Ph. Eur. 6.2 (Guar). Guar is obtained by grinding the endosperms of the seeds of *Cyamopsis tetragonolobus*. It consists mainly of guar galactomannan. Guar is a white or almost white powder, yielding a mucilage of variable viscosity when dissolved in water. Practically insoluble in alcohol.
Ph. Eur. 6.2 (Guar Galactomannan). A yellowish-white powder. It is soluble in cold and hot water; practically insoluble in organic solvents. Its main components are polysaccharides composed of D-galactose and D-mannose at molecular ratios of 1:1.4 to 1:2. The molecules consist of a linear main chain of β-(1→4)-glycosidically linked mannopyranoses and single α-(1→6)-glycosidically linked galactopyranoses.
USNF 26 (Guar Gum). A gum obtained from the ground endosperms of *Cyamopsis tetragonolobus* (Leguminosae). It consists chiefly of a high-molecular-weight hydrocolloidal polysaccharide, a galactomannan, composed of galactan and mannan units combined through glycosidic linkages. It is a white to yellowish-white, practically odourless, powder. Dispersible in hot or cold water forming a colloidal solution.

Adverse Effects and Precautions

Guar gum can cause gastrointestinal disturbance with flatulence, diarrhoea, or nausea, particularly at the start of treatment.

Because guar gum swells on contact with liquid it should always be washed down carefully with water and should not be taken immediately before going to bed. It should not be used in patients with dysphagia, oesophageal disease, or intestinal obstruction.

Interactions

Guar gum may retard the absorption of other drugs; where this is likely to pose a problem the other drug should be taken at least an hour before guar gum.

Uses and Administration

Guar gum is used in diabetes mellitus (p.431) as an adjunct to treatment with diet, insulin, or oral antidiabetics since it results in some reduction in both postprandial and fasting blood-glucose concentrations. It is given with or immediately before meals in doses of 5 g usually 3 times daily. Adverse gastrointestinal effects may be reduced by using a lower initial dose of 5 g once daily before breakfast for 1 week, then increasing to 5 g twice daily, then 3 times daily, as required. Each dose of guar gum granules should be taken stirred in about 200 mL of a cold drink. Alternatively it can be sprinkled over or mixed with food which must be taken with about 200 mL of fluid.

Guar gum is also used to slow gastric emptying in some patients with the dumping syndrome (p.1695). It is also used as an adjunct in the treatment of hyperlipidaemias.

Guar gum is also used as a thickening and suspending agent, and as a tablet binder. It has been incorporated into processed foods.

◊ Guar gum is an example of a soluble fibre.[1] On contact with water it forms a highly viscous gel, the viscosity of which varies with such factors as its plant source or the form in which it is given.[2]

Fibres such as guar gum reduce postprandial and fasting blood-glucose concentrations as well as plasma-insulin concentrations in healthy subjects and diabetic patients.[1,3,4] Such reductions in blood-glucose concentrations and in glycosylated haemoglobin have been demonstrated in both type 1 and type 2 **diabetes,** but they have generally been small.[3] Possible mechanisms for these effects of guar gum include a delay in gastric emptying,[1,3-5] decreased small-bowel motility,[1,4] decreased glucose absorption resulting from increased viscosity of the contents of the gastrointestinal tract,[1,3] or inhibition of gastrointestinal hormones.[3]

Guar gum also lowers serum total cholesterol and low-density-lipoprotein (LDL) cholesterol concentrations; high-density-lipoprotein (HDL) cholesterol and triglyceride concentrations appear to be unaffected.[4] The most likely mechanism is binding of bile acids, reducing their enterohepatic circulation in a similar way to bile-acid sequestrants.[3,4] When used alone in patients with **hypercholesterolaemia** guar gum has generally produced a modest reduction in plasma-cholesterol and LDL-cholesterol concentrations although some studies have been unable to demonstrate an effect. A few studies have suggested that the cholesterol-lowering effect is attenuated after 8 to 12 weeks of treatment but a long-term study observed a 17% decrease in total serum cholesterol that was maintained for 24 months.[6] Some studies have shown further reductions in cholesterol and LDL-cholesterol concentrations on addition of guar gum to therapy with other lipid regulating drugs.[4] The usual treatment of hyperlipidaemias is discussed on p.1169.

There have been suggestions that guar gum reduces appetite by promoting a feeling of fullness, but a meta-analysis has indicated that it is not effective for reducing body-weight.[7] Products containing guar gum have, however, been promoted as **slimming aids**. Their use cannot be advocated because of the risk of tablets swelling before reaching the stomach and causing oesophageal obstruction.

(human)

Pharmacopoeias. Most pharmacopoeias have monographs for insulin and a variety of insulin preparations.

Ph. Eur. 6.2 (Insulin, Bovine). The natural antidiabetic principle obtained from beef pancreas and purified. A white or almost white powder. Practically insoluble in water and in dehydrated alcohol. It dissolves in dilute mineral acids and, with decomposition, in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light. It should be stored at −20° until released by the manufacturer. When thawed, insulin may be stored at 2° to 8° and used for manufacturing purposes within a short period of time. To avoid absorption of humidity from the air during weighing, the insulin must be at room temperature.

Ph. Eur. 6.2 (Insulin, Porcine). The natural antidiabetic principle obtained from pork pancreas and purified. A white or almost white powder. Practically insoluble in water and in dehydrated alcohol. It dissolves in dilute mineral acids and, with decomposition, in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light. It should be stored at −20° until released by the manufacturer. When thawed, insulin may be stored at 2° to 8° and used for manufacturing purposes within a short period of time. To avoid absorption of humidity from the air during weighing, the insulin must be at room temperature.

Ph. Eur. 6.2 (Insulin, Human). A protein having the structure of the antidiabetic hormone produced by the human pancreas. It is produced either by enzymatic modification and suitable purification of insulin obtained from the pancreas of the pig or by a method based on recombinant DNA (rDNA) technology. A white or almost white powder. Practically insoluble in water and in alcohol. It dissolves in dilute mineral acids and, with decomposition, in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light. It should be stored at or below −18° or below until released by the manufacturer. When thawed, insulin is stored at 2° to 8° and used for manufacturing preparations within a short period of time. To avoid absorption of humidity from the air during weighing, the insulin must be at room temperature.

Ph. Eur. 6.2 (Insulin Aspart; Insulinum Aspartum). It is a 2-chain peptide containing 51 amino acids. The A-chain is composed of 21 amino acids and the B-chain is composed of 30 amino acids. It is identical in primary structure to human insulin, except that it has aspartic acid instead of proline at position 28 of the B-chain. As in human insulin, insulin aspart contains 2 interchain disulfide bonds and 1 intrachain disulfide bond. It is produced by a method based on recombinant DNA (rDNA) technology. A white or almost white powder. Practically insoluble in aqueous solutions with a pH around 5.1. In aqueous solutions below pH 3.5 or above pH 6.5, the solubility is greater than or equal to 25 mg/mL. Store in airtight containers. Protect from light. It should be stored at or below −18° until released by the manufacturer. When thawed, insulin aspart may be stored at 2° to 8° and used for manufacturing purposes within a short period of time. To avoid absorption of humidity from the air during weighing, insulin aspart must be at room temperature before opening the container.

Ph. Eur. 6.2 (Insulin Lispro; Insulinum Lisprum). It is a 2-chain peptide containing 51 amino acids. The A-chain is composed of 21 amino acids and the B-chain is composed of 30 amino acids. It is identical in primary structure to human insulin, only differing in amino acid sequence at positions 28 and 29 of the B-chain. Human insulin is Pro(B28), Lys(B29), whereas insulin lispro is Lys(B28), Pro(B29). As in human insulin, insulin lispro contains 2 interchain disulfide bonds and 1 intrachain disulfide bond. It is produced by a method based on recombinant DNA (rDNA) technology. A white or almost white powder. Practically insoluble in water and in alcohol. It dissolves in dilute mineral acids and with decomposition in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light. It should be stored at or below −18°. When thawed, insulin lispro is used for manufacturing purposes within a short period of time. To avoid absorption of humidity from the air during weighing, insulin aspart must be at room temperature before opening the container.

USP 31 (Insulin). A protein that affects the metabolism of glucose obtained from the pancreas of healthy bovine or porcine animals, or both, used for food by humans. White or practically white crystals. Soluble in solutions of dilute acids and alkalis. Store in airtight containers. Protect from light. It should be stored at −10° to −25°.

USP 31 (Insulin Human). A protein corresponding to the active principle elaborated in the human pancreas that affects the metabolism of carbohydrate (particularly glucose), fat, and protein. It is derived by enzymatic modification of insulin from pork pancreas in order to change its amino acid sequence appropriately, or produced by microbial synthesis via a recombinant DNA process. Store in airtight containers. Protect from light. It should be stored at −10° to −25°.

USP 31 (Insulin Lispro). Insulin Lispro is identical in structure to Insulin Human, except that it has lysine and proline at positions 28 and 29, respectively, of chain B, whereas this sequence is reversed in Insulin Human. It is produced by microbial synthesis via a recombinant DNA process. White or practically white crystals. Soluble in solutions of dilute acids and alkalis. Store in airtight containers. Protect from light. It should be stored at −10° to −25°.

