluctuations.[2] A gel formulation of levodopa 20 mg/mL with carbidopa 5 mg/mL is available in some countries for intraduodenal infusion.

2. Nilsson D, *et al.* Duodenal levodopa infusion in Parkinson's disease: long-term experience. *Acta Neurol Scand* 2001; **104:** 343–8.

Drug-induced extrapyramidal disorders. The management of drug-induced extrapyramidal disorders is discussed under the Adverse Effects of Chlorpromazine on p.971. Although the use of dopamine agonists, especially levodopa, to overcome antipsychotic-induced blockade of dopamine receptors might appear rational, levodopa has generally been reported to be ineffective or to increase psychiatric symptoms.

Dysphagia. Results of a small study[1] have suggested that levodopa may improve the impaired swallowing reflex in patients with basal ganglia infarctions and thereby help to prevent aspiration pneumonia.

1. Kobayashi H, *et al.* Levodopa and swallowing reflex. *Lancet* 1996; **348:** 1320–1.

Dystonias. A dystonia is a syndrome of sustained muscle contractions, frequently causing twisting and repetitive movements or abnormal postures; it may also have additional myoclonic or tremulous components. Typically it starts as a focal dystonia localised in one part of the body and to begin with may appear only during a specific motor act (action dystonia). If the syndrome is progressive the dystonias may become apparent at rest and spread first to more than one part of the body (segmental dystonia) and may eventually affect most or all of the body (generalised dystonia). Progression of the dystonia appears to be related to age of onset. Dystonia beginning in childhood usually starts in the legs and progresses to become segmental or generalised, whereas in adults the dystonia usually starts in other parts of the body and rarely becomes generalised. Examples of focal dystonias are blepharospasm (affecting the eye and surrounding facial muscles), writer's cramp (hand and arm), spasmodic torticollis (neck), spasmodic dysphonia, or dystonic dysphagia (larynx or pharynx), and leg dystonias. Some dystonias may be associated with metabolic disorders such as Wilson's disease or Lesch-Nyhan syndrome; with neurological disorders such as Huntington's disease; or with other causes including head trauma, manganese or carbon disulfide toxicity, or the adverse effects of antipsychotics or antiparkinsonian drugs. However, in the majority of cases the disease is idiopathic.

There are no cures for most types of dystonia, but with appropriate **management** symptomatic relief is possible in many patients.[1-5]

- It has been suggested that all children and adolescents presenting with dystonia, particularly starting in the legs, should first be given a trial with *levodopa*.[1,3,5] Although not licensed for children in the UK, the *BNFC* states that children aged 3 months and older with dopamine-sensitive dystonias, including dystonic cerebral palsy, may be given 250 micrograms/kg of levodopa (with carbidopa in the ratio of 4 to 1) two to three times daily increased according to response every 2 to 3 days to a maximum of 1 mg/kg of levodopa three times daily. Another suggested regimen is to gradually build up to a dose of levodopa 200 mg with carbidopa 50 mg given three times daily and to maintain this dose for 3 months; if there is no useful response in this period the drug is withdrawn.[1] Where there is benefit it is usually dramatic and is sustained as long as the drug is taken, which may be more than 10 years in some cases, in general without the long-term problems associated with levodopa for parkinsonism (see p.791).
- In children and adolescents who fail to respond to levodopa an *antimuscarinic* such as trihexyphenidyl is second choice; the *BNFC* also suggests using benzatropine or procyclidine. Adverse effects are minimised by starting with a low dose which is then gradually increased. General experience indicates that about half of all children and adolescents benefit from antimuscarinics; adults tolerate the drug less well and only about a fifth of adult patients with focal dystonia benefit.
- In patients who do not respond to levodopa or high-dose antimuscarinics other drugs may be used. Many benefit from *benzodiazepines* such as diazepam; a few have responded to *baclofen* or *carbamazepine*. *Antipsychotics* are sometimes useful but carry the risk of inducing tardive dyskinesia. *Tetrabenazine* carries less risk of tardive dyskinesia but may induce depression. In very severe dystonia combination therapy may be required: tetrabenazine with pimozide and trihexyphenidyl is sometimes effective.
- In patients refractory to oral therapy *intrathecal* baclofen, or surgery may be tried.
- The response in patients with adult onset focal dystonia is usually poor. However, the use of *botulinum A toxin* can produce relief in blepharospasm, spasmodic torticollis, and spasmodic dysphonia, and is under investigation for writer's cramp and other occupational dystonias. In some patients with generalised and segmental dystonia, botulinum A toxin injected into the most disabling or painful muscles has been used as adjunctive therapy. Local injections into the affected muscles produce weakness over the next week or so, thereby reducing or abolishing dystonic spasms. The effect lasts some 2 to 4 months. *Botulinum B toxin* has also been used in the management of spasmodic torticollis.

Further details of the management of blepharospasm and spasmodic torticollis can be found under Botulinum Toxins on p.1891. For a discussion of the management of antipsychotic-induced dystonic reactions, see Extrapyramidal Disorders under Adverse Effects of Chlorpromazine, p.971.

Hepatic encephalopathy. For the view that the evidence does not support the use of dopaminergics such as levodopa in the management of hepatic encephalopathy see p.1697.

Neuroleptic malignant syndrome. There have been isolated reports[1-4] that levodopa used alone or with bromocriptine has been successful in the treatment of patients with neuroleptic malignant syndrome (p.972). However, bromocriptine is usually preferred when a dopaminergic is required for the treatment of this condition.

Parkinsonism. Levodopa is the mainstay in the treatment of Parkinson's disease (p.791) but opinion varies on when it should be used in the course of the disease. Most patients respond to levodopa initially but after a few years benefit may be reduced. There may be problems with dyskinesias and psychiatric effects and fluctuations in mobility necessitating careful dosage adjustment or the use of adjunctive drugs. For most patients treatment with levodopa eventually becomes necessary, but many neurologists delay initial treatment with levodopa because of the increased risk of motor complications. New patients, especially younger patients, therefore often begin treatment with a dopamine agonist, with levodopa reserved for the elderly, the frail, or those with intercurrent illness or more severe symptoms. Levodopa should be given with a peripheral dopa-decarboxylase inhibitor; a peripheral catechol-*O*-methyltransferase (COMT) inhibitor may also be necessary for patients experiencing fluctuations in disability related to levodopa and dopa-decarboxylase inhibitor combinations. The various methods used for the pharmacokinetic optimisation of levodopa therapy as Parkinson's disease progresses include timing of doses, the use of modified-release formulations, oral solutions (but see Stability, p.804) and dispersible formulations for immediate absorption, the timing of food intake, and the use of other drugs to increase the absorption of levodopa. In some countries a gel formulation of levodopa with carbidopa is available for intraduodenal infusion.

Pituitary and hypothalamic disorders. ***DIAGNOSIS AND TESTING.*** Diminished growth hormone reserve is one of the earliest functional abnormalities in anterior pituitary failure and, since dopamine is believed to stimulate growth hormone secretion, levodopa has been used as a provocative test for the diagnosis of growth hormone deficiency.[1,2] Levodopa 500 mg has been given orally after an overnight fast and serum concentrations of growth hormone measured hourly at 0 to 3 hours; children may be given 10 mg/kg to a maximum of 500 mg. Transient nausea, vomiting, vertigo, and hypotension may occur and the patient should be kept recumbent during the test. A normal response is an increase in serum concentration of growth hormone of more than 5 nanograms/mL or to a level of more than 10 nanograms/mL, although 10 to 15% of normal subjects may not respond. However, there is some dispute as to whether stimulated growth hormone secretion tests are superior to measurements of circulating somatomedins in detecting growth hormone deficiency.[3-5] For a discussion of the management of growth retardation, including the problems of accurate diagnosis, see p.1798.

Sleep-associated movement disorders. The aetiology of *restless legs syndrome* and *periodic limb movements in sleep* is obscure and treatment has been largely empirical (p.958). Few of the treatments tried in these often co-existent disorders have been studied in a controlled manner but small controlled studies[1-6] have reported beneficial effects such as improved sleep quality and reduced leg movements from levodopa used with a peripheral dopa-decarboxylase inhibitor. Most patients received a bedtime dose of 50 to 200 mg of levodopa with possible additional doses during the night. A 1-year open-label extension study[7] confirmed the continued efficacy and safety of levodopa in patients with restless legs syndrome; the authors recommended a maximum daily dose of 400 mg levodopa to decrease the risk of exacerbation or rebound symptoms during the day. However, long-acting dopaminergic agonists are preferred in order to avoid the complications associated with levodopa.

Levodopa has also been reported to have been of benefit in a study of 10 patients with *sleep bruxism*.[8]

Lisuride Maleate *(BANM, rINNM)*

Lisurid Maleat; Lisuride, Maléate de; Lisuridi Hydrogenomaleas; Lisuridi Maleas; Lisuridivetymaleaatti; Lisuridvätemaleat; Lysuride Maleate; Maleato de lisurida; Methylergol Carbamide Maleate. 3-(9,10-Didehydro-6-methylergolin-8α-yl)-1,1-diethylurea hydrogen maleate; 8-Decarboxamido-8-(3,3-diethylureido)-D-lysergamide maleate.

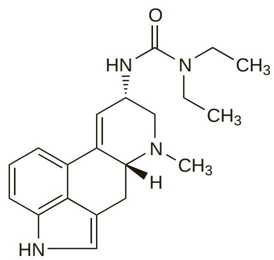
Лизурида Малеат

$C_{20}H_{26}N_4O,C_4H_4O_4$ = 454.5.

CAS — 18016-80-3 (lisuride); 19875-60-6 (lisuride maleate).

ATC — G02CB02; N02CA07.

ATC Vet — QG02CB02; QN02CA07.



(lisuride)

Adverse Effects and Precautions

As for Bromocriptine, p.798. Infusion of lisuride in parkinsonian patients has been associated with severe psychiatric adverse effects.

Effects on mental function. For reports of daytime somnolence occurring in patients receiving dopamine agonists including lisuride, see under Adverse Effects of Levodopa, p.805.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including lisuride, see under Adverse Effects of Bromocriptine, p.799.

Porphyria. Lisuride maleate is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

As for Bromocriptine, p.800.

Pharmacokinetics

◊ Plasma concentrations varied widely after a single oral dose of lisuride maleate 300 micrograms in 11 patients with Parkinson's disease.[1] Absorption was rapid and the mean plasma elimination half-life was 2.2 hours. Only a mean of 0.05% of the dose was excreted unchanged in the urine in 24 hours. The mean oral bioavailability of lisuride maleate has been reported[2] to be 10% after a 100-microgram dose and 22% after a 300-microgram dose.

A single dose of lisuride 25 micrograms given by intravenous, intramuscular, or subcutaneous injection reduced plasma-prolactin concentrations by up to 60% in 11 of 12 healthy subjects, the effect lasting for about 10 hours.[3] Plasma-lisuride concentrations after intravenous injection fell in 2 phases with half-lives of 14 minutes and 1.5 hours, respectively. Peak plasma concentrations after subcutaneous and intramuscular injection were obtained after 12 and 15 minutes, respectively.

3. Krause W, *et al*. The pharmacokinetics and pharmacodynamics of lisuride in healthy volunteers after intravenous, intramuscular, and subcutaneous injection. *Eur J Clin Pharmacol* 1991; **40:** 399–403.

Uses and Administration

Lisuride maleate, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p.798). It is also reported to have serotonergic activity. It is used similarly in the management of Parkinson's disease and has been used in disorders associated with hyperprolactinaemia. It is also used to suppress puerperal lactation for medical reasons; it is not recommended for the routine suppression of physiological lactation or for the treatment of postpartum breast pain and engorgement that can be adequately relieved with simple analgesics and breast support. Lisuride has been used in some countries for the treatment of acromegaly, and for the prophylaxis of migraine.

In the management of **Parkinson's disease** lisuride maleate has been given alone or added to treatment in patients having 'on-off' fluctuations in control with levodopa. It is normally given orally; doses should be taken with food. Initially 200 micrograms is taken at bedtime and additional doses of 200 micrograms may be added, at intervals of one week, first at midday and then in the morning. Further increases are made, until an optimum response is obtained, by adding 200 micrograms each week using the same sequence of increases, starting with the bedtime dose; dosage should not normally exceed 5 mg daily in divided doses.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels, although they are less effective than somatostatin analogues (p.1798). While bromocriptine has been the main dopamine agonist used, lisuride has been used in some countries, typically in a dose of 100 micrograms three times daily.

Hyperprolactinaemia and prolactinomas. Dopamine agonists have been widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (p.2079). Lisuride has been used as an alternative to bromocriptine. There is a report of plasma-prolactin concentrations being reduced to normal in 4 female patients with macroprolactinomas given lisuride 400 to 800 micrograms daily for 2 years.[1] Subsequent dosage reduction in 3 was followed by a rise in prolactin values. In the fourth patient prolactin remained in the normal range when the dose was progressively reduced from 400 to 50 micrograms daily, although complete withdrawal was followed by an increase in prolactin concentration within 3 months.

Vaginal dosage of lisuride has been studied in an attempt to avoid adverse effects associated with oral therapy. In a study[2] involving 40 women with hyperprolactinaemia a 200-microgram standard oral tablet placed in the vagina at night produced a similar reduction in prolactin concentrations to that obtained with 400 micrograms taken orally and was better tolerated.

1. Liuzzi A, *et al*. Low doses of dopamine agonists in the long-term treatment of macroprolactinomas. *N Engl J Med* 1985; **313:** 656–9.
2. Tasdemir M, *et al*. Vaginal lisuride for hyperprolactinaemia. *Lancet* 1995; **346:** 1362.

Lactation inhibition. Lisuride is used in some countries for the prevention of puerperal lactation (p.2003). However, the routine use of dopaminergics is not recommended for the suppression of physiological lactation.

Mastalgia. In a small placebo-controlled study,[1] lisuride 200 micrograms daily was effective in the treatment of cyclical mastalgia. However, since mastalgia (p.2092) can improve spontaneously, treatment should rarely be considered unless pain has been present for about 6 months.

1. Kaleli S, *et al*. Symptomatic treatment of premenstrual mastalgia in premenopausal women with lisuride maleate: a double-blind placebo-controlled randomized study. *Fertil Steril* 2001; **75:** 718–23.

Migraine. Although lisuride has been used in some countries for the prophylaxis of migraine (p.616) it is not usually considered to be the drug of choice or even one of the main alternatives.

Parkinsonism. While some neurologists use dopamine agonists such as lisuride early in the treatment of parkinsonism (p.791) in an attempt to delay therapy with levodopa, others reserve them for adjunctive use when levodopa is no longer effective alone or cannot be tolerated. They are sometimes useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations in mobility in the later stages of the disease.

Administration. Lisuride has been of benefit when given by continuous intravenous or subcutaneous infusion in patients having fluctuations in mobility with levodopa therapy[1-4] but severe psychiatric effects have been associated with the use of these routes.[3] Transdermal lisuride is also being investigated for the treatment of Parkinson's disease and restless legs syndrome.[5,6]

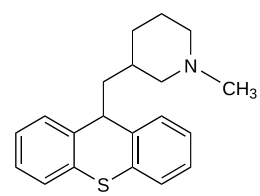
Метиксена Гидрохлорид

$C_{20}H_{23}NS,HCl,H_2O$ = 363.9.

CAS — 4969-02-2 (metixene); 1553-34-0 (anhydrous metixene hydrochloride); 7081-40-5 (metixene hydrochloride monohydrate).

ATC — N04AA03.

ATC Vet — QN04AA03.



(metixene)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Metixene Hydrochloride). A white or almost white, crystalline or fine crystalline powder. Soluble in water, in alcohol, and in dichloromethane. A 1.8% solution in water has a pH of 4.4 to 5.8. Protect from light.

Profile

Metixene hydrochloride is a tertiary antimuscarinic with actions similar to those of atropine (p.1219); it also has antihistaminic and direct antispasmodic properties.

It is used for the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. The usual oral dose of metixene hydrochloride is 2.5 mg three times daily initially, gradually increased according to response to a total of 15 to 60 mg daily in divided doses.

Metixene hydrochloride has also been used in preparations to relieve gastrointestinal spasms.

(*RS*)-Dimethyl[2-(2-methylbenzhydryloxy)ethyl]amine hydrochloride.

Орфенадрина Гидрохлорид

$C_{18}H_{23}NO,HCl$ = 305.8.

CAS — 341-69-5.

ATC — N04AB02.

ATC Vet — QN04AB02.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Orphenadrine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in alcohol. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Orphenadrine may cause insomnia.

Abuse. A 23-year-old schizophrenic man, whose treatment included orphenadrine 100 mg three times daily, obtained illicit supplies and increased the dose for euphoric effect.[1] On one occasion he had an epileptic convulsion after a 600-mg dose.

See also under Trihexyphenidyl Hydrochloride, p.820.

1. Shariatmadari ME. Orphenadrine dependence. *BMJ* 1975; **3:** 486.

Overdosage. A report[1] of acute poisoning with orphenadrine after massive overdosage in a schizophrenic patient, who responded to intensive supportive treatment, including large doses of adrenaline, dopamine, and dobutamine to restore blood pressure following asystole. Between 1977 and 1980 twelve deaths due to orphenadrine were recorded by the UK National Poisons Unit.

1. Clarke B, *et al*. Acute poisoning with orphenadrine. *Lancet* 1985; **i:** 1386.

Porphyria. Orphenadrine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Withdrawal. A suspected withdrawal syndrome was reported in a 56-year-old woman who showed slow neurological postoperative recovery after her orphenadrine treatment had been stopped abruptly;[1] her status improved when the drug was restarted.

1. Esler MD, *et al*. Postoperative orphenadrine withdrawal. *Br J Anaesth* 2000; **85:** 497.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220). Orphenadrine is an inhibitor of the cytochrome P450 isoenzyme CYP2B6, which is involved in the metabolism of bupropion to its major metabolite; licensed product information advises that orphenadrine should be used with caution in patients also receiving bupropion.

Chlorpromazine. For the effect of orphenadrine on plasma concentrations of chlorpromazine, see Antiparkinsonian Drugs, p.974.

Dextropropoxyphene. A suggested interaction between orphenadrine and dextropropoxyphene was open to question.[1,2]

1. Pearson RE, Salter FJ. Drug interaction? — orphenadrine with propoxyphene. *N Engl J Med* 1970; **282:** 1215.
2. Puckett WH, Visconti JA. Orphenadrine and propoxyphene (cont.). *N Engl J Med* 1970; **283:** 544.

Pharmacokinetics

Orphenadrine is readily absorbed from the gastrointestinal tract and after intramuscular injection. It is almost completely metabolised to at least 8 metabolites. It is mainly excreted in the urine as metabolites and small amounts of unchanged drug. The half-life of orphenadrine has been reported to be 14 hours (but see below).

Half-life. While the mean elimination half-life of orphenadrine in 5 healthy subjects given a single dose of the hydrochloride was found to be 15.5 hours, elimination half-lives of 30.5 and 40 hours were calculated in 2 patients given repeated oral doses.[1]

1. Labout JJM, *et al*. Difference between single and multiple dose pharmacokinetics of orphenadrine hydrochloride in man. *Eur J Clin Pharmacol* 1982; **21:** 343–50.

Uses and Administration

Orphenadrine, which is a congener of diphenhydramine (p.577) without sharing its soporific effect, is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820). It also has weak antihistaminic and local anaesthetic properties. Orphenadrine is used as the hydrochloride and the citrate; doses are expressed in terms of the relevant salt.

Orphenadrine is used as the hydrochloride in the symptomatic treatment of **parkinsonism** (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. The initial oral dose of orphenadrine hydrochloride is 150 mg daily in divided doses gradually increased by 50 mg every 2 or 3 days according to response; the usual maintenance dose is in the range of 150 to 300 mg daily, but some patients may require a total of up to 400 mg daily. Orphenadrine hydrochloride has also been given intramuscularly.

Orphenadrine is also used as the citrate to relieve pain due to **skeletal muscle spasm**. It is given orally in a dose of 100 mg twice daily or by intramuscular or slow intravenous injection in a dose of 60 mg which has been repeated every 12 hours.

Combinations of orphenadrine with an NSAID, usually diclofenac, or with paracetamol, have been used in the treatment of musculoskeletal and joint disorders.

Hiccup. Orphenadrine citrate has been used in some countries for the treatment of intractable hiccup. For the management of intractable hiccups see under Chlorpromazine, p.976.

Muscle and joint disorders. References to the use of orphenadrine in the management of leg cramps and other painful conditions associated with skeletal muscle spasm,[1,2] and with diclofenac in osteoarthritis and other musculoskeletal disorders.[3,4]

Pergolide Mesilate *(BANM, rINNM)*

LY-127809; Mesilato de pergolida; Pergolid Mesilat; Pergolid mesylát; Pergolide, mésilate de; Pergolide Mesylate *(USAN)*; Pergolidi mesilas; Pergolidimesilaatti; Pergolidmesilat; Pergolid-mezilát; Pergolido mesilatas. 8β-Methylthiomethyl-6-propylergoline methanesulphonate; Methyl (8*R*,10*R*)-6-propylergolin-8-ylmethyl sulphide methanesulphonate.

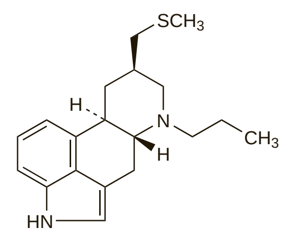
Перголида Мезилат

$C_{19}H_{26}N_2S,CH_4O_3S$ = 410.6.

CAS — 66104-22-1 (pergolide); 66104-23-2 (pergolide mesilate).

ATC — N04BC02.

ATC Vet — QN04BC02.



(pergolide)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Pergolide Mesilate). A white or almost white crystalline powder. Slightly soluble in water, in alcohol, and in dichloromethane; very slightly soluble in acetone; sparingly soluble in methyl alcohol. Protect from light.

USP 31 (Pergolide Mesylate). A white to off-white powder. Slightly soluble in water, in dehydrated alcohol, and in chloroform; very slightly soluble in acetone; practically insoluble in ether; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Bromocriptine, p.798.

An increased incidence of uterine neoplasms has been reported in *rodents* given high doses of pergolide mesilate.

Effects on mental function. For reports of daytime somnolence occurring in patients receiving dopamine agonists including pergolide, see under Adverse Effects of Levodopa, p.805.

Fibrosis. For reports of fibrotic reactions occurring in patients with Parkinson's disease receiving ergot derivative dopamine agonists including pergolide, see under Adverse Effects of Bromocriptine, p.799.

In Australia,[1] Canada,[2], and Europe[3] regulatory authorities recommended that patients undergo a cardiovascular evaluation before starting treatment with pergolide; periodic clinical monitoring for development of valvular disease or fibrosis is also recommended. Doses of pergolide above 3 mg daily are not recommended by the EMEA.[3] Furthermore, use is restricted to patients who are intolerant of, or who fail to respond to, non-ergot drug treatment and it is contra-indicated in patients with a history of fibrotic disorders or in those with anatomical evidence of cardiac valvulopathy.[4] In 2007, based on further evidence from 2 studies,[5,6] pergolide was withdrawn from the market in the USA[7] and Canada.[8]

Interactions

As for Bromocriptine, p.800.

Pharmacokinetics

Pergolide mesilate is absorbed from the gastrointestinal tract. It is reported to be about 90% bound to plasma proteins. It is excreted mainly in the urine in the form of metabolites.

◊ References.

1. Blin O. The pharmacokinetics of pergolide in Parkinson's disease. *Curr Opin Neurol* 2003; **16** (suppl 1): S9–S12.

Uses and Administration

Pergolide mesilate, an ergot derivative, is a dopamine D_2-agonist with actions and uses similar to those of bromocriptine (p.800), but in contrast to bromocriptine (a dopamine D_2-agonist) it also has agonist properties at D_1 and D_3 receptors. Pergolide is used in the management of Parkinson's disease as monotherapy, or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response; in the UK pergolide is restricted to patients who are intolerant of, or who fail to respond to, non-ergot drug treatment. Pergolide is given by mouth as the mesilate with doses expressed as the base. Pergolide mesilate 65.3 mg is equivalent to about 50 mg pergolide.

For use as *monotherapy* an initial dose equivalent to 50 micrograms of pergolide is given on the first evening of therapy. The dose is thereafter gradually increased: 50 micrograms twice daily is taken on days 2 to 4, then increased by 100 to 250 micrograms every 3 or 4 days, given in 3 divided doses, up to a daily dose of 1.5 mg at day 28. After day 30, the dose should be increased further by a maximum of 250 micrograms twice a week until an optimum response is achieved. Usual maintenance doses are 2.1 to 2.5 mg daily; doses above 3 mg daily are not recommended by the EMEA. The daily dose is usually given in 3 divided doses.

For use as *adjunctive therapy* with levodopa, pergolide should be introduced gradually and during this period patients can have their levodopa dosage decreased gradually until an optimum response is achieved. The initial dose of pergolide is the equivalent of 50 micrograms daily for the first 2 days, increased gradually by 100 or 150 micrograms every third day over the next 12 days of therapy. Further increases of 250 micrograms may then be made every third day until an optimum response is achieved. A usual maintenance dose is 3 mg daily; doses above 3 mg daily are not recommended by the EMEA. The daily dose is usually given in 3 divided doses.

Acromegaly. Dopaminergics can produce a paradoxical reduction in growth hormone secretion and may be used in the treatment of acromegaly as adjunctive therapy to surgery, radiotherapy, or somatostatin analogues to reduce circulating growth hormone levels, although they are less effective than somatostatin analogues (p.1798). While bromocriptine has been the main dopamine agonist used pergolide has also been tried.[1]

1. Kleinberg DL, *et al.* Pergolide for the treatment of pituitary tumors secreting prolactin or growth hormone. *N Engl J Med* 1983; **309:** 704–9.

Hyperprolactinaemia and prolactinomas. Dopamine agonists are widely used for the treatment of hyperprolactinaemia secondary to a prolactinoma (p.2079). Pergolide has been suggested as an alternative to bromocriptine in this condition.

Studies[1-3] of pergolide mesilate in patients with hyperprolactinaemia indicate that single doses reduce serum-prolactin concentrations for more than 24 hours. In most patients, the effective dose was between 50 and 150 micrograms daily. Adverse effects were similar to those seen with bromocriptine, although some patients who could not take bromocriptine were able to tolerate pergolide (and *vice versa*). Pergolide reportedly lost favour for this indication after reports of an increased incidence of uterine neoplasms in *rodents* receiving high doses. However, licensed product information states that no cases of uterine malignancies have to date been reported in humans receiving pergolide. The long-term outcome of treatment of macroprolactinomas with pergolide has been examined in 23 patients,[4] and efficacy and relative safety of pergolide was demonstrated after an average of 27 months (range: 9 to 64 months) treatment.

4. Freda PU, *et al.* Long-term treatment of prolactin-secreting macroadenomas with pergolide. *J Clin Endocrinol Metab* 2000; **85:** 8–13.

Parkinsonism. Dopamine agonists such as pergolide are often used to begin the treatment of parkinsonism (p.791) in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may sometimes be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations in mobility in the later stages of the disease. Pergolide has a relatively long duration of action compared with other dopamine agonists commonly used. Although the duration of the clinical antiparkinsonian effect of pergolide remains to be determined, studies suggest it is of the order of 5 to 8 hours. Depending on the dose used the response to other dopamine agonists in late parkinsonism is 1 to 4 hours for levodopa, 2 to 4 hours for lisuride, and 4 to 6 hours for bromocriptine.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p.958) is obscure and treatment has largely been empirical although dopaminergic therapy has emerged as a common first-line choice. Pergolide has produced some benefit in a number of studies.[1-6] In a randomised placebo-controlled study,[6] therapeutic effects were observed with mean daily doses of pergolide 400 micrograms after 6 weeks and maintained after 12 months with doses of up to 720 micrograms daily.

Piribedil *(rINN)*

ET-495; EU-4200; Piribédil; Piribedilum. 2-(4-Piperonylpiperazin-1-yl)pyrimidine.

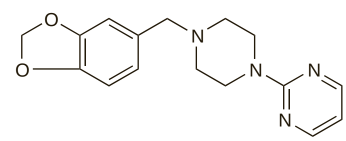
Пирибедил

$C_{16}H_{18}N_4O_2$ = 298.3.

CAS — 3605-01-4.

ATC — N04BC08.

ATC Vet — QN04BC08.



Profile

Piribedil is a non-ergot dopamine agonist that has been given orally in the treatment of parkinsonism and in circulatory disorders. Piribedil mesilate has been given by injection for circulatory disorders. Preparations of piribedil are licensed in some countries for the management of impaired memory and cognitive function in the elderly.

Adverse effects reported include nausea and vomiting, dizziness, hallucinations, confusion, drowsiness, hypothermia, dyskinesias, and occasional changes in liver function.

When used as monotherapy in Parkinson's disease a usual daily oral dose of piribedil is 150 to 250 mg in divided doses; a daily dose of 80 to 140 mg may be suitable when used as an adjunct to levodopa.

Effects on mental function. For reports of daytime somnolence occurring in patients receiving dopamine agonists including piribedil, see under Adverse Effects of Levodopa, p.805.

Parkinsonism. Piribedil is a dopamine D_2-agonist while its metabolite is reported to act on D_1 receptors. It has been mainly used as an adjunct to levodopa therapy in the treatment of Parkinson's disease (p.791).

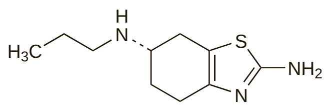
ATC — N04BC05.

ATC Vet — QN04BC05.



(pramipexole)

Adverse Effects and Precautions

As for Bromocriptine, p.798.

Pramipexole should be used with caution in patients with renal impairment and reduced doses are recommended.

Ophthalmological monitoring is recommended at regular intervals or if vision abnormalities occur.

Incidence of adverse effects. References.

1. Etminan M, *et al.* Comparison of the risk of adverse events with pramipexole and ropinirole in patients with Parkinson's disease: a meta-analysis. *Drug Safety* 2003; **26:** 439–44.

Effects on mental function. Pramipexole has been associated with attacks of sudden onset of sleep, sometimes without any prior feeling of drowsiness, that can occur at any time during treatment. Licensed product information states that the incidence of daytime **somnolence** is increased at daily doses of pramipexole hydrochloride higher than 1.5 mg. A retrospective analysis[1] of data to evaluate the incidence and nature of somnolence in patients receiving pramipexole in clinical studies showed that for patients with moderate or severe somnolence, the onset of worst-reported somnolence occurred at a mean daily dose of around 4 mg (range: 0.75 to 4.5 mg).

For further reports of daytime somnolence occurring in patients receiving dopamine agonists including pramipexole, see under Adverse Effects of Levodopa, p.805.

For reference to **pathological gambling** reported in patients with Parkinson's disease receiving dopamine agonists, including pramipexole, see under Levodopa, p.805.

1. Hauser RA, *et al.* Pramipexole-induced somnolence and episodes of daytime sleep. *Mov Disord* 2000; **15:** 658–63.

Interactions

As for Bromocriptine, p.800. Cimetidine is reported to reduce the renal clearance of pramipexole.

Caution is advised when other sedating drugs or alcohol are used with pramipexole because of possible additive effects and the risk of precipitating sudden onset of sleep (see above).

◊ References.

1. Wright CE, *et al.* Influence of probenecid and cimetidine on pramipexole pharmacokinetics. *Clin Pharmacol Ther* 1996; **59:** 183.

Pharmacokinetics

Pramipexole is readily absorbed from the gastrointestinal tract and peak plasma concentrations have been reached within about 2 hours in fasting patients and in about 3 hours when given with food. Oral bioavailability is reported to be about 90%. Pramipexole is widely distributed throughout the body and plasma-protein binding is less than 20%. Metabolism is minimal and more than 90% of a dose is excreted via renal tubular secretion unchanged into the urine. Elimination half-lives of 8 to 12 hours have been reported. On the basis of studies in *rats*, it is thought to be distributed into breast milk.

◊ References.

1. Wright CE, *et al.* Steady-state pharmacokinetic properties of pramipexole in healthy volunteers. *J Clin Pharmacol* 1997; **37:** 520–5.

Uses and Administration

Pramipexole is a non-ergot dopamine agonist with actions similar to those of bromocriptine (p.800). It is used similarly in the management of Parkinson's disease, either alone or as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response. Pramipexole is also used for the treatment of moderate to severe restless legs syndrome. It is given orally as the hydrochloride; doses have been described in terms of the hydrochloride (as below) or of the base. In terms of equivalency:

- pramipexole hydrochloride 125 micrograms is equivalent to about 88 micrograms of pramipexole
- pramipexole hydrochloride 250 micrograms is equivalent to about 180 micrograms of pramipexole
- pramipexole hydrochloride 500 micrograms is equivalent to about 350 micrograms of pramipexole
- pramipexole hydrochloride 1 mg is equivalent to about 700 micrograms of pramipexole

In the treatment of **Parkinson's disease**, the dose of pramipexole should be increased gradually and the dose of levodopa gradually reduced during the dose-titration and maintenance phases until an optimum response is achieved. The initial dose of pramipexole *hydrochloride* is 125 micrograms three times daily increased to 250 micrograms three times daily in the second week and then to 500 micrograms three times daily in the third week according to response. Thereafter the daily dose may be increased if necessary by 750 micrograms at weekly intervals to a maximum of 4.5 mg daily. The dosage should be reduced in patients with renal impairment (see below).

If it is necessary to stop pramipexole therapy, it should be withdrawn gradually. UK licensed product information suggests tapering off the dose of pramipexole hydrochloride at a rate of 750 micrograms daily until a daily dose of 750 micrograms has been reached; thereafter, the dose should be reduced by 375 micrograms daily. US licensed product information suggests that withdrawal should be gradual over a period of 1 week.

Pramipexole is also given as a single daily dose, 2 to 3 hours before bedtime, in the treatment of **restless legs syndrome**. The initial dose of pramipexole *hydrochloride* is 125 micrograms daily. This may be increased if necessary after 4 to 7 days to 250 micrograms daily. Subsequent doses may be increased if necessary by 250 micrograms every 4 to 7 days to a maximum of 750 micrograms daily. Response to therapy should be evaluated after 3 months; if treatment is interrupted for more than a few days, it should be restarted at 125 micrograms daily, and then increased, if required, as described above. For this indication, pramipexole may be withdrawn without gradual tapering of the dose.

Administration in renal impairment. The elimination of pramipexole is dependent on renal function and the dosage of pramipexole hydrochloride should therefore be reduced in patients with renal impairment.

In the treatment of *Parkinson's disease*, the following dosage schedule has been suggested in UK licensed product information for initial therapy adjusted according to the patient's creatinine clearance (CC):

- CC 20 to 50 mL/minute: 125 micrograms given twice daily
- CC less than 20 mL/minute: 125 micrograms once daily

Similar reductions are suggested in US licensed information for patients with a CC of 35 to 59 mL/minute and 15 to 34 mL/minute, respectively.

If renal function declines during maintenance therapy it is recommended that the daily dose of pramipexole should be reduced by the same percentage as the decline in CC.

Lower doses are used in the treatment of *restless legs syndrome* and UK licensed information considers dosage reductions unnecessary in patients with CC of more than 20 mL/minute. US licensed information recommends that the interval between titration steps is increased to 14 days in those patients with CC of 20 to 60 mL/minute.

Parkinsonism. Pramipexole is a dopamine agonist used in the treatment of Parkinson's disease (p.791) as an adjunct to levodopa therapy to reduce 'off' periods with levodopa and ameliorate other fluctuations of mobility in the later stages of the disease. It is also used as monotherapy early in the course of the disease in an attempt to delay therapy with levodopa.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p.958) is obscure and treatment has largely been empirical, although dopaminergic therapy has emerged as a common first-line choice. Low-dose pramipexole has produced some benefit in a number of studies[1-7] and is licensed for the treatment of moderate to severe RLS in some countries.

Procyclidine Hydrochloride

(BANM, rINNM)

Hidrocloruro de prociclidina; Procyclidine, Chlorhydrate de; Procyclidini Hydrochloridum. 1-Cyclohexyl-1-phenyl-3-(pyrrolidin-1-yl)propan-1-ol hydrochloride.

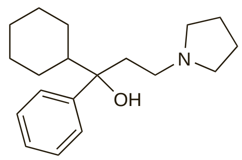
Проциклидина Гидрохлорид

$C_{19}H_{29}NO,HCl = 323.9.$

CAS — 77-37-2 (procyclidine); 1508-76-5 (procyclidine hydrochloride).

ATC — N04AA04.

ATC Vet — QN04AA04.



(procyclidine)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Procyclidine Hydrochloride). A white, odourless or almost odourless, crystalline powder. Sparingly soluble in water; soluble in alcohol; practically insoluble in acetone and in ether. A 1% solution in water has a pH of 4.5 to 6.5.

USP 31 (Procyclidine Hydrochloride). A white crystalline powder, having a moderate characteristic odour. Soluble 1 in 35 of water, 1 in 9 of alcohol, 1 in 6 of chloroform, and 1 in 11 000 of ether; insoluble in acetone. pH of a 1% solution in water is between 5.0 and 6.5. Store in a dry place in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Psychotic episodes may be precipitated in patients with mental disorders when procyclidine is used for the treatment of drug-induced extrapyramidal syndrome.

Abuse. Like other antimuscarinics (see also under Trihexyphenidyl Hydrochloride, p.820) procyclidine has been abused for its euphoriant effects.[1,2]

1. McGucken RB, *et al.* Teenage procyclidine abuse. *Lancet* 1985; **i:** 1514.
2. Dooris B, Reid C. Feigning dystonia to feed an unusual drug addiction. *J Accid Emerg Med* 2000; **17:** 311.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Paroxetine increases plasma-procyclidine concentrations and it is recommended that the dose of procyclidine should be reduced if antimuscarinic effects are seen in patients receiving both drugs.

Pharmacokinetics

Procyclidine hydrochloride is absorbed from the gastrointestinal tract and bioavailability has been reported to be 75% after oral doses; it disappears rapidly from the tissues. Procyclidine given intravenously acts within 5 to 20 minutes and has a duration of effect of up to 4 hours. The mean plasma elimination half-life after oral or intravenous doses is about 12 hours. About one-fifth of an oral dose is metabolised in the liver, mainly by the cytochrome P450 isoenzymes, followed by conjugation with glucuronic acid. A small amount of unchanged drug is excreted in the urine.

◊ References.

1. Whiteman PD, *et al.* Pharmacokinetics and pharmacodynamics of procyclidine in man. *Eur J Clin Pharmacol* 1985; **28:** 73–8.

Uses and Administration

Procyclidine hydrochloride is a tertiary amine antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820). It is used for the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias (but see under Uses and Administration of Levodopa, p.809).

In **parkinsonism**, the initial oral dose of 2.5 mg three times daily may be increased gradually by 2.5 to 5 mg every 2 or 3 days (or by 2.5 mg daily if used for drug-induced extrapyramidal syndrome) until the optimum maintenance dose, usually 10 to 30 mg daily in 3 (or occasionally 4) divided doses, is reached; daily doses of up to 60 mg have occasionally been required. As a rule, postencephalitic patients tolerate and require the larger doses; elderly and arteriosclerotic patients may require smaller doses.

In emergency, 5 to 10 mg may be given by intravenous injection; higher doses have sometimes been used. The intramuscular route has also been employed: 5 to 10 mg may be given as a single injection, repeated if necessary after 20 minutes to a maximum of 20 mg daily. Parenteral doses are usually effective within 5 to 10 minutes but may need 30 minutes to produce relief.

Although not licensed in the UK for management of **dystonias in children**, the *BNFC* suggests oral doses of 1.25 mg 3 times daily in those aged 7 to 12 years, and 2.5 mg 3 times daily in those aged 12 to 18 years. In an emergency, a single dose may be given by intramuscular or intravenous injection to children as follows: aged under 2 years, 0.5 to 2 mg; 2 to 10 years, 2 to 5 mg; 10 to 18 years, 5 to 10 mg or occasionally more.

Preparations

BP 2008: Procyclidine Injection; Procyclidine Tablets;
USP 31: Procyclidine Hydrochloride Tablets.

Profenamine Hydrochloride *(BANM, rINNM)*

Cloridrato de Profenamina; Ethopropazine Hydrochloride; Hidrocloruro de profenamina; Isothazine Hydrochloride; Profénamine, Chlorhydrate de; Profenamini Hydrochloridum; Prophenamini Chloridum. 10-(2-Diethylaminopropyl)phenothiazine hydrochloride.

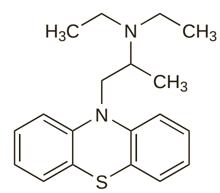
Профенамина Гидрохлорид

$C_{19}H_{24}N_2S,HCl = 348.9.$

CAS — 522-00-9 (profenamine); 1094-08-2 (profenamine hydrochloride).

ATC — N04AA05.

ATC Vet — QN04AA05.



(profenamine)

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

Profenamine may also cause muscle cramps, paraesthesia, and a sense of heaviness in the limbs, epigastric discomfort, and nausea.

Profenamine is a phenothiazine derivative; adverse effects associated with phenothiazines may occur, especially with high doses (see under Chlorpromazine, p.969).

Breast feeding. Profenamine is distributed into the milk of lactating mothers.[1]

1. Rowan JJ. Excretion of drugs in milk. *Pharm J* 1976; **217:** 184–7.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Uses and Administration

Profenamine hydrochloride is a phenothiazine derivative with antimuscarinic, adrenergic-blocking, antihistaminic, local anaesthetic, and ganglion-blocking properties. It has been used in the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as other phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in a usual initial oral dose of 50 mg three times daily, gradually increased to 500 mg or more daily in divided doses, according to response.

Preparations

Proprietary Preparations (details are given in Part 3)

Canad.: Parsitan.

Rasagiline Mesilate *(rINNM)*

Mesilato de rasagilina; Rasagiline, Mésilate de; Rasagiline Mesylate *(USAN)*; Rasagilini Mesilas; TVP-1012. (*R*)-*N*-2-Propynyl-1-indanamine methanesulfonate.

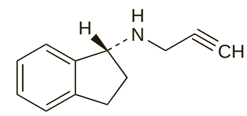
Разагилина Мезилат

$C_{12}H_{13}N,CH_4O_3S = 267.3.$

CAS — 136236-51-6 (rasagiline); 161735-79-1 (rasagiline mesilate).

ATC — N04BD02.

ATC Vet — QN04BD02.



(rasagiline)

Adverse Effects and Precautions

Common adverse effects reported with rasagiline monotherapy include headache, flu-like syndrome, malaise, neck pain, angina pectoris, dyspepsia, anorexia, leucopenia, arthralgia, arthritis, depression, vertigo, rhinitis, conjunctivitis, skin rashes, melanoma, and urinary urgency. Cerebrovascular accidents and myocardial infarction have been reported rarely. Other adverse effects include orthostatic hypotension and hallucinations.

Rasagiline should not be used in patients with severe hepatic impairment; use in moderate impairment should also be avoided. It should be used with caution in patients with mild hepatic impairment and therapy should be stopped in those who progress to moderate impairment.

Interactions

As for Selegiline Hydrochloride, p.817. Unlike the non-selective MAOIs, such as phenelzine, rasagiline can be used safely without dietary tyramine restrictions, although these have been recommended in some countries.

Rasagiline should not be given with other MAOIs because of the risk of non-selective MAO inhibition that may lead to hypertensive reactions.

It is metabolised by the cytochrome P450 isoenzyme CYP1A2 and potent inhibitors of this enzyme such as ciprofloxacin may increase the plasma levels of rasagiline. UK licensed product information for rasagiline advises caution when such drugs are used with rasagiline whereas US licensed product information recommends that the dose of rasagiline be reduced to 0.5 mg daily when given with CYP1A2 inhibitors. Tobacco smoking induces hepatic metabolic enzymes and may decrease the plasma levels of rasagiline.

Entacapone has been reported to increase the clearance of oral rasagiline by 28% when used together.

Pharmacokinetics

Rasagiline is rapidly absorbed from the gastrointestinal tract, with peak plasma levels occurring in about 30 minutes to an hour. Bioavailability is reported to be about 36%. Rasagiline is about 60 to 70% bound to plasma proteins.

It is extensively metabolised in the liver by *N*-dealkylation and hydroxylation, via the cytochrome P450 isoenzyme CYP1A2, and conjugation. 1-Aminoindan is a major metabolite and is stated to be active although it is not a monoamine oxidase B inhibitor. Metabolites are excreted mainly in the urine and partly in the faeces; less than 1% of a dose is excreted as unchanged drug in the urine. The terminal half-life is 0.6 to 2 hours.

Uses and Administration

Rasagiline is an irreversible selective inhibitor of monoamine oxidase type B, an enzyme involved in the metabolic degradation of dopamine in the brain. It enhances the effects of levodopa and is used in the treatment of Parkinson's disease (p.791), either alone or as an adjunct to levodopa therapy to reduce 'end-of-dose' fluctuations in response. Rasagiline is given orally as the mesilate and doses are expressed in terms of the base; rasagiline mesilate 1.56 mg is equivalent to about 1 mg of rasagiline. The usual dose is the equivalent of rasagiline 1 mg once daily. In the USA, an initial daily dose of 0.5 mg is recommended for adjunctive therapy.

The dose of rasagiline may need to be reduced when given with drugs that inhibit the cytochrome P450 isoenzyme CYP1A2 (see Interactions, above for details) and in patients with hepatic impairment (see below).

Ropinirole Hydrochloride

(BANM, USAN, pINNM)

Hidrocloruro de ropinirol; Ropinirole, Chlorhydrate de; Ropiniroli Hydrochloridum; SKF-101468 (ropinirole); SKF-0101468-A (ropinirole hydrochloride). 4-[2-(Dipropylamino)ethyl]-2-indolinone hydrochloride.

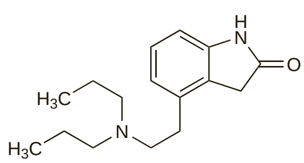
Ропинирола Гидрохлорид

$C_{16}H_{24}N_2O,HCl = 296.8.$

CAS — 91374-21-9 (ropinirole); 91374-20-8 (ropinirole hydrochloride).

ATC — N04BC04.

ATC Vet — QN04BC04.



(ropinirole)

Adverse Effects and Precautions

As for Bromocriptine, p.798. Licensed product information states that the pharmacokinetics of ropinirole have not been studied in patients with hepatic or severe renal impairment and therefore it should be used with caution, if at all, in such patients. No pharmacokinetic changes were noted in those with mild to moderate renal impairment.

In the treatment of restless legs syndrome, earlier onset of symptoms in the afternoon or evening (augmentation) and recurrence of symptoms in the early morning hours (rebound) have been reported with ropinirole.

Incidence of adverse effects. References.

1. Etminan M, *et al.* Comparison of the risk of adverse events with pramipexole and ropinirole in patients with Parkinson's disease: a meta-analysis. *Drug Safety* 2003; **26:** 439–44.

Effects on mental function. For reports of daytime somnolence occurring in patients receiving dopamine agonists including ropinirole, see under Adverse Effects of Levodopa, p.805.

Interactions

Since it is a dopamine agonist, ropinirole may share some of the pharmacological interactions of bromocriptine, p.800. In addition, high doses of oestrogens can increase plasma concentrations of ropinirole and dosage adjustments may be necessary if oestrogen therapy is started or withdrawn during treatment with ropinirole. Ropinirole is metabolised by the cytochrome P450 isoenzyme CYP1A2 and there is therefore the potential for interactions between ropinirole and other drugs that are metabolised similarly or more particularly with inducers or inhibitors of this enzyme. Dosage adjustments may be necessary if therapy with such drugs is started or withdrawn during treatment with ropinirole.

Pharmacokinetics

Ropinirole is rapidly absorbed from the gastrointestinal tract and mean peak plasma concentrations have been achieved 1.5 hours after oral doses; the rate of absorption, but not the extent, may be reduced if taken with food. Bioavailability is reported to be about 50%. It is widely distributed throughout the body and plasma protein binding is low (10 to 40%).

Ropinirole is extensively metabolised in the liver, primarily by the cytochrome P450 isoenzyme CYP1A2, and excreted in the urine as inactive metabolites; less than 10% of an oral dose is excreted as unchanged drug. A mean elimination half-life of about 6 hours has been reported for ropinirole. It is thought to be distributed into breast milk on the basis of studies in *rats*.

◊ References.

3. Kaye CM, Nicholls B. Clinical pharmacokinetics of ropinirole. *Clin Pharmacokinet* 2000; **39:** 243–54.

Uses and Administration

Ropinirole is a non-ergot dopamine D_2-agonist with similar actions to those of bromocriptine (p.800), but in contrast to bromocriptine it also has agonist properties at D_3 receptors. It is used similarly in the management of Parkinson's disease, either alone or as an adjunct to reduce 'on-off' fluctuations in levodopa response. Ropinirole is also used for the treatment of moderate to severe idiopathic restless legs syndrome. It is given by mouth as the hydrochloride; doses are expressed in terms of the base. Ropinirole hydrochloride 1.14 mg is equivalent to about 1 mg of ropinirole.

In the treatment of **Parkinson's disease**, ropinirole should be introduced gradually and during this period patients already receiving levodopa can have their levodopa dosage decreased gradually until an optimal response is achieved; the concurrent dose of levodopa may be reduced by about 20 to 30%. The daily dosage of ropinirole should be given in three divided doses, preferably with food. The initial daily dose of ropinirole is 750 micrograms increased at weekly intervals in steps of 750 micrograms for the first 4 weeks. After week 4, the weekly increments may be made in steps of 1.5 mg up to a dose of 9 mg daily according to response; subsequent weekly increments may be made in steps of up to 3 mg. The daily dosage should not exceed 24 mg. Optimal response is usually achieved within the range of 3 to 9 mg daily; higher doses may be required if used with levodopa. If it is necessary to stop ropinirole therapy, it should be withdrawn gradually by reducing the number of daily doses over the period of 1 week. Once adequate symptomatic control has been established, ropinirole may be given as once-daily modified-release tablets.

Ropinirole is also given as a single daily dose, 1 to 3 hours before bedtime, in the treatment of **restless legs syndrome**. The initial dose of ropinirole is 250 micrograms daily for 2 days; if tolerated, the dose is then increased to 500 micrograms daily for the rest of the first week. Subsequent increases may be made in weekly steps of 500 micrograms until a dose of 3 mg daily is reached; if necessary, the dose may then be increased after 1 further week to a maximum of 4 mg daily.

In the UK, it has been recommended that treatment should be re-assessed 3 months after starting therapy. For this indication, ropinirole may be withdrawn without gradual tapering of the dose.

If treatment with ropinirole is interrupted for more than a few days it should be restarted at the low initial dose and increased gradually as required.

◊ Reviews.

1. Tulloch IF. Pharmacologic profile of ropinirole: a nonergoline dopamine agonist. *Neurology* 1997; **49** (suppl 1): S58–S62.

Parkinsonism. Dopamine agonists such as ropinirole may be used to begin treatment of parkinsonism (p.791) in an attempt to delay therapy with levodopa, particularly in younger patients. They also have an adjunctive use when levodopa is no longer effective alone or cannot be tolerated, and may be useful in reducing 'off' periods with levodopa and in ameliorating other fluctuations of mobility in the later stage of the disease.

Restless legs syndrome. The aetiology of restless legs syndrome (RLS—see Sleep-associated Movement Disorders, p.958) is obscure and treatment has largely been empirical although dopaminergic therapy has emerged as a common first-line choice. Ropinirole is licensed for the treatment of moderate to severe RLS in some countries.

Rotigotine *(USAN, rINN)*

N-0923; Rotigotina; Rotigotinum; SPM-962. (−)-(S)-5,6,7,8-Tetrahydro-6-{propyl[2-(2-thienyl)ethyl]amino}-1-naphthol.

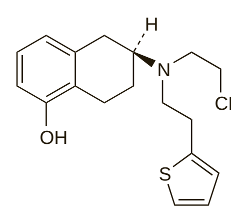
Ротиготин

$C_{19}H_{25}NOS = 315.5.$

CAS — 99755-59-6 (rotigotine); 125572-93-2 (rotigotine hydrochloride).

ATC — N04BC09.

ATC Vet — QN04BC09.



Adverse Effects and Precautions

As for Bromocriptine, p.798. Reactions may occur at the site of application and are usually mild or moderate in intensity. The site should be rotated on a daily basis and the same site should not be used within 14 days.

Licensed product information recommends that rotigotine should be used with caution in patients with severe hepatic impairment and reduced doses may be necessary in cases of worsening impairment; however, this is based on a lack of evidence in such patients.

Interactions

Since it is a dopamine agonist, rotigotine may share some of the pharmacological interactions of bromocriptine, p.800.

Caution is advised when other sedating drugs or alcohol are used with rotigotine because of possible additive effects.

Pharmacokinetics

Rotigotine has poor oral bioavailability as it undergoes extensive first-pass metabolism via glucuronidation in the gut wall and liver. Peak plasma concentrations are achieved 24 hours after transdermal application. Steady-state concentrations are reached after 24 to 48 hours of continuous daily application. It undergoes *N*-dealkylation and conjugation to form inactive metabolites. Rotigotine is excreted mainly in the urine and about 23% appears in the faeces. The elimination half-life is 5 to 7 hours. It is distributed into milk of *rats*.

Uses and Administration

Rotigotine is a non-ergot dopamine D_2-agonist with similar actions to those of bromocriptine (p.798), but in contrast to bromocriptine (a dopamine D_2-agonist) it also has agonist properties at D_1 and D_3 receptors. It is used as monotherapy in the management of Parkinson's disease (p.791), mainly in the early stage. It may also be used as an adjunct to levodopa therapy. Rotigotine is given as transdermal patches delivering amounts ranging from 2 to 8 mg per 24 hours.

When given as *monotherapy*, the initial dose is 2 mg daily, increased in weekly steps of 2 mg if necessary to a maximum of 8 mg daily.

Rotigotine may also be used as *adjunctive therapy* with levodopa in an initial dose of 4 mg daily, increased in weekly steps of 2 mg if necessary, to a maximum of 16 mg daily.

Patches are applied once daily and should be replaced every 24 hours with the new patch being applied to a different site. Treatment with rotigotine should be withdrawn gradually; the daily dose should be reduced in steps of 2 mg every other day until complete withdrawal is achieved.

Rotigotine is also being studied as a transdermal preparation in the treatment of restless legs syndrome.

(selegiline)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Selegiline Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in methyl alcohol; slightly soluble in acetone. A 2% solution in water has a pH of 3.5 to 4.5. Protect from light.

USP 31 (Selegiline Hydrochloride). A white, odourless crystalline powder. Freely soluble in water, in chloroform, and in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects

Selegiline is often given as an adjunct to levodopa therapy and many of the adverse effects reported may be attributed to enhanced levodopa activity; dosage of levodopa may have to be reduced. However, most reported adverse effects, with the possible exception of increased dyskinesias and cardiac arrhythmias, have also been seen with selegiline monotherapy. Adverse effects have included orthostatic hypotension, chest pain, nausea, vomiting, constipation, diarrhoea, confusion, headache, tremor, vertigo, dizziness, psychosis, depression, hallucinations, agitation, dry mouth, sore throat, difficulty in micturition, skin reactions, back pain, muscle cramps, joint pain, and myopathy. The amfetamine metabolites of selegiline may cause insomnia and abnormal dreams; evening doses should be avoided. Transient increases in liver enzymes have been reported. Mouth ulcers and stomatitis may occur with the oral lyophilisate.

Since the selectivity of selegiline is lost at higher doses, signs and symptoms of overdosage may resemble those of non-selective MAOIs such as phenelzine (see p.415).

Effects on carbohydrate metabolism. Profound hypoglycaemia developed in a 70-year-old man after selegiline was added to his existing medication for Parkinson's disease.[1] Hypoglycaemia was accompanied by hyperinsulinaemia and resolved 1 week after stopping selegiline.

1. Rowland MJ, *et al.* Hypoglycemia caused by selegiline, an antiparkinsonian drug: can such side effects be predicted? *J Clin Pharmacol* 1994; **34:** 80–5.

Effects on mortality. For reference to a study which observed an increased mortality rate in patients with Parkinson's disease taking selegiline and levodopa compared with those taking levodopa alone, see Parkinsonism under Uses and Administration, below.

Precautions

Selegiline should be used with caution in patients with a history of peptic ulceration and avoided in those with active ulceration. It should also be used with caution in uncontrolled hypertension, arrhythmias, angina, severe liver or kidney dysfunction, or psychosis.

Cardiovascular disorders. An investigation[1] of the autonomic effects of selegiline as a potential cause of the unexpected mortality observed in a study[2] in patients with Parkinson's disease receiving selegiline and levodopa (see Parkinsonism, below) suggested that the risk of orthostatic hypotension with this combination may have been underestimated. It was considered prudent to withdraw selegiline from those with symptomatic orthostatic hypotension or cardiovascular or cerebrovascular disease. For those without symptomatic morbidity, but a greater than 20 mmHg fall in blood pressure on standing for 2 minutes, gradual withdrawal of selegiline with adjustment of levodopa dosage should be considered.

1. Churchyard A, *et al.* Autonomic effects of selegiline: possible cardiovascular toxicity in Parkinson's disease. *J Neurol Neurosurg Psychiatry* 1997; **63:** 228–34.
2. Parkinson's Disease Research Group of the United Kingdom. Comparison of therapeutic effects and mortality data of levodopa and levodopa combined with selegiline in patients with early, mild Parkinson's disease. *BMJ* 1995; **311:** 1602–7.

Interactions

Selegiline is less likely than non-selective MAOIs, such as phenelzine, to interact with tyramine in food; such hypertensive reactions have been reported rarely at usual doses but UK licensed product information for oral formulations states that its selectivity is lost at higher doses and it must be assumed that selegiline can usually only be used safely without dietary restrictions at doses of up to 10 mg daily. US licensed information for the transdermal preparation states that dietary restrictions are necessary at doses of 9 mg daily and above. For dietary restrictions applicable to patients taking MAOIs, see p.417.

Even when given in therapeutic doses life-threatening interactions can occur between selegiline and pethidine. Serious reactions, sometimes fatal, have also been reported when selegiline was used with tricyclic antidepressants or serotonin reuptake inhibitors including the SSRIs and venlafaxine. Licensed drug information states that 14 days should elapse between stopping selegiline and starting treatment with tricyclic or serotonergic antidepressants. Conversely, selegiline should not be given to patients who have recently received these antidepressants; at least 5 weeks should elapse between stopping fluoxetine and starting treatment with selegiline. Use of selegiline with non-selective MAOIs may cause severe hypotension and such use is not recommended.

Antidepressants. Although there have been studies in which patients with parkinsonism have received selegiline with *SSRIs* such as fluoxetine[1] or paroxetine[2] (apparently without any problems) there have been reports of reactions[3-5] such as shivering and sweating, hypertension, hyperactivity, and ataxia occurring when selegiline and fluoxetine have been used together. The FDA noted[6] that reactions similar to those between SSRIs and non-selective MAOIs had also been reported in patients taking selegiline with paroxetine or sertraline.

Severe reactions, sometimes fatal, have also occurred in patients taking selegiline and *tricyclic antidepressants*.[6] For a report of serotonin syndrome developing when *venlafaxine* was given after selegiline (despite a drug-free period) see p.429.

There has been a report[7] of a patient receiving the non-selective MAOI *iproniazid* who experienced severe orthostatic hypotension when given selegiline. Selegiline given with the reversible MAOI *moclobemide* to healthy subjects markedly increased the pressor response to tyramine compared with the effects of each drug used alone.[8] The authors concluded that dietary restriction of tyramine-containing foods would be necessary if these drugs were to be used together.

One UK manufacturer (*Cephalon, UK*) states that oral selegiline should not be given with any type of antidepressant, while another (*Orion, UK*) advises that use with SSRIs or venlafaxine be avoided and recommends caution when used with the tricyclics. The US manufacturer of transdermal selegiline (*Bristol-Myers Squibb, USA*), used for depression, states that use with other antidepressants such as *bupropion*, *mirtazapine*, serotonin reuptake inhibitors, *St John's wort*, and tricyclics is contra-indicated.

6. Anonymous. Eldepryl and antidepressant interaction. *FDA Med Bull* 1995; **25** (Feb.): 6.
7. Pare CMB, *et al.* Attempts to attenuate the 'cheese effect': combined drug therapy in depressive illness. *J Affect Disord* 1985; **9:** 137–41.
8. Korn A, *et al.* Tyramine pressor sensitivity in healthy subjects during combined treatment with moclobemide and selegiline. *Eur J Clin Pharmacol* 1996; **49:** 273–8.

Antimigraine drugs. Some serotonin agonists including *rizatriptan*, *sumatriptan*, and *zolmitriptan* are metabolised via monoamine oxidase type A and therefore it is considered unlikely that selegiline, a monoamine oxidase type B inhibitor, would interact with these drugs. Nevertheless, one manufacturer (*Cephalon, UK*) of oral selegiline contra-indicates its use in patients also receiving serotonin agonists; it is also recommended that at least 24 hours should elapse between stopping selegiline and starting treatment with these drugs.

Opioid analgesics. Selegiline can produce life-threatening reactions when given with *pethidine*.[1]

Some manufacturers contra-indicate use of selegiline with pethidine and other opioid analgesics such as *dextropropoxyphene*, *methadone*, and *tramadol*.

1. Zornberg GL, *et al*. Severe adverse interaction between pethidine and selegiline. *Lancet* 1991; **337:** 246. Correction. *ibid.*; 440.

Oral contraceptives. The total area under the concentration-time curve for selegiline given in single doses of 5 to 40 mg was raised ten- to twentyfold in 4 women who were using oral hormonal contraceptives when compared with 4 women receiving no other medication.[1] It was suggested that use of selegiline and oral hormonal contraceptives should be avoided or the dosage of selegiline reduced.

1. Laine K, *et al.* Dose linearity study of selegiline pharmacokinetics after oral administration: evidence for strong drug interaction with female sex steroids. *Br J Clin Pharmacol* 1999; **47:** 249–54.

Sympathomimetics. Licensed information for a US product (*Eldepryl; Somerset, USA*) states that there has been a report of hypertensive crisis in a patient taking recommended doses of selegiline and *ephedrine*. A hypertensive reaction after low-dose *dopamine* infusion has been reported[1] in a 75-year-old patient taking selegiline 10 mg daily for Parkinson's disease. The authors suggest that this may indicate a non-specific action of selegiline at usual doses on peripheral monoamine oxidase type-A. UK licensed product information states that dopamine should be used with caution in patients taking selegiline.

1. Rose LM, *et al.* A hypertensive reaction induced by concurrent use of selegiline and dopamine. *Ann Pharmacother* 2000; **34:** 1020–4.

Pharmacokinetics

Selegiline is readily absorbed from the gastrointestinal tract and peak plasma concentrations are achieved in 30 minutes after oral doses of conventional preparations. Although subject to large interindividual variation, bioavailability is about 10% and is increased when given with food. Selegiline is rapidly distributed throughout the body and crosses the blood-brain barrier. It undergoes extensive first-pass metabolism in the liver to produce at least 5 metabolites, including *l*-(−)-desmethylselegiline (norselegiline), *l*-(−)-*N*-methylamfetamine, and *l*-(−)-amfetamine. Plasma concentrations of selegiline metabolites are greatly reduced after doses of the oral lyophilisate preparation, the majority of which undergoes absorption through the buccal mucosa. Selegiline is excreted as metabolites mainly in the urine and about 15% appears in the faeces. At steady state the elimination half-life is reported to be 10 hours.

Uses and Administration

Selegiline is an irreversible selective inhibitor of monoamine oxidase type B, an enzyme involved in the metabolic degradation of dopamine in the brain. It enhances the effects of levodopa and is used in the treatment of Parkinson's disease mainly as an adjunct to levodopa therapy to reduce 'end-of-dose' or 'on-off' fluctuations in response, but see Parkinsonism, below. Addition of selegiline to levodopa therapy may enable the dosage of levodopa to be reduced by about 10 to 30%. Selegiline may be given alone in early Parkinson's disease in an attempt to delay the need for levodopa therapy. It is also used in the treatment of depression (see also below).

In the treatment of **Parkinson's disease**, selegiline hydrochloride is given by mouth as conventional preparations such as capsules, tablets, or liquid, or as lyophilisate tablets. The dose of the conventional preparations is 10 mg daily, either as a single dose in the morning or in 2 divided doses of 5 mg at breakfast and lunchtime. The initial dose of the oral lyophilisate tablets is 1.25 mg daily at least 5 minutes before breakfast; patients already receiving 10 mg of conventional preparations can be transferred to 1.25 mg of the oral lyophilisate. In the USA, the initial oral lyophilisate dose of 1.25 mg daily may be increased, after at least 6 weeks, to 2.5 mg given once daily, if necessary.

To avoid initial confusion and agitation, particularly in the elderly, the *BNF* suggests it may be appropriate when using conventional preparations to start treatment with a dose of 2.5 mg daily.

In the USA, transdermal patches delivering 6, 9, or 12 mg of selegiline over 24 hours are available for the treatment of **depression**. The initial dose is 6 mg daily, increased in steps of 3 mg every 2 weeks if necessary, to a maximum of 12 mg daily. Patches are applied once daily and should be replaced every 24 hours with the new patch being applied to a different site. Dose increases should be made with caution in the elderly and patients should be closely observed for postural changes in blood pressure during treatment. Dietary restrictions are necessary at doses of 9 mg daily and above, see p.417.

Other conditions in which selegiline has been tried include dementia.

Dementia. The hypothesis that neurodegeneration in Alzheimer's disease (p.362) might be due to free radical formation has led to drugs such as selegiline being tried as antioxidant therapy.

Early double-blind studies[1,2] indicated that oral selegiline 10 mg daily might produce beneficial effects in patients with Alzheimer's disease but it was suggested that improvements in mood and cognitive function may have been due to a reduction in tension and depression.[3] A 15-month study in Alzheimers's patients with mild cognitive impairment showed oral selegiline 10 mg daily to have little effect,[4] although the authors pointed out that those with more severe dementia have shown more response in other studies. The conclusion of a later study[5] that oral selegiline 10 mg daily slowed progression in patients with moderate disease has been criticised[6] on the grounds that any effect was only evident after statistical adjustment to the original analysis. In addition a systematic review[7] examining the effects of selegiline concluded that there was no meaningful evidence of a beneficial effect of oral selegiline in patients with Alzheimer's disease. They also considered that there was no longer any justification for its use in patients with Alzheimer's disease.

Depression. Selegiline is a selective inhibitor of monoamine oxidase type B and there are reports[1-3] of it producing improvement in depression (p.373). However, at the doses usually required to produce an antidepressant effect the specificity of oral selegiline is reported to be lost and it has been suggested that the efficacy of selegiline as an antidepressant might depend on inhibition of monoamine oxidase A rather than inhibition of monoamine oxidase B alone. Such a loss of specificity would mean that patients taking selegiline for depression would need to observe the dietary restrictions applicable to non-selective MAOIs.

To overcome the problems associated with the oral route, transdermal selegiline has also been tried and may be more effective than placebo in the treatment of depression.[4] The use of the transdermal route allows sustained blood levels of selegiline to be delivered without extensive inhibition of peripheral monoamine oxidase A. Transdermal patches of selegiline are licensed for the treatment of depression in the USA.

Narcoleptic syndrome. Small controlled studies[1,2] have suggested that oral selegiline 20 to 40 mg daily has a beneficial effect on symptoms of narcolepsy and cataplexy (p.2148); at such a dosage a low-tyramine diet is considered necessary.

Parkinsonism. As a selective monoamine oxidase type B inhibitor, selegiline reduces the metabolism of dopamine and thereby enhances its actions. It reduces levodopa's 'end-of-dose' effect and has a dose-sparing effect. Some have used it as **monotherapy** in an attempt to delay the need for levodopa. If progression of Parkinson's disease (p.791) were due to a cytotoxic effect of free radicals, generated during the metabolism of dopamine, on dopaminergic neurones in the substantia nigra, selegiline might slow the process by reducing their formation. In a large early study,[1] the DATATOP study, selegiline monotherapy delayed the need to start levodopa in patients with early Parkinson's disease. These findings were corroborated by other smaller studies.[2,3] There has been much debate over whether the benefit was due to a neuroprotective or symptomatic effect. Re-analysis of the DATATOP data by independent workers[4,5] and findings of other studies[6] supported a symptomatic effect. Subsequent studies involving DATATOP patients were also consistent with a symptomatic effect; any benefit produced by selegiline appeared to be less pronounced as the duration of treatment increased[7] and was lost completely long term.[8,9] However, a later study[10] designed to minimise any symptomatic effect cast doubt on whether the delay in progression of the signs and symptoms of Parkinson's disease obtained with selegiline was entirely due to a symptomatic effect.

Studies of the use of selegiline as an **adjunct** to levodopa therapy[6,11,12] indicate that selegiline permits a modest reduction in the dosage requirements of levodopa. An interim analysis of a study of the early addition of selegiline to levodopa has also suggested that selegiline might stabilise the long-term daily levodopa dosage.[13] As with monotherapy, combined therapy has been reported to slow symptom progression.[14]

The use of selegiline in Parkinson's disease has been questioned after a UK study[11] found an unexpected increase in mortality in patients taking levodopa with selegiline compared with those taking levodopa alone. No difference in mortality had been detected at the 3-year follow-up[15] but after an average follow-up time of 5.6 years[11] mortality was 60% higher in the group also receiving selegiline. The study has been criticised on many grounds including the fact that mortality was very high in both arms of the study[16] and has been the subject of much debate.[17,18] The authors of the study[11] had stated that they would advise the study patients to withdraw selegiline therapy. Analysis of follow-up data[19] until the selegiline arm of the study was terminated (average 6.8 years) found an excess mortality of about 35%, a figure calculated[20] to be no longer significant. However, because of the premature termination of the study such results were considered[21] to be biased. Whether any excess in mortality is causally related to selegiline is still unclear. Some consider that changes in prescribing practice based on this study are not warranted.[17] Others[21] have made a cautious recommendation not to start combination treatment in patients with newly diagnosed Parkinson's disease but consider that there is little evidence to advise patients who have been using selegiline with levodopa for years without problem to change their treatment. An evaluation of mortality among patients taking antiparkinsonian drugs (using the UK General Practice Research Database) provided evidence against there being substantial excess mortality associated with the use of selegiline.[22] These results are supported by a systematic review[23] and meta-analyses[24,25] of randomised, double-blind studies which found no increase in mortality associated with selegiline treatment regardless of concurrent levodopa. Furthermore, increased mortality was not seen in patients in the original DATATOP trial[1] after an average follow-up time of 8.2 years. However, it was noted that the delay of disability observed in the early phase of selegiline therapy[1,7] was not associated with longer life during follow-up.[26] A recent systematic review[23] has also found no convincing evidence that selective monoamine oxidase type B inhibitors (selegiline and lazabemide) significantly delay disease progression in early Parkinson's disease and routine use is not recommended.

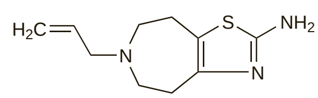
Talipexole Hydrochloride *(rINNM)*

Alefexole Hydrochloride; B-HT-920; Hidrocloruro de talipexol; Talipexole, Chlorhydrate de; Talipexoli Hydrochloridum. 6-Allyl-2-amino-5,6,7,8-tetrahydro-4*H*-thiazolo[4,5-*d*]azepine dihydrochloride.

Талипексола Гидрохлорид

$C_{10}H_{15}N_3S,2HCl = 282.2.$

CAS — 101626-70-4 (talipexole); 36085-73-1 (talipexole hydrochloride).



(talipexole)

Profile

Talipexole hydrochloride is a dopamine D_2-agonist that is used in the management of parkinsonism (p.791) in usual oral doses of 1.2 to 3.6 mg daily, in divided doses. It has also been investigated in the treatment of schizophrenia.

Preparations

Proprietary Preparations (details are given in Part 3)

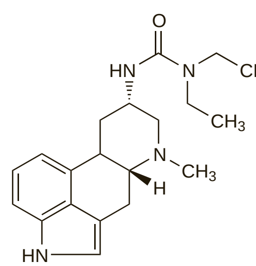
Terguride *(rINN)*

Tergurida; Terguridum. 1,1-Diethyl-3-(6-methylergolin-8α-yl)urea.

Тергурид

$C_{20}H_{28}N_4O = 340.5.$

CAS — 37686-84-3.



Profile

Terguride, an ergot derivative, is a partial dopamine agonist with general properties similar to those of bromocriptine (p.798). It is used in the treatment of disorders related to hyperprolactinaemia (p.2079) in a usual oral dose of 500 micrograms twice daily. It is also being investigated in the management of parkinsonism.

Pharmacopoeias. In *US.*

USP 31 (Tolcapone). A yellow, fine powder or fine powder with lumps. Insoluble in water and in *n*-hexane; Freely soluble in acetone and in tetrahydrofuran; sparingly soluble in chloroform and in dichloromethane; soluble in methyl alcohol and in ethyl acetate. Store in airtight containers at a temperature between 20° and 25°. Protect from light.

Adverse Effects

The most common adverse effects associated with tolcapone are diarrhoea, nausea, vomiting, constipation, abdominal pain, dry mouth, anorexia, dyskinesia, dystonia, dizziness, orthostatic hypotension, hallucinations, confusion, excessive dreaming, somnolence, headache, increased sweating, and sleep disorders. Diarrhoea may be severe enough for treatment to be stopped. Increases in liver enzyme values have occurred and hepatitis and hepatic failure, sometimes fatal, have been reported. Isolated cases of neuroleptic malignant syndrome have also been reported following dose reduction or stopping tolcapone; rhabdomyolysis may develop as a complication of the syndrome. Tolcapone and its metabolites can produce a yellow intensification in the colour of urine.

Effects on the liver. The UK CSM had noted[1] that, after a report[2] in September 1998 of fatal acute hepatic failure associated with tolcapone, the European Committee for Proprietary Medicinal Products (CPMP) had reviewed all reports of hepatic injury with tolcapone. There had been 10 reports of serious hepatic adverse reactions since tolcapone was marketed in October 1997, which included 7 reports of hepatitis, 3 of which had a fatal outcome. Serious hepatic reactions occurred unpredictably and their development was not always predicted by liver function monitoring. Consequently, in the EU, the marketing authorisation for tolcapone was suspended in November 1998. This suspension was lifted in April 2004 by the CPMP after further review.

In some countries such as the USA, tolcapone has always remained available albeit with restricted indications and strict monitoring requirements (see Precautions, below). Up to 2003, there had been no further reports of fatal hepatic failure following the introduction of these measures although the number of patients eligible to receive the drug has been reduced.[3]

3. Borges N. Tolcapone-related liver dysfunction: implications for use in Parkinson's disease therapy. *Drug Safety* 2003; **26:** 743–7.

Effects on the skin. For reference to the development of vitiligo in a patient following addition of tolcapone to levodopa/carbidopa treatment, see under Levodopa, p.806.

Precautions

Tolcapone should not be given to patients with hepatic impairment or raised liver enzyme values. Liver enzymes should be monitored:

- when starting treatment with tolcapone or on increasing the dose to 200 mg three times daily
- every 2 weeks during the first year of therapy
- every 4 weeks for a further 6 months
- every 8 weeks thereafter

Tolcapone should be stopped if liver enzyme levels exceed the upper limit of normal or if signs or symptoms suggestive of the onset of hepatic failure occur. Patients who have developed evidence of hepatic injury while receiving tolcapone should not be given the drug again.

Tolcapone should be used with caution in patients with severe renal impairment.

It is contra-indicated in patients with severe dyskinesia or with a history of neuroleptic malignant syndrome (NMS). It is also contra-indicated in patients with a history of nontraumatic rhabdomyolysis or symptoms of hyperpyrexia and confusion possibly related to NMS. Patients with phaeochromocytoma should not be given tolcapone.

Use with levodopa may cause dizziness and orthostatic hypotension; if affected patients should not drive or operate machinery. Excessive daytime sleepiness and sudden onset of sleep may also occur with combination use (see Effects on Mental Function, under Adverse Effects of Levodopa, p.805) and again, caution is advised when driving or operating machinery; patients who suffer such effects should not drive or operate machinery until the effects have stopped recurring.

Abrupt withdrawal or dose reduction of tolcapone should be monitored carefully because of the risk of developing symptoms resembling NMS.

The elderly. Confusion occurred in 3 elderly patients with severe Parkinson's disease after the addition of tolcapone to their antiparkinsonian therapy.[1] It was suggested that a starting dose of tolcapone 100 mg daily might be more suitable in frail patients with severe disease. It was noted[2] that a reduction in levodopa dosage is generally recommended when tolcapone is given to patients such as these, who were receiving 500 to 600 mg of levodopa daily.

2. Harper J, Vieira B. Catechol-O-methyltransferase inhibitors in Parkinson's disease. *Lancet* 1998; **352:** 578.

Genetic polymorphism. Two patients who developed elevated liver enzyme values while receiving tolcapone, one of whom also had hepatic dysfunction while receiving entacapone, were found to be poor metabolisers with regard to UDP-glucuronosyltransferase activity.[1] Such patients may be predisposed to COMT-inhibitor induced hepatotoxicity.

1. Martignoni E, *et al.* Two patients with COMT inhibitor-induced hepatic dysfunction and UGT1A9 genetic polymorphism. *Neurology* 2005; **65:** 1820–2.

Interactions

Tolcapone may influence the pharmacokinetics of drugs metabolised by catechol-*O*-methyltransferase; a dose reduction of such drugs should be considered when given with tolcapone. Increased concentrations of benserazide and its active metabolite have been reported when given with tolcapone. Licensed product information advises that non-selective MAOIs should not be used with tolcapone.

Pharmacokinetics

Tolcapone is rapidly absorbed from the gastrointestinal tract and maximum plasma concentrations have been obtained within 2 hours of an oral dose; food delays and decreases the absorption. Absolute bioavailability is reported to be about 65%. Tolcapone is more than 99% bound to plasma proteins (mainly albumin) and is not widely distributed into body tissues. It is extensively metabolised, mainly by conjugation to the inactive glucuronide, but methylation by catechol-*O*-methyltransferase to 3-*O*-methyltolcapone and metabolism by cytochrome P450 isoenzymes CYP3A4 and CYP2A6 also occurs. About 60% of a dose is excreted in the urine with the remainder appearing in the faeces. The elimination half-life has been reported to be about 2 to 3 hours. The clearance of unbound tolcapone may be reduced by 50% in patients with moderate cirrhotic liver disorders.

Uses and Administration

Tolcapone is a peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of dopamine and levodopa. It is used as an adjunct to levodopa and dopa-decarboxylase inhibitor combinations in the management of Parkinson's disease for patients who cannot be stabilised on these levodopa combinations or for those who experience 'end-of-dose' deterioration. Because of the risk of serious hepatotoxicity (see Effects on the Liver, above) the FDA in the USA restricted its use to when other adjunctive therapy was ineffective or contra-indicated. In the EU, tolcapone was withdrawn from the market in November 1998 and subsequently returned in 2004, its use being similarly restricted to patients who fail to respond to, or are intolerant of, other COMT inhibitors.

The usual recommended dosage of tolcapone is 100 mg given orally three times daily; up to a maximum of 200 mg three times daily may be considered if the clinical benefit justifies the increased risk of hepatotoxicity. The first dose of the day should be taken at the same time as the combined levodopa preparation. Most patients already taking more than 600 mg of levodopa daily will require a reduction in their dosage of levodopa; patients on lower levodopa doses may also require a dose reduction.

Tolcapone should be withdrawn if a substantial clinical benefit is not obtained within the first 3 weeks of treatment. An adjustment in the levodopa dose may be necessary following tolcapone withdrawal.

Parkinsonism. Tolcapone is a reversible peripheral inhibitor of catechol-*O*-methyltransferase (COMT), an enzyme involved in the metabolism of levodopa and dopamine.[1] It appears to differ from entacapone (p.804) by being a more potent COMT inhibitor in the periphery and by penetrating into the brain (although the significance of any central effects of COMT inhibition are not known).[1] When given to patients with Parkinson's disease (p.791) and levodopa-related fluctuations in disability or 'end-of-dose' effects, it has prolonged the clinical benefit obtained with levodopa and allowed the total daily dosage of levodopa to be reduced.[2,3] Benefit has also been reported[4] when added to levodopa therapy in patients with stable Parkinson's disease. However, a systematic review[5] concluded that there were insufficient data to demonstrate any significant difference in efficacy between tolcapone and bromocriptine or pergolide in the adjunctive treatment of levodopa-induced motor complications.

The use of tolcapone is restricted in some countries because of the risk of serious hepatotoxicity (see Effects on the Liver, above).

Trihexyphenidyl Hydrochloride

(BANM, rINNM)

Benzhexol Hydrochloride; Cloridrato de Triexilfenidila; Cyclodolum; Hidrocloruro de trihexifenidilo; Triheksifenidilio hidrochloridas; Triheksyfenidylu chlorowodorek; Triheksyfenidyylihydrokloridi; Trihexifenidilhidroklorid; Trihexyfenidyl-hydrochlorid; Trihexyfenidylhydroklorid; Trihexyphénidyle, chlorhydrate de; Trihexyphénidyle, Chlorhydrate de; Trihexyphenidyli hydrochloridum; Trihexyphenidylium Chloratum. 1-Cyclohexyl-1-phenyl-3-piperidinopropan-1-ol hydrochloride.

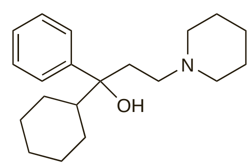
Тригексифенидила Гидрохлорид

$C_{20}H_{31}NO,HCl = 337.9.$

CAS — 144-11-6 (trihexyphenidyl); 52-49-3 (trihexyphenidyl hydrochloride).

ATC — N04AA01.

ATC Vet — QN04AA01.



(trihexyphenidyl)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of trihexyphenidyl: Artanes.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Trihexyphenidyl Hydrochloride). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol and in dichloromethane. A 1% solution in water has a pH of 5.2 to 6.2.

USP 31 (Trihexyphenidyl Hydrochloride). A white or slightly off-white, crystalline powder, having not more than a very faint odour. Slightly soluble in water; soluble in alcohol and in chloroform. Store in airtight containers.