Definitions and Terminology

Insulin is a hormone produced by the beta cells of the islets of Langerhans of the pancreas and consists of 2 chains of amino acids, the A and B chains, connected by 2 disulfide bridges. Insulin produced by different species conforms to the same basic structure but has different sequences of amino acids in the chains. **Porcine insulin** ($C_{256}H_{381}N_{65}O_{76}S_6$ = 5777.5) differs from **human insulin** ($C_{257}H_{383}N_{65}O_{77}S_6$ = 5807.6) in only one amino acid in the B chain, whereas **bovine insulin** ($C_{254}H_{377}N_{65}O_{75}S_6$ = 5733.5) differs from human insulin not only in this same amino acid in the B chain but also in 2 amino acids in the A chain.

The precursor of insulin in the pancreas is proinsulin which is a single polypeptide chain incorporating both the A and B chains of insulin connected by a peptide termed the C-peptide (or connecting-peptide). Although the insulins of various species may be similar in composition the proinsulins are not, in that the sequence and number of amino acids in the C-peptide may vary considerably.

Early commercial insulins were obtained by extraction from bovine or porcine or mixed bovine and porcine pancreases and were purified by recrystallisation only.

Table 2. Ph. Eur., BP, and USP insulin preparations.

Type	Ph. Eur./BP/USP Title	Synonyms	Description	pH	Common classification	Approximate action profile after subcutaneous administration		
						Onset	Time to peak	Duration
Soluble insulins (also known as regular or unmodified insulin)	Soluble Insulin Injection (Ph. Eur. 6.2)	Neutral Insulin Neutral Insulin Injection Soluble Insulin Insulin Injection	Solution of bovine, porcine, or human insulin	6.9 to 7.8				
	Insulin Injection (USP 31)		Solution of bovine or porcine, or a mixture of bovine and porcine, insulin	7.0 to 7.8	Short-acting	30 minutes to 1 hour	2 to 5 hours	6 to 8 hours
	Insulin Human Injection (USP 31)		Solution of human insulin	7.0 to 7.8				
Insulin analogues, rapid	Insulin Aspart Injection (BP 2008)		Solution of insulin aspart	6.9 to 7.8				
	Insulin Lispro Injection (BP 2008)		Solution of insulin lispro	6.9 to 7.8	Short-acting	5 to 20 minutes	1 to 3 hours	2 to 5 hours
	Insulin Lispro Injection (USP 31)		Solution of insulin lispro	7.0 to 7.8				
Biphasic insulins	Biphasic Insulin Injection (Ph. Eur. 6.2)	Biphasic Insulin	Suspension of crystals containing bovine insulin in a solution of porcine insulin	6.6 to 7.2				
	Biphasic Isophane Insulin Injection (Ph. Eur. 6.2)	Biphasic Isophane Insulin	Buffered suspension of porcine insulin or human insulin complexed with protamine sulfate or other suitable protamine, in a solution of porcine insulin or human insulin respectively.	6.9 to 7.8				
	Human Insulin Isophane Suspension and Human Insulin Injection (USP 31)		Buffered suspension of human insulin complexed with protamine sulfate, in a solution of human insulin	7.0 to 7.8				
Insulin suspensions	Isophane Insulin Injection (Ph. Eur. 6.2)	Isophane Insulin Isophane Insulin (NPH) Isophane Protamine Insulin Injection	Suspension of bovine, porcine, or human insulin complexed with protamine sulfate or another suitable protamine. Contains 300 to 600 micrograms of protamine sulfate per 100 units of insulin	6.9 to 7.8				
	Isophane Insulin Suspension (USP 31)		Buffered aqueous suspension of zinc-insulin (bovine or porcine) crystals and protamine sulfate, combined in a manner such that the solid phase of the suspension consists of crystals composed of insulin, protamine, and zinc	7.0 to 7.8	Intermediate-acting	Within 2 hours	4 to 12 hours	Up to 24 hours
	Isophane Insulin Human Suspension (USP 31)		Buffered aqueous suspension of zinc-insulin human crystals and protamine sulfate, combined in such a manner that the solid phase of the suspension consists of crystals composed of insulin human, protamine, and zinc	7.0 to 7.5				
	Insulin Zinc Injectable Suspension (Amorphous) (Ph. Eur. 6.2)	Amorph. I.Z.S. Insulin Semilente Insulin Zinc Suspension (Amorphous)	Suspension of bovine, porcine, or human insulin complexed with a suitable zinc salt; the insulin is in a form practically insoluble in water	6.9 to 7.8				

Table 2. Ph. Eur., BP, and USP insulin preparations.

Type	Ph. Eur./BP/USP Title	Synonyms	Description	pH	Common classification	Approximate action profile after subcutaneous administration: Onset	Time to peak	Duration
Insulin suspensions *cont*	Prompt Insulin Zinc Suspension (USP 31)		Buffered aqueous suspension of bovine or porcine, or a mixture of bovine and porcine, insulin modified by the addition of a suitable zinc salt in a manner such that the solid phase is amorphous	7.0 to 7.8				
	Insulin Zinc Injectable Suspension (Ph. Eur. 6.2)	Insulin Lente I.Z.S. I.Z.S. (Mixed) Insulin Zinc Suspension (Mixed) Insulin Zinc Suspension	Suspension of bovine or porcine, or a mixture of bovine and porcine, or human insulin with a suitable zinc salt; the insulin is in a form practically insoluble in water. It may be produced by mixing Insulin Zinc Injectable Suspension (Amorphous) (Ph. Eur. 6.2) and Insulin Zinc Injectable Suspension (Crystalline) (Ph. Eur. 6.2) in a ratio of 3 to 7	6.9 to 7.8				
	Insulin Zinc Suspension (USP 31)	Insulin Zinc	Buffered aqueous suspension of bovine or porcine, or a mixture of bovine and porcine, insulin modified by the addition of a suitable zinc salt in a manner such that the solid phase of the suspension consists of a mixture of approximately 3 parts of amorphous insulin to 7 parts of crystalline insulin	7.0 to 7.8	Intermediate or long-acting	2 to 3 hours	6 to 15 hours	Up to 30 hours
	Insulin Human Zinc Suspension (USP 31)		Buffered aqueous suspension of human insulin modified by the addition of a suitable zinc salt in a manner such that the solid phase of the suspension consists of a mixture of approximately 3 parts of amorphous insulin to 7 parts of crystalline insulin	7.0 to 7.8				
	Insulin Zinc Injectable Suspension (Crystalline) (Ph. Eur. 6.2)	Cryst. I.Z.S. Insulin Ultralente Insulin Zinc Suspension (Crystalline)	Suspension of bovine, porcine, or human insulin complexed with a suitable zinc salt; the insulin is in a form practically insoluble in water	6.9 to 7.8				
	Protamine Zinc Insulin Injection (BP 2008)	Protamine Zinc Insulin	Buffered suspension of bovine, porcine, or human insulin complexed with protamine sulfate or another suitable protamine and zinc chloride or another suitable zinc salt	6.9 to 7.8				
	Extended Insulin Zinc Suspension (USP 31)		Buffered aqueous suspension of bovine or porcine, or a mixture of bovine and porcine, insulin modified by the addition of a suitable zinc salt in a manner such that the solid phase is predominantly crystalline	7.0 to 7.8	Long-acting	4 hours	10 to 20 hours	Up to 36 hours
	Extended Insulin Human Zinc Suspension (USP 31)		Buffered aqueous suspension of human insulin modified by the addition of a suitable zinc salt in a manner such that the solid phase of the suspension is predominantly crystalline	7.0 to 7.8				

Insulins obtained by such methods were often termed '**conventional insulins**' to distinguish them from insulins which have undergone further purification processes. An extract which has been recrystallised only once can be separated into 3 components or fractions termed the 'a', 'b', and 'c' components. The 'a' component consists of high molecular weight substances and is only usually found in very impure preparations since repeated recrystallisation will remove most of it. The 'b' component consists largely of proinsulin and insulin dimers, and the 'c' component consists of insulin, insulin esters, arginine insulin, and desamidoinsulin. Other pancreatic peptides such as glucagon, pancreatic polypeptide, somatostatin, and vasoactive intestinal peptide are also usually found in products which have not undergone further purification. Gel filtration will substantially reduce the content of proinsulin but will not significantly reduce the content of insulin derivatives or pancreatic peptides; products purified by gel filtration are often termed '**single-peak insulins**'. Addition of ion-exchange chromatography to the purification methods will further reduce the proinsulin content and also reduce the contamination by insulin derivatives and pancreatic peptides. In the UK '**highly purified insulins**' and '**monocomponent insulins**' are terms sometimes applied to insulins which have undergone both gel filtration and ion-exchange chromatography. In the USA the FDA has designated the term '**purified insulins**' for preparations similarly prepared and containing less than 10 ppm of proinsulin.

Much of the insulin now produced has an amino-acid sequence identical to that of human insulin. **Human insulin (emp)** is produced by the enzymatic modification of insulin obtained from the porcine pancreas; it is also sometimes called **semisynthetic human insulin**. The term **human insulin (crb)** is used for insulin produced by the chemical combination of A and B chains which have been obtained from bacteria genetically modified by recombinant DNA technology. **Human insulin (prb)** is produced from proinsulin obtained from bacteria genetically modified by recombinant DNA technology. **Human insulin (pyr)** is insulin produced from a precursor obtained from a yeast genetically modified by recombinant DNA technology. Human insulin obtained by recombinant DNA technology is sometimes termed **biosynthetic human insulin**.

Insulin or human insulin is supplied in a variety of forms in solution or suspension for injection (see Table 2, p.444). Crystalline insulin may be prepared for therapeutic use merely by making a solution, either of acidic or neutral pH. **Soluble insulin** or '**neutral insulin**' is a short-acting preparation that can be given intravenously if necessary to cover emergencies. Soluble formulations are sometimes referred to as '**regular insulin**' or '**unmodified insulin**'; these names reflect the fact that the preparation has not been formulated in order to prolong the duration of action of the insulin.

In order to prolong the duration of action of insulin, preparations may be formulated as suspensions in 2 general ways. The first involves complexing insulin with a protein from which it is slowly released; examples are **protamine zinc insulin**, which contains an excess of protamine, and **isophane insulin** (NPH insulin), which contains equimolecular amounts of insulin and protamine. The second method of prolonging the action of insulin is to modify the particle size and the various **insulin zinc suspensions** are in this category.

Biphasic insulins are mixtures providing for both immediate and prolonged action.

Chemical modification of the insulin molecule has resulted in insulins such as **dalanated insulin** (prepared by the removal of the C-terminal alanine from the B chain of insulin), **insulin defalan** (prepared by the removal of the terminal phenylalanine), and **sulfated insulin**, but these insulins have not been widely used.

More recently, recombinant DNA technology has enabled production of *insulin analogues* with altered pharmacokinetic profiles. **Insulin lispro** is one such analogue, in which the B28 and B29 amino acid residues of human insulin are replaced with lysine and proline. It is available as a rapidly acting alternative to soluble insulin and as an intermediate-acting complex with protamine. **Insulin aspart** and **insulin glulisine** are other rapidly acting analogues. **Insulin glargine** is a long-acting form for once-daily use, and **insulin detemir** is used once or twice daily. Further information on these can be found under the heading Insulin Analogues and Proinsulin, in Uses, below.

Stability and Storage

Both the Ph. Eur. 6.2 and the USP 31 recommend that insulin preparations be stored in a refrigerator at 2° to 8° and not be allowed to freeze. The Ph. Eur. 6.2 directs that insulin preparations should be protected from light, and the USP 31 that they should be protected from sunlight. It is recognised that patients may not follow such stringent storage guidelines and most manufacturers of commercial insulin preparations consider that storage by the patient at a temperature of up to 25° would be acceptable for up to one month. Patients should still be advised not to expose their vials or cartridges to excessive heat or sunlight.

It is advisable to shake suspensions gently before a dose is withdrawn.

Insulin in powder form should be stored in airtight containers and protected from light. Storage at a low temperature is also recommended. The Ph. Eur. 6.2 advises storage at a temperature of −20° for bovine and porcine insulin and at −18° or below for Human Insulin, and for Insulin Aspart and Insulin Lispro; the USP 31 requires storage at −10° to −25° for all types of insulin. It is stressed that this temperature is for the powder and not for the preparations; preparations should not be subjected to storage conditions that lead to freezing.

Adsorption. The adsorption of insulin onto glass and plastics used in giving sets has been decreased by the addition of albumin or polygeline to insulin solutions but it has been stated[1,2] that in practice this was unnecessary since insulin adsorption was not a major problem. However, in studies of insulin infusions used in neonatal hyperglycaemia, various methods have been investigated and found to reduce the amount of insulin lost by adsorption to the giving set. These included flushing[3] or priming[4] the system with the insulin infusion, or using a concentrated insulin solution to prime the tubing.[5] A study[6] that compared different methods found wide variation in insulin delivery depending on solution concentration, flow rate, addition of albumin, catheter type, and priming or flushing of the system.

Aggregation. For discussion of the problems of insulin aggregation, see Intensive Administration Regimens under Uses, below.

Units

One unit of *bovine insulin* is contained in 0.03891 mg of the first International Standard (1986). One unit of *porcine insulin* is contained in 0.03846 mg of the first International Standard (1986). One unit of *human insulin* is contained in 0.03846 mg of the first International Standard (1986).

Adverse Effects

The most frequent complication of insulin therapy is hypoglycaemia, the speed of onset and duration of which may vary according to the type of preparation and the route used. It is usually associated with an excessive dosage of insulin, the omission of a meal by the patient, or increased physical activity. Patients, especially the elderly or those with tightly controlled diabetes or diabetes of long standing, may not experience the typical early warning symptoms of a hypoglycaemic attack. There have been reports of hypoglycaemia, sometimes with decreased warning symptoms, in patients changing from animal (especially bovine) to human insulin (see under Hypoglycaemia, below). Symptoms of hypoglycaemia resulting from increased sympathetic activity include hunger, pallor, sweating, palpitations, anxiety, and tremulousness. Other symptoms include headache, visual disturbances such as blurred or double vision, slurred speech, paraesthesia of the mouth and fingers, alterations in behaviour, and impaired mental or intellectual ability. If untreated, hypoglycaemia may lead to convulsions and coma which should not be confused with hyperglycaemic coma.

Insulin, given subcutaneously, may cause either lipoatrophy or lipohypertrophy. Lipoatrophy appears to occur less frequently with purified insulins than with conventional insulins; if it has occurred, it may be reversed by the injection of a purer animal insulin or human insulin into and around the atrophied site. Lipohypertrophy is usually associated with repeated injections at the same site and may usually be overcome by rotating the site of injection, although absorption of insulin may vary from different anatomical areas. Prolonged insulin therapy may result in weight gain.

Insulin occasionally causes local or systemic hypersensitivity reactions. Local reactions, characterised by erythema and pruritus at the injection site, usually disappear with continued use. Generalised hypersensitivity may produce urticaria, angioedema, and very rarely anaphylactic reactions; if continued therapy with insulin is essential hyposensitisation may be needed. Again, hypersensitivity reactions occur less frequently with purified than with conventional insulins and porcine insulin is less immunogenic than bovine insulin. Although hypersensitivity reactions have been reported in patients transferred from animal to human insulins, there are only isolated reports of such reactions in patients treated exclusively with human insulin.

Many patients treated with insulin, either animal or human insulin, develop antibodies but the clinical significance of this is not entirely clear.

◊ Of patients who received intensive insulin therapy for type 1 diabetes as part of the Diabetes Control and Complications Trial, those who experienced the greatest weight gain also had increased blood concentrations of triglycerides and low-density-lipoprotein cholesterol, and lowered high-density-lipoprotein cholesterol.[1] These lipid changes, with higher blood pressure, increased waist-to-hip ratio, and greater insulin requirements, were held to be similar to the symptoms of insulin resistance and to indicate a possible increased risk of macrovascular disease. Results from the UK Prospective Diabetes Study indicated that type 2 diabetic patients treated with insulin had greater weight gain than those managed with other therapies,[2] but demonstrated no evidence of harmful cardiovascular effects.

For discussion of some of the specific problems associated with continuous infusion of insulin, see Intensive Administration Regimens under Uses, below.

2. UK Prospective Diabetics Study (UKPDS) Group. Intensive blood-glucose control with sulphonylureas or insulin compared with conventional treatment and risk of complications in patients with type 2 diabetes (UKPDS 33). *Lancet* 1998; **352:** 837–53. Correction. *ibid.* 1999; **354:** 602.

Carcinogenicity. Primary lung malignancies have been found in a few patients receiving inhaled insulin; for further details, see Administration Routes, p.450.

Effects on the liver. For a report of hepatomegaly occurring after insulin overdosage, see under Abuse, in Precautions, below.

Effects on the skin. Delayed pressure urticaria, in the form of large wheals occurring 4 to 6 hours after prolonged pressure, and lasting for up to 24 hours, was seen in a patient with type 1 diabetes within 6 months of changing from animal to human insulin.[1] The condition improved after a switch back to insulin of animal origin, and grew worse again after a second attempt to switch to human insulin. Intermittent urticaria simultaneously affecting previous injection sites was reported in a child receiving human insulin, who had never received animal insulin.[2]

2. Sackey AH. Recurrent generalised urticaria at insulin injection sites. *BMJ* 2000; **321:** 1449.

Hypersensitivity. Hypersensitivity reactions to insulin preparations may be caused not only by the insulin itself, but also by other components of the formulation such as zinc[1-3] or protamine.[4-9] Hypersensitivity reactions and lipoatrophy (which is also thought to have an immune basis) have become rare since the introduction of highly purified and human insulins.[10] Although insulin analogues have been used successfully in patients with a history of hypersensitivity to human insulin,[11,12] there are also reports of both local and generalised reactions to insulin analogues.[13-15]

HYPOSENSITISATION. After failure of standard hyposensitisation measures in a patient with cutaneous hypersensitivity to insulin, hyposensitisation was attempted by giving insulin by mouth.[1] Aspirin 1.3 g three times daily by mouth was also given to antagonise vascular mediators of the reaction. After one week subsequent hyposensitisation using insulin by injection was successful. When the patient stopped taking aspirin after 6 months the original hypersensitivity reactions recurred; aspirin was then given permanently in a dose of 1.3 g twice daily.

1. Holdaway IM, Wilson JD. Cutaneous insulin allergy responsive to oral desensitisation and aspirin. *BMJ* 1984; **289:** 1565–6.

Hypoglycaemia. Hypoglycaemia is the major adverse effect of insulin treatment, with severe hypoglycaemic episodes occurring in up to a third of all insulin-treated patients at some point in their lives. Moves towards more intensive insulin therapy, in order to reduce the development of diabetic complications, increase the risk of hypoglycaemic episodes.[1,2] Patients maintaining strict glycaemic control are prone to 'hypoglycaemia unawareness' in which the normal adrenergic counter-response to hypoglycaemia (characterised by symptoms such as pallor, sweating, and tremor) is reduced or lost,[3] so that hypoglycaemia can develop without warning. Such a loss of awareness of impending hypoglycaemia also seems to develop as duration of diabetes increases.[4] One of the main reasons for reduced awareness of hypoglycaemia is that repeated hypoglycaemic episodes seem to trigger an adaptive conservation of glucose concentrations in the brain, resulting in higher central than peripheral blood glucose values;[5] avoidance of hypoglycaemia helps restore awareness.