Adverse Effects, Treatment and Precautions

As for Atropine Sulfate, p.1219. In some patients, such as those with arteriosclerosis or a history of drug idiosyncrasy, trihexyphenidyl may produce mental disturbances, excitement, or nausea and vomiting; such patients should be allowed to develop a tolerance by starting with a small initial dose and gradually increasing it until an effective level is reached. If a severe reaction occurs, trihexyphenidyl should be stopped for a few days and resumed at a lower dose. Trihexyphenidyl may provoke or exacerbate tardive dyskinesia.

Abuse. Trihexyphenidyl hydrochloride has been abused for its euphoric effect[1] especially by psychiatric patients.[2] Its abuse potential in schizophrenic patients has been questioned[3] and its unpleasant antimuscarinic effects tend to limit its repeated use,[4] but a small survey among psychiatric patients found that trihexyphenidyl was reported to be the antimuscarinic most frequently abused;[5] procyclidine, benzatropine, and orphenadrine (in decreasing order of frequency) were also misused. A later analysis of health insurance data from one region of France[6] examined prescriptions for trihexyphenidyl in 3028 subjects, most of whom were also receiving antipsychotics, and concluded that there was evidence of an abnormal pattern of use in about 2%. Patients in this subgroup were mostly young, male, and also receiving benzodiazepines or high doses of buprenorphine.

6. Frauger E, *et al.* Détournement d'usage du trihexyphénidyle (Artane , Parkinane): tendances récentes. *Therapie* 2003; **58:** 541–7.

Effects on the heart. Paradoxical sinus bradycardia developed in a schizophrenic patient after receiving trihexyphenidyl for extrapyramidal effects due to antipsychotic medication.[1] Normal sinus rhythm was restored after trihexyphenidyl was stopped. The patient had previously received trihexyphenidyl and suffered bradycardia which at the time was attributed to haloperidol.

1. Blumensohn R, *et al.* Bradycardia due to trihexyphenidyl hydrochloride. *Drug Intell Clin Pharm* 1986; **20:** 786–7.

Effects on mental function. Trihexyphenidyl 2 mg by mouth significantly impaired memory function compared with placebo in a study in 13 elderly patients.[1] Impairment of memory has also been observed in patients with Parkinson's disease given antimuscarinics such as trihexyphenidyl.[2] However, impairment may be reversible on stopping the antimuscarinic (see Atropine, p.1220).

2. Sadeh M, *et al.* Effects of anticholinergic drugs on memory in Parkinson's disease. *Arch Neurol* 1982; **39:** 666–7.

Overdosage. A 34-year-old woman developed a toxic reaction with widely dilated pupils, dry skin, and visual hallucinations within 24 hours of taking about 300 mg of trihexyphenidyl hydrochloride with suicidal intent.[1] After 3 to 4 days the hallucinations were replaced by illusions; complete recovery occurred after a week, with no special treatment. Death associated with moderate blood concentrations of trihexyphenidyl (0.12 micrograms/mL) has been reported[2] in a schizophrenic patient recovering from a respiratory infection. It was thought possible that he had increased his dose to counteract developing tardive dyskinesia, and that the toxic effects had been exacerbated by respiratory inflammation; there was no evidence of suicidal intent.

Withdrawal. A 61-year-old woman who had taken trihexyphenidyl 6 mg daily for a year for Parkinson's disease developed encephalopathy and miosis on two occasions when treatment was abruptly withdrawn.[1] Slowly tapered withdrawal avoided these effects.

1. Johkura K, *et al.* Trihexyphenidyl withdrawal encephalopathy. *Ann Neurol* 1997; **41:** 133–4.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Chlorpromazine. For the effect of trihexyphenidyl on plasma concentrations of chlorpromazine, see Antiparkinsonian Drugs, p.974.

Pharmacokinetics

Trihexyphenidyl hydrochloride is well absorbed from the gastrointestinal tract and has been stated to exert an effect within 1 hour of an oral dose.

Half-life. The reported half-life of trihexyphenidyl has varied according to the assay method used. Values reported when using radioreceptor and chromatographic techniques have ranged from about 1 to more than 24 hours[1] and from 10 to 29 hours,[2] respectively, but the sensitivity and specificity of these methods have been criticised.[3] With a more recently developed radio immunoassay it was found that after oral doses there was an initial elimination phase with an estimated half-life of 5.33 hours followed by a terminal elimination phase with an estimated half-life of 32.7 hours.

3. He H, *et al.* Development and application of a specific and sensitive radioimmunoassay for trihexyphenidyl to a pharmacokinetic study in humans. *J Pharm Sci* 1995; **84:** 561–7.

Uses and Administration

Trihexyphenidyl hydrochloride is a tertiary amine antimuscarinic with actions similar to those of atropine (p.1220). It also has a direct antispasmodic action on smooth muscle.

Trihexyphenidyl hydrochloride is given orally in the symptomatic treatment of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value against tardive dyskinesias. It has been used in the treatment of dystonias, but see Extrapyramidal Disorders, below. Trihexyphenidyl hydrochloride is given in 3 or 4 divided doses daily before or with food.

In **Parkinson's disease** the usual initial dose of 1 mg daily is gradually increased at intervals of 3 to 5 days by increments of 2 mg to 6 to 10 mg daily according to response; for advanced cases, 12 to 15 mg daily or even more (up to 20 mg daily) may be needed. As a rule, postencephalitic patients tolerate and require the larger doses.

Usual doses for **drug-induced extrapyramidal symptoms** lie within the range of 5 to 15 mg daily, although as little as 1 mg daily may be sufficient in some cases.

Since the elderly and arteriosclerotic patients are more susceptible to the adverse effects of antimuscarinics a dose at the lower end of the range is usually recommended.

Antimuscarinic treatment of parkinsonism should never be terminated suddenly and it is usual when changing from one drug to another to withdraw one in small amounts while gradually increasing the dose of the other.

Trihexyphenidyl hydrochloride may be given with other drugs used for the relief of parkinsonism, such as levodopa, but the dose of each drug may need to be reduced. Trihexyphenidyl hydrochloride 3 to 6 mg daily is usually adequate.

Extrapyramidal disorders. Antimuscarinics such as trihexyphenidyl are used in the management of dystonias (p.809) although only about half of all children and adolescents, and fewer adults (who tolerate antimuscarinics less well) show any response. Adverse effects may be limited by starting with a low dose: one suggested regimen[1] starts with trihexyphenidyl 1 mg daily and rises up to 12 mg daily over the next 4 to 6 weeks; some patients may require up to 60 to 100 mg daily. The *BNFC* suggests that children aged 1 month to 18 years may be given oral doses of 1 to 2 mg daily in 1 or 2 divided doses, adjusted according to response.

Profile

Tropatepine hydrochloride is an antimuscarinic with actions and uses similar to those of trihexyphenidyl (p.820). It is used in the management of parkinsonism (p.791), including the alleviation of the extrapyramidal syndrome induced by drugs such as phenothiazines, but, like other antimuscarinics, is of no value in tardive dyskinesias. Tropatepine hydrochloride is given orally in usual doses of 10 to 30 mg daily; it is also given intramuscularly or by slow intravenous injection in doses of 10 to 20 mg daily.

The drugs described in this chapter are those used mainly in the treatment of parasitic protozoal infections. In addition to their use as antiprotozoals, metronidazole and related nitroimidazole derivatives are also important in the treatment of anaerobic bacterial infections. Some veterinary antiprotozoal drugs are included. Drugs used in the treatment of malaria are described in the Antimalarials chapter; some of these are also used in other protozoal infections.

The principal antiprotozoal drugs are listed in Table 1, below.

Choice of Antiprotozoal

Protozoal infections occur throughout the world and are a major cause of morbidity and mortality in some regions. The choice of treatment for the principal protozoal diseases in humans is discussed below.

Amoebic infections

The most common amoebic infection of man is amoebiasis caused by infection with the protozoan parasite *Entamoeba histolytica* and related species. Free-living amoebae can also cause disease in man, though these infections are rare. Infection with *Naegleria fowleri* results in primary amoebic meningoencephalitis, while infection with *Acanthamoeba* species or leptomyxid amoebae leads to granulomatous amoebic encephalitis. *Acanthamoeba* is also a cause of keratitis.

Acanthamoeba infections. ***ACANTHAMOEBA KERATITIS.*** *Acanthamoeba* keratitis is usually associated with the wearing of soft contact lenses. It is treated by prompt topical antiamoebic therapy,[1-4] although an optimum regimen has yet to be determined. Surgery may be needed in severe cases. Propamidine isetionate applied topically was the first drug used with some success.[5,6] It was used with an aminoglycoside such as neomycin or a neomycin-polymyxin-gramicidin preparation and a cure was achieved in about 50% of cases. Due to surface toxicity and poor *in-vitro* sensitivity of neomycin, propamidine was later used with a biguanide such as chlorhexidine or polihexanide. However, poor cysticidal activity, chronic conjunctival infection, and resistance to some strains of *Acanthamoeba* to propamidine has prompted the suggestion that it should be replaced by another diamidine such as hexamidine. Systemic itraconazole or ketoconazole with topical miconazole have also been tried with some success. Clotrimazole has also been used successfully. Biguanides may also be used alone,[4] and are particularly effective in early infection.

Acanthamoeba keratitis in contact lens wearers should be preventable by good lens hygiene (see Contact Lens Care, p.1622).

Table 1. Classification of principal antiprotozoals.

Antimony compounds	*Nitrofurans*
Meglumine antimonate	Furazolidone
Sodium stibogluconate	Nifuratel

DISSEMINATED ACANTHAMOEBA INFECTION. Granulomatous amoebic encephalitis is caused by infection with free-living amoebae, usually *Acanthamoeba* spp. or sometimes leptomyxid amoebae. It is an opportunistic infection occurring mainly in debilitated or immunocompromised individuals. The protozoa spread to the CNS from pulmonary or skin lesions and produce focal neurological deficits that progress over days or weeks to a diffuse meningoencephalitis. The infection is usually fatal and most cases have been diagnosed postmortem so little is known about effective treatments; A few cases have been reported in which patients with encephalitis responded to combinations of pentamidine, sulfadiazine, flucytosine, and an azole such as itraconazole or fluconazole;[1] susceptibilities of species and strains appear to vary widely, and susceptibility testing is advisable.

Clinical responses to chemotherapy have also been reported in a few patients[2-4] with disseminated infection but no evidence of CNS involvement. Disseminated *Acanthamoeba* infection in an immunocompromised patient was successfully treated with intravenous pentamidine followed by maintenance therapy with oral itraconazole.[2] Skin lesions were treated topically with chlorhexidine and ketoconazole. Clinical improvement of disseminated acanthamoebiasis in a patient with AIDS followed treatment with intravenous pentamidine and oral flucytosine; an infant with HIV infection was treated with fluconazole, flucytosine, and sulfadiazine.[3] A lung transplant patient with disseminated acanthamoebiasis was also successfully treated with pentamidine, flucytosine, and azithromycin, plus topical chlorhexidine and ketoconazole.[4]

Amoebiasis. The term amoebiasis is generally applied to infections with obligate parasitic species of amoeba, principally *Entamoeba histolytica*.[1,2] Other parasitic species which occasionally cause human infections include *E. polecki* (primarily a parasite of pigs and reported mainly in Papua New Guinea) and *Dientamoeba fragilis* (often found in association with the helminth *Enterobius vermicularis* and now thought to be a trichomonad).

Transmission of *E. histolytica* is by the faeco-oral route and infection results from the ingestion of cysts, usually in contaminated food and drink. The cysts transform to trophozoites in the intestines and reproduction occurs by fission of the trophozoites. Further cysts develop and are excreted in the faeces. Amoebiasis occurs throughout the world. It is more prevalent and severe in the tropics and subtropics, but is more closely related to sanitation and socio-economic status than to climate. Colonisation with *E. histolytica* can result in asymptomatic infection, but in other cases the trophozoites invade the wall of the large intestine causing ulceration and may migrate to other tissues, especially the liver, where they continue to divide and destroy tissue. Factors increasing susceptibility to tissue invasion include malnutrition, immunosuppression, and pregnancy.

Symptomatic amoebiasis may be classified as intestinal or extra-intestinal amoebiasis. Intestinal amoebiasis comprises two main states, amoebic dysentery and non-dysenteric amoebic colitis; amoeboma, a localised form of intestinal amoebiasis, and amoebic appendicitis may also occur. Hepatic amoebiasis, the most common form of extra-intestinal amoebic disease, may present as acute non-suppurative disease or as amoebic liver abscess. Amoebic infection is a less common cause of liver abscess than bacterial infection. Amoebiasis may also involve the skin, genito-urinary tract, or organs such as the lungs and brain.

Drugs used in the **treatment** of amoebiasis may be classified according to their site of action as follows:

- *luminal amoebicides* acting principally in the bowel lumen.

  Diloxanide furoate is widely used as the luminal amoebicide of choice, although clefamide, etofamide, and teclozan are also effective.[3] Paromomycin and diiodohydroxyquinoline have also been used[1,2,4] although most oral preparations of halogenated hydroxyquinolines have been withdrawn because of the association between clioquinol and subacute myelo-opticoneuropathy
- *tissue* or *systemic amoebicides* acting principally in the intestinal wall and liver. These have included the alkaloid emetine, its synthetic derivative dehydroemetine, and the antimalarial chloroquine which acts principally in the liver
- *mixed amoebicides* acting at all sites of infection, that is within the intestinal lumen and in the intestinal wall and other tissues. These have included metronidazole and other 5-nitroimidazole derivatives. However, because of their rapid absorption from the gastrointestinal tract, the nitroimidazoles are less effective against parasites in the lumen

In non-endemic areas, patients with asymptomatic intestinal amoebiasis (cyst passers) are generally treated with a luminal amoebicide. The choice of drug is influenced by availability; diloxanide furoate is generally used in the UK while diiodohydroxyquinoline or paromomycin are used in the USA.[5] Standard treatment for invasive amoebiasis (amoebic dysentery; hepatic amoebiasis) is metronidazole, ornidazole, or tinidazole, followed by a luminal amoebicide to eradicate any surviving organisms from the lumen of the large intestine and prevent relapse. The majority of patients with amoebic liver abscess defervesce after 3 to 4 days of treatment with metronidazole. Addition of chloroquine is an option in patients who do not respond;[4] WHO recommends that hepatic abscesses should be lanced by needle aspiration.[3] Nitazoxanide has been used in mild to moderate intestinal disease.[5] In severe cases of amoebic dysentery tetracycline given with a systemic amoebicide lessens the risk of superinfection, intestinal perforation, and peritonitis.

In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p.1694.

Drugs suggested for the treatment of *Dientamoeba fragilis* infections include diiodohydroxyquinoline, metronidazole, paromomycin, or tetracycline.[5] Metronidazole has been suggested for *E. polecki* infections.[5]

Naegleria infections. ***PRIMARY AMOEBIC MENINGOENCEPHALITIS.*** Primary amoebic meningoencephalitis is usually caused by the free-living amoeba *Naegleria fowleri*. It occurs mainly in healthy children and young adults and is usually associated with swimming in warm fresh water. The protozoa invade the CNS directly through the nasal mucosa to produce a meningoencephalitis that is usually rapidly fatal. Few cases of successful treatment have been reported, and have generally involved intravenous, and usually intrathecal, amphotericin B;[1-3] some patients were also given oral rifampicin.

Babesiosis

Babesiosis (piroplasmosis) is an infection caused by intraerythrocytic protozoa of the *Babesia* genus, which are transmitted to man by the bite of infected *Ixodes* ticks. Transmission by blood transfusion has also been reported. *Ixodes scapularis*, one of the ticks that may cause babesiosis, may also be infected with, and transmit, *Anaplasma phagocytophilum* and/or *Borrelia burgdorferi* and therefore the bite from this tick may lead to babesiosis, human granulocytic anaplasmosis (see Ehrlichiosis, p.168), or Lyme disease (p.177) as a single infection or as a co-infection.[1] Babesiosis occurs worldwide in animals. In the US, human infection is most commonly due to *B. microti*; the disease is much rarer in Europe where it is usually caused by *B. divergens* or *B. bovis* .[1-3] Infection with the newly recognised babesia-like piroplasms WA-1 and MO-1 has also been reported in the USA.[1,2]

Clinical features of babesiosis acquired in the USA differ from that acquired in Europe. Infection in the USA is often asymptomatic and self-limiting, but may produce prolonged severe viral-like illness with fever and haemolytic anaemia, particularly in patients who are asplenic, elderly, debilitated, or immunocompromised (including those infected with HIV). Symptoms include chills, sweating, myalgia, arthralgia, weakness, fatigue, anorexia, nausea, vomiting, jaundice, and headache. The most common complications are heart failure, disseminated intravascular coagulation, acute respiratory distress syndrome, and renal failure.[1-3] Co-infection with *B. microti* and *Borrelia burgdorferi* has resulted in more severe symptoms. In Europe, infections have mostly been described in asplenic persons, in many of whom the infection was rapidly fatal. Clinical features include severe haemolytic anaemia, jaundice, pulmonary oedema, and renal failure.

There is no established specific **treatment** for babesiosis. Treatment is not recommended for asymptomatic patients although all symptomatic patients should be treated with antibacterials to prevent the development of complications.[1] For serious infections, supportive therapies include red blood cell exchange transfusions to reduce parasitaemia. Clindamycin with quinine was the first regimen used[4] for the treatment of *B. microti* infections, but has been associated with significant toxicity. A prospective randomised study[5] in 58 patients found azithromycin with atovaquone to be as effective as clindamycin and quinine and associated with less toxicity. Azithromycin with quinine has been reported to be effective in 2 patients who had not responded to quinine plus clindamycin.[6,7] Pentamidine has also been reported to produce clinical improvement in patients with *B. microti* infection,[8] but the efficacy and safety of pentamidine has been questioned.[9] Other drugs that have been tried with variable results include chloroquine, primaquine, pyrimethamine, sulfadiazine, and tetracycline.[2,3] The Infectious Diseases Society of America[1] recommends a combination of either clindamycin plus quinine or atovaquone plus azithromycin, both orally for 7 to 10 days; the combination of intravenous clindamycin plus oral quinine should be used in severe babesiosis. In immunocompromised patients higher doses of azithromycin may be used; they are prone to relapsing disease, and treatment should be given for 6 weeks or more, including 2 weeks after parasites are no longer detectable in blood smears.[10] Partial or complete exchange transfusion may also be given. Patients with persistent infection should be re-treated.

Patients *co-infected* or suspected to be co-infected with *Anaplasma phagocytophilum* and/or *Borrelia burgdorferi* should also be given doxycycline for 10 days.[1,3] For information on the treatment of co-infected patients see Lyme Disease, p.177. In *B. divergens* infections, treatment is complicated by the rapid progression of the disease. Antiprotozoal and antimalarial drugs have been tried with limited success, although pentamidine with co-trimoxazole was successful in a patient,[11] and a marked reduction in parasite load was seen in a patient treated with pentamidine plus exchange transfusions.[12] The combination of clindamycin plus quinine with exchange transfusion has also been suggested.[2]

Preventive measures against babesiosis include the use of tick repellents, physical protection, and prompt removal of attached ticks.[1]

Balantidiasis

Infection with the ciliate protozoan *Balantidium coli* results from the ingestion of cysts, the commonest sources of which are pigs. Water-borne epidemics of balantidiasis have been reported. Most infections are asymptomatic and the organism lives in the large intestine as a luminal commensal, but those with symptomatic infections have diarrhoea. Colonic ulceration resulting in a severe dysenteric syndrome resembling amoebic dysentery may occur in some individuals, especially if malnourished. Treatment is with tetracycline; metronidazole or diiodohydroxyquinoline are alternatives.[1]

1. Abramowicz M, ed. *Drugs for parasitic infections*. 1st ed. New Rochelle NY: The Medical Letter, 2007.

Blastocystis hominis infection

There is controversy over whether the protozoan parasite *Blastocystis hominis* is a pathogen or a harmless commensal of the intestinal tract. It has increasingly been reported both in immunocompetent and immunocompromised subjects,[1] with transmission probably by the faeco-oral route. Diarrhoea and other gastrointestinal symptoms have been ascribed to the organism.

Treatment with standard antiprotozoals, especially metronidazole, has had variable success; metronidazole resistance may occur.[2] Diiodohydroxyquinoline[3] and nitazoxanide[4] may also be effective. Co-trimoxazole was reported to have eliminated *B. hominis* from the stools of all but one of 47 otherwise healthy subjects with diarrhoea in one study,[5] and similarly in 36 of 38 children, and 14 of 15 adults, in another.[6]

Coccidiosis

Coccidiosis is a term sometimes applied to infections with protozoa of the order *Eucoccidiorida*. The predominant coccidian infections in man are caused by *Cryptosporidium* (below), *Cyclospora cayetanensis* (below), *Isospora* (below), *Plasmodium* (see Malaria, p.594), and *Toxoplasma* (below). Coccidian protozoa, primarily *Eimeria*, cause economically important infections in domesticated animals.

Cryptosporidiosis

Cryptosporidiosis is a gastrointestinal infection caused by species of the coccidian protozoan parasite *Cryptosporidium*. It has a worldwide distribution and occurs in many animal species as well as in man. Infection is acquired through ingestion, and perhaps inhalation, of oocysts. Infection in immunocompetent individuals usually causes a self-limiting diarrhoea lasting up to 2 weeks. In immunocompromised patients there may be profuse and persistent diarrhoea, profound weight loss, and severe abdominal pain, and the infection may be life-threatening. Cryptosporidiosis is a cause of diarrhoea in patients with AIDS. Other sites of infection include the respiratory and biliary tracts.

There is currently no consistently effective specific therapy[1] (evidence is perhaps best for nitazoxanide.[2]) and priority should be given to maintaining hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p.1694. In patients with AIDS the best treatment is improvement of immune function with HAART, but where this is not possible therapy with an antimicrobial and an antidiarrhoeal drug continues to be standard.[1] Paromomycin,[3-10] azithromycin,[11,12] and nitazoxanide[13,14] are widely used, although benefits are at best moderate.[1] Therapy with paromomycin plus azithromycin has produced some beneficial responses in patients with AIDS-related cryptosporidiosis.[15] Other treatments reported to have produced benefit include hyperimmune bovine colostrum,[16-20] eflornithine,[21] normal immunoglobulin with high cryptosporidium antibody titres,[22] or letrazuril,[23,24] but again the numbers of patients involved are small. Responses to spiramycin have not been consistent.[25-27] Beneficial responses to octreotide have been reported in a few cases,[28,29] but a study in patients with refractory AIDS-related diarrhoea suggested that response was better in patients without identifiable pathogens.[30]

Clarithromycin and rifabutin may be useful for disease prophylaxis,[31] although the efficacy of clarithromycin has been questioned.[32]

Cyclosporiasis

An organism originally described as cyanobacterium-like or coccidian-like bodies, but now identified as the coccidian protozoan *Cyclospora cayetanensis*, has been reported to be a cause of diarrhoea in both immunocompromised and immunocompetent patients. Infection results from ingestion of spores or oocysts in contaminated food or water. In immunocompetent patients, infection may be asymptomatic or cause a self-limiting diarrhoeal illness. Immunocompromised patients may develop severe or persistent symptoms. Beneficial responses have been reported with co-trimoxazole.[1-3] Ciprofloxacin may be an alternative in those unable to tolerate co-trimoxazole, although it is somewhat less effective.[3]

Gastro-enteritis

Although bacteria and viruses are responsible for many cases of infective diarrhoea, protozoal infections are also a cause of diarrhoea, which can be severe (especially in immunocompromised patients, including those with AIDS). In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p.1694. Specific therapy with antiprotozoals may also be necessary to control enteric protozoal infections. For the management of the protozoal infections that are generally associated with diarrhoea, see under Amoebiasis (above), Balantidiasis (above), *Blastocystis hominis* infections (above), Cryptosporidiosis (above), Cyclosporiasis (above), Giardiasis (below), Isosporiasis (below), and Microsporidiosis (below).

Giardiasis

Infection with *Giardia intestinalis* (*G. lamblia*; *Lamblia intestinalis*) occurs throughout the world and is one of the commonest intestinal protozoal infections. Infection is acquired by oral ingestion of *Giardia* cysts, and transmission may be person-to-person or from contaminated drinking water or foodstuffs. Infected patients may have acute or chronic diarrhoea or they may be asymptomatic. In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p.1694.

Treatment is with metronidazole or another nitroimidazole derivative such as tinidazole.[1] Albendazole, furazolidone, mebendazole, and mepacrine have all also been used but some of them may be less well tolerated than the nitroimidazoles. Nitazoxanide is also effective[2-4] and some consider it a drug of choice.[1] Paromomycin has been suggested;[1] although it is less effective than other drugs, it is not absorbed systemically and may be a useful alternative during pregnancy. Treatment may sometimes need to be repeated, possibly due to resistance,[5,6] and drug combinations such as metronidazole with mepacrine[5,7] have been reported to be of value in these cases.

Infections in immunocompromised patients

Patients with a defective immune system are at particular risk of infection. Primary immune deficiency is rare, whereas secondary deficiency is more common: immunosuppressive therapy, cancer and its treatment, HIV infection, and splenectomy may all cause neutropenia and impaired humoral and cellular immunity in varying degrees. The risk of infection is linked to the duration and severity of neutropenia. Most protozoal infections present in a more severe form in immunocompromised patients than in immunocompetent patients. Those of particular concern in patients with HIV infection include Cryptosporidiosis (above), Isosporiasis (below), Leishmaniasis (below), Microsporidiosis (below), and Toxoplasmosis (below).

Isosporiasis

Isosporiasis is a coccidian protozoal infection of the gastrointestinal tract caused by *Isospora belli*. Oocysts are excreted in faeces and infection is acquired when sporulated oocysts are ingested. In immunocompetent individuals the infection is usually mild and self-limiting but in immunocompromised patients there may be severe, chronic gastroenteritis. Treatment is usually with co-trimoxazole.[1,2] Ciprofloxacin may be an alternative in those unable to tolerate co-trimoxazole, although it is somewhat less effective.[2] Pyrimethamine has been used successfully in individual patients with sulfonamide sensitivity.[3] In acute diarrhoea of any aetiology the priority is to maintain hydration by prevention or treatment of fluid and electrolyte depletion, especially in infants and the elderly. Oral rehydration therapy is discussed under Diarrhoea on p.1694.

Recurrence of infection is common and long-term suppressive treatment with either co-trimoxazole or pyrimethamine plus sulfadoxine has been recommended.[4]

Leishmaniasis

Leishmaniasis[1,2] is caused by parasitic protozoa of the genus *Leishmania*. It occurs throughout Africa, the Middle East, Central Asia, and the Mediterranean (Old World leishmaniasis), and throughout Central and South America (New World leishmaniasis). In endemic areas there is generally a reservoir of disease in a mammalian host, often dogs or rodents. The usual vectors are sandflies of the genus *Phlebotomus* in the Old World and *Lutzomyia* in the New World. Leishmaniasis can be categorised as cutaneous, mucosal, and visceral and ranges from self-limiting, localised, cutaneous ulcers to widely disseminated progressive disease and involvement of the reticuloendothelial system. Incubation periods can be prolonged, with clinical features not appearing until several months or even years after the primary infection.

In endemic areas an integrated approach to controlling leishmaniasis involves case detection and treatment of patients, vector and animal reservoir control, environmental management to reduce suitable vector habitats, and personal protection against sandfly bites including the use of insect repellents and bednets.[3] Strategies aimed at controlling malaria are believed to have reduced leishmaniasis transmission dramatically.[3]

Visceral leishmaniasis of the Old World is mainly caused by *L. donovani* and *L. infantum* and of the New World by *L. chagasi*. The onset of the disease is gradual in residents of an endemic area but may present as an acute illness in non-immune visitors to the region. Many infections result in sub-clinical or self-limiting disease. Fever, malaise, shivering or chills, weight loss, anorexia, and discomfort in the left hypochondrium are common; there is often non-tender splenomegaly with or without hepatomegaly, wasting, pallor of mucous membranes, anaemia, leucopenia, and lymphadenopathy. Continued deterioration can lead to potentially fatal secondary infection. Darkening of the skin of the face, hands, feet, and abdomen is common in endemic visceral leishmaniasis in India (kala-azar = black sickness). Rare complications can include severe acute haemolytic anaemia, acute renal damage, and severe mucosal haemorrhage. In recent years, visceral leishmaniasis has emerged as an opportunistic infection in patients with HIV or other conditions associated with reduced immunity, in whom it is particularly difficult to treat.

A small percentage of patients develop post-kala-azar dermal leishmaniasis after recovery from visceral leishmaniasis and such patients represent a human reservoir for the disease.

The pentavalent antimonials meglumine antimonate and sodium stibogluconate are the traditional first-line drugs for the treatment of visceral leishmaniasis.[3-5] Patients relapsing after the initial course of treatment may be given a further course, but there is growing evidence that responsiveness to the antimonials is declining. Resistance to antimonials is widespread in parts of India.[5] Miltefosine has been shown to be effective[6-8] and has recently been introduced in India for treatment. Four regimens have been suggested for the first-line treatment of visceral leishmaniasis due to *L. infantum* in Mediterranean countries.[9] They are:

- pentavalent antimonials
- pentavalent antimonials plus allopurinol
- liposomal amphotericin B
- paromomycin alone or with pentavalent antimonials

These regimens have also been evaluated in other regions and in patients with HIV infection.[10-16] Amphotericin B has been tried successfully as a second-line drug in drug-resistant infections[17-20] and increasingly as a useful alternative first-line drug.[4,5,21,22] Lipid formulations of amphotericin B are better tolerated than conventional amphotericin B, and are likely to be preferred when the toxicity and duration of therapy with conventional forms would compromise patient compliance.[4] Pentamidine has also been used as a second-line drug but its usefulness as alternative first-line therapy is doubtful[23] given its toxicity, increasing failure rates, and slow disease response. Nevertheless it has been tried as an adjunct to meglumine antimonate for first-line therapy[24] and alone for long-term secondary prophylaxis in patients with HIV infection.[25] Beneficial responses to ketoconazole have been reported in some patients[26,27] but unfavourable reports have also appeared.[28,29] Another line of investigation is to boost the immune response to the parasite by adding interferon gamma to conventional treatment, although results have been variable.[30-33]

Cutaneous leishmaniasis is caused by various species of *Leishmania* and a wide variety of clinical presentations is possible. A 'classical' lesion starts as a nodule at the site of inoculation. A crust develops centrally which may fall away exposing an ulcer which heals gradually. Satellite nodules at the edge of the lesion are common. Cutaneous leishmaniasis of the Old World is normally caused by *L. tropica*, *L. major*, or *L. aethiopica*, although cutaneous lesions due to *L. infantum* have been reported. New World cutaneous leishmaniasis (American cutaneous leishmaniasis) is caused by numerous species and subspecies of *Leishmania* including *L. braziliensis*, *L. mexicana*, *L. panamensis*, and *L. peruviana*. In general, New World forms tend to be more severe and longer lasting than Old World forms. The disease ranges from single, self-healing lesions which are troublesome and unsightly but not a threat to life, to multiple, deep, and destructive ulcers which cause considerable disfigurement and disability.

Diffuse cutaneous leishmaniasis occurs occasionally after infection with *L. aethiopica* or members of the *L. mexicana* complex and involves dissemination of the disease from the original site of infection to distant skin sites, typically the face and exterior surfaces of the limbs. The lesions resemble lepromatous leprosy, do not heal spontaneously, and are resistant to treatment.

Another variant is leishmaniasis recidivans which is a lupoid or tuberculoid form. This chronic disease often occurs as slowly progressive, destructive and disfiguring lesions on the face which are very resistant to most forms of therapy.

There is no established treatment for cutaneous leishmaniasis.[5] The decision to treat depends upon the site and extent of the lesions and the likelihood of dissemination. Small lesions, particularly in Old World cutaneous leishmaniasis, may be left untreated if they are not troublesome to the patient. Treatment for disfiguring or potentially disabling lesions may be local or systemic. Systemic treatment is required where there is a risk that the infecting organism may be one causing mucocutaneous leishmaniasis (see below) or where there is evidence of lymphatic spread or extensive local involvement.

WHO[3] suggested that early noninflamed nodular lesions due to *L. tropica*, *L. major*, *L. mexicana*, *L. panamensis*, or *L. peruviana* might be treated with intralesional injections of mepacrine, sodium stibogluconate, or meglumine antimonate, or removed by surgery and curettage. Benefit has been reported with this therapy.[5,34,35] However, local infiltration of drugs can be difficult as well as painful. Surgical curettage may promote dissemination of the parasite.[36] Other local treatments include cryotherapy or, alternatively, application of heat to bring the temperature of the lesion to about 40° which may aid healing.[37] Topical treatment with paromomycin sulfate 15% plus methylbenzethonium chloride 5 or 12% has produced promising responses;[38-41] paromomycin 12 to 15% with urea 10% was better tolerated.[42] However, not all studies have shown benefit.[43,44]

Systemic treatment is similar to that of visceral leishmaniasis[3,5,45,46] (see above). Topical paromomycin plus systemic meglumine antimonate was initially found to be promising in patients with New World infections,[47] but a subsequent randomised, controlled study[48] found that application of paromomycin sulfate 15% with methylbenzethonium chloride 12% did not augment the clinical response to parenteral meglumine antimonate. Cutaneous leishmaniasis due to *L. aethiopica*, including diffuse cutaneous leishmaniasis, does not generally respond to antimonials[3] although responses to antimonials with paromomycin have been reported.[49] It may also be treated with pentamidine.[3,5]

Other drugs tried in cutaneous leishmaniasis have included fluconazole,[50] itraconazole,[51-54] and ketoconazole.[41,55-58] Variable responses to allopurinol have been reported in patients with New World infections.[59-61] Dapsone was reported to be effective in a study in patients in India[62] but not in Colombia.[63] Among the non-specific therapies tried in cutaneous leishmaniasis, topical application of the nitric oxide donor *S*-nitroso-*N*-acetylpenicillamine (SNAP)[64] and intralesional injection of hypertonic sodium chloride solution[65] have produced beneficial responses. Immunomodulation using leishmania antigens mixed with BCG,[66,67] or interferon gamma,[68,69] has produced encouraging results.

While there has been some work on vaccines against cutaneous leishmaniasis much more needs to be done. However, leishmanisation (deliberate infection with *L. major*) has been used as a last resort in some countries when other measures have failed.

Mucocutaneous leishmaniasis of the New World (espundia) is caused by *L. braziliensis* or *L. panamensis*. In mucocutaneous leishmaniasis the primary lesions do not heal spontaneously. Metastatic spread to the mucosa may occur during the presence of the primary lesion or up to 30 years later. The nasal mucosa is always affected. Ulceration and erosion progressively destroy the soft tissue and cartilage of the oronasal/pharyngeal cavity. Mutilation is severe and secondary bacterial infection is frequent and can be fatal.

Mucocutaneous leishmaniasis responds poorly to treatment and relapses are common. Initial treatment is with pentavalent antimony;[5] failure to respond is an indication to use amphotericin B or pentamidine. Nifurtimox may be effective in some cases of mucocutaneous leishmaniasis.[3] Treatment with corticosteroids may be needed to control severe inflammation. Mucosal disease in Old World leishmaniasis is much less common than visceral or cutaneous forms, but treatment with antimony compounds or ketoconazole has been described.[70]

Malaria

For a discussion of malaria, its prophylaxis and treatment, see p.594.

Microsporidiosis

Microsporidia are obligate intracellular spore-forming protozoal parasites. They were primarily regarded as a cause of disease in nonhuman species but some, including *Encephalitozoon*, *Enterocytozoon*, *Pleistophora*, and *Trachipleistophora* spp. and *Brachiola vesicularum* and *Vittaforma corneae (Nosema corneum)*, are now recognised as human pathogens. Transmission is believed to be predominantly faeco-oral although inhalation and direct inoculation also occur. Infections usually occur only in immunocompromised patients. Small bowel infection with *Enterocytozoon bieneusi* has been reported in AIDS patients as a cause of chronic diarrhoea and weight loss. Other manifestations of microsporidiosis in AIDS include keratoconjunctivitis, respiratory-tract infections, renal and urinary-tract infections, peritonitis, cholangitis, granulomatous hepatitis, and disseminated myositis.

There is no established treatment.[1] Beneficial responses have been reported with albendazole[2-6] and atovaquone.[7] Metronidazole has been reported to produce a transient symptomatic response in some patients[8] but not in those with severe diarrhoea.[9] There has also been a report of a patient treated successfully with nitazoxanide.[10] Fumagillin appears effective in the treatment of infection due to *E. bieneusi*.[11]

Topical treatment of keratoconjunctivitis has been disappointing, although there are reports of individual patients responding to topical propamidine isetionate,[12] topical fumagillin,[13,14] oral albendazole,[15] oral albendazole plus topical fumagillin,[16] or oral itraconazole plus topical antibacterials.[17]

Pneumocystis pneumonia

Although *Pneumocystis jirovecii* was formerly classified as a protozoan, it is now accepted to be a fungus. For the management of pneumocystis pneumonia, see p.521.

Toxoplasmosis

Toxoplasmosis[1] is a zoonosis with a worldwide distribution caused by the protozoan parasite *Toxoplasma gondii*. There is a high incidence of *Toxoplasma* antibody, an indication of previous infection, in the general population, although infection will have been diagnosed in few individuals. Sexual reproduction of *T. gondii* occurs in the gastrointestinal tract of cats. Soil becomes contaminated from excretion of oocysts in cat faeces. Other animals, such as pigs and sheep, may become infected by ingestion of these oocysts and act as intermediate hosts. In man, infection is acquired through contact with infected cat faeces or contaminated soil, or from eating raw or undercooked meat from infected animals. Ingested oocysts rapidly transform into trophozoites which multiply in tissue macrophages. The intracellular trophozoites disseminate in the bloodstream and lymphatic system to reach the brain, heart, and lungs. As immunity develops the trophozoites form latent cystic aggregates (bradyzoites), mainly in the brain, heart, and skeletal muscle, and these are subject to reactivation throughout the life of the host.

Toxoplasma infection in immunocompetent individuals is usually asymptomatic and if symptomatic infection does occur it is usually self-limiting. Very rarely myocarditis or encephalitis may occur. Patients with impaired immunity may develop serious complications such as encephalitis, chorioretinitis, myocarditis, and pneumonitis. Toxoplasmic encephalitis is the most common presentation in patients with AIDS.

Congenital toxoplasmosis is not a problem in women who have *Toxoplasma* antibody before conception, but primary toxoplasmosis during early pregnancy is serious because of the risk of transplacental transmission which may result in fetal death or congenital toxoplasmosis. Primary infection during later pregnancy can also result in congenital infection, although this often only becomes symptomatic later in life. The sequelae in live-born infants with signs of infection are generally severe and include a potentially fatal syndrome in which hydrocephalus, hepatosplenomegaly with jaundice, mental retardation, and chorioretinitis may occur. Congenital disease that becomes clinically evident later in life is usually less severe, but often results in ocular or neurological impairment. Infection in the pregnant woman is usually asymptomatic and antenatal screening programmes have been set up in some countries for the diagnosis of acute infections during pregnancy. However, the value and practicality of such schemes has been debated.[2-6] Ocular toxoplasmosis causes chorioretinitis and is often a result of congenital infection; patients may be asymptomatic until later in life.

Treatment. Toxoplasmosis in immunocompetent patients is not usually treated unless symptoms are severe. Currently there is no drug active against the cystic form, so any treatment is directed against the acute forms of the disease. Active toxoplasmosis in immunocompromised patients requires prompt treatment. Toxoplasmosis is normally treated with pyrimethamine plus sulfadiazine.[7,8] Folinic acid should also be given during treatment to counteract the megaloblastic anaemia associated with these drugs. Clindamycin plus pyrimethamine and folinic acid has been used as an alternative in patients unable to take the sulfonamide.[8] Other drug combinations have been studied and have been found to have activity in toxoplasmic encephalitis, notably atovaquone plus pyrimethamine and folinic acid, or atovaquone plus sulfadiazine, or azithromycin plus pyrimethamine and folinic acid. Atovaquone has also been given alone in patients unable to tolerate pyrimethamine or sulfadiazine.[8] Severely ill patients needing parenteral therapy have been given intravenous co-trimoxazole or clindamycin with oral pyrimethamine.[8] Adjunctive corticosteroids may be given occasionally for treatment of a mass effect associated with focal lesions or oedema, but should be stopped as soon as possible because of their immunosuppressant effect. Anticonvulsants should be given to patients with a history of seizures.[8] Acute treatment is ideally continued for 6 weeks, or for longer if disease is extensive or response is incomplete.

Patients who have successfully completed a 6-week course of acute therapy should be given chronic maintenance therapy, which should ideally be with pyrimethamine plus sulfadiazine and folinic acid, but alternatives are pyrimethamine plus clindamycin and folinic acid, or atovaquone, with or without pyrimethamine and folinic acid.[8] Chronic maintenance therapy should be lifelong unless immune reconstitution occurs because of antiretroviral therapy, in which case consideration may be given to stopping prophylaxis. It should, however, be restarted if the CD4+ T lymphocyte count falls to below 200 cells/microlitre.[8]

A systematic review[9] of the treatment of women during **pregnancy** has involved small studies with variations in period of gestation, duration of follow-up, and other aspects of methodology, making comparison of data problematical; consequently the evidence is inconclusive as to whether treatment is effective in preventing fetal infection or overt neonatal disease. If treatment is given, pyrimethamine should not be used to treat primary toxoplasmosis during the first trimester of pregnancy in immunocompetent patients. Spiramycin has been used throughout the first trimester but, although it reduces the risk of congenital transmission, it does not readily penetrate the cerebrospinal space and does not prevent toxoplasmic encephalitis in immunocompromised women. After the first trimester pyrimethamine may be given with sulfadiazine and folinic acid and, when there is evidence of placental or fetal infection, this treatment may be alternated with courses of spiramycin until term. In **neonates** with congenital toxoplasmosis, the preferred treatment is pyrimethamine together with sulfadiazine and folinic acid.[7] Infants without HIV infection should be treated for 12 months. In infants with mild toxoplasmosis, some experts recommend alternating pyrimethamine-sulfadiazine with spiramycin on a monthly basis from months 7 to 12, in order to reduce the risk of bone marrow suppression. However, infants with HIV infection and moderate to severe toxoplasmosis should receive the full 12-month regimen of pyrimethamine-sulfadiazine.[7] Longer courses of treatment may be given in cases of extensive disease. A corticosteroid, usually dexamethasone or prednisolone, has been added in children with CNS involvement.[7]

In immunocompetent individuals, **ocular toxoplasmosis** is a self-limiting disease and requires no treatment, unless visual acuity is threatened or there is a large retinal lesion with marked vitritis.[10-12] A systematic review[13] found a lack of evidence to support routine treatment for acute toxoplasma retinochoroiditis in immunocompetent patients, but did find weak evidence to suggest that long-term treatment of patients with chronic recurrent disease may reduce recurrence. All immunocompromised patients should be treated and prolonged treatment is necessary to prevent recrudescence. The best drug regimen is unknown. The most commonly used regimens are pyrimethamine with sulfadiazine or pyrimethamine with clindamycin (which is concentrated in the choroid). Benefit has been reported from clindamycin with corticosteroids,[14] although corticosteroids should never be used alone since fulminant cases may occur. Spiramycin is not indicated for ocular toxoplasmosis.

Prophylaxis. Primary prophylaxis against *T. gondii* infection has been investigated in AIDS patients and recipients of organ transplants. In HIV-infected persons who are seropositive for *Toxoplasma* and who have a CD4+ T lymphocyte count of less than 100 cells/microlitre, primary prophylaxis against encephalitis should be given.[15] Co-trimoxazole, in regimens designed for pneumocystis pneumonia prophylaxis, was found to be effective and is therefore recommended.[15] Alternatively, pyrimethamine plus dapsone may be given.[15] Atovaquone with or without pyrimethamine can also be considered.[15] Pyrimethamine plus sulfadoxine has also been tried, with promising results.[16] *Toxoplasma*-seronegative persons who are not receiving a pneumocystis prophylactic regimen known to be active against toxoplasmic encephalitis should be retested for *Toxoplasma* should their CD4+ T lymphocyte count fall below 100 cells/microlitre and if they have seroconverted primary prophylaxis should be instigated.[15] Primary prophylaxis should be stopped in adult and adolescent patients whose CD4+ T lymphocyte count rises in response to antiretroviral therapy to more than 200 cells/microlitre for 3 months or more. If the count subsequently falls to below 200 cells/microlitre it should be reinstigated.[15]

Trichomoniasis

Trichomoniasis is caused by invasion of the genito-urinary tract with the protozoan *Trichomonas vaginalis*. Transmission is primarily sexual. Trichomoniasis is a common cause of vaginitis and vaginal discharge; some infected women are asymptomatic but should still be treated to prevent sexual transmission and symptomatic infection. Men are usually asymptomatic, although they may experience urethritis.

Treatment is usually with a nitroimidazole such as metronidazole when a single oral dose can be effective.[1-4] Sexual partners should also be treated. The incidence of treatment failures appears to be increasing and some at least have been due to metronidazole resistance. Patients who do not respond to single-dose treatment may be given a more intensive course of metronidazole for 5 to 7 days. Tinidazole has been widely used as an alternative to metronidazole,[1] and may be effective in cases of metronidazole resistance.[5] A patient with metronidazole- and tinidazole-resistant infection was successfully treated with paromomycin.[6] Local application of paromomycin has also been tried in a small number of patients with moderate success.[7]

African trypanosomiasis

African trypanosomiasis (sleeping sickness) is caused by subspecies of the protozoan *Trypanosoma brucei*, transmitted by the bite of infected tsetse flies (*Glossina* spp.). Gambian or West African sleeping sickness is caused by *T. brucei gambiense*, carried by riverine tsetse flies, and Rhodesian or East African sleeping sickness is caused by *T. brucei rhodesiense*, carried by savannah tsetse flies. Infection can follow blood transfusion and congenital trypanosomiasis has also occurred.

Although it has proven impractical to eliminate trypanosomiasis from endemic areas, the intensity of transmission can be reduced by detection and treatment of cases and vector control, including insecticide spraying of breeding sites and the use of insecticide-impregnated traps and screens.[1] Control of infection in domestic animals may also be beneficial.[1]

Trypanosomiasis can be divided into the early haematolymphatic stage (infection of the bloodstream and lymph nodes), with lymphadenopathy, pruritus, fever, headache, and muscle and joint pain, and the late or meningoencephalitic stage (infection of the CNS) which is marked by signs including sleep disturbances, confusion, incoordination, psychiatric disorders, and eventual deterioration of consciousness.[1-3] Trypanosomiasis due to *T. b. gambiense* develops slowly over several months or even years and the disease stages are relatively distinct. Infection with *T. b. rhodesiense* is more acute with a rapid onset of symptoms and indistinct disease stages and, if left untreated, will usually lead to death in a matter of weeks or months.

The **haematolymphatic** phase of African trypanosomiasis is treated with suramin or pentamidine.[1-3] Pentamidine may be used for treatment of *T. b. gambiense* infections, but increasing resistance makes it unsuitable for *T. b. rhodesiense* infections; suramin is used for *T. b. rhodesiense* infections and for *T. b. gambiense* infections which are resistant to pentamidine. Giving both pentamidine and suramin for *T. b. gambiense* infections has not been shown to reduce the incidence of relapse.[4]

Suramin and pentamidine penetrate the blood-brain barrier poorly and are only used in the **meningoencephalitic** stage as adjuncts before starting treatment with melarsoprol or eflornithine. Melarsoprol, which is effective against both *T. b. gambiense* and *T. b. rhodesiense*, is usually only given to treat the meningoencephalitic stage of the infection because it may produce potentially fatal encephalopathy. However, protection against this toxicity may be provided by prophylaxis with prednisolone.[5,6] Patients with *T. b. gambiense* infection may be treated more safely with eflornithine than melarsoprol on its own.[7-9] Combination therapy with melarsoprol and eflornithine was reported to be effective in a patient who had not responded to either drug alone.[10] Eflornithine given with suramin produced disappointing results in 6 patients with *T. b. rhodesiense*.[11]

Nifurtimox[1,12,13] is an alternative treatment to melarsoprol for relapse of *T. b. gambiense* infection. Promising results have been obtained from a randomised controlled study[14] for the treatment of second stage *T.b. gambiense* infection with oral nifurtimox plus intravenous eflornithine.

There is no established effective alternative treatment for melarsoprol-resistant *T. b. rhodesiense*, although suramin given with high-dose metronidazole was successful in a patient.[15]

Patients should be seen every 6 months for a follow-up period of at least 2 years, to ascertain if treatment has been successful.

American trypanosomiasis

American trypanosomiasis (Chagas' disease) is caused by *Trypanosoma cruzi*, carried by reduviid or triatomine bugs which feed on human blood.[1] Infected bugs defecate on the human host while feeding and metacyclic trypanosomes are shed and enter the host via skin abrasions or by direct penetration of mucous membranes such as the conjunctiva. Transmission by blood transfusion has been a large problem. Congenital infection can also occur. Control measures include case detection and treatment, vector control by insecticide applications within domestic buildings, and screening of blood donors.[1]

Infection with *T. cruzi* is found throughout South and Central America and has been recorded in Mexico and Texas; there have also been reports of transfusion-induced infection in northern USA and Canada. Three phases of the disease are recognised. In the early acute phase of infection parasites are present in the blood; this phase may be asymptomatic or there may be a swelling or chagoma at the site of infection, allergic reactions, and more rarely acute heart failure or meningoencephalitis. The acute phase may be fatal in children, but patients usually survive to enter an indeterminate phase, in which infection may be present in tissue for years without clinical manifestations. Classical features of the final chronic phase are cardiomyopathy, megacolon, and mega-oesophagus. Parasitaemia falls to undetectable levels after the acute phase.

Available treatment is generally unsatisfactory but, despite their toxicity, nifurtimox or benznidazole are of value especially in the acute phase; it is not certain whether trypanocidal treatment during the indeterminate phase can prevent the development of chronic disease although favourable results were obtained in a small study in children given benznidazole.[2] Although it is generally felt that there is no benefit from treatment in the chronic phase, treatment during the early chronic phase was reported to be beneficial,[3] and long-term follow-up of patients who had received benznidazole showed a reduction in cardiac complications and parasitaemia.[4] Symptomatic treatment is often given, particularly in the chronic stage for cardiac and gastrointestinal lesions. A systematic review[5] considered that indications for treatment with benznidazole or nifurtimox included all cases of congenital infection, reactivated infection, and all children 18 years of age or less; antitrypanocidal treatment should also generally be offered to adults aged 19 to 50, and should be considered in older adults although the risks of drug therapy were greater in the last group. It was not recommended for advanced Chagasic cardiomyopathy, since the existing pathology would not benefit, but the potential to reduce development of cardiomyopathy should be considered in patients with gastrointestinal involvement.

The efficacy of treatment varies from country to country and may be linked to variations in the sensitivity of different strains of *T. cruzi*. Treatment is said to be successful when both parasitaemia and serological tests become negative and remain so for at least one year after the end of treatment.

Allopurinol and allopurinol riboside are under investigation for the treatment of American trypanosomiasis since they have shown trypanocidal activity. Allopurinol has been reported to be as effective as nifurtimox or benznidazole in reducing parasitaemia during the indeterminate phase and to be better tolerated.[6] Allopurinol and itraconazole, alone or in combination, have produced beneficial responses in patients with chronic disease.[7,8]

In areas where the proportion of seropositive blood donors is high, emergency blood supplies positive for *T. cruzi* have been made safe by the addition of methylrosanilinium chloride. It has been suggested that the risk of transmission to transplant recipients can be reduced considerably by nifurtimox or benznidazole treatment of the donor for 2 weeks before transplantation, and of the recipient for 2 weeks after transplantation. In laboratory workers at risk of an infection after an accident, treatment with benznidazole for 10 days should be started immediately.

Acetarsol *(BAN, rINN)*

Acetaminohydroxyphenylarsonsäure; Acétarsol; Acetarsolum; Acetarsone; Acetphenarsinum; Asetarsoli; Osarsolum. 3-Acetamido-4-hydroxyphenylarsonic acid.

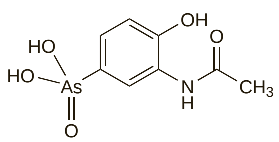
Ацетарсол

$C_8H_{10}AsNO_5$ = 275.1.

CAS — 97-44-9.

ATC — A07AX02; G01AB01; P01CD02.

ATC Vet — QA07AX02; QG01AB01; QP51AD05.



Profile

Acetarsol, a pentavalent organic arsenical derivative, was formerly given orally in the treatment of intestinal amoebiasis and vaginally in the treatment of trichomoniasis, but the use of pentavalent arsenical compounds has been abandoned in favour of more effective and less toxic drugs. For the adverse effects of arsenic and their treatment, see Arsenic Trioxide, p.2260.

Acetarsol suppositories were once tried in the treatment of proctitis. Acetarsol lithium and acetarsol sodium have been included in some preparations for minor mouth infections.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Rus.:*** Osarbon (Осарбон).

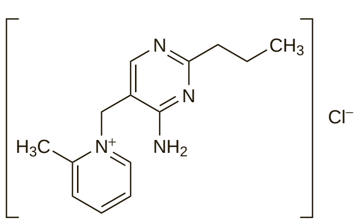
Amprolium Hydrochloride *(BANM, rINNM)*

Amprolii Hydrochloridum; Amprolium, Chlorhydrate d'; Hidrocloruro de amprolio. 1-(4-Amino-2-propylpyrimidin-5-ylmethyl)-2-methylpyridinium chloride hydrochloride.

Амлролия Гидрохлорид

$C_{14}H_{19}ClN_4,HCl$ = 315.2.

CAS — 121-25-5 (amprolium); 137-88-2 (amprolium hydrochloride).



(amprolium)

Pharmacopoeias. In *Fr.* and *US* for veterinary use only. Also in *BP(Vet).*

BP(Vet) 2008 (Amprolium Hydrochloride). A white or almost white, odourless or almost odourless powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in chloroform; very slightly soluble in ether.

USP 31 (Amprolium). A white to light yellow powder. Freely soluble in water, in alcohol, in dimethylformamide and in methyl alcohol; sparingly soluble in dehydrated alcohol; practically insoluble in acetone, in butyl alcohol, and in isopropyl alcohol.

Profile

Amprolium hydrochloride is an antiprotozoal used in veterinary practice, alone or with other drugs such as ethopabate, for the control of coccidiosis in pigeons and in poultry.

Pentavalent Antimony Compounds

Antimonio pentavalente, compuestos de.

Meglumine Antimonate

Antimoniato de meglumina; Antimony Meglumine; Meglumine Antimoniate; Protostib; RP-2168. 1-Deoxy-1-methylamino-D-glucitol antimonate.

Меглумина Антимонат

$C_7H_{18}NO_8Sb$ = 366.0.

CAS — 133-51-7.

ATC — P01CB01.

ATC Vet — QP51AB01.

Sodium Stibogluconate *(BAN, rINN)*

Estibogluconato de sodio; Natrii Stibogluconas; Natriumstiboglukonaatti; Natriumstiboglukonat; Sod. Stibogluc.; Sodium Antimony Gluconate; Sodyum Stiboglukonat; Stibogluconate de Sodium; Stibogluconat-Natrium.

Натрия Стибоглюконат

CAS — 16037-91-5.

ATC — P01CB02.

ATC Vet — QP51AB02.

Description. A pentavalent antimony compound of indefinite composition. It has been represented by the formula $C_6H_9Na_2O_9Sb$ but usually there are less than 2 atoms of Na for each atom of Sb. Solutions may be sterilised by autoclaving.

Pharmacopoeias. In *Br., Chin., Int.,* and *It.*

BP 2008 (Sodium Stibogluconate). It is mainly the disodium salt of μ-oxy-bis[gluconato(3-)O^2,O^3,O^4-hydroxo-antimony]. It contains not less than 30.0% and not more than 34.0% of antimony(V), calculated with reference to the dried and methanol-free substance. It is a colourless, odourless or almost odourless, mostly amorphous powder. Very soluble in water; practically insoluble in alcohol and in ether. A solution in water containing 10% of pentavalent antimony has a pH of 5.0 to 5.6 after autoclaving.

Adverse Effects, Treatment, and Precautions

As for Trivalent Antimony Compounds, p.141.

Adverse effects are generally less frequent and less severe with the pentavalent antimony compounds sodium stibogluconate and meglumine antimonate than with trivalent compounds such as antimony sodium tartrate. Nevertheless, similar precautions should be observed, especially in patients on high-dose therapy.

Intramuscular injections of sodium stibogluconate can be painful and intravenous use has been associated with thrombophlebitis.

◊ Common adverse effects of pentavalent antimony are anorexia, vomiting, nausea, malaise, arthralgia and myalgia, headache, lethargy, and pancreatitis. ECG changes are dose-dependent and most commonly include T-wave inversion and prolonged QT interval. Renal damage is a rarely reported toxic effect. Pentavalent antimony is usually well tolerated. Serious adverse effects when they occur usually involve the liver or the heart when it is prudent to interrupt the course temporarily.

Breast feeding. The amount of antimony distributed into the breast milk of a patient given sodium stibogluconate was considered not to constitute a hazard and oral absorption was not detected in an *animal* study.[1] The American Academy of Pediatrics also considers that the use of antimony is usually compatible with breast feeding.[2] Others, however, have felt that more safety evaluation was required before antimony could be considered completely safe during breast feeding.[3]

Effects on the heart. The ECG was monitored during 65 courses of treatment with sodium stibogluconate in 59 Kenyan patients with leishmaniasis.[1] ECG abnormalities developed during 35 treatment courses. They were qualitatively similar to those previously described during treatment with trivalent antimonial drugs, but occurred less frequently and later during the course of treatment. The most common abnormality was inversion and/or decreased amplitude of T waves. Incidence was related to total daily dose and duration of treatment. One patient died suddenly during the 4th week of treatment with antimony 60 mg/kg daily. Other deaths probably related to cardiac toxicity have been reported in patients receiving 60 mg/kg daily[2] and 30 mg/kg daily.[3] It has been recommended[1] that for treatment with sodium stibogluconate ECGs should be obtained every 3 to 4 days in patients given antimony 20 mg/kg daily for more than 20 days or a higher dose for more than 10 days. If Stokes-Adams attacks or ventricular tachyarrhythmias develop, sodium stibogluconate should be stopped and appropriate treatment given. A retrospective study[4] in patients treated with sodium stibogluconate for mostly cutaneous leishmaniasis found that the mean QT_c interval steadily increased throughout the period of treatment, reaching a potentially toxic threshold by the third week, but cardiotoxicity was seen only in one elderly patient who had hypokalaemia and pre-existing cardiovascular morbidity. Identification before treatment of factors that may increase cardiovascular risk is important.

4. Lawn SD, *et al.* Electrocardiographic and biochemical adverse effects of sodium stibogluconate during treatment of cutaneous and mucosal leishmaniasis among returned travellers. *Trans R Soc Trop Med Hyg* 2006; **100:** 264–9.

Effects on the kidneys. Sodium stibogluconate given for 10 days to 16 young men with cutaneous leishmaniasis had no apparent adverse effect on glomerular or tubular renal function.[1] However, evidence of renal tubular dysfunction has been reported in patients with mucocutaneous leishmaniasis given meglumine antimonate or sodium stibogluconate for 30 days or more[2] and acute renal failure has occurred in patients both with,[3] and without,[4] pre-existing renal impairment, the latter resulting in death.

4. Rodrigues MLO, *et al.* Nephrotoxicity attributed to meglumine antimoniate (Glucantime) in the treatment of generalized cutaneous leishmaniasis. *Rev Inst Med Trop Sao Paulo* 1999; **41:** 33–7.

Effects on the liver. WHO has reported that when serious adverse effects occur with sodium stibogluconate they usually involve the liver or the heart.[1] There have been reports of disturbed liver function[2,3] in patients given sodium stibogluconate, although there has also been a report[4] that signs of altered liver function, which may be a feature of visceral leishmaniasis, improved during treatment with sodium stibogluconate.

1. WHO. Control of the leishmaniases. *WHO Tech Rep Ser 793* 1990. Available at: http://libdoc.who.int/trs/WHO_TRS_793.pdf (accessed 17/07/08)

4. Misbahuddin M, *et al.* Stibogluconate for leishmaniasis. *Lancet* 1993; **342:** 804.

Effects on the musculoskeletal system. Arthralgia is common with pentavalent antimony compounds. It is usually dose-dependent[1] but a patient has been described who experienced symptoms early in treatment.[2] Palindromic arthropathy with effusion was associated with sodium stibogluconate treatment in another patient.[3]

1. Ballou WR, *et al.* Safety and efficacy of high-dose sodium stibogluconate therapy of American cutaneous leishmaniasis. *Lancet* 1987; **ii:** 13–16.
2. Castro C, *et al.* Severe arthralgia, not related to dose, associated with pentavalent antimonial therapy for mucosal leishmaniasis. *Trans R Soc Trop Med Hyg* 1990; **84:** 362.
3. Donovan KL, *et al.* Pancreatitis and palindromic arthropathy with effusions associated with sodium stibogluconate treatment in a renal transplant recipient. *J Infect* 1990; **21:** 107–10.

Effects on the nervous system. Peripheral neuropathy developed in a patient about 8 days after starting therapy with sodium stibogluconate.[1] The symptoms were generally reversible when treatment was stopped (after 17 days), although there was some slight persistent hypoaesthesia in the toes. An interaction with a single dose of amitriptyline, taken on the second day of stibogluconate therapy, seemed unlikely but could not be ruled out.

1. Brummitt CF, *et al.* Reversible peripheral neuropathy associated with sodium stibogluconate therapy for American cutaneous leishmaniasis. *Clin Infect Dis* 1996; **22:** 878–9.

Effects on the pancreas. Pancreatitis has been associated with sodium stibogluconate treatment.[1-3] Withdrawing treatment usually resulted in resolution of pancreatitis.

3. Domingo P, *et al.* Treatment of Indian kala-azar with pentavalent antimony. *Lancet* 1995; **345:** 584–5.

Pharmacokinetics

The pentavalent antimony compounds are poorly absorbed from the gastrointestinal tract. After intravenous doses an initial distribution phase is followed by biexponential elimination by the kidneys. The elimination half-life of the initial phase is about 1.7 hours and that of the slow terminal phase is about 33 hours. The corresponding half-lives after intramuscular doses are reported to be 2 hours and 766 hours respectively. The slow elimination phase may reflect reduction to trivalent antimony. Accumulation occurs on daily use and maximum tissue concentrations may not be reached for 7 days or more. Antimony has been detected in breast milk (see Breast Feeding, above).

Uses and Administration

Pentavalent antimony, as sodium stibogluconate or meglumine antimonate, is used as first-line treatment for all forms of leishmaniasis except *Leishmania aethiopica* infections.

For systemic use, sodium stibogluconate is given by intramuscular or intravenous injection as a solution containing the equivalent of pentavalent antimony 100 mg/mL. Intramuscular injection is generally preferable. Intravenous injections must be given very slowly (over at least 5 minutes) and preferably through a fine needle to avoid thrombophlebitis; as with trivalent antimony compounds, they should be stopped immediately if coughing, vomiting, or substernal pain occurs. Meglumine antimonate is given by deep intramuscular injection as a solution containing the equivalent of pentavalent antimony 85 mg/mL. Doses are expressed in terms of the equivalent amount of pentavalent antimony.

Local variations exist in treatment schedules but WHO recommends the following regimens:

- In **visceral leishmaniasis**, initial treatment is based on daily intramuscular injection of pentavalent antimony 20 mg/kg to a maximum of 850 mg (but see below) for at least 20 days. The length of treatment varies from one endemic area to another, but is continued until no parasites are detected in consecutive splenic aspirates taken at 14-day intervals. Patients who relapse are re-treated at the same dose.
- Early non-inflamed lesions of **cutaneous leishmaniasis** due to all forms of *Leishmania* except *L. aethiopica*, *L. amazonensis*, and *L. braziliensis* may be treated by infiltration with intralesional injections of 1 to 3 mL of sodium stibogluconate or meglumine antimonate (about 100 to 300 mg of pentavalent antimony), repeated once or twice if necessary at intervals of 1 to 2 days. Systemic therapy with intramuscular pentavalent antimony 10 to 20 mg/kg daily is given if the lesions are more severe and continued until a few days after clinical and parasitological cure is achieved.

  Cutaneous leishmaniasis due to *L. aethiopica* is not responsive to antimonials at conventional doses. In cutaneous leishmaniasis due to *L. braziliensis*, prolonged systemic treatment with intramuscular pentavalent antimony 20 mg/kg daily for a minimum of 4 weeks is indicated. Similar doses are required for **diffuse cutaneous leishmaniasis** due to *L. amazonensis* and are continued for several months after clinical improvement occurs. Relapses should be expected until immunity develops.
- In **mucocutaneous leishmaniasis**, daily doses of intramuscular pentavalent antimony 20 mg/kg are given for a minimum of 4 weeks; if the response is poor, 10 to 15 mg/kg may be given every 12 hours for the same period. Relapses are well known and have generally been associated with inadequate or interrupted treatment; they are treated with the same drug given for at least twice as long as the original treatment. Only when that fails should alternative treatment be given.

Leishmaniasis. The main treatment for leishmaniasis (p.824) is a pentavalent antimony compound such as sodium stibogluconate. Higher doses of antimony compounds than those recommended by WHO (see above) have been tried in order to overcome the unresponsiveness of leishmaniasis to therapy. In the USA, the use of 20 mg/kg daily of pentavalent antimony has been recommended, without restriction to an 850-mg maximum daily dose.[1,2] At 20 mg/kg daily the most common adverse effects are musculoskeletal disorders, elevated liver enzyme values, and T-wave changes on the ECG, and the CDC recommends that the ECG, blood chemistry, and blood count should be monitored throughout therapy if resources permit.[1] Severe cardiotoxicity is rare at this dose but fatal cardiac toxicity has been reported with doses of up to 60 mg/kg daily (see under Effects on the Heart, above). Drug-resistant strains of *Leishmania infantum* have been associated with unresponsiveness to treatment with meglumine antimonate.[3] It was suggested[4] that the use of suboptimal doses may be increasing the prevalence of drug-resistant strains of the parasite. However, low doses of antimony compounds (5 mg/kg daily for 30 days) have produced long-term cure in patients with cutaneous *L. braziliensis* infection followed for up to 10 years.[5]

INTRALESIONAL ADMINISTRATION. Intralesional infiltration of 3 doses of sodium stibogluconate on alternate days or once weekly was more effective than daily treatment in a study of 96 patients in Saudi Arabia.[6] Local infiltration of meglumine antimonate in usual doses of 150 to 900 mg (maximum 1500 mg) once each week for up to 6 weeks produced microbiological and clinical cures in all of 45 patients in Italy with cutaneous leishmaniasis.[7]

Atovaquone *(BAN, USAN, rINN)*

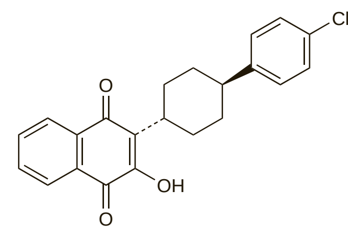
Atovacuona; Atovakon; Atovakvon; Atovakvoni; Atovaquonum; BW-A566C; BW-566C; BW-566C80; 566C; 566C80. 2-[*trans*-4-(4-Chlorophenyl)cyclohexyl]-3-hydroxy-1,4-naphthoquinone.

Атоваxон

$C_{22}H_{19}O_3Cl$ = 366.8.

CAS — 95233-18-4.

ATC — P01AX06.



Pharmacopoeias. In *US.*

USP 31 (Atovaquone). A yellow powder. Insoluble in water; slightly soluble in alcohol, in butanediol, in ethyl acetate, in glycerol, in octanol, and in macrogol 200; sparingly soluble in acetone, in di-*n*butyl adipate, in dimethyl sulfoxide, and in macrogol 400; soluble in chloroform; freely soluble in *N*-methyl-2-pyrrolidone and in tetrahydrofuran; very slightly soluble in 0.1N sodium hydroxide. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Adverse reactions to atovaquone include skin rashes, headache, fever, insomnia, and gastrointestinal effects such as nausea, diarrhoea, and vomiting. Raised liver enzyme values, hyponatraemia, and haematological disturbances such as anaemia and neutropenia may occur occasionally. Atovaquone should be avoided in patients with gastrointestinal disorders that may limit absorption of the drug.

Effects on the skin. Stevens-Johnson syndrome has been reported[1] in a patient taking atovaquone with proguanil.

1. Emberger M, *et al.* Stevens-Johnson syndrome associated with Malarone antimalarial prophylaxis. Abstract: *Clin Infect Dis* 2003; **37:** 158. Full version: http://www.journals.uchicago.edu/doi/pdf/10.1086/375073 (accessed 17/07/08)

Interactions

Use of atovaquone with either metoclopramide, tetracycline, or rifampicin (and possibly also rifabutin) may result in decreases in plasma-atovaquone concentrations. Other drugs which have produced small reductions in plasma-atovaquone concentrations include aciclovir, antidiarrhoeals, benzodiazepines, cephalosporins, laxatives, opioids, and paracetamol.

Atovaquone is reported to decrease the metabolism of zidovudine resulting in moderate increases in zidovudine plasma concentrations. A decrease in trough concentrations of indinavir, and in the area under the indinavir time-concentration curve has been reported when atovaquone was also given. Small decreases in the plasma concentrations of co-trimoxazole have been noted in patients taking atovaquone. There is a theoretical possibility that atovaquone could displace other highly protein-bound drugs from plasma-protein binding sites.

Pharmacokinetics

Atovaquone is poorly absorbed from the gastrointestinal tract after oral doses; bioavailability is especially poor in patients with AIDS. Bioavailability from commercial oral liquid formulations is better than from tablets and can be further improved if taken with food, particularly meals with a high fat content. Atovaquone is more than 99% bound to plasma proteins and has a long plasma half-life of 2 to 3 days, thought to be due to enterohepatic recycling. It is excreted almost exclusively in faeces as unchanged drug.

Uses and Administration

Atovaquone is a hydroxynaphthoquinone antiprotozoal that is also active against the fungus *Pneumocystis jirovecii*. It is used in the treatment and prophylaxis of pneumocystis pneumonia in patients unable to tolerate co-trimoxazole, and with proguanil in the treatment and prophylaxis of malaria.

In the treatment of mild to moderate **pneumocystis pneumonia**, atovaquone is given orally in a dose of 750 mg with food twice daily as a suspension, for 21 days. For prophylaxis 1500 mg of the suspension is given once daily with food.

Prophylaxis of falciparum **malaria** should start 1 to 2 days before travel to the malarious area, continue daily throughout exposure, and for 7 days after leaving the area. The following doses may be given once daily:

- adults and children over 40 kg: atovaquone 250 mg with proguanil hydrochloride 100 mg
- children 11 to 20 kg: one-quarter the adult dose
- children 21 to 30 kg: one-half the adult dose
- children 31 to 40 kg: three-quarters the adult dose

In the **treatment** of uncomplicated falciparum **malaria**, the following doses are given as a single daily dose for 3 days:

- adults and children over 40 kg: atovaquone 1000 mg with proguanil hydrochloride 400 mg
- children 5 to 8 kg: one-eighth the adult dose
- children 9 to 10 kg: three-sixteenths the adult dose
- children 11 to 20 kg: one-quarter the adult dose
- children 21 to 30 kg: one-half the adult dose
- children 31 to 40 kg: three-quarters the adult dose

Atovaquone with proguanil is one of the antimalarial drugs recommended by some experts to be carried as a **standby** for the emergency treatment of **malaria**. The dose recommended for self-treatment is the same as that for treatment of uncomplicated falciparum malaria.

Babesiosis. In a prospective, randomised study[1] involving 58 patients with babesiosis (p.823), atovaquone with azithromycin was found to be as effective as, and associated with fewer adverse effects than, standard therapy with quinine and clindamycin. Atovaquone 750 mg twice daily with azithromycin 600 mg once daily, or 500 to 1000 mg on day 1 followed by 250 mg once daily thereafter, both orally for 7 to 10 days, has been recommended by some experts[2,3] in the USA for the treatment of *Babesia microti* infections. Children may be given atovaquone 20 mg/kg twice daily with azithromycin 12 mg/kg once daily, or 10 mg/kg on day 1 followed by 5 mg/kg once daily thereafter, both by mouth for 7 to 10 days.

Malaria. Atovaquone with proguanil (*Malarone*) is used in the treatment and prophylaxis of uncomplicated malaria caused by *Plasmodium falciparum* (see p.594).

Atovaquone, a blood schizontocide, is associated with an unacceptably high rate of recrudescence when used alone[1,2] for *treatment* but is more successful in malaria when used with proguanil,[2,3] including that produced by multidrug-resistant strains.[4] Use of the combination to treat *P. ovale* and *P. malariae* malarias has also been studied.[5] Atovaquone with proguanil followed by primaquine may also be effective for the treatment of *P. vivax* malaria.[6]

Atovaquone with proguanil has also been found to be useful for *prophylaxis* of falciparum malaria in both children[7] and adults[8] in endemic areas. It may also be used for prophylaxis in non-immune travellers[9,10] and appears to be well tolerated.[10,11]

Microsporidiosis. There is no established effective treatment for microsporidiosis (p.826). Beneficial responses were reported with atovaquone in a preliminary study.[1]

1. Anwar-Bruni DM, *et al.* Atovaquone is effective treatment for the symptoms of gastrointestinal microsporidiosis in HIV-1-infected patients. *AIDS* 1996; **10:** 619–23.

Pneumocystis pneumonia. Atovaquone is one alternative to co-trimoxazole for the treatment of pneumocystis pneumonia (p.521). In open studies, a clinical response to atovaquone was reported in 78% of patients with mild to moderate disease and in 56% of patients with severe disease who were intolerant of, or who failed to respond to, both co-trimoxazole and pentamidine.[1] Comparative studies have shown atovaquone to be less effective than co-trimoxazole[2] and probably less effective than pentamidine,[3,4] but to produce fewer treatment-limiting adverse effects than either.

Atovaquone is also an alternative to co-trimoxazole for both primary or secondary *prophylaxis*, and was as effective as dapsone[5] or inhaled pentamidine[6] in studies in patients intolerant of co-trimoxazole.

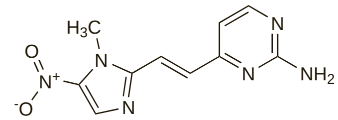
Azanidazole *(BAN, USAN, rINN)*

Azanidazol; Azanidazolum; F-4. 4-[(*E*)-2-(1-Methyl-5-nitroimidazol-2-yl)vinyl]pyrimidin-2-ylamine.

Азанидазол

$C_{10}H_{10}N_6O_2$ = 246.2.
CAS — 62973-76-6.
ATC — G01AF13; P01AB04.
ATC Vet — QG01AF13; QP51AA04.



Profile

Azanidazole is a 5-nitroimidazole derivative similar to metronidazole (p.837) and is used in the treatment of trichomoniasis in usual oral doses of 200 mg twice daily or 250 mg once daily intravaginally.

Preparations

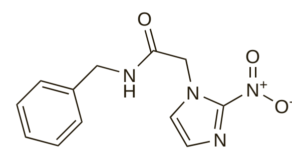
Proprietary Preparations (details are given in Part 3)
Ital.: Triclose.

Benznidazole *(rINN)*

Benznidazol; Benznidazolum; Ro-7-1051. *N*-Benzyl-2-(2-nitroimidazol-1-yl)acetamide.

Бензнидазол

$C_{12}H_{12}N_4O_3$ = 260.2.
CAS — 22994-85-0.
ATC — P01CA02.



Pharmacopoeias. In *Int.*

Adverse Effects

Nausea, vomiting, abdominal pain, peripheral neuropathy, blood dyscrasias, and severe skin reactions have been reported with benznidazole.

◊ A study[1] involving 20 patients with chronic American trypanosomiasis given benznidazole 5 mg/kg daily had to be stopped because of the high incidence of skin rashes and neurological symptoms.

1. Apt W, *et al.* Clinical trial of benznidazole and an immunopotentiator against Chagas disease in Chile. *Trans R Soc Trop Med Hyg* 1986; **80:** 1010.

Pharmacokinetics

Benznidazole is absorbed from the gastrointestinal tract after oral doses.

◊ References.

1. Raaflaub J, Ziegler WH. Single-dose pharmacokinetics of the trypanosomicide benznidazole in man. *Arzneimittelforschung* 1979; **29:** 1611–14.

Uses and Administration

Benznidazole is a 2-nitroimidazole derivative with antiprotozoal activity. It is of value in the treatment of American trypanosomiasis (Chagas' disease) due to infection with *Trypanosoma cruzi*, especially during the early acute stage of the disease.

Benznidazole has been given orally in a dose of 5 to 7 mg/kg daily in two divided doses usually for 60 days (but see below). Children have been given 10 mg/kg daily in two divided doses.

American trypanosomiasis. Available treatment for American trypanosomiasis (p.827) is generally unsatisfactory, but benznidazole is of value especially in the acute phase. WHO[1] recommends that benznidazole should be given for 60 days but some in the USA[2] suggest courses of 30 to 90 days. Although treatment is usually confined to the acute phase of the disease, therapy during the early chronic phase was reported to be beneficial,[3] and long-term follow-up in patients who had received benznidazole has shown a reduction in cardiac complications and parasitaemia.[4]

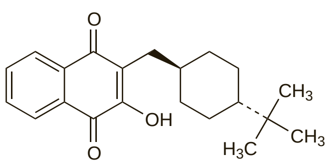
Бупарвахон

$C_{21}H_{26}O_3$ = 326.4.
CAS — 88426-33-9.
ATC Vet — QP51AX22.



Profile

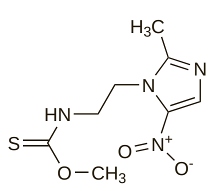
Buparvaquone is an antiprotozoal used in veterinary practice for the treatment of theileriosis in cattle.

Carnidazole *(BAN, USAN, pINN)*

Carnidazol; Carnidazolum; R-25831; R-28096 (carnidazole hydrochloride). *O*-Methyl [2-(2-methyl-5-nitroimidazol-1-yl)ethyl]-thiocarbamate.

Карнидазол

$C_8H_{12}N_4O_3S$ = 244.3.
CAS — 42116-76-7.
ATC Vet — QP51AA09.



Profile

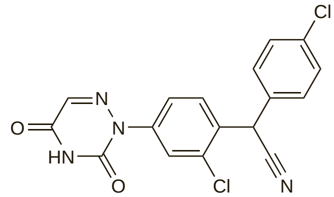
Carnidazole is a 5-nitroimidazole derivative similar to metronidazole. It is used in veterinary practice for the control of trichomoniasis in pigeons.

Clazuril *(BAN, USAN, rINN)*

Clazurilo; Clazurilum; Klatsuriili; Klazuril; R-62690. (±)-[2-Chloro-4-(4,5-dihydro-3,5-dioxo-*as*-triazin-2(3*H*)-yl)phenyl]-(*p*-chlorophenyl)acetonitrile.

Клазурил

$C_{17}H_{10}Cl_2N_4O_2$ = 373.2.
CAS — 101831-36-1.
ATC Vet — QP51AJ02.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.
Ph. Eur. 6.2 (Clazuril for Veterinary Use; Clazuril BP(Vet) 2008). A white or light yellow powder. Practically insoluble in water; slightly soluble in alcohol and in dichloromethane; freely soluble in dimethylformamide. Protect from light.

Profile

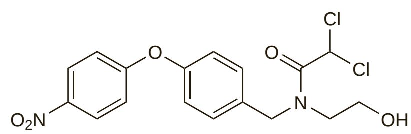
Clazuril is an antiprotozoal used in veterinary practice for the control of coccidiosis in pigeons.

Clefamide *(BAN, rINN)*

Chlorphenoxamide; Clefamida; Cléfamide; Clefamidum. 2,2-Dichloro-*N*-(2-hydroxyethyl)-*N*-[4-(4-nitrophenoxy)benzyl]-acetamide.

Клефамид

$C_{17}H_{16}Cl_2N_2O_5$ = 399.2.
CAS — 3576-64-5.
ATC — P01AC02.



Profile

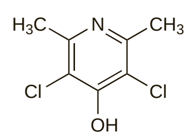
Clefamide is an antiprotozoal that has been used as a luminal amoebicide in the treatment of *Entamoeba histolytica* infections.

Clopidol *(BAN, USAN, rINN)*

Clopidolum; Clopindol; Meticlorpindol. 3,5-Dichloro-2,6-dimethylpyridin-4-ol.

Клопидол

$C_7H_7Cl_2NO$ = 192.0.
CAS — 2971-90-6.



Profile

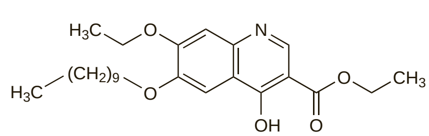
Clopidol is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry and rabbits either alone or with methyl benzoquate (p.837).

Decoquinate *(BAN, USAN, rINN)*

Décoquinate; Decoquinato; Decoquinatum; HC-1528; M&B-15497. Ethyl 6-decyloxy-7-ethoxy-4-hydroxyquinoline-3-carboxylate.

Декохинат

$C_{24}H_{35}NO_5$ = 417.5.
CAS — 18507-89-6.
ATC Vet — QP51AX14.



Pharmacopoeias. In *US* for veterinary use only. Also in *BP(Vet)*.
BP(Vet) 2008 (Decoquinate). A cream to buff-coloured, odourless or almost odourless, microcrystalline powder. Insoluble in water; practically insoluble in alcohol; very slightly soluble in chloroform and in ether.
USP 31 (Decoquinate). Store in airtight containers.

Profile

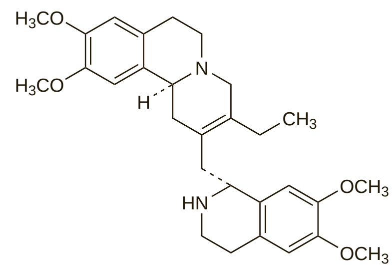
Decoquinate is an antiprotozoal used in veterinary practice for the control of coccidiosis in calves, sheep, and chickens. It is also used for toxoplasmosis in sheep.

Dehydroemetine Hydrochloride *(BANM, rINNM)*

BT-436; Déhydroémétine, Chlorhydrate de; 2,3-Dehydroemetine Hydrochloride; Dehydroemetini Hydrochloridum; DHE; Hidrocloruro de dehidroemetina; Ro-1-9334. 2,3-Didehydro-6′,7′,10,11-tetramethoxyemetan dihydrochloride; 3-Ethyl-1,6,7,11b-tetrahydro-9,10-dimethoxy-2-(1,2,3,4-tetrahydro-6,7-dimethoxy-1-isoquinolylmethyl)-4*H*-benzo[*a*]quinolizine dihydrochloride.

Дегидроэметина Гидрохлорид

$C_{29}H_{38}N_2O_4$,2HCl = 551.5.
CAS — 4914-30-1 (dehydroemetine); 2228-39-9 (dehydroemetine hydrochloride).



(dehydroemetine)

NOTE. The name DHE has been used to denote a preparation of dihydroergotamine mesilate.

Pharmacopoeias. In *Int.*

Profile

Dehydroemetine, a synthetic derivative of emetine (p.833), is a tissue amoebicide with similar actions and uses, although probably of a lower toxicity.

Dehydroemetine should be avoided in patients with cardiac, renal, or neuromuscular disease and patients should be monitored for cardiac toxicity during treatment.

When used in the treatment of amoebiasis (p.822), dehydroemetine hydrochloride is given by intramuscular injection in a dose of 1 mg/kg daily (maximum daily dose of 60 mg), generally for up to 4 to 6 days, but for no more than 5 days in children. A dose of 0.5 mg/kg has been suggested for elderly or severely ill patients. At least 6 weeks should elapse before treatment is repeated. Following treatment with dehydroemetine, all patients should receive a luminal amoebicide to eliminate organisms from the colon. Patients with hepatic amoebiasis may be given supplementary treatment with chloroquine.

Liver fluke infections. Dehydroemetine has been given[1] in the treatment of the liver fluke infection fascioliasis (see p.137).

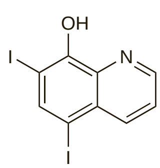
ATC Vet — QG01AC01.



Pharmacopoeias. In *US.*

USP 31 (Iodoquinol). A light yellowish to tan, microcrystalline powder, not readily wetted in water, odourless or has a faint odour. Practically insoluble in water; sparingly soluble in alcohol and in ether.

Adverse Effects

Major concerns have been expressed about the safety of the halogenated hydroxyquinolines since the recognition of severe neurotoxicity with clioquinol (p.254). In Japan, the epidemic development of subacute myelo-opticoneuropathy (SMON) in the 1960s was associated with the ingestion of normal or high doses of clioquinol for prolonged periods and the sale of clioquinol and related hydroxyquinolines was subsequently banned there. Symptoms of SMON are principally those of peripheral neuropathy, including optic atrophy, and myelopathy. Abdominal pain and diarrhoea often precede neurological symptoms such as paraesthesias in the legs, progressing to paraplegia in some patients, and loss of visual acuity sometimes leading to blindness. Cerebral disturbances, including confusion and retrograde amnesia, have also been reported. Although many patients improved when clioquinol was withdrawn, others had residual disability.

It was suggested that the Japanese epidemic might have been due to genetic susceptibility, but a few cases of SMON associated with clioquinol or related hydroxyquinoline derivatives, including broxyquinoline and diiodohydroxyquinoline, have been reported elsewhere.

Diiodohydroxyquinoline has also been associated with gastrointestinal effects such as abdominal cramps, nausea, and diarrhoea. Adverse effects which may be attributable to the iodine content of diiodohydroxyquinoline include pruritus ani, skin eruptions, and enlargement of the thyroid gland. Fever, chills, headache, and vertigo have also occurred.

Precautions

Diiodohydroxyquinoline is contra-indicated in patients known to be hypersensitive to iodine or halogenated hydroxyquinolines and in those with hepatic or renal impairment. It should be used with caution in thyroid disease and may interfere with determinations of protein-bound iodine in tests for thyroid function for up to 6 months after therapy. Its use is best avoided in patients with neurological disorders. Long-term use should be avoided.

Children. The Committee on Drugs of the American Academy of Pediatrics[1] considered that there was a potential risk of toxicity to infants and children from clioquinol and diiodohydroxyquinoline applied topically. Since alternative effective preparations are available for dermatitis, the Committee recommended that products containing either of these compounds should not be used.

WHO considers that the use of halogenated hydroxyquinolines for the treatment of acute diarrhoea or amoebiasis in children cannot be justified.[2] There is no evidence of their efficacy in acute diarrhoea and they have been associated with severe neurological effects. On the rare occasions when a luminal amoebicide is required, other less toxic and more effective agents are available.

1. Kauffman RE, *et al.* American Academy of Pediatrics Committee on Drugs. Clioquinol (iodochlorhydroxyquin, Vioform) and iodoquinol (diiodohydroxyquin): blindness and neuropathy. *Pediatrics* 1990; **86:** 797–8.
2. WHO. The rational use of drugs in the management of acute diarrhoea in children. Geneva: WHO, 1990.

Pharmacokinetics

Diiodohydroxyquinoline is poorly absorbed from the gastrointestinal tract. Concern has been expressed about possible absorption after application to the skin (see Children, under Precautions, above).

Uses and Administration

Diiodohydroxyquinoline, a halogenated hydroxyquinoline, is a luminal amoebicide acting principally in the bowel lumen and is used in the treatment of intestinal amoebiasis, although a less toxic amoebicide such as diloxanide furoate is usually preferred; children should not be treated with diiodohydroxyquinoline (see Precautions, above). It is given alone in the treatment of asymptomatic cyst passers and with an amoebicide that acts in the tissues, such as metronidazole, in patients with invasive amoebiasis (p.822). The usual oral dosage in the treatment of amoebiasis is 630 or 650 mg three times daily for 20 days.

Diiodohydroxyquinoline has also been given in the treatment of *Dientamoeba fragilis* infections, in balantidiasis (p.823) as an alternative to tetracycline, and in *Blastocystis hominis* infections (p.823).

Diiodohydroxyquinoline was formerly used in the treatment of acrodermatitis enteropathica; it is reported to act by enhancing zinc absorption and has now been superseded by oral zinc therapy.

Diiodohydroxyquinoline is claimed to have some antibacterial and antifungal activity and has been used topically (but see Children, under Precautions, above).

Preparations

USP 31: Iodoquinol Tablets.

Diloxanide Furoate *(BANM, rINNM)*

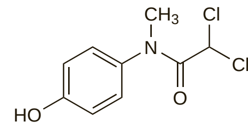
Diloksanid Furoat; Diloxanide, Furoate de; Diloxanidi Furoas; Furoato de diloxanida. 4-(*N*-Methyl-2,2-dichloroacetamido)-phenyl 2-furoate.

Дилоксанида Фуроат

$C_{14}H_{11}Cl_2NO_4$ = 328.1.

CAS — 579-38-4 (diloxanide); 3736-81-0 (diloxanide furoate).

ATC — P01AC01.



(diloxanide)

Pharmacopoeias. In *Br., Int.,* and *US.*

BP 2008 (Diloxanide Furoate). A white or almost white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in ether; freely soluble in chloroform. Protect from light.

USP 31 (Diloxanide Furoate). A white or almost white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol and in ether; freely soluble in chloroform. Store in airtight containers. Protect from light.

Adverse Effects

Flatulence is the most common adverse effect during treatment with diloxanide furoate. Vomiting, pruritus, and urticaria may occasionally occur.

Pharmacokinetics

Diloxanide furoate is hydrolysed before absorption from the gastrointestinal tract. The resulting diloxanide is readily absorbed and excreted mainly in the urine as the glucuronide; less than 10% of a dose appears in the faeces.

Uses and Administration

Diloxanide furoate, a dichloroacetamide derivative, is a luminal amoebicide acting principally in the bowel lumen and is used in the treatment of intestinal amoebiasis (p.822). It is given alone in the treatment of asymptomatic cyst passers and with an amoebicide that acts in the tissues, such as metronidazole, in patients with invasive amoebiasis.

Diloxanide furoate is given orally in a dosage of 500 mg three times daily for 10 days; children weighing more than 25 kg may be given 20 mg/kg daily, in 3 divided doses, for 10 days. The course of treatment may be repeated if necessary.

Preparations

BP 2008: Diloxanide Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***India:*** Aristogyl Plus; Dyrade-M; Entamizole; Entrolate†; Qugyl; Tinidafyl Plus; Wotinex.

Dimetridazole *(BAN, pINN)*

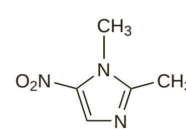
Dimetridatsoli; Dimetridazol; Dimétridazole; Dimetridazolum. 1,2-Dimethyl-5-nitroimidazole.

Диметридазол

$C_5H_7N_3O_2$ = 141.1.

CAS — 551-92-8.

ATC Vet — QP51AA07.



Pharmacopoeias. In *Fr.* for veterinary use. Also in *BP(Vet).*

BP(Vet) 2008 (Dimetridazole). An almost white to brownish-yellow, odourless or almost odourless powder which darkens on exposure to light. Slightly soluble in water; sparingly soluble in alcohol; freely soluble in chloroform; slightly soluble in ether. Protect from light.

Profile

Dimetridazole is a 5-nitroimidazole derivative similar to metronidazole. It is used in veterinary practice for the control of various protozoal infections in birds, fish, and reptiles. It is also used for swine dysentery.

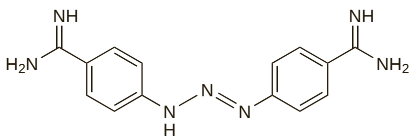
Diminazene Aceturate (BANM, rINNM)

Aceturato de diminazeno; Diminazène, Acéturate de; Diminazeni Aceturas. 1,3-Bis(4-amidinophenyl)triazene bis(*N*-acetylglycinate).

Диминазена Ацетурат

$C_{22}H_{29}N_9O_6$ = 515.5.

CAS — 536-71-0 (diminazene); 908-54-3 (diminazene aceturate).



(diminazene)

NOTE. Diminazene aceturate is often referred to by its veterinary proprietary name Berenil.

Profile

Diminazene aceturate, an aromatic diamidine derivative related to pentamidine, is an antiprotozoal that has been used in veterinary practice in the treatment of trypanosomiasis and babesiosis. It has also been tried in human infections.

Dinitolmide (BAN, rINN)

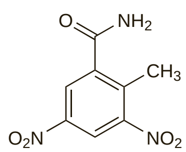
Dinitolmida; Dinitolmidum; Dinitrotoluamide; Methyldinitrobenzamide. 3,5-Dinitro-*o*-toluamide.

Динитолмид

$C_8H_7N_3O_5$ = 225.2.

CAS — 148-01-6.

ATC Vet — QP51AX12.



Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2008 (Dinitolmide). A cream to light tan powder. Practically insoluble in water; slightly soluble in alcohol, in chloroform, and in ether; soluble in acetone.

Profile

Dinitolmide is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry.

Eflornithine Hydrochloride

(BANM, USAN, rINNM)

DFMO; α-Difluoromethylornithine Hydrochloride; Éflornithine, Chlorhydrate d'; Eflornithini Hydrochloridum; Hidrocloruro de eflornitina; MDL-71782; MDL-71782A; RMI-71782. 2-(Difluoromethyl)-DL-ornithine monohydrochloride monohydrate.

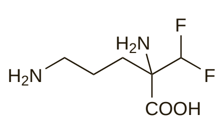
Эфлорнитина Гидрохлорид

$C_6H_{12}F_2N_2O_2,HCl,H_2O$ = 236.6.

CAS — 67037-37-0 (eflornithine); 96020-91-6 (eflornithine hydrochloride).

ATC — D11AX16; P01CX03.

ATC Vet — QD11AX16.



(eflornithine)

Adverse Effects and Precautions

Myelosuppression may lead to anaemia, leucopenia, and thrombocytopenia. Some patients have had hearing loss and alopecia. Gastrointestinal disturbances, especially diarrhoea, may occur. Seizures have occurred in about 8% of patients given eflornithine but they may have been related to the disease rather than treatment.

Dosage should be reduced in patients with renal impairment.

Skin irritation, such as erythema or a stinging or burning sensation, has been reported after topical application of eflornithine.

Effects on the ears. A study in 58 patients[1] receiving eflornithine alone or with interferon alfa for the treatment of metastatic melanoma found that hearing loss was related to the cumulative dose of eflornithine and was worse in patients with pre-existing hearing deficit.

1. Croghan MK, *et al.* Dose-related α-difluoromethylornithine ototoxicity. *Am J Clin Oncol* 1991; **14:** 331–5.

Effects on the heart. Fatal cardiac arrest occurred in an AIDS patient with pneumocystis pneumonia during the intravenous infusion of eflornithine 100 mg/kg over 1 hour.[1] Sudden death after infusion of eflornithine had occurred in several other critically ill patients with AIDS.

1. Barbarash RA, *et al.* Alpha-difluoromethylornithine infusion and cardiac arrest. *Ann Intern Med* 1986; **105:** 141–2.

Pharmacokinetics

Eflornithine hydrochloride is absorbed from the gastrointestinal tract. After intravenous doses about 80% is excreted unchanged in the urine in 24 hours. The terminal elimination half-life is about 3 hours. It is distributed to the CSF.

Less than 1% of a dose is absorbed after topical application.

◊ References.

1. Haegele KD, *et al.* Kinetics of α-difluoromethylornithine: an irreversible inhibitor of ornithine decarboxylase. *Clin Pharmacol Ther* 1981; **30:** 210–17.
2. Milord F, *et al.* Eflornithine concentrations in serum and cerebrospinal fluid of 63 patients treated for Trypanosoma brucei gambiense sleeping sickness. *Trans R Soc Trop Med Hyg* 1993; **87:** 473–7.
3. Malhotra B, *et al.* Percutaneous absorption and pharmacokinetics of eflornithine HCl 13.9% cream in women with unwanted facial hair. *J Clin Pharmacol* 2001; **41:** 972–8.

Uses and Administration

Eflornithine is an antiprotozoal that acts as an irreversible inhibitor of ornithine decarboxylase, the rate-limiting enzyme in polyamine biosynthesis; trypanosomes are more susceptible to the effects of eflornithine than are humans, probably because of their slower turnover of this enzyme.

Eflornithine is used in African trypanosomiasis due to *Trypanosoma brucei gambiense*. It is effective in the early and, more importantly, in the late stage of the disease (when there is CNS involvement).

In the treatment of African trypanosomiasis, eflornithine hydrochloride is given by intravenous infusion. The dose is 100 mg/kg every 6 hours for at least 14 days. Each dose should be given over a period of at least 45 minutes. Dosage should be reduced in patients with renal impairment.

Eflornithine hydrochloride is also applied topically twice daily for the reduction of unwanted facial hair in women. It is available as a cream containing 15% eflornithine hydrochloride monohydrate; in the UK this content is expressed as 11.5% eflornithine and in the USA as 13.9% anhydrous eflornithine hydrochloride.

Cryptosporidiosis. Eflornithine has been tried in the treatment of cryptosporidiosis (p.823) in AIDS patients.[1]

1. Rolston KVI, *et al.* Intestinal cryptosporidiosis treated with eflornithine: a prospective study among patients with AIDS. *J Acquir Immune Defic Syndr* 1989; **2:** 426–30.

Hirsutism. Topical eflornithine hydrochloride applied twice daily as a 13.9% cream is effective in reducing the growth of unwanted facial hair in females (see Hirsutism, p.2089), although it must be used indefinitely to prevent regrowth.[1] Its action is thought to be due to the irreversible inhibition of ornithine decarboxylase in hair follicles. It has also been used successfully in combination with laser hair removal.[2]

1. Barman Balfour JA, McClellan K. Topical eflornithine. *Am J Clin Dermatol* 2001; **2:** 197–201.

Malignant neoplasms. Eflornithine has antimetabolic activity and is being studied as a potential chemopreventive agent in patients at high risk of a variety of malignant diseases, including cancer of the bladder, breast, cervix, colon, oesophagus, prostate, and skin.[1]

1. Meyskens FL, Gerner EW. Development of difluoromethylornithine (DFMO) as a chemoprevention agent. *Clin Cancer Res* 1999; **5:** 945–51.

African trypanosomiasis. Eflornithine is effective in the treatment of *Trypanosoma brucei gambiense* infections (p.827), and is particularly valuable in providing an alternative to melarsoprol in meningoencephalitic disease.[1-3] Eflornithine 100 mg/kg intravenously every 6 hours for 7 days, rather than the standard 14 days, produced long-term responses in 42 of 47 patients who had relapsed after other treatment regimens.[4] Similar positive results in relapsing cases were obtained with a short 7-day course in a multicentre randomised controlled study,[5] although this short course was inferior to the 14-day course for new cases, in whom it could not be recommended. A patient who had relapsed after treatment with melarsoprol and eflornithine given singly was cured when the drugs were given together.[6] Eflornithine is not effective when given alone in *T. b. rhodesiense* infections, and early reports of its use with suramin were not encouraging.[7] However, benefit has been reported from use with nifurtimox.[8]

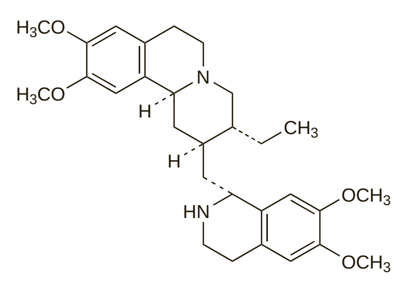
Эметина Гидрохлорид

$C_{29}H_{40}N_2O_4,2HCl,7H_2O$ = 679.7.

CAS — 483-18-1 (emetine); 316-42-7 (anhydrous emetine hydrochloride); 7083-71-8 (emetine hydrochloride, hydrate); 79300-08-6 (emetine hydrochloride, heptahydrate).

ATC — P01AX02.



(emetine)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *Viet.*
Eur. also has a monograph for Emetine Hydrochloride Pentahydrate; *Int.* permits the heptahydrate or pentahydrate in the same monograph. *US* has a monograph for the anhydrous salt.

Ph. Eur. 6.2 (Emetine Hydrochloride Heptahydrate; Emetine Hydrochloride BP 2008). A white or slightly yellow crystalline powder. Freely soluble in water and in alcohol. A 2% solution in water has a pH of 4.0 to 6.0. Protect from light.

Ph. Eur. 6.2 (Emetine Hydrochloride Pentahydrate). A white or slightly yellow crystalline powder. Freely soluble in water and in alcohol. A 2% solution in water has a pH of 4.0 to 6.0. Protect from light.

USP 31 (Emetine Hydrochloride). The hydrochloride of an alkaloid obtained from ipecacuanha, or prepared by methylation of cephaëline, or prepared synthetically. Anhydrous emetine hydrochloride is a white or slightly yellowish, odourless, crystalline powder. Freely soluble in water and in alcohol. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

Emetine hydrochloride is commonly associated with aching, tenderness, stiffness, and weakness of the muscles in the area of the injection site; there may be necrosis and abscess formation. After injection, diarrhoea and nausea and vomiting, sometimes with dizziness and headache, are common. There may be generalised muscle weakness and muscular pain, especially in the neck and limbs, and, more rarely, mild sensory disturbances. Eczematous, urticarial, and purpuric skin lesions have been reported.

Cardiovascular effects are considered the most serious and include precordial pain, dyspnoea, tachycardia, and hypotension. Changes in the ECG, particularly flattening or inversion of the T-wave and prolongation of the QT interval, occur in many patients. Emetine accumulates in the body and large doses or prolonged use may cause lesions of the heart, gastrointestinal tract, kidneys, liver, and skeletal muscle. Severe acute degenerative myocarditis may occur and may give rise to sudden cardiac failure and death. In some patients cardiotoxic effects have appeared after the completion of treatment with therapeutic doses.

Emetine hydrochloride is very irritant and contact with mucous membranes should be avoided.

Precautions

Emetine is contra-indicated in cardiac, renal, or neuromuscular disease. Its use should be avoided during pregnancy and it should not be given to children, except in severe amoebic dysentery unresponsive to other drugs. It should be used with great caution in old or debilitated patients. Patients given emetine should be closely supervised; ECG monitoring is advisable during treatment.

Pharmacokinetics

After injection emetine hydrochloride is concentrated in the liver, and to some extent in kidney, lung, and spleen. Excretion is slow and detectable amounts may persist in urine 40 to 60 days after treatment has been stopped.

Uses and Administration

Emetine, an alkaloid of ipecacuanha (p.1562), is a tissue amoebicide acting principally in the bowel wall and in the liver. It has been given by deep subcutaneous or intramuscular injection in the treatment of severe invasive amoebiasis (p.822), including hepatic amoebiasis in patients who do not respond to metronidazole, although dehydroemetine has tended to replace it. Emetine was formerly given orally as emetine and bismuth iodide.

Emetine has also been included in combination preparations for the symptomatic relief of cough.

Preparations

USP 31: Emetine Hydrochloride Injection.

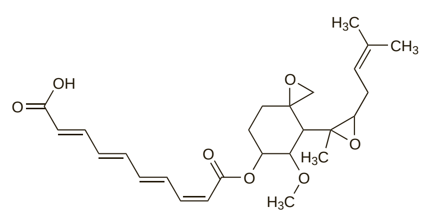
Фумагиллин

$C_{26}H_{34}O_7$ = 458.5.
CAS — 23110-15-8.
ATC — P01AX10.
ATC Vet — QP51AX23.



Profile

Fumagillin is an alicyclic antibiotic produced by certain strains of *Aspergillus fumigatus*. It has activity against Microsporidia and is used in veterinary practice to control *Nosema apis* infection in honeybees. Fumagillin is given in an oral dose of 20 mg three times daily for 14 days in the treatment of diarrhoea due to intestinal microsporidial infection with *Enterocytozoon bieneusi* in patients with HIV infection. It has also been tried in humans in the topical treatment of microsporidial keratoconjunctivitis. It was formerly given orally in the treatment of intestinal amoebiasis, but produced an unacceptably high frequency of adverse effects. Analogues of fumagillin have been studied for effects on angiogenesis in solid tumours.

Microsporidiosis. As discussed on p.826, topical treatment of microsporidial keratoconjunctivitis has been disappointing. There have been several reports of successful treatment in individual patients using fumagillin topically,[1-3] usually as a solution of bicyclohexylammonium fumagillin containing the equivalent of fumagillin 70 micrograms/mL.

Oral fumagillin has been effective in the treatment of diarrhoea due to intestinal microsporidial infection with *Enterocytozoon bieneusi* in patients with HIV infection.[4-7]

Preparations

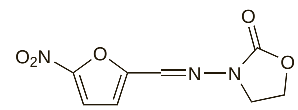
Proprietary Preparations (details are given in Part 3)
Fr.: Flisint.

Furazolidone *(BAN, rINN)*

Furatsolidoni; Furazolidon; Furazolidona; Furazolidonum; Nifurazolidonum. 3-(5-Nitrofurfurylideneamino)-2-oxazolidone.

Фуразолидон

$C_8H_7N_3O_5$ = 225.2.
CAS — 67-45-8.
ATC — G01AX06.
ATC Vet — QG01AX06.



Pharmacopoeias. In *Br., Fr.,* and *US.*
BP 2008 (Furazolidone). A yellow odourless or almost odourless crystalline powder. Very slightly soluble in water and in alcohol; slightly soluble in chloroform; practically insoluble in ether. The filtrate from a 1% suspension in water has a pH of 4.5 to 7.0. Protect from light.
USP 31 (Furazolidone). A yellow, odourless, crystalline powder. Practically insoluble in water, in alcohol, and in carbon tetrachloride. Store in airtight containers. Protect from light and avoid exposure to direct sunlight.

Adverse Effects

The most common adverse effects of furazolidone involve the gastrointestinal tract and include nausea and vomiting. Dizziness, drowsiness, headache, and a general malaise have also been reported.

Allergic reactions, most commonly skin reactions such as rashes or angioedema, may occur. There have been instances of acute pulmonary reactions, similar to those seen with the structurally related drug nitrofurantoin, and of hepatotoxicity. Agranulocytosis has been reported rarely. Haemolytic anaemia may occur in patients with G6PD deficiency given furazolidone.

Darkening of the urine has been attributed to the presence of metabolites.

Precautions

Furazolidone should be used with caution in those with G6PD deficiency because of the risk of haemolytic anaemia. It should not be given to infants under 1 month of age since their enzyme systems are immature.

Interactions

A disulfiram-like reaction has been reported in patients taking alcohol while on furazolidone therapy; alcohol should be avoided during, and for a short period after, treatment with furazolidone.

Furazolidone is an MAOI and the cautions advised for these drugs regarding use with other drugs, especially indirect-acting sympathomimetic amines, and the consumption of food and drink containing tyramine, should be observed (see Phenelzine Sulfate, p.417). However, there appear to be no reports of hypertensive crises in patients receiving furazolidone and it has been suggested that, since furazolidone inhibits monoamine oxidase gradually over several days, the risks are small if treatment is limited to a 5-day course. Toxic psychosis has been reported in a patient receiving furazolidone and amitriptyline (see Antiprotozoals, under Interactions of Amitriptyline, p.380).

Pharmacokinetics

Although furazolidone has been considered to be largely unabsorbed when given orally, the occurrence of systemic adverse effects and coloured metabolites in the urine suggest that this may not be the case. Rapid and extensive metabolism, possibly in the intestine, has been proposed.

Uses and Administration

Furazolidone is a nitrofuran derivative with antiprotozoal and antibacterial activity. It is active against the protozoan *Giardia intestinalis* (*Giardia lamblia*) and against a range of enteric bacteria *in vitro*, including staphylococci, enterococci, *Escherichia coli*, *Salmonella* spp., *Shigella* spp., and *Vibrio cholerae*. Furazolidone is bactericidal and appears to act by interfering with bacterial enzyme systems. Resistance is reported to be limited. It is used in the treatment of giardiasis (p.824) and cholera (p.172). It has been suggested for other bacterial gastrointestinal infections, but antibacterial therapy is regarded as unnecessary in mild and self-limiting gastro-enteritis (see p.171).

Furazolidone is given orally in a dose of 100 mg four times daily; children and infants from 1 month of age may be given 1.25 mg/kg four times daily. It is usually given for 2 to 5 days, but may be given for up to 7 days in some patients, or for up to 10 days for giardiasis.

Peptic ulcer disease. Furazolidone is not one of the main antibacterials used in *Helicobacter pylori* eradication regimens for peptic ulceration (p.1702), but there are some studies suggesting its efficacy.[1-8]

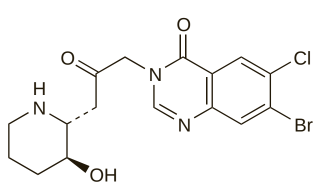
Halofuginone Hydrobromide *(BANM, USAN, rINNM)*

Halofuginone, Bromhydrate d'; Halofuginoni Hydrobromidum; Hidrobromuro de halofuginona; RU-19110. (±)-*trans*-7-Bromo-6-chloro-3-[3-(3-hydroxy-2-piperidyl)acetonyl]quinazolin-4(3*H*)-one hydrobromide.

Галофугинона Гидробромид

$C_{16}H_{17}BrClN_3O_3,HBr = 495.6.$

CAS — 55837-20-2 (halofuginone); 64924-67-0 (halofuginone hydrobromide).



(halofuginone)

Profile

Halofuginone is an antiprotozoal used as the hydrobromide in veterinary practice for the prevention of coccidiosis in poultry and for the control of cryptosporidiosis in calves. It is also under investigation for use in neoplastic disease in humans and in the treatment of scleroderma (p.1817).

Imidocarb *(BAN, rINN)*

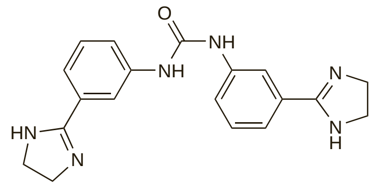
Imidocarbe; Imidocarbo; Imidocarbum. 1,3-Bis[3-(2-imidazolin-2-yl)phenyl]urea.

Имидокарб

$C_{19}H_{20}N_6O = 348.4.$

CAS — 27885-92-3.

ATC Vet — QP51AE01.



Imidocarb Dipropionate *(BANM, rINNM)*

Dipropionato de imidocarbo; Imidocarbe, Dipropionate d'; Imidocarbi Dipropionas.

Имидокарба Дипропионат

$C_{19}H_{20}N_6O,2C_3H_6O_2 = 496.6.$

CAS — 55750-06-6.

Imidocarb Hydrochloride *(BANM, USAN, rINNM)*

4A65; Hidrocloruro de imidocarbo; Imidocarbe, Chlorhydrate d'; Imidocarbi Hydrochloridum. 3,3′-Di(2-imidazolin-2-yl)carbanilide dihydrochloride.

Имидокарба Гидрохлорид

$C_{19}H_{20}N_6O,2HCl = 421.3.$

CAS — 5318-76-3.

Profile

Imidocarb has antiprotozoal and antibacterial activity and is used as the dipropionate in veterinary practice in the treatment of babesiosis and anaplasmosis in cattle. Imidocarb hydrochloride has also been used.

Isometamidium Chloride *(BAN, rINN)*

Cloruro de isometamidio; Isometamidii Chloridum; Isometamidium; Isométamidium, Chlorure d'. 8-[3-(*m*-Amidinophenyl)-2-triazeno]3-amino-5-ethyl-6-phenylphenanthridinium chloride.

Изометамидия Хлорид

$C_{28}H_{26}ClN_7 = 496.0.$

CAS — 34301-55-8.

Profile

Isometamidium is an antiprotozoal used as the chloride in veterinary practice for the control of trypanosomiasis.

Lasalocid *(BAN, USAN, rINN)*

Lasalocide; Lasalócido; Lasalocidum; Ro-02-2985.
6-[(3*R*,4*S*,5*S*,7*R*)-7-{(2*S*,3*S*,5*S*)-5-Ethyl-5-[(2*R*,5*R*,6*S*)-5-ethyltetrahydro-5-hydroxy-6-methyl-2*H*-pyran-2-y]tetrahydro-3-methyl-2-fury1}4-hydroxy-3,5-dimethyl-6-oxononyl]-2-hydroxy-*m*-toluic acid.

Лазалоцид

$C_{34}H_{54}O_8 = 590.8.$

CAS — 11054-70-9; 25999-31-9.

ATC Vet — QP51AH02.

Lasalocid Sodium *(BANM, rINNM)*

Lasalocid sódico; Lasalocide Sodique; Lasalocidum Natricum.

Лазалоцид Натрий

$C_{34}H_{53}NaO_8 = 612.8.$

CAS — 25999-20-6.

ATC Vet — QP51AH02.

Profile

Lasalocid, an antibiotic produced by *Streptomyces lasaliensis*, is an antiprotozoal used as the sodium salt in veterinary practice for the prevention of coccidiosis in birds.

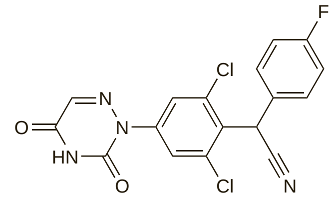
Letrazuril *(rINN)*

Létrazuril; Letrazurilo; Letrazurilum. (±)-[2,6-Dichloro-4-(4,5-dihydro-3,5-dioxo-*as*-triazin-2(3*H*)-yl)phenyl](*p*-fluorophenyl)acetonitrile.

Летразурил

$C_{17}H_9Cl_2FN_4O_2 = 391.2.$

CAS — 103337-74-2.



Profile

Letrazuril is an antiprotozoal that has been investigated in the treatment of cryptosporidiosis (p.823) in patients with AIDS.

Maduramicin *(BAN, USAN, rINN)*

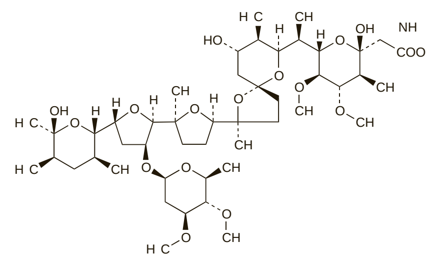
CL-273703; Maduramicin Ammonium; Maduramicina; Maduramicine; Maduramicinum. Ammonium (2*R*,3*S*,4*S*,5*R*,6*S*)-tetrahydro-2-hydroxy-6-{(*R*)-1-[(2*S*,5*R*,7*S*,8*R*,9*S*)-9-hydroxy-2,8-dimethyl-2-{(2*S*,2′*R*,3′*S*,5*R*,5′*R*)-octahydro-2-methyl-3′-[(2*R*,4*S*,5*S*,6*S*)-tetrahydro-4,5-dimethoxy-6-methyl-2*H*-pyran-2-yl]oxy}-5′-[(2*S*,3*S*,5*R*,6*S*)-tetrahydro-6-hydroxy-3,5,6-trimethyl-2*H*-pyran-2-yl](2,2′-bifuran-5-yl)-1,6-dioxaspiro[4.5]dec-7-yl]ethyl}-4,5-dimethoxy-3-methyl-2*H*-pyran-2-acetate.

Мадурамицин

$C_{47}H_{80}O_{17},NH_3 = 934.2.$

CAS — 84878-61-5.

ATC Vet — QP51AX10.



NOTE. The name maduramicin has also been used to denote the acid.

Profile

Maduramicin is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry.

Melarsoprol *(BAN, rINN)*

Mel B; Melarsen Oxide-BAL; Mélarsoprol; Melarsoprolum; RP-3854. 2-[4-(4,6-Diamino-1,3,5-triazin-2-ylamino)phenyl]-1,3,2-dithiarsolan-4-ylmethanol.

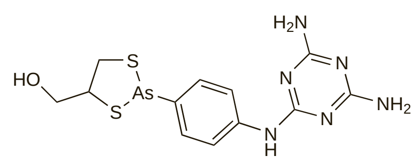
Меларсопрол

$C_{12}H_{15}AsN_6OS_2 = 398.3.$

CAS — 494-79-1.

ATC — P01CD01.

ATC Vet — QP51AD04.



Adverse Effects and Treatment

Adverse effects are common and may be severe during the treatment of African trypanosomiasis with melarsoprol. It may be difficult to distinguish between effects of the disease, Jarisch-Herxheimer reactions resulting from the release of antigens from trypanosomes killed by melarsoprol, and adverse effects due to the drug's arsenic content or to hypersensitivity. For the adverse effects of arsenic and their treatment, see Arsenic Trioxide, p.2260.

A severe febrile reaction may occur after the first injection of melarsoprol, especially in patients with large numbers of trypanosomes in their blood. It is therefore common practice to give 2 or 3 injections of suramin or pentamidine before starting melarsoprol therapy.

The greatest risk is from reactive encephalopathy which occurs in about 10% of patients treated with melarsoprol and is usually seen between the end of the first 3- or 4-day course of injections and the start of the second course. Encephalopathy may be sudden in onset or develop slowly. Symptoms include fever, headache, tremor, slurring of speech, convulsions, and coma; death has occurred in up to 5% of patients treated with melarsoprol. Less commonly, haemorrhagic encephalopathy may occur. The prophylactic use of corticosteroids has been suggested during treatment courses of melarsoprol (see African Trypanosomiasis, below). Treatment of reactive encephalopathy has included the use of corticosteroids, hypertonic solutions to combat cerebral oedema, anticonvulsants such as diazepam, and subcutaneous adrenaline; dimercaprol has been given on the assumption that encephalopathy resulted from arsenic poisoning, but has not generally been of benefit.

Hypersensitivity reactions to melarsoprol may occur during the second and subsequent courses of treatment. Desensitisation with gradually increasing doses of melarsoprol has been attempted; corticosteroids may help to control symptoms during this procedure. Some authorities consider that the use of small doses of melarsoprol may increase the risk of resistance.

Melarsoprol injection is very irritant and extravasation during intravenous use should be avoided. Vomiting and abdominal colic may occur if it is injected too rapidly. Other adverse effects reported include agranulocytosis, hypertension, peripheral neuropathy, proteinuria, severe diarrhoea, myocardial damage, exfoliative dermatitis, and hepatic disturbances.

3. Pepin J, *et al.* Risk factors for encephalopathy and mortality during melarsoprol treatment of Trypanosoma brucei gambiense sleeping sickness. *Trans R Soc Trop Med Hyg* 1995; **89:** 92–7.

Precautions

Use of melarsoprol in febrile patients has been associated with an increased incidence of reactive encephalopathy, and therefore it should not be given during epidemics of influenza. Intercurrent infections such as malaria and pneumonia should be treated before melarsoprol is used. Severe haemolytic reactions have been reported in patients with G6PD deficiency. It may precipitate erythema nodosum when given to patients with leprosy.

Patients should be in hospital when they are treated with melarsoprol and dosage decided after taking into account their general condition.

Treatment of pregnant women with trypanosomiasis should be deferred until after delivery. Pregnant women with meningoencephalitis may be treated with pentamidine (*Trypanosoma brucei gambiense*) or suramin (*T. b. rhodesiense*).

Pharmacokinetics

Melarsoprol is reported to be unreliably absorbed if given orally and is usually given by intravenous injection. A small amount penetrates into the CSF where it has a local trypanocidal action. It is rapidly metabolised and excreted in the faeces and urine so any prophylactic effect is short-lived.

Uses and Administration

Melarsoprol, a trivalent arsenical derivative, is a trypanocide which appears to act by inhibiting trypanosomal pyruvate kinase. It is effective in the treatment of all stages of African trypanosomiasis due to *Trypanosoma brucei gambiense* or *T. brucei rhodesiense*, but because of its toxicity its use is usually reserved for stages of the disease involving the CNS. Resistance has been reported to develop.

Patients undergoing therapy with melarsoprol should be treated in hospital. Melarsoprol is given by intravenous injection as a 3.6% solution in propylene glycol. The injection should be given slowly, care being taken to prevent leakage into the surrounding tissues, and the patient should remain supine and fasting for several hours after the injection.

Treatment protocols vary, but in general melarsoprol is given in low doses initially, especially in children and debilitated patients, increased gradually to the maximum daily dose of 3.6 mg/kg. Doses are given daily for 3 or 4 days and the course repeated 2 or 3 times with an interval of 7 to 10 days between courses. Since massive destruction of parasites resulting in a Jarisch-Herxheimer reaction is particularly dangerous during treatment with melarsoprol, several doses of suramin or pentamidine may be given to induce the reaction before melarsoprol is started.

Melarsonyl potassium is a water-soluble derivative of melarsoprol which was formerly used as an alternative to melarsoprol but was probably more toxic and less effective.

African trypanosomiasis. Melarsoprol, which is effective against both *Trypanosoma brucei gambiense* and *T. b. rhodesiense*, is usually only given to treat the meningoencephalitic stage of African trypanosomiasis (p.827) because it may produce potentially fatal encephalopathy. However, protection against this toxicity may be provided by prophylaxis with prednisolone.[1,2] Therapy with melarsoprol and eflornithine was reported to be effective in a patient who had not responded to either drug alone.[3] A comparative study[4] in 500 patients with second-stage infection with *T. b. gambiense* found that a more concise dosage regimen of melarsoprol 2.2 mg/kg daily, as a single course over 10 days, was similar in efficacy to standard regimens of 1.2 to 3.6 mg/kg daily for 3 or 4 days repeated twice over a 26-day period with 7-day intervals between series, although there was no difference between the regimens in the incidence of associated encephalopathy.

Mepacrine Hydrochloride *(BANM, rINNM)*

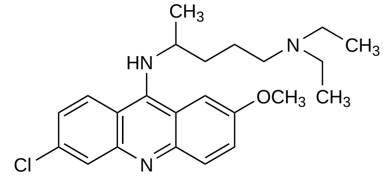
Acrichinum; Acrinamine; Antimalarinae Chlorhydras; Chinacrina; Hidrocloruro de mepacrina; Mépacrine, Chlorhydrate de; Mepacrini Hydrochloridum; Mepakrin Hidroklorür; Quinacrine Hydrochloride. 6-Chloro-9-(4-diethylamino-1-methylbutylamino)-2-methoxyacridine dihydrochloride dihydrate.

Мепакрина Гидрохлорид

$C_{23}H_{30}ClN_3O,2HCl,2H_2O = 508.9.$

CAS — 83-89-6 (mepacrine); 69-05-6 (anhydrous mepacrine dihydrochloride); 6151-30-0 (mepacrine dihydrochloride dihydrate).

ATC — P01AX05.



(mepacrine)

Adverse Effects

The most common adverse effects associated with mepacrine are dizziness, headache, and gastrointestinal disturbances such as nausea and vomiting. Reversible yellow discoloration of the skin, conjunctiva, and urine may occur during long-term use or after large doses; blue/black discoloration of the palate and discoloration of the nails have also been reported. Doses such as those used in the treatment of giardiasis may occasionally cause transient acute toxic psychosis and CNS stimulation. Convulsions have been reported at high doses. Ocular toxicity similar to that seen with chloroquine (p.600) and chronic dermatoses, including severe exfoliative dermatitis and lichenoid eruptions, have also occurred after prolonged use of mepacrine. Hepatotoxicity and aplastic anaemia occur rarely.

Effects on the nervous system. Two patients had convulsions a few hours after mepacrine hydrochloride 400 mg was given intrapleurally for malignant effusions. One developed status epilepticus and died and the other was successfully treated with anticonvulsants.[1]

1. Borda I, Krant M. Convulsions following intrapleural administration of quinacrine hydrochloride. *JAMA* 1967; **201:** 1049–50.

Precautions

Mepacrine should be used with caution in elderly patients or patients with a history of psychosis, or in the presence of hepatic disease. Mepacrine can cause exacerbation of psoriasis and should be avoided in psoriatic patients.

Porphyria. Mepacrine should be used with caution in patients with porphyria.

Interactions

Mepacrine has been reported to produce a mild disulfiram-like reaction (see p.2296) when taken with alcohol.

Theoretically, mepacrine may increase the plasma concentrations of primaquine resulting in a higher risk of toxicity, and it has been recommended that these drugs should not be used together.

Pharmacokinetics

Mepacrine is readily absorbed from the gastrointestinal tract and widely distributed throughout the body. It accumulates in body tissues, particularly the liver, and is liberated slowly. It is excreted slowly mainly in the urine, and is still detectable in the urine after 2 months. Mepacrine crosses the placenta.

Intrapleural administration. Peak plasma concentrations of mepacrine far above those associated with CNS effects were rapidly attained in 3 of 4 patients after intrapleural instillation of a solution of mepacrine hydrochloride and remained at these levels for several hours.[1]

1. Björkman S, *et al.* Pharmacokinetics of quinacrine after intrapleural instillation in rabbits and man. *J Pharm Pharmacol* 1989; **41:** 160–73.

Uses and Administration

Mepacrine is a 9-aminoacridine antiprotozoal used as the hydrochloride mainly as an alternative to the nitroimidazoles in the treatment of giardiasis (p.824).

In giardiasis, mepacrine hydrochloride is given orally in doses of 100 mg three times daily after food for 5 to 7 days. A dose for children is 2 mg/kg given three times daily (maximum 300 mg daily).

Mepacrine hydrochloride may also be used, alone or with hydroxychloroquine, for the treatment of discoid and subcutaneous lupus erythematosus. It has also been used locally in the treatment of some forms of cutaneous leishmaniasis, as a sterilisation technique for contraception, and in the management of malignant effusions. It was formerly used to treat malaria.

The mesilate was also formerly used.

Mepacrine is under investigation for the treatment of variant Creutzfeldt-Jakob Disease.

Contraception. Sterilisation with intra-uterine mepacrine has been attempted as an irreversible method of contraception (p.2070). It produces occlusion of the fallopian tube and has been reported to be an effective nonsurgical means of female sterilisation,[1] although it may be less effective than other methods.[2] There has been speculation about the risk of cancer from this technique but there appeared to be no evidence to confirm such a risk.[3-5] However, the method remains controversial and a full evaluation of its safety and efficacy has been recommended.[6] The Indian government has banned the use of mepacrine for sterilisation.

1. Hieu DT, *et al.* 31 781 Cases of non-surgical female sterilisation with quinacrine pellets in Vietnam. *Lancet* 1993; **342:** 213–17.

4. Hieu DT. Quinacrine method of family planning. *Lancet* 1994; **343:** 1040.
5. Sokal DC, *et al.* Safety of quinacrine contraceptive pellets: results from 10-year follow-up in Vietnam. *Contraception* 2008; **78:** 66–72.
6. Benagiano G. Sterilisation by quinacrine. *Lancet* 1994; **344:** 689.

Leishmaniasis. Mepacrine has been suggested for intralesional injection in the treatment of early noninflamed nodular lesions of cutaneous leishmaniasis (p.824) due to *Leishmania tropica*, *L. major*, *L. mexicana*, *L. panamensis*, or *L. peruviana*.[1] The suggested course of treatment was 3 intralesional injections of a 5% solution of mepacrine given at intervals of 3 to 5 days. However, local infiltration of drugs can be difficult and painful.

1. WHO. Control of the leishmaniases. *WHO Tech Rep Ser 793* 1990.

Sclerotherapy. Intrapleural instillations of mepacrine hydrochloride or mesilate have been used as sclerosants in the management of malignant pleural effusions (p.659) and recurrent pneumothorax but the treatment is associated with pain and a high frequency of toxic effects.

Preparations

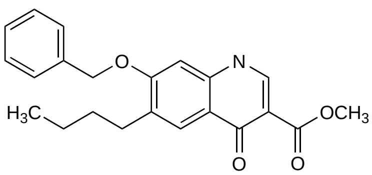
Proprietary Preparations (details are given in Part 3)
India: Maladin.

Methyl Benzoquate *(BAN)*

Nequinate *(USAN, pINN)*; AY-20385; ICI-55052; Néquinate; Nequinato; Nequinatum. Methyl 7-benzyloxy-6-butyl-1,4-dihydro-4-oxoquinoline-3-carboxylate.

Нехинат

$C_{22}H_{23}NO_4$ = 365.4.
CAS — 13997-19-8.



Profile

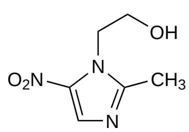
Methyl benzoquate is an antiprotozoal used in veterinary practice with clopidol (p.831) for the prevention of coccidiosis in poultry.

Metronidazole *(BAN, USAN, rINN)*

Bayer-5360; Metronidatsoli; Metronidazol; Metronidazolas; Métronidazole; Metronidazolum; NSC-50364; RP-8823; SC-10295. 2-(2-Methyl-5-nitroimidazol-1-yl)ethanol.

Метронидазол

$C_6H_9N_3O_3$ = 171.2.
CAS — 443-48-1.
ATC — A01AB17; D06BX01; G01AF01; J01XD01; P01AB01.
ATC Vet — QA01AB17; QD06BX01; QG01AF01; QJ01XD01; QP51AA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Metronidazole). A white or yellowish, crystalline powder. Slightly soluble in water, in alcohol, in acetone, and in dichloromethane. Protect from light.

USP 31 (Metronidazole). White to pale yellow, odourless crystals or crystalline powder. It darkens on exposure to light. Sparingly soluble in water and in alcohol; slightly soluble in chloroform and in ether. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. See below.

Metronidazole Benzoate *(BAN, rINNM)*

Benzoato de metronidazol; Benzoyl Metronidazole; Metronidatsolibentsoaatti; Metronidazolbensoat; Metronidazol-benzoát; Métronidazole, benzoate de; Metronidazoli benzoas; Metronidazolo benzoatas; RP-9712. 2-(2-Methyl-5-nitroimidazol-1-yl)ethyl benzoate.

Метронидазола Бензоат

$C_{13}H_{13}N_3O_4$ = 275.3.
CAS — 13182-89-3.
ATC — A01AB17; D06BX01; G01AF01; J01XD01; P01AB01.
ATC Vet — QA01AB17; QD06BX01; QG01AF01; QJ01XD01; QP51AA01.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Metronidazole Benzoate). White or slightly yellowish, crystalline powder or flakes. Practically insoluble in water; slightly soluble in alcohol; soluble in acetone; freely soluble in dichloromethane. Protect from light.

USP 31 (Metronidazole Benzoate). A white to slightly yellow, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; soluble in acetone; freely soluble in dichloromethane; very slightly soluble in solvent ether. Store at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Metronidazole Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro de metronidazol; Métronidazole, Chlorhydrate de; Metronidazoli Hydrochloridum; SC-32642.

Метронидазола Гидрохлорид

$C_6H_9N_3O_3,HCl$ = 207.6.
CAS — 69198-10-3.
ATC — A01AB17; D06BX01; G01AF01; J01XD01; P01AB01.
ATC Vet — QA01AB17; QD06BX01; QG01AF01; QJ01XD01; QP51AA01.

Incompatibility. Solutions of metronidazole hydrochloride have a low pH, usually of less than 2.0, before dilution and neutralisation for intravenous use. These undiluted solutions react with aluminium in equipment such as needles to produce reddish-brown discoloration, and a precipitate has been reported with ready-to-use preparations of metronidazole hydrochloride, although this occurred after contact for 6 hours or more.[1,2]

Several studies have assessed the compatibility of antibacterial injections and other drugs when added to metronidazole solution for intravenous infusion.[3-7] Results have varied according to the criteria applied and the preparations and conditions used. Physical incompatibilities due to the low pH of metronidazole injections appear to be more of a problem than chemical incompatibility. Regardless of these studies, it is generally recommended that other drugs should not be added to intravenous solutions of metronidazole or its hydrochloride. Specific information on the compatibility of individual formulations may be found in the manufacturers' literature.

Adverse Effects

The adverse effects of metronidazole are generally dose-related. The most common are gastrointestinal disturbances, especially nausea and an unpleasant metallic taste. Vomiting, and diarrhoea or constipation may also occur. A furred tongue, glossitis, and stomatitis may be associated with an overgrowth of *Candida*. There have been rare reports of antibiotic-associated colitis associated with metronidazole, although it is also used in the treatment of this condition.

Weakness, dizziness, ataxia, headache, drowsiness, insomnia, and changes in mood or mental state such as depression or confusion have also been reported. Peripheral neuropathy, usually presenting as numbness or tingling in the extremities, and epileptiform seizures have been associated with high doses of metronidazole or prolonged treatment.

Temporary moderate leucopenia and thrombocytopenia may occur in some patients receiving metronidazole. Skin rashes, urticaria, and pruritus occur occasionally and erythema multiforme, angioedema, and anaphylaxis have been reported rarely. Other adverse effects include urethral discomfort and darkening of the urine. Raised liver enzyme values, cholestatic hepatitis, and jaundice have occasionally been reported. Thrombophlebitis may follow intravenous use of metronidazole.

Studies have shown metronidazole to be mutagenic in bacteria and carcinogenic in some *animals*.

Carcinogenicity and mutagenicity. Metronidazole is mutagenic in bacterial assays, and its hydroxy metabolite even more so, but studies of mammalian cells *in vitro* and *in vivo* have not consistently demonstrated a mutagenic effect. Similarly, there is no uniformity in the limited data concerning genotoxicity in humans,[1] and although metronidazole has been classified as a carcinogen in *animals*, the evidence of human carcinogenicity is ambiguous. There was no appreciable increase in the incidence of cancer in a retrospective study of 771 patients given metronidazole for vaginal trichomoniasis,[2] nor in another similar study of 2460 patients.[3] The first study[2] did show an excess of cases of lung cancer, although all 4 were in women who were smokers. Subsequent follow-up[4] to 1984, covering a period of 15 to 25 years, still showed an excess of lung cancer cases even after allowing for smoking status. However, this follow-up also continued to show no significant increase overall in cancer-related morbidity or mortality. Follow-up[5] of the patients from the second study for 11 to 15 years to 1984 also showed no increase in the overall incidence of cancers nor did it confirm any increase in lung cancer.

Risks to the fetus are discussed under Pregnancy in Precautions, below.

5. Friedman GD, Selby JV. Metronidazole and cancer. *JAMA* 1989; **261:** 866.

Effects on the blood. Adverse haematological effects associated with metronidazole therapy include a report of bone marrow aplasia, with leucopenia and markedly reduced erythropoiesis and granulopoiesis,[1] aplastic anaemia,[2] and the haemolytic-uraemic syndrome.[3]

1. White CM, *et al.* Bone marrow aplasia associated with metronidazole. *BMJ* 1980; **280:** 647.
2. Raman R, *et al.* Metronidazole induced aplastic anaemia. *Clinician* 1982; **46:** 464–8.
3. Powell HR, *et al.* Haemolytic-uraemic syndrome after treatment with metronidazole. *Med J Aust* 1988; **149:** 222–3.

Effects on the ears. A review of reports of ototoxicity notified to the Australian Adverse Drug Reactions Advisory Committee revealed a number of cases of deafness associated with the use of metronidazole.[1]

1. Anonymous. Drug-induced ototoxicity. *WHO Drug Inf* 1991; **5:** 12.

Effects on the eyes. Myopia which developed in a patient after 11 days of oral metronidazole for trichomoniasis had resolved 4 days after withdrawal of treatment, but recurred when she resumed treatment.[1]

Optic neuropathies have also occurred.[2,3] In one report, retrobulbar or optic neuritis was seen in 7 patients given oral metronidazole.[2] Dosage varied from 0.75 to 1 g daily and duration of treatment from 7 days to a year. Abnormalities included defects in colour vision, decreased vision, and scotomas. Vision improved on withdrawal of metronidazole, although there was a residual deficit in 2 patients.

1. Grinbaum A, *et al.* Transient myopia following metronidazole treatment for Trichomonas vaginalis. *JAMA* 1992; **267:** 511–12.

3. McGrath NM, *et al.* Reversible optic neuropathy due to metronidazole. *Clin Experiment Ophthalmol* 2007; **35:** 585–6.

Effects on the gastrointestinal tract. ***ANTIBIOTIC-ASSOCIATED COLITIS.*** Reports of pseudomembranous colitis associated with the use of metronidazole.

1. Thomson G, *et al.* Pseudomembranous colitis after treatment with metronidazole. *BMJ* 1981; **282:** 864–5.
2. Daly JJ, Chowdary KVS. Pseudomembranous colitis secondary to metronidazole. *Dig Dis Sci* 1983; **28:** 573–4.

Effects on the liver. Severely elevated liver enzyme values, consistent with a drug-induced hepatitis, occurred in a patient given metronidazole hydrochloride 500 mg every 6 hours intravenously for 4 days. He was also receiving cefapirin sodium and tobramycin sulfate.[1] A case of reversible hepatotoxicity caused by an overdose of metronidazole 12.5 g has also been reported.[2]

1. Appleby DH, Vogtland HD. Suspected metronidazole toxicity. *Clin Pharm* 1983; **2:** 373–4.
2. Lam S, Bank S. Hepatotoxicity caused by metronidazole overdose. *Ann Intern Med* 1995; **122:** 803.

Effects on the nervous system. ***ASEPTIC MENINGITIS.*** A 42-year-old man had 3 episodes of aseptic meningitis during treatment with oral metronidazole as part of an eradication regimen for *Helicobacter pylori* infection.[1] On each occasion his symptoms resolved spontaneously when eradication treatment was stopped and recurred when treatment was restarted. The aseptic meningitis was attributed to the metronidazole and the patient later tolerated an eradication treatment regimen containing a proton-pump inhibitor and a macrolide.

1. Khan S, *et al.* Metronidazole-induced aseptic meningitis during Helicobacter pylori eradication therapy. *Ann Intern Med* 2007; **146:** 395–6.

CEREBELLAR TOXICITY. Ataxia and dysarthria have been reported in 2 patients taking oral metronidazole plus intravenous cefepime or oral levofloxacin.[1] Symptoms occurred about one month after starting treatment and resolved 2 to 5 weeks after stopping metronidazole.

1. Woodruff BK, *et al.* Reversible metronidazole-induced lesions of the cerebellar dentate nuclei. *N Engl J Med* 2002; **346:** 68–9.

CONVULSIONS. Reports of convulsions associated with metronidazole therapy (usually in high doses or in patients with renal impairment).

1. Halloran TJ. Convulsions associated with high cumulative doses of metronidazole. *Drug Intell Clin Pharm* 1982; **16:** 409.

EFFECTS ON MENTAL FUNCTION. Although metronidazole is sometimes used to reduce colonic flora in the treatment of hepatic encephalopathy, impaired metabolism of metronidazole in such patients can result in elevated plasma concentrations and consequent toxicity. Psychosis and manic behaviour were reported in one such patient during treatment for hepatic encephalopathy with metronidazole and lactulose, although plasma-metronidazole concentrations were not found to be raised (24 micrograms/mL).[1] Symptoms resolved when metronidazole was stopped. Acute psychosis has also been reported in a patient following a 5-day course of intravenous metronidazole 1 g daily for a gynaecological disorder.[2]

2. Schreiber W, Spernal J. Metronidazole-induced psychotic disorder. *Am J Psychiatry* 1997; **154:** 1170–1.

PERIPHERAL NEUROPATHY. Peripheral neuropathy has been reported in patients receiving prolonged treatment with metronidazole.[1-4] Stopping metronidazole or lowering the dose usually results in complete resolution or improvement of the neuropathy but in some patients it may persist despite these measures. For reports of retrobulbar or optic neuritis associated with metronidazole, see Effects on the Eyes, above.

5. Friedman G, Selby JV. How often does metronidazole induce pancreatitis? *Gastroenterology* 1990; **98:** 1702–3.

Gynaecomastia. Gynaecomastia occurred in a 36-year-old man with ulcerative colitis after taking metronidazole for about a month.[1]

1. Fagan TC, *et al.* Metronidazole-induced gynecomastia. *JAMA* 1985; **254:** 3217.

Hypersensitivity. A hypersensitivity reaction with chills, fever, generalised erythema, and a maculopapular rash developed after a single dose of metronidazole in a patient who had previously developed a rash during treatment with intravaginal metronidazole.[1]

1. Knowles S, *et al.* Metronidazole hypersensitivity. *Ann Pharmacother* 1994; **28:** 325–6.

Precautions

Peripheral neuropathy, transient epileptiform seizures, and leucopenia have sometimes been associated with prolonged or intensive treatment with metronidazole (see Adverse Effects, above). Clinical and laboratory monitoring is advised in patients given metronidazole for more than 10 days. Doses should be reduced in patients with severe hepatic impairment.

It is suggested that the use of metronidazole should be avoided during pregnancy, and this caution applies especially to use during the first trimester and to the use of high-dose regimens (see also below).

Patients are advised not to drink alcoholic beverages while taking metronidazole (see under Interactions, below).

Breast feeding. Metronidazole is distributed into breast milk giving it a bitter taste which may impair feeding.[1] The American Academy of Pediatrics considers that although the effects of metronidazole on breast-fed infants are unknown they may be of concern. It recommends that breast feeding should be stopped for 12 to 24 hours when single-dose therapy is used;[2] no specific recommendations are given for long-term treatment.

1. Rubin PC. Prescribing in pregnancy: general principles. *BMJ* 1986; **293:** 1415–17.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 03/02/04)

Pregnancy. Metronidazole is mutagenic in bacteria and carcinogenic in *rodents*. It readily crosses the placenta achieving similar concentrations in the placental cord and maternal plasma and its use in pregnancy is controversial. Meta-analyses of studies involving the use of metronidazole in the first trimester of pregnancy[1,2] concluded that there did not appear to be an increased risk of teratogenicity. However, in the USA licensed product information considers metronidazole to be contra-indicated during the first trimester in patients with trichomoniasis; use for trichomoniasis during the second and third trimesters may be acceptable. For other indications the risks and benefits of treatment with metronidazole should be weighed carefully, especially in the first trimester.

2. Caro-Patón T, *et al.* Is metronidazole teratogenic? A meta-analysis. *Br J Clin Pharmacol* 1997; **44:** 179–82.

Interactions

When given with alcohol, metronidazole may provoke a disulfiram-like reaction in some patients. Acute psychoses or confusion have been associated with the use of metronidazole and disulfiram together.

Metronidazole is reported to impair the metabolism or excretion of several drugs including warfarin (p.1429), phenytoin (p.499), lithium (see Antimicrobials, p.404), ciclosporin, and fluorouracil (p.723), with the consequent potential for an increased incidence of adverse effects. There is some evidence that phenytoin might accelerate the metabolism of metronidazole. Plasma concentrations of metronidazole are decreased by phenobarbital, with a consequent reduction in the effectiveness of metronidazole. Cimetidine has increased plasma concentrations of metronidazole and might increase the risk of neurological adverse effects. For references to some of these interactions, see below.

For incompatibilities between metronidazole and other drugs in solutions for injection, see above.

Alcohol. Metronidazole may provoke a disulfiram-like reaction in some individuals when given with alcohol; reactions have occurred after the use of preparations formulated with alcohol, including injections, as well as after drinking alcohol.[1] Acute psychosis or confusional state was reported in 6 of 29 alcoholic patients who were also taking disulfiram.[2] However, an analysis of published reports[3] and a study in healthy subjects[4] both found that there was no convincing evidence of a disulfiram-like reaction between metronidazole and alcohol although caution was still advised.

1. Edwards DL, *et al.* Disulfiram-like reaction associated with intravenous trimethoprim-sulfamethoxazole and metronidazole. *Clin Pharm* 1986; **5:** 999–1000.

4. Visapää J-P, *et al.* Lack of disulfiram-like reaction with metronidazole and ethanol. *Ann Pharmacother* 2002; **36:** 971–4.

Antineoplastics. For reference to the effect of metronidazole on busulfan, see p.691.

Carbamazepine. For a report of a possible interaction between metronidazole and carbamazepine, see p.475.

Cimetidine. In a study in 6 healthy subjects metronidazole plasma concentrations were increased by twice-daily doses of cimetidine. The effect was presumed to be due to inhibition of cytochrome P450 isoenzymes responsible for metronidazole metabolism.[1] However, cimetidine was not found to affect the pharmacokinetics of metronidazole in a study in patients with Crohn's disease[2] nor in a single-dose study in healthy subjects.[3]

1. Gugler R, Jansen JC. Interaction between cimetidine and metronidazole. *N Engl J Med* 1983; **309:** 1518–19.
2. Eradiri O, *et al.* Interaction of metronidazole with cimetidine and phenobarbital in Crohn's disease. *Clin Pharmacol Ther* 1987; **41:** 235.
3. Loft S, *et al.* Lack of effect of cimetidine on the pharmacokinetics and metabolism of a single oral dose of metronidazole. *Eur J Clin Pharmacol* 1988; **35:** 65–8.

Disulfiram. For a report of acute psychosis or confusional state following metronidazole treatment in alcoholic patients receiving disulfiram, see under Alcohol, above.

Mycophenolate mofetil. For details of a pharmacokinetic study reporting reduced exposure to mycophenolate mofetil when given with metronidazole or metronidazole plus norfloxacin, see Antibacterials, p.1837.

Omeprazole. Although concentrations in plasma and saliva of metronidazole and its hydroxy metabolite were unaffected by omeprazole in healthy subjects, those in gastric juice were substantially lowered, possibly as a result of a reduction in transfer from the plasma.[1] However, this may be of limited clinical significance during treatment of *Helicobacter pylori* infections.

1. Jessa MJ, *et al.* The effect of omeprazole on the pharmacokinetics of metronidazole and hydroxymetronidazole in human plasma, saliva and gastric juice. *Br J Clin Pharmacol* 1997; **44:** 245–53.

Phenobarbital. An increase in the rate of metabolism of metronidazole, resulting in treatment failure, was reported in a patient taking phenobarbital.[1] In a retrospective survey of patients who had not responded to treatment with metronidazole, 80% were found to be on long-term phenobarbital therapy.[2] It was found that up to 3 times the usual dose was required to produce a parasitological cure of giardiasis in such patients.

2. Gupte S. Phenobarbital and metabolism of metronidazole. *N Engl J Med* 1983; **308:** 529.

Phenytoin. In addition to conflicting reports on the effects of metronidazole on the metabolism of phenytoin (p.499), increased metabolism of metronidazole was reported in a patient during treatment with phenytoin.[1]

1. Wheeler LA, *et al.* Use of high-pressure liquid chromatography to determine plasma levels of metronidazole and metabolites after intravenous administration. *Antimicrob Agents Chemother* 1978; **13:** 205–9.

Antimicrobial Action

Metronidazole is active against several protozoa including *Balantidium coli*, *Blastocystis hominis*, *Entamoeba histolytica*, *Giardia intestinalis* (*Giardia lamblia*), and *Trichomonas vaginalis*. Most obligate anaerobic bacteria, including *Bacteroides* and *Clostridium* spp., are sensitive *in vitro* to metronidazole. It is bactericidal. It also has activity against the facultative anaerobes *Gardnerella vaginalis* and *Helicobacter pylori* and against some spirochaetes. Resistance to metronidazole has been reported and cross-resistance to other nitroimidazoles, such as tinidazole, may occur.

◊ Metronidazole has well-established bactericidal activity against obligate anaerobic bacteria *in vitro*, including the Gram-negative organisms *Bacteroides fragilis* and other *Bacteroides* spp., *Fusobacterium* spp., and *Veillonella* spp., and the Gram-positive organisms *Clostridium difficile, Cl. perfringens,* and other *Clostridium* spp., *Eubacterium* spp., *Peptococcus* spp., and *Peptostreptococcus* spp.; *Propionibacterium* and *Actinomyces* spp. are often resistant.[1-6] It also has activity against the facultative anaerobe *Gardnerella vaginalis*, although its bactericidal effect is reported to be much slower than against obligate anaerobes,[7] against some strains of *Campylobacter* spp. including *C. fetus* subsp. *jejuni*,[8,9] and against *Helicobacter pylori*.[10,11]

The oxidative metabolites of metronidazole also have antibacterial activity; the hydroxy metabolite has been reported to be consistently more active than metronidazole against strains of *G. vaginalis*.[12,13]

The mode of action of metronidazole is not entirely clear, but is thought to involve reduction by bacterial 'nitroreductases' to an unstable intermediate which interacts with DNA, effectively preventing further replication.[14] A number of factors affect the sensitivity of micro-organisms to metronidazole *in vitro*. Anaerobic conditions are important for optimal activity. Interactions between micro-organisms and metronidazole have been described, including inhibition of *Escherichia coli* by metronidazole in the presence of *B. fragilis* and enhancement of the rate of killing of *B. fragilis* by metronidazole in the presence of *E. coli*.

Resistance to metronidazole has developed in sensitive species. Although no resistance among the *B. fragilis* group was observed over several years,[15,16] there have been occasional reports of resistance in this group[17-22] and in other *Bacteroides* spp.[23-25] now known as *Prevotella* spp. Nitroimidazole resistance in *Helicobacter pylori* has been increasing and may be associated with reduced response rates to anti-*Helicobacter* therapy for peptic ulcer disease in some populations (see Peptic Ulcer Disease under Uses, below).

Pharmacokinetics

Metronidazole is readily and almost completely absorbed after oral doses. Peak plasma concentrations of about 6 and 12 micrograms/mL are achieved, usually within 1 to 2 hours, after single doses of 250 and 500 mg respectively. Some accumulation occurs and consequently there are higher concentrations when multiple doses are given. Absorption may be delayed, but is not reduced overall by food. Metronidazole benzoate given orally is hydrolysed in the gastrointestinal tract to release metronidazole, which in turn is then absorbed.

Peak steady-state plasma concentrations of about 25 micrograms/mL with trough concentrations of about 18 micrograms/mL have been reported in patients given an intravenous loading dose of 15 mg/kg followed by 7.5 mg/kg every 6 hours. The bioavailability of metronidazole from rectal suppositories is 60 to 80%; peak plasma concentrations are half those achieved with equivalent oral doses and effective concentrations occur after about 5 to 12 hours. Absorption from vaginal pessaries is poor with a reported bioavailability of about 20 to 25%; absorption is gradual producing peak plasma concentrations of about 2 micrograms/mL after a dose of 500 mg. An intravaginal gel formulation providing a dose of 37.5 mg metronidazole produced peak plasma concentrations of 0.3 micrograms/mL at 8 hours, with a bioavailability of 56%.

Metronidazole is widely distributed. It appears in most body tissues and fluids including bile, bone, breast milk, cerebral abscesses, CSF, liver and liver abscesses, saliva, seminal fluid, and vaginal secretions, and achieves concentrations similar to those in plasma. It also crosses the placenta and rapidly enters the fetal circulation. No more than 20% is bound to plasma proteins.

Metronidazole is metabolised in the liver by side-chain oxidation and glucuronide formation. The principal oxidative metabolites are 1-(2-hydroxyethyl)-2-hydroxymethyl-5-nitroimidazole (the hydroxy metabolite), which has antibacterial activity and is detected in plasma and urine, and 2-methyl-5-nitroimidazole-1-acetic acid (the acid metabolite), which has virtually no antibacterial activity and is often not detected in plasma, but is excreted in urine. Small amounts of reduced metabolites, acetamide and *N*-(2-hydroxyethyl)oxamic acid (HOA), have also been detected in urine and are probably formed by the intestinal flora.

The elimination half-life of metronidazole is about 8 hours; that of the hydroxy metabolite is slightly longer. The half-life of metronidazole is reported to be longer in neonates and in patients with severe hepatic impairment; that of the hydroxy metabolite is prolonged in patients with substantial renal impairment.

The majority of a dose of metronidazole is excreted in the urine, mainly as metabolites; a small amount appears in the faeces.

Hepatic impairment. There have been differing results from pharmacokinetic studies of the elimination of metronidazole in patients with hepatic impairment. No marked difference was reported[1] between patients with cirrhosis or hepatosplenic schistosomiasis given a single 500-mg oral dose of metronidazole when compared with healthy subjects; this suggested that, in the absence of renal impairment, dosage adjustment was not needed in patients with hepatic impairment. However, others found[2] that elimination of metronidazole, given intravenously, was considerably impaired in a study of 10 patients with alcoholic liver disease or chronic active hepatitis, 7 of whom also had reduced creatinine clearance. Responding to the comment[3] that these differing results were probably due to impaired renal elimination, the authors suggested[4] that impaired elimination of metronidazole was due to impaired hepatic metabolism rather than decreased renal clearance; other studies have shown metronidazole clearance to be normal in renal impairment. They nevertheless agreed that reduction in the dosage of metronidazole is required only when hepatic function is very poor, particularly when renal function is impaired. A study in 10 severely ill patients with or without impaired hepatic and/or renal function[5] also suggested that hepatic function is a very important determinant of metronidazole elimination.

Infants and children. A single intravenous dose of 15 mg/kg has been suggested for neonates[1] which would produce therapeutic concentrations of metronidazole for around 24 hours in term neonates and 48 hours in preterm neonates. Renal and hepatic function is incompletely developed in newborn infants and consequently the elimination half-life of metronidazole is prolonged and has been reported to range from 25 to 109 hours.[1] Elimination half-life is inversely proportional to gestational age[1,2] and as the infant matures half-life is reduced to values closer to those in adults.[1,3]

3. Amon I, *et al.* Disposition kinetics of metronidazole in children. *Eur J Clin Pharmacol* 1983; **24:** 113–19.

Renal impairment. Pharmacokinetic studies have indicated that doses of metronidazole need not be altered in patients with renal impairment,[1] although adjustments might be required in patients undergoing haemodialysis, since metronidazole and its hydroxy metabolite are efficiently cleared and extensively removed in such patients.[2] However, in another study[3] the amount of metronidazole and its hydroxy metabolite cleared was found to depend on the type of dialysis membrane used; the authors concluded that dosage supplementation may be needed only for seriously ill patients undergoing haemodialysis with a membrane having high metronidazole clearance.

Routine adjustment of dosage was not considered necessary in patients undergoing peritoneal dialysis.[4] However, the potential for metabolites to accumulate was noted in patients on continuous ambulatory peritoneal dialysis[5] and it was suggested that dosage reduction may be necessary if excessive concentrations of metabolites are found to be toxic.

Uses and Administration

Metronidazole is a 5-nitroimidazole derivative with activity against anaerobic bacteria and protozoa (see Antimicrobial Action, above); it also has a radiosensitising effect on hypoxic tumour cells. Its mechanism of action is thought to involve interference with DNA by a metabolite in which the nitro group of metronidazole has been reduced.

Metronidazole is used in the treatment of susceptible protozoal infections such as amoebiasis, balantidiasis, *Blastocystis hominis* infections, giardiasis, and trichomoniasis; it has also been tried in leishmaniasis and microsporidiosis. For details of these infections and their treatment see under Choice of Antiprotozoal, p.822. Metronidazole is also used in the treatment and prophylaxis of anaerobic bacterial infections. Specific bacterial infections treated with metronidazole include bacterial vaginosis, acute necrotising ulcerative gingivitis, pelvic inflammatory disease, tetanus, and antibiotic-associated colitis. For details of these infections and their treatment see under Choice of Antibacterial, p.162.

Metronidazole is used to eradicate *Helicobacter pylori* in peptic ulcer disease (with other antimicrobials, and either bismuth compounds or proton pump inhibitors) and in the management of malodorous tumours and ulcers where there is anaerobic infection. It is also used in the treatment of rosacea and of dracunculiasis (guinea-worm infection) and has been given in the treatment of perianal Crohn's disease and hepatic encephalopathy. It has also been tried as an adjunct to the radiotherapy of malignant neoplasms. See also below for these miscellaneous uses.

ADMINISTRATION AND DOSAGE. Metronidazole is given orally in tablets or, as metronidazole benzoate, in oral suspension; the tablets are taken with or after food and the suspension at least 1 hour before food. Metronidazole is also given rectally in suppositories, applied topically as a cream or gel, or given by intravenous infusion of metronidazole or metronidazole hydrochloride. Doses are expressed in terms of metronidazole base.

In **amoebiasis**, metronidazole acts as an amoebicide at all sites of infection with *Entamoeba histolytica*. Because of its rapid absorption it is probably less effective against parasites in the bowel lumen and is therefore used with a luminal amoebicide such as diloxanide furoate or diiodohydroxyquinoline in the treatment of invasive amoebiasis. Metronidazole is given in oral doses of 400 to 800 mg three times daily for 5 to 10 days. Children aged 1 to 3 years may be given one-quarter, those aged 3 to 7 years one-third, and those aged 7 to 10 years one-half the total adult daily dose; alternatively 35 to 50 mg/kg daily in divided doses has been used. An alternative adult dose is 1.5 to 2.5 g as a single daily dose for 2 or 3 days.

In **balantidiasis** and ***Blastocystis hominis* infection**, metronidazole has been given orally in a dose of 750 mg three times daily for 5 and 10 days, respectively.

In **giardiasis**, the usual oral dose of metronidazole is 2 g once daily for 3 successive days, or 400 mg three times daily for 5 days, or 500 mg twice daily for 7 to 10 days. Dosage for children is proportional, as for amoebiasis (above). An alternative schedule for children is 15 mg/kg daily in divided doses.

In **trichomoniasis**, metronidazole is given orally either as a single 2-g dose, as a 2-day course of 800 mg in the morning and 1.2 g in the evening, or as a 7-day course of 600 mg to 1 g daily in two or three divided doses. Sexual partners should also be treated. If treatment needs to be repeated, an interval of 4 to 6 weeks between courses has been recommended. Vaginal preparations containing metronidazole are available for the treatment of vaginal trichomoniasis in some countries. Children with trichomoniasis may be given a 7-day course of metronidazole by mouth as follows: 1 to 3 years, 50 mg three times daily; 3 to 7 years, 100 mg twice daily, and 7 to 10 years, 100 mg three times daily. An alternative children's dose is 15 mg/kg daily in 3 divided doses for 7 days.

Bacterial vaginosis is treated similarly to vaginal trichomoniasis with which it may co-exist; metronidazole is usually given orally as a single 2-g dose or as a 5 to 7-day course of 400 or 500 mg twice daily. Alternatively it may be applied locally as 5 g of a 0.75% gel once or twice daily for 5 days.

In **acute necrotising ulcerative gingivitis**, metronidazole 200 mg three times daily is given orally for 3 days; similar doses are used in acute dental infections. A 25% dental gel has also been used as an adjunct to the treatment of chronic periodontal infections.

For the treatment of most **anaerobic bacterial infections**, metronidazole is given orally in an initial dose of 800 mg followed by 400 mg every 8 hours, usually for about 7 days. A regimen of 500 mg every 8 hours is alternatively used. When oral therapy is precluded metronidazole may be given intravenously, 500 mg being infused as 100 mL of a 5 mg/mL solution at a rate of 5 mL/minute every 8 hours, or rectally as a 1-g suppository every 8 hours for 3 days, then every 12 hours; oral therapy should be substituted as soon as possible. Suppositories may be unsuitable for beginning therapy in serious infections because of the slower absorption of metronidazole. Children may be given 7.5 mg/kg every 8 hours by mouth or by intravenous infusion; recommended rectal doses for children, to be given every 8 hours for 3 days, then every 12 hours thereafter, are: for those aged under 1 year, 125 mg; 1 to 5 years, 250 mg; 5 to 10 years, 500 mg. In the USA recommended adult doses of metronidazole are 7.5 mg/kg every 6 hours by mouth or 15 mg/kg by intravenous infusion followed by 7.5 mg/kg every 6 hours, doses being infused over 1 hour; by either route a total dose of 4 g in 24 hours should not be exceeded. In mixed anaerobic and aerobic infections metronidazole is given with the appropriate antibacterials.

For the **prevention of postoperative anaerobic bacterial infections**, especially in patients undergoing abdominal or gynaecological surgery, metronidazole is given orally, intravenously, or rectally in doses similar to those used for treatment, usually with a beta-lactam or an aminoglycoside antibacterial. Various schedules have been employed. In the UK, licensed doses for adults are:

- orally 400 mg every 8 hours in the 24 hours before surgery followed postoperatively by intravenous or rectal dosage until oral therapy is possible
- by intravenous infusion, 500 mg shortly before operation and repeated every 8 hours, oral doses of 200 or 400 mg every 8 hours being substituted as soon as possible
- by rectum, 1 g every 8 hours starting 2 hours before surgery.

The *BNF*, however, recommends that oral doses should be started only 2 hours before the operation and that the number of doses for all dose routes be limited to a total of four. In the USA the recommended schedule for adults undergoing colorectal surgery is metronidazole 15 mg/kg by intravenous infusion over 30 to 60 minutes, completed about 1 hour before surgery, followed by two further intravenous doses of 7.5 mg/kg infused at 6 and 12 hours after the initial dose.

In **peptic ulcer disease**, metronidazole is used in combination therapy to eradicate *Helicobacter pylori*. Typical regimens include metronidazole plus another antibacterial (clarithromycin or amoxicillin) given with either a proton pump inhibitor (omeprazole or lansoprazole) or with ranitidine bismuth citrate. The usual dose of metronidazole is 400 mg twice daily except when given with omeprazole and amoxicillin, when metronidazole 400 mg three times daily is used. Treatment is continued for 1 week.

For **leg ulcers** and **pressure sores** infected with anaerobic bacteria, oral metronidazole 400 mg may be given three times daily for 7 days. Metronidazole is also applied topically as a 0.75% or 0.8% gel to reduce the odour associated with anaerobic infection in **fungating tumours**.

In the treatment of **rosacea** metronidazole is given orally or applied topically.

Administration in hepatic impairment. Since metronidazole is mainly metabolised by hepatic oxidation, accumulation of metronidazole and its metabolites is likely in patients with severely impaired hepatic function. Metronidazole should therefore be given with caution and at reduced doses to patients with severe hepatic impairment, and especially hepatic encephalopathy when adverse affects of metronidazole can add to the symptoms of the disease. One-third of the usual daily dose may be given once daily in these patients. For patients with lesser degrees of hepatic impairment, pharmacokinetic studies have not produced consistent results (see under Pharmacokinetics, above) and no recommendations about dosage reduction have been made by licensed product information.

Administration in renal impairment. The elimination of metronidazole is largely unchanged in patients with renal impairment, although metabolites may accumulate in patients with end-stage renal disease on dialysis (see under Pharmacokinetics, above). Dosage reductions are therefore not usually recommended for patients with renal impairment although, since both metronidazole and its metabolites are removed by haemodialysis, doses need to be given immediately after haemodialysis.

Dracunculiasis. Metronidazole may be beneficial in the management of dracunculiasis (p.136). It provides symptomatic relief and is also thought to weaken the anchorage of the worms within subcutaneous tissue, thus allowing them to be removed more quickly.

Metronidazole has been given in a variety of regimens, including doses of 400 mg three times daily for 5 days,[1] 40 mg/kg daily in three divided doses (to a maximum daily dose of 2.4 g) for 3 days,[2] and 400 mg daily for 10 to 20 days.[3] WHO recommends 25 mg/kg daily for 10 days;[4] a dose of 250 mg three times daily for 10 days has also been recommended.

Hepatic encephalopathy. The treatment of hepatic encephalopathy is discussed on p.1697. It includes the use of an antimicrobial such as metronidazole to reduce the intestinal flora.

Inflammatory bowel disease. Metronidazole is used in the treatment of perineal Crohn's disease (see Inflammatory Bowel Disease, p.1697) and may also be used in colonic Crohn's disease, when it has been tried with ciprofloxacin. It has also proved effective for the prevention of postsurgical recurrence. Duration of therapy is usually limited to 3 months.

Metabolic disorders. Children with excesses of methylmalonic[1,2] and propionic[3] acid in their blood or urine have shown clinical improvement when given metronidazole, which reduced the excretion of faecal propionate and urinary methylmalonate. Metronidazole is considered to act through its antimicrobial effect on gut anaerobes that are involved in propionate production; such propionate cannot be handled by these children who are deficient in the relevant enzyme.

Mouth disorders and infections. Ciclosporin-induced gingival hyperplasia resolved in 4 patients after treatment with metronidazole.[1]

Metronidazole is considered to be effective for the treatment of acute necrotising ulcerative gingivitis and is an alternative to penicillin in other dental infections (see Mouth Infections, p.180).

1. Wong W, *et al.* Resolution of cyclosporin-induced gingival hypertrophy with metronidazole. *Lancet* 1994; **343:** 986.