When recombinant human insulin became generally available in the late 1980s a number of patients complained of a loss of awareness of impending hypoglycaemia after transfer to human insulin,[6,7] and there were reports of severe or even fatal hypoglycaemia occurring in patients who had been well stabilised on animal insulins.[6-8]

This was, and remains, a somewhat controversial area. Despite some small studies suggesting a problem, others failed to find evidence of a difference between animal and human insulins, and a systematic review[9] concluded that the available evidence did not support the suggestion that human insulin increased the frequency or severity of hypoglycaemia, or affected the symptoms of hypoglycaemia, compared with animal insulins. However, most commentators appear to consider that patients should continue to have access to animal insulins if desired, and that those well maintained on animal insulin should not be transferred to human insulin without appropriate clinical grounds,[4,8,10-12] and then only with careful monitoring.

There has also been concern about possible long-term sequelae of hypoglycaemic episodes on the CNS. However, a report on patients participating in the Diabetes Control and Complications Trial (DCCT) suggested that the increased risk of hypoglycaemia seen with intensive therapy was not associated with neuropsychological impairment.[13]

Oedema. Severe, acute oedema is a rare adverse effect of insulin treatment, occurring most often when starting therapy.[1-4] It should be distinguished from chronic and subacute forms of oedema which may be complications of the diabetic disease process.[2,3] Possible mechanisms of acute oedema are sodium retention resulting from a direct action of insulin on the renal tubule or an effect of insulin on vascular permeability.[1,3] The oedema is usually self-limiting,[2,4] but does respond to a decrease in insulin dosage, or diuretic therapy.[1,3]

Treatment of Insulin-induced Hypoglycaemia

In the conscious and cooperative patient hypoglycaemia is treated by eating a readily absorbable form of carbohydrate, such as sugar lumps or a glucose-based drink; all diabetics should always carry a suitable sugar source by way of precaution.

If the patient is drowsy or unconscious, then glucose must be given parenterally. Doses of 50 mL of a 20% solution of glucose or 25 to 50 mL of glucose 50% can be given intravenously; the higher concentration is more viscous and irritant to the veins. Lower concentrations are equally effective, and carry less risk of irritant effects, but larger volumes are required, e.g. up to 500 mL of glucose 5%, or 250 mL of 10%, titrated to patient response. Smaller quantities (e.g. 5 to 10 mL/kg of a 10% solution) are required in children. Bolus doses may need to be repeated, or a maintenance infusion started, to prevent persistent hypoglycaemia. If the patient has not regained consciousness within a few minutes after a bolus dose of glucose, the possibility of cerebral oedema should be considered.

In situations where giving intravenous glucose is impractical or not feasible, glucagon 1 mg for adults and children above 25 kg or 0.5 mg for children below 25 kg by subcutaneous, intramuscular, or intravenous injection may arouse the patient sufficiently to allow oral glucose to be given. If the patient fails to respond to glucagon within about 10 to 15 minutes, then glucose has to be given intravenously despite any impracticalities.

After a return to consciousness, oral carbohydrates may need to be given until the action of insulin has ceased, which for preparations with a relatively long duration of action such as isophane insulin, some insulin zinc suspensions, and protamine zinc insulin, may be several hours.

Carbohydrate. A comparative study[1] of 7 different preparations of oral carbohydrate for the treatment of hypoglycaemia in the conscious patient found no significant difference in effectiveness between glucose or sucrose in solution or tablet form; a hydrolysed polysaccharide solution containing glucose, maltose, and various more complex saccharides (*Glucidex 19*) was also roughly comparable. However, a glucose gel and orange juice were each less effective than the other formulations in treating hypoglycaemia.

1. Slama G, *et al.* The search for an optimized treatment of hypoglycemia: carbohydrates in tablets, solution, or gel for the correction of insulin reactions. *Arch Intern Med* 1990: **150:** 589–93.

Glucagon. A discussion of the relative merits of parenteral glucose and glucagon in unconscious hypoglycaemic patients[1] suggested that glucagon should be encouraged as first-line treatment, although in practice (see above) parenteral glucose is usually preferred. The effect of glucagon relies upon the patient having adequate liver glycogen stores, which may not always be the case.

1. Gibbins RL. Treating hypoglycaemia in general practice. *BMJ* 1993; **306:** 600–601.

Overdose. The requirements for glucose are greater and more prolonged when hypoglycaemia is caused by insulin overdosage rather than therapeutic doses.[1] Correction of insulin-induced hypokalaemia may also be required. Surgical excision of tissue at the site of injection has been used for massive overdose of a long-acting insulin.[2,3]

Precautions

Dosage requirements of insulin may be altered by many factors. Increased doses are usually necessary during infection, emotional stress, accidental or surgical trauma, puberty, and the latter two trimesters of pregnancy. Decreased doses are usually necessary in patients with impaired renal or hepatic function or during the first trimester of pregnancy. On first stabilising therapy in newly diagnosed diabetic patients, a temporary decrease in requirements may also occur (the so-called honeymoon period).

Because of the possibility of differing responses to insulins from different species, inadvertent change from insulin of one species to another should be avoided. Reduction in insulin dosage may be required on transfer from animal (especially bovine) to human insulin. Hypoglycaemic problems associated with a change to human insulin are discussed under Adverse Effects, above. Care is also necessary during excessive exercise; hypoglycaemia caused by metabolic effects and increased insulin absorption is the usual response, but hyperglycaemia may sometimes occur.

The use of insulin requires monitoring of therapy, such as testing blood or urine for glucose concentrations and the urine for ketones, by the patient.

Drugs which have an effect on blood-glucose concentrations may alter glycaemic control with consequent need for a change in insulin dose (see Interactions, below).

CAUTION. *Biphasic insulin, insulin zinc suspensions, isophane insulin, protamine zinc insulin, insulin detemir, and insulin glargine should never be given intravenously and they are not suitable for the emergency treatment of diabetic ketoacidosis.*

Abuse. Transient recurrent hepatomegaly associated with hypoglycaemia was associated with the surreptitious injection of additional insulin doses in an insulin-dependent diabetic. Increased storage of glycogen in the liver resulting from insulin excess was considered responsible for the hepatomegaly.[1]

Decreased plasma C-peptide concentrations or the presence of anti-insulin antibodies may be used to confirm insulin abuse as a cause of hypoglycaemia in patients who have never been treated with insulin medically.[2] Insulin has been abused by bodybuilders and other sportspersons;[3,4] severe brain damage after prolonged neuroglycopenia has resulted.[3] There are rare reports of the misuse of insulin to induce mind-altering effects of hypoglycaemia.[5]

Accelerated absorption. Factors such as a hot bath, sauna, or use of a sunbed have been reported to accelerate the absorption of subcutaneous injection, presumably by an increase in skin blood flow.[1-4] There may, therefore, be a risk of hypoglycaemia.[4]

1. Koivisto VA. Sauna-induced acceleration in insulin absorption from subcutaneous injection site. *BMJ* 1980; **280:** 1411–13.

4. Husband DJ, Gill GV. "Sunbed seizures": a hypoglycaemic hazard for insulin-dependent diabetics. *Lancet* 1984; **ii:** 1477.

Adrenocortical insufficiency. Recurrent severe hypoglycaemia, which occurred in 2 patients with type 1 diabetes, persisted despite a reduction in insulin doses and proved to be due to Addison's disease.[1] Insulin requirements rose again in both patients after replacement therapy with fludrocortisone and hydrocortisone.

1. Armstrong L, Bell PM. Addison's disease presenting as reduced insulin requirement in insulin dependent diabetics. *BMJ* 1996; **312:** 1601–2.

Driving. In the UK, patients with diabetes mellitus treated with insulin or oral hypoglycaemics are required to notify their condition to the Driver and Vehicle Licensing Agency, who then assess their fitness to drive. Patients treated with oral hypoglycaemics are generally allowed to retain standard driving licences; those treated with insulin receive restricted licences which must be renewed (with appropriate checks) every 1 to 3 years. Patients should be warned of the dangers of hypoglycaemic attacks while driving, and should be counselled in appropriate management of the situation (stopping driving as soon as it is safe to do so, taking carbohydrate immediately, and quitting the driving seat and removing the ignition key from the car) should such an event occur. Patients who have lost hypoglycaemic awareness, or have frequent hypoglycaemic episodes, should not drive. In addition, eyesight must be adequate (field of vision of at least 120°) for a licence to be valid. Patients treated with diet or oral hypoglycaemics are normally allowed to hold vocational driving licences for heavy goods vehicles or passenger carrying vehicles; those treated with insulin may not drive such vehicles, and are restricted in driving some other vehicles such as small lorries and minibuses.[1,2]

Regulations in other countries differ widely.[3]

1. British Diabetic Association (Diabetes UK). Information sheet: driving and diabetes: May 2008. Available at: http://www.diabetes.org.uk/Documents/catalogue/driving_and_diabetes-may_08.pdf (accessed 20/08/08)

Fasting. Reduction in food intake or alteration in the pattern of meal times may affect insulin requirements and predispose to the development of hypoglycaemia (above). Muslim patients who are receiving antidiabetic therapy and who fast during Ramadan have been shown to be at increased risk of severe hypoglycaemic episodes during this month.[1] A study in 17 fasting patients with type 1 diabetes recommended reduction of the total insulin dose to 85% of that before the fasting period, and supplying 70% as long-acting ultralente insulin and 30% as a rapidly acting soluble insulin; the daily dose was divided into 2 equal portions given before sunrise and after sunset.[2] Others have made similar recommendations: 2 daily injections of an intermediate- or long-acting insulin, given before the predawn and sunset meals, together with a short-acting insulin at the meal itself; or possibly a single daily injection of insulin glargine, or twice-daily insulin detemir, plus a rapidly acting analogue just before the meal.[3]