Peptic ulcer disease. The use of metronidazole is well established in regimens for eradicating *Helicobacter pylori* (see Peptic Ulcer Disease, p.1702). However, the emergence of metronidazole-resistant strains of *H. pylori* has been associated with an increased rate of treatment failures with some regimens.[1-4] Difficulties arise in assessing metronidazole resistance and in correlating *in-vitro* results with clinical response.[5] In populations in which the incidence of resistance is high, it may become necessary to use alternative regimens,[6] but in other areas, such as the UK, regimens including metronidazole continue to be among the standard alternatives (although the *BNF* recommends that they should not be used for initial treatment in patients who have been given metronidazole for other infections).

Skin disorders. Metronidazole may be effective in the management of malodorous anaerobic skin infections associated with ulceration (p.194), including *pressure sores* and *fungating tumours*. Both the oral and topical routes have been employed but the evidence in favour of its use is largely anecdotal as few randomised controlled studies have yet been performed.[1,2]

Metronidazole has also been used[3] in the treatment of *rosacea* (p.1583). Metronidazole 200 mg twice daily by mouth was more effective than placebo[4] and as effective as oral oxytetracycline.[5] Similarly, topical preparations (for example, 0.75% cream, gel, or lotion or 1% cream) have been found to be better than placebo and as effective as oral oxytetracycline.[6,7]

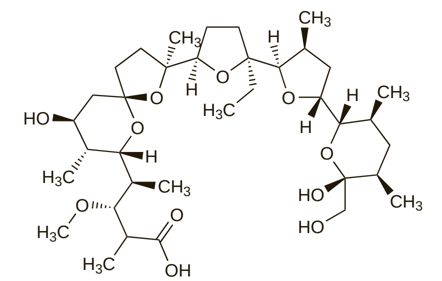
Monensin *(BAN, USAN, rINN)*

Lilly-67314; Monensina; Monensinum. 4-{2-[2-Ethyl-3′-methyl-5′-(tetrahydro-6-hydroxy-6-hydroxymethyl-3,5-dimethylpyran-2-yl)perhydro-2,2′-bifuran-5-yl]-9-hydroxy-2,8-dimethyl-1,6-dioxaspiro[4.5]dec-7-yl}3-methoxy-2-methylpentanoic acid.

Монензин

$C_{36}H_{62}O_{11}$ = 670.9.
CAS — 17090-79-8.
ATC Vet — QP51AH03.



Pharmacopoeias. In *US* for veterinary use only.
USP 31 (Monensin). A mixture of antibiotic substances produced by *Streptomyces cinnamonensis*.

Monensin Sodium *(BANM, rINNM)*

Monensin Sodique; Monensina sódica; Natrii Monensinum.

Натрий Монензин

$C_{36}H_{61}NaO_{11}$ = 692.9.
CAS — 22373-78-0.

Pharmacopoeias. In *US* for veterinary use only.
USP 31 (Monensin Sodium). An off-white to tan crystalline powder. Slightly soluble in water; soluble in chloroform and in methyl alcohol; practically insoluble in petroleum spirit. Avoid moisture and excessive heat.

Profile

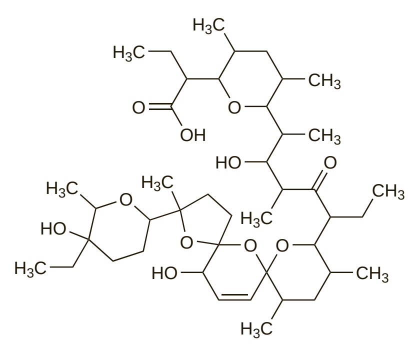
Monensin is an antiprotozoal used as the sodium salt in veterinary practice for the prevention of coccidiosis in poultry and as a growth promotor for cattle.

Narasin *(BAN, USAN, rINN)*

Compound 79891; Lilly-79891; Narasina; Narasine; Narasinum. 2-(6-{5-[2-(5-Ethyltetrahydro-5-hydroxy-6-methylpyran-2-yl)-15-hydroxy-2,10,12-trimethyl-1,6,8-trioxadispiro[4.1.5.3]pentadec-13-en-9-yl]-2-hydroxy-1,3-dimethyl-4-oxoheptyl}tetrahydro-3,5-dimethylpyran-2-yl)butyric acid.

Наразин

$C_{43}H_{72}O_{11}$ = 765.0.
CAS — 55134-13-9.
ATC Vet — QP51AH04.



Pharmacopoeias. In *US* for veterinary use only.
USP 31 (Narasin Granular). It contains narasin mixed with suitable carriers and inactive ingredients prepared in a granular form that is free-flowing and free of aggregates. Narasin is a white to off-white crystalline powder. Soluble in water and in methyl alcohol.

Profile

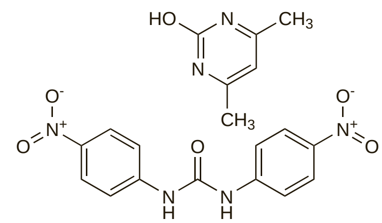
Narasin, an antibiotic produced by *Streptomyces aureofaciens*, is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in chickens.

Nicarbazin *(BAN)*

Nicarbazina. An equimolecular complex of 1,3-bis(4-nitrophenyl)urea ($C_{13}H_{10}N_4O_5$) and 4,6-dimethylpyrimidin-2-ol ($C_6H_8N_2O$).

Никарбазин

$C_{19}H_{18}N_6O_6$ = 426.4.
CAS — 330-95-0.
ATC Vet — QP51AE03.



Profile

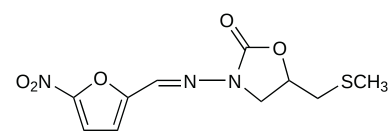
Nicarbazin is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry.

Nifuratel *(BAN, USAN, rINN)*

Methylmercadone; Nifurateeli; Nifuratelum. 5-Methylthiomethyl-3-(5-nitrofurfurylideneamino)-2-oxazolidone.

Нифурател

$C_{10}H_{11}N_3O_5S$ = 285.3.
CAS — 4936-47-4.
ATC — G01AX05.
ATC Vet — QG01AX05.



Adverse Effects

Adverse effects associated with nifuratel include gastrointestinal disturbances, peripheral neuropathy, and thrombocytopenic purpura. Allergic reactions, hepatotoxicity, blood dyscrasias, and pulmonary reactions similar to those seen with the structurally related drug nitrofurantoin have been reported rarely. Haemolytic anaemia may occur in patients with G6PD deficiency given nifuratel.

Hypersensitivity. There have been several reports of contact dermatitis associated with nifuratel, including a report after only one application of nifuratel ointment in a man whose wife was undergoing treatment with nifuratel vaginal pessaries.[1]

1. Bedello PG, *et al.* Contact dermatitis from nifuratel. *Contact Dermatitis* 1983; **9:** 166.

Precautions

Nifuratel should not be given to patients with renal impairment, neuropathies, or G6PD deficiency.

Interactions

A disulfiram-like reaction may occur in patients taking alcohol while on nifuratel therapy.

Pharmacokinetics

When taken orally nifuratel is absorbed from the gastrointestinal tract. A metabolite, with activity against bacteria but not against trichomonads, is excreted in the urine.

Uses and Administration

Nifuratel is a nitrofuran derivative with a broad antimicrobial spectrum. It is active against the protozoan *Trichomonas vaginalis* and has an antibacterial spectrum similar to that of nitrofurantoin and some antifungal activity against *Candida albicans*. Although other drugs are preferred, nifuratel has been used to treat susceptible infections of the genito-urinary tract in oral doses of 200 to 400 mg three times daily. It has also been given vaginally.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Macmiror; ***Cz.:*** Macmiror; ***Ger.:*** Inimur; ***Hong Kong:*** Macmiror; ***Ital.:*** Macmiror; ***Mex.:*** Macmiror; ***Pol.:*** Macmiror; ***Rus.:*** Macmiror (Макмирор).

Nifursol *(BAN, USAN, pINN)*

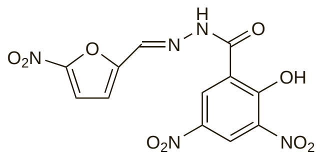
Nifursolum. 3,5-Dinitro-2′-(5-nitrofurfurylidene)salicylohydrazide.

Нифурсол

$C_{12}H_7N_5O_9$ = 365.2.

CAS — 16915-70-1.

ATC Vet — QP51AX05.



Profile

Nifursol is an antiprotozoal used in veterinary practice for the prevention of blackhead (histomoniasis) in poultry.

Nifurtimox *(BAN, rINN)*

Bayer-2502; Nifurtimoxum. Tetrahydro-3-methyl-4-(5-nitrofurfurylideneamino)-1,4-thiazine 1,1-dioxide.

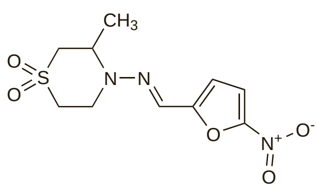
Нифуртимокс

$C_{10}H_{13}N_3O_5S$ = 287.3.

CAS — 23256-30-6.

ATC — P01CC01.

ATC Vet — QP51AC01.



Pharmacopoeias. In *Fr.* and *Int.*

Adverse Effects

Adverse effects are common with nifurtimox and include gastrointestinal effects such as anorexia with loss of weight, abdominal pain, nausea and vomiting, and effects on the nervous system, especially peripheral neuropathy. Psychoses, CNS excitement, insomnia, drowsiness, headache, myalgia, arthralgia, dizziness, and convulsions have also been reported. Skin rashes and other allergic reactions may occur.

Mutagenicity. An increase in chromosomal aberrations has been seen in children given nifurtimox.[1]

1. Gorla NB, *et al.* Thirteenfold increase of chromosomal aberrations non-randomly distributed in chagasic children treated with nifurtimox. *Mutat Res* 1989; **224:** 263–7.

Pharmacokinetics

Nifurtimox is well absorbed and rapidly metabolised after oral doses.

◊ References.

2. Gonzalez-Martin G, *et al.* The pharmacokinetics of nifurtimox in chronic renal failure. *Eur J Clin Pharmacol* 1992; **42:** 671–3.

Uses and Administration

Nifurtimox is a nitrofuran derivative with antiprotozoal activity. It is of value in the treatment of American trypanosomiasis (Chagas' disease) due to infection by *Trypanosoma cruzi*, especially the early acute stage of the disease. In African trypanosomiasis it has some activity against *T. brucei gambiense*, the organism responsible for West African sleeping sickness.

Nifurtimox is given orally in 3 to 4 divided doses. It is better tolerated by children than by adults. Treatment for American trypanosomiasis is given for 60 to 120 days (but see below). Doses for adults are 8 to 10 mg/kg daily. Doses for children are: aged 1 to 10 years, 15 to 20 mg/kg daily for 90 days; aged 11 to 16 years, 12.5 to 15 mg/kg daily for 90 days.

Leishmaniasis. Mucocutaneous leishmaniasis of the New World (p.824) is usually treated with pentavalent antimony or, in those who do not respond, with amphotericin B or pentamidine. However, nifurtimox 10 mg/kg daily for a minimum of 4 weeks has been shown to be effective in cases of mucocutaneous leishmaniasis in Colombia and Brazil. Despite this, toxic effects with nifurtimox are common and its role as a second-line drug or with pentavalent antimony has not been established.[1]

1. WHO. Control of the leishmaniases. *WHO Tech Rep Ser 793*, 1990.

African trypanosomiasis. Nifurtimox has been tried as an alternative to melarsoprol or eflornithine in the meningoencephalitic stage of *Trypanosoma brucei gambiense* infection (p.827), but higher doses than those used in American trypanosomiasis are necessary. A good initial response was achieved[1] in 25 patients with nifurtimox 15 mg/kg daily for 60 days, but 3 patients relapsed while still receiving nifurtimox and a further 12 of 19 patients who were followed up relapsed subsequently. An attempt[2] to improve the response by increasing the daily dose even higher to 30 mg/kg for 30 days resulted in substantial toxicity and only a modest improvement in results, with 9 of 25 patients relapsing. However, promising results have been reported[3] from use of oral nifurtimox 15 mg/kg daily for 10 days with eflornithine 400 mg/kg daily intravenously for 7 days.

1. Pepin J, *et al.* An open clinical trial of nifurtimox for arseno-resistant Trypanosoma brucei gambiense sleeping sickness in central Zaire. *Trans R Soc Trop Med Hyg* 1989; **83:** 514–17.
2. Pépin J, *et al.* High-dose nifurtimox for arseno-resistant Trypanosoma brucei gambiense sleeping sickness: an open trial in central Zaire. *Trans R Soc Trop Med Hyg* 1992; **86:** 254–6.
3. Priotto G, *et al.* Nifurtimox-eflornithine combination therapy for second-stage Trypanosoma brucei gambiense sleeping sickness: a randomized clinical trial in Congo. *Clin Infect Dis* 2007; **45:** 1435–42.

American trypanosomiasis. The treatment of American trypanosomiasis (p.827) is generally unsatisfactory, but nifurtimox is of value especially in the acute phase. However, there has been controversy over its ability to cure completely, that is to eradicate all parasites, in chronic disease.[1] Doses recommended by WHO[2,3] are 8 to 10 mg/kg daily in three divided doses for adults, and 15 to 20 mg/kg daily in four divided doses for children. WHO recommends that nifurtimox should be given for 60 or 90 days.[2,3] Some in the USA[4] suggest a 90- to 120-day regimen for adults but nifurtimox is not well tolerated and the experience of other workers[1] suggests that few patients may complete the full course.

Nimorazole *(BAN, rINN)*

Nimorazol; Nimorazolum; Nitrimidazine. 4-[2-(5-Nitroimidazol-1-yl)ethyl]morpholine.

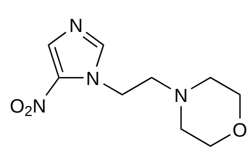
Ниморазол

$C_9H_{14}N_4O_3$ = 226.2.

CAS — 6506-37-2.

ATC — P01AB06.

ATC Vet — QP51AA06.



Pharmacopoeias. In *It.*

Adverse Effects and Precautions

As for Metronidazole, p.837.

Pharmacokinetics

Nimorazole is readily absorbed from the gastrointestinal tract. Peak blood concentrations are achieved within 2 hours, and high concentrations are reported to occur in salivary and vaginal secretions. Trichomonicidal urinary concentrations may persist for up to 48 hours after a dose. It is excreted in the urine together with 2 active metabolites. Unchanged drug and metabolites also appear in breast milk.

Uses and Administration

Nimorazole is a 5-nitroimidazole derivative. It has antimicrobial actions and uses similar to those of metronidazole (p.839).

In the treatment of trichomoniasis, the usual dose of nimorazole is 2 g orally as a single dose with a main meal. It may alternatively be given in a dose of 1 g every 12 hours for three doses, or 250 mg three times daily for 5 to 7 days. In amoebiasis, nimorazole 1 g is given twice daily, usually for 5 to 10 days and in giardiasis a dose of 500 mg is given twice daily, usually for 5 to 7 days.

Nimorazole may also be used in the treatment of acute ulcerative gingivitis in a dose of 500 mg twice daily for 2 days.

Preparations

Proprietary Preparations (details are given in Part 3)

Arg.: Naxogin; Vagarne†; ***Austria:*** Naxogin; ***Belg.:*** Naxogin; ***Braz.:*** Naxogin; ***Chile:*** Naxogin†; ***Ger.:*** Esclama†; ***Rus.:*** Naxogin (Наксоджин).

Nitazoxanide *(BAN, USAN, rINN)*

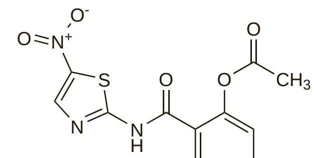
Nitazoxanida; Nitazoxanidum; PH-5776. *N*-(5-Nitro-2-thiazolyl)salicylamide acetate.

Нитазоксанид

$C_{12}H_9N_3O_5S$ = 307.3.

CAS — 55981-09-4.

ATC — P01AX11.



Adverse Effects

The most common adverse effects associated with nitazoxanide are abdominal pain and diarrhoea. Nausea and vomiting, flatulence, and increased appetite have also been reported. Headache may occur. Other reported adverse effects include fever, malaise, pruritus, sweating, dizziness, and rhinitis. Discoloration of urine and of the eyes has been reported rarely. Increased creatinine and liver enzyme values have been noted.

Pharmacokinetics

Nitazoxanide is absorbed from the gastrointestinal tract after oral dosage and is rapidly hydrolysed to an active desacetyl metabolite, tizoxanide. Tizoxanide then partially undergoes conjugation, primarily by glucuronidation. The extent of absorption is enhanced if given with food and peak plasma concentrations of tizoxanide and the glucuronide are seen 1 to 4 hours after an oral dose. The parent drug is not detected in plasma. Tizoxanide is more than 99% bound to plasma proteins. About two-thirds of an oral dose of nitazoxanide is eliminated in the faeces and one-third in the urine; tizoxanide is excreted in the urine, bile, and faeces, while the glucuronide is excreted in only the urine and bile.

Uses and Administration

Nitazoxanide is used for the treatment of cryptosporidiosis and giardiasis in immunocompetent patients. It is given orally and should be taken with food. Doses are 100 mg twice daily for 3 days in those aged 1 to 3 years, 200 mg twice daily for 3 days in those aged 4 to 11 years, and 500 mg twice daily for 3 days in adults. Nitazoxanide has also been tried in a number of other protozoal and helminth infections, particularly in immunocompromised patients, including those with HIV infection. It is also being investigated for the treatment of rotavirus disease and *Clostridium difficile* colitis.

◊ Reviews.

4. Anderson VR, Curran MP. Nitazoxanide: a review of its use in the treatment of gastrointestinal infections. *Drugs* 2007; **67:** 1947–67.

Protozoal infections. As well as its established use in cryptosporidiosis (p.823) and giardiasis (p.824), nitazoxanide has been used in other protozoal infections including intestinal amoebiasis (p.822), blastocytosis (p.823), and microsporidiosis (p.826).

Rotavirus diarrhoea. A randomised double-blind placebo-controlled study[1] in 38 young children (median age 11 months) with confirmed rotavirus diarrhoea found that oral nitazoxanide 7.5 mg/kg twice daily for 3 days significantly reduced the duration of rotavirus disease. The median time to resolution of illness after the first dose was 31 hours for those given nitazoxanide compared with 75 hours for those in the placebo group.

Ornidazole *(USAN, rINN)*

Ornidatsoli; Ornidazol; Ornidazolum; Ro-7-0207. 1-Chloro-3-(2-methyl-5-nitroimidazol-1-yl)propan-2-ol.

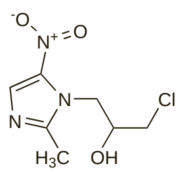
Орнидазол

$C_7H_{10}ClN_3O_3$ = 219.6.

CAS — 16773-42-5.

ATC — G01AF06; J01XD03; P01AB03.

ATC Vet — QG01AF06; QJ01XD03; QP51AA03.



Adverse Effects and Precautions

As for Metronidazole, p.837.

Pharmacokinetics

Ornidazole is readily absorbed from the gastrointestinal tract and peak plasma concentrations are reached within 3 hours. After repeated oral doses of 500 mg every 12 hours, steady-state peak and trough concentrations are 14 and 6 micrograms/mL respectively.

The plasma elimination half-life of ornidazole is 12 to 14 hours. Less than 15% is bound to plasma proteins. It is widely distributed in body tissues and fluids, including the CSF.

Ornidazole is metabolised in the liver and is excreted in the urine, mainly as conjugates and metabolites, and to a lesser extent in the faeces. Biliary excretion may be important in the elimination of ornidazole and its metabolites.

6. Bourget P, *et al.* Disposition of ornidazole and its metabolites during pregnancy. *J Antimicrob Chemother* 1995; **35:** 691–6.

Hepatic impairment. The elimination of ornidazole after a single intravenous dose of 500 mg was impaired in 10 patients with severe liver cirrhosis when compared with 10 healthy subjects; mean half-lives were 21.9 hours and 14.1 hours respectively.[1] These results suggested that the interval between doses of ornidazole should be doubled in patients with marked hepatic impairment. The need for dose adjustment was confirmed in further studies of patients with other forms of liver disease.[2,3]

1. Taburet AM, *et al.* Pharmacokinetics of ornidazole in patients with severe liver cirrhosis. *Clin Pharmacol Ther* 1986; **40:** 359–64.
2. Bourget P, *et al.* Ornidazole pharmacokinetics in several hepatic diseases. *J Pharmacol Clin* 1988; **7:** 25–32.
3. Taburet AM, *et al.* Pharmacokinetics of ornidazole in patients with acute viral hepatitis, alcoholic cirrhosis, and extrahepatic cholestasis. *Clin Pharmacol Ther* 1989; **45:** 373–9.

Renal impairment. The half-life of intravenous ornidazole was not prolonged in a study in patients with advanced chronic renal failure, including those on continuous ambulatory peritoneal dialysis, although total plasma clearance was halved; modification of the usual dosage is not necessary in such patients. However, the drug was removed by haemodialysis and ornidazole should be given after the dialysis session rather than before.[1] In another study[2] the systemic availability and total body clearance of ornidazole were unaffected in chronic renal failure; it was considered that an additional dose should be given before haemodialysis to compensate for removal during that procedure.

1. Merdjan H, *et al.* Pharmacokinetics of ornidazole in patients with renal insufficiency; influence of haemodialysis and peritoneal dialysis. *Br J Clin Pharmacol* 1985; **19:** 211–17.
2. Horber FF, *et al.* High haemodialysis clearance of ornidazole in the presence of a negligible renal clearance. *Eur J Clin Pharmacol* 1989; **36:** 389–93.

Uses and Administration

Ornidazole is a 5-nitroimidazole derivative. It has the antimicrobial actions of metronidazole and is used similarly (see p.839) in the treatment of susceptible protozoal infections and also in the treatment and prophylaxis of anaerobic bacterial infections.

It is given orally after food, or intravenously. Intravenous solutions of ornidazole should be diluted to 5 mg or less per mL and 100 or 200 mL infused over 15 to 30 minutes.

In **amoebiasis**, 500 mg of ornidazole is given orally twice daily for 5 to 10 days; children are given 25 mg/kg as a single daily dose for 5 to 10 days. Patients with amoebic dysentery may be given 1.5 g as a single daily dose for 3 days; the children's dose is 40 mg/kg daily. An alternative regimen for adults over 60 kg is 1 g twice daily for 3 days. In severe amoebic dysentery and amoebic liver abscess, ornidazole may be given by intravenous infusion in a dose of 0.5 to 1 g initially, followed by 500 mg every 12 hours for 3 to 6 days; the children's dose is 20 to 30 mg/kg daily.

In **giardiasis**, 1 or 1.5 g of ornidazole is given orally as a single daily dose for 1 or 2 days; the children's dose is 30 or 40 mg/kg daily.

In **trichomoniasis**, a single oral dose of 1.5 g is given; alternatively, a 5-day oral course of ornidazole 500 mg twice daily may be used. Sexual partners should also be treated. The children's dose is 25 mg/kg as a single dose by mouth.

For the treatment of **anaerobic bacterial infections,** ornidazole is given by intravenous infusion in an initial dose of 0.5 to 1 g, followed by 1 g daily as a single dose or in two divided doses for 5 to 10 days; oral therapy with 500 mg every 12 hours should be substituted as soon as possible. Children may be given 10 mg/kg intravenously every 12 hours for 5 to 10 days.

For the prevention of postoperative anaerobic bacterial infections, 1 g is given by intravenous infusion about 30 minutes before surgery.

Administration in hepatic impairment. In view of the prolonged half-life and reduced clearance of ornidazole reported in patients with hepatic dysfunction (see above), the interval between doses should be doubled in patients with severe hepatic impairment.

Administration in renal impairment. The elimination of ornidazole is reported to be largely unaltered in patients with impaired renal function (see under Pharmacokinetics, above). Dosage adjustment is therefore usually unnecessary, although patients receiving haemodialysis should be given a supplemental dose of ornidazole before dialysis; a supplemental dose of 500 mg should be given if the daily dose is 2 g daily or 250 mg should be given if the daily dose is 1 g daily.

Паромомицина Сульфат

$C_{23}H_{45}N_5O_{14},xH_2SO_4$.

CAS — 59-04-1 (paromomycin); 7542-37-2 (paromomycin); 1263-89-4 (paromomycin sulfate).

ATC — A07AA06.

ATC Vet — QA07AA06.

Pharmacopoeias. In *Chin.*, *Int.*, *It.*, and *US*.
USP 31 (Paromomycin Sulfate). The sulfate salt of an antibiotic substance produced by the growth of *Streptomyces rimosus* var. *paromomycinus*, or a mixture of two or more such salts.
A creamy-white to light yellow, odourless or practically odourless, very hygroscopic powder. It loses not more than 5% of its weight on drying. Very soluble in water; insoluble in alcohol, in chloroform, and in ether. pH of a 3% solution in water is between 5.0 and 7.5. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Neomycin, p.305.

Effects on the pancreas. Pancreatitis was associated with use of paromomycin during treatment of cryptosporidiosis in a patient with HIV infection.[1]

1. Tan WW, *et al.* Paromomycin-associated pancreatitis in HIV-related cryptosporidiosis. *Ann Pharmacother* 1995; **29:** 22–4.

Interactions

As for Neomycin, p.305.

Antimicrobial Action

Paromomycin is active against various protozoa including *Leishmania* spp., *Entamoeba histolytica*, and *Cryptosporidium* spp. In addition, it has an antibacterial spectrum similar to that of neomycin (p.305). There is cross-resistance between paromomycin and kanamycin, framycetin, neomycin, and streptomycin.

Paromomycin also has anthelmintic properties against tapeworms.

Antimycobacterial activity. References.

2. Piersimoni C, *et al.* Bacteriostatic and bactericidal activities of paromomycin against Mycobacterium avium complex isolates. *J Antimicrob Chemother* 1994; **34:** 421–4.
3. Kanyok TP, *et al.* In vivo activity of paromomycin against susceptible and multidrug-resistant Mycobacterium tuberculosis and M. avium complex strains. *Antimicrob Agents Chemother* 1994; **38:** 170–3.

Pharmacokinetics

Paromomycin is poorly absorbed from the gastrointestinal tract and most of the dose is eliminated unchanged in the faeces.

Parenteral administration. References.

1. Kanyok TP, *et al.* Pharmacokinetics of intramuscularly administered aminosidine in healthy subjects. *Antimicrob Agents Chemother* 1997; **41:** 982–6.

Uses and Administration

Paromomycin is an aminoglycoside antibiotic that has been given orally in the treatment of intestinal protozoal infections, including amoebiasis, cryptosporidiosis, and giardiasis. It has also been tried parenterally for visceral, and topically for cutaneous, leishmaniasis. For details of these infections and their treatment, see under Choice of Antiprotozoal, p.822. It has been used in the treatment of tapeworm infection, but it is not the treatment of choice. Like neomycin (p.305), it has been used in the suppression of intestinal flora both pre-operatively and in the management of hepatic encephalopathy.

Paromomycin is given as the sulfate although doses are expressed in terms of the base. In intestinal amoebiasis, the dose for both adults and children is the equivalent of paromomycin 25 to 35 mg/kg daily in 3 divided oral doses with meals for 5 to 10 days. Similar doses have been tried in cryptosporidiosis.

In taeniasis and other tapeworm infections, a dose of 4 g is given orally as a single dose or in divided doses over the course of one hour.

For hepatic coma, 4 g is given daily in divided oral doses at regular intervals for 5 to 6 days.

Leishmaniasis. Topical treatment with paromomycin 15% plus methylbenzethonium chloride 5 or 12% has produced promising results[1-3] in *cutaneous leishmaniasis* (p.824); paromomycin 12 to 15% with urea 10% was better tolerated.[4] However, benefit has not been seen in all studies.[5,6] Treatment with topical paromomycin plus systemic meglumine antimonate was initially promising in patients with New World cutaneous leishmaniasis;[7] however, a subsequent study[8] found no clear advantage over treatment with meglumine antimonate alone. Good responses to parenteral paromomycin 14 mg/kg daily, with sodium stibogluconate 10 mg/kg daily, in cases of *diffuse cutaneous leishmaniasis* have also been reported.[9]

Paromomycin has also been used intramuscularly, either alone[10] or with sodium stibogluconate,[11] in the treatment of *visceral leishmaniasis* in an area of India with increasing resistance to pentavalent antimony compounds. The authors of one study[10] found paromomycin 16 or 20 mg/kg daily for 21 days to be significantly more effective than sodium stibogluconate 20 mg/kg daily for 30 days and suggested that paromomycin be considered as first-line treatment for visceral leishmaniasis in this region. Oral paromomycin plus intravenous pentamidine was reported to be effective in the treatment of amphotericin-resistant visceral leishmaniasis in an HIV-infected patient.[12]

Pharmacopoeias. In *Int.*

Adverse Effects

Pentamidine is a toxic drug and adverse effects are frequent and sometimes severe when given parenterally; fatalities have been reported. Renal impairment is common, usually manifesting as mild and reversible raised blood urea nitrogen and serum creatinine concentrations, but acute renal failure can occur. Raised liver enzyme values and haematological disturbances such as leucopenia, anaemia, and occasionally thrombocytopenia, may develop. Hypoglycaemia, sometimes followed by hyperglycaemia and type 1 diabetes mellitus, is well documented; there have been occasional reports of acute pancreatitis.

The rapid intravenous injection of pentamidine has resulted in sudden hypotension and immediate reactions such as dizziness, headache, vomiting, breathlessness, tachycardia, and fainting. Hypotension may also occur when pentamidine is given intramuscularly or by slow intravenous infusion. Intramuscular pentamidine often causes pain, swelling, sterile abscess formation, and tissue necrosis at the site of injection. Similar damage can follow extravasation during intravenous dosage.

Other adverse effects reported include hypocalcaemia, hyperkalaemia, skin rashes, the Stevens-Johnson syndrome, fever, flushing, gastrointestinal effects such as nausea, vomiting, and taste disturbances, confusion, hallucinations, and cardiac arrhythmias.

Pentamidine is not as toxic when given by inhalation for the prophylaxis of pneumocystis pneumonia. The commonest adverse effects with this route are cough and bronchoconstriction and may be controlled by a bronchodilator. Inhalation may leave a bitter taste. Pneumothorax has been reported, but may be associated with the disease. There have been rare reports of adverse effects such as those seen when pentamidine is given by injection.

Incidence of adverse effects. Adverse effects were seen in 46.8% of 404 patients given pentamidine parenterally for the treatment of pneumocystis pneumonia, according to an analysis from the CDC in the USA.[1] The reactions included impaired renal function (23.5% of patients), abnormal liver function (9.6%), hypoglycaemia (6.2%), haematological disturbances (4.2%), skin rashes (1.5%), and hypocalcaemia (1.2%). Local reactions at injection sites such as pain and abscess occurred in 18.3% and immediate adverse effects such as hypotension in 9.6%.

Retrospective studies[2-4] suggest that adverse reactions occur more commonly in patients with AIDS.

An evaluation of pentamidine in the treatment of 82 patients with visceral leishmaniasis further illustrates its toxicity.[5] Cardiotoxicity (tachycardia, hypotension, and ECG changes of non-specific myocarditis), occurred in about 23% of patients. No hypoglycaemic reaction was noted, but 4 patients developed diabetes mellitus and 3 of them were found to be insulin-dependent. Other adverse reactions included gastrointestinal effects (anorexia, nausea, vomiting, abdominal pain, or diarrhoea) in about 78%, CNS effects (headache associated with flushing, delirium, or sensory disturbances resembling pins and needles) in about 24%, mild reversible albuminuria in about 7%, and allergic manifestations (generalised urticaria, itching, and conjunctival congestion) in about 5%. One patient had severe anaphylaxis.

5. Jha TK. Evaluation of diamidine compound (pentamidine isethionate) in the treatment of resistant cases of kala-azar occurring in North Bihar, India. *Trans R Soc Trop Med Hyg* 1983; **77:** 167–70.

Effects on the blood. Haemolytic anaemia has been reported in a 55-year-old man with AIDS being treated with intravenous pentamidine for pneumocystis pneumonia. Symptoms developed after a cumulative dose of 3740 mg of pentamidine had been given and resolved several days after stopping the pentamidine.[1]

1. Taguchi H, *et al.* Pentamidine-induced hemolytic anemia in an AIDS patient. *Ann Pharmacother* 1999; **33:** 503.

Effects on carbohydrate metabolism. As reported under Incidence of Adverse Effects, above, pentamidine can have a range of effects on carbohydrate metabolism. Four patients receiving pentamidine for pneumocystis pneumonia developed severe fasting hypoglycaemia followed later by hyperglycaemia and type 1 diabetes mellitus.[1] It has been suggested that pentamidine has a toxic effect on the β-cells of the pancreatic islets and can induce an early cytolytic release of insulin and hypoglycaemia, followed by β-cell destruction, insulin deficiency, and diabetes mellitus.[1,2] AIDS patients appear to be highly susceptible and have a higher incidence of hypoglycaemia due to pentamidine.[3] The action on the pancreas has led to fatal acute *pancreatitis*;[4-6] fatal hypoglycaemia has also been reported.[7] These reports[1-5,7] involved pentamidine given by injection; pancreatitis[8,9] and diabetes mellitus[10,11] have also been reported in patients given pentamidine by aerosol inhalation.

Effects on the cardiovascular system. *Hypotension* is a problem with intravenous pentamidine, but can be reduced by infusing the dose over 60 minutes, when the incidence of hypotension appears to be similar to that with the intramuscular route.[1,2] Intravenous pentamidine has also been associated with *torsade de pointes*.[3-5]

Effects on the kidneys. In an analysis[1] of the adverse effects of parenteral pentamidine (see also under Incidence of Adverse Effects above), *nephrotoxicity* was often the most serious adverse reaction, although it was impossible to attribute it solely to pentamidine. Severe renal impairment occurred in 15 of 404 patients and contributed materially to 12 of 14 ensuing deaths. However, elevation of blood urea nitrogen was usually relatively mild and reversible in those patients who had normal pretreatment renal function and had received no other nephrotoxic agents. In two studies in patients with AIDS,[2,3] severe nephrotoxicity (increase in serum creatinine concentration of 0.5 mg per 100 mL) was reported in about 40% of patients. Analysis of risk factors suggested that the development of adverse reactions to parenteral pentamidine is correlated with the total dose received and the duration of treatment,[2,3] but not with the initial degree of renal function.[2] It has been observed that renal toxicity is more common when pentamidine is given intramuscularly, rather than intravenously, to AIDS patients with diarrhoea, suggesting that fluid status might have an important role.[4] There have been instances of renal failure occurring when pentamidine is inhaled as an aerosol for its local effect.[5,6]

1. Walzer PD, *et al.* Pneumocystis carinii pneumonia in the United States: epidemiologic, diagnostic and clinical features. *Ann Intern Med* 1974; **80:** 83–93.

6. Chapelon C, *et al.* Renal insufficiency with nebulised pentamidine. *Lancet* 1989; **ii:** 1045–6.

Effects on the nervous system. Paraesthesias have been reported with pentamidine therapy. Perioral numbness occurred in a patient soon after starting the third intravenous infusion of pentamidine for treatment of pneumocystis pneumonia and disappeared after the end of the infusion; numbness recurred with all subsequent pentamidine infusions.[1]

1. Milligan KS, Phillips DL. Perioral numbness associated with intravenous pentamidine administration. *Ann Pharmacother* 2007; **41:** 153–6.

Effects on the respiratory system. Although inhaled pentamidine has produced reactions that are normally associated with the parenteral route, the main problem after inhalation is bronchoconstriction;[1] it can be prevented by prior use of a bronchodilator. Acute eosinophilic pneumonia associated with nebulised pentamidine has been reported in a patient.[2] Concern has also been expressed at the risks to those who are with the patient at the time of inhalation and are exposed to nebulised pentamidine.[3-5]

Precautions

Pentamidine should be used under close supervision and great care is necessary if it is used in patients suffering from any condition likely to be exacerbated by its adverse effects. The CSF should be checked for signs of CNS involvement before giving pentamidine for trypanosomiasis, since it is unlikely to be effective in such cases. Patients should remain supine while it is given and their blood pressure should be monitored. Kidney and liver function, blood-glucose concentrations, blood and platelet counts, and other parameters indicative of developing toxicity, such as serum-calcium concentrations and the ECG, should also be assessed regularly during courses of treatment with pentamidine.

Patients with a history of asthma or smoking may be at increased risk of cough and bronchospasm during inhalation of nebulised pentamidine. Symptoms may be controlled by giving a bronchodilator before pentamidine. Pentamidine solution should not be mixed with other drugs nor should a bronchodilator be given in the same nebuliser. Extrapulmonary *Pneumocystis jirovecii* infections may occur in patients given nebulised pentamidine and should be considered in patients with unexplained signs and symptoms. Precautions should be taken to minimise atmospheric pollution with pentamidine during nebulisation and to minimise exposure of medical personnel to pentamidine.

Interactions

Use of pentamidine with other nephrotoxic drugs such as amphotericin B or foscarnet should preferably be avoided. Extreme caution is also necessary if pentamidine is given with other drugs, such as foscarnet, that can cause hypocalcaemia. There is an increased risk of ventricular arrhythmias if pentamidine is given with drugs which prolong the QT interval such as amiodarone, levacetylmethadol, or terfenadine. There may be an increased risk of pancreatitis when intravenous pentamidine is used with didanosine or zalcitabine and such combinations should be avoided.

Pharmacokinetics

After intravenous doses of the isetionate, pentamidine is rapidly distributed to body tissues and this is followed by a prolonged elimination phase. Elimination half-lives of 6 hours after intravenous infusion and 9 hours after intramuscular injection have been cited, but probably represent an intermediate value, and terminal elimination half-lives of between several days and weeks have been reported. During repeated dosing accumulation is believed to occur, particularly in the liver and kidneys, and only small concentrations of pentamidine are found in the urine.

Distribution to the lung is relatively poor after injection. Systemic absorption after inhalation is reported to result in peak plasma concentrations of 5 to 10% of those after parenteral use, and there have been a few reports of systemic adverse effects. Particle or droplet size appears to be important in achieving adequate pulmonary distribution.

Renal impairment. In a study[1] of patients with normal renal function or on haemodialysis, renal clearance of pentamidine during the 24 hours after intravenous use was 2.1% of the plasma clearance in those with normal renal function, suggesting that pentamidine elimination would be largely unaffected by renal impairment. In those with end-stage renal disease on haemodialysis the terminal elimination half-life after a single dose was prolonged to about 75 hours, compared with 30 hours in the patients with normal renal function, but the volumes of distribution and area under the concentration-time curve were not significantly different. In patients with normal or mildly impaired renal function who had received between 12 and 21 doses, the terminal elimination half-life after the final dose was about 12 days and pentamidine was still detectable in the plasma after 6 weeks. There was evidence of accumulation of pentamidine during repeated daily dosing.

Uses and Administration

Pentamidine, an aromatic diamidine derivative, is an antiprotozoal used in the treatment of the early stages of African trypanosomiasis, especially *Trypanosoma brucei gambiense* infections, and in some forms of leishmaniasis. It is also used in the treatment and prophylaxis of pneumocystis pneumonia. It may act by several mechanisms, including interference with protozoal DNA and folate transformation and by inhibition of RNA and protein synthesis.

Pentamidine has been given as the isetionate or mesilate salt, but the isetionate is the only form now available in most countries. There is considerable confusion in the literature regarding the dosage of pentamidine since it is often not clear whether doses are being expressed in terms of pentamidine base, the isetionate salt, or the mesilate salt. In general it would appear that when the isetionate is used doses are expressed in terms of pentamidine isetionate, whereas when the mesilate is used doses are expressed in terms of pentamidine base. Pentamidine isetionate 4 mg/kg is equivalent to about 2.3 mg/kg of pentamidine base; pentamidine mesilate 3.6 mg/kg is equivalent to about 2.3 mg/kg of pentamidine base.

Pentamidine isetionate is given by deep intramuscular injection or by slow intravenous infusion over at least 60 minutes; direct intravenous injection must be avoided. Patients should be lying down. The mesilate has usually been given intramuscularly.

In the treatment of early **African trypanosomiasis** due to *T. b. gambiense*, pentamidine isetionate 4 mg/kg may be given daily or on alternate days by intramuscular injection or intravenous infusion to a total of 7 to 10 doses. Pentamidine is not effective in trypanosomiasis with CNS involvement, but 2 doses of pentamidine may be given in late-stage *T. b. gambiense* infection before starting treatment with melarsoprol or eflornithine.

In the treatment of visceral **leishmaniasis**, and of mucocutaneous leishmaniasis due to *Leishmania braziliensis* or *L. aethiopica* that have not responded to antimonials, pentamidine isetionate 4 mg/kg may be given, preferably intramuscularly three times weekly, for 5 to 25 weeks or longer. An alternative regimen in visceral leishmaniasis is to give 3 to 4 mg/kg on alternate days to a maximum of 10 injections; the course may need to be repeated. In cutaneous leishmaniasis due to *L. aethiopica* or *L. guyanensis*, pentamidine isetionate 3 to 4 mg/kg may be given, preferably intramuscularly once or twice weekly, until the condition resolves. A weekly dose of 3 to 4 mg/kg is also used for diffuse cutaneous leishmaniasis due to *L. aethiopica* and should be continued for at least 4 months after parasites are no longer detectable on skin smears.

In the treatment of **pneumocystis pneumonia**, pentamidine isetionate 4 mg/kg is given once daily for 14 days or longer, by intramuscular injection or preferably slow intravenous infusion. Pentamidine isetionate is given by inhalation through a nebuliser to prevent pneumocystis pneumonia in HIV-positive patients in a dose of 300 mg once every 4 weeks; in those who cannot tolerate this dose 150 mg every 2 weeks may be used. It has also occasionally been used by this route for treating mild to moderate *P. jirovecii* infection in a dose of 600 mg daily for 3 weeks. Nebuliser design can affect the droplet size delivered and hence the amount of pentamidine reaching sites of action within the lungs. The optimal particle size is 1 to 2 μm. Precautions should be taken to minimise atmospheric pollution with pentamidine during nebulisation and to minimise exposure of medical personnel to the drug.

Administration in renal impairment. Since renal clearance accounts for only a small proportion of pentamidine elimination, dosage adjustment is not generally considered necessary for mild to moderate degrees of renal impairment. UK licensed product information recommends dosage reductions in patients with pneumocystis pneumonia who have a creatinine clearance of less than 10 mL/minute. In patients with life-threatening disease the recommended dose of 4 mg/kg daily should be given for 7 to 10 days and then on alternate days for the remainder of the 14-dose course. In less severe disease the suggested dose is 4 mg/kg on alternate days for 14 doses.

Amoebic infections. *ACANTHAMOEBA INFECTIONS.* Pentamidine was used to treat disseminated *Acanthamoeba* infection (p.822) without evidence of CNS involvement in 2 immunocompromised patients.[1,2] It is unlikely that pentamidine would be effective in infections involving the CNS.

Babesiosis. Pentamidine has been tried for babesiosis (p.823), but while some patients showed clinical improvements,[1-3] the efficacy and safety of pentamidine in this infection has been questioned.[4]

4. Teutsch SM, Juranek DD. Babesiosis. *Ann Intern Med* 1981; **95:** 241.

Leishmaniasis. Pentamidine has been used in the treatment of visceral leishmaniasis (p.824) both alone and with antimonials in patients who have failed to respond to antimonials alone.[1,2] It has also been tried for long-term secondary prophylaxis in patients with HIV infection.[3] Cutaneous leishmaniasis due to *L. guyanensis* is usually treated with pentamidine to reduce the risk of dissemination;[1] beneficial results in patients infected with *L. infantum*, *L. major*, or *L. tropica* have also been reported.[4] Lesions due to *L. aethiopica* may also respond to pentamidine, but can be left to heal spontaneously since the risk of diffuse cutaneous involvement is small.[1] Diffuse cutaneous or mucocutaneous disease which is unresponsive to antimonials may respond to pentamidine.[1]

For mention of the use of pentamidine with paromomycin to treat visceral leishmaniasis in an HIV-infected patient, see p.844.

Pneumocystis pneumonia. In the treatment of pneumocystis pneumonia (p.521) intravenous pentamidine is generally reserved for patients with moderate to severe disease who do not respond to, or cannot tolerate, co-trimoxazole. Co-trimoxazole with pentamidine is no more effective than pentamidine alone in these patients and is potentially more toxic than either drug.[1] Inhaled pentamidine has occasionally been suggested for mild to moderate infection, but is now generally only used for prophylaxis. However, patients given inhaled pentamidine may be prone to extrapulmonary *Pneumocystis* infections.[2,3]

In both primary and secondary prophylaxis of pneumocystis pneumonia in immunocompromised patients, co-trimoxazole is preferred to inhaled pentamidine. Comparative studies have shown that, in the short term, inhaled pentamidine has been less effective than co-trimoxazole[4,5] and no more effective than another common prophylactic drug, dapsone.[6,7] In addition, both co-trimoxazole and dapsone (given with pyrimethamine) also provide protection against toxoplasmosis and extrapulmonary pneumocystis infections. However, inhaled pentamidine is better tolerated than either of these, and studies have suggested that in the long term the efficacy of the three drugs is comparable,[8,9] at least in patients with CD4+ T lymphocyte counts of more than 100 cells/microlitre. Increasing the dose of pentamidine from 300 mg every four weeks to 300 mg every two weeks[10,11] or 600 mg every week[12] may improve efficacy further. Intermittent parenteral dosage of pentamidine has been used when the more usual drugs cannot be given.[13]

African trypanosomiasis. Pentamidine is used for the haemolymphatic phase of African trypanosomiasis caused by *Trypanosoma brucei gambiense* (p.827), and as an adjunct to other treatment for the meningoencephalitic stage of the infection.[1] It is reported to be less effective against *T. b. rhodesiense* and in some areas resistance of *T. b. gambiense* to pentamidine is increasing. Pentamidine has been used with suramin for *T. b. gambiense* infections but this has not been shown to be clinically superior to pentamidine alone.[2]

Preparations

BP 2008: Pentamidine Injection.

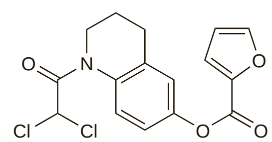
Proprietary Preparations (details are given in Part 3)
Austria: Pentacarinat; ***Belg.:*** Pentacarinat; ***Braz.:*** Pentacarinat; Sideron†; ***Canad.:*** Pentacarinat†; ***Denm.:*** Pentacarinat; ***Fin.:*** Pentacarinat†; ***Fr.:*** Pentacarinat; ***Ger.:*** Pentacarinat; ***Gr.:*** Pentacarinate; Pentam; ***Irl.:*** Pentacarinat; ***Israel:*** Pentacarinat†; ***Ital.:*** Pentacarinat; ***Neth.:*** Pentacarinat; ***NZ:*** Pentacarinat; ***Port.:*** Pentacarinat†; Pentamina; ***Spain:*** Pentacarinat; ***Swed.:*** Pentacarinat; ***Switz.:*** Pentacarinat; ***Thai.:*** Pentacarinat; ***UK:*** Pentacarinat; ***USA:*** NebuPent; Pentacarinat; Pentam.

Quinfamide *(USAN, rINN)*

Quinfamida; Quinfamidum; Win-40014. 1-(Dichloroacetyl)-1,2,3,4-tetrahydroquinolin-6-ol 2-furoic acid ester.

Хинфамид

$C_{16}H_{13}Cl_2NO_4$ = 354.2.
CAS — 62265-68-3.



Profile

Quinfamide is a luminal amoebicide. It is given orally for intestinal amoebiasis in a dose of 300 mg, either as a single dose or as three divided doses over 24 hours.

Preparations

Proprietary Preparations (details are given in Part 3)
Mex.: Amefin; Amefur; Amenox; Amofur; Bisidim; Celemin; Doffler; Falacid; Luminovag; Protosin; Quocel; Serphamida.

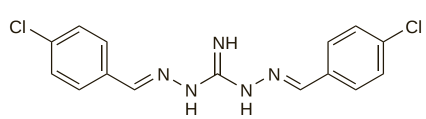
Multi-ingredient: *Mex.:* Amibriz†; Amoebriz; Oxal; Vermox-Plus.

Robenidine Hydrochloride *(BANM, USAN, rINNM)*

CL-78116; Hidrocloruro de robenidina; Robénidine, Chlorhydrate de; Robenidini Hydrochloridum; Robenzidene Hydrochloride. 1,3-Bis(4-chlorobenzylideneamino)guanidine hydrochloride.

Робенидина Гидрохлорид

$C_{15}H_{13}Cl_2N_5,HCl$ = 370.7.
CAS — 25875-51-8 (robenidine); 25875-50-7 (robenidine hydrochloride).



(robenidine)

Profile

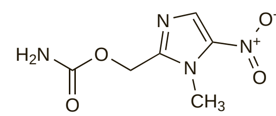
Robenidine is an antiprotozoal used as the hydrochloride in veterinary practice for the prevention of coccidiosis in poultry and rabbits.

Ronidazole *(BAN, USAN, pINN)*

Ronidazol; Ronidazolum. (1-Methyl-5-nitroimidazol-2-yl)methyl carbamate.

Ронидазол

$C_6H_8N_4O_4$ = 200.2.
CAS — 7681-76-7.
ATC Vet — QP51AA08.



Pharmacopoeias. In *BP(Vet)*.

BP(Vet) 2008 (Ronidazole). A white to yellowish-brown, odourless or almost odourless powder. Slightly soluble in water, in alcohol, and in chloroform; very slightly soluble in ether. Protect from light.

Profile

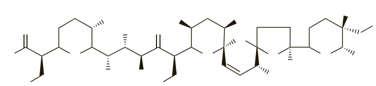
Ronidazole is a 5-nitroimidazole antiprotozoal that is used in veterinary practice for the control of trichomoniasis in cage birds and pigeons. It has also been added to turkey feeding stuffs and has been used for the control of swine dysentery.

Salinomycin Sodium *(BANM, rINNM)*

AHR-3096 (salinomycin); K-364 (salinomycin); K-748364A (salinomycin); Natrii Salinomycinum; Salinomicina sódica; Salinomycine Sodique. Sodium (2*R*)-2-{(2*R*,5*S*,6*R*)-6-[(1*S*,2*S*,3*S*,5*R*)-5-{(2*S*,5*S*,7*R*,9*S*,10*S*,12*R*,15*R*)-2-[(2*R*,5*R*,6*S*)-5-ethyltetrahydro-5-hydroxy-6-methylpyran-2-yl]-15-hydroxy-2,10,12-trimethyl-1,6,8-trioxadispiro[4.1.5.3]pentadec-13-en-9-yl}-2-hydroxy-1,3-dimethyl-4-oxoheptyl]tetrahydro-5-methylpyran-2-yl}butyrate.

Натрий Салиномицин

$C_{42}H_{69}NaO_{11}$ = 773.0.
CAS — 53003-10-4 (salinomycin); 55721-31-8 (salinomycin sodium).



(salinomycin)

Profile

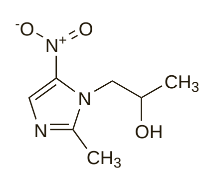
Salinomycin, an antibiotic produced by *Streptomyces albus*, is an antiprotozoal used as the sodium salt in veterinary practice for the prevention of coccidiosis in poultry and as a growth promotor in pigs.

Secnidazole *(BAN, rINN)*

PM-185184; 14539-RP; RP-14539; Secnidazol; Secnidazolum; Seknidazol. 1-(2-Methyl-5-nitroimidazol-1-yl)propan-2-ol.

Секнидазол

$C_7H_{11}N_3O_3$ = 185.2.
CAS — 3366-95-8.
ATC — P01AB07.



Profile

Secnidazole is a 5-nitroimidazole derivative with properties similar to those of metronidazole (p.837), apart from a much longer plasma half-life of 20 hours or more. It is used in the treatment of amoebiasis, giardiasis, and trichomoniasis.

Secnidazole is given orally, usually as a single dose of 2 g in adults or 30 mg/kg in children. In invasive (hepatic) amoebiasis a dose of 1.5 g daily is given in single or divided doses for 5 days; children may be given 30 mg/kg daily.

Semduramicin *(BAN, USAN, rINN)*

Semduramicina; Semduramicine; Semduramicinum; UK-61689; UK-61689-2 (semduramicin sodium). (2*R*,3*S*,4*S*,5*R*,6*S*)-Tetrahydro-2,4-dihydroxy-6-{(*R*)-1-[(2*S*,5*R*,7*S*,8*R*,9*S*)-9-hydroxy-2,8-dimethyl-2-{(2*S*,2′*R*,3′*S*,5′*R*)-octahydro-2-methyl-5′-[(2*S*,3*S*,5*R*,6*S*)-tetrahydro-6-hydroxy-3,5,6-trimethyl-2*H*-pyran-2-yl]-3′-[(2*S*,5*S*,6*R*)-tetrahydro-5-methoxy-6-methyl-2*H*-pyran-2-yloxy]-2,2′-bifuran-5-yl}-1,6-dioxaspiro[4.5]dec-7-yl]ethyl}-5-methoxy-3-methyl-2*H*-pyran-2-ylacetic acid.

Семдурамицин

$C_{45}H_{76}O_{16}$ = 873.1.

CAS — 113378-31-7 (semduramicin); 119068-77-8 (semduramicin sodium).

Profile

Semduramicin is an antiprotozoal used in veterinary practice for the prevention of coccidiosis in poultry. It is also used as the sodium salt.

Suramin Sodium *(rINN)*

Antrypol; Bayer-205; CI-1003; Fourneau-309; Naganinum; Naganol; Suramin Hexasodium *(USAN)*; Suramina sódica; Suramine Sodique; Suraminum Natricum. The symmetrical 3″-urea of the sodium salt of 8-(3-benzamido-4-methylbenzamido)naphthalene-1,3,5-trisulphonic acid; Hexasodium 8,8′-{carbonylbis[imino-3,1-phenylenecarbonylimino(4-methyl-3,1-phenylene)carbonylimino]}bis(1,3,5-naphthalenetrisulfonate).

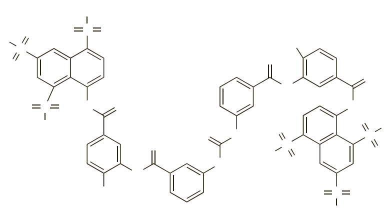
Сурамин Натрий

$C_{51}H_{34}N_6Na_6O_{23}S_6$ = 1429.2.

CAS — 145-63-1 (suramin); 129-46-4 (suramin sodium).

ATC — P01CX02.

ATC Vet — QP51AE02.



(suramin)

Pharmacopoeias. In *Fr., Int.,* and *It.*

Adverse Effects

An immediate and potentially fatal reaction, with nausea, vomiting, shock, seizures, and loss of consciousness, may follow the injection of suramin sodium in some patients and thus it is usual practice to give a small test dose before starting treatment.

Abdominal pain, mouth ulceration, and skin reactions such as urticaria and pruritus may occur. The risk of hypersensitivity reactions is reported to be greater when onchocerciasis is present.

Other adverse effects include paraesthesia, hyperaesthesia of the palms and soles, skin eruptions, blood dyscrasias, fever, polyuria, increased thirst, raised liver enzyme values, fatigue, and effects on the eye including photophobia and lachrymation. Proteinuria is common; haematuria and casts in the urine may also occur. There have been occasional reports of adrenal insufficiency.

Effects on the blood. Thrombocytopenia has been reported in patients receiving suramin, generally during treatment for AIDS or cancer.[1-4] An immune-mediated mechanism has been proposed[3] although there is evidence that multiple mechanisms may be involved.[4] Other adverse effects on the blood include neutropenia,[1,5] anaemia,[1] deterioration of pre-existing lymphocytopenia,[5] and fatal myelosuppression.[5] Agranulocytosis and haemolytic anaemia have occurred rarely.

4. Tisdale JF, *et al.* Severe thrombocytopenia in patients treated with suramin: evidence for an immune mechanism in one. *Am J Hematol* 1996; **51:** 152–7.
5. Rosen PJ, *et al.* Suramin in hormone-refractory metastatic prostate cancer: a drug with limited efficacy. *J Clin Oncol* 1996; **14:** 1626–36.

Effects on the eyes. Late effects on the eyes associated with suramin include photophobia, lachrymation, and palpebral oedema. Keratopathy characterised by corneal deposits has been reported in patients receiving suramin. In a study of 114 patients receiving suramin for prostatic cancer, 13 developed corneal deposits similar to those reported with chloroquine therapy after 34 to 98 days of therapy.[1] Symptoms in 10 of the 13 included lachrymation and foreign body sensation. The remaining 3 patients were asymptomatic. Shifts in refractive error were also found. Keratopathy has also been reported in patients with AIDS receiving suramin.[2] In patients treated with suramin for ocular onchocerciasis, the incidence of optic atrophy was higher after 3 years than in untreated patients.[3] A prolonged inflammatory response to dying microfilariae in the optic nerve might be responsible, although a direct toxic or allergic effect could not be ruled out.

1. Hemady RK, *et al.* Ocular symptoms and signs associated with suramin sodium treatment for metastatic cancer of the prostate. *Am J Ophthalmol* 1996; **121:** 291–6.
2. Teich SA, *et al.* Toxic keratopathy associated with suramin therapy. *N Engl J Med* 1986; **314:** 1455–6.
3. Thylefors B, Rolland A. The risk of optic atrophy following suramin treatment of ocular onchocerciasis. *Bull WHO* 1979; **57:** 479–80.

Effects on the kidneys. In addition to the proteinuria commonly seen during suramin therapy, there have been reports of individual cases of renal glycosuria[1] and of acute renal dysfunction.[2]

1. Awadzi K, *et al.* The chemotherapy of onchocerciasis XVIII: aspects of treatment with suramin. *Trop Med Parasitol* 1995; **46:** 19–26.
2. Figg WD, *et al.* Acute renal toxicity associated with suramin in the treatment of prostate cancer. *Cancer* 1994; **74:** 1612–14.

Effects on the nervous system. Neurological disorders reported in patients receiving suramin include paraesthesia and polyneuropathy. Severe polyneuropathy with generalised flaccid paralysis has generally been associated with serum-suramin concentrations greater than 350 micrograms/mL,[1,2] but motor neuropathy was reported in 8 patients with serum concentrations of 275 micrograms/mL.[3]

1. La Rocca RV, *et al.* Suramin-induced polyneuropathy. *Neurology* 1990; **40:** 954–60.

4. Falkson G, Rapoport BL. Lethal toxic epidermal necrolysis during suramin treatment. *Eur J Cancer* 1992; **28A:** 1294.

Precautions

Suramin sodium should be used under close supervision, and the general condition of patients improved as far as possible before treatment starts. Patients who have a severe reaction to the first dose should never receive suramin again. It should not be used in elderly or infirm patients or in the presence of severe hepatic or renal disease. The urine should be tested before treatment starts and weekly during treatment; dosage should be reduced if moderate proteinuria develops and stopped if it becomes severe or if casts appear in the urine.

Pregnancy. Suramin has been reported to be teratogenic in *mice* but not in *rats*.[1] WHO[2] recommends that when necessary suramin should be used in pregnant women with *T. b. rhodesiense* trypanosomiasis, even those with meningoencephalitic disease, because melarsoprol is contra-indicated; in onchocerciasis, suramin treatment should be delayed until after delivery.

2. WHO. *WHO model formulary.* Geneva: WHO, 2004.

Pharmacokinetics

After intravenous injection, suramin becomes bound to plasma proteins and plasma concentrations over 100 micrograms/mL are maintained for several weeks. Unbound suramin is excreted in the urine. Penetration of suramin into the CSF appears to be poor.

◊ The clinical pharmacokinetics of suramin were studied in 4 patients with AIDS given 6.2 g intravenously over 5 weeks.[1] Suramin accumulated during treatment and plasma concentrations exceeded 100 micrograms/mL for several weeks. After the last dose the terminal half-life of suramin ranged from 44 to 54 days. At least 99.7% was bound to plasma proteins. Renal clearance accounted for most of the elimination of suramin from the body. There appeared to be little or no metabolism of suramin.

In another study,[2] ten male patients with onchocerciasis received weekly infusions of suramin for 6 weeks, according to the dose regimen recommended by WHO (see below). In these patients the median elimination half-life was about 92 days, and in each case, the maximum plasma concentration remained below 300 micrograms/mL.

2. Chijioke CP, *et al.* Clinical pharmacokinetics of suramin in patients with onchocerciasis. *Eur J Clin Pharmacol* 1998; **54:** 249–51.

Uses and Administration

Suramin is a trypanocide used in the treatment of African trypanosomiasis and as an anthelmintic in the treatment of onchocerciasis.

Suramin is given as suramin sodium by slow intravenous injection, usually as a 10% solution. Because of the danger of severe reactions it is advisable to give a test dose before starting treatment.

In African trypanosomiasis suramin is used mainly for the early (haematolymphatic) stages of *Trypanosoma brucei rhodesiense* infection; pentamidine may be preferred for early-stage treatment of *T. b. gambiense* infection. Suramin is not used as sole therapy for late-stage infections with CNS involvement. Early-stage trypanosomiasis may be treated with a dose of 5 mg/kg of suramin on day 1, 10 mg/kg on day 3, then 20 mg/kg on days 5, 11, 17, 23, and 30. Another schedule consists of 5 doses of 1 g given over 3 weeks after a test dose of 100 to 200 mg. In late-stage trypanosomiasis injections of suramin are often given before starting treatment with melarsoprol; 5 and 10 mg/kg are given on days 1 and 3 respectively, and in some regimens 20 mg/kg is also given on day 5.

For doses used in onchocerciasis see below.

Malignant neoplasms. Suramin is reported to have antineoplastic activity and has been studied in a number of malignant neoplasms, in particular hormone-resistant prostatic cancer (p.671). However, its clinical usefulness is hindered by dose-limiting toxicity and problems in developing a simple dose schedule. It has also been investigated as a chemosensitiser.

Onchocerciasis. Although suramin is the only drug in clinical use for onchocerciasis that is effective against adult worms, its use is restricted because of the frequency of associated compli-

The symbol † denotes a preparation no longer actively marketed

cations and its intrinsic toxicity. Treatment of onchocerciasis (p.137) is currently based on continuous suppression of microfilariae by regular use of ivermectin. WHO[1] advises that suramin should only be considered for the curative treatment of individuals in areas without transmission of onchocerciasis and of individuals leaving an endemic area, and for severe hyperreactive onchodermatitis where symptoms are not adequately controlled with ivermectin. WHO[2] also recommends that it should not be used to treat onchocerciasis in the elderly or infirm, in patients with severe liver or renal disease, in totally blind patients (unless they require relief from intensely itchy lesions), or in pregnant women (who should be treated after delivery).

A total dose of 66.7 mg/kg in six incremental weekly doses is recommended.[1,2] The first (test) dose of suramin sodium 3.3 mg/kg should be given very cautiously by slow intravenous injection; this is followed at weekly intervals by incremental doses of 6.7 mg/kg, 10.0 mg/kg, 13.3 mg/kg, 16.7 mg/kg and 16.7 mg/kg.[2]

African trypanosomiasis. Suramin is used in the treatment of the early haematolymphatic phase of African trypanosomiasis (p.827) caused by *Trypanosoma brucei rhodesiense* and for *T. b. gambiense* infections which are resistant to pentamidine.[1] In some regions, suramin is used with pentamidine for *T. b. gambiense* infections but it has not been shown to be clinically superior to pentamidine alone.[2] Although suramin does not reach sufficient concentrations in the CSF to produce a cure in the meningoencephalitic phase, it is used to reduce the number of trypanosomes in the blood and lymph before treatment with melarsoprol.[1] Case reports have suggested that suramin with metronidazole[3] or eflornithine[4] could be useful in *T. b. rhodesiense* infections, although response to suramin plus eflornithine was disappointing in a study involving 6 patients.[5]

Preparations

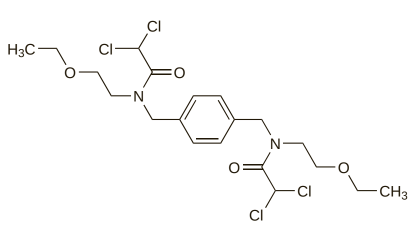
Proprietary Preparations (details are given in Part 3)
Ger.: Germanin.

Teclozan *(USAN, rINN)*

NSC-107433; Téclozan; Teclozán; Teclozanum; Win-13146. *NN'*-*p*-Phenylenedimethylenebis[2,2-dichloro-*N*-(2-ethoxyethyl)-acetamide].

Теклозан

$C_{20}H_{28}Cl_4N_2O_4$ = 502.3.
CAS — 5560-78-1.
ATC — P01AC04.



Profile

Teclozan, a dichloroacetamide derivative, is a luminal amoebicide with actions and uses similar to those of diloxanide furoate (p.832). It has been given orally in the treatment of intestinal amoebiasis.

Preparations

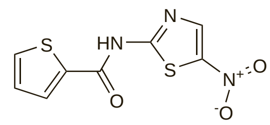
Proprietary Preparations (details are given in Part 3)
Braz.: Falmonox; ***Venez.:*** Falmonox.

Tenonitrozole *(rINN)*

TC-109; Tenonitrozol; Ténonitrozole; Tenonitrozolum; Thenitrazole. *N*-(5-Nitrothiazol-2-yl)thiophene-2-carboxamide.

Тенонитрозол

$C_8H_5N_3O_3S_2$ = 255.3.
CAS — 3810-35-3.
ATC — P01AX08.



Profile

Tenonitrozole is an antiprotozoal given in the treatment of trichomoniasis (p.827). It is given orally in a dose of 250 mg twice daily with meals, for 4 days.

Preparations

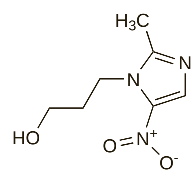
Proprietary Preparations (details are given in Part 3)
Fr.: Atrican; ***Rus.:*** Atrican (Атрикан); ***Venez.:*** Detrican†.

Ternidazole *(rINN)*

Ternidazol; Ternidazolum. 2-Methyl-5-nitroimidazole-1-propanol.

Тернидазол

$C_7H_{11}N_3O_3$ = 185.2.
CAS — 1077-93-6.



Profile

Ternidazole is a 5-nitroimidazole antiprotozoal with properties similar to those of metronidazole (p.837). It has been an ingredient of preparations used for the treatment of vaginitis.

Preparations

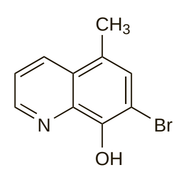
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Rus.:*** Tergynan (Тержинан).

Tilbroquinol *(pINN)*

Tilbroquinolum. 7-Bromo-5-methylquinolin-8-ol.

Тильброхинол

$C_{10}H_8BrNO$ = 238.1.
CAS — 7175-09-9.
ATC — P01AA05.



Profile

Tilbroquinol is a halogenated hydroxyquinoline antiprotozoal with properties similar to those of diiodohydroxyquinoline (p.832). It has been used with tiliquinol (below) in the treatment of intestinal infections including amoebiasis but less toxic drugs are preferred.

Adverse effects. A report of neurotoxicity, considered to be subacute myelo-opticoneuropathy, in a patient who had taken tilbroquinol with tiliquinol for 4 years.[1] Hepatotoxicity has also been reported[2] with this combination.

1. Soffer M, *et al*. Oxyquinoline toxicity. *Lancet* 1983; **i:** 709.

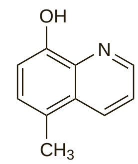
Multi-ingredient: ***Fr.:*** Intetrix; ***Rus.:*** Intetrix (Интетрикс).

Tiliquinol *(rINN)*

Tiliquinolum. 5-Methylquinolin-8-ol.

Тилихинол

$C_{10}H_9NO$ = 159.2.
CAS — 5541-67-3.



Profile

Tiliquinol has been used with tilbroquinol (above) in the treatment of intestinal infections including amoebiasis but less toxic drugs are preferred.

Preparations

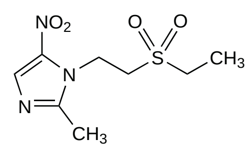
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Fr.:*** Intetrix; ***Rus.:*** Intetrix (Интетрикс).

Tinidazole *(BAN, USAN, rINN)*

CP-12574; Tinidatsoli; Tinidazol; Tinidazolas; Tinidazolum; Tynidazol. 1-[2-(Ethylsulphonyl)ethyl]-2-methyl-5-nitroimidazole.

Тинидазол

$C_8H_{13}N_3O_4S$ = 247.3.
CAS — 19387-91-8.
ATC — J01XD02; P01AB02.
ATC Vet — QJ01XD02; QP51AA02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Tinidazole). An almost white or pale yellow, crystalline powder. Practically insoluble in water; soluble in acetone and in dichloromethane; sparingly soluble in methyl alcohol. Protect from light.
USP 31 (Tinidazole). An almost white or pale yellow crystalline powder. Practically insoluble in water; soluble in acetone and in dichloromethane; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Metronidazole, p.837.

Breast feeding. The American Academy of Pediatrics[1] considers that the use of tinidazole by mothers during breast feeding may be of concern, since it is mutagenic *in vitro*. After single-dose therapy, breast feeding may be stopped for 12 to 24 hours to allow excretion of the dose.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 03/06/04)

Porphyria. Tinidazole is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Shock. An acute severe toxic reaction, considered not to be allergic, occurred in a healthy subject shortly after the intravenous infusion of tinidazole 1.6 g over 80 minutes.[1] He fainted for about 10 seconds and low blood pressure, nausea, and tiredness persisted for several hours. Spasms in the left arm were also experienced but no generalised convulsions. Anaphylactic shock has also been reported,[2] with severe bronchospasm and subsequent development of Stevens-Johnson syndrome, in a patient who had reactions of increasing severity after 3 separate exposures to tinidazole.

1. Aase S, *et al.* Severe toxic reaction to tinidazole. *Eur J Clin Pharmacol* 1983; **24:** 425–7.
2. Singbal SS, Rataboli PV. Anaphylaxis and hypersensitivity syndrome reactions in increasing severity following repeated exposure to tinidazole. *J Postgrad Med* 2005; **51:** 243–4.

Interactions

Tinidazole may, like metronidazole (p.838), produce a disulfiram-like reaction with alcohol.

Pharmacokinetics

The pharmacokinetics of tinidazole resemble those of metronidazole although the half-life is longer.

Tinidazole is rapidly and almost completely absorbed after oral doses and, typically, a peak plasma concentration of about 40 micrograms/mL is achieved 2 hours after a single 2-g dose, falling to about 10 micrograms/mL at 24 hours and 2.5 micrograms/mL at 48 hours; concentrations above 8 micrograms/mL are maintained by daily maintenance doses of 1 g. Comparable concentrations are achieved with equivalent intravenous doses. The plasma elimination half-life of tinidazole is 12 to 14 hours.

Tinidazole is widely distributed and concentrations similar to those in plasma have been achieved in bile, breast milk, CSF, saliva, and a variety of body tissues; it crosses the placenta readily. Only 12% is reported to be bound to plasma proteins. An active hydroxy metabolite has been identified.

Unchanged drug and metabolites are excreted in the urine and, to a lesser extent, in the faeces.

Renal impairment. Single-dose studies indicate that the pharmacokinetics of tinidazole in patients with chronic renal failure are not significantly different from those in healthy subjects and that no modification of tinidazole dosage is necessary. However, tinidazole is rapidly removed by haemodialysis.[1,2]

1. Flouvat BL, *et al.* Pharmacokinetics of tinidazole in chronic renal failure and in patients on haemodialysis. *Br J Clin Pharmacol* 1983; **15:** 735–41.
2. Robson RA, *et al.* Tinidazole pharmacokinetics in severe renal failure. *Clin Pharmacokinet* 1984; **9:** 88–94.

Uses and Administration

Tinidazole is a 5-nitroimidazole derivative. It has the antimicrobial actions of metronidazole and is used similarly (see p.839) in the treatment of susceptible protozoal infections and in the treatment and prophylaxis of anaerobic bacterial infections. It has also been used in regimens for the eradication of *Helicobacter pylori* in peptic ulcer disease.

Tinidazole is usually given as a single daily oral dose with or after food; it is also given by intravenous infusion and as vaginal pessaries.

In invasive **amoebiasis**, tinidazole is usually given with a luminal amoebicide. In intestinal amoebiasis, a single daily dose of 2 g is given orally for 2 or 3 days; in hepatic amoebiasis, 1.5 to 2 g as a single daily dose may be given for 3 days or occasionally up to 6 days. Children are given 50 to 60 mg/kg daily for 3 or 5 days respectively.

A single dose of tinidazole 2 g is given orally in the treatment of **giardiasis**, **trichomoniasis**, and acute necrotising **ulcerative gingivitis**; 50 to 75 mg/kg as a single dose is given to children with giardiasis or trichomoniasis. It may sometimes be necessary to repeat this dose once. In trichomoniasis, sexual partners should also be treated.

In **bacterial vaginosis**, a single 2-g dose of tinidazole is usually given orally, although higher cure rates have been achieved with a 2-g dose on 2 successive days or 1 g daily for 5 days.

For the treatment of most **anaerobic bacterial infections**, tinidazole is given orally, usually for 5 or 6 days, in an initial dose of 2 g followed on subsequent days by 1 g daily or 500 mg twice daily. If oral therapy is not possible, tinidazole may be given intravenously, 800 mg being infused as 400 mL of a 2 mg/mL solution at a rate of 10 mL/minute; this initial dose is followed by 800 mg daily or 400 mg twice daily until oral therapy can be substituted. For the *prevention* of postoperative anaerobic bacterial infections, 2 g is given by mouth about 12 hours before surgery. Alternatively 1.6 g is given as a single intravenous infusion before surgery.

In regimens for the treatment of **peptic ulcer disease**, tinidazole 500 mg twice daily has been given with clarithromycin and omeprazole for 7 days.

◊ Reviews.

1. Manes G, Balzano A. Tinidazole: from protozoa to Helicobacter pylori—the past, present and future of a nitroimidazole with peculiarities. *Expert Rev Anti Infect Ther* 2004; **2:** 695–705.
2. Fung HB, Doan TL. Tinidazole: a nitroimidazole antiprotozoal agent. *Clin Ther* 2005; **27:** 1859–84.
3. Nailor MD, Sobel JD. Tinidazole for bacterial vaginosis. *Expert Rev Anti Infect Ther* 2007; **5:** 343–8.

Administration in renal impairment. The elimination of tinidazole is largely unchanged in patients with impaired renal function (see under Pharmacokinetics, above) and dosage adjustment is not generally considered necessary. However tinidazole is removed by haemodialysis, and patients may need additional doses to compensate.

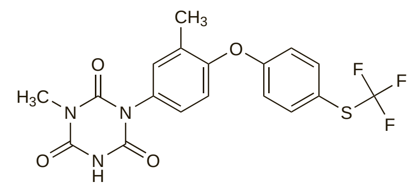
Toltrazuril (BAN, USAN, rINN)

Bay-Vi-9142; Toltrazurilo; Toltrazurilum. 1-Methyl-3-(4-{*p*-[(trifluoromethyl)thio]phenoxy}-*m*-tolyl)-*s*-triazine-2,4,6(1*H*,3*H*,5*H*)-trione.

Тольтразурил

$C_{18}H_{14}F_3N_3O_4S$ = 425.4.
CAS — 69004-03-1.
ATC Vet — QP51AJ01.



Profile

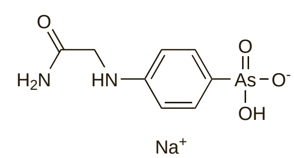
Toltrazuril is an antiprotozoal used in veterinary practice for the treatment of coccidiosis in poultry and piglets, and for the treatment of isosporiasis in piglets.

Tryparsamide (rINN)

Glyphenarsine; Triparsamida; Tryparsam.; Tryparsamidum; Tryparsone. Sodium hydrogen 4-(carbamoylmethylamino)-phenylarsonate hemihydrate.

Трипарсамид

$C_8H_{10}AsN_2NaO_4,\frac{1}{2}H_2O$ = 305.1.
CAS — 554-72-3 (anhydrous tryparsamide); 6159-29-1 (tryparsamide hemihydrate).



(anhydrous tryparsamide)

Profile

Tryparsamide, a pentavalent arsenical compound, is a trypanocide which penetrates into the CSF and has been used with suramin in the treatment of late-stage African trypanosomiasis due to *Trypanosoma brucei gambiense*, as an alternative to melarsoprol or eflornithine (see p.827). However, because of its toxicity, especially the risk of blindness resulting from damage to the optic nerve, melarsoprol or eflornithine are preferred.

For the adverse effects of arsenic and their treatment, see Arsenic Trioxide, p.2260. Like melarsoprol, tryparsamide can cause encephalopathy.

The drugs described in this chapter are used in the treatment of viral infections; they may also be used to provide protection, usually for a brief period only, against infection. Drug treatment has to be started early in the infection to be effective and inhibit the replicating virus. There is little evidence that antiviral drugs affect latent or nonreplicating viruses. They do not provide an alternative to available immunisation for the long-term prophylaxis of viral infection—for details of such treatment see the chapter on Vaccines Immunoglobulins and Antisera, p.2201.

Choice of Antiviral

Antiviral drugs are effective for the treatment and prophylaxis of a range of viral infections as described below. Non-specific symptomatic and supportive treatments are also important in the management of viral infections. Those viral infections not amenable to antiviral drug therapy include mumps, poliomyelitis, rabies, and rubella.

Common cold

The common cold is a term used for viral upper respiratory tract illness. Rhinoviruses are the commonest cause in all age groups. Adenoviruses, coronaviruses, enteroviruses, and metapneumovirus may also be responsible. Infecting organisms in these groups may be of many different serotypes.

Colds are usually self-limiting and last for 4 to 10 days. Symptoms include nasal discharge and stuffiness, sneezing, sore throat, and cough (see also p.1547); there is little or no malaise, headache, or fever. Colds may predispose to concurrent or subsequent bacterial infection of the upper respiratory tract; exacerbation of asthma or chronic obstructive pulmonary disease may also occur. Acute otitis media or acute sinusitis may result from obstruction of the Eustachian tube and mucosal swelling.

The successful development of a single cure or vaccine is unlikely, given the variety of causative viruses and large number of serotypes. Treatment is symptomatic. Analgesics, cough suppressants, antihistamines, and decongestants relieve symptoms but do not tend to reduce the duration of illness. Antibacterial and antiviral therapy has consistently failed to show any benefit and antibacterials are indicated only if there is secondary bacterial infection.[1] Very large doses of vitamin C have been widely used to prevent and treat colds but a systematic review[2] has concluded that, despite some evidence of benefit in published studies, its failure to reduce the incidence of colds in the normal population indicated that routine high-dose prophylaxis was not justified for community use; it might, however, be of use in persons exposed to brief periods of severe physical exercise or to cold environments. For treatment, no benefit has been found for doses up to 4 g, although one study reported equivocal benefit from a dose of 8 g given at the onset of symptoms.[2] Other drugs[3] tried have included mast-cell stabilisers, interferon alfa-2b, and zinc lozenges. Intranasal interferons have shown some benefit in prophylactic use, but high incidences of unacceptable nasal adverse effects have resulted in interferons failing to fulfill their early promise. Results of studies of zinc treatment have been inconclusive, although 1 study reported benefit from zinc nasal gel.[4] Similarly, there is little consistent evidence to support the use of *Echinacea* for treatment or prevention of colds.[5,6] However, available *Echinacea* products differ greatly and there is some evidence that treatment with those based on the aerial parts of *E. purpurea* might be effective in adults if started early.[5] Pleconaril, a viral capsid binder, has also been studied but there have been concerns with the oral formulation over viral resistance and interactions with oral contraceptives; the intranasal formulation appears more promising.[7]

Encephalitis

Encephalitis refers to an acute inflammatory process affecting the brain parenchyma; it is distinct from meningitis which is an inflammation of the meninges. Meningoencephalitis involves both the brain parenchyma and meninges. Viral infection is the commonest cause of encephalitis,[1-4] with the herpes simplex virus (p.854) being the commonest organism involved in immunocompetent individuals. Other viruses that may cause encephalitis include enteroviruses (e.g. poliovirus), Epstein-Barr, influenza, Lassa fever, measles and mumps (paramyxoviruses), rabies, rubella, and varicella zoster. CMV and HIV cause encephalitis almost exclusively in immunocompromised individuals. In the 1990s, Hendra virus and Nipah virus, which belong to the paramyxoviridae family, were newly discovered causes of encephalitis. The reservoir for these viruses is *bats*, but transmission to humans can occur via close contact with secondary hosts such as *horses* and *pigs*. A group of viruses known as the arthropod-borne encephalitis viruses (arboviruses) may cause infections in which encephalitis is a major clinical feature. They include:

- bunyaviruses including California encephalitis virus and La Crosse virus (both transmitted by mosquitoes)
- flaviviruses (previously arbovirus Group B) including Japanese encephalitis virus, St Louis encephalitis virus, Murray Valley encephalitis virus, Rocio virus, and West Nile virus (all transmitted by mosquitoes) and the tick-borne viruses of this group, louping ill virus, Powassan virus, and the Eastern and Western subtype viruses
- reoviruses including Colorado tick fever virus (transmitted by ticks)
- togaviruses including Eastern, Western, and Venezuelan equine viruses (transmitted by mosquitoes)

In endemic regions viral encephalitis should be suspected in patients presenting with fever, headache, neck rigidity, altered level of consciousness (which may range from drowsiness to coma), and signs of diffuse cerebral dysfunction (hallucinations, psychosis, personality changes, and agitation). Seizures are common and patients who recover from encephalitis may be left with permanent neurological damage.

Since herpes simplex virus is the commonest cause of viral encephalitis, it is recommended that patients with encephalitis be given intravenous aciclovir empirically until the causative virus has been identified. (Antibacterial treatment for meningitis may also be given empirically until the cause of symptoms has been established.) No specific treatment exists for non-herpetic encephalitis (although investigational treatments, including passive immunisation and the use of inhibitory RNA molecules, are under development[5]), and patients must be managed with vigorous supportive care. Corticosteroids are advocated in some circumstances,[4] but their use is controversial. Pleconaril is under investigation for use in enteroviral encephalitis. Control of mosquito and tick populations in endemic areas and minimising contact with these vectors are important means of preventing infections. Japanese encephalitis vaccine and tick-borne encephalitis vaccine are available for active immunisation of individuals at risk of infection and tick-borne encephalitis immunoglobulins are available in some countries for passive immunisation against infection.

Gastro-enteritis

Gastro-enteritis (inflammation of the stomach and intestines) may be caused by viruses, bacteria, or protozoa.[1-3] Viral gastro-enteritis is an important cause of diarrhoea, especially in children and immunocompromised patients. Viruses causing diarrhoea and other gastrointestinal symptoms include adenovirus, astrovirus, calicivirus (such as norovirus and sapovirus), and rotavirus. Rotavirus infection is recognised as a prominent cause of endemic acute diarrhoea in infants and young children and may occasionally cause acute or chronic diarrhoea in AIDS patients. Infection may be subclinical, although symptomatic rotavirus infection usually presents with fever and vomiting for 2 to 3 days, followed by watery diarrhoea that lasts for 4 to 5 days. Other symptoms include abdominal cramps and headache. Noroviruses (such as the Norwalk virus) are a more common cause of viral gastro-enteritis in older children and adults, but do not appear to cause severe disease in infants. They have been the cause of waterborne outbreaks of gastro-enteritis in nursing homes, military bases, and cruise ships. Sapoviruses (such as the Sapporo virus) are more commonly seen in young children. While illness resulting from these viruses is usually mild and lasts for 24 to 72 hours, the presenting symptoms are usually nausea and abdominal cramps. Other symptoms include diarrhoea, vomiting, headache, myalgias, and low-grade fever. CMV is an important cause of diarrhoea in AIDS (see HIV-associated Wasting, below).

In acute diarrhoea of any cause it is most important to maintain hydration by preventing and replacing fluid and electrolyte loss, especially in infants and the elderly (see p.1694). For further discussion see Oral Rehydration Solutions, p.1672. Antivirals are not used in the management of viral diarrhoeas, except for that caused by CMV, where ganciclovir, valganciclovir, or foscarnet may be beneficial. A 3-day course of oral nitazoxanide was found to significantly reduce the duration of rotavirus disease in young children.[4] Frequent handwashing and good personal hygiene may prevent person-to-person spread of infection. Washing of contaminated clothing and surfaces, and boiling of contaminated water will also assist in preventing infection. Several live oral rotavirus vaccines (p.2236) for use in the prevention of childhood diarrhoea have been developed and some are now licensed.

Haemorrhagic fevers

The viral haemorrhagic fevers are a group of viral illnesses characterised by a febrile illness that in some patients may be followed by severe bleeding, progressive organ failure, and death. The viruses are typically transmitted by mosquitoes, ticks, or rodents, and are largely geographically restricted. The more important viruses responsible for haemorrhagic fevers in man include:

- arenaviruses causing South American haemorrhagic fever syndromes (including Argentine, Bolivian, Brazilian, and Venezuelan haemorrhagic fever) and Lassa fever (transmitted by rodents)
- filoviruses causing Ebola and Marburg haemorrhagic fever, the natural host for which is unknown

- flaviviruses (previously arbovirus Group B) causing dengue fever and yellow fever (transmitted by mosquitoes), and Kyasanur forest fever and Omsk haemorrhagic fever (transmitted by ticks)
- hantaviruses causing haemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome (transmitted by rodents)
- nairovirus causing Crimean Congo haemorrhagic fever (transmitted by ticks)
- phlebovirus causing Rift Valley fever (transmitted by mosquitoes)

Specific symptoms and the incubation time vary according to the infecting virus; in general the incubation time is short (up to 21 days but commonly less than 7 days) and followed by sudden (or, in the case of Lassa fever, more gradual) onset of fever, headache, myalgia, rash, and gastrointestinal disturbances such as abdominal pain, anorexia, diarrhoea, nausea, and vomiting. In patients who develop severe haemorrhagic manifestations (skin or mucosal bleeding, haematemesis, haematuria, or melaena), hepatitis, circulatory, renal, and respiratory failure, and coma are common. Depending on the causative virus, jaundice (yellow fever and Crimean Congo fever), muscle and joint pains (dengue fever), or pulmonary symptoms (hantavirus) may be more pronounced. Mortality is variable and ranges from less than 5% in dengue haemorrhagic fever and Lassa fever with optimal supportive care, to 15 to 30% in yellow fever and Crimean Congo haemorrhagic fever, and 70 to 80% in severe Ebola and Marburg virus infections.

Infection precautions, source isolation, and optimal supportive care are cornerstones of the management of viral haemorrhagic fevers. Vector control and prevention of bites are very important. There is generally no specific drug treatment for haemorrhagic fevers, although ribavirin may reduce mortality in patients with Lassa fever or haemorrhagic fever with renal syndrome, and possibly in Crimean Congo and Bolivian haemorrhagic fevers. Vaccines have been developed for the active immunisation of individuals at risk of Argentine haemorrhagic fever, Rift Valley fever, and yellow fever, and others are being developed for dengue fever and haemorrhagic fever with renal syndrome. Studies are ongoing for a vaccine against Ebola and Marburg viruses. Crimean Congo haemorrhagic fever immunoglobulins are available in some countries for passive immunisation against the disease. Guidelines for the prevention, control, and treatment of dengue and yellow fevers have been produced by WHO[1,2] and related organisations.[3] Guidelines for the management of haemorrhagic fevers have been published for some European countries.[4,5] The Pan American Health Organization[6] and the CDC[7] have also produced guidelines for the management of hantavirus pulmonary syndrome.

Hepatitis

Though hepatitis may have many causes, viral hepatitis describes infections caused by agents that primarily target the liver. Five hepatitis viruses are recognised to be primarily responsible for infection in humans and have been named hepatitis A, B, C, D, and E. Hepatitis may also occur as part of the clinical course of other viral infections, including CMV, Epstein-Barr virus, herpes simplex virus, rubella, varicella-zoster, and yellow fever infections.

Hepatitis A and E are spread via the faecal-oral route. Hepatitis B, C, and D are spread via contaminated blood and blood products, perinatal transmission, or sexual contact. All of these viruses may cause acute and occasionally fulminant hepatitis; hepatitis B, C, and D viruses can also cause chronic hepatitis. The herpesviruses may cause hepatitis during primary infection or during reactivation of a latent infection in immunocompromised persons. (For discussion on the management of herpesvirus infections, see p.853.) Yellow fever virus is transmitted by mosquitoes and may cause fulminant hepatitis in non-immunised persons.

Acute viral hepatitis results in hepatocyte necrosis and inflammation of the liver. Clinical presentation ranges widely from asymptomatic infection to fulminant hepatic failure. Symptomatic acute hepatitis is characterised by abdominal pain, anorexia, fatigue, jaundice, low-grade fever, nausea, vomiting, and raised liver enzymes (AST and ALT). Chronic viral hepatitis is commonly asymptomatic but may result in hepatic fibrosis, cirrhosis, or hepatocellular carcinoma. Acute and chronic hepatitis may be complicated by fulminant hepatitis and liver failure, characterised by hepatic encephalopathy, coma, and death. As HIV and hepatitis B and C share risk factors for transmission, there are a significant number of people co-infected with 2 or all 3 viruses. HIV and hepatitis B or C co-infected patients have been found to have higher rates of hepatitis-related morbidity and mortality, with accelerated progression to cirrhosis, end-stage liver disease, and hepatocellular carcinoma.[1]

Viral hepatitis can be **prevented** by active immunisation against hepatitis A, hepatitis B, and yellow fever. Vaccination against hepatitis A is recommended, for example, for travellers to endemic regions, haemophiliacs, and for those considered to be at high risk due to their occupation or lifestyle (see p.2214). Postexposure prophylaxis with hepatitis A immunoglobulin is recommended in some countries for household and intimate contacts of patients with hepatitis A infection, while others recommend normal immunoglobulins. Vaccination with hepatitis B vaccine is frequently recommended as part of the infant immunisation schedules and for non-immunised infants and adults at risk of infection (see, p.2216). Hepatitis B immunoglobulin is recommended for passive immunisation of individuals exposed to a patient infected with the hepatitis B virus and after liver transplantation in persons infected with the hepatitis B virus, in order to prevent hepatitis B virus induced damage to the grafted liver (see, p.2215). Yellow fever vaccination is recommended for persons at high risk of infection, including travellers to endemic areas and may be considered as part of the standard infant immunisation schedule in countries where the virus is endemic (see, p.2243).

The **treatment of acute hepatitis** infections is largely symptomatic, as no effective antiviral therapy is available. Acute hepatitis B infection resolves without therapy in the majority of immunocompetent adults. A small pilot study[2] reported rapid clinical and biochemical responses to *lamivudine* in 13 of 15 patients with severe acute hepatitis B infection. Acute hepatitis C is more commonly asymptomatic but, if diagnosed, therapy with an *interferon alfa* may be considered[3] as there is some evidence that they may reduce the risk of progression to chronic infection.[4] A study[5] in a small number of patients with acute hepatitis C concluded that if spontaneous clearance has not occurred by 12 weeks, a 6-month course of peginterferon alfa-2b should be given, as response rates to antiviral therapy are higher in patients with acute infection compared to those with established infection. The American Association for the Study of Liver Diseases (AASLD)[4] has stated that either interferon or peginterferon given for a period of at least 6 months should be considered for the treatment of acute hepatitis C if the infection persists 2 to 4 months after diagnosis. Similar views have been published by the Clinical Effectiveness Group of the British Association of Sexual Health and HIV[6] and by the Scottish Intercollegiate Guidelines Network.[7]

Treatment of chronic hepatitis B aims to achieve seroconversion from e antigen (HBeAg)-positive to e antigen-negative chronic infection (which is associated with lower rates of viral replication and lower rates of disease progression), to suppress viral replication, to delay the progression of chronic hepatitis to cirrhosis or hepatocellular carcinoma, and to treat extrahepatic complications such as glomerulonephritis. Complete suppression of viral replication is important to reduce the risk of viral resistance. Treatment is only recommended in patients with active or advanced liver disease and with high levels of HBV DNA. Drugs used for the treatment of chronic hepatitis B include immune modulators (interferon alfa-2b and peginterferon alfa-2a) and nucleoside/nucleotide analogues (lamivudine, adefovir, entecavir, telbivudine, and tenofovir). Emtricitabine is being investigated for use in chronic hepatitis B and clevudine is under development.[8]

Interferon alfa was the first drug approved for the management of chronic hepatitis B. A meta-analysis[9] found that a significantly higher percentage of patients with chronic hepatitis B who were HBeAg-positive, and treated with interferon alfa for 3 to 6 months, became HBeAg-negative compared with the untreated control group. Interferon alfa was found to be most effective when it was used in patients with recently acquired hepatitis B infection, high pre-treatment ALT, and low hepatitis B DNA levels.[10] Studies have suggested that subcutaneous *peginterferon alfa* is as effective or slightly more effective than interferon alfa given subcutaneously.[10] Results from various studies[11] have shown peginterferon alfa to be more effective than the antiviral lamivudine, in both HBeAg-positive[12] and HBeAg-negative patients with chronic hepatitis B,[13] when peginterferon alfa was given subcutaneously once weekly for 48 weeks.

Lamivudine has a similar efficacy to interferon but fewer adverse effects. Studies[14,15] have shown favourable effects on histologic, virologic, and biochemical features of the disease from long-term therapy, including decreased disease progression and progression to hepatocellular carcinoma in patients with cirrhosis or advanced fibrosis. In HBeAg-positive patients, treatment with lamivudine is generally continued for at least 6 months after seroconversion, while HBeAg-negative patients may need indefinite treatment due to high relapse rates when treatment is stopped.[10]

Studies with daily oral *adefovir dipivoxil* for 48 weeks have shown a mean drop in hepatitis B viral DNA of about 3.5 logs (factors of 10) in patients with HBeAg-positive chronic hepatitis B[16] and of about 4 logs in patients with HBeAg-negative chronic hepatitis B.[17] When adefovir dipivoxil was continued in HBeAg-negative patients for 144 weeks benefit was maintained whereas viral load rebounded in those patients who stopped treatment at 48 weeks.[17] Hepatitis B virus DNA was undetectable in 71% and 79% of patients after 96 and 144 weeks of treatment respectively.[17] Most HBeAg-positive and HBeAg-negative patients also had improvements in serum-ALT and liver histology.[16,17]

The most recent drugs to be approved for the treatment of chronic hepatitis B, including in patients with lamivudine-resistant disease, are entecavir and telbivudine. Studies with daily oral *entecavir* for 48 weeks have shown a mean drop in hepatitis B viral DNA of about 6.9 logs in patients with HBeAg-positive chronic hepatitis B[18] and of about 5 logs in patients with HBeAg-negative chronic hepatitis B.[19] Entecavir treatment continued through to 96 weeks, in those patients with HBeAg-positive hepatitis B, continued to show benefit.[20] In both these studies entecavir was found to be more potent than oral lamivudine in suppressing hepatitis B virus. *Telbivudine* was reported to be superior to lamivudine in patients with HBeAg-positive chronic hepatitis B and as effective as lamivudine in those with HBeAg-negative disease after 52 weeks of treatment.[21] A small open label study[22] with telbivudine or adefovir for 52 weeks, or adefovir for 24 weeks followed by telbivudine for 28 weeks, in patients with HBeAg-positive hepatitis B, reported greater and more consistent reductions in HBV DNA with telbivudine than with adefovir after 24 weeks of treatment. After 52 weeks, HBV DNA suppression was greater in patients given continuous telbivudine or who switched from adefovir to telbivudine after 24 weeks than in those given adefovir for 52 weeks.

The development of antiviral ***resistance*** is a concern with long-term nucleoside/nucleotide treatment. About 14% of patients who initially respond to lamivudine develop drug resistance within the first year of therapy and resistance increases to about 70% after 5 years of treatment; lamivudine is therefore generally not recommended as first-line treatment.[23] Adefovir dipivoxil showed no resistance after 1 year of treatment, but the rate increased over time to about 11%, 18%, and 29% at year 3, 4, and 5 respectively.[16,17,24,25] Long-term therapy with adefovir dipivoxil resulted in the development of resistance mutations in less than 6% of patients and it was effective in patients who had previously developed resistance to lamivudine.[17] Entecavir showed no resistance up to 2 years of treatment and the resistance rate with telbivudine is reported to be 2 to 4% after 1 year of treatment.[26] Combination therapy with different nucleoside and nucleotide analogues is being investigated in order to prevent drug resistance and improve efficacy.[27] The addition of lamivudine to peginterferon alfa did not significantly enhance efficacy.[13,28,29] The combination of lamivudine and adefovir was found to be as effective as lamivudine monotherapy.[30] The combination of lamivudine and telbivudine was less effective than telbivudine alone[31] but emtricitabine and adefovir was more effective than adefovir alone.[30]

While the AASLD[10] states that all the approved treatments may be given as initial therapy, their preferred ***choice*** is peginterferon alfa or the nucleoside analogues adefovir dipivoxil or entecavir, in adults with HBeAg-positive or -negative chronic hepatitis B; interferon alfa or the nucleoside analogues lamivudine and telbivudine may also be used. In children with HBeAg-positive chronic hepatitis B, standard interferon alfa or lamivudine are recommended. In patients who are HBeAg-positive interferon is given for a defined duration (interferon alfa is given for 4 months and peginterferon alfa for 12 months), while a nucleoside/nucleotide analogue is usually given for an additional 6 months after HBeAg seroconversion. Most patients who are HBeAg-negative will relapse after treatment is stopped. In these patients interferon is also given for a defined duration (both interferon and peginterferon alfa are given for 12 months), but treatment with a nucleoside or nucleotide analogue is indefinite. Patients who have not responded to interferon alfa (standard or pegylated) therapy may be re-treated with a nucleoside analogue. Those who fail to respond after 6 months treatment should be switched to an alternative regimen. Adefovir[23,32] or tenofovir[32] may be given with lamivudine in those patients with lamivudine-resistant hepatitis B virus. Interferon alfa is not recommended in patients with compensated cirrhosis as it may cause hepatitis flares and hepatic decompensation. Guidelines are also available for other countries.[33-36]

Hepatitis B patients co-infected with **hepatitis D virus** are less responsive to interferon therapy than patients infected with hepatitis B virus alone. A study[37] with high-dose interferon alfa (9 million units) given 3 times a week for 48 weeks reported normalisation of ALT and inhibition of hepatitis D viral replication in 50% of the patients. However, relapse was common after treatment was stopped, although biochemical responses persisted for up to 4 years. Long-term follow-up of this same group of patients for 2 to 14 years revealed that high-dose interferon alfa may improve long-term outcome and patient survival.[38]

Treatment of chronic hepatitis C aims to decrease viral replication or eradicate hepatitis C virus, delay the progression to cirrhosis, and thereby decrease the frequency of hepatocellular carcinoma, and to treat extrahepatic complications of infection. The first available treatment was *interferon* alfa-2b, and this was followed by interferon alfa-2a, given subcutaneously 3 times a week. Patients treated with these interferons had a 10 to 20% chance of obtaining a sustained virological response (SVR), but had a high relapse rate. The combination of daily oral *ribavirin* with non-pegylated interferon alfa improved the rate of SVR after 48 weeks of treatment to about 40%. Further improvements in the SVR rates to about 60% have been reported since the introduction of weekly subcutaneous peginterferon alfa given with daily oral ribavirin. Studies[39,40] have found peginterferon alfa and ribavirin (SVR of 54 to 56%) to be more effective than interferon alfa and ribavirin (SVR of 44 to 47%). Factors predictive of a poor SVR are viral genotype 1, a high pretreatment viral load, increased body-weight, and the presence of cirrhosis. A study[39] with peginterferon alfa-2b or interferon alfa-2b and ribavirin showed an SVR of 42% in patients with genotype 1, compared with about 80% in patients with genotypes 2 and 3. Furthermore, patients infected with hepatitis C virus genotype 1 require treatment for 48 weeks with the standard dose of ribavirin (1 or 1.2 g daily) compared with 24 weeks of ribavirin 800 mg daily in those infected with genotypes 2 or 3.[41] Other studies[42-46] suggest that SVR can be achieved in some patients infected with genotypes 2 and 3 with a 12 to 16 week course of treatment. This is particularly true for patients in whom hepatitis C virus RNA is undetectable after 4 weeks of treatment. In patients with genotype 1 infection, longer durations of therapy (up to 72 weeks), may be appropriate in slow responders (patients who achieved a 2 log fall in the viral load but in whom viral RNA is still detectable by week 12).[47,48] In one study,[47] a SVR rate of 44% was reported for slow responders who continued treatment for 72 weeks, compared with a SVR rate of 28% in those who received 48 weeks of treatment.

Detailed guidelines have been produced in the UK,[7,49,50] Canada,[51] and in the USA[4,52] for the management of chronic hepatitis C. They all recommend weekly subcutaneous peginterferon alfa plus daily oral ribavirin as the first choice of treatment in patients with moderate to severe chronic hepatitis C. For genotype 2 and 3 infection, 24 weeks of treatment is usually recommended[4,49] but some suggest that 12 or 16 weeks of therapy may be sufficient in patients with genotypes 2 and 3 with undetectable viral RNA at week 4.[7,52] For genotype 1, treatment for 48 weeks is generally recommended. An early prediction of treatment failure in patients with genotype 1 infection is detectable hepatitis C virus RNA with less than a 2-log fall in viral load after 12 weeks of treatment. Some[4,7,50] suggest that stopping treatment in these patients may be considered at this point, while the British Society for Gastroenterology recommends stopping treatment after 24 weeks if hepatitis C virus RNA is still detectable. Some guidelines[4,7] suggest re-treatment (with peginterferon and ribavirin) of nonresponders and relapsers who have significant fibrosis or cirrhosis and who initially received interferon with or without ribavirin. Patients with other genotype infections should be treated with combination therapy for 48 weeks.[50,52]

Thymalfasin is being investigated as an adjunct to conventional therapy for the treatment of chronic hepatitis B and C.

Treatment of chronic hepatitis in HIV co-infected patients. HIV infection reduces the efficacy of current therapies for **hepatitis B**; it decreases response to interferon alfa and increases the incidence of lamivudine-resistant hepatitis B mutations.[1] Guidelines for the management of HIV and hepatitis B co-infection have been developed by various expert groups.[53-55] The British HIV Association guidelines[53] discuss appropriate choice of antivirals and their activity against hepatitis B virus and HIV. In patients not requiring HIV therapy, hepatitis B treatment should be with drugs that have no anti-HIV activity. *Interferon alfa* for 4 to 6 months is considered suitable for non-cirrhotic HBeAg-positive patients but limited evidence suggests that peginterferon alfa may be more effective. Long-term treatment with *adefovir dipivoxil* may be given as an alternative to interferon therapy. Patients who require both HIV and hepatitis B therapy may be given *tenofovir* alone or with either *lamivudine* or *emtricitabine*, as part of, or in addition to, their antiretroviral regimen.[53] Successful treatment of HIV with HAART may result in severe exacerbation of hepatitis B in co-infected patients. Treatment of **hepatitis C** in HIV co-infected patients has been associated with an increased rate of adverse effects and reduced response rates. While combination therapy for hepatitis C is not as effective in co-infected patients as in those with hepatitis C alone, studies[56-58] have shown sustained virological responses with peginterferon alfa and ribavirin treatment in co-infected patients. Two studies[57,58] reported an SVR rate of 27% for patients given peginterferon alfa plus ribavirin as opposed to 12 to 20% in those treated with interferon alfa plus ribavirin. The APRICOT study group[56] reported an SVR rate of 40% for patients treated with peginterferon alfa plus ribavirin, compared with 20% for those given peginterferon alfa monotherapy and 12% for those given interferon alfa plus ribavirin. A much reduced rate of SVR to peginterferon alfa plus ribavirin therapy was found, however, in co-infected patients with hepatitis C virus genotype 1 (29%) compared with hepatitis C virus of genotypes 2 and 3 (62%) and further study is required to develop strategies for treating infection with genotype 1.[56,58] The British HIV Association guidelines[59] for the treatment and management of HIV and hepatitis C co-infection recommend combination therapy with *peginterferon alfa* and *ribavirin* for 48 weeks in patients with moderate liver disease and well controlled HIV disease. Similar recommendations have been made by the AASLD.[4] Other guidelines[7,60] recommend reassessment of virologic response at weeks 4 and 12 and that treatment should only be continued in those with an early virologic response. Some experts[60] suggest that shorter periods of treatment (24 weeks) may be considered for patients with genotypes 2 and 3. Patients with genotype 1 and 4 who have no virological response at 4 weeks but response at 12 weeks may be given a longer treatment course of 60 to 72 weeks. Significant haemolytic anaemia may occur with ribavirin, and therefore concurrent use with zidovudine should be avoided and when possible stavudine should be replaced. Didanosine should never be given with ribavirin due to potentially life-threatening complications, such as lactic acidosis, myopathy, neuropathy, pancreatitis, and steatosis.[59-61]

Herpesvirus infections

Established herpesvirus pathogens discussed below include Cercopithecine herpesvirus 1, CMV, Epstein-Barr virus, herpes simplex virus, and varicella-zoster virus. Herpesviruses 6, 7, and 8 have also emerged as potential pathogens and have been associated with a variety of disorders including childhood febrile illnesses, various malignancies including Kaposi's sarcoma (p.675), and multiple sclerosis (p.892).

Cercopithecine herpesvirus 1 infections. *Cercopithecine herpesvirus 1* (herpesvirus simiae, monkey B virus, herpes B virus) is a herpesvirus that usually infects macaque monkeys, but may rarely be transmitted to man by laboratory accidents or bites or scratches from infected monkeys. Initial symptoms and signs may include vesicles at the site of the bite or scratch, fatigue, fever, headache, and myalgia. Lymphadenitis or lymphadenopathy, abdominal pain, nausea, and vomiting may occur. As the infection spreads to the CNS there is increasing neurological involvement that can lead to encephalitis, coma, and death. Those patients who survive usually have serious neurologic impairment.

Initial **treatment**[1,2] should be prompt with thorough cleaning of the wound or exposure site. Intravenous high-dose *aciclovir* or *ganciclovir*, followed by oral therapy, is recommended for symptomatic or culture-confirmed infection. Ganciclovir is recommended in patients who have signs or symptoms of peripheral nervous system or CNS involvement. Routine **prophylactic** use of antivirals is not recommended, although postexposure prophylaxis with oral *valaciclovir* started within a few hours of exposure and given for 14 days may be considered for potential exposures.

2. Huff JL, Barry PA. B-virus (Cercopithecine herpesvirus 1) infection in humans and macaques: potential for zoonotic disease. *Emerg Infect Dis* 2003; **9:** 246–50.

Cytomegalovirus infections. Cytomegalovirus (CMV) is a member of the herpesvirus group. Infection may be by intra-uterine, perinatal, or sexual transmission, by oral contact with the saliva of infected individuals, by blood transfusion, or by transplantation of infected tissue. After infection, viral DNA becomes incorporated into the host cell DNA where it persists, with occasional reactivation, for the life of the individual. Primary infections in immunocompetent adolescents and adults are generally asymptomatic, although they may occasionally present as infectious mononucleosis, lymphocytosis, or lymphadenopathy. Most congenitally infected infants are also asymptomatic, but some may present with intra-uterine growth retardation, jaundice, hepatosplenomegaly, encephalitis, and thrombocytopenia. Conversely, CMV is a major cause of morbidity and mortality in immunocompromised persons, particularly transplant recipients and patients with AIDS where it may present as CMV retinitis, colitis, oesophagitis, hepatitis, pneumonitis, or neurological disease in the form of dementia, ventriculoencephalitis, or ascending polyradiculomyelopathy. Pneumonitis is more common in transplant recipients while retinitis is most frequent in AIDS patients.

Treatment for CMV disease is usually only given to immunocompromised patients, in whom relapses are likely to occur after treatment is stopped due to the latent nature of the virus. Ganciclovir and its oral prodrug valganciclovir are used in the treatment of severe infections in transplant recipients and patients with AIDS but ganciclovir may cause neutropenia. Foscarnet is an alternative to ganciclovir with similar efficacy and does not produce myelosuppression, although nephrotoxicity and electrolyte disturbances are common. Cidofovir may also be used for the treatment of CMV retinitis, and has the advantage of intermittent use. However, long-term treatment may be limited by renal toxicity.

HIV-infected patients. US guidelines[1] for the **initial treatment** of ***CMV retinitis*** in HIV-infected adults and adolescents recommend, for immediate sight-threatening lesions, intra-ocular ganciclovir implants along with oral valganciclovir. For patients with peripheral retinal lesions, oral valganciclovir alone is recommended. Alternatives are intravenous ganciclovir, intravenous ganciclovir followed by oral valganciclovir, intravenous foscarnet, or intravenous cidofovir. For HIV-infected children, intravenous ganciclovir is recommended;[2] intravenous foscarnet is an alternative.

After induction therapy, **maintenance therapy** (secondary prophylaxis) is recommended in AIDS patients with CMV retinitis until immune reconstitution as a result of antiretroviral therapy has been achieved or for life if it is not. The drugs of choice for retinitis are oral valganciclovir or intravenous foscarnet, both of which provide protection for the contralateral eye. Alternatives are intravenous cidofovir or intravitreal injections of fomivirsen.[1] Maintenance therapy may be stopped in patients with inactive CMV disease who have an increase in CD4+ T lymphocyte count to 100 to 150 cells/microlitre sustained for 6 months or more, although continued ophthalmic monitoring should be performed. Maintenance therapy should begin again if the CD4+ T lymphocyte count falls below 100 cells/microlitre.[1]

Relapse of CMV retinitis in patients with persistent immunodeficiency is common and is generally due to poor penetration of drugs into the eye when given systemically, rather than drug resistance. Hence, ganciclovir intra-ocular implants, with re-induction by the same systemic therapy used previously, are recommended in patients who relapse after systemic treatment. An alternative drug should only be considered if drug resistance is suspected or toxicity precludes use of the initial drug. Combined ganciclovir and foscarnet may be considered for patients who are not suitable for other alternatives, but is associated with greater toxicity. In patients who relapse later in therapy due to drug resistance, repeated intravitreal injections of fomivirsen can be given, but should be combined with systemic therapy.[1]

In HIV-infected adults and adolescents, ***CMV colitis*** or ***oesophagitis*** should be treated initially with intravenous ganciclovir or foscarnet, or with oral valganciclovir.[1] Chronic maintenance therapy is not routinely recommended but should be considered if relapse occurs.[1] For ***neurological*** disease, starting therapy promptly is critical for an optimal clinical response. Combination treatment with intravenous ganciclovir and foscarnet is currently favoured. Maintenance therapy should be continued for life.[1] Treatment of CMV ***pneumonitis*** is usually reserved for patients with histological evidence of CMV disease who do not respond to treatment for other pathogens. The role of maintenance in these patients is yet to be established.[1]

In HIV-infected adults and adolescents, ***primary prophylaxis*** with oral ganciclovir can be considered for all patients who are CMV-seropositive and who have a CD4+ T lymphocyte count below 50 cells/microlitre.[3] The US guidelines[3] consider aciclovir and valaciclovir unsuitable for prophylaxis in patients with HIV infection, although preliminary studies have suggested that valaciclovir may be effective in these patients.[4]

Transplant recipients. Primary **prophylaxis** of CMV disease in high-risk patients, particularly transplant recipients, has been reported using intravenous ganciclovir,[5-7] valganciclovir,[8,9] foscarnet,[10] valaciclovir,[11-15] and CMV immunoglobulins.[16,17] Oral ganciclovir has also been used for primary prophylaxis and for *pre-emptive therapy* (treatment when active CMV infection is documented but disease has not yet been evident) in some transplant patients.[18-20] A systematic review[21] found that giving CMV immunoglobulins did not reduce the risk of CMV disease or all-cause mortality in solid organ transplant recipients and adding them to aciclovir or ganciclovir was not more effective than an antiviral given as monotherapy.

The British Transplantation Society has published recommendations for the prevention and management of CMV disease after ***solid organ transplantation***.[22] These recommend that CMV-seronegative recipients of a solid organ transplant from a seropositive donor should be offered primary prophylaxis. The following options are available in the UK and are recommended by the British Transplantation Society:[22]

- oral valganciclovir for 100 days (in heart, kidney, kidney/pancreas, or liver transplant recipients)
- valaciclovir for 90 days (heart, kidney, kidney/pancreas, liver, or lung)
- intravenous ganciclovir for at least 28 days (heart, kidney, kidney/pancreas, liver, or lung)
- high-dose oral aciclovir for 12 weeks (kidney)
- intermittent CMV hyperimmune globulin for 12 weeks (kidney)

Frequent monitoring and possible pre-emptive treatment, usually with intravenous ganciclovir, may also be required.[22]

The above regimens are also used to prevent CMV disease when the donor and recipient are both CMV-seropositive and the patient is being treated with antithymocyte globulin, antilymphocyte immunoglobulin, or muromonab-CD3. If these drugs are not used, no prophylaxis is needed for CMV-seropositive recipients of kidney, kidney and pancreas, liver, or heart transplants from seropositive donors; lung transplant recipients should be given chemoprophylaxis as for seronegative patients above.[22]

The British Transplantation Society also recommended oral ganciclovir for 90 days as an option for prophylaxis after heart, kidney, kidney/pancreas, liver, or lung transplant, but acknowledged in their recommendations that, during their preparation, the UK manufacturer ceased production of oral ganciclovir; it was, however, retained as an option in the recommendations in case of availability in the future.[22]

Recommendations have also been produced for the management of CMV infection in recipients of allogeneic ***stem cell transplantation*** by the Infectious Diseases Working Party of the European Group for Blood and Marrow Transplantation.[23] For treatment of CMV pneumonia, normal immunoglobulin is given with ganciclovir, but normal immunoglobulin is not required in other forms of CMV disease.[23] For prevention of CMV disease, pre-emptive therapy with either intravenous ganciclovir or foscarnet rather than primary prophylaxis, is the recommended approach. Intravenous ganciclovir is, however, effective for primary prophylaxis but should be reserved for patients at high risk of developing disease. Aciclovir or valaciclovir may also be used for primary prophylaxis but their use must be combined with monitoring and pre-emptive therapy with either intravenous ganciclovir or foscarnet. If, however, ganciclovir has been given for primary prophylaxis then foscarnet should be used for first-line pre-emptive therapy. The use of valganciclovir for primary prophylaxis is under investigation, but if it is given then foscarnet should be used subsequently for first-line pre-emptive therapy. Cidofovir may be used as second-line pre-emptive therapy.[23]

CMV vaccines are currently in development.

Epstein-Barr virus infections. Epstein-Barr virus (EBV) is a DNA virus of the herpesvirus group occurring worldwide. EBV is the causative agent in infectious mononucleosis and many people acquire a non-symptomatic infection, frequently in childhood. After primary exposure the individual becomes a lifelong carrier of the virus. Chronic EBV infection, particularly in immunocompromised individuals, is associated with several malignant diseases including Burkitt's lymphoma, nasopharyngeal carcinoma, lymphoproliferative diseases, Hodgkin's disease, T-cell lymphomas, and some gastric cancers. EBV is also associated with chronic interstitial pneumonitis in infants with AIDS and with oral hairy leucoplakia and CNS lymphomas in older AIDS patients.

Infectious mononucleosis (glandular fever) is an acute, self-limiting, lymphoproliferative infection that is seen when primary infection occurs in adolescents or young adults.[1] Transmission is by intimate oral contact and the incubation period ranges from 30 to 50 days. Illness is characterised by fever, sore throat, and lymphadenopathy. Other signs and symptoms include malaise, myalgias, jaundice, rash, and hepatosplenomegaly. Symptoms may last for about 2 to 3 weeks and most patients recover uneventfully with only supportive treatment, although fatigue may continue for some months. Complications, including encephalitis, anaemias, or cytopenias, may occur in a few patients but are rarely fatal. Very rarely the illness may become chronic. Chronic active EBV is defined as severe illness lasting longer than 6 months, evidence of major organ involvement, and elevated titres of antibody to EBV. Prognosis in these patients is poor and many die due to progressive pancytopenia and hypogammaglobulinaemia, or lymphomatous disease.

There is no specific **treatment** for EBV infections[1] although various experimental approaches have been investigated.[2] Treatment is generally symptomatic: hydration, paracetamol or NSAIDs, and throat lozenges or sprays. A meta-analysis[3] of five randomised controlled studies involving 339 patients with mild, moderate, or severe EBV infection, found that patients who took aciclovir had less oropharyngeal shedding, but clinical benefit was marginal and not sustained on stopping treatment. In a small number of patients with chronic active EBV, ganciclovir[4,5] and interferons[6,7] appeared to have a beneficial effect on symptoms or EBV replication. Corticosteroids are generally not indicated in uncomplicated EBV infection[8] but may be useful in patients with airways obstruction.[1,9] They may also be considered in systemic complications such as autoimmune haemolytic anaemia, aplastic anaemia, and thrombocytopenia and some also consider that they may be used for CNS involvement, myocarditis or pericarditis. However, concern has been expressed that they may impair immunity, resulting in a larger reservoir of latent virus and thereby potentially increasing the risk of developing EBV-related tumours in later years.

Concurrent throat infection with streptococci should not be treated with amoxicillin or ampicillin since they may cause a maculopapular rash in patients with infectious mononucleosis.

Herpes simplex infections. Herpes simplex virus (HSV, herpesvirus hominis) is a DNA virus belonging to the herpesviridae family and occurs worldwide.[1] HSV can be divided into serotypes HSV-1 and HSV-2. Both viruses establish chronic infection of sensory nerve ganglia from where reactivation may occur by various triggers such as stress, bacterial infection, fever, irradiation (including sunlight), menstruation, and immunosuppression.

Herpes is characterised by an initial, primary infection, which may be followed by recurrent episodes in the same area. **Primary** HSV infection is acquired through direct contact with lesions or mucosal secretions of persons with active HSV lesions or persons shedding virus asymptomatically. Primary HSV-1 infections usually occur in the perioral area, and HSV-2 in the genital area, but infection may be acquired at other sites, including the fingers (whitlow), and rectum (herpes proctitis) after anal intercourse. The incubation period for both viruses ranges from 2 to 12 days and most primary HSV infections are asymptomatic.

- HSV-1 commonly causes symptomatic *oropharyngeal herpes* presenting as acute gingivostomatitis or pharyngitis and characterised by lesions of the buccal and gingival mucosa, fever, and cervical adenopathy.

  HSV-1 infections are common among immunocompromised patients, especially organ transplant recipients and those undergoing chemotherapy. In these patients infection may be more severe with extensive mucocutaneous and disseminated disease.
- *Genital herpes* is characterised by a painful ulcerative rash, and may be accompanied by dysuria, vaginal or urethral discharge, and tender inguinal lymphadenopathy. Genital herpes is most commonly caused by HSV-2 but may also be caused by HSV-1. Genital herpes tends to be more extensive when caused by HSV-2 and may include complications such as aseptic meningitis, disseminated disease, extragenital lesions, and bacterial superinfection.

  Herpes lesions are common among HIV-positive patients and may be severe, painful, and atypical; HSV recurrences and asymptomatic shedding are also increased.
- *Ocular herpes* is generally caused by HSV-1. It usually affects only one eye and most often occurs on the cornea resulting in epithelial or stromal keratitis. Epithelial keratitis usually heals without scarring whereas stromal keratitis infection involves the deeper layers and may lead to scarring, loss of vision, and occasionally blindness. Less commonly, HSV may also cause uveitis, chorioretinitis, or acute necrotising retinitis.
- HSV has been identified as one of the commonest causes of Bell's palsy and acute, sporadic viral *encephalitis*. Both HSV-1 and HSV-2 may cause encephalitis and if left untreated it is often fatal or may result in neurologic sequelae, especially in those over 35 years of age.
- *Neonatal herpes* may result from transmission of HSV-2 (or HSV-1) from mother to child during the perinatal period. Risk of neonatal herpes is highest when the mother develops primary genital herpes near the time of delivery whereas risk is much reduced with recurrent episodes. Neonatal herpes is a severe disseminated infection and often results in CNS disease. Untreated it is often fatal and survivors often have persistent ocular disease.

Recurrent herpes results from **reactivation** of latent infection and is usually milder and the duration is shorter than the primary infection. Reactivation is frequently associated with prodromal signs and symptoms, ranging from a mild tingling sensation to shooting pains. Systemic symptoms and lymphadenopathy are rare. *Herpes labialis*, also known as fever blisters or cold sores, are the most common infection resulting from reactivation of HSV-1. Recurrence of genital herpes is more likely with HSV-2 than HSV-1 infections.

Management. The most widely used antiviral for herpes simplex infections is aciclovir. Alternatives with improved bioavailability include famciclovir and valaciclovir. Antiviral treatment of primary herpes simplex infections, while relieving symptoms and reducing the duration of viral shedding, does not prevent recurrences. Antiviral therapy is generally more effective for primary infections than for recurrences, and should be given as early as possible during the course of an active infection, preferably within 3 days of the onset of symptoms. Resistance to aciclovir is emerging, mainly in immunocompromised patients.[2] Herpes simplex vaccines have also been tried but with generally disappointing results.

- **Orofacial herpes simplex infection.** Primary mucocutaneous HSV infection can be treated with topical, oral, or intravenous aciclovir. Oral famciclovir and valaciclovir have similar efficacy to oral aciclovir and are recommended alternatives.[1] Mucocutaneous HSV in HIV co-infected patients may be treated with intravenous or oral aciclovir, oral famciclovir, or oral valaciclovir. Recurrent episodes of herpes labialis are usually self-limiting and rarely require antiviral therapy. In immunocompetent patients careful hygiene, symptomatic treatment with analgesics, and the use of antiseptics to reduce secondary infection will usually suffice. The use of sunscreens may also reduce the frequency of recurrences. If antivirals are used they should be started early in the prodromal phase. Topical antivirals, including aciclovir, penciclovir, and tromantadine, have been used and are most effective when started during the prodromal phase.[3] Docosanol may be a further alternative for topical use.[4] Oral antivirals (aciclovir, famciclovir, and valaciclovir) may shorten the duration of symptomatic lesions by about 1 day.[3] High-dose oral valaciclovir has also been reported to be effective for suppression of recurrences and may provide the convenience of single-day treatment.[5] In immunocompromised patients with primary symptomatic infection or recurrent episodes of infection, intravenous or oral aciclovir, oral famciclovir, or valaciclovir may be used. An oral antiviral (aciclovir, famciclovir, or valaciclovir) is recommended for patients with herpes labialis and concurrent HIV infection.[6]
- **Genital herpes** is usually treated with oral aciclovir, famciclovir, or valaciclovir.[6-9] Intravenous aciclovir is given for severe disease or neurological complications. A study[10] found that both oral aciclovir and oral valaciclovir were effective in suppressing the frequency of recurrences and amount of HSV shedding. However, treatment of the primary HSV infection appears to have no effect on subsequent recurrences. Symptomatic recurrences in patients with a recognisable prodrome may be aborted or the severity reduced by a 5-day course of oral aciclovir, famciclovir, or valaciclovir begun by the patient.[7-9] Alternative regimens include high oral doses of aciclovir for 2 days,[8,11] famciclovir for 1 day, or valaciclovir for 3 days.[7,8] Symptomatic HSV recurrences in HIV-positive patients respond more slowly to anti-HSV treatment and longer treatment courses and higher doses of antivirals are needed.[8,12]

  In HIV-negative patients without a prodrome, or those with frequent recurrences, continuous suppressive therapy with aciclovir, famciclovir, or valaciclovir should be considered.[7-9] Once-daily suppressive therapy with valaciclovir was found to significantly reduce the risk of transmission of genital herpes among heterosexual, HSV-2-discordant couples.[13] Suppressive therapy should be considered for all HIV-infected persons.[7,12]
- **Ocular herpes simplex infections** usually require treatment with antivirals and/or interferons. Topical antivirals include aciclovir, ganciclovir, trifluridine, and vidarabine; no one drug appears to be more effective than another.[14] Systemic antivirals include aciclovir, famciclovir, and valaciclovir. Other systemic antivirals that have been evaluated are ganciclovir, foscarnet, and cidofovir.[14] HSV epithelial keratitis can be treated with a topical antiviral, a topical interferon (alfa or beta), or a combination of both. Benefit appears to be similar after 7 days of treatment with either an interferon or antiviral monotherapy, but combination therapy with interferon and an antiviral produces faster healing than a topical antiviral alone.[14] Trifluridine eye drops are the treatment of choice for herpes simplex epithelial keratitis in HIV-infected patients.[6]

  Topical corticosteroid monotherapy is contra-indicated for epithelial keratitis as disease severity can be increased; however, the treatment for stromal keratitis does consists of both topical trifluridine and topical corticosteroids. The Herpes Eye Disease Study[15] reported that the addition of topical prednisolone to trifluridine reduced the risk of persistent or progressive stromal kerato-uveitis by 68%, while the further addition of oral aciclovir provided no additional benefit.[16] Stromal keratitis or iritis was not prevented by the addition of oral aciclovir in patients with epithelial keratitis and currently receiving topical trifluridine.[17] Oral aciclovir, however, was effective in reducing the rate of recurrent HSV ocular disease, particularly in patients with prior stromal keratitis,[18] and may be of benefit to patients in uveitis when added to topical corticosteroid and antiviral therapy.[19]
- **Severe or disseminated herpes simplex infections**, particularly in immunocompromised patients, require intravenous therapy. Aciclovir is given for CNS infections and disseminated HSV infections,[1,6,20] with foscarnet or cidofovir as alternatives for infections resistant to aciclovir.[6] Neonates with evidence of herpes infection should be given high-dose intravenous aciclovir.[7,9,20] Immunocompromised patients with frequent or disabling recurrences may benefit from prophylactic oral aciclovir or famciclovir.[6,20,21]

Prevention. Intravenous aciclovir is recommended for all HSV-seropositive patients undergoing allogeneic haematopoietic stem cell transplants to prevent reactivation of latent HSV. Aciclovir may also be considered for HSV-seropositive patients undergoing autologous haematopoietic stem cell transplantation who are at risk of developing severe mucositis from the conditioning chemotherapy.[22] Oral aciclovir, famciclovir, or valaciclovir may be given to patients who can tolerate oral therapy. There is a risk of neonatal herpes in the infants of mothers with genital herpes infection. Prophylactic use of aciclovir in late pregnancy is not routinely recommended[7] but may be considered in HIV-infected mothers with frequent recurrences.[21] Although antivirals reduce viral shedding and recurrence at labour and birth and the use of caesarean section there is no evidence they reduce the occurrence of neonatal herpes.[23]

Varicella-zoster infections. Varicella-zoster virus (VZV) belongs to the herpesviridae and causes 2 separate diseases: chickenpox (varicella) and herpes zoster (zoster, shingles). Infection may be acquired through the respiratory tract via airborne droplets or by close contact with infected individuals. Primary infection with VZV usually occurs in childhood and results in chickenpox. In immunocompetent persons chickenpox is self-limiting and results in lifelong immunity. However, the virus is not eliminated and remains dormant within sensory nerve ganglia. In later life or in immunocompromised persons, reactivation of the virus from the sensory nerve may occur and give rise to nerve pain and a dermatomal rash (herpes zoster). Immunocompromised patients may develop a second episode of chickenpox.

The incubation period for *chickenpox* is about 14 to 15 days. In children it usually presents with a generalised rash, fever, and malaise. The rash rapidly progresses from macules to papules and then to vesicular lesions before crusting, with successive crops appearing over several days. Chickenpox acquired in childhood is commonly a mild disease lasting 3 to 5 days, with secondary bacterial skin infections the commonest complication. Chickenpox in adults may be more severe, and have a higher incidence of complications. Immunocompromised individuals may develop severe chickenpox with multiple organ involvement, high fever, more extensive vesicular skin eruption, severe pneumonia, and encephalitis.

Primary varicella infection in the first 20 weeks of pregnancy has been associated rarely with congenital varicella syndrome, characterised by skin scarring, local muscular atrophy, chorioretinitis, encephalitis, cortical atrophy, and microcephaly. Maternal infection until at least 5 days before delivery may result in a mild neonatal infection, while maternal infection from 7 days before to 7 days after delivery may result in a severe infection of the neonate with a reported fatality of about 30%.

Herpes zoster is characterised by painful vesicular eruptions in a dermatomal distribution. It may be preceded by a prodromal phase with fever and malaise or pain over the affected dermatome. Lesions continue to form over a period of 3 to 5 days, and disappear, often with a degree of scarring, after 10 to 15 days. Chronic pain that may persist after the rash has healed is termed postherpetic neuralgia (p.9) and occurs in about 10% of patients. Involvement of the trigeminal nerve can lead to sight-threatening ophthalmic herpes zoster. Herpes zoster may be more severe and extensive in immunocompromised patients but is rarely fatal.

Treatment. Recommendations for the treatment of ***chickenpox*** in children,[1] adults,[2] and during pregnancy[3] have been developed. Treatment in otherwise healthy patients is usually symptomatic using antipyretics, analgesics, and antipruritics and is aimed at reducing complications. Antibacterials may be required for secondary skin infections. Antivirals are not recommended for the treatment of uncomplicated chickenpox in otherwise healthy children.[1] However, oral aciclovir may shorten the duration of fever and the number of lesions when given within 24 hours of onset of symptoms.[4] Antivirals do not reduce the incidence of chickenpox-associated complications in otherwise healthy children but may be useful in adults or immunocompromised patients. Intravenous therapy may be used in severe chickenpox.

The place of antivirals in the treatment of ***herpes zoster*** is well established and guidelines on management have been produced.[5-7] Antiviral treatment can reduce the severity and duration of acute pain, minimise complications and propagation of the rash, and reduce viral shedding.[5] Systemic antivirals are recommended for all immunocompetent patients who are over 50 years of age, have moderate to severe pain or rash, or have nontruncal involvement. Treatment should be started within 72 hours of the onset of the rash and is usually continued for 7 to 10 days. Antiviral therapy may also be considered in those presenting 72 hours after the onset of the rash when there are skin, motor, neurological, or ocular complications, when new vesicles are still forming, in the elderly, or in those with severe pain.[7] Topical antivirals are not recommended.

Aciclovir may be given orally or intravenously, depending upon the severity of the infection. Oral famciclovir, valaciclovir, or brivudine are alternatives.[7] Bioavailabilities of these drugs are better than aciclovir and they also appear to be superior in terms of healing lesions and equally or more effective in relieving pain.[7-9]

There has been controversy over the use of oral aciclovir to prevent **postherpetic neuralgia** and ocular complications. A meta-analysis suggested that treatment of herpes zoster with oral aciclovir within 72 hours of the onset of rash could reduce the *incidence* of residual pain at 6 months by 46% in immunocompetent adults.[10] A more recent analysis[11] considered that there was only marginal evidence that aciclovir decreased the incidence of postherpetic neuralgia and that there was no reduction in incidence with either famciclovir or valaciclovir. It is, however, generally agreed that antivirals do reduce the *duration* of postherpetic neuralgia[11] and some experts recommend antivirals in patients at low risk for developing postherpetic neuralgia and other complications.[7] The addition of corticosteroids to antiviral therapy does not reduce the incidence or duration of postherpetic neuralgia, but may improve the rate of resolution of the neuritis or improve pain control.[12,13]

Severely **immunocompromised** patients or others at high risk of severe or disseminated herpes zoster should receive intravenous aciclovir. Oral aciclovir, famciclovir, or valaciclovir may be considered in less severely immunocompromised patients.[7] Sorivudine and brivudine are also effective against zoster infections.[14] Brivudine is as effective, if not more, than aciclovir in immunocompromised patients[15] but is not recommended in such patients because of a potentially fatal interaction with fluorouracil (and related drugs).[7] Sorivudine has been withdrawn from the market after deaths in patients also taking fluorouracil. Foscarnet may be of value in aciclovir-resistant varicella-zoster infections[16-18] although treatment failures have been reported.[19]

Ophthalmic herpes zoster is treated with an oral antiviral, given within 72 hours of the onset of the rash; additional treatment with topical aciclovir to the eye may also be considered. Oral aciclovir, famciclovir, and valaciclovir are all effective in reducing the pain associated with ophthalmic zoster.[20,21]

Prevention. Varicella-zoster immunoglobulins are used for the prevention of chickenpox in patients at high risk of developing complications, such as the immunocompromised, neonates whose mothers developed chickenpox 7 days before to 7 days after delivery, and in susceptible pregnant women after significant exposure. There have been reports of severe chickenpox occurring in patients undergoing corticosteroid therapy. In the UK, use of varicella-zoster immunoglobulins is recommended in persons exposed to the virus who have received high doses of corticosteroids within the previous 3 months[22] (see also Varicella, under Precautions for Corticosteroids, p.1494).

Varicella-zoster vaccines are available in some countries and in the UK vaccination is recommended for active immunisation against chickenpox in persons considered to be at high risk of either infection or complications, including healthy contacts of immunocompromised patients. In the USA, a 2-dose vaccination regimen is recommended as part of the primary immunisation schedule of infants and children. Routine vaccination is also recommended for persons over the age of 13 years without evidence of immunity[23] and a high-potency vaccine against herpes zoster is recommended for persons 60 years of age and older.[24] For further discussion of varicella-zoster vaccines, see p.2242.

Transmission of chickenpox to household contacts is not prevented by giving aciclovir to the primary case but there is evidence to suggest that transmission can be suppressed by giving aciclovir to susceptible contacts during the incubation period.[25,26] Although the need for such prophylaxis has been questioned, especially in otherwise healthy children,[27] prophylaxis or early treatment with antivirals may be useful for household contacts in whom the infection might prove to be more severe.[1,28,29]

HIV infection and AIDS

The causative agent of AIDS (acquired immunodeficiency syndrome) is the human immunodeficiency virus (HIV; previously known as HTLV-III or LAV), a retrovirus transmitted by sexual contact, blood and blood products, the use of contaminated needles, or vertically from mother to fetus. Two subtypes of HIV have been identified. The most common is HIV-1, which occurs worldwide. HIV-2 is found mainly in West Africa and is associated with a slower progression to AIDS than HIV-1.

HIV uses the CD4 receptor and the CCR5 or CXCR4 co-receptors to enter T lymphocytes and monocytes/macrophages, where viral RNA is reverse transcribed into DNA and inserted into the host genome. Viral replication results in immune activation and progressive depletion of CD4+ T lymphocytes. Primary HIV infection is characterised by the development of non-neutralising HIV antibodies (seroconversion), and in some patients may manifest as a transient rash, sore throat, and lymphadenopathy (seroconversion illness). Primary HIV infection is usually followed by a largely asymptomatic chronic infection, during which persistent generalised lymphadenopathy may be noted. Chronic HIV infection is characterised by gradual depletion of CD4+ T lymphocytes resulting in progressive immunodeficiency. This may become clinically apparent when symptoms such as fatigue, weight loss, recurrent fever, diarrhoea, or thrush occur. Alternatively, patients may develop severe opportunistic infections such as pneumocystis pneumonia, toxoplasma encephalitis, oesophageal candidiasis, cryptococcal meningitis, CMV retinitis, *Mycobacterium avium* complex, recurrent bacterial pneumonia, pulmonary or extrapulmonary tuberculosis, or neoplasms such as Kaposi's sarcoma, cervical carcinoma, and lymphomas; these are collectively referred to as AIDS-defining illnesses. AIDS-defining illnesses generally do not occur until severe immunodeficiency is present (CD4+ T lymphocyte count of less than 200 cells/microlitre or less than 14% of the total lymphocyte count). Most AIDS-defining events can therefore be prevented if effective HIV treatment is started before the CD4+ count has fallen to this level. Since the availability of highly active antiretroviral therapy (HAART), the incidence of AIDS-defining illnesses has markedly declined. However, antiretroviral therapy may result in toxicity or paradoxical worsening of underlying opportunistic infections.

During the course of chronic HIV infection, measurement of the CD4+ count and HIV RNA (viral load) will aid prognosis. The absolute CD4+ count or CD4% reflects the susceptibility to opportunistic infections while a high HIV viral load is associated with a more rapid decline in CD4+ count and more rapid clinical disease progression. The HIV viral load is also used to monitor success of antiretroviral therapy, where the goal is complete suppression of viral replication (resulting in undetectable HIV viral loads). CD4+ counts and viral loads are both taken into consideration in the decision to start antiretroviral therapy.

TREATMENT.

The following discussion relates to the use of antiretrovirals in HIV infection and AIDS. The treatment of secondary and opportunistic infections and other complications is covered under the relevant sections, below.

Treatment strategies for HIV infection are changing rapidly and guidelines for the treatment of HIV infection have been published and frequently updated for the USA,[1-3] for the UK,[4] and by WHO[5-7] for resource-limited settings.

Data from clinical studies in support of treatment of *acute* HIV infection are limited. Treatment of the primary HIV infection may be beneficial in relieving symptoms due to HIV during the seroconversion illness; it may restrict damage to the immune system, reduce the viral load set point once treatment is stopped and reduce the rate of viral mutation and risk of HIV transmission to sexual partners.[8] The UK guidelines do not recommend early treatment of acute HIV infection, but suggest that patients be offered enrolment in clinical studies to evaluate the issue.[4] US guidelines[2] state that treatment of acute infection is optional.

In *chronic* infection, the goal of antiretroviral therapy is to prevent or reverse immunodeficiency, prevent opportunistic infections, and prolong survival. The decision of when to start antiretroviral therapy should be individualised to take into account patient-specific relative risks and benefits of treatment. Guidelines[1,2,4-6] recommend that antiretroviral treatment should be given to patients whose CD4+ counts have fallen below 200 to 350 cells/microlitre or who have symptomatic disease, irrespective of their viral load or CD4+ count. Treatment is generally not indicated for asymptomatic patients with a CD4+ count greater than 350 cells/microlitre but may be considered for patients with a viral load greater than 100 000 copies/mL.

Combination therapy with antiretroviral drugs aims to improve potency, minimise toxicity, and delay drug resistance. The drugs used in combination therapy are:

- nucleoside reverse transcriptase inhibitors (abacavir, didanosine, emtricitabine, lamivudine, stavudine, zalcitabine, and zidovudine) or the nucleotide reverse transcriptase inhibitor tenofovir
- HIV-protease inhibitors (amprenavir, atazanavir, darunavir, fosamprenavir, indinavir, lopinavir, nelfinavir, ritonavir, saquinavir, and tipranavir)

- non-nucleoside reverse transcriptase inhibitors (delavirdine, efavirenz, nevirapine, and etravirine)
- the entry inhibitors, including the HIV-fusion inhibitor enfuvirtide, the CCR5-antagonist maraviroc, and the HIV-integrase inhibitors raltegravir and elvitegravir

Although ritonavir inhibits HIV-protease when given in high doses, it is almost exclusively used in low doses for its CYP450 inhibitory properties, to boost the plasma concentrations of co-administered HIV-protease inhibitors. Combination of three antiretrovirals, typically two nucleoside/nucleotide reverse transcriptase inhibitors (NsRTI/NtRTI) plus either a (boosted) HIV-protease inhibitor (PI) or a non-nucleoside reverse transcriptase inhibitor (NNRTI), is referred to as ***highly active antiretroviral therapy*** (***HAART***). Such regimens have produced sustained reductions in viral load often to levels below the limit of detection, and have been associated with improvements in CD4+ count, immune function, and clinical well-being. This is reflected by the decline in morbidity and mortality among patients with HIV infection since the availability of HAART. Triple therapy regimens, consisting of at least 2 classes of antiretrovirals, are superior to monotherapy, dual therapy, or triple NRTI therapy. Quadruple therapy regimens may be of benefit in some patients but are likely to increase toxicity. Complete suppression of viral replication minimises the emergence of drug-resistant HIV.[9-11]

When considering combination antiretroviral therapy several factors need to be taken into consideration. Drug combinations should provide additive or synergistic antiviral activity without increased toxicity or pharmacokinetic interactions that may affect the efficacy of co-administered drugs. Drugs with maximal potency should be combined so as to minimise the risk of drug resistance developing. The patient's ability to adhere to a regimen and the likelihood of pregnancy should also be taken into consideration.

In the developed world the availability of co-formulations of zidovudine with lamivudine, abacavir with lamivudine, and tenofovir with emtricitabine, and concerns over the toxicity of stavudine and zalcitabine have resulted in most treatment-naive patients starting with one of these combinations. There has been a shift from zidovudine/lamivudine to abacavir/lamivudine or to tenofovir/emtricitabine because of concern over the adverse effects and long-term toxicity (lipoatrophy) associated with zidovudine. Similarly, among the NNRTIs, delavirdine is now rarely used and a shift from nevirapine to efavirenz has occurred because of the potential of nevirapine to cause severe skin and liver toxicity. HIV-protease inhibitors are almost exclusively used with ritonavir boosting. Giving amprenavir, atazanavir, darunavir, fosamprenavir, indinavir, lopinavir, saquinavir, or tipranavir, with ritonavir, improves the pharmacokinetic properties and clinical efficacy of these HIV-protease inhibitors.

Although HAART regimens are generally most effective in antiretroviral-naive patients, good responses can also be achieved in treatment-experienced patients.[12] In patients who have an inadequate response to therapy, adherence needs to be carefully assessed and reasons for potential non-adherence addressed. If a patient has drug toxicity, intolerance to therapy, or for any other reason is unable to adhere to therapy, a change of drugs should be considered. Change of treatment should also be considered if the patient has a suboptimal virologic response to their current antiretroviral therapy and may be considered in those with limited gains or decreases in their CD4+ count or clinical deterioration while on fully suppressive regimens.

Choice of second-line regimen is essentially empirical, since there is a lack of evidence from controlled studies.[13] When a new regimen is started, 2 to 3 drugs should be included to which the patient has not been exposed or to which the virus is not resistant. A failing regimen of two NRTIs and an NNRTI may be replaced by a boosted HIV-protease inhibitor with one or two different NRTIs. When patients fail on an NRTI and a boosted HIV-protease inhibitor, consideration needs to be given to an increase in the dose of the HIV-protease inhibitor, substitution with a HIV-protease inhibitor with limited cross-resistance, and/or the addition of a drug with a different mechanism of action, such as the HIV-fusion inhibitor enfuvirtide.[1,2,4] Boosted tipranavir[14,15] or darunavir,[16] when used as part of a multi-drug regimen, result in better viral suppression and CD4+ count increases in patients with multidrug resistant HIV-1 infection than standard ritonavir-boosted HIV-protease inhibitors, particularly when given with at least one (preferably two) active agents such as enfuvirtide or etravirine.[17,18] Addition of a single antiretroviral drug to a failing combination regimen is generally not recommended because further resistance may result.[1,2,4]

While HAART maintains plasma viral load at undetectable levels in most patients, viral replication rapidly returns to pretreatment levels once treatment is stopped. Treatment interruption may be associated with a precipitous decline of CD4+ count, clinical disease progression, and the development of drug resistance. Structured treatment interruptions (or planned breaks) are generally not recommended in patients with HIV infection, even if drug-resistance results in chronic non-suppression of HIV RNA.[1,2,4,19] The continued effectiveness of any HAART regimen is dependent on strict adherence to treatment. The improved formulation and co-formulation of several antiretrovirals has reduced the pill burden and newer drugs tend to have fewer adverse effects. However, the cost of treatment is high and access to effective treatment in developing countries with high burdens of disease, although improving, remains limited.[5]

Newer antiretroviral drugs to further reduce pill burden and limit toxicity are in development. In addition, drugs with enhanced activity against resistant isolates, such as HIV-entry inhibitors (that inhibit the three steps of HIV entry: CD4 attachment, chemokine receptor binding, and membrane fusion) and HIV-integrase inhibitors are under investigation.[20,21] Interleukin-2 may improve the CD4+ count in patients with advanced HIV infection, or preserve CD4+ counts in patients with early HIV infection (see p.736). However, it is unclear whether this prevents opportunistic infections and the role of interleukin-2 remains to be defined. A number of vaccines aimed at preventing HIV infection or reducing the HIV viral load are currently under investigation (see AIDS Vaccines, p.2203).

HIV-associated infections and complications. Infections. Patients with HIV infection and AIDS are at increased risk of specific bacterial, fungal, protozoal, and viral infections largely as a result of impaired cell-mediated immunity. With the introduction of antimicrobial prophylaxis and HAART there has been a significant decrease in the incidence of most AIDS-defining opportunistic infections, especially in the developed world. However, HIV-related opportunistic infections and deaths still occur in patients newly diagnosed with HIV infection, in those in the early course of HAART, in those non-adherent to their HIV treatment, or in those with drug-resistant HIV infection; deaths also result from non-opportunistic infections and chronic viral hepatitis.[1]

- Infections affecting the *lungs* include recurrent bacterial pneumonia (p.186), pneumocystis pneumonia (p.521), and pulmonary tuberculosis (p.196).
- Many pathogens cause *gastrointestinal-tract disease* in HIV-infected patients, including candida oesophagitis (p.518), CMV colitis (p.853), and amoebiasis (p.822), cryptosporidiosis (p.823), giardiasis (p.824), isosporiasis (p.824), or microsporidiosis (p.826).
- AIDS-defining *neurological* infections include AIDS dementia complex (HIV encephalopathy), cryptococcal meningitis (p.519), cerebral toxoplasmosis (p.826), and progressive multifocal leukoencephalopathy (see Infections in Immunocompromised Patients, p.859).
- *Systemic* opportunistic infections in AIDS patients include tuberculosis, coccidioidomycosis (p.518), histoplasmosis (p.519), and *Mycobacterium avium* complex infections (see Nontuberculous Mycobacterial Infections, p.181). CMV retinitis (p.853) may be a cause of blindness, while chronic herpesvirus infections (p.853) may affect the skin and gastrointestinal tract.

Recommendations have been published for both treatment[2,3] and prophylaxis[4] of opportunistic infections in AIDS patients. Recovery of immune function in patients responding to HAART may be sufficient to protect against certain opportunistic infections and to allow primary or secondary prophylaxis to be stopped.[1,5]

Other complications. Non-infectious complications of HIV infection include renal disease, metabolic and skeletal disorders, toxicities of HAART, and malignancies (below).

Black patients with HIV infection may develop chronic or end-stage *renal disease* due to HIV-associated nephropathy (HIVAN) or thrombotic microangiopathy. Acute renal failure is common in hospitalised patients with (opportunistic) infections, malignancies, or hepatitis C co-infection, while proteinuria is common in all HIV patients and may reflect an increased risk of cardiovascular events. Antiretrovirals, in particular tenofovir and indinavir, may cause renal dysfunction.[6-9] Guidelines for the management of chronic kidney disease in HIV-infected patients have been developed by the HIV Medicine Association of the Infectious Diseases Society of America.[6]

Metabolic complications associated with HIV infection and HAART include dyslipidaemia, abnormal glucose metabolism (insulin resistance, impaired glucose tolerance, and diabetes mellitus), and bone disorders (osteopenia, osteoporosis, and osteonecrosis); hepatic steatosis may occur with or without lipodystrophy in the form of lipohypertrophy (fat accumulation) or lipoatrophy (fat loss). HAART may occasionally cause lactic acidosis.[10,11]

Pancytopenia is commonly seen in patients with advanced HIV infection, and *neurological syndromes* such as aseptic meningitis, headache, neuropathy, myopathy, and Guillain-Barré syndrome, may occur at any stage of the infection.

HIV-associated malignancies. There is an increased incidence of certain malignancies in patients with HIV infection. Malignancies commonly associated with HIV infection are Kaposi's sarcoma (p.675), Hodgkin's disease, non-Hodgkin's lymphoma and primary CNS lymphoma (see AIDS-related Lymphomas, p.657), invasive cervical cancer (p.663), and anal cancer (see Malignant Neoplasms of the Anus, p.666). Some tumours may regress in response to effective antiretroviral therapy. Guidelines for the management of HIV-associated malignancies have been issued by the British HIV association.[1]

1. Bower M, *et al.* AIDS Malignancy Subcommittee. British HIV Association guidelines for HIV-associated malignancies 2008. *HIV Med* 2008; **9:** 336–88. Also available at: http://www.bhiva.org/files/file1030995.pdf (accessed 28/08/08)

HIV-associated wasting. Severe malnutrition in HIV-infected patients is recognised as wasting syndrome[1-4] and has been defined as an involuntary loss of body-weight of 10% or more (of both lean and fat tissue) and may be associated with fatigue, fever, and diarrhoea (not explained by another cause). However, there is some debate as to whether it should be defined as the loss of 5 or 10% of usual weight and whether changes in body composition, rather than weight alone, better define the syndrome. Wasting is associated with morbidity and mortality in advanced HIV infection and AIDS. Wasting syndrome has been associated with inadequate oral intake, malabsorption syndrome, metabolic disorders, hypogonadism, and increased cytokine production. Weight loss and malnutrition tend to be less severe in patients taking HAART. However, loss of body cell mass may occur in patients given HAART and needs to be differentiated from fat redistribution (lipodystrophy).

Since HIV replication is central to the pathogenesis of wasting syndrome, antiretroviral therapy is indicated. Nutritional intervention, exercise, and drug treatment may be indicated in patients who have an incomplete response to antiretroviral therapy. Drugs that have been tried include growth hormone, the appetite stimulants dronabinol and megestrol, the growth hormone mediator mecasermin, steroid hormones (testosterone and testosterone analogues), synthetic anabolic steroids (nandrolone, oxandrolone, and oxymetholone), and drugs that decrease cytokine production such as pentoxifylline and thalidomide. A suggested initial approach to the management of wasting[3] is to increase dietary intake of protein or total calories. Nutritional supplementation and exercise should always be considered and encouraged before drug treatment is started. Testosterone replacement may be given to HIV-infected men with significant weight loss and low testosterone levels, and megestrol may be given to patients who are unable to voluntarily increase or maintain total energy intake. Other drug treatments such as growth hormone and anabolic steroids may be considered where rapid weight loss is associated with acute infection and in severe cases of continued weight loss refractory to non-drug therapies.

HIV infection prophylaxis

Non-occupational exposure to HIV. Behavioural changes are the most effective methods of reducing the spread of HIV infection in the general population. These include the promotion of safe sex practices and needle exchange schemes for intravenous drug users. Guidelines have been published in the USA[1] for postexposure prophylaxis (PEP) after sexual activity, intravenous drug use, or other non-occupational exposure to HIV amongst the general population:

- a 28-day course of HAART is recommended for persons who have had non-occupational exposure to potentially infected body fluids of a person known or suspected to have HIV infection when there is a substantial risk of transmission and when the person presents within 72 hours of exposure
- for persons seeking care within 72 hours of non-occupational exposure from a person of unknown HIV status, or when such exposure would represent a substantial risk for transmission if the source were HIV-infected, it is recommended that risks and benefits of PEP be evaluated on an individual case basis
- PEP is generally not recommended for persons seeking care where there is no substantial risk for HIV transmission or for those presenting more than 72 hours after exposure (although it may be considered for persons seeking care after more than 72 hours if the exposure represents a substantial risk for transmission)

Guidelines for non-occupational PEP have also been produced in the UK[2] for exposure outside the healthcare setting and are similar to those for occupational exposures (see below); when given, PEP should be started as soon as possible after exposure.

Occupational exposure to HIV. The risk of seroconversion is estimated at about 0.3 to 0.4% after percutaneous contamination with HIV-infected blood and considerably less for accidents involving contamination of intact skin or mucous membranes. In view of potential toxicity of antiretrovirals, the decision whether to give PEP should balance the risk of infection against the potential drug toxicity and PEP should generally only be offered to intermediate to high-risk cases. Factors associated with increased risk of occupationally-acquired HIV infection include:

- deep injury
- visible blood on the device which caused the injury
- injury with a needle which had been placed in a source patient's artery or vein
- primary HIV infection or terminal HIV-related illness in the source patient

If PEP is given it should be started as soon as possible after the exposure. Zidovudine monotherapy has been extensively used for PEP and reduces seroconversion after percutaneous exposure by 79%. PEP with combination antiretroviral drugs is now preferred as it results in more complete suppression of viral replication and is more likely to afford some protection against drug-resistant HIV strains.

Guidelines for the UK[2] recommend a 4-week course of antiretroviral therapy after occupational percutaneous, mucous membrane, or broken skin site exposure to high-risk body fluids or tissues known to be, or suspected of being, infected with HIV. They advise that PEP emergency starter packs should contain two nucleoside reverse transcriptase inhibitors (NsRTIs) (zidovudine and lamivudine) and a boosted HIV-protease inhibitor (lopinavir-ritonavir). Nelfinavir was the recommended HIV-protease inhibitor of choice but it was recalled from the European market in June 2007. Alternative HIV-protease inhibitors include saquinavir and amprenavir.

Guidelines in the USA[3] recommend selection of PEP regimens based on the level of risk of transmission presented by the exposure and other considerations such as possible antiretroviral drug resistance in the source. Most occupational HIV exposures can be managed with a two-drug regimen, using two NsRTIs or one NsRTI and one nucleotide reverse transcriptase inhibitor (NtRTI). Although there are no definitive data to show increased efficacy of 3-drug PEP regimens over 2-drug regimens, the addition of further drugs may be considered for exposures that pose an increased risk of transmission or if antiretroviral drug resistance is likely. HIV-protease inhibitors are recommended as the preferred drug for inclusion into 3- or 4- drug regimens but the NNRTI, efavirenz, may be considered when resistance to HIV-protease inhibitors in the source person is known or suspected. Due to the higher risk for potentially serious or life-threatening adverse effects abacavir, delavirdine, nevirapine, zalcitabine, and the combination of didanosine and stavudine, are not recommended for PEP.

Measures aimed at reducing **vertical transmission** of HIV from mothers to their infants include antiretroviral therapy to the mother and baby, elective caesarean section, and avoidance of breast feeding when replacement feeding is acceptable, affordable, and safe.[4-8]

The risk of vertical transmission is directly proportional to the maternal plasma HIV viral load at the time of delivery, and very few HIV-infected children are born to mothers whose HIV viral load is undetectable (below 400 copies/mL). The benefit of elective caesarean section is therefore most profound in women with detectable or high HIV viral loads. In contrast, zidovudine monotherapy given during pregnancy and labour, and to the infant postpartum, reduces the rate of vertical transmission by about 70%, irrespective of maternal viral load or CD4+ count.[9,10] However, zidovudine monotherapy is suboptimal for mothers with high viral loads, in whom combination antiretroviral therapy should be used to prevent vertical transmission.

Guidelines for the management of HIV infection in pregnant women and for the prevention of transmission of HIV from mother to child have been developed for the USA[6] and the UK.[8] The US guidelines[6] recommend that zidovudine-based therapy is of proven benefit in preventing perinatal HIV transmission, but combination drug regimens should be considered the standard of care for both treatment of HIV infection in pregnant women and prevention of perinatal HIV transmission. Treatment to prevent the latter should be offered to all women, regardless of CD4 count:

- women who are taking HAART and become pregnant should continue with their regimen, although regimens with potentially teratogenic drugs such as efavirenz should be substituted in the first trimester, as should combinations with known adverse potential for the mother, such as stavudine/didanosine. Nelfinavir should be avoided because of concerns about potentially teratogenic contaminants from manufacturing. Treatment should be continued both during labour (with zidovudine given intravenously and other drugs orally), and postpartum
- women who have not had antiretroviral treatment and have indications for therapy should also begin HAART, subject to the same precautions as above; those who do not require HAART for their own health should be offered it for prevention of perinatal transmission, but treatment may be delayed until after the first trimester, and should be stopped postpartum unless indications for continuing it develop. If the regimen includes a long half-life NNRTI, consideration should be given to continuing NRTIs for 7 days after stopping the former
- women who have previously had antiretrovirals should be offered an HAART regimen based on resistance testing; use of zidovudine as a component of the regimen is recommended when feasible. Need for continuing therapy should be evaluated postpartum
- in all cases above, the *infant* should be treated with zidovudine intravenously or orally for 6 weeks, starting 6 to 12 hours after birth
- in women who have had no antiretroviral therapy before labour, treatment should be offered with:
  - *mother*: continuous infusion of zidovudine during labour; *infant*: zidovudine for 6 weeks started within 6 to 12 hours of birth

    or
  - *mother*: continuous infusion of zidovudine during labour, plus a single dose of nevirapine at onset; consideration should be given to adding lamivudine during labour and zidovudine and lamivudine for 7 days

postpartum, to reduce development of nevirapine resistance; *infant*: single oral dose of nevirapine at 2 to 3 days after birth, plus zidovudine for 6 weeks

- if the mother has no antiretroviral therapy either before or during labour, the infant should still be given zidovudine for 6 weeks, started as soon as possible after birth. The use of other drugs for prophylaxis in infants requires specialist consulation

While similar to those of the USA, the UK guidelines[8] recommend that zidovudine monotherapy combined with elective caesarean section may still be an option for pregnant women in whom HAART is contra-indicated and whose HIV viral load is less than 10 000 copies/mL, or for women not wishing to take HAART during pregnancy. Infants born to HIV-infected mothers should be given zidovudine for 4 weeks after birth. Alternative antiretroviral therapy may be given to infants whose mothers did not take zidovudine in their treatment regimen and triple therapy may be considered for infants whose mothers had no antiretroviral therapy or whose mothers are infected with drug-resistant HIV.

WHO has published guidelines on the use of antiretrovirals in pregnancy and for preventing HIV transmission to infants in resource-limited settings.[4,7] In countries where HAART is available, women with a CD4+ T lymphocyte count below 250 cells/microlitre and those with a CD4+ T lymphocyte count between 250 and 350 cells/microlitre who have other indications for antiretroviral treatment should start HAART during their pregnancy. The preferred regimen is zidovudine plus lamivudine and nevirapine. Women already taking antiretrovirals should continue their therapy; but consideration should be given to switching those who are in the first trimester of pregnancy and taking efavirenz to a nevirapine-containing regimen. Infants born to mothers taking HAART should be given zidovudine for 7 days from birth. Women in whom maternal HAART is not indicated, or those living in countries where HAART is not available, should be given short-course zidovudine starting at 28 weeks of pregnancy or as soon as feasible thereafter and continued into labour. A single dose of nevirapine should be given at the onset of labour to the mother followed by 7 days treatment with zidovudine and lamivudine to reduce the emergence of nevirapine resistance. Infants born to these mothers should be given zidovudine for 7 days from birth and a single dose of nevirapine within 72 hours of birth. Women presenting late in pregnancy and who have not received HAART or completed at least 4 weeks of zidovudine may be given one of the following regimens:

- a single dose of oral nevirapine plus oral zidovudine and lamivudine during delivery followed by 7 days postpartum treatment with oral zidovudine and lamivudine; the newborn should be given a single oral dose of nevirapine plus oral zidovudine for 4 weeks
- oral zidovudine and lamivudine during delivery, followed by 7 days postpartum treatment with oral zidovudine and lamivudine; the newborn should also get 7 days treatment with oral zidovudine and lamivudine
- a single dose of oral nevirapine at the onset of labour; the newborn should also have a single oral dose of nevirapine.

Infants born within 2 hours of the mother taking a single oral dose of nevirapine or to mothers who have taken less than 4 weeks of antiretroviral prophylaxis (or none at all), should be given a single dose of oral nevirapine immediately after birth plus 4 weeks of oral zidovudine.

Other measures necessary to minimise the transmission of infection include the rigorous selection of blood donors, microbiological screening of blood, and, where possible, heat treatment of blood products. Maternal vitamin A deficiency has been identified as a risk factor for vertical transmission in Africa (see p.1974). Nutritional intervention and vaginal cleansing during labour could reduce vertical transmission in regions where zidovudine therapy is not readily available.

Infections in immunocompromised patients

Most viral infections present in a more severe form in immunocompromised patients than in immunocompetent patients. Among the viral infections that may be a particular problem in immunocompromised patients are hepatitis, herpesvirus infections (including CMV and Epstein-Barr virus infections), measles, and RSV infections. For further information and treatment of these infections, see under the individual diseases. For secondary infections occurring in HIV-infected patients, see p.857.

Persistent infection with human **parvovirus B19** can cause red cell aplasia with resultant anaemia, particularly in immunocompromised patients; treatment with immunoglobulin has been reported to be successful.

Infection with a polyomavirus (JC virus)[1,2] can cause **progressive multifocal leukoencephalopathy**. Although no treatment has been consistently successful,[1] prolonged survival has been reported in patients receiving interferon alfa[3] and in those receiving HAART.[4-6] Cidofovir may be of benefit in patients unresponsive to HAART.[7,8]

Influenza

Influenza is an acute respiratory-tract infection caused by RNA viruses of the family Orthomyxoviridae. Three types of influenza virus, A, B, and C, have been classified. Type A causes most infections in man; type B causes a similar though possibly milder infection than type A; type C generally only causes mild infection. Epidemic influenza is usually caused by the type A influenza virus. Outbreaks of influenza due to the type A virus occur in most years while those due to the type B virus tend to occur at intervals of several years. Influenza viruses are antigenically labile with the principal surface antigens, haemagglutinin and neuraminidase, undergoing frequent changes. Major changes (antigenic shifts) in these surface antigens occur periodically and are responsible for the emergence of the subtypes of virus which may cause pandemic influenza; minor changes (antigenic drift) occur more frequently and are responsible for the annual epidemic outbreaks of influenza.

Influenza is transmitted from person to person in respiratory droplets with an incubation period of 1 to 2 days. Infection with influenza A or B virus usually lasts for about 1 to 2 weeks and is characterised by sudden onset of fever, chills, headache, malaise, myalgia, dry cough, nasal obstruction, and a dry or sore throat. Infections are usually acute but self-limiting and persons with pre-existing immunity, or those who have received influenza vaccine, have less severe symptoms. Complications that may occur in the course of infection include primary viral pneumonia, secondary bacterial pneumonia, croup, exacerbation of asthma or chronic bronchitis, myositis, Reye's syndrome, and the toxic shock syndrome. Patients at high risk of complications include the elderly, those with heart disease or chronic chest disease, and immunocompromised individuals.

Since 1997, infection of humans with avian influenza virus H5N1 (so-called 'bird flu') has been reported, initially in Hong Kong. Avian influenza may cause severe illness and is associated with high mortality. Since then cases have also been reported in other Asian countries and in the near East. Although the current H5N1 influenza strains appear not to be transmissible from human to human, it is of major concern that further mutations or mixing with human influenza strains could convert H5N1 to a strain that would spread from human to human and cause a serious pandemic.[1,2] WHO[3,4] has developed detailed guidelines for the pharmacological management of avian influenza in humans. Similar guidelines for the management of an influenza pandemic have been developed in many countries.[5-7]

The most effective means of **preventing** influenza is to provide seasonal vaccination with *influenza vaccine* adjusted to take account of current antigenic drifts and shifts and to provide protection against both influenza A and B. WHO[8] recommends that elderly individuals and persons of any age who are considered to be at high risk of influenza-related complications should be vaccinated. Similar recommendations have been made in the UK[9] and USA.[10]

In healthy adults living in industrialised countries, protective efficacy of influenza vaccine is about 70 to 90%, and vaccination of the elderly living in the community reduces the number of hospitalisations by 25 to 39% and death by 39 to 75%.[8] No vaccine is currently available for avian influenza.[2,11]

Four antiviral drugs are available for the prevention of influenza: the M2 ion channel inhibitors, amantadine and rimantadine, and the neuraminidase inhibitors, oseltamivir and zanamivir. Antivirals appear to act independently of vaccination and provide additional barriers to the virus, but should not be used as a substitute for vaccination. They may be considered for postexposure prophylaxis, for seasonal prophylaxis in unvaccinated individuals at high risk, for persons who take care of those at high risk, and in vaccinated individuals if an influenza outbreak occurs less than 2 weeks after vaccination with an inactivated vaccine, or if circulating influenza strains are thought to be different to the vaccine strain. Prophylaxis with antivirals may also be considered in vaccinated immunocompromised individuals whose antibody response to the vaccine is likely to be incomplete.[11,12]

Amantadine and *rimantadine*, when started before exposure and continued throughout the period of exposure, are effective in preventing influenza A in 60 to 90% of patients. They are ineffective against influenza B and therefore cannot be considered as a substitute for vaccination unless the vaccine is contra-indicated.[11,13] Additional problems with these drugs are the rapid development of viral resistance and subsequent spread of resistant virus to close contacts and the potential to cause serious CNS adverse effects.