Patients with type 2 diabetes maintained on insulin may be managed similarly, by judicious use of intermediate or long-acting insulin plus a short-acting insulin given before meals. A single injection of a long-acting analogue such as insulin glargine, or two injections of isophane or lente insulin or insulin detemir before the sunset and predawn meals, may provide adequate coverage provided the dosage is appropriately individualised. However, most patients will still require a short-acting insulin to be added at the sunset meal to cover the large caloric load. Many will also require an additional dose of short-acting insulin at predawn.[3] Studies have suggested that insulin lispro may produce good blood sugar control in fasting patients with type 2 diabetes during Ramadan.[4,5]

Care is also required in patients with type 2 diabetes being treated with oral antidiabetic drugs. Patients being treated with metformin or insulin sensitisers such as the glitazones have a low risk of hypoglycaemia, although it has been suggested that the timing of metformin doses be altered so that two-thirds of the daily dose is taken just before the sunset meal and the other third before the predawn meal. Short-acting secretagogues such as repaglinide or nateglinide can also be taken twice daily before the sunset and predawn meals. However, sulfonylureas should be used with caution, and the use of chlorpropamide may be contra-indicated because of the high risk of prolonged and unpredictable hypoglycaemia.[3]

Hypersensitivity to protamine. Retrospective surveys have indicated that patients receiving isophane insulin, which contains protamine, have an increased risk of severe anaphylactoid reactions when protamine is used to reverse systemic heparinisation after cardiac catheterisation or cardiac surgery. The degree of increase in risk is unclear, however, as it has been reported as both large[1] and small.[2,3] A review of the literature suggested that surgical patients may be at greater risk because of a higher rate of prior sensitisation to protamine and the larger doses used.[3] A mechanism involving IgE and IgG antibodies to protamine has been proposed.[4]

4. Weiss ME, *et al.* Association of protamine IgE and IgG antibodies with life-threatening reactions to intravenous protamine. *N Engl J Med* 1989; **320:** 886–92.

Infections. Decreased requirements of insulin, added to the dialysate, occurred in 6 diabetic patients undergoing continuous ambulatory peritoneal dialysis for chronic renal failure during episodes of severe bacterial peritonitis.[1] This was contrary to the increased insulin requirements of most diabetic patients during severe infections and probably resulted from increased absorption of insulin due to mesothelial damage.

1. Henderson IS, *et al.* Decreased intraperitoneal insulin requirements during peritonitis on continuous ambulatory peritoneal dialysis. *BMJ* 1985; **290:** 1474.

Menstruation. Changes in glycaemic control associated with the menstrual cycle have been recorded in women with type 1 diabetes mellitus. In a retrospective review of 124 women,[1] 61% reported perimenstrual changes in glucose concentrations and 36% made adjustments to their insulin dose, usually a small increase in the premenstrual insulin dose followed by a small decrease at the onset of menstruation. Based on mean glycosylated haemoglobin measurements, there was no evidence of improved glycaemic control in women adjusting their insulin dose compared with those leaving it unchanged despite changes in capillary glucose measurements. Changes in appetite and food consumption associated with the menstrual cycle may affect variations in glucose concentrations and insulin requirements.

1. Lunt H, Brown LJ. Self-reported changes in capillary glucose and insulin requirements during the menstrual cycle. *Diabet Med* 1996; **13:** 525–30.

Morning hyperglycaemia. Morning hyperglycaemia may be the result of mere waning of subcutaneously injected insulin. It may also be rebound hyperglycaemia (posthypoglycaemic hyperglycaemia or the Somogyi phenomenon) occurring after an episode of nocturnal hypoglycaemia. Morning hyperglycaemia has also been observed without antecedent hypoglycaemia even during constant intravenous infusion of insulin, when the waning of previously injected insulin would not be a factor and this is commonly referred to as the dawn phenomenon. Clinically, it is important to distinguish between the dawn phenomenon, simple waning of previously injected insulin, and rebound hyperglycaemia as a cause of early-morning hyperglycaemia because their treatment differs. Management of the dawn phenomenon and insulin waning generally consists of adjusting the evening dose of insulin to provide additional coverage between 4 a.m. and 7 a.m. Management of rebound hyperglycaemia consists of reducing insulin doses or providing additional late-evening carbohydrate, or both, to avoid nocturnal hypoglycaemia. Mistaking rebound hyperglycaemia for the dawn phenomenon or mere waning of injected insulin could result in more serious nocturnal hypoglycaemia, if evening doses of insulin were increased.[1]

Pregnancy. For discussion of the precautions necessary in the management of diabetes mellitus during pregnancy, see p.431.

There has been a report of 2 cases of fetal malformation in the offspring of well-controlled diabetic women who received *insulin lispro*.[1] However, the incidence of fetal malformation is increased in infants of women with diabetes. At that time the manufacturers were aware of 19 live births among women treated with insulin lispro, 1 of which exhibited a congenital abnormality.[2] Since then, a number of retrospective studies[3-7] have looked at the rates of fetal malformations in the offspring of women treated with insulin lispro, for either pre-existing diabetes mellitus or gestational diabetes. These have included groups ranging in size from 62 to 496 women, and none have found any evidence of an increase in the incidence of abnormalities with insulin lispro compared with rates published for women treated with other insulins.

There is less information available about the use of other insulin analogues, but a few cases and studies of *insulin glargine* use during pregnancy have been described. It was started in one woman[8] during the fourteenth week of gestation, and continued until delivery with no apparent adverse effect on the baby. In another report,[9] insulin glargine was inadvertently continued by 5 women during the first 6 to 12 weeks of unplanned pregnancies. In these cases, therapy was changed from insulin glargine to isophane insulin, and no fetal malformations were detected. The use of insulin glargine during the entire pregnancy, without adverse effect, has also been described,[10] and successful pregnancies were reported in 4 women given insulin glargine for gestational diabetes.[11] Furthermore, a small case-control study[12] found no significant difference in neonatal outcomes for insulin glargine and human insulin in women with type 1 or gestational diabetes, and another study[13] found no unexpected adverse effects in the babies of 115 women given insulin glargine. A single-dose study has reported[14] that *insulin aspart* was effective in reducing postprandial glucose concentration in gestational diabetes. Randomised studies in women with type 1 diabetes[15] or gestational diabetes[16] have also found no indication of an increase in congenital malformations with insulin aspart compared with human insulin.

Interactions

Many drugs have an effect on blood-glucose concentrations and may alter insulin requirements. Drugs with hypoglycaemic activity or which may decrease insulin requirements include ACE inhibitors, alcohol, anabolic steroids, aspirin, beta blockers (which may also mask the warning signs of hypoglycaemia), disopyramide, fenfluramine, guanethidine, some MAOIs, mebendazole, octreotide, some tetracyclines, and the tricyclic antidepressant amitriptyline.

On the other hand, increased requirements of insulin may possibly be seen with chlordiazepoxide, chlorpromazine, some calcium-channel blockers such as diltiazem or nifedipine, corticosteroids, diazoxide, lithium, thiazide diuretics, and thyroid hormones.

Both increased and decreased requirements may occur with cyclophosphamide, isoniazid, and oral contraceptives.

ACE inhibitors. Although ACE inhibitors are favoured for use in diabetic patients with hypertension or evidence of incipient nephropathy or both, they may increase insulin sensitivity and thus decrease insulin requirements.[1,2] A study[3] of hospital admissions found that ACE inhibitors increased the risk of severe hypoglycaemia in patients receiving insulin. However, an analysis of pharmacovigilance data[4] and a case-control study[5] have both found no such increase in risk.

3. Morris AD, *et al.* ACE inhibitor use is associated with hospitalization for severe hypoglycemia in patients with diabetes. *Diabetes Care* 1997; **20:** 1363–7.
4. Moore N, *et al.* Reports of hypoglycaemia associated with the use of ACE inhibitors and other drugs: a case/non-case study in the French pharmacovigilance system database. *Br J Clin Pharmacol* 1997; **44:** 513–8.
5. Thamer M, *et al.* Association between antihypertensive drug use and hypoglycemia: a case-control study of diabetic users of insulin or sulfonylureas. *Clin Ther* 1999; **21:** 1387–1400.

Alcohol. Severe hypoglycaemic episodes have been reported in type 1 diabetics after heavy drinking episodes.[1,2] Alcohol inhibits gluconeogenesis, and its effects are therefore likely to be greatest if taken without food; however, it seems to be generally agreed that diabetics need not abstain from a moderate alcohol intake with meals.

2. Potter J, *et al.* Insulin induced hypoglycaemia in an accident and emergency department: the tip of an iceberg. *BMJ* 1982; **285:** 1180–2.

Aspirin. Aspirin produces a modest decrease in blood-glucose concentrations but a significant interaction at conventional analgesic doses appears to be unlikely. One study in children with type 1 diabetes found an average 15% decrease in blood glucose values following treatment with aspirin 1.2 to 2.4 g daily for 3 days, but there were no significant changes in insulin requirements.[1] However, high doses of aspirin can reduce or even replace the insulin dose required.[2] Other salicylates might be expected to have similar properties.

2. Reid J, Lightbody TD. The insulin equivalence of salicylate. *BMJ* 1959; **1:** 897.

Beta blockers. There are a few reports of severe hypoglycaemia in patients, including insulin-treated diabetics, who were given *propranolol* or *pindolol*;[1-3] there is also a report of an interaction with *timolol* given as eye drops.[4] Some evidence exists of an interaction with *metoprolol*,[5] but little evidence for some of the more selective beta blockers. Because of the effects of beta blockers on the sympathetic nervous system the usual premonitory signs of hypoglycaemia may not occur, allowing a severe episode to develop before the patient is aware and able to counter it.

5. Newman RJ. Comparison of propranolol, metoprolol, and acebutolol on insulin-induced hypoglycaemia. *BMJ* 1976; **2:** 447–9.

Calcium-channel blockers. Diabetes worsened in an insulin-treated diabetic when given *diltiazem*.[1] The resultant intractable hyperglycaemia improved when the drug was withdrawn, and recurred, although at a more manageable level, when diltiazem was restarted at a lower dose. There are also reports of a diabetogenic effect of *nifedipine*.[2,3] However, reports of significant disturbances of metabolic control appear to be uncommon.

3. Heyman SN, *et al.* Diabetogenic effect of nifedipine. *DICP Ann Pharmacother* 1989; **23:** 236–7.

Interferons. Markedly increased insulin requirements developed in a previously well controlled diabetic after treatment with *interferon alfa 2a*.[1] Insulin requirements rapidly fell once interferon therapy was stopped.

1. Campbell S, *et al.* Rapidly reversible increase in insulin requirement with interferon. *BMJ* 1996; **313:** 92.

Oral contraceptives. Both increases and decreases (mainly the former) in insulin requirements have been reported in insulin-dependent diabetics given various oral contraceptives.[1] However, it appears that in most cases the effects of a hormonal contraceptive on diabetic control are modest or insignificant: limited data suggest that progestogen-only and combined oral contraceptives in general have little effect.[2,3]

Pharmacokinetics

Insulin has no hypoglycaemic effect when given by mouth since it is inactivated in the gastrointestinal tract.

It is fairly rapidly absorbed from subcutaneous tissue on injection and although the half-life of unmodified insulin in blood is very short (being only a matter of minutes), the duration of action of most preparations is considerably longer because of their formulation (for further details see Uses and Administration, below). The rate of absorption from different anatomical sites depends on local blood flow, with absorption from the abdomen being faster than that from the arm, and that from the arm faster than from buttock or thigh. Absorption may also be increased by exercise. The absorption of insulin after intramuscular injection is more rapid than that after subcutaneous doses. Human insulin may be absorbed slightly faster from subcutaneous tissue than porcine or bovine insulin.

Insulin is rapidly metabolised, mainly in the liver but also in the kidneys and muscle tissue. In the kidneys it is reabsorbed in the proximal tubule and either returned to venous blood or metabolised, with only a small amount excreted unchanged in the urine.

◊ For discussion of factors which may affect the absorption of insulin, see under Precautions, Accelerated Absorption, above, and Uses, Administration Routes, below.

Resistance to Insulin

The term insulin resistance has traditionally been used to describe a state in which diabetic patients exhibit considerably increased insulin requirements. It is now used in a much wider sense, and is for instance also applied to patients in whom a subnormal biological response to insulin can be demonstrated, although many of these patients do not apparently present difficulties in their clinical management. Insulin resistance is found particularly in obese patients; resistance to endogenous insulin is thought to be linked to the development of type 2 diabetes in such patients. Insulin resistance is frequently associated with lipid disorders, hypertension, and ischaemic heart disease, a complex sometimes described as the metabolic syndrome. In women, it may also be linked to polycystic ovary syndrome.

Insulin resistance of the type manifested by greatly increased insulin requirements may be due to factors including antibody formation and inadequate absorption of insulin from subcutaneous sites. A few patients with severe insulin resistance have responded to insulin lispro (see Insulin Analogues and Proinsulin under Uses, below).

Mecasermin (insulin-like growth factor I) has been observed to improve insulin sensitivity in insulin resistance (see p.1808).

Uses and Administration

Insulin is a hormone that plays a key role in regulating carbohydrate, protein, and fat metabolism. The main stimulus for its secretion is glucose, although many other factors including amino acids, catecholamines, glucagon, and somatostatin, are involved in its regulation. The secretion of insulin is not constant and peaks occur in response to the intake of food.

The major effects of insulin on carbohydrate homoeostasis follow its binding to specific cell-surface receptors on insulin-sensitive tissues, notably the liver, muscles, and adipose tissue. It inhibits hepatic glucose production and enhances peripheral glucose disposal thereby reducing blood-glucose concentration. It also inhibits lipolysis thereby preventing the formation of ketone bodies.

Therapy with insulin is essential for the long-term survival of all patients with type 1 diabetes mellitus. It may also be necessary in some patients with type 2 disease. The management of diabetes mellitus and the role of insulin in type 1 and type 2 disease is discussed on p.431. Insulin is generally the treatment chosen for all types of diabetes mellitus during pregnancy.

Choice of insulin. The different types of insulin and their formulations are described under Definitions, above. In some countries including the UK the commercially available preparations have been standardised to a single **strength** containing 100 units/mL; a strength of 40 units/mL is still available in some other countries, and in others concentrated injections (500 units/mL) are available to enable high doses to be given subcutaneously in a small volume. All formulations can be given by subcutaneous injection, most by intramuscular injection, but only soluble insulins can be given by the intravenous **route**. The long-term management of diabetic patients usually involves the subcutaneous route. Syringes and needles for subcutaneous injection are preferably disposable. Pen-injector devices which hold the insulin in cartridge form and meter the required dose are becoming increasingly popular. Soluble insulin is often given by the intraperitoneal route to patients on continuous ambulatory peritoneal dialysis. More recently, products supplying short-acting insulin by inhalation have been developed.

The various formulations of insulin are classified, according to their **duration of action** after subcutaneous injection, as short-, intermediate-, or long-acting. The exact duration of action for any particular preparation, however, is variable and may depend upon factors such as interindividual variation, the patient's antibody status, whether the insulin is of human or animal origin, the dose, and the site of injection. *Short-acting* insulins are the soluble insulins, which have an onset after about 30 minutes to 1 hour, a peak activity at about 2 to 5 hours, and a duration of about 6 to 8 hours. Some analogues, such as insulins lispro and aspart, are also short-acting, with a faster onset and shorter duration of action than soluble insulin and are sometimes known as rapid-acting insulins. *Intermediate-acting* insulins include biphasic insulins, isophane insulins, and amorphous insulin zinc suspensions. In general these have an onset within about 2 hours, peak activity after about 4 to 12 hours, and a duration of up to 24 hours. Commercially available mixtures of soluble insulins and isophane insulins have activities which would normally place them within the intermediate-acting category. Mixed insulin zinc suspensions may be classified as either *intermediate- or long-acting* as the duration of action may be up to 30 hours; the onset of action is generally 2 to 3 hours and the time to peak activity 6 to 15 hours. *Long-acting* insulins include crystalline insulin zinc suspensions and protamine zinc insulins. These generally have an onset after about 4 hours, a peak activity at about 10 to 20 hours, and a duration of up to 36 hours. The insulin analogues insulin glargine and insulin detemir are also long-acting. After intramuscular injection, the onset of action of all insulins is generally more rapid and the duration of action shorter.

The type of formulation, its dose, and the frequency of administration are chosen to suit the needs of the individual patient. Whatever the formulation, human insulin is generally used for all newly diagnosed diabetics.

Control. The **dosage** of insulin must be determined for each patient and although a precise dose range cannot be given a total dose in excess of about 80 units daily would be unusual and may indicate the presence of a form of insulin resistance. The dose should be adjusted as necessary according to the results of regular monitoring of blood concentrations (or occasionally urine concentrations) of glucose by the patient.

The WHO has recommended that the glucose concentration of venous whole blood under fasting conditions should be kept within the range of 3.3 to 5.6 mmol/litre (60 to 100 mg per 100 mL) and after meals should not be allowed to exceed 10 mmol/litre (180 mg per 100 mL); blood-glucose concentrations should not be allowed to fall below 3 mmol/litre (55 mg per 100 mL). In practice it seems to be generally acceptable for patients to aim for blood-glucose concentrations between 4 and 10 mmol/litre, with the understanding that occasional variations outside this range may occur. It should be remembered that the glucose concentrations in venous plasma, venous whole blood, and capillary whole blood may be slightly different. Control may also be determined by monitoring of glycosylated haemoglobin concentrations; ideally the aim is an HbA_{1c} level of less than 7% or an HbA_1 of less than 8.8%, compared with normal ranges of 4 to 6% and 5 to 7.5% respectively. Insulin requirements may be altered by various factors (see Precautions, above). The aim of any regimen should be to achieve the best possible control of blood glucose by attempting to mimic as closely as possible the pattern of optimum endogenous insulin secretion. Many **regimens** involve the use of a short-acting soluble insulin with an intermediate-acting insulin, such as isophane insulin or mixed insulin zinc suspension, often given twice daily. It may sometimes be necessary, though, to give 3 or 4 injections daily to achieve good control and this typically involves giving a soluble insulin before meals and an intermediate- or long-acting insulin in the evening. A once-daily injection of an intermediate- or long-acting insulin is now generally considered to be acceptable only for those patients with type 2 diabetes mellitus who still retain some endogenous insulin secretion but nevertheless require insulin therapy, or for those patients with type 1 disease unable to cope satisfactorily with more intensive regimens. If a more intensive regimen is desired, **continuous subcutaneous infusion** may be employed using soluble insulin in an infusion pump. This delivers a constant basal infusion of insulin supplying about half of the total daily requirements, the remainder being provided by patient-activated bolus doses before each meal. The technique has a limited place in the management of diabetes; patients using it need to be well-motivated, reliable, and able to monitor their own blood glucose, and must have access to expert advice at all times. Formulations in which the insulin is in suspension are not suitable for continuous subcutaneous infusion and some brands of soluble insulin are unsuitable for this purpose because of the risk of precipitation in the pump catheter.