Clinical studies in healthy adults indicate that both the neuraminidase inhibitors, *oseltamivir* and *zanamivir* are effective in preventing infection with influenza A and B in about 80% of individuals and both have been reported to prevent illness in persons in close contact with infected household members.[14,15]

In the USA, all 4 antiviral drugs are licensed for prophylaxis of influenza but only oseltamivir and zanamivir are recommended by the Advisory Committee on Immunization Practices[10] and the American Academy of Pediatrics.[16] In the UK, amantadine and oseltamivir are licensed for prophylaxis, but only oseltamivir is recommended by

NICE[17] for postexposure prophylaxis in persons 13 years of age or older at high risk of complications of influenza. Neither drug is recommended for seasonal prophylaxis of influenza.

For most people **treatment** of influenza is largely symptomatic and supportive. However, antivirals may be used for the treatment of vaccinated or unvaccinated individuals who develop symptoms. *Amantadine* and *rimantadine* have been shown to reduce the duration of uncomplicated influenza A infection when given within 48 hours of the onset of symptoms. These drugs may be considered for patients at high risk of complications. Treatment failures may be due to the rapid emergence of drug resistance.[11,13,18] They are not effective against influenza B or the avian influenza H5N1 strain.[11] *Oseltamivir* and *zanamivir* given within 48 hours of the onset of symptoms are active against both influenza A and B viruses and reduce the duration of uncomplicated influenza by about 1 day in healthy adults and adolescents. Data is limited and inconclusive for all 4 drugs in terms of effectiveness when given to individuals at high risk of complications of influenza. Neuraminidase inhibitors have several advantages compared with amantadine, including reduced viral resistance, additional efficacy against influenza B, fewer adverse effects (including CNS effects), and reduction in clinical symptoms. Viral strains resistant to amantadine and rimantadine generally remain susceptible to neuraminidase inhibitors.[14,15,18,19]

In the UK, oseltamivir and zanamivir are recommended[20] for the treatment of adults at risk of complications of influenza who can start treatment within 48 hours of the onset of symptoms. Only oseltamivir is recommended for the treatment of influenza in children. In the UK NICE does not recommend the use of amantadine for the treatment of influenza. In the USA, the Advisory Committee on Immunization Practices[10] and the American Academy of Pediatrics[16] recommend oseltamivir or zanamivir for treatment of acute illness caused by influenza A or B. Neuraminidase inhibitors have also been effective against some strains of avian influenza in animal studies and may be considered for both prophylaxis and treatment of suspected H5N1 disease.[2,11,16]

Measles

Measles[1] is an acute viral illness caused by an RNA virus of the Morbillivirus genus and of the family Paramyxoviridae. It is a highly contagious disease spread by airborne droplets or direct contact with respiratory secretions of infected persons. Infection confers lifelong immunity.

The incubation period for measles is about 8 to 12 days followed by a prodromal phase lasting several days. This phase is usually characterised by malaise, fever, conjunctivitis, cough, rhinitis, congestion, and later Koplik's spots on the buccal mucosa. An erythematous, maculopapular rash appears towards the end of the prodromal phase, starting on the face and spreading over the trunk and limbs. Measles is generally benign and uncomplicated and recovery usually takes place during the week after the rash's appearance. However, severe disease and complications may develop and are more common in adults and in children who are undernourished or immunocompromised. Most complications occur when the measles virus further suppresses host immune responses, resulting in a reactivation of latent infections or superinfection by bacteria. Respiratory complications include giant cell pneumonia, bronchopneumonia, and laryngotracheobronchitis, while neurological complications include febrile seizures, acute encephalitis, progressive subacute encephalitis, and the more slowly progressive subacute sclerosing panencephalitis (SSPE) which may develop several years after the original measles infection. Other complications include diarrhoea, otitis media, thrombocytopenia with purpura and bleeding, hepatitis, myocarditis, pericarditis, and severe keratitis that may progress to blindness.

Measles can be **prevented** by active immunisation with measles vaccine, and measles immunoglobulins may be used for passive immunisation against measles. Normal immunoglobulins may be used to prevent, or possibly modify, an attack of measles in those at risk of developing severe or fatal disease such as immunocompromised patients.

Measles usually requires only symptomatic and supportive **treatment** such as antipyretics and fluid replacement. *Vitamin A* treatment for children with measles in developing countries has been associated with a significant reduction in mortality (see p.1974). A systematic review of randomised studies concluded that a dose of 200 000 units of vitamin A given on 2 consecutive days reduced mortality in children under 2 years with measles.[2] WHO recommends that supplementary vitamin A be given to all children with measles in developing countries in order to prevent keratitis and blindness. A recent review has suggested that prophylactic antibacterials may be of benefit in preventing complications such as pneumonia, purulent otitis media, and tonsillitis in children with measles but of no benefit for conjunctivitis or gastro-enteritis;[3] evidence from earlier reviews did not support such use.[4,5] However, prompt antibacterial therapy should be given to those patients who develop keratitis, otitis media, or pneumonia. There appears to be no good evidence for the use of antivirals, although there are case reports of ribavirin being used to treat severely affected and immunocompromised adults with acute measles[6] or patients with subacute sclerosing panencephalitis (intravenous ribavirin plus intrathecal high-dose interferon alfa[7] or intraventricular ribavirin[8]). No controlled studies have been conducted and the use of ribavirin should be considered experimental.

Respiratory syncytial virus infection

Respiratory syncytial virus (RSV) is an RNA virus of the family Paramyxoviridae and occurs worldwide. RSV is a prominent cause of respiratory infections in infants and young children and is generally confined to the respiratory tract. However, disease may occur at any age, and it has been recognised as a cause of morbidity and mortality among the elderly,[1] as well as among children and adults with compromised cardiac, respiratory, or immune systems. RSV is spread from respiratory secretions through close contact with infected persons or contact with contaminated environmental surfaces. RSV infection is highly contagious and may result in extensive nosocomial transmission. RSV outbreaks tend to occur annually, usually from late autumn through to early spring.

Primary infection in infants and young children is characterised by fever, cough, runny or congested nose, vomiting, and sometimes wheezing. During the primary infection up to 50% of infants develop lower respiratory-tract disease, most commonly bronchiolitis and pneumonia, and about 1 to 2% of these infants may require hospitalisation. Most infants needing hospitalisation are less than 6 months old or at risk of severe infection, for example because of a history of prematurity, or pre-existing cardiac or respiratory diseases or immunodeficiency. Otitis media and persistent wheezing are common complications of RSV infection in infants and young children. RSV infection may trigger acute respiratory distress syndrome and exacerbate pre-existing, underlying cardiac, renal (nephrotic syndrome), or lung (cystic fibrosis) disease. Acquired immunity does not prevent re-infection, although subsequent infections are typically milder.

The **management** of mild RSV infection in infants and children[2-7] consists of supportive care such as fever control and adequate hydration. Children with more severe lower respiratory-tract disease may require hospitalisation for supplementary oxygen. Measures to limit the spread of infection in hospitals and institutions are important. Pharmacological therapies are of limited benefit. Beta$_2$-agonist *bronchodilators* are often used in the management of bronchiolitis even though systematic reviews and meta-analyses of studies have indicated only modest short-term benefit of clinical symptoms and no reduction in hospital admission rates, length of hospital stay, or improvement in oxygen saturation.[2,4,5,8] A review[9] of the use of the anticholinergic bronchodilator ipratropium bromide reported no proven efficacy. An evaluation of clinical studies[2] using nebulised or intravenous adrenaline to treat RSV infection has reported clinical benefit in some infants, as well as a reduction in hospital admission or stay. However, a systematic review[10] found insufficient evidence to support the use of adrenaline in inpatients, although there was a suggestion that it might be of short-term benefit in outpatients. Some recommend that if a trial with a bronchodilator or inhaled adrenaline is considered, treatment should be stopped if no response is evident after 1 or 2 treatments.[2,4,6]

Systemic *corticosteroids* are also widely used despite a lack of documented clear benefit. A systematic review[11] found little benefit in terms of length of hospital stay or admission rate and no evidence of improvement in clinical scores, respiratory rate, or oxygen saturation when compared with placebo. Although a later study[12] found that a 3-day course of oral prednisolone given to children aged 6 to 35 months with respiratory distress reduced disease severity, length of hospital stay, and the duration of symptoms another[13] showed that a single oral dose of dexamethasone was of no benefit in infants with moderate to severe bronchiolitis. Inhaled corticosteroids given during the initial acute phase of bronchiolitis did not prevent post-bronchiolitic wheezing.[14] The routine use of systemic corticosteroids is not recommended by expert groups.[6,7]

Ribavirin is the only antiviral drug that has been licensed for the treatment of infants and children with severe RSV bronchiolitis (and it is only available in some countries). Although some studies with aerosolised ribavirin have shown some clinical benefit in infants with lower respiratory-tract RSV infection, days of hospitalisation and short-term outcomes have not been affected.[2,15] Due to the small number of patients enrolled in these studies, evaluation of the effects has been difficult. Also, there are some difficulties in giving the drug, and concerns about occupational health and safety, and the high cost. Routine use is not recommended;[6,7] but it may be used for selected infants and children at risk of severe disease and complications. If used, ribavirin should be started early in the course of the disease.[2,3,6]

Antibacterials, although often used in the management of bronchiolitis, are not routinely recommended.[6,7] The results from three small studies[16] suggest that *surfactant* may reduce duration of ventilation and length of intensive care stay.

Prevention of RSV infection involves good infection control practices and use of *RSV immunoglobulin* and a human monoclonal antibody to RSV, *palivizumab*. Both RSV immunoglobulin and palivizumab can be given during an RSV outbreak to prevent serious complications of infection in infants and children considered at high risk. The effectiveness of RSV immunoglobulin[17] and palivizumab[18] were tested in randomised, placebo-controlled clinical studies involving high-risk infants and children (history of prematurity or with bronchopulmonary dysplasia). A 41% overall reduction in hospital admissions was reported in those given RSV immunoglobulin prophylaxis. Prophylaxis with palivizumab resulted in a 55% overall reduction in hospitalisation; reduction rates were 39% and 78% in those with and without bronchopulmonary dysplasia respectively. Respiratory severity scores, hospital days, days of oxygen requirement, and the rate of intensive care admission were also significantly lower in the palivizumab group than for the placebo group. Prophylaxis with palivizumab was also found to reduce post-bronchiolitic wheezing in premature infants.[19] It is recommended by some expert groups for prophylaxis in infants and children at high risk of severe RSV infections.[6,7,20] Vaccines to prevent RSV infection are currently under development.

SARS

Severe acute respiratory syndrome (SARS)[1,2] is a respiratory illness caused by a newly identified coronavirus (SARS-CoV). SARS presents primarily in previously healthy adults although there have been some cases reported in children. SARS-CoV is transmitted by contact or droplets and transmission mainly occurs during the second week of illness. The incubation period for SARS is usually 2 to 10 days but may be as long as 16 days. The disease manifests initially as flu-like prodromal symptoms, usually characterised by fever, malaise, myalgia, headache, and rigors. Cough (initially dry), dyspnoea, and diarrhoea may be present in the first week but are more commonly present in the second week of illness. Severe cases develop rapidly progressive respiratory distress and hypoxia and up to about 20% of patients may require intubation or mechanical ventilation. About 20% of patients develop large volume, watery diarrhoea. The overall fatality rate during the 2002–2003 SARS outbreak was about 9.5%.

There is currently no consensus on the optimal treatment for SARS and treatment recommendations are based on the experience gained during the 2002–2003 SARS outbreak. Guidelines for the **surveillance and management** of SARS have been developed by WHO.[3] In the UK guidelines[4] have been issued for the hospital management of adults with SARS, and others have also been developed by clinicians involved in the SARS outbreak in Hong Kong.[5] Because SARS is indistinguishable from pneumonia caused by viral and bacterial pathogens, empirical antibacterial treatment in accordance with local guidelines for severe community-acquired pneumonia (p.186) is recommended. Fluids and oxygen therapy should be given as required. Other treatments tried have included corticosteroids, ribavirin, interferons, normal immunoglobulins, and the co-formulated HIV-protease inhibitor ritonavir-boosted lopinavir. Corticosteroids, usually with ribavirin, were widely used and the timely use of high-dose corticosteroids may decrease fever, improve radiographic appearances, and reduce oxygen requirements.[6-8] There is, however, concern that high-dose and long-term use of corticosteroids may suppress the patient's immune system resulting in increased viral replication and possible bacterial or fungal superinfection. The UK guidelines recommend that their use be considered in moderate doses in severely ill patients with increased oxygen requirements.[4] Additionally there is no convincing clinical evidence that the use of ribavirin alters clinical outcome and the UK guidelines state that its routine use is not recommended.[4] Although interferon beta shows greater *in-vitro* antiviral activity against SARS-CoV, most experience during the 2002–2003 outbreak was with interferon alfa with or without normal immunoglobulins.[6] An open study[9] using interferon-alfacon-1 and high-dose pulse methylprednisolone reported more rapid improvement in radiographic appearance and oxygenation than corticosteroids alone. Better clinical improvement was reported in patients treated with daily interferon alfa plus high-dose corticosteroids than in those given interferon plus low-dose or limited corticosteroids.[8] The UK guidelines state that no recommendation can be given regarding the use of interferons.[4] Although normal immunoglobulins have been used in SARS their effectiveness cannot be established as they were usually given with other therapies.[6] A preliminary open study[10] with ritonavir-boosted lopinavir in 41 patients with probable SARS and receiving the local standard treatment of ribavirin and corticosteroids, reported an improved outcome at 21 days and reductions in viral load, corticosteroid dose, and the incidence of nosocomial infections.

Warts

Warts are caused by human papillomaviruses. The lesions present in several different forms and can affect any skin site although the hands, feet, and anogenital areas are most frequently affected. Anogenital warts are known as condylomata acuminata. Treatment generally relies on some form of local tissue destruction (see p.1584). Interferons have also been used (see p.891).

Abacavir *(BAN, rINN)*

Abacavirum; Abakaviiri; Abakavir. {(1*S*,4*R*)-4-[2-Amino-6-(cyclopropylamino)-9*H*-purin-9-yl]cyclopent-2-enyl}methanol.

ATC Vet — QJ05AF06.

NOTE. The code 1592U89 has been applied to abacavir succinate but is more properly reserved for abacavir sulfate.

Abacavir Sulfate *(USAN, rINNM)*

Abacavir, Sulfate d'; Abacavir Sulphate *(BANM)*; Abacaviri Sulfas; Sulfato de abacavir; 1592U89.

Абакавира Сульфат

$(C_{14}H_{18}N_6O)_2,H_2SO_4$ = 670.7.
CAS — 188062-50-2.
ATC — J05AF06.
ATC Vet — QJ05AF06.

NOTE. The code 1592U89 and its abbreviated form, 1592, have also been applied to abacavir and abacavir succinate.

Adverse Effects

The most significant adverse effects associated with antiretroviral regimens containing abacavir are severe hypersensitivity reactions, sometimes fatal, that may occur in up to 9% of patients given abacavir, especially (but not exclusively) during the first 6 weeks of treatment, or during intermittent therapy. Symptoms of hypersensitivity often include fever, rash, cough, dyspnoea, lethargy, malaise, headache, myalgia, and gastrointestinal disturbances, particularly nausea and vomiting, diarrhoea, and abdominal pain. Anaphylaxis has occurred. Caution is needed as hypersensitivity may be misdiagnosed as influenza, respiratory disease, or gastroenteritis. Erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis have occurred rarely. Other adverse effects associated with abacavir include pancreatitis and raised liver enzyme values. Lactic acidosis, sometimes fatal and usually associated with severe hepatomegaly and steatosis, has been reported in patients receiving NRTIs.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including abacavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been observed in patients receiving antiretroviral therapy, including abacavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction such as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Effects on the heart. For the possible risk of myocardial infarction in patients taking abacavir, see Effects on the Heart under Adverse Effects of Zidovudine, p.914.

Effects on the skin. Stevens-Johnson syndrome occurring in a patient receiving antiretroviral therapy with abacavir, lamivudine, and zidovudine was probably associated with abacavir.[1] Resolution occurred upon stopping antiretroviral therapy and the condition did not recur upon rechallenge with an alternative regimen also containing lamivudine and zidovudine.

Hypersensitivity. Reviews of hypersensitivity associated with abacavir.[1,2]

1. Hewitt RG. Abacavir hypersensitivity reaction. *Clin Infect Dis* 2002; **34:** 1137–42.
2. Hughes CA, *et al.* Abacavir hypersensitivity reaction: an update. *Ann Pharmacother* 2008; **42:** 387–96.

Precautions

Patients considered to be at increased risk for an abacavir hypersensitivity reaction are those that carry the human leucocyte antigen (HLA) HLA-B(*)5701 allele; screening patients for HLA-B(*)5701 allele before starting treatment with abacavir has been shown to reduce the risk of hypersensitivity reactions. Routine screening of all patients before starting treatment with an abacavir-containing product is therefore recommended. Abacavir should be stopped immediately if symptoms associated with hypersensitivity occur and should *never be restarted* in patients who have stopped therapy due to a hypersensitivity reaction. Patients should be closely monitored for signs of hypersensitivity during the first 2 months of treatment, although hypersensitivity reactions can occur at any time. Patients restarting therapy after an interruption are at particular risk even if they have not previously had symptoms of hypersensitivity. Since intermittent therapy may increase the risk of hypersensitivity developing, patients should be advised of the importance of regular dosing.

Abacavir should not be used in patients with moderate to severe hepatic impairment, and should be used with caution and reduced doses in those with lesser degrees of impairment and those with risk factors for liver disease. Treatment should be stopped if liver function deteriorates rapidly or if hepatomegaly or unexplained metabolic acidosis develop.

Abacavir should be avoided in patients with end-stage renal disease.

Interactions

Use of alcohol with abacavir may result in decreased elimination of abacavir and consequent increases in exposure. Abacavir increases the systemic clearance of oral methadone and patients should be monitored for signs of withdrawal symptoms. The dose of methadone may need to be increased in some patients.

Alcohol. References.

1. McDowell JA, *et al.* Pharmacokinetic interaction of abacavir (1592U89) and ethanol in human immunodeficiency virus-infected adults. *Antimicrob Agents Chemother* 2000; **44:** 1686–90.

Antiviral Action

Abacavir is converted intracellularly in stages to its active form carbovir triphosphate. This halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA.

◊ References.

Pharmacokinetics

Abacavir is rapidly absorbed after oral doses with a bioavailability of about 80%. Absorption is delayed slightly by food but the extent is unaffected. Abacavir crosses the blood-brain barrier. It is about 50% bound to plasma proteins. The elimination half-life is about 1.5 hours after a single dose. Abacavir undergoes intracellular metabolism to the active antiviral metabolite carbovir triphosphate. Elimination is via hepatic metabolism primarily by alcohol dehydrogenase and by glucuronidation and the metabolites are excreted mainly in the urine. There is no significant metabolism by hepatic cytochrome P450 isoenzymes.

Uses and Administration

Abacavir is a nucleoside reverse transcriptase inhibitor with antiretroviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when abacavir is used alone, and it is therefore used with other antiretrovirals.

Abacavir is given orally as the sulfate but doses are expressed in terms of the base; 1.17 g of abacavir sulfate is equivalent to about 1 g of abacavir. The adult dose is 300 mg twice daily or 600 mg once daily. For details of doses in children, see below. Doses should be reduced in patients with hepatic impairment (see below).

Fixed-dose combination products have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing abacavir in combination with lamivudine and with lamivudine and zidovudine are available in some countries.

3. Castillo SA, *et al.* Long-term safety and tolerability of the lamivudine/abacavir combination as components of highly active antiretroviral therapy. *Drug Safety* 2006; **29:** 811–26.

Administration in children. For the treatment of HIV infection in children 3 months of age and older, abacavir may be given orally as a tablet or solution with other antiretroviral drugs. Doses are based on body-weight:

- 14 to 21 kg: 150 mg (half a tablet) twice daily
- 22 to 29 kg: 150 mg (half a tablet) in the morning and 300 mg (1 tablet) in the evening
- 30 kg or more: 300 mg (1 tablet) twice daily

or

- the solution may be given in a dose of 8 mg/kg twice daily to a maximum dose of 300 mg twice daily

Administration in hepatic impairment. Abacavir should not be used in patients with moderate to severe hepatic impairment, although reduced oral doses of 200 mg twice daily may be given to patients with mild impairment (Child-Pugh score 5 to 6).

Aciclovir *(BAN, rINN)*

Aciclogunanosina; Aciclovirum; Aciklovír; Aciklovir; Acikloviras; Acycloguanosine; Acyclovir *(USAN)*; Acyklowir; Asikloviiri; Asiklovir; BW-248U. 9-[(2-Hydroxyethoxy)methyl]guanine; 2-Amino-1,9-dihydro-9-(2-hydroxyethoxymethyl)-6*H*-purin-6-one.

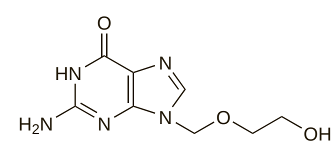
Ацикловир

$C_8H_{11}N_5O_3$ = 225.2.

CAS — 59277-89-3.

ATC — D06BB03; J05AB01; S01AD03.

ATC Vet — QD06BB03; QJ05AB01; QS01AD03.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Aciclovir). A white to almost white crystalline powder. Slightly soluble in water; very slightly soluble in alcohol; freely soluble in dimethyl sulfoxide; soluble in dilute solutions of alkali hydroxides and mineral acids.

USP 31 (Acyclovir). A white to off-white crystalline powder. Slightly soluble in water; insoluble in alcohol; soluble in dilute hydrochloric acid. Store in airtight containers. Protect from light and moisture.

Aciclovir Sodium *(BANM, rINNM)*

Aciclovir sódico; Aciclovir Sodique; Acyclovir Sodium *(USAN)*; Natrii Aciclovirum.

Натрий Ацикловир

$C_8H_{10}N_5NaO_3$ = 247.2.

CAS — 69657-51-8.

ATC — D06BB03; J05AB01; S01AD03.

ATC Vet — QD06BB03; QJ05AB01; QS01AD03.

Incompatibility. Aciclovir is reported to be incompatible with foscarnet.[1,2]

1. Lor E, Takagi J. Visual compatibility of foscarnet with other injectable drugs. *Am J Hosp Pharm* 1990; **47:** 157–9.
2. Baltz JK, *et al.* Visual compatibility of foscarnet with other injectable drugs during simulated Y-site administration. *Am J Hosp Pharm* 1990; **47:** 2075–7.

Stability. A study[1] found that aciclovir sodium solutions prepared with sodium chloride 0.9% and with dextrose 5% were stable for 7 and 21 days respectively when stored at 23°. Solutions stored at 4° were found to be stable for 35 days although subsequent storage at room temperature produced irreversible precipitation. Precipitation may also occur when freshly prepared solutions are refrigerated but the precipitate redissolves at room temperature. US licensed product information recommends that diluted solutions be used within 24 hours of preparation.

Adverse Effects

Aciclovir is generally well tolerated. When given intravenously as aciclovir sodium it may cause local reactions at the injection site with inflammation and phlebitis; these reactions may be associated with extravasation that can lead to tissue necrosis.

Renal impairment may be associated with systemic use of aciclovir in some patients; it is usually reversible and is reported to respond to hydration and/or dosage reduction or withdrawal, but may progress to acute renal failure. The risk of renal toxicity is increased by conditions favouring deposition of aciclovir crystals in the tubules such as when the patient is poorly hydrated, has existing renal impairment, or when the drug is given at a high dosage or by rapid or bolus injection. Some patients taking systemic aciclovir may have transient increases in blood concentrations of urea and creatinine although this is more acute with intravenous dosage.

Occasional adverse effects after systemic use include increased serum bilirubin and liver enzymes, haematological changes, skin rashes (including erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis), fever, headache, dizziness, and gastrointestinal effects such as nausea, vomiting, and diarrhoea. Anaphylaxis has been reported. Hepatitis and jaundice have been reported rarely. Reversible neurological effects including lethargy, somnolence, confusion, hallucinations, agitation, tremors, psychosis, convulsions, and coma have been reported in a small number of patients, particularly in those given intravenous aciclovir and with predisposing factors such as renal impairment; these effects may be more marked in older patients. Thrombotic thrombocytopenic purpura and haemolytic uraemic syndrome, sometimes resulting in death, have occurred in immunocompromised patients given high parenteral doses of aciclovir. Accelerated diffuse hair loss has also been reported.

Topical application of aciclovir may produce transient stinging, burning, itching, or erythema. Eye ointments may occasionally produce transient stinging, superficial punctate keratopathy, blepharitis, or conjunctivitis.

Effects on the blood. There has been no evidence of bone-marrow toxicity in patients given aciclovir after bone marrow transplantation.[1,2] However, megaloblastic haematopoiesis was seen in the bone marrow of 3 patients given aciclovir for suspected or proven herpes simplex encephalitis.[3] There has also been a report of inhibition of human peripheral blood lymphocytes in samples taken from healthy subjects given aciclovir.[4]

4. Tauris P, *et al.* Evaluation of the acyclovir-induced modulation of the plaque-forming cell response of human peripheral blood lymphocytes. *J Antimicrob Chemother* 1984; **13:** 71–7.

Effects on the kidneys. Aciclovir is excreted mostly by the kidney, and reaches high concentrations in the tubular lumen, but is relatively insoluble in urine and may therefore cause intratubular precipitation of crystals in the kidney. High doses, volume depletion, or pre-existing renal impairment increase the risk of aciclovir-associated acute renal failure, which has been reported in 12 to 48% of patients in some series. Although usually asymptomatic there may be nausea, vomiting, and flank pain, together with haematuria and pyuria. Most patients recover on stopping the drug and volume replacement, though some need temporary dialysis; use of a loop diuretic may be helpful in some cases. Slow infusion and adequate hydration can help to prevent crystal precipitation, and doses should be reduced in patients with underlying renal impairment.[1]

There are also occasional reports of renal toxicity apparently unrelated to crystal precipitation.[2-4]

1. Perazella MA. Crystal-induced acute renal failure. *Am J Med* 1999; **106:** 459–65.
2. Giustina A, *et al.* Low-dose acyclovir and acute renal failure. *Ann Intern Med* 1988; **108:** 312.
3. Eck P, *et al.* Acute renal failure and coma after a high dose of oral acyclovir. *N Engl J Med* 1991; **325:** 1178.
4. Johnson GL, *et al.* Acute renal failure and neurotoxicity following oral acyclovir. *Ann Pharmacother* 1994; **28:** 460–3.

Effects on the nervous system. Neurotoxicity, including tremor, confusion, myoclonus, agitation, lethargy, or hallucination, is an uncommon adverse effect of aciclovir, and may be hard to distinguish from progression of the underlying disease state. Renal impairment may increase the risk, although no clear relationship with peak plasma concentrations has been demonstrated; cases are also more common in elderly patients and those taking other neurotoxic drugs.[1] Of 143 patients given aciclovir by intravenous infusion in doses ranging from 0.75 to 3.6 g/m^2 daily for the treatment of herpesvirus infections after bone marrow transplantation, 6 developed reversible neurological symptoms including tremor, agitation, nausea, lethargy, mild disorientation, autonomic instability, hemiparaesthesia, and slurred speech.[2] EEGs were diffusely abnormal in all 6. Symptoms improved in all patients on withdrawing aciclovir; reinstituting aciclovir in 2 produced a recurrence of symptoms. Concomitant therapy included irradiation and methotrexate intrathecally for all 6, interferon alfa for 3, and ciclosporin for 1.

2. Wade JC, Meyers JD. Neurologic symptoms associated with parenteral acyclovir treatment after marrow transplantation. *Ann Intern Med* 1983; **98:** 921–5.

Effects on the skin. A report of vesicular lesions associated with intravenous use of aciclovir in a patient thought to have herpes simplex encephalitis.[1] Careful evaluation is necessary to differentiate the reaction from herpetic lesions.

1. Buck ML, *et al.* Vesicular eruptions following acyclovir administration. *Ann Pharmacother* 1993; **27:** 1458–9.

Vasculitis. Aciclovir has been associated with vasculitis. In one patient[1] it was one of many drugs given that may have caused a necrotising vasculitis. In another report an immunocompromised child with chickenpox given aciclovir by infusion developed a vasculitic rash which diminished on withdrawal of the drug.[2]

For a report of peripheral neuropathy associated with vasculitis due to the prodrug valaciclovir, see Effects on the Nervous System, p.911.

2. Platt MPW, Eden OB. Vasculitis in association with chickenpox treatment in childhood acute lymphoblastic leukaemia. *Lancet* 1982; **ii:** 763–4.

Precautions

Systemic aciclovir should be used with caution and in reduced doses in patients with renal impairment. The elderly and patients with existing renal impairment should be closely monitored for neurological adverse effects. Adequate hydration should be maintained in patients given parenteral or high oral doses of aciclovir. Intravenous doses should be given by infusion over one hour to avoid precipitation of aciclovir in the kidney; rapid or bolus injection should be avoided. The risk of renal impairment is increased by use with other nephrotoxic drugs. Intravenous aciclovir should also be used with caution in patients with underlying neurological abnormalities, with significant hypoxia, or with serious hepatic or electrolyte abnormalities.

Breast feeding. Aciclovir is distributed into breast milk[1-4] and in some instances higher concentrations are obtained than in maternal serum.[1-3] Licensed product information reports that a maternal oral dose of 200 mg five times daily could expose a breast-fed infant to 300 micrograms/kg daily and advises caution when giving nursing mothers aciclovir. However, no adverse effects have been seen in breast-fed infants whose mothers were taking aciclovir, and the American Academy of Pediatrics considers[5] that it is therefore usually compatible with breast feeding.

Pregnancy. The incidence of congenital abnormality and spontaneous fetal loss in 1246 cases of prenatal exposure to aciclovir did not significantly differ from those in the general population.[1]

1. Stone KM, *et al.* Pregnancy outcomes following systemic prenatal acyclovir exposure: conclusions from the International Acyclovir Pregnancy Registry, 1984-1999. *Birth Defects Res A Clin Mol Teratol* 2004; **70:** 201–7.

Sodium content. Each g of aciclovir sodium represents 4.05 mmol of sodium.

Interactions

Probenecid is reported to block the renal clearance of aciclovir. The risk of renal impairment is increased by use with other nephrotoxic drugs.

Antivirals. Use of *zidovudine* with aciclovir is not generally associated with additional toxicity.[1] However, there is a report[2] of a patient who had overwhelming fatigue when given aciclovir and zidovudine together; no such effect occurred when each drug was given alone.

Former product information for *interferon alfa-n1* reported progressive renal failure in patients also given aciclovir.

1. Tartaglione TA, *et al.* Pharmacokinetic evaluations of low- and high-dose zidovudine plus high-dose acyclovir in patients with symptomatic human immunodeficiency virus infection. *Antimicrob Agents Chemother* 1991; **35:** 2225–31.
2. Bach MC. Possible drug interaction during therapy with azidothymidine and acyclovir for AIDS. *N Engl J Med* 1987; **316:** 547.

Xanthines. For reference to evidence that aciclovir inhibits *theophylline* metabolism, resulting in accumulation, see p.1144.

Antiviral Action

Aciclovir is active against herpes simplex virus type 1 and type 2 and against varicella-zoster virus. This activity requires intracellular conversion of aciclovir by viral thymidine kinase to the monophosphate with subsequent conversion by cellular enzymes to the diphosphate and the active triphosphate. This active form inhibits viral DNA synthesis and replication by inhibiting the herpesvirus DNA polymerase enzyme as well as being incorporated into viral DNA. This process is highly selective for infected cells. Studies in *animals* and *in vitro* have found various sensitivities but show that target viruses are inhibited by concentrations of aciclovir that are readily achieved clinically. Herpes simplex virus type 1 appears to be the most susceptible, then type 2, followed by varicella-zoster virus.

The Epstein-Barr virus and CMV are also susceptible to aciclovir to a lesser extent. However, for CMV it does not appear to be activated by thymidine kinase and may act via a different mechanism. Epstein-Barr virus may have reduced thymidine kinase activity but its DNA polymerase is very sensitive to inhibition by aciclovir triphosphate, which may account for the partial activity.

Aciclovir has no activity against latent viruses, but there is some evidence that it inhibits latent herpes simplex virus at an early stage of reactivation.

Resistance

Herpes simplex virus develops resistance to aciclovir *in vitro* and *in vivo* by selection of mutants deficient in thymidine kinase. Other mechanisms of resistance include altered substrate specificity of thymidine kinase and reduced sensitivity of viral DNA polymerase. Resistance has also been reported with varicella-zoster virus, probably by similar mechanisms.

Although occasional treatment failures have been reported, resistance has not yet emerged as a major problem in treating herpes simplex infections. However, resistant viruses are more likely to be a problem in patients with a suppressed immune response; AIDS patients may be particularly prone to aciclovir-resistant mucocutaneous herpes simplex virus infections.

Viruses resistant to aciclovir because of absence of thymidine kinase may be cross-resistant to other antivirals phosphorylated by this enzyme, such as brivudine, idoxuridine, and ganciclovir. Viruses resistant because of altered substrate specificity of thymidine kinase may display cross-resistance to brivudine; those with altered DNA polymerase sensitivity may be resistant to brivudine and vidarabine. However, those viruses with altered enzyme specificity or sensitivity tend to have variable cross-resistance patterns and may be relatively susceptible to the aforementioned antivirals.

Pharmacokinetics

Aciclovir is poorly absorbed from the gastrointestinal tract after oral doses. Bioavailability of oral aciclovir is about 10 to 20%; orally active prodrugs such as valaciclovir (p.911) have been developed to overcome this poor absorption.

After intravenous dosage as aciclovir sodium it is widely distributed to body tissues and fluids including the CSF where concentrations achieved are about 50% of those achieved in plasma. Protein binding is reported to range from 9 to 33%.

Aciclovir is excreted largely unchanged in the urine, by glomerular filtration and some active tubular secretion, with up to 14% appearing in the urine as the inactive metabolite 9-carboxymethoxymethylguanine. In patients with normal renal function, the half-life is about 2 to 3 hours. In patients with chronic renal failure, this value is increased and may be up to 19.5 hours in anuric patients. During haemodialysis the half-life has been reported to be reduced to 5.7 hours, with 60% of a dose of aciclovir being removed. Faecal excretion may account for about 2% of a dose.

Probenecid increases the half-life and the area under the plasma concentration-time curve of aciclovir.

Aciclovir crosses the placenta and is distributed into breast milk in concentrations about 3 times higher than those in maternal serum.

Absorption of aciclovir is usually slight after topical application to intact skin, although it may be increased by changes in formulation. Aciclovir is absorbed after application of a 3% ointment to the eye giving a relatively high concentration in the aqueous humour but negligible amounts in the blood.

Uses and Administration

Aciclovir is a synthetic purine nucleoside analogue structurally related to guanine. It is used mainly for the treatment and prophylaxis of viral infections due to herpes simplex virus types 1 and 2 (p.854) and varicella-zoster virus (herpes zoster and chickenpox—p.855).

Herpes simplex infections, including herpes keratitis, herpes labialis, and genital herpes, respond to aciclovir by the intravenous, oral, or topical route, given as soon as possible after symptoms appear. Both initial and recurrent infections can be successfully treated. Prolonged treatment can reduce the incidence of recurrence which is particularly important in immunocompromised patients. However, when prolonged treatment is withdrawn, infections may recur.

Aciclovir also improves the healing of herpes zoster lesions and reduces acute pain when given intravenously or by mouth; use to prevent postherpetic neuralgia is controversial (see p.9). Beneficial effects may be more marked in immunocompromised patients.

Aciclovir is given by ***intravenous infusion*** as the sodium salt over 1 hour. Doses are expressed in terms of the base. Aciclovir sodium 1.1 g is equivalent to about 1 g of aciclovir. Solutions for infusion are usually prepared to give a concentration of aciclovir of 25 or 50 mg/mL; this must then be further diluted to a final concentration not greater than about 5 mg/mL (0.5%). Alternatively, a solution containing 25 mg/mL may be given by injection using a controlled-rate infusion pump, over 1 hour. In obese patients the dose should be calculated on the basis of ideal body-weight, to avoid overdosage.

For **herpes simplex infections** in the *immunocompromised*, and for severe initial *genital herpes*, or for *prophylaxis* of herpes simplex infections in *immunocompromised* patients the dose by the intravenous route is 5 mg/kg given every 8 hours, and recommended periods of treatment range from 5 to 7 days. A higher dose of 10 mg/kg every 8 hours is given in the treatment of *herpes simplex encephalitis*, and treatment is usually continued for 10 days.

For **varicella-zoster infections** in immunocompetent patients, a dose of 5 mg/kg every 8 hours may also be given. In *immunocompromised* patients the higher dose of 10 mg/kg every 8 hours should be used.

Oral doses of aciclovir also vary according to indication. In **herpes simplex infections**:

- for treatment of *primary infections*, including genital herpes, the usual oral dose is 200 mg five times daily (usually every 4 hours while awake) for 5 to 10 days
- severely *immunocompromised* patients or those with *impaired absorption* may be given 400 mg five times daily for 5 days
- for *suppression* of recurrent herpes simplex in *immunocompetent* patients, the oral dose is 800 mg daily in two to four divided doses; dosage reduction to 400 to 600 mg daily can be tried. Higher doses of 1 g daily have also been used. Therapy should be interrupted every 6 to 12 months for reassessment of the condition

  Chronic suppressive treatment is not suitable for mild or infrequent recurrences of herpes simplex. In such cases *episodic treatment* of recurrences may be preferred; a dose of 200 mg five times daily for 5 days has been recommended, preferably begun during the prodromal period.
- for *prophylaxis* of herpes simplex in *immunocompromised* patients, the dose is 200 to 400 mg four times daily.

The usual oral dose of aciclovir for treatment of **chickenpox** is 800 mg four or five times daily for 5 to 7 days; for herpes zoster 800 mg five times daily may be given for 7 to 10 days.

In **herpes simplex infections of the skin**, including genital herpes and herpes labialis, ***topical treatment*** with an ointment or cream containing aciclovir 5% may be applied 5 or 6 times daily for periods of 5 to 10 days, preferably beginning in the prodromal period as soon as signs or symptoms occur. In herpes simplex **keratitis** a 3% eye ointment may be applied 5 times daily until 3 days after healing.

Doses should be reduced in *renal impairment* (see below).

For details of doses in children, see Administration in Children, below.

◊ Reviews.

1. Wagstaff AJ, *et al.* Aciclovir: a reappraisal of its antiviral activity, pharmacokinetic properties and therapeutic efficacy. *Drugs* 1994; **47:** 153–205.
2. Leflore S, *et al.* A risk-benefit evaluation of aciclovir for the treatment and prophylaxis of herpes simplex virus infections. *Drug Safety* 2000; **23:** 131–42.

Administration in children. Aciclovir is licensed for use in infants and children for the treatment of herpes simplex and varicella-zoster infections, and for the prophylaxis of herpes simplex infections in the immunocompromised. It may be given by slow intravenous infusion over 1 hour, or orally.

Recommended ***intravenous doses*** vary according to country and age of the patient.

In the *UK* the 8-hourly dose for children aged 3 months to 12 years is calculated by body-surface. The usual course of treatment is 5 to 10 days:

- herpes simplex and varicella-zoster infections in immunocompetent patients: 250 mg/m^2
- varicella-zoster infection in immunocompromised children or those with herpes simplex encephalitis: 500 mg/m^2

In the *USA*, the 8-hourly intravenous dose for children aged 3 months to 12 years is calculated by body-weight:

- herpes simplex infections: 10 mg/kg for 7 days
- varicella-zoster infections in immunocompromised children: 20 mg/kg for 7 days
- herpes simplex encephalitis: 20 mg/kg for 10 days

In the *UK* and the *USA* the intravenous dose for neonates and infants up to 3 months of age is calculated by body-weight; an 8-hourly intravenous dose of 10 mg/kg may be given for the treatment of herpes simplex infections. Treatment for neonatal herpes simplex usually continues for 7 or 10 days. Higher intravenous doses of up to 20 mg/kg for at least 7 days have been recommended by the *BNFC* in neonates with varicella-zoster infections. A similar dose given for 14 days (21 days if CNS involvement) is also recommended in the treatment of disseminated herpes simplex in neonates and infants up to 3 months of age.

In the *UK* the following ***oral doses*** are permitted in the treatment of herpes simplex infections, and in the prophylaxis of herpes simplex infections in the immunocompromised:

- 2 years and over: usual adult dose (see above)
- under 2 years: half usual adult dose

In the *UK* and the *USA* the oral doses for the treatment of chickenpox are:

- over 2 years: 20 mg/kg, up to a maximum of 800 mg, four times daily for 5 days

  Alternatively, the following oral doses may be used:
- under 2 years: 200 mg four times daily
- 2 to 5 years: 400 mg four times daily
- 6 years and over: 800 mg four times daily

Administration in renal impairment. Doses of aciclovir should be reduced in renal impairment according to creatinine clearance (CC) and licensed product information gives the following guidance:

intravenous dosage:

- CC between 25 and 50 mL/minute: the interval between infusions may be increased to 12 hours
- CC 10 to 25 mL/minute: the interval between infusions may be increased to 24 hours
- CC less than 10 mL/minute: patients on *peritoneal dialysis* should receive half the usual appropriate dose given once every 24 hours; patients on *haemodialysis* should receive half the usual dose every 24 hours plus an extra half-dose after haemodialysis

oral dosage:

- CC less than 10 mL/minute: *herpes simplex infections*: 200 mg every 12 hours; *varicella-zoster infections*: 800 mg every 12 hours
- CC between 10 and 25 mL/minute: *varicella-zoster infections*: 800 mg three times daily every 8 hours

Erythema multiforme. For patients with recurrent erythema multiforme (p.1580) associated with herpes simplex infection a 5-day course of oral aciclovir at the start of the infection has been proposed to prevent the subsequent skin lesions.[1] If this fails, a 6-month course of oral aciclovir has been found to be of benefit,[2] even if the association with herpes is not obvious. It should be noted, however, that erythema multiforme may occur as an adverse effect of systemic aciclovir.

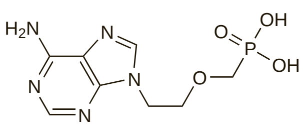
ATC Vet — QJ05AF08.



Adefovir Dipivoxil *(BANM, USAN, rINNM)*

Adefovir Dipivoksil; Adéfovir Dipivoxil; Adefovirum Dipivoxilum; Dipivoxilo de adefovir; GS-0840; Piv2PMEA; *Bis*(POM)PMEA. 9-[2-({Bis[(pivaloyloxy)methoxy]phosphinyl}methoxy)ethyl]adenine.

Адефовир Дипивоксил

$C_{20}H_{32}N_5O_8P$ = 501.5.

CAS — 142340-99-6.

ATC — J05AF08.

ATC Vet — QJ05AF08.

Adverse Effects

The most common adverse effects reported from adefovir have been gastrointestinal effects including nausea, flatulence, diarrhoea, dyspepsia, and abdominal pain. Other common adverse effects are headache and asthenia. There have also been reports of pruritus and skin rashes. Increases in serum-creatinine concentrations may occur and there have been instances of renal impairment and acute renal failure; proximal renal tubulopathy, Fanconi syndrome, and hypophosphataemia have also been reported. Raised liver enzyme concentrations may occur and severe acute exacerbation of hepatitis has been reported after stopping treatment with adefovir.

Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with nucleoside analogues alone or with antiretrovirals (see Zidovudine, p.914).

Precautions

Adefovir should be withdrawn if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. Adefovir should be given with caution to patients with hepatomegaly or other risk factors for liver disease. Careful differentiation should be made between patients whose liver enzyme concentrations become elevated due to response to treatment and those in whom it is indicative of toxicity. Exacerbation of hepatitis has been reported in patients who developed resistance to adefovir and in those who stopped adefovir; patients who stop treatment should be monitored closely for an appropriate period. In order to minimise the risk of resistance in patients with lamivudine-resistant hepatitis B, adefovir should be used with lamivudine and not as monotherapy. Patients taking adefovir should be monitored every 3 months for signs of deteriorating renal function; particular care should be exercised in patients with a creatinine clearance of less than 50 mL/minute, who may require dosage modification, and in those receiving other drugs that may affect renal function.

Use of adefovir to treat chronic hepatitis B infection in patients with undiagnosed or untreated HIV infection may result in the emergence of resistant strains of HIV. US licensed product information recommends that all patients be tested for HIV antibodies before starting treatment with adefovir.

Breast feeding. It is not known whether adefovir is distributed into breast milk but licensed product information recommends that mothers should not breast feed if taking adefovir.

Pregnancy. Studies in *rodents* given high intravenous doses of adefovir (systemic exposure 38 times that in the human) have found it to be fetotoxic or embryotoxic; those given high oral doses (systemic exposure 23 to 40 times that in the human) or lower intravenous doses (systemic exposure 12 times that in the human) did not show evidence of teratogenicity or embryotoxicity. There are no studies available on the use of adefovir in pregnant women and licensed product information recommends that it should only be given to pregnant women if the potential benefit justifies the potential risk.

Interactions

Caution should be exercised when adefovir is given with other drugs eliminated by active tubular secretion as competition for the elimination pathway may increase the serum concentrations of either drug. Care is required when adefovir is given with other drugs with the potential for nephrotoxicity.

Antiviral Action

Adefovir is converted intracellularly in stages to the diphosphate, which then inhibits the DNA synthesis of hepatitis B virus through competitive inhibition of reverse transcriptase and incorporation into viral DNA. At high doses it has some activity against HIV.

Antiviral resistance. The development of antiviral resistance is a concern with long-term nucleoside or nucleotide treatment for chronic hepatitis B. Studies[1-4] in patients with chronic hepatitis B showed no resistance to adefovir after 1 year of treatment, but resistance rates increased over time to about 11%, 18%, and 29% at year 3, 4, and 5 respectively. Adefovir was found to be effective in patients who had previously developed resistance to lamivudine.[4]

2. Hadziyannis SJ, *et al.* Adefovir dipivoxil for the treatment of hepatitis B e antigen-negative chronic hepatitis B. *N Engl J Med* 2003; **348:** 800–7. Correction. *ibid.*; 1192.
3. Hadziyannis SJ, *et al.* Long-term therapy with adefovir dipivoxil for HBeAg-negative chronic hepatitis B. *N Engl J Med* 2005; **352:** 2673–81.
4. Delaney WE. Progress in the treatment of chronic hepatitis B: long-term experience with adefovir dipivoxil. *J Antimicrob Chemother* 2007; **59:** 827–32.

Pharmacokinetics

After oral doses adefovir dipivoxil is rapidly converted to adefovir. Peak plasma concentrations of adefovir occur after about 0.6 to 4 hours. Bioavailability is reported to be 59% after a single oral dose. Absorption is delayed but not reduced when given with food. Adefovir is widely distributed to body tissues, particularly into the kidneys, liver, and intestines. Less than 4% is bound to plasma or serum proteins. Adefovir is excreted renally by glomerular filtration and active tubular secretion; the terminal elimination half-life is reported to be about 7 hours. Adefovir is partially removed by haemodialysis.

Uses and Administration

Adefovir is a nucleotide reverse transcriptase inhibitor, structurally related to adenine, that is given orally as the prodrug adefovir dipivoxil for the treatment of chronic **hepatitis B** (p.851). It is used in adults with decompensated liver disease, or with compensated liver disease with evidence of active viral replication, persistently raised serum alanine aminotransferase concentrations, and histological evidence of active liver inflammation and fibrosis. The usual dose of adefovir dipivoxil is 10 mg once daily. For details of dosage modification in patients with renal impairment, see below.

Adefovir was initially investigated for the treatment of **HIV infection**, but its use is limited by nephrotoxicity due to the high doses needed.

2. Rivkin AM. Adefovir dipivoxil in the treatment of chronic hepatitis B. *Ann Pharmacother* 2004; **38:** 625–33.
3. Danta M, Dusheiko G. Adefovir dipivoxil: review of a novel acyclic nucleoside analogue. *Int J Clin Pract* 2004; **58:** 877–86.

Administration in renal impairment. The dosage of adefovir dipivoxil should be reduced in patients with renal impairment. The dosing interval should be modified according to the creatinine clearance (CC) of the patient:

- CC 50 mL or more per minute: usual 10 mg once-daily dosage (above)
- CC 30 to 49 mL/minute: 10 mg every 48 hours
- CC 10 to 29 mL/minute: 10 mg every 72 hours
- haemodialysis patients: 10 mg every 7 days after dialysis

Amprenavir *(BAN, USAN, rINN)*

Amprenaviiri; Amprénavir; Amprenavirum; KVX-478; VX-478; 141W94. (3*S*)-Tetrahydro-3-furyl{(*S*)-α-[(1*R*)-1-hydroxy-2-(*N*[1]-isobutylsulfanilamido)ethyl]phenethyl}carbamate.

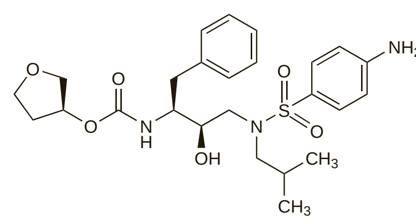
Ампренавир

$C_{25}H_{35}N_3O_6S$ = 505.6.

CAS — 161814-49-9.

ATC — J05AE05.

ATC Vet — QJ05AE05.



Adverse Effects

Adverse effects associated with antiretroviral regimens containing amprenavir are mostly mild to moderate. The most common adverse effects are gastrointestinal disturbances such as diarrhoea, flatulence, nausea, and vomiting. Other commonly reported adverse effects include fatigue, headache, oral paraesthesia, and taste disorders, while the most frequently reported serious adverse effects include peripheral paraesthesias, skin rash, and mood disorders (including depression). Mild to moderate rashes (usually erythematous or maculopapular and sometimes pruritic), generally occur during the second week of treatment and resolve within 2 weeks. A possible association with Stevens-Johnson syndrome has been reported with amprenavir.

Precautions

Amprenavir (when given with ritonavir) is contra-indicated in patients with severe hepatic impairment, and should be used with caution (and liver enzyme values monitored), in patients with mild to moderate liver disease. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors. Treatment with amprenavir should be permanently stopped in patients who develop a severe or life-threatening skin rash or a skin rash with associated systemic or allergic symptoms or mucosal involvement.

Amprenavir is a sulfonamide and should be used with caution in patients known to be allergic to sulfonamides. The oral solution and capsule formulations (*Agenerase, GlaxoSmithKline*) also provide high daily doses of vitamin E (see p.1993). The oral solution has a high content of propylene glycol, present as an excipient, and appropriate precautions should be taken; it is contra-indicated in infants and young children, in pregnancy, and in hepatic or renal impairment. For further information on propylene glycol toxicity, see Adverse Effects and Precautions, p.2374.

Pregnancy. Amprenavir has been associated with teratogenicity in *animals*. The solution is contra-indicated in pregnancy due to the high propylene glycol content.

Interactions

Amprenavir is reported to be metabolised by the cytochrome P450 isoenzyme CYP3A4. It is also a modest inhibitor of the cytochrome P450 isoenzymes CYP3A4 and CYP2C19. Drugs that affect these isoenzymes may modify amprenavir plasma concentrations and amprenavir may alter the pharmacokinetics of other drugs that are metabolized by this enzyme system.

Amprenavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone, bepridil, flecainide, propafenone, and quinidine), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam) and statins (simvastatin and lovastatin). Rifampicin and St John's wort decrease the concentration of amprenavir; use with the antiretroviral is not recommended due to possible loss of its activity and development of resistance.

Agenerase oral solution (*GlaxoSmithKline*) is contra-indicated in patients taking disulfiram or other products that reduce alcohol metabolism (such as metronidazole) and in those taking alcohol-containing products (such as ritonavir oral solution) because of the potential risk of toxicity from its propylene glycol content.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Amprenavir is a selective, competitive, reversible inhibitor of HIV-1 and HIV-2 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Cross-resistance between HIV-protease inhibitors may occur, but cross-resistance between HIV-protease inhibitors and reverse transcriptase inhibitors is considered unlikely. Mechanisms of resistance to amprenavir may differ from those of other HIV-protease inhibitors.

Pharmacokinetics

Amprenavir is rapidly and well absorbed from the gastrointestinal tract after oral doses. Absorption is impaired by ingestion with a high-fat meal. Amprenavir capsules and oral solution are not bioequivalent; oral bioavailability is about 14% lower from the oral solution formulation than from the capsule formulation (*Agenerase, GlaxoSmithKline*). Peak plasma concentrations are attained 1 to 2 hours after a single dose. It is about 90% bound to plasma proteins. Amprenavir is metabolised by hepatic cytochrome P450 isoenzyme CYP3A4. It is excreted mainly in the faeces as metabolites. The plasma elimination half-life is 7.1 to 10.6 hours.

◊ References.

3. Yogev R, *et al.* Single-dose safety and pharmacokinetics of amprenavir (141W94), a human immunodeficiency virus type 1 (HIV-1) protease inhibitor, in HIV-infected children. *Antimicrob Agents Chemother* 2005; **49:** 336–41.

Uses and Administration

Amprenavir is an HIV-protease inhibitor with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when amprenavir is used alone, and it is therefore used with other antiretrovirals.

Amprenavir is given orally as capsules or solution but the bioavailability of these formulations (*Agenerase, GlaxoSmithKline*) differ and their doses are not interchangeable.

- In adults and adolescents (13 to 16 years) weighing 50 kg or more the *capsules* are given in a dose of 1.2 g twice daily; when given with ritonavir (ritonavir-boosted amprenavir) the recommended dose is amprenavir 600 mg with ritonavir 100 mg twice daily or amprenavir 1.2 g with ritonavir 200 mg once daily.
- The *oral solution* is given in a dose of 17 mg/kg three times daily (maximum daily dose 2.8 g) or 1.4 g twice daily.

For details of doses in children and patients weighing less than 50 kg, see below. For dosage in hepatic impairment, also see below.

Amprenavir is also used in the form of the prodrug fosamprenavir (see p.877), which may aid compliance by reducing adverse effects and increasing flexibility of dosing.

◊ Reviews.

1. Noble S, Goa KL. Amprenavir: a review of its clinical potential in patients with HIV infection. *Drugs* 2000; **60:** 1383–1410.

Administration in children. For the treatment of HIV infection in children 4 to 12 years of age and in adolescents (13 to 16 years) weighing less than 50 kg, amprenavir is given daily with other antiretroviral drugs. Doses are based on body-weight:

- the *capsules* are given in an oral dose of 20 mg/kg twice daily or 15 mg/kg three times daily, to a maximum daily dose of 2.4 g, or
- the *solution* is given in an oral dose of 22.5 mg/kg twice daily or 17 mg/kg three times daily, to a maximum daily dose of 2.8 g

Administration in hepatic impairment. Amprenavir should be used with caution and in reduced doses in patients with hepatic impairment. Additionally, the oral solution contains propylene glycol and extra restrictions may apply.

The following doses have been recommended in UK licensed product information:

oral solution:
- do not use

capsules:
- moderate impairment: 450 mg twice daily
- severe impairment: 300 mg twice daily

The following doses have been recommended in US product information:

oral solution:
- Child-Pugh score 5 to 8: 513 mg twice daily
- Child-Pugh score 9 to 12: 342 mg twice daily
- hepatic failure: do not use

capsules:
- Child-Pugh score 5 to 8: 450 mg twice daily
- Child-Pugh score 9 to 12: 300 mg twice daily

Atazanavir Sulfate *(USAN, rINNM)*

Atazanavir, Sulfate d'; Atazanavir Sulphate *(BANM)*; Atazanaviri Sulfas; BMS-232632-05; BMS-232632 (atazanavir); Sulfato de atazanavir. Dimethyl (3*S*,8*S*,9*S*,12*S*)-9-Benzyl-3,12-di-*tert*-butyl-8-hydroxy-4,11-dioxo-6-(*p*-2-pyridylbenzyl)-2,5,6,10,13-pentaazatetradecanedioate sulfate (1:1).

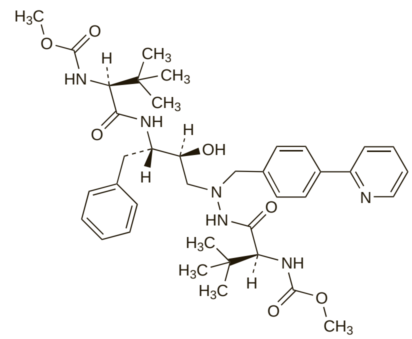
Атазанавира Сульфат

$C_{38}H_{52}N_6O_7,H_2SO_4 = 802.9.$

CAS — 198904-31-3 (atazanavir); 229975-97-7 (atazanavir sulfate).

ATC — J05AE08.

ATC Vet — QJ05AE08.



(atazanavir)

Adverse Effects

Commonly reported adverse effects of moderate or greater intensity associated with antiretroviral regimens containing atazanavir include gastrointestinal disturbances (abdominal pain, diarrhoea, dyspepsia, nausea, vomiting, and jaundice), headache, insomnia, and peripheral neurological symptoms, and scleral icterus. Other commonly reported adverse effects are asthenia and fatigue. Mild to moderate rashes (usually maculopapular) generally occurring after 8 weeks of treatment and resolving within 1 to 2 weeks have been reported. Stevens-Johnson syndrome and erythema multiforme have also been reported in patients given atazanavir. Atazanavir may prolong the PR interval of the ECG and asymptomatic first-degree AV block has been reported in some patients. Cases of nephrolithiasis have occurred. Most patients taking atazanavir have asymptomatic elevations in unconjugated bilirubin, which is reversible upon stopping treatment. Other abnormal laboratory results include elevated amylase and lipase, elevated liver enzymes, and low neutrophils.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including atazanavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including atazanavir. Metabolic abnormalities such as insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported; atazanavir does not appear to have a negative effect on lipid levels. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Atazanavir is contra-indicated in patients with severe hepatic impairment and when given with ritonavir is also contra-indicated in more moderate hepatic impairment. It should be used with caution, and liver enzymes values monitored, in patients with mild liver disease. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events.

Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors. Caution should be exercised in patients with pre-existing cardiac conduction disorders or in those taking drugs that prolong the PR or increase the QT intervals. Patients developing jaundice or scleral icterus associated with hyperbilirubinaemia should be tried on an alternative antiretroviral; dose reductions of atazanavir should not be considered.

Pregnancy. Atazanavir has not been associated with teratogenicity in *animals*. It is not known whether atazanavir given to mothers will exacerbate physiologic hyperbilirubinaemia and lead to kernicterus in neonates and young infants.

Interactions

Atazanavir is extensively metabolised in the liver by the cytochrome P450 isoenzyme CYP3A4 and inhibits CYP3A4, CYP2C8, and UGT1A1. Use with drugs primarily metabolised by these isoenzymes may result in increases in their plasma concentrations, while drugs that inhibit CYP3A4 may increase atazanavir plasma concentrations. When ritonavir-boosted atazanavir is given, the drug interaction profile for ritonavir may predominate because ritonavir is a more potent CYP3A4 inhibitor than atazanavir.

Atazanavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone, bepridil, flecainide, propafenone, and quinidine), antihistamines (astemizole and terfenadine), antineoplastic (irinotecan), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam, triazolam), and statins (simvastatin and lovastatin). Proton pump inhibitors, rifampicin, and St John's wort decrease the concentration of atazanavir; use with the antiretroviral is not recommended due to possible loss of its activity and development of resistance. Atazanavir should also not be given to patients taking indinavir, as indirect hyperbilirubinaemia may result. Atazanavir is also contra-indicated with irinotecan as azatanavir's inhibition of UGT1A1 may increase irinotecan toxicity.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Atazanavir is a selective, competitive, reversible inhibitor of HIV-1 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Various degrees of cross-resistance between HIV-protease inhibitors may occur.

Pharmacokinetics

Atazanavir is rapidly absorbed from the gastrointestinal tract after oral doses with peak plasma concentrations occurring after 2 to 2.5 hours. On multiple dosing with a ritonavir-boosted regimen peak plasma concentrations are achieved after 3 hours. Bioavailability (of both ritonavir-boosted and non-boosted regimens) is enhanced if given with food. Atazanavir is reported to be 86% bound to serum proteins. It is distributed into semen and into the CSF. Atazanavir is extensively metabolised, mainly by oxidation by cytochrome P450 isoenzyme CYP3A; the metabolites appear to be inactive. Atazanavir is predominantly excreted in faeces, mainly as metabolites, and to a smaller extent in the urine. The terminal elimination half-life of atazanavir is reported to be about 7 hours and 8.6 hours after a ritonavir-boosted regimen.

◊ Reviews.

1. Le Tiec C, *et al.* Clinical pharmacokinetics and summary of efficacy and tolerability of atazanavir. *Clin Pharmacokinet* 2005; **44:** 1035–50.

Uses and Administration

Atazanavir is an HIV-protease inhibitor with antiviral activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when atazanavir is used alone, and it is therefore used with other antiretrovirals.

Atazanavir is given orally as the sulfate with food, but doses are expressed in terms of atazanavir; 228 mg of atazanavir sulfate is equivalent to about 200 mg of atazanavir.

The usual adult dose in treatment-naive patients is 400 mg once daily. Ritonavir-boosted atazanavir (atazanavir 300 mg once daily with ritonavir 100 mg once daily) should be used when given with tenofovir, efavirenz, H_2-receptor antagonists, or proton pump inhibitors.

The usual dose in therapy-experienced patients is 300 mg once daily with ritonavir 100 mg once daily. A dose of atazanavir 400 mg once daily with ritonavir 100 mg once daily should be used when given with both tenofovir and an H_2-receptor antagonist.

For details of doses in children and adolescents, see below.

For details of recommended doses of atazanavir in patients with hepatic or renal impairment, see below.

◊ Reviews.

2. Musial BL, *et al.* Atazanavir: a new protease inhibitor to treat HIV infection. *Am J Health-Syst Pharm* 2004; **61:** 1365–74.
3. Orrick JJ, Steinhart CR. Atazanavir. *Ann Pharmacother* 2004; **38:** 1664–74.
4. Swainston Harrison T, Scott LJ. Atazanavir: a review of its use in the management of HIV infection. *Drugs* 2005; **65:** 2309–36.

Administration in children. For the treatment of HIV infection in children 6 years of age and older and adolescents, atazanavir is given orally with food. Doses are based on body-weight.

The recommended dosage of atazanavir with ritonavir in *treatment-naive* patients at least 6 years of age is:

- 15 to 24 kg: atazanavir 150 mg once daily with ritonavir 80 mg once daily
- 25 to 31 kg: atazanavir 200 mg once daily with ritonavir 100 mg once daily
- 32 to 38 kg: atazanavir 250 mg once daily with ritonavir 100 mg once daily
- 39 kg or more: atazanavir 300 mg once daily with ritonavir 100 mg once daily

For *treatment-naive* patients at least 13 years of age and 39 kg, who are unable to tolerate ritonavir, the recommended dose is atazanavir 400 mg once daily.

The recommended dosage of atazanavir with ritonavir in *treatment-experienced* patients at least 6 years of age is:

- 25 to 31 kg: atazanavir 200 mg once daily with ritonavir 100 mg once daily
- 32 to 38 kg: atazanavir 250 mg once daily with ritonavir 100 mg once daily
- 39 kg or more: atazanavir 300 mg once daily with ritonavir 100 mg once daily

Administration in hepatic impairment. In treatment-naive patients the oral dose of atazanavir should be adjusted in hepatic impairment as follows:

- mild hepatic impairment (Child-Pugh category A): use with caution (no specific reduction recommended)
- moderate impairment (Child-Pugh category B): atazanavir 300 mg daily
- severe hepatic impairment (Child-Pugh category C): not recommended

Ritonavir-boosted atazanavir regimens should be used with caution in patients with mild hepatic impairment and should not be used in those with moderate to severe hepatic impairment.

Administration in renal impairment. Oral dose adjustments are not usually necessary for patients with renal impairment. However, US licensed product information recommends that treatment-naive patients on haemodialysis should be given atazanavir 300 mg once daily with ritonavir 100 mg once daily and that atazanavir should not be used in treatment-experienced patients on haemodialysis.

Brivudine *(rINN)*

Brivudin; Brivudina; Brivudinum; BVDU. (*E*)-5-(2-Bromovinyl)-2′-deoxyuridine.

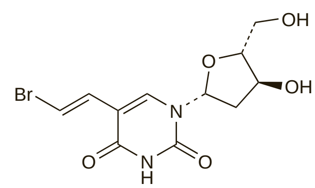
Бривудин

$C_{11}H_{13}BrN_2O_5$ = 333.1.

CAS — 69304-47-8.

ATC — J05AB15.

ATC Vet — QJ05AB15.



Profile

Brivudine is a nucleoside analogue effective *in vitro* against herpes simplex virus type 1 and varicella-zoster virus; other viruses including herpes simplex virus type 2 have been reported to be sensitive, but only at relatively high concentrations. The activity appears to be due, at least in part, to selective phosphorylation of brivudine by viral deoxythymidine kinase in preference to cellular kinases. There is the possibility of cross-resistance developing between brivudine and aciclovir because of some similar features in their mode of action (see p.863).

Brivudine is given orally in the treatment of herpes zoster (p.855) in a dose of 125 mg daily for 7 days. It has also been given orally for herpes simplex infection and has been used topically.

The symbol † denotes a preparation no longer actively marketed

Adverse Effects

The most serious dose-limiting adverse effect of cidofovir is nephrotoxicity, the incidence and severity of which can be reduced by use with probenecid and by ensuring adequate hydration. There have been instances of acute renal failure after only 1 or 2 doses, and some fatalities. Low plasma-bicarbonate concentrations and metabolic acidosis, sometimes associated with proximal tubule injury and renal wasting syndrome (including Fanconi's syndrome) or with liver dysfunction and pancreatitis, have been reported. Reversible neutropenia has also occurred. Other adverse effects include nausea and vomiting, fever, asthenia, skin rash, dyspnoea, alopecia, and ocular hypotony (decreased intra-ocular pressure). Iritis or uveitis has been reported.

Cidofovir is carcinogenic and embryotoxic in *animals* and may have the potential to cause male infertility (see Precautions, below).

Effects on the eyes. Ocular adverse effects associated with intravenous use of cidofovir include iritis,[1] uveitis,[2-4] and ocular hypotony.[4] While development of ocular hypotony is considered to warrant withdrawal of cidofovir,[2] uveitis or iritis alone may respond to topical corticosteroids and cycloplegics thus allowing antiviral therapy to be continued; cidofovir must be stopped if there is no response or worsening of symptoms.

Effects on the kidneys. Dose-related nephrotoxicity is the most severe adverse effect of cidofovir and marked proteinuria has been reported in up to 50% of patients. There have been instances of acute renal failure after only 1 or 2 doses, and some fatalities. Fanconi's syndrome associated with renal tubular damage has been reported in 2% of patients and, in one such patient, occurred on the third injection of cidofovir and resulted in irreversible renal impairment.[1] Reversible renal impairment with persisting Fanconi syndrome was reported in another.[2] A case of nephrogenic diabetes insipidus without premonitory laboratory abnormalities has also been reported in a patient given cidofovir.[3]

1. Vittecoq D, *et al.* Fanconi syndrome associated with cidofovir therapy. *Antimicrob Agents Chemother* 1997; **41:** 1846.
2. Kazory A, *et al.* Simultaneous development of Fanconi syndrome and acute renal failure associated with cidofovir. *J Antimicrob Chemother* 2007; **60:** 193–4.
3. Schliefer K, *et al.* Nephrogenic diabetes insipidus in a patient taking cidofovir. *Lancet* 1997; **350:** 413–14. Correction. *ibid.*; 1558.

Precautions

Cidofovir is contra-indicated in patients with renal impairment. Renal function should be measured before each dose. In the UK it is recommended that treatment should be interrupted or stopped if renal function deteriorates, but in the USA reduction of the dosage is permitted for increases in serum creatinine up to 300 to 400 micrograms/dL above baseline. Patients should receive oral probenecid and intravenous hydration with each dose of cidofovir. Neutrophil counts should also be monitored and regular ophthalmological follow-up is recommended. Patients with diabetes mellitus are at increased risk of ocular hypotony.

Cidofovir is carcinogenic and embryotoxic in *animals*. Cidofovir should not be given during pregnancy and both sexes should use effective methods of contraception during treatment; in addition, effective contraception should be used, for 1 month by women and for 3 months by men, after the end of treatment. There is also a possibility that cidofovir may cause male infertility.

Cidofovir should be given intravenously only; direct intra-ocular injection has been associated with significant ocular hypotony and visual impairment and is contra-indicated.

Interactions

Additive nephrotoxicity may occur if cidofovir is used with other nephrotoxic drugs such as aminoglycosides, amphotericin B, foscarnet, intravenous pentamidine, vancomycin, or NSAIDs. Potentially nephrotoxic drugs should be stopped at least 7 days before starting cidofovir. Probenecid, which is given with cidofovir, may alter the clearance of other drugs (see Interactions under Probenecid, p.558).

Patients with CMV retinitis are at increased risk of adverse inflammatory effects if cidofovir is given within 2 to 4 weeks of intravitreal fomivirsen.

Antiviral Action

Cidofovir undergoes intracellular phosphorylation by cellular kinases to the antiviral metabolite, cidofovir diphosphate, which acts as a competitive inhibitor of viral DNA polymerase. It is active against a range of herpesviruses including CMV, and, since its activity is not reliant on viral enzymes, may retain activity against some aciclovir- and foscarnet-resistant viruses. Cross-resistance with ganciclovir is common.

2. Jabs DA, *et al.* Incidence of foscarnet resistance and cidofovir resistance in patients treated for cytomegalovirus retinitis. *Antimicrob Agents Chemother* 1998; **42:** 2240–4.

Pharmacokinetics

After intravenous doses of cidofovir, serum concentrations decline with a reported terminal half-life of about 2.2 hours (the intracellular half-life of the active diphosphate may be up to 65 hours). Cidofovir is eliminated mainly by renal excretion, both by glomerular filtration and tubular secretion. About 80 to 100% of a dose is recovered unchanged from the urine within 24 hours. Use with probenecid may reduce the excretion of cidofovir to some extent by blocking tubular secretion, although 70 to 85% has still been reported to be excreted unchanged in the urine within 24 hours.

Uses and Administration

Cidofovir is a nucleoside analogue that is active against herpesviruses. It is used in the treatment of CMV retinitis (p.853) in patients with AIDS, and is being investigated for ocular herpes simplex and other viral infections.

In the treatment of CMV retinitis, cidofovir is given in a dose of 5 mg/kg by intravenous infusion over 1 hour once a week for 2 consecutive weeks, then once every 2 weeks for maintenance. Probenecid 2 g is given orally 3 hours before each dose of cidofovir and further 1-g doses of probenecid at 2 and 8 hours after completion of the infusion. To ensure adequate hydration, 1 litre of sodium chloride 0.9% is given by intravenous infusion over 1 to 2 hours immediately before each infusion of cidofovir; if the additional fluid load can be tolerated, a further 1 litre of sodium chloride 0.9% may be infused over 1 to 3 hours, starting at the same time as (or immediately after) the cidofovir infusion. For details of modified use of cidofovir in patients with renal impairment, see below.

Cidofovir has also been given experimentally by intravitreal injection but the commercially available formulation is unsuitable for use by this route and licensed product information advises against it (see Precautions, above).

An orally active prodrug of cidofovir known as cyclic-HPMPC (GS-930) is under investigation. Cidofovir has also been investigated for topical use.

5. Snoeck R, De Clercq E. Role of cidofovir in the treatment of DNA virus infections, other than CMV infections, in immunocompromised patients. *Curr Opin Investig Drugs* 2002; **3:** 1561–6.

Administration in renal impairment. Cidofovir is contra-indicated in patients with pre-existing renal impairment (serum creatinine more than 1.5 mg/dL) and should be interrupted or stopped if serum creatinine increases by more than 500 micrograms/dL during therapy; in the USA, a reduction in the maintenance dose from 5 to 3 mg/kg is permitted for increases of serum creatinine of up to 300 to 400 micrograms/dL above baseline.

Viral infections. In addition to its use in CMV retinitis, cidofovir has been studied in herpes simplex infections,[1-6] papillomavirus infections,[7-13] molluscum contagiosum,[11,14,15] and progressive multifocal leukoencephalopathy.[16-20]

Darunavir *(USAN, rINN)*

Darunavirum; TMC-114; UIC-94017. (3*R*,3a*S*,6a*R*)-Hexahydrofuro[2,3-*b*]furan-3-yl *N*-[(1*S*,2*R*)-1-benzyl-2-hydroxy-3-(N^1-isobutylsulfanilamido)propyl]carbamate.

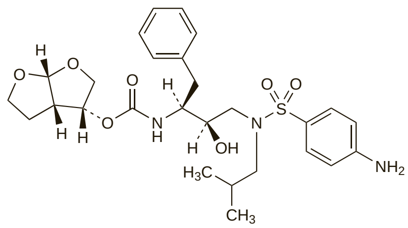
Дарунавир

$C_{27}H_{37}N_3O_7S = 547.7$.

CAS — 206361-99-1.

ATC — J05AE10.

ATC Vet — QJ05AE10.



Darunavir Ethanolate *(rINNM)*

Darunavir monoethanolate.

$C_{27}H_{37}N_3O_7S,C_2H_5OH = 593.7$.

ATC — J05AE10.

ATC Vet — QJ05AE10.

Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing darunavir are gastrointestinal disturbances (abdominal pain, diarrhoea, nausea, and vomiting), nasopharyngitis, and hypertriglyceridaemia. Other reported adverse effects are asthenia, dizziness, fatigue, headache, and insomnia. Less frequently reported adverse effects include folliculitis, myocardial infarction, osteopenia, osteoporosis, polyuria, somnolence, tachycardia, transient ischaemic attacks, and vertigo. Severe cases of skin rashes have been reported, including erythema multiforme and Stevens-Johnson syndrome. Cases of drug-induced hepatitis, including fatalities, have been reported. Abnormal liver and pancreatic function tests and decreases in white blood cell counts have also occurred.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including darunavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including darunavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

For further information on adverse effects associated with HIV-protease inhibitors see under Indinavir Sulfate, p.882.

Precautions

Patients should undergo liver function tests before starting and during treatment with darunavir. It should not be used in patients with severe hepatic impairment (Child-Pugh class C), and should be used with caution (and liver enzymes values monitored), in those with mild to moderate impairment (Child-Pugh A or B) and those with chronic hepatitis B or C co-infection. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. All patients should be instructed to seek medical advice if symptoms suggestive of new or worsening hepatotoxicity occur. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors. An association with erythema multiforme and Stevens-Johnson syndrome has been reported and treatment should be stopped in patients who develop skin rashes.

Interactions

Darunavir is extensively metabolised by the cytochrome P450 isoenzyme CYP3A4. It may compete with other drugs metabolised by this enzyme, potentially resulting in increased plasma concentrations and toxicity.

Darunavir is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antiarrhythmics (amiodarone, bepridil, quinidine, and systemic lidocaine), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (midazolam and triazolam), and statins (simvastatin and lovastatin). Ritonavir-boosted lopinavir, rifampicin, antiepileptics (carbamazepine, phenobarbital, and phenytoin), and St John's wort decrease the concentration of darunavir; use with darunavir is not recommended due to the possible loss of its activity and development of resistance.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action

Darunavir is a selective inhibitor of HIV-1 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Cross-resistance may develop between some HIV-protease inhibitors, but mechanisms of resistance to darunavir may differ from those to other drugs of the class.

Pharmacokinetics

Darunavir is rapidly absorbed after oral doses, resulting in a bioavailability of 82% when taken with recommended doses of ritonavir; food increases the bioavailability. Peak plasma concentrations are reached within 2.5 to 4 hours. Darunavir is about 95% bound to plasma proteins. It is metabolised by oxidation by the cytochrome P450 system (primarily the isoenzyme CYP3A4), with at least 3 metabolites showing some antiretroviral activity. About 80% of a dose is excreted in the faeces, with 41.2% of this as unchanged drug; 14% is excreted in the urine, with 7.7% being unchanged drug. The mean terminal elimination half-life of darunavir is about 15 hours.

◊ Reviews.

1. Rittweger M, Arastéh K. Clinical pharmacokinetics of darunavir. *Clin Pharmacokinet* 2007; **46:** 739–56.

Uses and Administration

Darunavir is an HIV-protease inhibitor with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when darunavir is used alone, and it is therefore used with other antiretrovirals.

Darunavir is boosted with low-dose ritonavir, which acts as a pharmacokinetic enhancer. It is given orally as the ethanolate, but doses are expressed in terms of the base; 325 mg of darunavir ethanolate is equivalent to about 300 mg of darunavir. The dose is 600 mg (with ritonavir 100 mg) twice daily with food.

Delavirdine Mesilate *(rINNM)*

Délavirdine, Mésilate de; Delavirdine Mesylate *(USAN)*; Delavirdini Mesilas; Mesilato de delavirdina; U-90152S. 1-[3-(Isopropylamino)-2-pyridyl]-4-[(5-methanesulfonamidoindol-2-yl)carbonyl]-piperazine monomethanesulfonate.

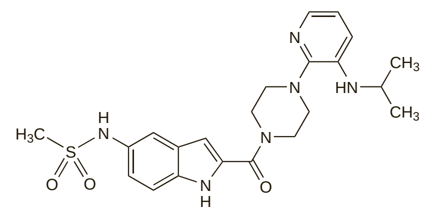
Делавирдина Мезилат

$C_{22}H_{28}N_6O_3S,CH_4O_3S = 552.7$.

CAS — 136817-59-9 (delavirdine); 147221-93-0 (delavirdine mesilate).

ATC — J05AG02.

ATC Vet — QJ05AG02.



(delavirdine)

Adverse Effects

Adverse effects associated with antiretroviral regimens containing delavirdine are mostly mild to moderate. The most common adverse effect of delavirdine is skin rash, (usually diffuse, maculopapular, erythematous, and often pruritic), generally appearing within the first 3 weeks of starting therapy and resolving in 3 to 14 days. Severe skin reactions, including erythema multiforme and Stevens-Johnson syndrome, have occurred. Additional adverse effects of moderate to severe intensity include generalised abdominal pain, asthenia, fatigue, fever, flu syndrome, headache, and localised pain. Other reported adverse effects include gastrointestinal disturbances (diarrhoea, nausea, vomiting), increased liver enzyme values, anxiety, depressive symptoms, insomnia, and respiratory effects (bronchitis, cough, pharyngitis, sinusitis, and upper respiratory-tract infections). Liver failure, haemolytic anaemia, rhabdomyolysis, and acute renal failure have been reported during postmarketing use.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including delavirdine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including delavirdine.

Precautions

Delavirdine should be stopped if a severe skin rash develops or if a rash is accompanied by fever, blistering, oral lesions, conjunctivitis, swelling, or muscle or joint aches. Delavirdine should be used with caution in patients with hepatic impairment.

Pregnancy. Delavirdine has been shown to be teratogenic in *animals*. Clinical studies and postmarketing data have identified 10 infants born to mothers who took delavirdine during pregnancy. Eight of the infants were born healthy, 1 infant was born HIV-positive but had no congenital abnormalities, and 1 infant was born prematurely with a small muscular ventricular septal defect that spontaneously resolved.

Interactions

Delavirdine is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4. Consequently it may compete with other drugs metabolised by this system, potentially resulting in mutually increased plasma concentrations and toxicity. Alternatively, enzyme inducers may decrease plasma concentrations of delavirdine. The absorption of delavirdine is reduced by drugs that raise gastric pH such as antacids and histamine H_2-antagonists.

Delavirdine is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life threatening events. These drugs include antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), and sedatives and hypnotics (alprazolam, midazolam, triazolam). The antiepileptics carbamazepine, phenytoin, and phenobarbital, the antimycobacterials rifabutin and rifampicin, and St John's wort decrease the concentration of delavirdine; use with the antiretroviral is not recommended due to the possible loss of antiviral activity and development of resistance. For further information on drug interactions of NNRTIs see Table 2, p.944.

Antibacterials. Plasma concentrations of *dapsone* and *rifabutin* may be increased by delavirdine; *rifabutin* and *rifampicin*[1] may reduce delavirdine plasma concentrations and the use of either of these drugs with delavirdine is not recommended.

1. Borin MT, *et al.* Pharmacokinetic study of the interaction between rifampin and delavirdine mesylate. *Clin Pharmacol Ther* 1997; **61:** 544–53.

Antivirals. Use of delavirdine with buffered *didanosine* may result in reduced plasma concentrations of both drugs[1] and they should be given at least 1 hour apart; plasma concentrations of HIV-protease inhibitors including *indinavir* and *saquinavir* may be increased by delavirdine (see Antivirals, under Interactions of Indinavir, p.883) and liver function should be monitored in patients given delavirdine and saquinavir.

1. Morse GD, *et al.* Single-dose pharmacokinetics of delavirdine mesylate and didanosine in patients with human immunodeficiency virus infection. *Antimicrob Agents Chemother* 1997; **41:** 169–74.

Antiviral Action

Delavirdine acts by non-competitive inhibition of HIV-1 reverse transcriptase; it binds to the enzyme, disrupting the conformation of its catalytic site and impairing its RNA- and DNA-dependent polymerase activity.

Resistance to delavirdine and emergence of cross-resistance to other non-nucleoside reverse transcriptase inhibitors has been seen.

Pharmacokinetics

Delavirdine is rapidly absorbed after oral doses, peak plasma concentrations occurring after about 1 hour. The bioavailability of delavirdine tablets is about 85% of that from an oral solution after a single dose. The bioavailability of the 100-mg tablet can be increased by about 20% by dissolving it in water before use; the 200-mg tablets do not readily disperse in water and should be swallowed intact. Delavirdine is about 98% bound to plasma proteins. It is extensively metabolised by hepatic microsomal enzymes, principally by the cytochrome P450 isoenzyme CYP3A4 (although CYP2D6 may play some role), to several inactive metabolites. The plasma half-life after usual dosage is about 5.8 hours and ranges from 2 to 11 hours. Delavirdine is excreted as metabolites in the urine and faeces. Less than 5% is excreted in the urine unchanged.

4. Smith PF, *et al.* Population pharmacokinetics of delavirdine and N-delavirdine in HIV-infected individuals. *Clin Pharmacokinet* 2005; **44:** 99–109.