Ketoacidosis. Insulin is also an essential part of the emergency management of diabetic ketoacidosis. Only short-acting soluble insulins should be used. Treatment includes adequate fluid replacement, usually by infusing sodium chloride 0.9% initially, and the use of potassium salts to prevent or correct hypokalaemia. Insulin should be given by continuous intravenous infusion if possible, although other routes have also been used—for details of regimens see Diabetic Emergencies, under Diabetes Mellitus, below. Since insulin normally corrects hyperglycaemia before ketosis it is usually necessary to continue giving insulin once normoglycaemia has been achieved but to change the rehydration fluid to glucose-saline so that the additional glucose prevents the development of hypoglycaemia.

◊ General reviews of insulin and its use.[1-5] It has been suggested that the plethora of insulin preparations available might sensibly be reduced,[2] although others dispute this.[6]

Administration. ADMINISTRATION ROUTES. The long-term management of diabetic patients usually involves injection by the **subcutaneous** route. The advice to diabetics has been to inject their insulin using a full-depth perpendicular injection.[1] In many non-obese patients, however, such a technique can result in inadvertent intramuscular injection.[1,2] Since insulin is absorbed more rapidly after intramuscular than subcutaneous injection, this may lead to greater day-to-day variability in blood-glucose control. In particular, overnight control may be inadequate if intermediate-acting preparations such as isophane insulin are used.[1] Some therefore consider that extended-action insulins should be injected at an angle into a raised skin fold. Although injection of soluble insulin into muscle may produce a more physiological action profile, until more data are available a technique that ensures subcutaneous injection may be prudent with soluble insulins as well.[1]

The anatomic *site* of subcutaneous insulin injection is usually rotated in an attempt to decrease local adverse effects (see Adverse Effects, above). However, the rate of absorption varies between sites and such a practice may also contribute to day-to-day variability in blood-glucose concentrations.[3] For example, large variations in blood-glucose concentrations have been reported on subcutaneous injection into the thigh.[4] Some have suggested rotation of injection sites within an anatomic region, or possibly use of the same anatomic region for injections given at a specific time of day.[3]

Jet injectors deliver insulin at high pressure across the skin into the subcutaneous tissue without use of a needle.[5,6] The greater dispersion obtained gives more rapid absorption of short- and intermediate-acting insulins and consequently reduces the total duration of action.[5] Mild pain, bruising, and bleeding may be a problem.[5-7] Despite having been available for some years, there is little information about their benefits and risks and they are not widely used.[6] However, results in a small study in women with gestational diabetes have suggested that jet injection may be associated with less variation in postprandial blood-glucose concentration and a lower incidence of insulin antibodies.[8]

Insulin preparations may also be given by **intramuscular** injection. Absorption is more rapid than from a subcutaneous injection. However, exercise may produce considerable variations in insulin absorption after intramuscular injection.[1] Soluble insulins may be given **intravenously**; this route is used in diabetic ketoacidosis, and also in surgery and labour.[9] Intermittent pulsed intravenous insulin therapy added to a conventional subcutaneous regimen has been reported to improve symptoms of orthostatic hypotension[10] and hypertension.[11]

The subcutaneous and intravenous routes, and, rarely, the intramuscular route have all been used for the continuous administration of insulin (see Intensive Administration Regimens, below).

Formulations of insulin for **intranasal** use are under investigation.[7,12,13] They have been tried in both type 1 and type 2 diabetes, but bioavailability is low and variable. Absorption enhancers have been used to facilitate uptake of insulin from the nasal mucosa and local adverse effects are dependent, in part, on their irritancy. Similarly, **buccal** formulations are under investigation,[7] and have become available in some countries.

Devices for delivering insulin to the lungs via oral **inhalation** have been developed.[7,14,15] Inhaled insulin is effective in maintaining glycaemic control in both type 1 and type 2 diabetes,[16-19] although there is some evidence from longer-term studies that it is slightly less effective than subcutaneous injection; however, patient acceptability is higher.[16] It is given before meals as a short-acting insulin in patients also receiving intermediate or long-acting subcutaneous insulins or oral antidiabetics; in type 2 diabetes it has also been used alone. UK recommendations from NICE are that it should be reserved for patients who are unable to start or intensify subcutaneous insulin therapy because of a marked, persistent fear of injections or severe difficulties with injection sites (for example, due to lipoatrophy).[17] Data regarding the long-term safety of inhaled insulin also need to be collected, given reports of pulmonary effects and higher levels of insulin antibodies in people with type 1 diabetes. A few cases of primary lung malignancies have occurred in clinical trials of inhaled insulin, at a higher incidence than in comparator-treated patients. However, the number of cases was too small to determine whether these events were related to inhaled insulin, and all affected patients had a history of cigarette smoking.

Endogenous insulin is delivered into the portal venous system, and then passes immediately to the liver where a large fraction of the insulin is extracted. The above routes of administration all deliver insulin into the peripheral circulation, with the risk of peripheral hyperinsulinaemia which has been considered a risk factor for atherosclerotic complications.[20] Giving insulin via the **intraperitoneal** or **oral** routes may overcome this problem to some extent. Peritoneal insulin is used routinely in diabetics undergoing chronic ambulatory peritoneal dialysis, but has also been used for continuous administration (see Intensive Administration Regimens, below). Various formulations of insulin for oral delivery are also under investigation.[7,13,21] **Rectal**[13] or **transdermal**[7] insulin has also been tried.

INSULIN ANALOGUES AND PROINSULIN. Recombinant-DNA technology has enabled the production of insulin analogues with altered pharmacokinetic profiles.[1,2] Most of the insulin in pharmaceutical preparations is in the form of hexamers, which require time to dissociate before absorption from a subcutaneous site. Substitution of amino-acid residues at the monomer-monomer interface has produced monomeric insulin analogues that retain the biological activity of insulin.

Good results have been reported with an analogue, **insulin lispro**, in which the B28 and B29 residues are replaced with lysine and proline. This analogue is commercially available and has been widely reviewed.[3-7] In comparative studies of insulin lispro versus soluble insulin given before meals to patients also receiving a long-acting insulin, insulin lispro was reported to result in good glycaemic control, and could be given immediately before meals (5 to 15 minutes) rather than 20 to 40 minutes before as with soluble insulin. There is a suggestion that it may result in fewer severe hypoglycaemic episodes in such regimens.[8] However, an analysis of 10 clinical trials did not find any difference between insulin lispro and neutral insulin (Humulin R) with respect to overall adverse effects or development of long-term diabetic complications.[9] (See also insulin aspart, below.) A few cases of response to insulin lispro in patients with severe insulin resistance have been reported.[10,11] Insulin lispro has been complexed with protamine to produce an intermediate-acting form, which is available as a biphasic preparation.

Insulin aspart is another short-acting insulin analogue, with aspartic acid substituted for proline at position B28.[12-15] It is also used immediately before meals and controls postprandial blood glucose concentrations at least as well as regular human insulin, and may cause fewer hypoglycaemic episodes. A meta-analysis involving 42 studies of insulin lispro or insulin aspart versus regular insulin found that there was evidence of a minor benefit of the analogues in improving HbA_{1c} values in adult patients with type 1 diabetes; no superiority could be shown in patients with type 2 diabetes.[16]

Insulin glulisine is another insulin analogue, with asparagine at position B3 replaced by lysine, and lysine at B29 replaced by glutamic acid. It also has a rapid onset and short duration of action.[17,18]

Recombinant-DNA technology has also been used to produce a long-acting basal insulin analogue, **insulin glargine**, suitable for once-daily use.[19-23] It is available as a solution at pH 4; on subcutaneous injection and neutralisation by tissue buffering processes, microprecipitates are formed that slowly release insulin glargine over 24 hours with no pronounced peak in concentration or in metabolic activity. Controlled studies have reported insulin glargine to be more effective than human isophane insulin in producing glycaemic control as part of a basal-bolus regimen, and to be associated with fewer hypoglycaemic episodes.

Insulin detemir is another long-acting insulin analogue that may have some benefit over isophane insulin. It is a neutral soluble human insulin analogue in which the terminal amino acid at B30 has been replaced by a 14-carbon fatty acid chain. This allows insulin detemir to bind reversibly to albumin, producing slow absorption and a prolonged and consistent metabolic effect for up to 24 hours. It appears to be at least as effective as isophane insulin in maintaining overall glycaemic control but with less intrapatient variability, a similar or lower risk of hypoglycaemia, and less body-weight gain.[24]

Proinsulin (the natural precursor of insulin) appears to be more active than insulin in suppressing the hepatic production rather than the peripheral uptake of glucose.[25,26] It has therefore been studied particularly in patients with type 2 diabetes mellitus. However, development by some manufacturers has been suspended because of a higher rate of adverse cardiac effects in patients treated with proinsulin than in controls.[25]

INTENSIVE ADMINISTRATION REGIMENS. Intensive insulin regimens aim to mimic more closely the physiological insulin pattern in which a basal insulin concentration is supplemented by a preprandial boost of insulin. Such intensive regimens are used to provide tight control in an attempt to avoid long-term complications (see p.433).