Uses and Administration

Delavirdine is a non-nucleoside reverse transcriptase inhibitor with activity against HIV-1. Viral resistance emerges rapidly when delavirdine is used alone, and it is therefore used with other antiretrovirals for combination therapy of HIV infection and AIDS (p.856).

Delavirdine is given orally as the mesilate in a usual dose of 400 mg three times daily. Some tablet formulations may be dispersed in water before use in order to increase bioavailability (see above).

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Didanosine). A white or almost white, crystalline powder. Sparingly soluble in water; slightly soluble in alcohol and in methyl alcohol; freely soluble in dimethyl sulfoxide.

USP 31 (Didanosine). A white to off-white crystalline powder. Practically insoluble or insoluble in acetone and in methyl alcohol; very soluble in dimethyl sulfoxide. Store at a temperature of 20° to 25°, excursions permitted between 15° and 30°.

Adverse Effects

The most common serious adverse effects of didanosine are peripheral neuropathy and potentially fatal pancreatitis. Other commonly reported adverse effects include abdominal pain, diarrhoea, fatigue, headache, nausea, rash, and vomiting. Abnormal liver function tests may occur and hepatitis or fatal hepatic failure has been reported rarely; fatalities were reported most often in patients taking didanosine with stavudine and hydroxycarbamide. Retinal and optic-nerve changes have been reported in children, particularly in those taking higher than recommended doses; retinal depigmentation has been reported in adult patients. Other adverse effects include alopecia, anaemia, asthenia, dry mouth, fever, flatulence, parotid gland enlargement, leucopenia, hypersensitivity reactions including anaphylaxis, hyperuricaemia, and thrombocytopenia. Lactic acidosis and severe hepatomegaly with steatosis, sometimes fatal, and generally occurring after some months of treatment has been reported.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including didanosine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including didanosine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction such as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Effects on the blood. In general, haematological abnormalities are less common in patients taking didanosine than in those taking zidovudine. However, there have been reports of thrombocytopenia associated with didanosine.[1-3]

1. Butler KM, *et al.* Dideoxyinosine in children with symptomatic human immunodeficiency virus infection. *N Engl J Med* 1991; **324:** 137–44.

3. Herranz P, *et al.* Cutaneous vasculitis associated with didanosine. *Lancet* 1994; **344:** 680.

Effects on the eyes. Retinal lesions with atrophy of the retinal pigment epithelium at the periphery of the retina were reported in 4 children receiving didanosine doses of 270 to 540 mg/m^2 daily.[1]

1. Whitcup SM, *et al.* Retinal lesions in children treated with dideoxyinosine. *N Engl J Med* 1992; **326:** 1226–7.

Effects on the heart. For the possible risk of myocardial infarction in patients taking didanosine, see Effects on the Heart under Adverse Effects of Zidovudine, p.914.

Effects on the liver. Fatal fulminant hepatic failure was reported[1] in a patient receiving didanosine. A further 14 cases had been noted by the manufacturer, and elevated liver enzymes have been recorded during clinical studies.[2-5]

1. Lai KK, *et al.* Fulminant hepatic failure associated with 2′,3′-dideoxyinosine (ddI). *Ann Intern Med* 1991; **115:** 283–4.
2. Dolin R, *et al.* Zidovudine compared with didanosine in patients with advanced HIV type 1 infection and little or no experience with zidovudine. *Arch Intern Med* 1995; **155:** 961–74.

5. Gatell JM, *et al.* Switching from zidovudine to didanosine in patients with symptomatic HIV infection and disease progression. *J Acquir Immune Defic Syndr Hum Retrovirol* 1996; **12:** 249–58.

Effects on mental state. Recurrent mania associated with didanosine treatment has been reported in a patient.[1]

1. Brouillette MJ, *et al.* Didanosine-induced mania in HIV infection. *Am J Psychiatry* 1994; **151:** 1839–40.

Effects on metabolism. Hyperuricaemia has been reported to be a common adverse effect during clinical studies of didanosine.[1,2] Hypokalaemia occurred during didanosine therapy in 3 patients, 2 of whom had diarrhoea.[3] There has also been a report of hypertriglyceridaemia occurring on 2 occasions in a patient given didanosine;[4] it was suggested that this hyperlipidaemic effect might be a possible aetiological factor in the development of pancreatitis.

1. Cooley TP, *et al.* Once-daily administration of 2′,3′-dideoxyinosine (ddI) in patients with the acquired immunodeficiency syndrome or AIDS-related complex: results of a phase I trial. *N Engl J Med* 1990; **322:** 1340–5.
2. Montaner JSG, *et al.* Didanosine compared with continued zidovudine therapy for HIV-infected patients with 200 to 500 CD4 cells/mm : a double-blind, randomized, controlled trial. *Ann Intern Med* 1995; **123:** 561–71.

4. Tal A, Dall L. Didanosine-induced hypertriglyceridemia. *Am J Med* 1993; **95:** 247.

Effects on the mouth. Xerostomia (dry mouth) may be a troublesome effect in patients receiving didanosine.[1,2]

1. Dodd CL, *et al.* Xerostomia associated with didanosine. *Lancet* 1992; **340:** 790.
2. Valentine C, *et al.* Xerostomia associated with didanosine. *Lancet* 1992; **340:** 1542.

Effects on the nervous system. Peripheral neuropathy is a well recognised adverse effect of didanosine and has been the subject of a review.[1]

1. Moyle GJ, Sadler M. Peripheral neuropathy with nucleoside antiretrovirals: risk factors, incidence and management. *Drug Safety* 1998; **19:** 481–94.

Effects on the pancreas. Pancreatitis is recognised as being the most serious adverse effect of didanosine and can be fatal.[1-3] It appears to be dose-related, occurring in up to 13% of patients receiving 750 mg of didanosine daily.[2,4] Pancreatitis can resolve if didanosine is withdrawn[5] and cautious reintroduction of didanosine has been possible in some patients.[6] Raised amylase concentrations[3] and glucose intolerance have been reported in patients who subsequently developed pancreatitis.

1. Bouvet E, *et al.* Fatal case of 2′,3′-dideoxyinosine-associated pancreatitis. *Lancet* 1990; **336:** 1515.
2. Kahn JO, *et al.* A controlled trial comparing continued zidovudine with didanosine in human immunodeficiency virus infection. *N Engl J Med* 1992; **327:** 581–7.

6. Butler KM, *et al.* Pancreatitis in human immunodeficiency virus-infected children receiving dideoxyinosine. *Pediatrics* 1993; **91:** 747–51.

Effects on the skin. Didanosine has been implicated in a case of Stevens-Johnson syndrome[1] and of cutaneous vasculitis.[2]

1. Parneix-Spake A, *et al.* Didanosine as probable cause of Stevens-Johnson syndrome. *Lancet* 1992; **340:** 857–8.
2. Herranz P, *et al.* Cutaneous vasculitis associated with didanosine. *Lancet* 1994; **344:** 680.

Precautions

Didanosine should be used with extreme caution in patients with a history of pancreatitis and those with increased triglyceride concentrations should be observed carefully for signs of pancreatitis and treatment with didanosine interrupted in all patients with signs and symptoms of possible pancreatitis, until it has been excluded. Use with other drugs likely to cause pancreatitis or peripheral neuropathy (see Interactions, below) should preferably be avoided; treatment with didanosine should be suspended if possible when use of such drugs is essential.

It may be necessary to interrupt didanosine treatment in patients who develop peripheral neuropathy; on recovery from peripheral neuropathy a reduced dose may be tolerated. Treatment should also be interrupted if uric acid concentrations are elevated.

Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Didanosine should be given with caution to patients with hepatomegaly or other risk factors for liver disease and patients with renal or hepatic impairment; dosage reduction may be necessary. Regular checks of liver function are recommended. If liver enzymes increase to 5 times the upper limit of normal during treatment then didanosine should be stopped. Treatment with didanosine may be associated with lactic acidosis and should also be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly, steatosis, or metabolic or lactic acidosis of unknown aetiology.

Children should be monitored for retinal lesions and didanosine withdrawn if they occur. Monitoring should also be considered in adults.

Interactions

Use of didanosine with other drugs known to cause pancreatitis (for example intravenous pentamidine) or with drugs that may cause peripheral neuropathy (for example metronidazole, isoniazid, and vincristine) should be avoided. If co-administration is unavoidable, patients should be monitored carefully for these adverse effects.

An increase in the area under the plasma concentration-time curve for didanosine has been reported when allopurinol or other xanthine oxidase inhibitors are given concurrently.

Plasma concentrations of didanosine may be reduced by methadone and increased by ganciclovir.

Didanosine formulations (chewable or dispersible preparation) contain an antacid and other drugs that could be affected by an increased gastric pH (for example HIV-protease inhibitors, ketoconazole, fluoroquinolone antibacterials, and dapsone) should be given at least 2 hours before didanosine. Didanosine preparations containing magnesium or aluminium antacids should not be given with tetracyclines.

Use of didanosine with tenofovir results in increased plasma concentrations of didanosine and consequently an increased risk of didanosine-related adverse effects such as peripheral neuropathy, pancreatitis, and lactic acidosis. Fatalities have been reported. There have also been reports of virological failure and emergence of resistance at an early stage of treatment when didanosine and tenofovir were given with lamivudine as part of a once daily triple nucleoside regimen. UK licensed product information for both didanosine and tenofovir does not recommend co-administration of these drugs either at standard or reduced doses of didanosine. A 250 mg daily dose of didanosine had been evaluated, but resulted in virological failure and the emergence of resistance. US product information for didanosine, however, recommends that co-administration may be undertaken with caution in patients with normal renal function. For patients weighing greater than 60 kg the dose of didanosine should be reduced to 250 mg daily, while for those weighing less than 60 kg a dose of 200 mg daily is recommended. US product information for tenofovir advises against using didanosine with tenofovir in patients under 60 kg due to a lack of data.

Ribavirin has been shown *in vitro* to increase the intracellular triphosphate levels of didanosine and to potentially increase the risk of adverse effects related to didanosine. UK product information for didanosine recommends that co-administration be undertaken with caution, while the US information does not recommend use of the two drugs together.

See also below for interactions with antivirals.

Antidiabetics. Fatal lactic acidosis has been reported[1] in a patient given *metformin* with didanosine, stavudine, and tenofovir.

1. Worth L, *et al.* A cautionary tale: fatal lactic acidosis complicating nucleoside analogue and metformin therapy. *Clin Infect Dis* 2003; **37:** 315–16.

Antivirals. Plasma concentrations of didanosine are roughly doubled when given *ganciclovir.*[1-3] *Valganciclovir,* the prodrug of ganciclovir, inhibits purine nucleoside phosphorylase and increases didanosine concentrations. Significant CD4+ T lymphocyte count decline and symptoms of didanosine toxicity, despite complete viral suppression, occurred in an HIV-positive patient given an antiretroviral regimen containing didanosine plus valganciclovir for the treatment of CMV enteritis. Complete CD4+ count recovery and resolution of symptoms occurred when didanosine was replaced with abacavir.[4]

Changes in the pharmacokinetics of didanosine and *zidovudine* have occurred when these drugs are given together, but results of studies have not been consistent, and the effects have generally been of limited clinical significance. For further details, see under Interactions in Zidovudine, p.915.

Tenofovir has been reported to significantly increase plasma concentrations of didanosine,[5] and may increase the risk of pancreatitis associated with didanosine.[6,7] There has also been a report of acute renal failure and fatal lactic acidosis when tenofovir was added to a regimen containing didanosine.[8]

Use of didanosine with *delavirdine* resulted in reductions in the area under the concentration-time curve for both drugs in a single-dose study.[9] Licensed product information for delavirdine recommends that these two drugs should be given at least 1 hour apart.

Absorption of some *HIV-protease inhibitors* may be reduced by the buffers in some didanosine formulations and doses should be at least 2 hours apart (see p.883).

Antiviral Action

Didanosine is converted intracellularly to its active form dideoxyadenosine triphosphate. This triphosphate halts the DNA synthesis of retroviruses, including HIV, through competitive inhibition of reverse transcriptase and incorporation into viral DNA.

Didanosine-resistant strains of HIV emerge during didanosine therapy. Cross-resistance to other nucleoside reverse transcriptase inhibitors has been recognised.

Resistance. Evidence for the development of didanosine-resistant HIV was reported in 36 of 64 patients with advanced HIV infection within 24 weeks of switching from zidovudine to didanosine monotherapy.[1] Patients with the didanosine resistance mutation for HIV reverse transcriptase showed a greater decline in CD4+ T cell count and increase in viral burden than those without.

Multiple-drug resistant mutations have been found in patients taking long-term combination antiretroviral therapy containing didanosine.[2]

1. Kozal MJ, *et al.* Didanosine resistance in HIV-infected patients switched from zidovudine to didanosine monotherapy. *Ann Intern Med* 1994; **121:** 263–8.
2. Kavlick MF, *et al.* Emergence of multi-dideoxynucleoside-resistant human immunodeficiency virus type 1 variants, viral sequence variation, and disease progression in patients receiving antiretroviral chemotherapy. *J Infect Dis* 1998; **98:** 1506–13.

Pharmacokinetics

Didanosine is rapidly hydrolysed in the acid medium of the stomach and is therefore given orally with pH buffers or antacids. Bioavailability is reported to range from 20 to 40% depending on the formulation used; the bioavailability is substantially reduced if taken with or after food. Maximum plasma concentrations are achieved about 1 hour after oral dosage. Binding to plasma proteins is reported to be less than 5%. Didanosine has been reported not to cross the blood brain barrier.

Didanosine is metabolised intracellularly to the active antiviral metabolite dideoxyadenosine triphosphate. The plasma elimination half-life is reported to be about 1.5 hours. Renal clearance is by glomerular filtration and active tubular secretion; about 20% of an oral dose is recovered in the urine. Didanosine is partially cleared by haemodialysis but not by peritoneal dialysis.

Uses and Administration

Didanosine is a nucleoside reverse transcriptase inhibitor structurally related to inosine with antiviral activity against HIV-1. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when didanosine is used alone, and it is therefore used with other antiretrovirals.

Didanosine is given orally, usually as buffered chewable/dispersible tablets or enteric-coated capsules. Doses should be taken at least 30 minutes before, or 2 hours after, a meal. The total daily dose may be given as either a single dose or as two divided doses, the choice being dependent upon both the formulation and the strength used. For adults weighing more than 60 kg the recommended dose is 400 mg daily and for those under 60 kg, 250 mg daily is given.

For details of doses in children, see below.

Doses of didanosine may need to be amended when given with some other antiretrovirals. For further details see under Interactions, above.

Dosage reduction may be necessary in patients with renal (see below) or hepatic impairment, although no specific dose reductions are recommended in patients with hepatic impairment and close monitoring is required.

◊ Reviews.

1. Shelton MJ, *et al.* Didanosine. *Ann Pharmacother* 1992; **26:** 660–70.

3. Perry CM, Noble S. Didanosine: an updated review of its use in HIV infection. *Drugs* 1999; **58:** 1099–1135.
4. Moreno S, *et al.* Didanosine enteric-coated capsule: current role in patients with HIV-1 infection. *Drugs* 2007; **67:** 1441–62.

Administration in children. For the treatment of HIV infection in children, didanosine is given daily with other antiretroviral drugs in doses based on body-surface. Doses are taken on an empty stomach. In the USA an oral solution is available for paediatric use:

- in children aged between 2 weeks and 8 months the recommended dose is 100 mg/m^2 twice daily
- in children over 8 months of age the recommended dose is 120 mg/m^2 twice daily

In the UK chewable or dispersible tablets or enteric-coated capsules are available for use:

- the chewable or dispersible tablets may be given orally to children older than 3 months of age, as either a single dose or as two divided doses, in a dose of 240 mg/m^2 daily *or* 180 mg/m^2 daily if given with zidovudine
- enteric-coated capsules may be given orally to children older than 6 years of age in a dose of 240 mg/m^2 daily *or* 180 mg/m^2 daily if given with zidovudine

Administration in renal impairment. Dosage of didanosine should be reduced in patients with renal impairment. The following doses are recommended based on the patient's creatinine clearance (CC):

Adults greater than 60 kg:

- CC more than 60 mL/minute: usual adult doses
- CC 30 to 59 mL/minute: 200 mg daily as a single dose or in two equally divided doses
- CC 10 to 29 mL/minute: 150 mg once daily
- CC less than 10 mL/minute: 100 mg once daily

Adults less than 60 kg:

- CC more than 60 mL/minute: usual adult doses
- CC 30 to 59 mL/minute: 150 mg daily as a single dose or in two equally divided doses
- CC 10 to 29 mL/minute: 100 mg once daily
- CC less than 10 mL/minute: 75 mg once daily

$C_{22}H_{46}O$ = 326.6.

CAS — 661-19-8.

ATC — D06BB11.

ATC Vet — QD06BB11.

Profile

Docosanol is an antiviral used topically five times daily as a 10% cream in the treatment of recurrent herpes labialis (p.854). Docosanol acts by inhibiting fusion between the cell plasma membrane and the herpes simplex virus, thereby preventing viral entry into cells and subsequent viral replication. It has been investigated for genital herpes.

Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing efavirenz are skin rashes and psychiatric or CNS disturbances. Mild to moderate rashes (usually maculopapular eruptions) generally appear within the first 2 weeks of starting therapy and may resolve within a month of continued treatment; of severe forms including erythema multiforme and Stevens-Johnson syndrome have been reported occasionally. CNS symptoms include agitation, amnesia, confusion, dizziness, euphoria, headache, insomnia or somnolence, impaired concentration, abnormal thinking or dreaming, convulsions, depersonalisation, and hallucinations. Nervous system symptoms usually begin during the first one or two days of therapy and generally resolve after the first 2 to 4 weeks; they may occur more frequently when efavirenz is taken with meals, possibly due to increased efavirenz plasma concentrations. Serious psychiatric adverse effects include severe depression, suicidal ideation and attempts, aggressive behaviour, and psychotic reactions including paranoia and mania. Other adverse effects include nausea and vomiting, diarrhoea, fatigue, and pancreatitis. Raised liver enzyme values and raised serum-cholesterol and -triglyceride concentrations have been reported. Hepatic failure and photoallergic dermatitis have occurred.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including efavirenz, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including efavirenz. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported.

◊ References.

1. Clifford DB, *et al.* Impact of efavirenz on neuropsychological performance and symptoms in HIV-infected individuals. *Ann Intern Med* 2005; **143:** 714–21.

Effects on the mouth. Burning mouth syndrome was diagnosed in a patient 2 weeks after adding efavirenz to her long-standing combination antiretroviral treatment regimen.[1] Efavirenz was stopped and the syndrome resolved within 1 week.

1. Borrás-Blasco J, *et al.* Burning mouth syndrome due to efavirenz therapy. *Ann Pharmacother* 2006; **40:** 1471–2.

Precautions

Efavirenz is contra-indicated in patients with severe hepatic impairment (Child-Pugh class C), and should be used with caution, and liver enzymes values monitored, in patients with mild to moderate liver disease. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events. Caution should be exercised in patients with a history of seizures or psychiatric disorders including depression. Efavirenz should be stopped if a severe skin rash, associated with blistering, desquamation, mucosal involvement, or fever, develops. Monitoring of serum lipids and blood-glucose may be considered during efavirenz treatment. Food may increase exposure to efavirenz and lead to an increase in the frequency of undesirable effects.

False-positive results in some urinary cannabinoid tests have been reported in subjects receiving efavirenz.

Pregnancy. Licensed product information states that efavirenz has been associated with teratogenicity in *animals*. No specific malformation pattern was noted in more than 200 pregnancies with first-trimester exposure to efavirenz as part of a combination antiretroviral regimen. However, retrospective analysis of these pregnancies noted a few cases of neural tube defects, including meningomyelocele. The use of adequate contraceptive measures is recommended during, and for 12 weeks after, treatment with regimens containing efavirenz.

Interactions

Efavirenz is metabolised mainly by cytochrome P450 isoenzymes including CYP3A4. Consequently, it may compete with other drugs metabolised by this system, potentially resulting in mutually increased plasma concentrations and toxicity. Enzyme inducers may decrease plasma concentrations of efavirenz; efavirenz itself acts as an enzyme inducer and can reduce plasma concentrations of other drugs. Inhibition of some P450 isoenzymes has also been found *in vitro*.

Efavirenz is contra-indicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These drugs include antihistamines (astemizole and terfenadine), calcium-channel blockers (bepridil), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), and sedatives and hypnotics (midazolam and triazolam). St John's wort decreases the concentration of efavirenz; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance. For further information on drug interactions of NNRTIs see Table 2, p.944.

Antibacterials. Plasma concentrations of efavirenz may be reduced by *rifampicin* and may necessitate an increase in the dose of efavirenz. A similar interaction might occur with *rifabutin*.

Use of efavirenz with *clarithromycin* has resulted in a decrease in the plasma concentration of clarithromycin and an increase in its active hydroxy metabolite. The combination has been associated with a high incidence of skin rashes.

Antifungals. Giving efavirenz with voriconazole results in a 2-way interaction; efavirenz decreases the concentration of voriconazole and voriconazole increases the concentration of efavirenz. When efavirenz is given with voriconazole, licensed product information for efavirenz suggests the voriconazole maintenance dose should be increased to 400 mg twice daily and the efavirenz dose reduced to 300 mg once daily.

Antivirals. For the effect of efavirenz on *HIV-protease inhibitors*, see p.883.

Grapefruit. The metabolism of efavirenz may be inhibited by concomitant ingestion of grapefruit juice.

Antiviral Action

Efavirenz acts by non-competitive inhibition of HIV-1 reverse transcriptase; it binds to the enzyme, disrupting the conformation of its catalytic site and impairing its RNA- and DNA-dependent polymerase activity.

Resistance to efavirenz and emergence of cross-resistance to other non-nucleoside reverse transcriptase inhibitors has been seen.

Pharmacokinetics

Efavirenz is absorbed after oral doses with peak plasma concentrations being achieved after about 3 to 5 hours. Steady-state plasma concentrations are reached in 6 to 7 days after multiple dosing. Bioavailability is increased after a high-fat meal. Efavirenz is more than 99% bound to plasma proteins and is distributed into the CSF. It is metabolised mainly by hepatic cytochrome P450 isoenzymes CYP3A4 and CYP2B6 into inactive hydroxylated, metabolites. Efavirenz acts as an enzyme inducer and induces its own metabolism resulting in a terminal half-life of 40 to 55 hours after multiple doses compared with 52 to 76 hours after a single dose. About 14 to 34% of a dose is excreted in the urine (less than 1% unchanged), and 16 to 61% in the faeces (primarily as unchanged drug).

Uses and Administration

Efavirenz is a non-nucleoside reverse transcriptase inhibitor with activity against HIV. It is used with other antiretrovirals for combination therapy of HIV infection and AIDS (p.856).

Efavirenz is given orally as *capsules* or *tablets* in a dose of 600 mg once daily; alternatively, it may be given as an *oral solution* in a dose of 720 mg once daily. Efavirenz tablets and capsules should be given on an empty stomach. Dosing at bedtime is recommended during the first 2 to 4 weeks of therapy to improve tolerability. Bioavailability of efavirenz from the oral solution is less than that from the capsule and so proportionately higher doses of the solution are used.

For details of doses in children and adolescents, see below.

Fixed-dose combination products have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing efavirenz in combination with emtricitabine and tenofovir are available in some countries.

◊ References.

3. Frampton JE, Croom KF. Efavirenz/emtricitabine/tenofovir disoproxil fumarate: triple combination tablet. *Drugs* 2006; **66:** 1501–12.

Administration in children. For the treatment of HIV infection in children 3 years of age and older and adolescents efavirenz is given daily with other antiretroviral drugs. In the USA oral *capsules* and *tablets* are available and the dose is based on body-weight:

- 10 to 14 kg: 200 mg once daily
- 15 to 19 kg: 250 mg once daily
- 20 to 24 kg: 300 mg once daily
- 25 to 32.4 kg: 350 mg once daily
- 32.5 to 39 kg: 400 mg once daily
- 40 kg or more: as for adults (above)

Capsules are also available in the UK for use in children and adolescents; doses are similar to those used in the USA.

In the UK an *oral solution* is also available; the dose ranges, which are again calculated in terms of body-weight, also depend on the age range:

- 13 to 14 kg: children less than 5 years, 360 mg daily; children 5 years and older, 270 mg once daily
- 15 to 19 kg: children less than 5 years, 390 mg daily; children 5 years and older, 300 mg once daily
- 20 to 24 kg: children less than 5 years, 450 mg daily; children 5 years and older, 360 mg once daily
- 25 to 32.4 kg: children less than 5 years, 510 mg daily; children 5 years and older, 450 mg once daily
- 32.5 to 39 kg: children 5 years and older, 510 mg once daily
- 40 kg or more: children 5 years and older, as for adults, above

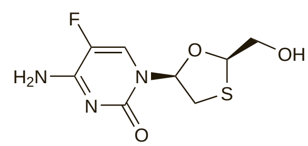
Эмтрицитабин

$C_8H_{10}FN_3O_3S$ = 247.2.

CAS — 143491-57-0.

ATC — J05AF09.

ATC Vet — QJ05AF09.



Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing emtricitabine are headache, diarrhoea, and nausea; hyperpigmented skin discoloration is very common in children and common in adults. Other common adverse effects include abdominal pain, vomiting, dyspepsia, abnormal dreams, asthenia, dizziness, insomnia, pain, allergic skin reactions, pruritus, rashes, and urticaria. Abnormal laboratory test results associated with emtricitabine-containing regimens include hyperbilirubinaemia, increases in serum lipase and pancreatic amylase, and raised liver enzymes. There have also been reports of neutropenia and anaemia. Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with NRTIs.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including emtricitabine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been observed in patients receiving antiretroviral therapy, including emtricitabine. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. NRTIs have also been associated with mitochondrial dysfunction manifesting as abnormal behaviour, anaemia, convulsions, hyperlipasaemia, hypertonia, and neutropenia. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported, particularly when nucleoside analogues have been given with HIV-protease inhibitors. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy. For further information on adverse effects associated with NRTIs see Zidovudine, p.914.

Precautions

Treatment with emtricitabine should be stopped if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. Emtricitabine should be given with caution to patients with hepatomegaly or other risk factors for liver disease. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events; treatment should be interrupted or stopped if there is evidence of exacerbation of liver disease. It is recommended that all patients should be tested for the presence of hepatitis B infection before treatment is begun, and that patients co-infected with HIV and hepatitis B should be monitored for several months after stopping treatment with emtricitabine for signs of exacerbations of hepatitis. Emtricitabine should be used with caution and doses adjusted in patients with renal impairment.

Interactions

Caution should be exercised when emtricitabine is given with other drugs eliminated by active tubular secretion as competition for the elimination pathway may increase the serum concentrations of either drug.

Antiviral Action

Emtricitabine is converted intracellularly in stages to the triphosphate. This triphosphate halts the DNA synthesis of HIV through competitive inhibition of reverse transcriptase. Emtricitabine-resistant strains of HIV have been identified and cross-resistance to other nucleoside reverse transcriptase inhibitors may occur.

Pharmacokinetics

Emtricitabine is rapidly and extensively absorbed from the gastrointestinal tract after oral doses, with peak plasma concentrations occurring after 1 to 2 hours. Bioavailability is reported to be 93% for the capsules. Binding to plasma proteins is reported to be less than 4%. The plasma elimination half-life is about 10 hours. Emtricitabine is metabolised to a limited degree, but is excreted largely unchanged in the urine and to a lesser extent in the faeces. It is partially removed by haemodialysis.

Uses and Administration

Emtricitabine is a nucleoside reverse transcriptase inhibitor related to cytosine with antiviral activity against HIV-1 and hepatitis B virus. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when emtricitabine is used alone, and it is therefore used with other antiretrovirals.

Emtricitabine is given orally once daily as capsules in a usual adult dose of 200 mg or 240 mg as oral solution.

For details of doses in infants, children, and adolescents, see below.

For details of doses of emtricitabine to be used in patients with renal impairment, see below.

Fixed-dose combination products have been developed in order to improve patient adherence and avoid monotherapy, thereby decreasing the risk of acquired drug resistance. Products containing emtricitabine in combination with tenofovir, and with efavirenz plus tenofovir are available in some countries.

◊ Reviews.

1. Dando TM, Wagstaff AJ. Emtricitabine/tenofovir disoproxil fumarate. *Drugs* 2004; **64:** 2075–82.
2. Modrzejewski KA, Herman RA. Emtricitabine: a once-daily nucleoside reverse transcriptase inhibitor. *Ann Pharmacother* 2004; **38:** 1006–14.

4. Saag MS. Emtricitabine, a new antiretroviral agent with activity against HIV and hepatitis B virus. *Clin Infect Dis* 2006; **42:** 126–31.

Administration in children. For the treatment of HIV infection in infants, children, and adolescents emtricitabine is given with other antiretroviral drugs. Doses, given once daily, are based on body-weight:

- in infants up to 3 months of age the *oral solution* is given in a dose of 3 mg/kg daily
- in infants, children, and adolescents over 3 months of age the oral solution is given in a dose of 6 mg/kg daily to a maximum daily dose of 240 mg
- the *capsules* may be given to children and adolescents weighing more then 33 kg in the usual adult dose of 200 mg daily.

Administration in renal impairment. Doses of emtricitabine should be reduced in patients with renal impairment, according to the patient's creatinine clearance (CC):

- CC at least 50 mL/minute: usual adult doses (as capsules or solution)
- CC 30 to 49 mL/minute: 200 mg every 48 hours (capsules) or 120 mg every 24 hours (oral solution)
- CC 15 to 29 mL/minute: 200 mg every 72 hours (capsules) or 80 mg every 24 hours (oral solution)
- CC less than 15 mL/minute: 200 mg every 96 hours (capsules) or 60 mg every 24 hours (oral solution)

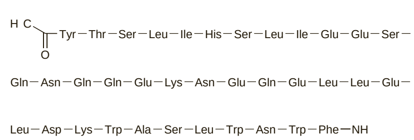
ATC Vet — QJ05AX07.



Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing enfuvirtide are local injection site reactions with resultant pain, erythema, induration, nodules and cysts, pruritus, and ecchymosis. These reactions have been reported to occur in 98% of patients, but only a small minority needed to stop therapy. Other very common adverse effects include nausea, diarrhoea, weight loss, and peripheral neuropathy. Anorexia, abdominal pain, constipation, pancreatitis, myalgia, weakness or loss of strength, lymphadenopathy, insomnia, depression, 'flu-like' illness, sinusitis, and conjunctivitis are also common. An increased incidence of some bacterial infections, in particular of pneumonia, has occurred in patients receiving enfuvirtide. Hypersensitivity reactions have occurred in about 1% of patients. Other adverse effects have included anxiety, hyperglycaemia, hypertriglyceridaemia, and eosinophilia.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy in HIV-infected patients with severe immune deficiency. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

◊ References.

1. Maggi P, *et al.* Cutaneous injection site reactions to long-term therapy with enfuvirtide. *J Antimicrob Chemother* 2004; **53:** 678–81.

Precautions

Enfuvirtide should be stopped immediately and should not be restarted in patients who develop signs of a systemic hypersensitivity reaction. An increased incidence of some bacterial infections, in particular of pneumonia, has been seen and patients receiving enfuvirtide should be closely monitored for signs of pneumonia. UK licensed product information recommends that enfuvirtide be used with caution in patients with hepatic impairment and in those with moderate to severe renal impairment. Patients co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events.

Antiviral Action

Enfuvirtide is an HIV fusion inhibitor that interferes with entry of HIV into cells by binding to the gp41 subunit of the viral envelope glycoprotein, thereby inhibiting fusion of viral and cellular membranes. Strains of HIV with reduced susceptibility to enfuvirtide have been isolated in patients receiving the drug but, owing to the different mode of action of enfuvirtide and the fact that it does not require intracellular activation for its activity, cross-resistance with other antiretrovirals may occur less frequently.

Resistance. References to the development of resistance to enfuvirtide.

1. Greenberg ML, Cammack N. Resistance to enfuvirtide, the first HIV fusion inhibitor. *J Antimicrob Chemother* 2004; **54:** 333–40.

Pharmacokinetics

Enfuvirtide is absorbed after subcutaneous injection with a mean absolute bioavailability of 84%. It is 92% bound to plasma proteins. Enfuvirtide is a peptide and is metabolised by hydrolysis; it does not inhibit cytochrome P450 isoenzymes. The elimination half-life is 3.8 hours after subcutaneous use, although elimination pathways have yet to be identified.

◊ References.

1. Patel IH, *et al.* Pharmacokinetics, pharmacodynamics and drug interaction potential of enfuvirtide. *Clin Pharmacokinet* 2005; **44:** 175–86.
2. Zhang X, *et al.* Population pharmacokinetics of enfuvirtide in HIV-1-infected pediatric patients over 48 weeks of treatment. *J Clin Pharmacol* 2007; **47:** 510–17.

Uses and Administration

Enfuvirtide is a synthetic 36-amino acid peptide that blocks HIV cell fusion and viral entry. It is used with other antiretrovirals for combination therapy of HIV infection and AIDS. Enfuvirtide is given by subcutaneous injection into the upper arm, anterior thigh, or abdomen in a usual dose of 90 mg twice daily. Each injection should be given at a different site from the preceding one. For details of doses in children and adolescents, see below.

7. Saberi P, *et al.* Immunologic benefits of enfuvirtide in patients enrolled in a drug assistance program. *Ann Pharmacother* 2008; **42:** 621–6.

Administration in children. For the treatment of HIV infection, enfuvirtide may be given to children 6 to 16 years of age by subcutaneous injection into the upper arm, anterior thigh, or abdomen in a dose of 2 mg/kg twice daily (to a maximum of 90 mg twice daily). Each injection should be given at a different site from the preceding one.

Entecavir *(USAN, rINN)*

BMS-200475-01; Entécavir; Entecavirum; SQ-34676. 9-[(1S,3R,4S)-4-Hydroxy-3-(hydroxymethyl)-2-methylenecyclopentyl]guanine monohydrate.

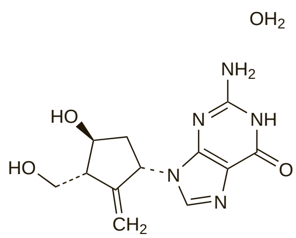
Энтекавир

$C_{12}H_{15}N_5O_3,H_2O$ = 295.3.

CAS — 142217-69-4 (anhydrous entecavir); 209216-23-9 (entecavir monohydrate).

ATC — J05AF10.

ATC Vet — QJ05AF10.



Adverse Effects

The most common adverse effects of entecavir have been headache, fatigue, dizziness, and nausea. Other adverse effects include diarrhoea, dyspepsia, insomnia, somnolence, and vomiting.

Raised liver enzyme concentrations may occur and exacerbation of hepatitis has been reported after stopping treatment with entecavir. Lactic acidosis, usually associated with severe hepatomegaly and steatosis, has been associated with treatment with nucleoside analogues alone or with antiretrovirals (see Zidovudine, p.914).

Entecavir is carcinogenic in *rodents*, but a relationship with human cancer has not been established.

Precautions

Entecavir should be withdrawn if there is a rapid increase in aminotransferase concentrations, progressive hepatomegaly or steatosis, or metabolic or lactic acidosis of unknown aetiology. Entecavir should be given with caution to patients with hepatomegaly or other risk factors for liver disease. Careful differentiation should be made between patients whose liver enzyme concentrations become elevated due to response to treatment and those in whom it is indicative of toxicity. Exacerbation of hepatitis B has been reported both during and after stopping treatment with entecavir. Hepatic function should be monitored closely while on treatment and for several months after treatment is stopped. Dosage reduction may be necessary in patients with renal impairment.

Limited clinical experience suggests there is a potential for HIV to develop resistance to NRTIs if entecavir is used to treat chronic hepatitis B virus infection in patients with undiagnosed or untreated HIV infection. Treatment with entecavir is not recommended for co-infected patients who are not also receiving HAART. US licensed product information recommends that all patients be tested for HIV antibodies before starting treatment with entecavir.

HIV-infected patients. It was initially thought that entecavir did not inhibit replication of HIV-1 at clinically relevant doses. However, a small consistent decrease in HIV-1 RNA was noted in 3 patients with HIV-1 and hepatitis B virus co-infection being treated with entecavir monotherapy.[1] In 1 of these patients, an HIV variant containing the M184V resistance substitution was found. Subsequent *in vitro* analyses showed that HIV-1 strains containing M184V were resistant to entecavir.

1. McMahon MA, *et al.* The HBV drug entecavir—effects on HIV-1 replication and resistance. *N Engl J Med* 2007; **356:** 2614–21.

Interactions

Caution should be exercised when entecavir is given with other drugs eliminated by active tubular secretion as competition for the elimination pathway may increase the serum concentrations of either drug.

Antiviral Action

Entecavir is phosphorylated intracellularly to the active triphosphate form which competes with deoxyguanosine triphosphate, the natural substrate of hepatitis B virus reverse transcriptase, thereby inhibiting every stage of the enzyme's activity.

Although initially thought to be inactive against HIV at clinically relevant doses, entecavir may have sufficient action to result in the selection of resistant HIV variants (see HIV-infected Patients, under Precautions, above).

Pharmacokinetics

Entecavir is rapidly absorbed from the gastrointestinal tract after oral doses. Peak plasma concentrations occur 30 to 90 minutes after an oral dose and steady state concentrations after 6 to 10 days of treatment. Absorption is both delayed and reduced by food; this is not considered to be clinically relevant in nucleoside treatment-naive patients but may affect efficacy in lamivudine-refractory patients in whom entecavir should be taken on an empty stomach. Bioavailability of the tablet formulation is equal to that of the oral solution and they may be given interchangeably. Binding of entecavir to plasma proteins is about 13% *in vitro*. Entecavir is not metabolised by the cytochrome P450 system. It is mainly eliminated by the kidneys by glomerular filtration and active tubular secretion, with a terminal elimination half-life of 128 to 149 hours. Small amounts of glucuronide and sulfate conjugates are formed. Entecavir is partially removed by haemodialysis.

Uses and Administration

Entecavir is a nucleoside reverse transcriptase inhibitor, structurally related to guanosine with selective antiviral activity against hepatitis B virus. It is used for the treatment of chronic hepatitis B (p.851) in adults with compensated liver disease with evidence of active viral replication, persistently elevated liver enzyme values, and histologically active disease, including those resistant to lamivudine. The usual oral dose of entecavir in nucleoside treatment-naive patients is 500 micrograms once daily, either with or without food. An oral dose of 1 mg once daily on an empty stomach should be used in patients with a history of hepatitis B viraemia during lamivudine therapy or with known resistance to lamivudine. For details of reduced doses to be used in patients with renal impairment, see below.

◊ Reviews.

2. Robinson DM, *et al.* Entecavir: a review of its use in chronic hepatitis B. *Drugs* 2006; **66:** 1605–22.
3. Matthews SJ. Entecavir for the treatment of chronic hepatitis B virus infection. *Clin Ther* 2006; **28:** 184–203.

Administration in renal impairment. Doses of entecavir should be reduced in patients with renal impairment according to creatinine clearance (CC) as follows:

- CC 30 to 49 mL/minute: 250 micrograms once daily or 500 micrograms every 48 hours in nucleoside treatment-naive patients; 500 micrograms once daily in lamivudine-refractory patients
- CC 10 to 29 mL/minute: 150 micrograms once daily or 500 micrograms every 72 hours in nucleoside treatment-naive patients; 300 micrograms once daily or 500 micrograms every 48 hours in lamivudine-refractory patients
- CC less than 10 mL/minute (and patients on haemodialysis or continuous ambulatory peritoneal dialysis): 50 micrograms once daily or 500 micrograms every 5 to 7 days in nucleoside treatment-naive patients; 100 micrograms once daily or 500 micrograms every 72 hours in lamivudine-refractory patients

Patients receiving haemodialysis should receive the appropriate dose after each dialysis session.

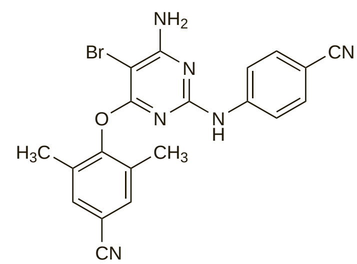
Etravirine *(USAN, rINN)*

Etravirina; Étravirine; Etravirinum; R-165335; TMC-125. 4-[6-Amino-5-bromo-2-(4-cyanoanilino)pyrimidin-4-yloxy]-3,5-dimethylbenzonitrile.

Этравирин

$C_{20}H_{15}BrN_6O$ = 435.3.

CAS — 269055-15-4.



Adverse Effects

The most common adverse effects associated with antiretroviral regimens containing etravirine are nausea and skin rash (usually mild to moderate) and generally appearing in the second week of treatment and resolving within 1 to 2 weeks. Severe skin reactions, including erythema multiforme and Stevens-Johnson syndrome, have occurred. Additional adverse events of moderate to severe intensity reported by at least 2% of patients receiving etravirine in clinical studies included gastrointestinal complaints (abdominal pain, diarrhoea, nausea, and vomiting), fatigue, headache, hypertension, and peripheral neuropathy. Raised liver enzyme values, glucose levels, and serum-cholesterol and -triglyceride concentrations have been reported.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including etravirine, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been seen in patients receiving antiretroviral therapy, including etravirine.

Precautions

Etravirine should be stopped if a severe skin rash develops. Patients co-infected with chronic hepatitis B or C have experienced worsening of hepatitis-related symptoms when treated with etravirine. Patients who have virologic failure on a NNRTI-containing regimen should not be given etravirine in a regimen containing only NRTIs.

Interactions

Etravirine is metabolised mainly by the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2C19. It is an inducer of CYP3A4 and an inhibitor of CYP2C9 and CYP2C19. Consequently it may compete with other drugs metabolised by these systems, potentially resulting in mutually altered plasma concentrations and possibly toxicity. Enzyme inducers may decrease plasma concentrations of etravirine.

Etravirine should not be given with other NNRTIs. It should also not be used in regimens with HIV-protease inhibitors given without ritonavir-boosting but use with ritonavir-boosted tipranavir, fosamprenavir, or atazanavir should be avoided. For further information on drug interactions of NNRTIs see Table 2, p.944.

Antiviral Action

Etravirine acts by inhibition of HIV-1 reverse transcriptase and blocks viral RNA- and DNA-dependent DNA polymerase activities. It is a flexible molecule designed to fit in the active pocket of viral reverse transcriptase in different ways, even when the shape of that pocket changes because of viral mutations. This is considered to reduce the risk of the development of resistance; phase II studies in treatment-experienced patients have shown activity against HIV resistant to other NNRTIs (delavirdine, efavirenz, and nevirapine).

Pharmacokinetics

Etravirine is readily absorbed after oral doses and peak plasma concentrations occur after about 2.5 to 4 hours; absorption is increased by food. It is about 99.9% bound to plasma proteins. Etravirine is extensively metabolised by hepatic microsomal enzymes, principally by the cytochrome P450 isoenzymes CYP3A4, CYP2C9, and CYP2C19 families, to substantially less active metabolites. The mean plasma half-life after usual dosage is about 41 hours and ranges from 21 to 61 hours. About 93.7% of a dose appears in the faeces (81.2 to 86.4% as unchanged drug), and 1.2% in the urine (unchanged drug was not detected in the urine).

Uses and Administration

Etravirine is a non-nucleoside reverse transcriptase inhibitor with activity against HIV-1. It is given with other antiretrovirals for the treatment of HIV infection and AIDS (p.856) in treatment-experienced patients, who have evidence of viral replication and HIV-1 strains resistant to a NNRTI and other antiretrovirals. Etravirine is given orally in a usual dose of 200 mg twice daily after food.

Pharmacopoeias. In *Chin.*

Adverse Effects and Precautions

The most common adverse effects of famciclovir are headache and nausea. Other adverse effects rarely reported include jaundice, vomiting, dizziness, skin rash, pruritus, urticaria, somnolence, confusion, and hallucinations. In addition, abdominal pain and fever have been reported in immunocompromised patients given famciclovir.

Dosage should be reduced in patients with renal impairment. Acute renal failure has occurred in patients with renal impairment taking inappropriately high doses of famciclovir.

◊ References.

1. Saltzman R, *et al*. Safety of famciclovir in patients with herpes zoster and genital herpes. *Antimicrob Agents Chemother* 1994; **38:** 2454–7.

Interactions

As for Penciclovir, p.901.

Antiviral Action

As for Penciclovir, p.901.

Pharmacokinetics

Famciclovir is rapidly absorbed after oral doses. Absorption is delayed but not reduced by food. Famciclovir is rapidly converted to penciclovir (see p.901), peak plasma concentrations occurring within about 1 hour of a dose, and virtually no famciclovir is detectable in the plasma or urine. Bioavailability of penciclovir is reported to be 77%. Famciclovir is mainly excreted in the urine (partly by renal tubular secretion) as penciclovir and its 6-deoxy precursor; elimination is reduced in patients with renal impairment.

◊ References.

4. Gill KS, Wood MJ. The clinical pharmacokinetics of famciclovir. *Clin Pharmacokinet* 1996; **31:** 1–8.

Uses and Administration

Famciclovir is a prodrug of the antiviral penciclovir (p.901). It is given orally in the treatment of herpes zoster (see Varicella-zoster Infections, p.855) and genital and mucocutaneous herpes (see Herpes Simplex Infections, p.854).

For **herpes zoster**, famciclovir is given in a dose of 250 mg three times daily, or 750 mg once daily, for 7 days (in the USA the recommended dose is 500 mg three times daily for 7 days); immunocompromised patients are given 500 mg three times daily for 10 days.

For **herpes simplex infections**, famciclovir is given in a dose of 250 mg three times daily for 5 days for first episodes of genital herpes; immunocompromised patients are given 500 mg twice daily for 7 days. For acute treatment of recurrent episodes of genital herpes, 125 mg is given twice daily for 5 days (in the USA, the recommended dose is 1 g twice daily for 1 day). Treatment should start in the prodromal period as soon as the first signs or symptoms appear. Immunocompromised patients are given 500 mg twice daily for 7 days.

For suppression of recurrent episodes of genital herpes, 250 mg is given twice daily; HIV patients may be given 500 mg twice daily. Such suppressive treatment is interrupted every 6 to 12 months to observe possible changes in the natural history of the disease.

For acute treatment of recurrent mucocutaneous herpes in HIV-infected patients, 500 mg is given twice daily for 7 days.

In the USA, famciclovir may also be given for the treatment of recurrent herpes labialis as a single 1.5 g dose, preferably begun in the prodromal period.

Doses of famciclovir should be reduced in patients with renal impairment (see below).

◊ Reviews.

4. Simpson D, Lyseng-Williamson KA. Famciclovir: a review of its use in herpes zoster and genital and orolabial herpes. *Drugs* 2006; **66:** 2397–2416.

Administration in renal impairment. Doses of famciclovir need to be reduced in patients with renal impairment. UK licensed product information recommends the following oral doses based on creatinine clearance (CC):

Immunocompetent patients:

Herpes zoster or an initial episode of genital herpes
- CC 30 to 59 mL/minute per 1.73 m^2: 250 mg twice daily
- CC 10 to 29 mL/minute per 1.73 m^2: 250 mg once daily

Acute recurrent genital herpes, treatment
- CC 30 to 59 mL/minute per 1.73 m^2: no dosage adjustment necessary
- CC 10 to 29 mL/minute per 1.73 m^2: 125 mg once daily

Recurrent genital herpes, suppression
- CC 30 mL/minute per 1.73 m^2 and over: 250 mg twice daily
- CC 10 to 29 mL/minute per 1.73 m^2: 125 mg twice daily

Immunocompromised patients:

Herpes zoster
- CC 40 mL/minute per 1.73 m^2 and over: 500 mg three times daily
- CC 30 to 39 mL/minute per 1.73 m^2: 250 mg three times daily
- CC 10 to 29 mL/minute per 1.73 m^2: 125 mg three times daily

Herpes simplex infections
- CC 40 mL/minute per 1.73 m^2 and over: 500 mg twice daily
- CC 30 to 39 mL/minute per 1.73 m^2: 250 mg twice daily
- CC 10 to 29 mL/minute per 1.73 m^2: 125 mg twice daily

Patients on haemodialysis should be given doses of famciclovir immediately after dialysis.

Натрий Фомивирсен

$C_{204}H_{243}N_{63}Na_{20}O_{114}P_{20}S_{20}$ = 7122.0.
CAS — 144245-52-3 (fomivirsen); 160369-77-7 (fomivirsen sodium).
ATC — S01AD08.
ATC Vet — QS01AD08.

Adverse Effects and Precautions

Adverse effects after intra-ocular injection of fomivirsen are confined to the treated eye. They include intra-ocular inflammation, transient increases in intra-ocular pressure, retinal detachment and oedema, and visual abnormalities. Other adverse effects associated with the intravitreal injection procedure include vitreal haemorrhage, endophthalmitis, uveitis, and cataract formation.

Patients should be monitored during treatment for changes in intra-ocular pressure and visual field and for extra-ocular CMV disease or disease in the contralateral eye.

Interactions
In order to reduce the risk of inflammation, intra-ocular use of fomivirsen is not recommended within 2 to 4 weeks of cidofovir treatment.

Antiviral Action
Fomivirsen is an antisense oligonucleotide that inhibits human CMV replication. It is active against strains of CMV resistant to ganciclovir, foscarnet, and cidofovir. Resistance to fomivirsen has been induced *in vitro*, but cross-resistance to antivirals with other modes of action is unlikely.

Uses and Administration
Fomivirsen is an antisense oligonucleotide that has been used as the sodium salt for the local treatment of CMV retinitis (p.853) in patients with AIDS. For newly diagnosed disease, a dose of 165 micrograms has been given by intravitreal injection into the affected eye once each week for 3 weeks, then on alternate weeks thereafter. For previously treated disease, 330 micrograms has been injected into the affected eye; this dose may be repeated once after 2 weeks and then once every 4 weeks thereafter.

Fosamprenavir Calcium *(USAN, rINNM)*

Calcii Fosamprenavirum; Fosamprenavir cálcico; Fosamprénavir Calcique; GW-433908G. (3*S*)-Tetrahydro-3-furyl{(α*S*)-α-[(1*R*)-1-hydroxy-2-(N^1-isobutylsulfanilamido)ethyl]phenethyl}carbamate calcium phosphate (1:1).

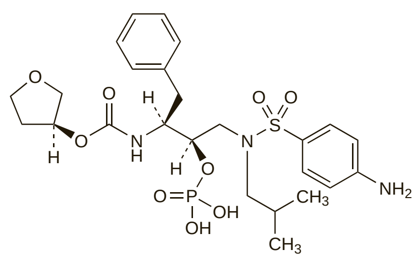
Кальций Фосампренавир

$C_{25}H_{36}CaN_3O_9PS$ = 625.7.

CAS — 226700-79-4 (fosamprenavir); 226700-81-8 (fosamprenavir calcium).

ATC — J05AE07.

ATC Vet — QJ05AE07.



(fosamprenavir)

Adverse Effects and Precautions
As for Amprenavir, p.865.

Interactions
Drugs interacting with amprenavir (p.866) might reasonably also be expected to interact with fosamprenavir.

For further information on drug interactions of HIV-protease inhibitors see under Indinavir Sulfate, p.883 and Table 1, p.917.

Antiviral Action
As for Amprenavir (see p.866). Fosamprenavir is a prodrug that is rapidly hydrolysed to amprenavir (p.865) by cellular phosphatases in the gut epithelium as it is absorbed. Fosamprenavir itself has little or no antiviral activity *in vitro*

Pharmacokinetics
After oral doses, fosamprenavir is rapidly hydrolysed to amprenavir in the gastrointestinal epithelium as it is absorbed. Peak plasma concentrations of amprenavir are attained after 1.5 to 4 hours. Fosamprenavir may be given with or without food. For details of the pharmacokinetics of amprenavir, see p.866.

◊ Reviews.

1. Wire MB, *et al.* Fosamprenavir: clinical pharmacokinetics and drug interactions of the amprenavir prodrug. *Clin Pharmacokinet* 2006; **45:** 137–68.

Uses and Administration
Fosamprenavir is a prodrug of amprenavir, which is an HIV-protease inhibitor with antiviral activity against HIV. Fosamprenavir is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when fosamprenavir is used alone, and it is therefore used with other antiretrovirals.

Fosamprenavir may be given with or without food. It is given orally as the calcium salt, but doses are expressed in terms of the base. Fosamprenavir calcium 748 mg is equivalent to about 700 mg of fosamprenavir or to 600 mg of amprenavir and 50 mg of fosamprenavir solution is equivalent to about 43 mg of amprenavir.

In the UK, the recommended dose of ritonavir-boosted fosamprenavir in both treatment-experienced and treatment-naive adult patients is fosamprenavir 700 mg twice daily *plus* ritonavir 100 mg twice daily.

In the USA, recommended doses in treatment-naive adult patients are:
- fosamprenavir 1.4 g twice daily *without ritonavir*, or
- fosamprenavir 1.4 g once daily *plus* ritonavir 200 mg once daily, or
- fosamprenavir 1.4 g once daily *plus* ritonavir 100 mg once daily, or
- fosamprenavir 700 mg twice daily *plus* ritonavir 100 mg twice daily

The recommended dose in treatment-experienced patients is fosamprenavir 700 mg twice daily *plus* ritonavir 100 mg twice daily.

For details of doses in children and adolescents, see below.

Doses should be reduced in patients with mild or moderate hepatic impairment (see below).

◊ Reviews.

1. Chapman TM, *et al.* Fosamprenavir: a review of its use in the management of antiretroviral therapy-naive patients with HIV infection. *Drugs* 2004; **64:** 2101–24.
2. Hester EK, *et al.* Fosamprenavir: drug development for adherence. *Ann Pharmacother* 2006; **40:** 1301–10.

Administration in children. For the treatment of HIV infection in children and adolescents, fosamprenavir is given daily with other antiretroviral drugs. Doses are based on body-weight and should not exceed the adult dose.

In the UK, the recommended dose of fosamprenavir oral solution in children and adolescents weighing 25 to 38 kg is 18 mg/kg twice daily *plus* ritonavir oral solution 3 mg/kg twice daily. Children and adolescents weighing at least 39 kg may be given the adult fosamprenavir tablet dose, see above. It is not licensed for use in children below 25 kg in weight or 6 years of age.

In the USA, the recommended dose of fosamprenavir oral suspension in treatment-naive children 2 to 5 years of age is fosamprenavir 30 mg/kg twice daily. Treatment-naive children 6 years of age or older may be given fosamprenavir 30 mg/kg twice daily or 18 mg/kg twice daily *plus* ritonavir 3 mg/kg twice daily. Treatment-experienced patients 6 years of age or older may be given fosamprenavir 18 mg/kg twice daily *plus* ritonavir 3 mg/kg twice daily.

Ritonavir 100-mg capsules may be given to children and adolescents taking fosamprenavir oral suspension if they weigh at least 33 kg.

Administration in hepatic impairment. Fosamprenavir should be used with caution in all patients with hepatic impairment.

UK licensed product information recommends:
- in patients with mild hepatic impairment (Child-Pugh score 5 to 6): fosamprenavir 700 mg twice daily *plus* ritonavir 100 mg once daily
- in patients with moderate hepatic impairment (Child-Pugh score 7 to 9): fosamprenavir 450 mg twice daily *plus* ritonavir 100 mg once daily

US licensed product information recommends:
- in treatment-naive patients with mild hepatic impairment (Child-Pugh score 5 to 6): fosamprenavir 700 mg twice daily *without ritonavir*, or *plus* ritonavir 100 mg once daily
- in treatment-experienced patients with mild hepatic impairment (Child-Pugh score 5 to 6): fosamprenavir 700 mg twice daily *plus* ritonavir 100 mg once daily
- in treatment-naive patients with moderate hepatic impairment (Child-Pugh score 7 to 9): fosamprenavir 700 mg twice daily *without ritonavir*, or fosamprenavir 450 mg twice daily *plus* ritonavir 100 mg once daily
- in treatment-experienced patients with moderate hepatic impairment (Child-Pugh score 7 to 9): fosamprenavir 450 mg twice daily *plus* ritonavir 100 mg once daily
- in treatment-naive patients with severe hepatic impairment (Child-Pugh score 10 to 12): fosamprenavir 350 mg twice daily *without ritonavir*

Fosamprenavir *plus* ritonavir should not be used in patients with severe hepatic impairment.

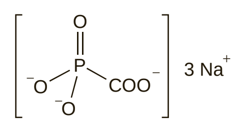
Фоскарнет Натрий

$CNa_3O_5P,6H_2O$ = 300.0.

CAS — 63585-09-1 (foscarnet sodium); 34156-56-4 (foscarnet sodium hexahydrate).

ATC — J05AD01.

ATC Vet — QJ05AD01.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Foscarnet Sodium Hexahydrate; Foscarnet Sodium BP 2008). A white or almost white crystalline powder. Soluble in water; practically insoluble in alcohol. A 2% solution in water has a pH of 9.0 to 11.0. Protect from light.

Incompatibility. Foscarnet sodium has been found to be visually incompatible with some commonly used injectable drugs including amphotericin B, aciclovir sodium, co-trimoxazole, ganciclovir, and pentamidine isetionate;[1,2] licensed product information also lists incompatibilities with vancomycin, glucose 30% solution, and solutions containing calcium. It is therefore recommended that foscarnet should not be infused via an intravenous line with any other drug.

1. Lor E, Takagi J. Visual compatibility of foscarnet with other injectable drugs. *Am J Hosp Pharm* 1990; **47:** 157–9.
2. Baltz JK, *et al.* Visual compatibility of foscarnet with other injectable drugs during simulated Y-site administration. *Am J Hosp Pharm* 1990; **47:** 2075–7.

Adverse Effects and Treatment
The most serious common adverse effect of foscarnet sodium is renal impairment, which may be severe. Anaemia may be common and granulocytopenia and thrombocytopenia have been reported. Foscarnet can chelate bivalent metal ions, and may be associated with an acute decrease in ionised calcium in the plasma that is not necessarily reflected by measurements of total calcium; the decrease is proportional to the rate of infusion. Other electrolyte disturbances may occur. Some patients may have convulsions. Excretion of high concentrations in the urine can cause local irritation and genital ulceration. Other adverse effects reported include nausea, vomiting, diarrhoea, malaise, fatigue, fever, headache, dizziness, paraesthesia, tremor, mood disturbances, rash, abnormal liver function tests, blood pressure and ECG changes, and isolated reports of pancreatitis. Intravenous injection may cause phlebitis at the site of injection.

In cases of overdosage it is important to maintain hydration. Foscarnet elimination may be increased by haemodialysis.

Effects on the CNS. Convulsions may occur in up to 10% of AIDS patients receiving foscarnet and have been reported after overdoses. Contributing factors include underlying CNS pathology (HIV-related encephalopathy or other infections) and foscarnet-related electrolyte disturbances. However, seizures have occurred in patients without apparent risk factors.[1]

1. Lor E, Liu YQ. Neurologic sequelae associated with foscarnet therapy. *Ann Pharmacother* 1994; **28:** 1035–7.

Effects on electrolyte balance. Acute hypocalcaemia has been reported to occur in about 30% of AIDS patients receiving foscarnet. Other electrolyte disturbances include hypokalaemia and hypomagnesaemia (each in about 15%), hypophosphataemia (8%), and hyperphosphataemia (6%). Hypocalcaemia may cause paraesthesias and, together with hypomagnesaemia and hypokalaemia, may predispose to seizures and cardiovascular disturbances.

Electrolyte abnormalities (increased calcium, magnesium, phosphate, and potassium requirements, and a reduction in the need for sodium) have been reported to be dramatically accelerated by foscarnet in a patient being given total parenteral nutrition.[1]

1. Matarese LE, *et al.* Foscarnet-induced electrolyte abnormalities in a bone marrow transplant patient receiving parenteral nutrition. *J Parenter Enteral Nutr* 2000; **24:** 170–3.

Effects on the kidneys. The most serious common adverse effect of foscarnet sodium is nephrotoxicity. Clinically significant increases in serum-creatinine concentrations occur in about 30% of patients, and the incidence of nephrotoxicity tends to increase with increasing dose[1] and with duration of therapy.[2] Foscarnet sodium is excreted unchanged in the urine and tubulo-interstitial lesions and deposition of crystals in the glomerular capillary lumen have been implicated.[3] Acute renal failure has occurred and haemodialysis has been reported to have reduced plasma-foscarnet concentrations.[4] The risk of nephrotoxicity can be minimised by ensuring adequate hydration, the use of intermittent dosing schedules,[5] and by adjusting the dose according to serum-creatinine concentrations. Nephrogenic diabetes insipidus and renal tubular acidosis associated with foscarnet have been reported.[6-8]

Effects on the skin and mucous membranes. A generalised pruritic macular rash was reported in a patient given foscarnet, which subsided after the drug was withdrawn.[1]

There have been several reports of genital ulceration,[2-7] possibly related to local toxicity arising from high concentrations of foscarnet in the urine. Oral ulceration, usually with genital ulceration, has occurred during foscarnet treatment.[3-5] Uvular and oesophageal ulcerations have also been reported.[4,8]

8. Saint-Marc T, *et al.* Uvula and oesophageal ulcerations with foscarnet. *Lancet* 1992; **340:** 970–1.

Precautions

Foscarnet sodium should be used with caution in renal impairment and doses should be reduced if serum creatinine is raised. Serum-creatinine concentrations should be measured on alternate days throughout induction treatment; monitoring may be weekly during maintenance therapy. An adequate state of hydration must be maintained during therapy to prevent renal toxicity. Electrolytes, especially calcium and magnesium, should also be monitored and deficiencies corrected before and during foscarnet therapy.

Electrolyte content. Each g of foscarnet sodium (hexahydrate) represents about 10 mmol of sodium and about 3.3 mmol of phosphate.

Interactions

Foscarnet should not be given with other nephrotoxic drugs such as aminoglycosides, amphotericin B, and ciclosporin, or with other drugs that can affect serum-calcium concentrations. Intravenous pentamidine can produce both of these effects and severe additive toxicity may result from its use with foscarnet; fatalities have occurred.

Ciprofloxacin. Tonic-clonic seizures associated with foscarnet use in 2 patients receiving multiple antimicrobial drugs were thought to have been exacerbated by the concurrent use of ciprofloxacin.[1]

1. Fan-Havard P, *et al.* Concurrent use of foscarnet and ciprofloxacin may increase the propensity for seizures. *Ann Pharmacother* 1994; **28:** 869–72.

Parenteral nutrition. For mention that foscarnet may exacerbate the need for electrolyte replacement in patients receiving total parenteral nutrition see Effects on Electrolyte Balance, above.

Antiviral Action

Foscarnet inhibits replication of human herpesviruses including CMV, herpes simplex virus types 1 and 2, herpesvirus 6, Epstein-Barr virus, and varicella-zoster virus. Activity is also reported against hepatitis B virus and HIV. Foscarnet acts by inhibition of virus-specific DNA polymerases and reverse transcriptases: unlike the nucleoside reverse transcriptase inhibitors and ganciclovir, foscarnet does not require intracellular conversion to an active triphosphate.

Pharmacokinetics

The pharmacokinetics of foscarnet are complicated by the high incidence of renal impairment induced during therapy and by the deposition and subsequent gradual release of foscarnet from bone. Thus the estimation of half-life depends upon the duration of foscarnet therapy and the duration of the observation period. The plasma half-life in patients with normal renal function is about 2 to 4 hours, but terminal half-lives up to about 8 days have been reported when accumulation in bone has taken place. Plasma protein binding is about 14 to 17%. Foscarnet crosses the blood-brain barrier in variable amounts; CSF concentrations ranging from zero to more than 3 times the plasma concentration have been reported. Foscarnet is mostly excreted unchanged in the urine mainly through glomerular filtration.

◊ In 13 HIV-infected male patients with lymphadenopathy or AIDS-related complex[1] foscarnet [sodium] by continuous intravenous infusion (0.14 to 0.19 mg/kg per minute) produced plasma-foscarnet concentrations of about 100 to 500 nanomol/mL. There appeared to be a link between the degree of adverse effects experienced and plasma-foscarnet concentrations above 350 nanomol/mL. Foscarnet was excreted mainly via the kidneys. It was thought that up to 20% of the cumulative intravenous dose may have been deposited in bone 7 days after the end of infusion.

Penetration of foscarnet into the CSF is very variable and in 5 patients[1] CSF concentrations of foscarnet were found to be 13 to 68% of those in the plasma. Subsequent studies showed that CSF concentrations of foscarnet would be virostatic in most patients,[2] attaining a mean concentration of about 25% of plasma concentration after a single infusion[2,3] and 66% under steady state conditions.[3] CSF concentrations ranged from 0 to 340%[2] and 5 to 72%[3] of those in plasma. There was a correlation between the amount of foscarnet in the CSF and inflammation of the meninges in one study,[2] and with the HIV infection stage in another,[3] but neither reported a correlation with plasma concentration.

Uses and Administration

Foscarnet is a non-nucleoside pyrophosphate analogue active against herpesviruses. It is used as the trisodium salt mainly for the treatment of CMV retinitis in AIDS patients and for aciclovir-resistant mucocutaneous herpes simplex virus infections in immunocompromised patients (see below).

Foscarnet is given by intravenous infusion. A solution containing foscarnet sodium 24 mg/mL may be given via a central vein or diluted with glucose 5% or sodium chloride 0.9% to a concentration of 12 mg/mL and given via a peripheral vein. Hydration with 0.5 to 1 litre of sodium chloride 0.9% is recommended with each infusion to reduce renal toxicity.

For the treatment of **CMV retinitis** in patients with normal renal function, the usual dose is 60 mg/kg infused over at least 1 hour every 8 hours, or 90 mg/kg infused over 1½ to 2 hours every 12 hours, for 2 to 3 weeks; this should then be followed by maintenance therapy with 60 mg/kg daily, increasing to 90 to 120 mg/kg daily infused over 2 hours if tolerated.

For the treatment of aciclovir-resistant mucocutaneous **herpes simplex virus infections** in patients with normal renal function, a dose of 40 mg/kg, infused over at least 1 hour every 8 or 12 hours is given for 2 to 3 weeks or until lesions have healed.

Doses of foscarnet should be reduced in patients with renal impairment (see below).

◊ Reviews.

1. Chrisp P, Clissold SP. Foscarnet: a review of its antiviral activity, pharmacokinetic properties and therapeutic use in immunocompromised patients with cytomegalovirus retinitis. *Drugs* 1991; **41:** 104–29.
2. Wagstaff AJ, Bryson HM. Foscarnet: a reappraisal of its antiviral activity, pharmacokinetic properties and therapeutic use in immunocompromised patients with viral infections. *Drugs* 1994; **48:** 199–226.

Administration in renal impairment. Doses of intravenous foscarnet sodium may need to be reduced in patients with renal impairment. The following doses, given every 8 hours, are suggested by the UK licensed product information according to creatinine clearance (CC):

treatment of CMV retinitis:

- CC more than 1.6 mL/kg per minute: 60 mg/kg
- CC 1.6 to 1.4 mL/kg per minute: 55 mg/kg
- CC 1.4 to 1.2 mL/kg per minute: 49 mg/kg
- CC 1.2 to 1.0 mL/kg per minute: 42 mg/kg
- CC 1.0 to 0.8 mL/kg per minute: 35 mg/kg
- CC 0.8 to 0.6 mL/kg per minute: 28 mg/kg
- CC 0.6 to 0.4 mL/kg per minute: 21 mg/kg
- CC less than 0.4 mL/kg per minute: use not recommended

treatment of aciclovir-resistant mucocutaneous herpes simplex infections:

- CC more than 1.6 mL/kg per minute: 40 mg/kg
- CC 1.6 to 1.4 mL/kg per minute: 37 mg/kg
- CC 1.4 to 1.2 mL/kg per minute: 33 mg/kg
- CC 1.2 to 1.0 mL/kg per minute: 28 mg/kg
- CC 1.0 to 0.8 mL/kg per minute: 24 mg/kg
- CC 0.8 to 0.6 mL/kg per minute: 19 mg/kg
- CC 0.6 to 0.4 mL/kg per minute: 14 mg/kg
- CC less than 0.4 mL/kg per minute: use not recommended

In the USA modification of doses by extending the dose interval has been recommended, resulting in proportional reductions in daily dose similar to those in the UK.

Cytomegalovirus infections. Foscarnet is used in the treatment of severe CMV infections (p.853) in immunocompromised patients and appears to possess similar efficacy to ganciclovir[1] (see also under Ganciclovir, p.880). It has been particularly useful in patients who require antiretroviral therapy for AIDS and are unable to tolerate ganciclovir (because of haematological toxicity). For patients unable to tolerate systemic therapy foscarnet has been tried as an intravitreal injection.[2-4] Beneficial responses have been reported with various regimens including intravitreal injections of foscarnet 1.2 mg every 48 hours for 4 doses[2] or induction with 2.4 mg twice weekly[4] or every 72 hours for 6 doses,[3] then once weekly maintenance thereafter.[3,4] Combined treatment with foscarnet and ganciclovir each given intravitreally has also been reported to be effective;[5] however, although combination systemic therapy has been widely used where resistance to ganciclovir is suspected, the evidence for a synergistic effect against CMV is not very strong.[6]

Foscarnet has also been investigated for primary prophylaxis of CMV infection in bone marrow transplant recipients at high risk of infection.[7,8]

Herpes simplex infections. Although foscarnet is effective in the treatment of herpes simplex infections it is usually reserved for severe or disseminated herpes simplex infections, particularly in immunocompromised patients who have infections resistant to aciclovir (see p.854). A 2% cream applied topically is effective in the treatment of refractory herpes simplex infections of the skin,[1] and is licensed for such use in some countries. Topical use of a 1% foscarnet cream has also been investigated.[2]

Varicella-zoster infections. Foscarnet is the recommended treatment for aciclovir-resistant varicella-zoster infections (p.855). In a study[1] of 5 patients with AIDS and aciclovir-resistant zoster infection complete healing was reported for 3 patients after treatment with foscarnet 120 mg/kg daily for 14 to 26 days. Two patients relapsed 7 and 14 days respectively after stopping treatment. In another study[2] 10 of 13 HIV-infected patients with aciclovir-resistant zoster infection had complete healing after treatment with 100 mg/kg twice daily of foscarnet for 12 to 30 days. Five of the patients relapsed after stopping treatment with the median time to relapse being 110 days.

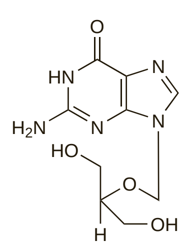
ATC Vet — QJ05AB06; QS01AD09.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Ganciclovir). A white to off-white crystalline powder. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Ganciclovir Sodium *(BANM, USAN, rINNM)*

Ganciclovir sódico; Ganciclovir Sodique; Natrii Ganciclovirum.

Натрий Ганцикловир

$C_9H_{12}N_5NaO_4$ = 277.2.

CAS — 107910-75-8.

ATC — J05AB06; S01AD09.

ATC Vet — QJ05AB06; QS01AD09.

Incompatibility. Ganciclovir is reported to be incompatible with foscarnet.

Stability. Ganciclovir sodium solution in sodium chloride 0.9% was found[1] to be stable when stored in polypropylene infusion-pump syringes for 12 hours at 25° and for 10 days at 4°. Little variation was found in ganciclovir concentration after storage of a 2% solution at room temperature, 5°, and –8° for 10 to 24 days.[2]

2. Morlet N, *et al.* High dose intravitreal ganciclovir for CMV retinitis: a shelf life and cost comparison study. *Br J Ophthalmol* 1995; **79:** 753–5.

Adverse Effects and Treatment

The most common adverse effects of systemic ganciclovir are haematological and include neutropenia and thrombocytopenia; anaemia also occurs. Neutropenia affects up to 50% of patients given ganciclovir, most commonly starting in the first or second week of use. It is usually reversible but may be prolonged or irreversible and can lead to potentially fatal infections. AIDS patients may be at a greater risk of neutropenia than other immunosuppressed patients. Thrombocytopenia occurs in about 20% of patients given ganciclovir. Those with iatrogenic immunosuppression may be more at risk of developing thrombocytopenia than AIDS patients. Other adverse effects occurring in patients given systemic ganciclovir include dyspnoea, headache, fever, rash, pruritus, asthenia, CNS and gastrointestinal disturbances, infection, increased serum-creatinine concentration, and abnormal liver function tests. Less frequent adverse effects reported include anaphylaxis, arrhythmias, hypotension, pancreatitis, haematuria, as well as metabolic, musculoskeletal, urogenital, and cutaneous symptoms. When given intravenously, irritation or phlebitis may occur at the site of injection due to the high pH.

Local adverse effects have been associated with the insertion of ocular implants of ganciclovir.

Animal studies have suggested that there may be a risk of adverse testicular effects with temporary or permanent inhibition of spermatogenesis. Female fertility may also be affected. Such studies also suggest that ganciclovir is a potential mutagen, teratogen, and carcinogen.

Haemodialysis and hydration may be useful in reducing plasma concentrations of ganciclovir. Haematological adverse effects may be reversed in some patients by stopping treatment or reducing dosage; blood cell counts should return to normal within 3 to 7 days.

Colony-stimulating factors have been given with ganciclovir to limit its haematological toxicity.

Effects on the blood. Ganciclovir-induced neutropenia was successfully treated in a patient with CMV retinitis and bone-marrow suppression by intravenous *molgramostim* 5 micrograms/kg.[1] In a multicentre, randomised placebo-controlled study[2] in 69 AIDS patients with CMV infection who developed neutropenia from ganciclovir therapy, *lenograstim* given in a dose of 50 micrograms/m^2 subcutaneously yielded similar positive results.

1. Russo CL, *et al.* Treatment of neutropenia associated with dyskeratosis congenita with granulocyte-macrophage colony-stimulating factor. *Lancet* 1990; **336:** 751–2.
2. Dubreuil-Lemaire M-L, *et al.* Lenograstim for the treatment of neutropenia in patients receiving ganciclovir for cytomegalovirus infection: a randomised, placebo-controlled trial in AIDS patients. *Eur J Haematol* 2000; **65:** 337–43.

Effects on mental function. Psychosis has been associated with intravenous ganciclovir use in 2 patients with normal renal function.[1,2] In both cases, psychotic symptoms such as agitation, confusion, and hallucination, occurred within 2 to 6 days of starting treatment with ganciclovir; symptoms resolved after ganciclovir was stopped.

1. Hansen BA, *et al.* Ganciclovir-induced psychosis. *N Engl J Med* 1996; **335:** 1397.
2. Southworth MR, Dunlap SH. Psychotic symptoms and confusion associated with intravenous ganciclovir in a heart transplant recipient. *Pharmacotherapy* 2000; **20:** 479–83.

Effects on the skin. An interstitial granulomatous drug reaction was reported[1] in a 57-year old woman after about one month of treatment with intravenous ganciclovir for CMV pneumonia. No other new drugs were given before the onset of the lesions and they resolved spontaneously within 2 weeks of stopping the ganciclovir.

1. Marcollo Pini A, *et al.* Interstitial granulomatous drug reaction following intravenous ganciclovir. *Br J Dermatol* 2008; **158:** 1391–3.

Precautions

Ganciclovir should be used with caution in patients with renal impairment and doses should be adjusted according to creatinine clearance. It should not be given by rapid or bolus injection and adequate hydration should be maintained during intravenous infusion. It should be given with caution to patients with low blood counts or with a history of cytopenic reactions to drugs. Complete blood and platelet counts should be performed every 2 days or daily during the first 14 days of intravenous therapy and once weekly thereafter; ganciclovir should be withdrawn if the neutrophil count falls below 500 cells/microlitre or the platelet count falls below 25 000 cells/microlitre. Patients receiving oral ganciclovir should also be monitored regularly.

Ganciclovir is contra-indicated in pregnancy; contraception is recommended during ganciclovir treatment and, additionally for men, for 90 days thereafter. Adverse effects have occurred in the offspring of *animals* given ganciclovir during pregnancy and lactation.

Because of the risk of carcinogenicity and the high pH of the solution, contact with the skin and eyes should be avoided during the reconstitution of ganciclovir sodium injection.

Sodium content. Each g of ganciclovir sodium represents about 3.6 mmol of sodium.

Interactions

Zidovudine given with ganciclovir may have an additive neutropenic effect and should not normally be given during intravenous ganciclovir induction therapy, although it has been given with caution during oral maintenance therapy. Probenecid and other drugs that inhibit renal tubular secretion and resorption may reduce the renal clearance of ganciclovir, and so increase its serum concentrations. Use of intravenous ganciclovir with oral mycophenolate mofetil may result in increased plasma concentrations of both drugs due to competition for renal tubular secretion. Drugs that inhibit rapid cell division such as amphotericin B, some antineoplastic drugs, co-trimoxazole, dapsone, flucytosine, hydroxycarbamide, nucleoside analogues, and pentamidine may have additive toxic effects if given with ganciclovir. Convulsions have been reported when ganciclovir was given with imipenem and cilastatin.

Antivirals. Additive haematological toxicity, including neutropenia, may occur if ganciclovir is given with *zidovudine* (see Zidovudine, p.915), and there are reports of increased plasma concentrations of *didanosine* when given with ganciclovir (see p.871). There has also been a report[1] of decreased blood concentrations of ganciclovir when didanosine (200 mg every 12 hours) was given orally 2 hours before oral ganciclovir (1 g every 8 hours) but not when the two drugs were given at the same time. However, a later study[2] using twice the dose of oral ganciclovir found no effect irrespective of whether ganciclovir was given 2 hours before or 2 hours after didanosine.

When ganciclovir was given orally with *zalcitabine*, a 22% increase in the area under the concentration-time curve for ganciclovir was noted although it was believed that this did not necessitate any dosage modification.[3] No pharmacokinetic changes were reported when ganciclovir was given orally with *stavudine*.[3]

1. Cimoch PJ, *et al.* Pharmacokinetics of oral ganciclovir alone and in combination with zidovudine, didanosine, and probenecid in HIV-infected subjects. *J Acquir Immune Defic Syndr Hum Retrovirol* 1998; **17:** 227–34.

The symbol † denotes a preparation no longer actively marketed

Ciclosporin. Reversible acute unilateral or bilateral eye movement disorders typical of sixth cranial nerve palsies[1] occurred in 4 patients who received ciclosporin and ganciclovir after bone marrow transplantation.

1. Openshaw H, *et al.* Eye movement disorders in bone marrow transplant patients on cyclosporin and ganciclovir. *Bone Marrow Transpl* 1997; **19:** 503–5.

Antiviral Action

Ganciclovir inhibits replication of human herpesviruses *in vivo* and *in vitro*. It is active against CMV, herpes simplex virus types 1 and 2, Epstein-Barr virus, varicella-zoster virus, and herpesvirus 6, 7, and 8. This activity is due to intracellular conversion of ganciclovir by viral thymidine kinase (in herpes simplex and varicella-zoster infected cells) or possibly by cellular deoxyguanosine kinase (in Epstein-Barr infected cells) to ganciclovir monophosphate with subsequent cellular conversion to the diphosphate and the active triphosphate. Ganciclovir triphosphate inhibits viral DNA synthesis by inhibiting the viral DNA polymerase enzyme as well as being incorporated into the viral DNA. This process is selective for infected cells; the concentration of ganciclovir triphosphate may be up to a hundredfold higher in CMV-infected cells than in uninfected cells.

Ganciclovir has a similar spectrum of activity to aciclovir, herpes simplex virus types 1 and 2 being the most susceptible of the herpesviruses. However, CMV is much more susceptible to ganciclovir than aciclovir.

Resistance

Resistance to ganciclovir has been found *in vitro* in herpes simplex viruses, varicella-zoster virus, and CMV. Possible mechanisms of resistance include a reduction in the phosphorylation of ganciclovir to the active form and reduced sensitivity of viral DNA polymerase. Resistance has been reported in CMV strains isolated from patients receiving ganciclovir for prolonged periods and in those with an initially high viral load. It has also been seen in AIDS patients with CMV retinitis who have never previously received the drug. Cross-resistance with cidofovir is common.

◊ The development of CMV resistance to ganciclovir may be a factor in disease progression in patients receiving prolonged therapy with ganciclovir and the incidence of resistance is reported to increase with duration of therapy.[1] A ganciclovir-resistant isolate of CMV has been detected in about 30% of 95 patients after 9 months of treatment and correlated with dissemination of infection to the contralateral eye.[2] Treatment of unilateral retinitis with systemic ganciclovir (intravenously, or orally together with an implant) was associated with a higher incidence of ganciclovir-resistant CMV infection developing in the contralateral eye, compared with treatment with ganciclovir implant alone.[3]

Ganciclovir-resistant CMV has been reported[4] to be an important cause of late morbidity in seronegative patients who received CMV-seropositive organ transplants; in one study,[5] 5 of 67 seronegative recipients developed ganciclovir-resistant CMV disease compared with none of 173 seropositive subjects.

Pharmacokinetics

Ganciclovir is poorly absorbed from the gastrointestinal tract after oral doses and there is minimal systemic absorption after intravitreal injection. Bioavailability of oral ganciclovir is about 5%, and is increased by intake with food to 6 to 9%. After intravenous dosage as ganciclovir sodium it is widely distributed to body tissues and fluids including intra-ocular fluid and CSF. Binding to plasma proteins is reported to be 1 to 2%. Ganciclovir is excreted unchanged in the urine mainly by glomerular filtration and also active tubular secretion. In patients with normal renal function the half-life is about 2.5 to 4.5 hours after intravenous doses and about 4 to 5.7 hours after oral doses. In patients with renal impairment, the renal clearance decreases and the half-life increases; a half-life of 28.5 hours has been reported when the serum-creatinine concentration was greater than 398 micromol/litre.

Haemodialysis has been reported to reduce plasma-ganciclovir concentrations by about 50%.

Uses and Administration

Ganciclovir is a synthetic nucleoside analogue of guanine closely related to aciclovir (p.862), but has greater activity against CMV. It is used for the treatment and suppression of life-threatening or sight-threatening CMV infections in immunocompromised patients, including those with AIDS and those with iatrogenic immunosuppression associated with organ transplantation or chemotherapy of neoplastic disease (see also below). It has also been used for superficial ocular herpes simplex infections.

Ganciclovir is given by intravenous infusion as the sodium salt but doses are expressed in terms of ganciclovir; 54.3 mg of ganciclovir sodium is equivalent to about 50 mg of ganciclovir. Solutions for infusion are usually prepared to give a concentration of ganciclovir of 50 mg/mL, then further diluted to contain not more than 10 mg/mL. An intravenous solution is given over 1 hour.

In **CMV infections**, the usual initial dose for ***treatment*** is 5 mg/kg by intravenous infusion every 12 hours for 14 to 21 days. This induction period may be followed by *maintenance* therapy to prevent recurrence or progression of the disease. The usual maintenance dosage is 5 mg/kg by intravenous infusion as a single daily dose for 7 days each week or 6 mg/kg daily for 5 days each week. If retinitis recurs or progresses a further induction course of ganciclovir may be given. AIDS patients who have received initial treatment with intravenous ganciclovir, and who have stable CMV retinitis following at least 3 weeks of intravenous therapy, may be given oral valganciclovir. In some countries oral formulations of ganciclovir sodium are available for maintenance; typical dosage is 3 g daily in divided doses.

For ***prevention*** of CMV infection in immunocompromised patients, specifically those receiving immunosuppressive therapy after organ transplantation, ganciclovir may be given in an *initial* dose of 5 mg/kg by intravenous infusion every 12 hours for 7 to 14 days, followed by intravenous *maintenance* therapy as above.

Doses of ganciclovir should be reduced in renal impairment (see below).

Intravitreal implants providing controlled release of ganciclovir are available for those patients with CMV retinitis who are unable to tolerate systemic therapy; the implants are designed to release ganciclovir over a period of 5 to 8 months.

Ganciclovir has been used as a topical ophthalmic 0.15% gel for the treatment of superficial ocular **herpes simplex infections**.

Administration in renal impairment. Doses of ganciclovir should be reduced in renal impairment. Licensed product information recommends the following intravenous doses based on creatinine clearance (CC):

- CC 70 mL/minute or more: 5 mg/kg every 12 hours for induction, followed by 5 mg/kg every 24 hours for maintenance
- CC 50 to 69 mL/minute: 2.5 mg/kg every 12 hours for induction, 2.5 mg/kg every 24 hours for maintenance
- CC 25 to 49 mL/minute: 2.5 mg/kg every 24 hours for induction, 1.25 mg/kg every 24 hours for maintenance
- CC 10 to 24 mL/minute: 1.25 mg/kg every 24 hours for induction, 0.625 mg/kg every 24 hours for maintenance
- dialysis patients: on days when dialysis is performed 1.25 mg/kg for induction, or 0.625 mg/kg for maintenance, in each case given shortly after the end of dialysis. In the USA, a maximum of 3 doses each week is recommended

Cytomegalovirus infections. Ganciclovir is used in both the treatment and prophylaxis of CMV infections (p.853) in immunocompromised patients although the prodrug valganciclovir, which is as effective as ganciclovir and has a more convenient oral dosage regimen, may now be preferred.

As with other herpesvirus infections, antiviral treatment tends to be suppressive rather than curative, and long-term maintenance therapy is necessary. Treatment in patients with AIDS is complicated by the additive haematological toxicity of ganciclovir and zidovudine. Clinical studies comparing ganciclovir with foscarnet for AIDS-related CMV retinopathy have shown higher mortality rates in patients given ganciclovir than in those given foscarnet.[1,2] The use of ganciclovir with CMV immunoglobulins[3,4] or normal immunoglobulins,[5] or with foscarnet[6,7] has been reported to improve both efficacy and tolerance.

An alternative is the use of *intravitreal* controlled-release ganciclovir implants[8-11] to avoid systemic adverse effects. Intravitreal ganciclovir used with intravitreal foscarnet has been reported to be effective.[12]

Oral preparations of ganciclovir have been tried for maintenance therapy and may be a useful adjunct to prevent systemic infection in patients treated with the intravitreal implants[13] (but see under Resistance, above). The use of oral ganciclovir in high doses has been investigated;[14] daily doses of up to 6 g have been reported to be of benefit, although a conclusive comparison with standard intravenous doses could not be made. CMV infections at other sites in AIDS patients, including gastrointestinal and pulmonary infections, respond less well to ganciclovir than does retinitis.

Ganciclovir is also valuable for prophylaxis and early treatment of CMV infections in *transplant recipients*.[7,15-22] It is not clear whether pre-emptive therapy in infected patients is a better strategy than prophylaxis.[23] For established infections, ganciclovir is reported to be more effective in solid organ transplant recipients than in bone marrow transplant recipients. Ganciclovir has also been tried for prevention of CMV infection in patients with AIDS, although results are conflicting.[24,25]

Treatment of *congenital infections* has a generally poor outcome. Prolonged treatment periods may improve the response, but the safety of extended treatment with ganciclovir in this age group has not been fully evaluated and there is a need for further randomised controlled studies.[26] There is some recent evidence[27] that a 6-week course started in neonates with clinically apparent disease affecting the CNS prevents hearing deterioration at 6 months and may also prevent deterioration at or beyond 1 year of age.

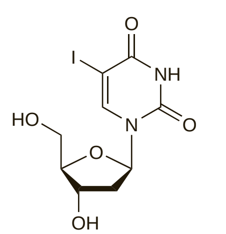
ATC Vet — QD06BB01; QJ05AB02; QS01AD01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn*, and *US.*

Ph. Eur. 6.2 (Idoxuridine). A white or almost white crystalline powder. M.p. about 180°, with decomposition. Slightly soluble in water and in alcohol; dissolves in dilute solutions of alkali hydroxides. A 0.1% solution in water has a pH of 5.5 to 6.5. Protect from light.

USP 31 (Idoxuridine). A white, practically odourless, crystalline powder. Slightly soluble in water and in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers. Protect from light.

Stability. Iodine vapour is liberated on heating idoxuridine. It has been reported that some decomposition products such as iodouracil are more toxic than idoxuridine and reduce its antiviral activity.

Adverse Effects

Hypersensitivity reactions such as irritation, pain, and pruritus may occur occasionally when idoxuridine is applied to the eyes. Other adverse effects include stinging, conjunctivitis, oedema and inflammation of the eye or eyelids, photophobia, pruritus, and rarely, occlusion of the lachrymal duct. Prolonged or excessive use may damage the cornea.

Idoxuridine applied to the skin may produce irritation, stinging, and hypersensitivity reactions. Taste disturbance may also occur. Excessive application of topical idoxuridine to the skin may cause skin maceration.

Idoxuridine is a potential carcinogen and teratogen.

Carcinogenicity. Squamous carcinoma has been reported in association with topical idoxuridine treatment.[1]

1. Koppang HS, Aas E. Squamous carcinoma induced by topical idoxuridine therapy? *Br J Dermatol* 1983; **108:** 501–3.

Precautions

Idoxuridine should be used with caution in conditions where there is deep ulceration involving the stromal layers of the cornea, as delayed healing has resulted in corneal perforation. Prolonged topical use should be avoided.

The potential teratogenicity of idoxuridine should be taken into account when treating pregnant patients or patients likely to become pregnant. Corticosteroids should be applied with caution in patients also receiving idoxuridine as they may accelerate the spread of viral infection.

Interactions

Preparations containing boric acid should not be applied to the eye in patients also receiving ocular preparations of idoxuridine as irritation ensues.

Antiviral Action

After intracellular phosphorylation to the triphosphate, idoxuridine is incorporated into viral DNA instead of thymidine so inhibiting replication of sensitive viral strains. Idoxuridine is also incorporated into mammalian DNA. Idoxuridine is active against herpes simplex and varicella zoster viruses. It has also been shown to inhibit vaccinia virus, CMV, and adenovirus.

Pharmacokinetics

Penetration of idoxuridine into the cornea and skin is reported to be poor. Idoxuridine is rapidly metabolised in the body to iodouracil, uracil, and iodide, which are excreted in the urine.

Uses and Administration

Idoxuridine is a pyrimidine nucleoside structurally related to thymidine. It is used topically in the treatment of herpes simplex keratitis and cutaneous infections with herpes simplex (p.854) and herpes zoster (see Varicella-zoster Infections, p.855), but has generally been superseded by other antivirals.

In the treatment of herpes simplex keratitis, idoxuridine is applied as a 0.1% ophthalmic solution or a 0.5% eye ointment.

Idoxuridine 5% in dimethyl sulfoxide (to aid absorption) may be painted onto the lesions of cutaneous herpes simplex and herpes zoster four times daily for 4 days.

Preparations

BP 2008: Idoxuridine Eye Drops;
USP 31: Idoxuridine Ophthalmic Ointment; Idoxuridine Ophthalmic Solution.

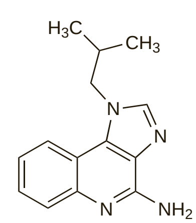
Imiquimod *(BAN, USAN, rINN)*

Imikimod; Imikimodi; Imiquimodum; R-837; S-26308. 4-Amino-1-isobutyl-1*H*-imidazo[4,5-*c*]quinoline.

Имихимод

$C_{14}H_{16}N_4$ = 240.3.
CAS — 99011-02-6.
ATC — D06BB10.
ATC Vet — QD06BB10.



Adverse Effects

Adverse effects after topical application of imiquimod include local skin erosion, erythema, excoriation, flaking, and oedema. There have been reports of localised hypopigmentation and hyperpigmentation. Skin reactions away from the site of application have been reported. Systemic effects after topical application include headache, flu-like symptoms, and myalgia.

Hypotension has occurred after repeated ingestion.

Hypersensitivity. Angioedema, initially of both the hands and feet and later the tongue, occurred in a 61-year-old man 3 weeks after starting treatment with a 5% imiquimod cream for squamous cell carcinoma *in situ* (Bowen's disease).[1]

1. Barton JC. Angioedema associated with imiquimod. *J Am Acad Dermatol* 2004; **51:** 477–8.

Uses and Administration

Imiquimod is an immune response modifier used topically in the treatment of external genital and perianal warts (p.1584), superficial basal cell carcinomas, and actinic keratoses (see below). For the treatment of genital and perianal **warts**, it is applied as a

5% cream three times each week for up to 16 weeks and is left on the skin for 6 to 10 hours. For the management of superficial **basal cell carcinoma**, a 5% cream is applied 5 times each week for 6 weeks and left on the skin for about 8 hours. For the treatment of **actinic keratoses** on the face or scalp, a 5% cream is also used and is again left on the skin for 8 hours. In the UK, this is applied 3 times each week for 4 weeks, repeated after a 4-week break for a further 4 weeks if necessary; in the USA, application twice a week for 16 weeks is recommended.

Imiquimod is also under investigation for the treatment of other squamous cell carcinomas.

◊ Reviews.

(indinavir)

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Indinavir Sulphate). A white or almost white, hygroscopic powder. Freely soluble in water; soluble in methyl alcohol; practically insoluble in heptane. Store in airtight containers. Protect from light.

USP 31 (Indinavir Sulfate). Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from moisture.

Adverse Effects

The most commonly reported adverse effects associated with antiretroviral regimens containing indinavir include gastrointestinal disturbances (abdominal pain, diarrhoea, dyspepsia, nausea and vomiting), taste disturbances, headache, and dizziness. Nephrolithiasis, often with flank pain and occurring with or without haematuria, is the most frequently reported serious adverse effect. It appears to be dose-related and is more frequent in patients taking more than 2.4 g daily; it also occurs more often in children. Temporarily stopping treatment and giving fluids often resolve the symptoms, but interstitial nephritis and acute renal failure have been reported. Dry skin and skin rashes occur commonly and may occasionally be severe. Cases of Stevens-Johnson syndrome and erythema multiforme have also been reported. Hypersensitivity reactions, including vasculitis and sometimes anaphylaxis, have been associated with indinavir. Hepatitis, including cases resulting in hepatic failure and death has occurred. Cases of acute haemolytic anaemia have been reported again with some fatalities. Other commonly reported adverse effects are dry mouth, dysuria, fatigue, flatulence, hypoaesthesia, insomnia, paraesthesia, pruritus, and acid regurgitation. Neutrophil counts may be reduced and mean corpuscular volume increased. Abnormal laboratory test results associated with indinavir-containing regimens have included crystalluria, haematuria, proteinuria, raised liver enzymes, and asymptomatic hyperbilirubinaemia.

Immune reconstitution syndrome (an inflammatory immune response resulting in clinical deterioration) has been reported during the initial phase of treatment with combination antiretroviral therapy, including indinavir, in HIV-infected patients with severe immune deficiency. Accumulation or redistribution of body fat (lipodystrophy) including central obesity, dorsocervical fat enlargement (buffalo hump), peripheral wasting, facial wasting, breast enlargement, and cushingoid appearance have been observed in patients receiving antiretroviral therapy, including indinavir. Metabolic abnormalities such as hypertriglyceridaemia, hypercholesterolaemia, insulin resistance, hyperglycaemia, and hyperlactataemia have also been reported. Elevated creatine phosphokinase, myalgia, myositis, and rarely rhabdomyolysis have been reported with HIV-protease inhibitors, particularly when given with nucleoside analogues. Osteonecrosis has been reported, particularly in patients with advanced HIV disease or long-term exposure to combination antiretroviral therapy.

◊ Reviews.

1. Moyle GJ, Gazzard BG. A risk-benefit assessment of HIV protease inhibitors. *Drug Safety* 1999; **20:** 299–321.

Effects on carbohydrate and lipid metabolism. HIV-protease inhibitors have been associated with a lipodystrophy syndrome characterised by peripheral fat wasting, central adiposity and the so called 'buffalo hump', hyperlipidaemia, and insulin resistance.[1]

A survey of 113 HIV-infected patients receiving HIV-protease inhibitors found lipodystrophy in 83% (severe in 11%) and impaired glucose tolerance in 23% (including diabetes mellitus in 7%) after a mean of 21 months of therapy.[2]

A systematic review[3] of published material has concluded that use of HIV-protease inhibitors is associated with increased concentrations of total cholesterol, triglycerides, and low-density lipoprotein; that use is often associated with morphological signs of cardiovascular disease such as increased carotid intima thickness or atherosclerotic lesions; and that there is some evidence of an increased risk of myocardial infarction. Comparison of the effect of specific protease inhibitors showed that ritonavir was consistently associated with elevated lipids and that, although some studies showed that saquinavir was associated with elevated lipids, it was to a lesser degree than other drugs. Guidelines[4] have been published outlining the management, including drug therapy, of antiretroviral-induced lipid disorders in HIV-infected patients.

Impaired glucose tolerance has been linked to reduction in insulin sensitivity[5] and has responded to treatment with sulfonylureas or insulin.[6]

6. Dubé MP, *et al.* Protease inhibitor-associated hyperglycaemia. *Lancet* 1997; **350:** 713–14.

Effects on the cardiovascular system. For adverse effects of HIV-protease inhibitors on carbohydrate and lipid metabolism that increase the risk of coronary vascular disease, see above.

Effects on the kidneys. Nephrolithiasis has been reported in about 10% of patients receiving indinavir, and the incidence may be higher in patients with haemophilia or hepatitis C infection.[1] Both asymptomatic[2] and symptomatic[3,4] crystalluria have been reported in patients receiving indinavir, with symptomatic urinary-tract disease in 8%. Indinavir has been identified as the major constituent of both urinary crystals[2] and calculi.[5] In addition there have been reports of acute interstitial nephritis associated with indinavir[6] and deterioration of renal function associated with both indinavir[7] and ritonavir.[8,9] Renal atrophy was associated with long-term treatment with indinavir.[10,11]

3. Picard O, *et al.* Hepatotoxicity associated with ritonavir. *Ann Intern Med* 1998; **129:** 670–1.

Effects on the menstrual cycle. Irregular, prolonged, or heavy menstruation[1] in 4 patients receiving ritonavir subsequently returned to normal in the 3 who were transferred to a different HIV-protease inhibitor.

1. Nielsen H. Hypermenorrhoea associated with ritonavir. *Lancet* 1999; **353:** 811–12.

Effects on mental state. Acute paranoid reactions occurred on two occasions in a patient receiving saquinavir.[1]

1. Finlayson JA, Laing RBS. Acute paranoid reaction to saquinavir. *Am J Health-Syst Pharm* 1998; **55:** 2016–17.

Effects on the pancreas. Pancreatitis was associated with use of ritonavir with saquinavir in 1 patient,[1] and with ritonavir (other drugs unspecified) in 2 others,[2] and was believed to be secondary to hyperlipidaemia (see Effects on Carbohydrate and Lipid Metabolism, above).

1. McBride M, *et al.* Lipid lowering therapy in patients with HIV infection. *Lancet* 1998; **352:** 1782–3.
2. Di Perri G, *et al.* HIV-protease inhibitors. *N Engl J Med* 1998; **339:** 773–4.

Effects on sexual function. Sexual dysfunction has been reported in patients given combination therapy with HIV-protease inhibitors and reverse transcriptase inhibitors.[1,2]

1. Martínez E, *et al.* Sexual dysfunction with protease inhibitors. *Lancet* 1999; **353:** 810–11.
2. Colebunders R, *et al.* Sexual dysfunction with protease inhibitors. *Lancet* 1999; **353:** 1802.

Effects on the skin. Skin rashes have been reported in about 20% of patients receiving indinavir and in 3 to 5% of patients receiving nelfinavir or saquinavir. Rash is described as a frequent adverse effect of ritonavir. In patients taking indinavir who reported rashes,[1] the rash commonly appeared within 2 weeks of starting treatment, was frequently accompanied by pruritus, and was usually self-limiting, commonly resolving within 4 weeks.

Paronychia and pyogenic granuloma of the great toes has been reported in patients receiving indinavir.[2]

1. Gajewski LK, *et al.* Characterization of rash with indinavir in a national patient cohort. *Ann Pharmacother* 1999; **33:** 17–21.
2. Bouscarat F, *et al.* Paronychia and pyogenic granuloma of the great toes in patients treated with indinavir. *N Engl J Med* 1998; **338:** 1776–7.

Precautions

Indinavir is primarily metabolised in the liver and therefore caution and possible dosage reduction are required in hepatic impairment. Patients with pre-existing liver disease or co-infected with chronic hepatitis B or C and treated with combination antiretroviral therapy are at increased risk for severe and potentially fatal hepatic adverse events.

Although renal excretion is a relatively minor route of elimination, adequate hydration is recommended to reduce the risk of nephrolithiasis; monitoring is advised in the presence of renal impairment. Treatment may need to be temporarily interrupted or stopped completely in patients developing nephrolithiasis. Caution is advised in treating patients with haemophilia A and B as reports of spontaneous bleeding have been associated with the use of HIV-protease inhibitors.

Mycobacterial infections. Patients with a previously unsuspected *Mycobacterium avium* complex infection experienced a severe febrile syndrome with inflammatory lymphadenitis after starting indinavir treatment.[1] The reaction resolved with appropriate antimycobacterial therapy.

1. Race EM, *et al.* Focal mycobacterial lymphadenitis following initiation of protease-inhibitor therapy in patients with advanced HIV-1 disease. *Lancet* 1998; **351:** 252–5.

Pregnancy. A retrospective survey[1] involving 89 women who received HIV-protease inhibitors during pregnancy indicated that these antivirals appeared generally safe.

1. Morris AB, *et al.* Multicenter review of protease inhibitors in 89 pregnancies. *J Acquir Immune Defic Syndr* 2000; **25:** 306–11.

Interactions

Indinavir is metabolised mainly by the cytochrome P450 isoenzyme CYP3A4. It may compete for the same metabolic pathways with a wide range of drugs that are metabolised similarly, often resulting in mutually increased plasma concentrations. A drug that is a significant inducer of microsomal enzymes, particularly CYP3A4, may reduce plasma concentrations of indinavir. HIV-protease inhibitors may themselves induce metabolism and may reduce plasma concentrations of other drugs.

Indinavir is contraindicated with drugs that are highly dependent on CYP3A4 for clearance and for which elevated plasma concentrations are associated with serious or life-threatening events. These include antiarrhythmics (amiodarone and flecainide), antihistamines (astemizole and terfenadine), ergot derivatives (dihydroergotamine, ergometrine, ergotamine, and methylergometrine), gastrointestinal prokinetics (cisapride), antipsychotics (pimozide), sedatives and hypnotics (alprazolam, midazolam, and triazolam), and statins (lovastatin and simvastatin). Rifampicin and St John's wort decrease the concentration of indinavir; use with the antiretroviral is not recommended due to the possible loss of its activity and development of resistance. Use of indinavir with atazanavir is contra-indicated as both drugs have been associated with indirect hyperbilirubinaemia.

Other HIV-protease inhibitors may have similar interactions. The principal interactions that have been reported as a risk for one or more of the various HIV-protease inhibitors are listed below. For further information on drug interactions of HIV-protease inhibitors see Table 1, p.917.

◊ References to interactions associated with HIV-protease inhibitors.

1. Eagling VA, *et al.* Differential inhibition of cytochrome P450 isoforms by the protease inhibitors, ritonavir, saquinavir and indinavir. *Br J Clin Pharmacol* 1997; **44:** 190–4.
2. von Moltke LL, *et al.* Protease inhibitors as inhibitors of human cytochromes P450: high risk associated with ritonavir. *J Clin Pharmacol* 1998; **38:** 106–11.
3. Malaty LI, Kuper JJ. Drug interactions of HIV protease inhibitors. *Drug Safety* 1999; **20:** 147–69.

Amfetamines. For mention of interactions, including a fatal serotonergic reaction, with *methylenedioxymethamfetamine* (Ecstasy) in patients receiving ritonavir, see p.2159.

Analgesics. Ritonavir and possibly other HIV-protease inhibitors produce complex and potentially serious interactions with some opioids (see p.103). Interactions between ritonavir and *dextropropoxyphene* (p.41) or *pethidine* (p.114) are considered to be especially hazardous. Ritonavir might also prolong *fentanyl*-induced respiratory depression (see p.57). Amprenavir, nelfinavir, ritonavir, and ritonavir-boosted HIV-protease inhibitors may reduce plasma concentrations of *methadone* (see p.84). For the effect of some HIV-protease inhibitors on the pharmacokinetics of *buprenorphine*, see p.30.

Use of ritonavir with *piroxicam* can result in potentially toxic concentrations of piroxicam (see p.118).

Antiarrhythmics. Use of HIV-protease inhibitors with the antiarrhythmics *amiodarone, encainide, flecainide, propafenone*, or *quinidine* may result in potentially toxic plasma concentrations of these drugs with an increased risk of ventricular arrhythmias.

Antibacterials. Plasma concentrations of HIV-protease inhibitors may be reduced to subtherapeutic levels by *rifabutin* or *rifampicin*. In addition, plasma concentrations of rifabutin may be increased, with a consequent risk of uveitis. In general, HIV-protease inhibitors should not be used with rifampicin (p.327) and dosage modifications may be necessary if used with rifabutin; licensed product information for indinavir recommends increasing the dose of the antiretroviral to 1 g every 8 hours and halving the dose of rifabutin. Further information is given in Rifabutin under Interactions, p.324 and Uses, Tuberculosis and HIV Infection, p.325.

HIV-protease inhibitors may inhibit the metabolism of *clarithromycin* (p.249) and possibly other macrolides.

Antidepressants. HIV-protease inhibitors may inhibit the metabolism of *desipramine* and other tricyclic antidepressants (p.380). Interactions may also occur between HIV-protease inhibitors and SSRIs such as *fluoxetine* (p.396), and have also occurred with *bupropion* (p.384).

Plasma concentrations of HIV-protease inhibitors may be reduced by *St John's wort* as a result of induction of cytochrome P450; concomitant use should be avoided.[1]

1. Piscitelli SC, *et al.* Indinavir concentrations and St John's wort. *Lancet* 2000; **355:** 547–8. Correction. *ibid.* 2001; **357:** 1210.

Antiepileptics. Reduced plasma concentrations of HIV-protease inhibitors may be anticipated if the enzyme inducers *carbamazepine, phenobarbital*, or *phenytoin* are given concurrently. Nelfinavir has been reported to reduce the plasma concentration of phenytoin (p.499); a similar effect may occur with ritonavir. In addition, carbamazepine concentrations have been reported to be increased by ritonavir (p.475).

Antifungals. Plasma concentrations of HIV-protease inhibitors may be increased by azole antifungals. Licensed product information recommends that the dose of indinavir should be reduced to 600 mg every 8 hours when given with *itraconazole* 200 mg twice daily. A dose reduction is not considered necessary by the UK licensed product information when indinavir is given with *ketoconazole*, but the US product information recommends a reduction to indinavir 600 mg every 8 hours.

Conversely, plasma concentrations of ketoconazole are increased by ritonavir.

Antihistamines. HIV-protease inhibitors inhibit the metabolism of non-sedating antihistamines such as *astemizole* and *terfenadine* resulting in increased plasma concentrations of these drugs and an increased risk of serious ventricular arrhythmias. Such combinations should be avoided.

Antipsychotics. Ritonavir and possibly other HIV-protease inhibitors may increase plasma concentrations of *clozapine* (but see p.984), *pimozide* (p.1018), and *sertindole* (p.1028) resulting in increased toxicity. Concomitant use should be avoided. Plasma concentrations of *thioridazine* may also be increased when given with some HIV-protease inhibitors.

Antivirals. HIV-protease inhibitors can inhibit metabolism of other drugs from the same class and increases in adverse effects have resulted.

Plasma concentrations of atazanavir, indinavir,[1] and lopinavir-ritonavir may be reduced by *nevirapine*; the UK licensed product information for indinavir recommends a dose increase of indinavir to 1 g every 8 hours be considered.

Plasma concentrations of indinavir[2] and saquinavir may be increased by *delavirdine*; the UK licensed product information for indinavir recommends a dose reduction of indinavir to 400 to 600 mg every 8 hours in patients receiving delavirdine and the UK licensed information for saquinavir recommends that liver function should be monitored if saquinavir is given with delavirdine.

Plasma concentrations of amprenavir, atazanavir, indinavir, *lopinavir*, and saquinavir are decreased when given with *efavirenz*. The use of efavirenz with ritonavir is associated with an increased frequency of adverse effects, presumably due to competitive inhibition of metabolism, and liver enzymes should be monitored in patients receiving this combination. Plasma concentrations of nelfinavir are increased when given with efavirenz, but the combination is usually well tolerated at standard doses.

Although there is no direct interaction between HIV-protease inhibitors and *didanosine*, the buffer included in the didanosine formulation can impair their absorption; doses should be separated by at least 1 to 2 hours from didanosine doses, which should be given on an empty stomach.

For a report of reduced area under the plasma concentration-time curve for *zidovudine* in patients receiving ritonavir, see p.915.

1. Murphy RL, *et al.* Antiviral effect and pharmacokinetic interaction between nevirapine and indinavir in persons infected with human immunodeficiency virus type 1. *J Infect Dis* 1999; **179:** 1116–23.
2. Ferry JJ, *et al.* Pharmacokinetic drug-drug interaction study of delavirdine and indinavir in healthy subjects. *J Acquir Immune Defic Syndr Hum Retrovirol* 1998; **18:** 252–9.

Benzodiazepines. For the effect of HIV-protease inhibitors on benzodiazepines, see Diazepam, p.990.

Cardiac glycosides. For details of a possible interaction between ritonavir and *digoxin*, see p.1262.

Ciclosporin. Mutual increases in the area under the plasma concentration-time curves for saquinavir and ciclosporin were reported in a kidney transplant recipient.[1] The resultant adverse effects subsided when doses of both drugs were reduced by half. Similar interactions with other HIV-protease inhibitors are possible.

1. Brinkman K, *et al.* Pharmacokinetic interaction between saquinavir and cyclosporine. *Ann Intern Med* 1998; **129:** 914–15.

Corticosteroids. Corticosteroids, in particular *dexamethasone*, may induce the metabolism of HIV-protease inhibitors resulting in reduced plasma concentrations. For the effect of ritonavir on plasma concentrations of *fluticasone*, see p.1495

Ergot alkaloids. For reports of ergotism in patients receiving HIV-protease inhibitors and ergot alkaloids, see Ergotamine, p.621.

Gastrointestinal drugs. The antidiarrhoeal *loperamide* markedly reduced exposure to saquinavir in 12 healthy subjects given a single dose of both drugs.[1] Exposure was reduced by about 54%, a reduction of the same order of magnitude as seen with enzyme inducers such as rifampicin, although the mechanism in this case was thought likely to be impaired absorption of the antiviral. Prolonged use of loperamide might lead to substantial reductions in saquinavir plasma concentrations, and reduced clinical efficacy. Plasma concentrations of loperamide were also increased, and those of its metabolite desmethylloperamide correspondingly reduced, but this was thought unlikely to be of clinical significance.

Atazanavir and indinavir depend on acid pH in the stomach for adequate absorption, and acid-suppressive therapies such as *histamine H_2-antagonists* and *proton pump inhibitors* may significantly reduce their absorption; if acid-suppressive therapy is necessary, these HIV-protease inhibitors should be boosted with low-dose ritonavir to ensure adequate antiretroviral activity.[2]

For the effect of HIV-protease inhibitors on *cisapride*, see p.1721.

1. Mikus G, *et al.* Reduction of saquinavir exposure by coadministration of loperamide: a two-way pharmacokinetic interaction. *Clin Pharmacokinet* 2004; **43:** 1015–24.
2. Fulco PP, *et al.* Acid suppressive therapy and the effects on protease inhibitors. *Ann Pharmacother* 2006; **40:** 1974–83.

Grapefruit. Exposure to saquinavir was increased by 50% when taken with grapefruit juice;[1] however, licensed product information does not recommend any adjustment of dosage of saquinavir.

1. Kupferschmidt HHT, *et al.* Grapefruit juice enhances the bioavailability of the HIV protease inhibitor saquinavir in men. *Br J Clin Pharmacol* 1998; **45:** 355–9.

Hormonal contraceptives. For the effect of HIV-protease inhibitors on hormonal contraceptives, see p.2068.

Interleukin-2. Plasma concentrations of indinavir were increased[1] during use with interleukin-2.

1. Piscitelli SC, *et al.* Alteration in indinavir clearance during interleukin-2 infusions in patients infected with the human immunodeficiency virus. *Pharmacotherapy* 1998; **18:** 1212–16.

Paclitaxel. For the effect of HIV-protease inhibitors on paclitaxel, see Interactions, Antivirals, p.759.

Phenylpropanolamine. For a possible interaction between phenylpropanolamine and antiretrovirals including indinavir, see Stavudine, p.907.

Sildenafil. For the effect of HIV-protease inhibitors on sildenafil, including a report of fatal myocardial infarction after sildenafil in a patient receiving ritonavir and saquinavir, see p.2194.

Statins. HIV-protease inhibitors may inhibit the metabolism of statins metabolised by CYP3A4 isoenzymes resulting in an increased risk of myopathy. Although those statins less dependent on CYP3A4 for metabolism may be used in certain circumstances to manage HIV-protease inhibitor-induced lipid disorders, use with lovastatin or simvastatin should be avoided, and HIV-protease inhibitors should be given with caution in patients receiving atorvastatin or rosuvastatin.

Tacrolimus. HIV-protease inhibitors may inhibit the metabolism of tacrolimus (see Antivirals, p.1845).

Theophylline. For a potential effect of ritonavir on theophylline, see p.1144.

Warfarin. For the effect of HIV-protease inhibitors on warfarin, see p.1430.

Antiviral Action

Indinavir is a selective, competitive, reversible inhibitor of HIV-1 and HIV-2 proteases with a tenfold greater selectivity for HIV-1 protease. It interferes with the formation of essential viral proteins making them incapable of infecting other cells. Viral resistance develops rapidly when HIV-protease inhibitors are given alone and therefore they are used with other antiretrovirals. Various degrees of cross-resistance between HIV-protease inhibitors may occur.

Pharmacokinetics

Indinavir is rapidly absorbed after oral doses producing peak plasma concentrations in 0.8 hours (range 0.5 to 1.1 hours). Bioavailability is about 65% after a single 800-mg dose. Absorption is reduced if given with a meal high in calories, fat, and protein but is less affected by a light meal (for the effect of pH see Gastrointestinal Drugs under Interactions, above). At doses up to 1 g, increases in plasma concentration are proportionately greater than increases in dose. Plasma protein binding is about 60%. Indinavir is reported to cross the blood-brain barrier. It undergoes oxidative metabolism by cytochrome P450 isoenzyme CYP3A4 and glucuronidation. At least seven metabolites (1 glucuronide and 6 oxidative metabolites) have been identified. The elimination half-life is 1.8 hours. Less than 20% of the absorbed dose is excreted in the urine, about half of this as unchanged drug. The remainder is excreted in the faeces.

Uses and Administration

Indinavir is an HIV-protease inhibitor with antiviral activity against HIV. It is used in the treatment of HIV infection and AIDS (p.856). Viral resistance emerges rapidly when indinavir is used alone, and it is therefore used with other antiretrovirals.

Indinavir is given orally as the sulfate, but doses are expressed in terms of the base; 116 mg of indinavir sulfate is equivalent to about 100 mg of indinavir. It is given in a usual adult dose of 800 mg every 8 hours. For the *reduced* doses recommended in patients taking azole antifungals or the NNRTI delavirdine, and *increased* doses in those also taking rifabutin or nevirapine, see Antibacterials, Antifungals, and Antivirals, under Interactions, above. Indinavir should be given either 1 hour before or 2 hours after meals, or with a light, low-fat meal. Adequate hydration should be maintained. Treatment may have to be interrupted if acute episodes of nephrolithiasis occur.

For details of doses in children and adolescents, see below. For details of modified dosage to be used in patients with hepatic impairment, see below.

Administration in children. For the treatment of HIV infection in children 4 years of age and older indinavir is given orally with other antiretroviral drugs. A dose of 500 mg/m² every 8 hours is recommended; doses should not exceed the adult dose (see above).

Administration in hepatic impairment. A reduction in the oral dose of indinavir to 600 mg every 8 hours is recommended for patients with mild to moderate hepatic insufficiency due to cirrhosis.

$C_{10}H_{12}N_4O_5{:}C_{14}H_{22}N_2O_4$ (1:3) = 1115.2.

CAS — 36703-88-5.

ATC — J05AX05.

ATC Vet — QJ05AX05.

NOTE. Dimepranol Acedoben is *pINN* and *USAN*.

Adverse Effects and Precautions

Some patients have had transient nausea, vomiting, headaches, arthralgia, fatigue, vertigo, raised liver enzymes, pruritus, and skin rashes. Metabolism of the inosine content of inosine pranobex leads to increased serum and urine concentrations of uric acid; caution is therefore recommended in treating patients with renal impairment, gout, or hyperuricaemia.

Antiviral Action

Inosine pranobex appears to owe its activity in viral infections more to its capacity to modify or stimulate cell-mediated immune processes than to a direct action on the virus.

Pharmacokinetics

Inosine pranobex is reported to be rapidly absorbed from the gastrointestinal tract with peak plasma concentrations occurring 1 hour after an oral dose. It is also rapidly metabolised with a plasma half-life of 50 minutes, the inosine portion of the complex yielding uric acid; the other components undergo oxidation and glucuronidation. The metabolites are excreted in the urine.

Uses and Administration

Inosine pranobex is a complex of inosine (p.2325) with dimepranol acedoben ((±)-1-(dimethylamino)-2-propanol *p*-acetamidobenzoate). It has been used in the treatment of various viral infections (see below), including herpes simplex, genital warts, and subacute sclerosing panencephalitis, although other treatments or measures are preferred. The oral dose in mucocutaneous herpes simplex is 1 g four times daily for 7 to 14 days. An oral dose of 1 g three times daily is given for 14 to 28 days as an adjunct to standard topical treatment for genital warts. In subacute sclerosing panencephalitis, the oral dose is 50 to 100 mg/kg daily in divided doses given every 4 hours.

Alopecia. Oral inosine pranobex (50 mg/kg daily in 5 divided doses for 12 weeks) has been investigated[1] with some apparent benefit in the treatment of recalcitrant alopecia areata (p.1577).

1. Georgala S, *et al.* Inosiplex for treatment of alopecia areata: a randomized placebo-controlled study. *Acta Derm Venereol* 2006; **86:** 422–4.

Subacute sclerosing panencephalitis. Inosine pranobex has been tried[1,2] in the treatment of subacute sclerosing panencephalitis, a complication of measles (p.860), but the results of clinical studies have been equivocal. Some success has been reported when inosine pranobex has been given with interferons and other antivirals. However, a randomised study involving 121 patients, of whom 67 completed analysis, was unable to show any difference between an oral regimen of inosine pranobex 100 mg/kg daily in 3 divided doses (up to a maximum of 3 g daily) for 6 months, and the same dose combined with intraventricular interferon alfa, although the outcomes, which were considered satisfactory in about 35% of cases, were better than the 10% remission rate in historical controls, implying some benefit with either treatment.[3]

Warts. Although of no apparent benefit in the treatment of palmar/plantar warts,[1] oral inosine pranobex has been shown to be of value in the treatment of refractory genital warts (p.1584) in the cervix,[2] as well as producing some apparent epithelial morphological improvement in women with subclinical human papillomavirus infection of the vulva.[3]

Interferon Alfa *(BAN, rINN)*

IFN-α; Interferón-α; Interferon-α; Interferón alfa; Interféron alfa; Interferon alpha; Interferoni alfa; Interferonialfa; Interferonum Alfa; Ro-22-8181 (interferon alfa-2a); Sch-30500 (interferon alfa-2b).

Интерферон Альфа

CAS — 74899-72-2 (interferon alfa); 76543-88-9 (interferon alfa-2a); 99210-65-8 (interferon alfa-2b); 118390-30-0 (interferon alfacon-1); 198153-51-4 (peginterferon alfa-2a); 215647-85-1 (peginterferon alfa-2b).

ATC — L03AB01 (natural); L03AB04 (2a); L03AB05 (2b); L03AB06 (n1); L03AB09 (alfacon-1); L03AB10 (peginterferon alfa-2b); L03AB11 (peginterferon alfa-2a).

ATC Vet — QL03AB01 (natural); QL03AB04 (2a); QL03AB05 (2b); QL03AB06 (n1); QL03AB09 (alfacon-1); QL03AB10 (peginterferon alfa-2b); QL03AB11 (peginterferon alfa-2a).

NOTE. Interferon alfa was previously known as leucocyte interferon or lymphoblastoid interferon.

Interferon alfa-2a, alfa-2b, alfa-n1, and alfa-n3 are *USAN*.

Interferon alfacon-1 (*BAN*, *USAN*, *rINN*) is a recombinant non-naturally occurring alfa interferon. Peginterferon alfa-2a (*BAN*, *USAN*, *rINN*) and peginterferon alfa-2b (*BAN*, *rINN*) are interferons pegylated by conjugation with macrogols.

Pharmacopoeias. *Chin.* includes monographs for recombinant human alfa-2a and alfa-2b. *Eur.* (see p.vii) includes Interferon Alfa-2 Concentrated Solution.

Ph. Eur. 6.2 (Interferon Alfa-2 Concentrated Solution; Interferoni Alfa-2 Solutio Concentrata). It is produced by a method based on recombinant DNA technology using bacteria as host cells. It is a clear, colourless or slightly yellowish liquid. Store in airtight containers at a temperature of −20° or below. Protect from light.

Nomenclature. Interferon alfa may be derived from leucocytes or lymphoblasts, or produced by recombinant DNA technology. Sub-species of the human alfa gene may produce interferon alfa with protein variants or a mixture of proteins. The protein variants may be designated by a number (as in interferon alfa-2) which may be further qualified by a letter to indicate the amino-acid sequences at positions 23 and 34:

- interferon alfa-2a has lysine at 23 and histidine at 34
- interferon alfa-2b has arginine at 23 and histidine at 34
- interferon alfa-2c has arginine at both positions

In the case of a mixture of proteins an alphanumeric designation is given (as in interferon alfa-n1). Interferon alfacon-1 varies from interferon alfa-2 in 20 of 166 amino acids.

The name may be further elaborated on the label by approved sets of initials in parentheses to indicate the method of production: (rbe) indicates production from bacteria (*Escherichia coli*) genetically modified by recombinant DNA technology; (lns) indicates production from cultured lymphoblasts from the Namalwa cell line that have been stimulated by a Sendai virus; (bls) indicates production from leucocytes from human blood that have been stimulated by a Sendai virus.

Adverse Effects and Treatment

The adverse effects of interferon are varied and the natural products appear to be less toxic than the pure synthetic compounds. The frequency and severity of adverse effects of peginterferon alfa appear to be similar to those for interferon alfa although dose-related neutropenia and thrombocytopenia and injection site reactions are more common. Clinical experience suggests that interferons beta and gamma have similar adverse effects.

Adverse effects are generally mild and reversible at doses less than 5 million international units/day. The majority of patients on interferon treatment have 'flu-like' symptoms such as loss of appetite, fever, chills, fatigue, headache, malaise, myalgia, arthralgia, and sweating. These symptoms tend to be dose-related, are most likely to occur at the start of treatment, and mostly respond to paracetamol (but for a possible interaction with paracetamol, see Interactions, below).

Other common adverse effects are alopecia, asthenia, weight loss, anxiety, depression, dermatitis, diarrhoea, irritability, nausea, nervousness, neutropenia, pruritus, sleep disturbances, taste alteration, and vomiting. Serious adverse effects reported include neuropsychiatric disorders (homicidal ideation, suicidal ideation, suicide attempt, and suicide) and neurological disturbances (confusion, coma, and seizures), severe bacterial infections (sepsis), bone marrow toxicity (cytopenia and rarely, aplastic anaemia), cardiovascular disorders (hypo- or hypertension, supraventricular arrhythmias and myocardial infarction), endocrine disorders (such as thyroid disorders and diabetes mellitus), pulmonary disorders (dyspnoea, pneumonia, bronchiolitis obliterans, interstitial pneumonitis and sarcoidosis), colitis (ulcerative and hemorrhagic or ischaemic colitis), pancreatitis, and ophthalmologic disorders (such as decrease or loss of vision, retinopathy including macular oedema and retinal thrombosis or haemorrhages, optic neuritis and papilloedema).

Hypersensitivity reactions, including anaphylaxis, have occurred, and interferon therapy may cause or exacerbate auto-immune disorders (such as idiopathic thrombocytopenic purpura, thrombotic thrombocytopenic purpura, psoriasis, SLE, rheumatoid arthritis, and interstitial nephritis).

Hypertriglyceridaemia, sometimes severe, has been seen. High doses may cause electrolyte disturbances including decreased calcium concentrations. There may be signs of altered liver function and hepatitis has been reported. Renal failure and nephrotic syndrome have also occurred. Interferons may impair fertility and menstrual irregularities have been reported, particularly with interferon beta. Subcutaneous injection may produce a reaction at the injection site, predominantly mild inflammation or erythema, but pain, hypersensitivity, and other non-specific reactions have been reported. The reaction is reported frequently with interferon beta, which can produce severe reactions including local necrosis.

Adverse effects of peginterferon alfa (alone or with ribavirin) reported in patients co-infected with hepatitis C virus and HIV, are similar to those reported in patients infected only with hepatitis C virus. Although haematological adverse effects such as neutropenia, thrombocytopenia, and anaemia occurred more often in co-infected patients, most patients could be managed by dose adjustments. Other adverse effects reported in co-infected patients given peginterferon and ribavirin include apathy, raised blood amylase, chapped lips, chromaturia, raised gamma-glutamyltransferase and hepatitis, influenza, lactic acidosis (including hyperlactacidaemia), lipodystrophy, mood alteration, pain in the pharynx, larynx, back, and limbs, pneumonia, and tinnitus. Peginterferon treatment was associated with decreases in CD4+ cell counts within the first 4 weeks that were reversible when the dose was reduced or stopped; no negative impact was noted on the control of HIV viraemia during treatment or follow-up.

Nasal dosage may produce mucosal irritation and damage.

◊ Reviews.

Effects on the blood. Interferon alfa has myelosuppressive effects and the commonest haematological adverse effects associated with its use are dose-related leucopenia, neutropenia, and thrombocytopenia; anaemia is rarely reported. Other reported effects associated with interferon alfa include immune haemolytic anaemia[1] and immune thrombocytopenia.[2,3] Haemorrhage occurred in a patient with immune thrombocytopenic purpura treated with interferon alfa,[4] and it was thought prudent to use interferons with caution, if at all, in this condition.[3,4] Reports of clotting disorders are rare; bleeding associated with induction of factor VIII inhibitor has been seen in a patient given interferon alfa to enhance hydroxycarbamide therapy for chronic myeloid leukaemia.[5] Thrombosis associated with interferon alfa has also been reported.[6]

Restoration of bone-marrow function after marrow transplantation was delayed in 3 patients given a human interferon alfa preparation.[7] Laboratory results showed an inhibition of granulocyte colony growth by human leucocyte interferon alfa. It was considered that interferon alfa was contra-indicated in patients with severe bone-marrow insufficiency and should not be given to marrow transplant patients before the graft was fully functional. However, in another 5 patients recombinant interferon alfa did not affect bone marrow transplants, although 3 patients experienced fever and chills, 4 had more than a 60% reduction in absolute peripheral granulocyte counts, and 4 had a 37 to 80% reduction in absolute platelet counts.[8] Lymphocytes were increased in all patients; blood counts returned to normal when interferon therapy stopped. Interferon alfa produced a decline in CD4+ T-lymphocytes resulting in opportunistic infections in 2 HIV-positive patients treated for chronic hepatitis C.[9]

Effects on the cardiovascular system. Hypotension or hypertension, tachycardia, and distal cyanosis are the most commonly reported cardiovascular adverse effects. Other reported cardiac complications include cardiac arrhythmias, atrioventricular block, symptoms of ischaemic heart disease, including myocardial infarction and sudden death, congestive heart failure, acute dyspnoea, pericardial effusion,[1,2] and cardiomyopathy.[1,3,4] Cardiac toxicity was not related to the daily or cumulative total dose, or duration of treatment and is usually reversible on stopping interferon treatment.[1]

Peripheral vascular complications such as Raynaud's syndrome[5-9] have been associated with interferon alfa therapy and other types of interferon.

Effects on the endocrine system. Both hypothyroidism[1,2] and hyperthyroidism[2,3] have been associated with interferon alfa therapy. Thyroid disorders are usually minor and regress on stopping the interferon (with or without other specific treatment). However a case of long-lasting ophthalmopathy as a result of interferon alfa-induced Graves' disease has been reported in a patient being treated for hepatitis C.[4]

The development of type 1 diabetes has also been associated with interferon alfa therapy,[5-8] and exacerbation of existing type 2 diabetes has been reported.[9,10] Reversible hypopituitarism has been reported in patients receiving interferon alfa.[11,12] Recombinant interferon gamma was reported not to affect thyroid function.[13]

Effects on the eyes. The most typical ocular adverse effect associated with interferon alfa treatment is retinopathy, which is characterised by cotton wool spots and superficial retinal haemorrhages. Reports of interferon-associated retinopathy have been reviewed.[1,2] Reduced vision or complete visual loss is rare or limited and is usually reversible after stopping treatment. In a study of 43 patients with chronic hepatitis given interferon alfa, retinopathy developed in 11 of 37 non-diabetic patients and in 3 of 6 diabetic patients after about 8 to 10 weeks of therapy.[3] None of the patients had had retinopathy before treatment; the condition was reversible in the non-diabetic patients on stopping therapy. Visual acuity remained unchanged. Subconjunctival haemorrhage occurred in a further 3 of the non-diabetic patients. Severe irreversible loss of vision has been reported in a non-diabetic patient given interferon alfa.[4] A prospective study[5] of 156 patients treated with interferon alfa or peginterferon alfa (with or without ribavirin) reported signs of retinopathy in 24% of the patients; 29 patients developed cotton-wool spots, 7 developed retinal haemorrhage, and 2 patients developed both lesions during treatment; none of the patients had retinopathy before starting treatment. The lesions remained asymptomatic and resolved in all the patients. Patient age above 45 years, hypertension, and the use of pegylated alpha-interferon were identified as risk factors for retinopathy. Neurovisual impairment was present in 31 patients before interferon treatment and in 74 patients during treatment. Another study[6] of 19 patients reported that 8 patients developed asymptomatic retinopathy while on treatment with interferon alfa (with or without ribavirin); patients who had previously failed to respond to interferon monotherapy seemed more likely to develop retinopathy when given combined therapy than patients who had responded and then relapsed. The changes were transient and sometimes disappeared while the patients were still on treatment. Retinopathy has been reported in patients being treated with interferon beta for the management of multiple sclerosis.[7,8] Symptoms also resolved after stopping treatment.

Pain in one eyeball leading to exophthalmos and complete visual loss has been reported in a patient given interferon alfa;[9] despite withdrawal of interferon and instigation of antibacterial and corticosteroid treatment, the eyeball subsequently ruptured necessitating ophthalmectomy. Other severe ocular effects reported during interferon alfa treatment include a disorder resembling Vogt-Koyanagi-Harada disease, central retinal vein occlusion, central retinal artery occlusion, and bilateral ischaemic optic neuropathy with severe visual impairment.[10]

Effects on the gastrointestinal tract. Mild and transient gastrointestinal adverse effects such as nausea, diarrhoea, vomiting, and anorexia occur in about 30 to 40% of patients being treated with interferon alfa. There have been reports[1-4] of the onset of coeliac disease during treatment of hepatitis C with interferon or peginterferon alfa, in some cases used with ribavirin. Symptoms generally resolved after interferon was stopped and a gluten-free diet started. A case[5] of eosinophilic enteritis has been reported in a patient, with no history of digestive disorders, after 12 weeks of recombinant interferon alfa-2b treatment; symptoms resolved after stopping interferon and on treatment with prednisolone. New[6,7] or exacerbated[8] cases of ulcerative colitis have been reported in patients on interferon or peginterferon alfa treatment (with or without ribavirin). Treatment with interferon was usually stopped[7,8] and symptoms tended to resolve or improve with appropriate therapy (such as mesalazine and/or corticosteroids).[6-8] Cases of ischaemic colitis associated with interferon or peginterferon alpha have been reported rarely.[9]

Effects on the hair. Excessive temporary loss of telogen hair causing moderate and reversible alopecia occurs in about 7 to 30% of patients on interferon or peginterferon alfa treatment. Alopecia areata[1-3] and alopecia universalis[4,5] have occasionally been reported; complete regrowth of the hair usually occurs on completing interferon treatment.

A report of marked greying of the hair in a patient beginning after 5 months of treatment with interferon alfa for metastatic malignant melanoma; on completion of interferon therapy the hair regrowth returned to its normal colour.[6] Marked straightening of scalp and body hair has been reported in 2 patients after combined treatment with interferon alfa-2b or peginterferon alfa-2b and ribavirin for chronic hepatitis C.[7] In the first patient, there was also diffuse thinning of scalp hair, change in hair texture, increased greying of the hair, and eyebrow lengthening; the original curly hair began to regrow 6 months after stopping treatment, but the hair abnormalities recurred on rechallenge despite switching from interferon alfa-2b to peginterferon alfa-2b. In the second patient, treatment with peginterferon alfa-2b and ribavirin was associated with straightening of scalp hair, eyebrow hair, and pubic hair.[7] Lengthening and thickening of eyelashes has also been reported with interferon alfa therapy.[8,9] A case of eyelid and eyebrow trichomegaly has also been reported[10] in a patient treated with peginterferon alfa and ribavirin.

Effects on hearing. Sensorineural hearing loss, mostly unilateral, has been rarely reported in patients treated with interferon or peginterferon. A prospective study[1] reported sensorineural hearing loss in 18 of 49 patients and tinnitus in 14 of 49 patients given interferons. The authors reported that effects were more common in those given interferon beta than in those given interferon alfa, and resolved in all patients on stopping therapy. A report[2] of 6 patients who experienced sudden hearing loss while on treatment with peginterferon alfa plus ribavirin found that hearing loss did not fully resolve after stopping treatment; but neither did it worsen in those who continued their treatment. A case report[3] of a patient who had acute sensorineural hearing loss 2 months after starting treatment with peginterferon alfa and ribavirin found that when treatment was re-started 4 months after stopping, the patient did not experience further hearing loss and hearing on the left-side was unaffected. In another case report[4] a patient who developed hearing loss 22 weeks after starting treatment with peginterferon alfa, continued with treatment and symptoms did not worsen. Hearing loss resolved within 2 weeks of stopping treatment.

Effects on the kidneys. Renal adverse effects associated with interferon alfa are usually limited to mild, asymptomatic proteinuria and moderate increases in serum creatinine in 15 to 20% of patients. Dose-related asymptomatic proteinuria has been reported with interferon gamma treatment.[1] Acute renal failure and nephrotic syndrome associated with interferon alfa treatment is rare and has mostly been reported in patients with underlying renal disease, or malignancies,[2-5] and in those receiving high doses.[6] Cases have also been reported in patients receiving interferon or peginterferon alfa treatment for chronic hepatitis C.[7-9] Nephrotic syndrome has also occurred after use of interferon beta.[10-12] Renal dysfunction usually resolves after stopping treatment, but incomplete resolution and fatalities have been reported.[5,8]

Effects on lipids. Cases[1-3] of reversible hypertriglyceridaemia (with or without elevation of total cholesterol level) have been reported in association with interferon alfa treatment. Hypertriglyceridaemia more often occurs with longer treatment durations and does not appear to be related to pre-existing cardiovascular disorders or baseline dyslipidaemia; frequency and severity are not dose dependent. Lifestyle modifications and drug treatment with a fibrate or statin are usually needed to reduce triglyceride levels. A small study[4] reported that taking omega-3 fatty acid supplements (3 g daily for 6 months) reduced serum triglyceride levels in patients on interferon alfa for the management of chronic hepatitis C.

Effects on the liver. Mild hepatotoxicity with an asymptomatic and reversible rise in serum aminotransferases has been reported in about 25 to 30% of patients receiving interferon alfa; severe hepatotoxicity is rare[1] but cases of fatal liver failure have been reported,[2-5] sometimes due to severe exacerbation of chronic hepatitis B and/or C infection.[4,5] An analysis of the toxicity of adjuvant high-dose interferon alfa in 40 patients being treated for melanoma reported hepatotoxicity in 39 patients, with 26 patients experiencing grade 3 to 4 hepatotoxicity.[6] Cases[7,8] of peginterferon alfa-induced auto-immune hepatitis have been reported in patients receiving treatment for chronic hepatitis C.

Raised serum-alanine aminotransferase values have been reported in about 37% of patients given interferon beta therapy for the treatment of multiple sclerosis, with grade 3 to 4 hepatotoxicity being reported in about 1.4% of patients.[9]

Effects on the nervous system and mental state. Neurological adverse effects have been reported in association with interferon alfa treatment for chronic hepatitis C virus or for malignant diseases;[1-5] notably, an acute confusional state may develop rapidly after starting high-dose interferon alfa treatment and a depressive syndrome may develop more slowly over weeks to months of treatment. Less commonly a manic condition, usually characterised by extreme irritability and agitation but also occasionally by euphoria, may occur.

Acute interferon alfa-induced confusional states are typically characterised by disorientation, lethargy, difficulties with speaking and writing, parkinsonism, psychomotor retardation, psychotic symptoms (such as hallucinations), and somnolence.

Depression[5-9] occurs in about 16 to 58% of patients receiving interferon alfa. Patients considered to be at risk for developing depression are those with pre-existing symptoms of mood and anxiety disorders, those with a history of major depression, and those receiving higher doses of interferon alfa or on long treatment regimens. SSRIs have been used successfully to both treat patients with interferon-associated depression, thus allowing therapy to be continued,[10,11] and as pretreatment to prevent its occurrence.[12]

Should manic symptoms[13] occur, interferon alfa and antidepressant treatment should be stopped and a mood stabiliser given. Interferon alfa-induced mood disorders may also consist of an overlap between depressive and manic symptoms. A prospective study[14] of 93 patients treated with peginterferon alfa plus ribavirin for chronic hepatitis C reported that mood disorders occurred in 30 patients; 3 cases of mania, 15 cases of irritable hypomania, and 12 cases of mixed depressive states. The distinction between the 2 states is important in terms of management as depression-specific symptoms respond well to SSRIs, whereas antidepressants may worsen manic or hypomanic states.

Seizures[15-17] attributed to interferon alfa have been described.

Cases of neurological toxicity have been reported in patients receiving interferon beta,[1,18] although interferon beta is considered to be slightly less neurotoxic.

Chronic hepatitis C virus infection may be complicated by the development of systemic vasculitis caused by mixed cryoglobulinemia or of a non-cryoglobulinemic vasculitis resembling polyarteritis nodosa. Successful treatment of the hepatitis infection with interferon alfa usually results in the improvement of vasculitic symptoms, including neuropathy. However, vasculitis may also be precipitated or exacerbated by treatment with interferon (including peginterferon alfa)[19-21] resulting in development of vasculitic neuropathy; cases of apparently non-vasculitic peripheral neuropathy have also been reported.[20-22] Others[23] have reported no association between peginterferon alfa and peripheral neuropathy. In most cases symptoms improved on treatment with corticosteroids or spontaneously, but fatal exacerbations of vasculitis have occurred despite stopping the interferon treatment and giving immunosuppressants.[21]

Effects on the oral mucosa. Painful oral ulcers, necessitating withdrawal of interferon alfa therapy, have occurred in a patient treated for chronic hepatitis.[1] Interferon alfa treatment has been reported to exacerbate pre-existing lichen planus associated with chronic hepatitis C.[2,3] New cases of oral lichen planus have been reported in patients receiving interferon alfa treatment for malignant diseases[4] and chronic hepatitis.[5]

5. Guijarro Guijarro B, *et al.* Aparición de un liquen plano erosivo durante el tratamiento con interferón alfa-2a por una hepatitis C crónica. *Med Oral* 2001; **6:** 358–63.

Effects on the respiratory system. Pulmonary adverse effects have occasionally been reported in association with interferon or peginterferon alfa treatment. A literature review[1] found that the most commonly reported adverse effect was interstitial pneumonitis, followed by a sarcoid-like reaction with non-caseating granuloma formation. Other, less commonly reported events were asthma exacerbation, pleural effusion, bronchiolitis obliterans with organizing pneumonia, and a case of fatal acute respiratory distress-like syndrome.

1. Midturi J, *et al.* Spectrum of pulmonary toxicity associated with the use of interferon therapy for hepatitis C: case report and review of the literature. *Clin Infect Dis* 2004; **39:** 1724–9.

Effects on skeletal muscle. Myalgia is one of the 'flu-like' symptoms frequently associated with interferons. Rhabdomyolysis[1-3] has occurred in patients being treated with interferon alfa and proved fatal when associated with multiple organ failure in a patient receiving adjuvant high-dose interferon alfa for multiple myeloma.[1] Rhabdomyolysis has also been reported in a patient receiving interferon beta for the treatment of multiple sclerosis.[4]

4. Lünemann JD, *et al.* Rhabdomyolysis during interferon-beta 1a treatment. *J Neurol Neurosurg Psychiatry* 2002; **72:** 274. Correction. *ibid.*; **73;** 354.

Effects on the skin. Dermatological adverse effects such as dryness, erythema, rash, or urticaria, have been reported in about 5 to 12% of patients given interferon alfa; severe events occur rarely.[1] Exacerbation or development of psoriasis was reported in patients given recombinant interferon alfa[2-4] and peginterferon alfa.[5] However, no such effect was seen in 7 patients given interferon gamma.[6] Both vitiligo and psoriasis developed in a 10-year-old girl with chronic hepatitis B infection given interferon alfa; the skin conditions did not improve on stopping the interferon treatment.[7] A case[8] of vitiligo occurring during the third month of treatment for chronic hepatitis C with peginterferon alfa and ribavirin has been reported; the condition persisted after treatment with peginterferon was completed. Exacerbation of lichen planus has also been reported[9] during interferon alfa treatment (see also Effects on the Oral Mucosa, above). Cases of cutaneous sarcoidosis have been reported in patients with chronic hepatitis C being treated with interferon or pegylated interferon alfa plus ribavirin; skin lesions are usually benign and treatment with interferon alfa may sometimes be continued with resolution of the skin lesions occurring spontaneously or within a few months of completing treatment.[10,11] Cutaneous vascular lesions with punctate telangiectasias were noted in 18 of 44 patients treated with interferon alfa-2a; lesions did not appear at the injection site.[12] Severe necrotising cutaneous lesions were reported at injection sites in a patient given recombinant interferon beta-1b; the lesions healed when interferon alfa-n3 was substituted.[13] However, cutaneous necrosis has also been associated with interferon alfa[14,15] and peginterferon alfa.[16] Five cases[17] of a self-resolving cutaneous lesion at the injection site of interferon, mimicking lupus erythematosus, have been reported; 3 of them involved interferon alfa therapy for malignant melanoma and the other 2 patients were being given interferon beta for multiple sclerosis. Fatal paraneoplastic pemphigus developed in a patient given interferon alfa-2a.[18] Hyperpigmentation of the skin and tongue has been described[19] in 2 dark-skinned patients during treatment with interferon alfa and ribavirin.

Shock. Fatal non-cardiogenic shock occurred after the third dose of interferon alfa-2b in a patient with malignant melanoma.[1] There were similarities to a fatal reaction reported in another patient with malignant melanoma (see under Effects on Skeletal Muscle, above).

1. Carson JJ, *et al.* Fatality and interferon α for malignant melanoma. *Lancet* 1998; **352:** 1443–4.

Precautions

Interferons should be used with caution or avoided altogether in patients with depression or psychiatric disorders, epilepsy or other CNS diseases, severe renal or hepatic impairment, chronic hepatitis with advanced, decompensated hepatic disease or cirrhosis of the liver, auto-immune hepatitis, cardiac disorders, myelosuppression, poorly controlled thyroid dysfunction, pulmonary disease, diabetes mellitus, auto-immune diseases, coagulation disorders, or a history of these conditions.

All patients receiving interferons should be closely monitored for any signs or symptoms of psychiatric disorders; if psychiatric symptoms continue or worsen, or suicidal ideation is identified, then interferon therapy should be stopped.

Interferon treatment is not advised for patients whose hypoglycaemia, hyperglycaemia and/or diabetes mellitus is not effectively controlled; patients who develop these conditions during treatment and cannot be controlled with medication should stop interferon treatment. Standard blood and biochemical laboratory tests (including thyroid function) should be done before starting treatment with interferon and then periodically during therapy. Interferon should be used with caution in patients also receiving other potentially myelosuppressive agents.

Assessment of cardiac function is advised before treatment is started in patients with pre-existing cardiac abnormalities and if there is any deterioration of cardiovascular status interferon should be suspended or stopped.

Hepatic and renal function should be monitored during treatment with interferons. Interferon treatment should be stopped in patients who develop evidence of liver decompensation during treatment. Treatment should also be stopped in those patients who despite the dose of interferon being reduced still have progressive and clinically significant increases in serum-alanine aminotransferase.

Patients receiving interferons who have visual disturbances should undergo eye examination. A baseline ocular examination is recommended before treatment, and periodic eye examinations should be performed throughout treatment in patients predisposed to retinopathy, such as those with diabetes mellitus or hypertension; treatment should be stopped in patients who develop new or worsening ophthalmologic disorders.

Patients with psoriasis or sarcoidosis have been reported to experience exacerbations during interferon alfa therapy.

Patients should receive adequate fluids to maintain hydration during treatment with interferon alfa since hypotension related to fluid depletion has been seen in some patients.

Interferons may affect the ability to drive or operate machinery.

Antibodies may develop to exogenous interferon that reduce its activity.

Asthma. For a report of severe exacerbation of asthma in patients receiving interferon alfa, see Effects on the Respiratory System, above.

Breast feeding. The American Academy of Pediatrics[1] states that there have been no reports of any clinical effect on the infant associated with the use of interferon alfa by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding. It has been suggested that interferons are too large in molecular weight to transfer into breast milk in clinically relevant amounts.[2]

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 12/06/08)
2. Kumar AR, *et al.* Transfer of interferon alfa into human breast milk. *J Hum Lact* 2000; **16:** 226–8.

Psychiatric disorders. For comment on the risk of mood disorders in patients with a history of such disorders, see Effects on the Nervous System and Mental State, above.

Interactions

Interactions involving interferons have not been fully evaluated, but it is known that they can inhibit hepatic oxidative metabolism via cytochrome P450 enzymes; the clinical relevance of this interaction is unclear and thus caution should be exercised during use with drugs metabolised in this way. Studies with peginterferon alfa showed increased activity of the cytochrome P450 isoenzymes CYP2C8/9 and CYP2D6; caution is advised when giving peginterferon alfa with drugs that are metabolised by these isoenzymes, such as warfarin, phenytoin, and flecainide. Interferon and peginterferon alfa have been shown to inhibit the metabolism of theophylline which is metabolised via the cytochrome P450 isoenzyme CYP1A2. Drugs likely to exacerbate the haematological effects of interferons, such as ribavirin and zidovudine, should also be used with caution. Interferons may also increase the neurotoxic and cardiotoxic effects of other drugs.

ACE inhibitors. For a report of possible synergistic haematological toxicity in patients receiving interferon alfa and ACE inhibitors, see p.1196.

Anticoagulants. For reference to potentiation of *acenocoumarol* or *warfarin* necessitating dosage reduction in patients also receiving interferon alfa, see p.1430.

Antineoplastics. For reduction in the area under the plasma concentration-time curve for *melphalan* in patients receiving interferon alfa, see p.742.

Antivirals. For a report of synergistic bone-marrow toxicity with interferon alfa and *zidovudine*, see p.915.

Paracetamol. Three patients had increases in liver enzyme values when given paracetamol 1 g two or three times daily on the same three days each week as interferon alfa; vinblastine was also given every third week.[1] Paracetamol has also been found to enhance the antiviral effect of interferon alfa in healthy subjects.[2]

Thalidomide. For reports of toxicity associated with interferons and thalidomide, see p.2398.

Theophylline. For reference to reduced clearance of theophylline in patients receiving interferon alfa, see p.1144.

Antiviral Action

Interferons are naturally occurring proteins produced by eukaryotic cells in response to viral infection and other biological inducers that confer protection on uninfected cells of the same species. They are cytokines that affect many cell functions and have, in addition to their antiviral activity, antiproliferative and immunoregulatory properties. Three major classes have been identified: alfa, beta and gamma. Interferon alfa and beta are classified as Type I interferons and interferon gamma is a Type II interferon. These interferons have overlapping but clearly distinct biological activities; interferon gamma in particular is a potent macrophage-stimulating factor.

Interferons exert their biological effect by binding to specific receptors on the surface of human cells. After binding, a cascade of intracellular events, including the induction of certain enzymes, occurs. This process is thought to be responsible for the various cellular responses to interferon, including inhibition of virus replication in virus-infected cells, suppression of cell proliferation and such immunomodulating activities as enhancement of the phagocytic activity of macrophages and augmentation of the specific cytotoxicity of lymphocytes for target cells.

Pegylated interferons have similar, but possibly slightly weaker, actions to the native forms.

Studies have shown interferons to have benefit in infections with hepatitis B virus, hepatitis C virus, herpes simplex viruses, varicella-zoster virus, CMV, rhinoviruses, and papillomaviruses.

Pharmacokinetics

Interferons are not absorbed from the gastrointestinal tract. More than 80% of a subcutaneous or intramuscular dose of interferon alfa is absorbed. After intramuscular injection, interferon alfa produced by recombinant techniques and that from cultured leucocytes produce similar plasma concentrations although there is a large interindividual variation. Plasma concentrations are dose-related; and peak concentrations are usually reached within 4 to 8 hours returning to baseline by 16 to 24 hours. After intravenous doses, serum interferon levels decline at a slightly faster rate than after subcutaneous or intramuscular use and are undetectable 4 hours after infusion. After systemic use low levels of interferon are detected in respiratory secretions, CSF, eye, and brain. The elimination half-life of interferon alfa is about 2 to 7 hours after subcutaneous or intramuscular injections and 2 hours after intravenous infusion. Interferon alfa undergoes renal catabolism and negligible amounts of interferons are excreted in the urine; biliary excretion and liver metabolism are minor pathways of elimination.

The attachment of interferon to large inert macrogol (polyethylene glycol; PEG) molecules, termed pegylation, substantially reduces the rate of absorption and excretion of interferon and increases the plasma concentration. After a subcutaneous dose of peginterferon alfa-2b the maximum serum concentration is attained in about 15 to 44 hours and high concentrations are sustained for 48 to 72 hours; the mean elimination half-life is approximately 40 hours. The maximum serum concentration of peginterferon alfa-2a is attained about 72 to 96 hours after subcutaneous dosing and the mean terminal half-life is approximately 160 hours. The absolute bioavailability of peginterferon alfa-2a is 84% and is similar to that of unmodified interferon alfa-2a.

Uses and Administration

The interferons are cytokines that have a range of activities. In addition to their action against viruses they are active against malignant neoplasms and have an immunomodulating effect. Several alfa interferons are available: interferon alfa-2a (rbe), interferon alfa-2b (rbe), alfa-n3 (bls), alfacon-1 (rbe), and the pegylated interferons peginterferon alfa-2a (rbe) and peginterferon alfa-2b (rbe).

Alfa interferons are used in chronic hepatitis B (*alfa-2a and its pegylated form and alfa-2b*) and chronic hepatitis C (*alfa-2a and its pegylated form, alfa-2b and its pegylated form, and alfacon-1*); in several malignant neoplasms including AIDS-related Kaposi's sarcoma (*alfa-2a and alfa-2b*), hairy-cell leukaemia (*alfa-2a and alfa-2b*), chronic myeloid leukaemia (*alfa-2a and alfa-2b*), follicular lymphoma (*alfa-2a and alfa-2b*), cutaneous T-cell lymphoma (*alfa-2a*), carcinoid tumours (*alfa-2b*), melanoma (*alfa-2a and alfa-2b*), multiple myeloma (*alfa-2b*), and renal cell carcinoma (*alfa-2a*); and in condylomata acuminata (*alfa-2b and alfa-n3*).

ADMINISTRATION AND DOSAGE. Dosage regimens for alfa interferons are as follows:

- **Chronic active hepatitis B.** *Interferon alfa-2a* is given in a dose of 2.5 to 5 million units/m^2 three times weekly by subcutaneous injection for 4 to 6 months. *Peginterferon alfa-2a* is given in a dose of 180 micrograms once weekly subcutaneously for 48 weeks. *Interferon alfa-2b* is given in a dose of 5 to 10 million units three times weekly for 4 to 6 months, or 5 million units daily for 16 weeks, by subcutaneous or intramuscular injection.
- **Chronic hepatitis C.** *Interferon alfa-2a* is given in a dose of 3 to 4.5 million units three times weekly by subcutaneous injection for 6 months when it is used with ribavirin. In patients unable to tolerate ribavirin, interferon alfa-2a monotherapy is given either in an initial dose of 3 to 6 million units three times weekly for 6 months followed by 3 million units three times weekly for an additional 6 months, or in a dose of 3 million units three times weekly for 12 months, by subcutaneous injection. *Peginterferon alfa-2a* is given in a dose of 180 micrograms once weekly subcutaneously, with ribavirin or as monotherapy, for 24 to 48 weeks (depending on genotype). *Interferon alfa-2b* is given in a dose of 3 million units three times weekly for 6 to 12 months (depending on genotype) with ribavirin or, when given as monotherapy, for 6 to 18 months, or for up to 24 months (depending on genotype), by subcutaneous or intramuscular injection. *Peginterferon alfa-2b* is given subcutaneously in a dose of 1.5 micrograms/kg once weekly for 24 to 48 weeks with ribavirin, or in a dose of 0.5 or 1 microgram/kg once weekly for 24 to 48 weeks when given as monotherapy. *Interferon alfacon-1* is given in a dose of 9 micrograms three times weekly by subcutaneous injection for 24 weeks followed by 15 micrograms three times weekly for up to 48 weeks if necessary.
- **AIDS-related Kaposi's sarcoma.** *Interferon alfa-2a* is usually given in an escalating dose of 3 million units daily for 3 days, 9 million units daily for 3 days, 18 million units daily for 3 days, and 36 million units daily, if tolerated, on days 10 to 84, by subcutaneous injection; thereafter the maximum tolerated dose (up to 36 million units) may be given three times weekly. *Interferon alfa-2b* is given in a dose of 30 million units/m^2 three times weekly, by subcutaneous or intramuscular injection.
- **Hairy-cell leukaemia.** *Interferon alfa-2a* is given in an initial subcutaneous dose of 3 million units daily for 16 to 24 weeks, then the same dose three times weekly, by subcutaneous injection. Treatment has continued for up to 24 months. *Interferon alfa-2b* is given in a dose of 2 million units/m^2 three times weekly by subcutaneous or intramuscular injection for up to 6 months or more.

- **Chronic myeloid leukaemia.** *Interferon alfa-2a* is given by subcutaneous injection in an escalating dose of 3 million units daily for 3 days, 6 million units daily for 3 days, and 9 million units daily thereafter. Patients showing a response after 12 weeks should continue treatment until a complete haematological response is achieved or for a maximum of 18 months; those who achieve a complete haematological response should continue on 9 million units daily (or a minimum of 9 million units three times weekly) in order to achieve a cytogenetic response. *Interferon alfa-2b* is given in a dose of 4 to 5 million units/m^2 daily by subcutaneous injection, continuing at the maximum tolerated dose to maintain remission (usually 4 to 5 million units/m^2 daily).
- **Follicular lymphoma.** *Interferon alfa-2a* is given as an adjunct to chemotherapy in a dose of 6 million units/m^2 daily by subcutaneous injection on days 22 to 26 of each 28-day chemotherapy cycle. *Interferon alfa-2b* is given as an adjunct to chemotherapy in a dose of 5 million units three times weekly by subcutaneous injection for 18 months.
- **Cutaneous T-cell lymphoma.** *Interferon alfa-2a* is given by subcutaneous injection in an escalating dose of 3 million units daily for 3 days, then 9 million units daily for 3 days, and then 18 million units daily to complete 12 weeks of treatment. The maximum tolerated dose (up to 18 million units) is then given three times weekly for a minimum of 12 months in responding patients.
- **Carcinoid tumours.** *Interferon alfa-2b* is given in a dose of 3 to 9 million units (usually 5 million units) three times weekly by subcutaneous injection. In advanced disease, 5 million units may be given daily.
- **Melanoma.** *Interferon alfa-2a* is given in a dose of 3 million units three times weekly by subcutaneous injection for 18 months. Treatment should start no later than 6 weeks after surgery. *Interferon alfa-2b* is given in an initial dose of 20 million units/m^2 daily on 5 days each week for 4 weeks by intravenous infusion over 20 minutes, and then for maintenance 10 million units/m^2 three times weekly by subcutaneous injection for 48 weeks.
- **Multiple myeloma.** *Interferon alfa-2b* is given as maintenance treatment following chemotherapy induction at a dose of 3 million units/m^2 three times weekly by subcutaneous injection.
- **Renal cell carcinoma.** *Interferon alfa-2a* is given as an adjunct to cytotoxic chemotherapy in an escalating dose of 3 million units three times weekly for one week, then 9 million units three times weekly for one week, then 18 million units three times weekly thereafter for 3 to 12 months, by subcutaneous injection.
- **Condylomata acuminata.** *Interferon alfa-2b* is given in a dose of 1 million units injected into each lesion three times weekly for 3 weeks, and repeated after 12 to 16 weeks if necessary. No more than 5 lesions should be treated in each treatment course. *Interferon alfa-n3* is given in a dose of 0.25 million units per lesion twice weekly for up to 8 weeks, to a maximum of 2.5 million units in each session.

See below for further details of these as well as some other uses of alfa interferons.

◊ General reviews of interferons.

Age-related macular degeneration. In age-related macular degeneration (senile macular degeneration), a common cause of visual impairment in the elderly, there is a gradual and progressive deterioration of central vision usually affecting both eyes (p.785). Although some encouraging preliminary results[1-4] have been obtained with interferon alfa, controlled data showed no benefit after treatment for one year.[5]

Angiomatous disease. Encouraging responses were reported in 4 of 5 children treated with interferon alfa-2a for various angiomatous diseases.[1] Regression of haemangioma size by more than 50% was achieved in 11 of 18 infants and children given interferon alfa-2a for 1 to 5 months,[2] and in 11 of 19 children treated for at least 4 months.[3] Interferon alfa-2b has also been found to cause regression of haemangioma in 27 of 38 children treated for at least 6 months.[4] In addition, there have been reports of the successful use of interferon alfa-2a to treat infantile giant cell angioblastoma[5] and pelvic metastases of adult haemangioendothelioma of the liver.[6]

The use of interferons as anti-angiogenic agents has been reviewed.[7]

Behçet's syndrome. Behçet's syndrome (p.1499) is a systemic inflammatory disorder characterised by recurrent attacks of oral aphthous ulcers, genital ulcers, skin lesions, uveitis or other manifestations affecting the blood vessels, gastrointestinal tract, and respiratory and central nervous systems. Treatment is essentially symptomatic and empirical. A review of the literature[1] identified 338 patients who had been given interferon alfa (264 patients had received interferon alfa-2a and 74 interferon alfa-2b). Mucocutaneous symptoms improved in 86% of the patients; articular manifestations were present in 90 patients and 95% of them showed a partial or complete response to interferon alfa treatment. Ocular manifestations were present in 182 patients and 94% of them showed a partial or complete response to treatment. Higher doses were reported to be more effective than low-dose regimens. A review[2] on the management of Behçet's syndrome reported that treatment with interferon-alfa during an inflammatory attack improved the duration of and pain associated with oral aphthous ulcers; beneficial effects were also reported in patients with ocular manifestations. Randomised, controlled studies had shown that interferon alfa prevented recurrent attacks and it was considered to be effective in suppressing more severe systemic features, as well as mucocutaneous ones. Open studies with interferon alfa indicated that it might be of benefit in patients with disease resistant to conventional immunosuppressive treatments.

Blood disorders. Interferon alfa may be used in the management of the myeloproliferative disorders such as *primary (essential) thrombocythaemia*[1-3] (p.654), *polycythaemia vera*,[1-4] (p.654) and *agnogenic myeloid metaplasia*.[2] Benefit has also been reported with interferon alfa in patients with HIV-associated thrombocytopenia,[5] although interferons have been reported to induce immune thrombocytopenia, and there has been a report of bleeding in a patient with idiopathic thrombocytopenic purpura (see Effects on the Blood under Adverse Effects, above).

In addition to case reports of interferon alfa producing improvements in patients with idiopathic *hypereosinophilic syndrome*[6-8] who had not responded to corticosteroids or hydroxycarbamide, studies have also shown beneficial responses to interferon alfa used alone[9] or with corticosteroids or hydroxycarbamide.[10,11]

See also under Malignant Neoplasms, below.

Paradoxically, interferon alfa has also been used with some success in patients with *thrombocytopenia* associated with hepatitis C.[12-14]

Churg-Strauss syndrome. For reports that interferon alfa may be beneficial in Churg-Strauss syndrome, see p.1501.

Hepatitis. Interferon alfa (including peginterferon alfa) is one of the main drugs used in the treatment of viral hepatitis B and C and chronic hepatitis B and C co-infection with HIV (p.851) and has been the subject of several general reviews.[1-3]

Interferon alfa was the first drug approved for the management of chronic **hepatitis B**. A meta-analysis[4] found that a significantly higher percentage of patients with chronic hepatitis B who were HBeAg-positive, and treated with interferon alfa for 3 to 6 months, became HbeAg-negative compared with the untreated control group. Interferon alfa was found to be most effective when it was used in patients with recently acquired hepatitis B infection, high pre-treatment ALT, and low hepatitis B DNA levels. Studies have suggested that subcutaneous peginterferon alfa is as effective or slightly more effective than interferon alfa given subcutaneously.[5] Results from various studies[6] have shown peginterferon alfa to be more effective than the antiviral lamivudine, in both HBeAg-positive[7] and HBeAg-negative patients with chronic hepatitis B,[8] when peginterferon alfa was given subcutaneously, once weekly for 48 weeks. However, the addition of lamivudine to peginterferon alfa did not significantly enhance efficacy.[8,9] Interferon alfa can produce benefit in some patients co-infected with chronic **hepatitis B and D**.[10] However, these co-infected patients are less responsive to interferon therapy than patients infected with hepatitis B virus alone. A study[10] with high-dose interferon alfa (9 million units) given 3 times a week for 48 weeks reported normalisation of ALT and inhibition of hepatitis D viral replication in 50% of the patients. However, relapse was common after treatment was stopped, although biochemical responses persisted for up to 4 years. Long-term follow-up of this same group of patients for 2 to 14 years revealed that high-dose interferon alfa may improve long-term outcome and patient survival.[11]

The first available treatment for **chronic hepatitis C** was interferon alfa-2b, and this was followed by interferon alfa-2a, given subcutaneously 3 times a week. A meta-analysis[12] of studies involving interferon treatment of hepatitis C suggested that treatment with interferon alfa 3 million units three times weekly for at least 12 months had the best risk-benefit ratio for patients with chronic hepatitis C. Studies[13,14] with once-weekly peginterferon alfa showed it to be more effective than interferon alfa given three times weekly in patients with chronic hepatitis C, including those with cirrhosis or extensive fibrosis.[15]

Combination therapy with interferon alfa and oral ribavirin for the treatment of chronic hepatitis C is more effective than either drug alone with sustained responses having been recorded, and is now generally considered to be the treatment of first choice.[16,17] A meta-analysis[18] of randomised studies has concluded that combination therapy is also more effective for chronic hepatitis C in patients who had failed to respond to interferon alone or to any other previous treatment. Studies[19,20] suggest that combination therapy with peginterferon alfa and ribavirin may be more effective and better tolerated than interferon alfa plus ribavirin. One study[19] with peginterferon alfa-2b or interferon alfa-2b and ribavirin showed a sustained virological response (SVR) of around 42% in patients with viral genotype 1, compared with about 80% in patients with genotypes 2 and 3. A review[21] of the use of peginterferon alfa with ribavirin has also concluded that this combination is superior to interferon alfa plus ribavirin or to peginterferon alfa alone. The British Society for Gastroenterology[22] and the American Association for the Study of Liver Diseases (AASLD)[23] recommend weekly subcutaneous peginterferon alfa with daily oral ribavirin as the first choice of treatment for chronic hepatitis C.