Intensified insulin regimens have the advantage of improving the patient's lifestyle and allowing flexibility in timing of meals. However, careful dietary control must still be maintained and regular monitoring of blood-glucose concentrations is an important component of such regimens. Therefore patients must be well-motivated, reliable, and able to monitor their own blood glucose, and must have access to expert 24-hour help. Although there are reports of success with intensive regimens in brittle (labile) diabetics,[1] these patients are generally unlikely to benefit from such regimens.

In **multiple-injection regimens**, the basal insulin is provided by an injection of intermediate- or long-acting insulin given usually at night, and soluble insulin is given before each main meal. Systems for **continuous administration** may be designed on an open-loop or closed-loop delivery system. *Open-loop systems* comprise an infusion pump with the infusion rate programmed or controlled manually according to manual blood-glucose monitoring. *Closed-loop systems* (the 'artificial pancreas') consist of an insulin pump, a glucose sensor, and a computer for analysis of blood-glucose data. Systems for continuous administration have most commonly used the subcutaneous route, but intraperitoneal, intravenous, or intramuscular infusion have also been used.

The most extensively used **open-loop** system is *continuous subcutaneous insulin infusion* (CSII) using an external pump. A battery-powered pump infuses soluble insulin via a subcutaneous catheter which is resited every 2 to 3 days. A background infusion is given at a predetermined rate, and preprandial bolus doses given using an override switch or manual drive.[2] CSII provides better glycaemic control than conventional injection therapy, but may be only slightly more effective than optimised multiple daily injection therapy.[3] Complications include erythema, abscess, or cellulitis at the injection site and, rarely, contact dermatitis to components of the giving set, pump malfunction, or precipitation of insulin and catheter obstruction.[2] Pump therapy increases the risk of ketoacidosis and intensive regimens are associated with decreased hypoglycaemic awareness and more severe hypoglycaemic episodes compared with conventional therapy,[4] although there is some suggestion that CSII might reduce the risk of severe hypoglycaemia compared with multiple daily injection therapy.[2] If the pump fails or there is an acute increase in insulin requirements, the onset of ketoacidosis may be more rapid and more likely to be associated with dangerous hyperkalaemia than with conventional regimens because there is no depot of insulin.[2,5]

Further development of open-loop delivery systems has been in the design of *implantable insulin pumps.* The first pumps delivered insulin at a constant basal rate, but variable rate models are now available. Studies[6,7] have shown that intravenous or intraperitoneal delivery of insulin from an implantable pump can produce excellent glycaemic control, and fewer episodes of severe hypoglycaemia than are associated with intensive subcutaneous multiple-injection regimens. The main problems associated with such therapy are pump slow-down or catheter obstruction due to aggregation of insulin within the device; these can normally be corrected by procedures to flush the pump and catheter,[7,8] although alternative insulin formulations (e.g. with poloxamer) have been investigated. Other problems may include fibrinous obstruction of the catheter or local intolerance of the pump.[8]

Closed-loop continuous infusion systems are generally confined to research and experimental work because glucose sensors suitable for implantation are still being developed.[8] However, results in *animals* have suggested that an alternative to such systems may be a vascularised artificial pancreas containing islet cells.[9]

MIXING OF INSULINS. Mixtures of insulin with differing durations of action may be used in order to produce a more normal pattern of blood glucose variation than can be achieved with a single insulin. However, physicochemical changes in the mixture may occur, either immediately on mixing or over time, and the physiological response to the mixture may therefore be different than if the components were given separately. An early review[1] suggested that insulins from different manufacturers should not be mixed, since formulation differences might render them incompatible. It is important that a consistent routine is followed in preparing and using such mixtures, and manufacturers advise that the shorter-acting insulin should be drawn into the syringe first, to avoid contamination of the vial with the longer-acting component. Prepared mixtures are available from many manufacturers and may be preferable provided that the proportions are suited to the patient's needs.

The American Diabetes Association has issued guidelines[2] for mixing of insulins, including:

- patients well controlled on a particular mixed regimen should maintain their standard procedure for preparing doses
- no other medication or diluent should be mixed with insulin unless approved by the prescriber
- insulin glargine should not be mixed with other forms of insulin because of the low pH of its diluent
- currently available isophane and short-acting insulin formulations when mixed may be used immediately or stored for future use
- rapid-acting insulins (insulin aspart, insulin lispro) can be mixed with isophane, lente, and ultralente insulins. Ultralente insulins do not affect the onset of action of the rapid-acting component; a slight decrease in absorption rate but not bioavailability is seen if rapid-acting insulins are mixed with isophane insulin but postprandial blood-glucose response is similar to that seen with mixtures of rapid-acting and ultralente insulin
- mixtures of rapid-acting insulin with an intermediate- or long-acting insulin should be injected within 15 minutes before a meal
- mixing of short-acting (soluble) and lente or ultralente insulin is not recommended, as zinc ions present in the lente insulin may bind with the short-acting insulin and delay its effects. The degree and rate of binding vary with the insulins used, and may not reach equilibrium for 24 hours; if such mixtures are used the patient should standardise the interval between mixing and injection
- phosphate-buffered insulins (e.g. isophane insulin) should not be mixed with zinc-containing (lente or ultralente) insulins, as zinc phosphate may be precipitated, and the longer acting insulin may be partially and unpredictably converted to a short-acting form

Insulin formulations may change and the manufacturers should be consulted if their recommendations differ from those in the guidelines.

Diabetes mellitus. Insulin is the mainstay of the treatment of **type 1 diabetes mellitus**. For a discussion of the treatment of diabetes mellitus, including the contexts in which insulin is used, see p.431. The possible role of tight glycaemic control with insulin to prevent the development of microvascular and macrovascular complications in patients with type 1 diabetes is discussed on p.433, while further discussion of specific regimens and approaches to insulin therapy is given under Administration, above.

DIABETIC EMERGENCIES. As discussed on p.435, **diabetic ketoacidosis** and hyperosmolar hyperglycaemic state are medical emergencies and should be treated immediately with fluid replacement and insulin. Potassium, and possibly phosphate, replacement may also be required, but bicarbonate should not be given unless acidaemia is very severe. In the *UK* the *BNF* recommends that insulin be given by intravenous infusion for diabetic ketoacidosis, as a solution of soluble insulin 1 unit/mL via an infusion pump. An infusion rate of 6 units/hour in adults and 0.1 units/kg per hour in children is recommended initially, with the rate doubled or quadrupled if the blood glucose concentration fails to decrease by about 5 mmol/litre per hour. When blood glucose concentrations have fallen to 10 mmol/litre the infusion rate can be reduced to 3 units/hour in adults or about 0.05 units/kg per hour in children, and continued, with glucose 5% to prevent hypoglycaemia, until the patient is ready to take food by mouth. The insulin infusion should not be stopped before subcutaneous insulin has been started. Potassium chloride is included in the infusion as appropriate to prevent insulin-induced hypokalaemia. If facilities for intravenous infusion are not available the insulin is given by intramuscular injection: in adults an initial loading dose of 20 units intramuscularly is followed by 6 units intramuscularly every hour until the blood glucose concentration falls to 10 mmol/litre, when the dose is given every 2 hours. Late hypoglycaemia due to insulin accumulation should be watched for and managed appropriately.

In the *USA* the intramuscular or the subcutaneous route have been used as alternatives to intravenous insulin, with other appropriate management. One successful set of protocols for insulin dosage in diabetic ketoacidosis is as follows:[1] an initial intravenous bolus of 0.15 units/kg is followed by infusion of 0.1 units/kg per hour; if blood glucose does not fall by about 2.5 to 3.5 mmol/litre in the first hour the infusion rate is doubled every hour until this rate of decline is achieved. (A similar insulin regimen has proved effective in patients with hyperosmolar hyperglycaemic state.[1]) When given by the intramuscular or subcutaneous routes an initial bolus of 0.4 units/kg is divided and given half by the intravenous route and half either intramuscularly or subcutaneously as appropriate. This is followed by 0.1 units/kg every hour intramuscularly or subcutaneously; if response is inadequate it is replaced by an intravenous bolus of 10 units until blood glucose falls by 2.5 to 3.5 mmol/litre. In children intravenous infusion of 0.1 units/kg per hour is recommended, or if intravenous infusion is impractical an initial intramuscular bolus of 0.1 units/kg followed by 0.1 units/kg per hour either intramuscularly or subcutaneously. Treatment is continued at this rate until a serum-glucose concentration of about 12.5 mmol/litre is reached (or about 15 mmol/litre for hyperosmolar hyperglycaemic state), when the rate is decreased to 0.05 to 0.1 units/kg per hour until acidosis is controlled and subcutaneous insulin replacement treatment can be started.

TYPE 2 DIABETES MELLITUS. Traditionally the use of insulin in patients with type 2 diabetes has tended to be reserved for those who cannot be controlled by diet and oral antidiabetics alone.[1,2] Given the possible association between circulating insulin and atherosclerotic cardiovascular symptoms[3] there has been some concern about the use of exogenous insulin in insulin-resistant patients who are already hyperinsulinaemic. Furthermore, patients switched to insulin tend to gain weight[2] which is undesirable in a frequently obese patient group.

Insulin is nonetheless being used more frequently in type 2 patients. This is largely because of a trend toward more intensive regimens designed to produce tighter glycaemic control, on the hypothesis that, as in patients with type 1 disease, this will reduce the development and progression of diabetic complications. Results from the UK Prospective Diabetes Study,[4-6] show that insulin is an effective option in type 2 diabetes, and confirm both the value of intensive therapy in retarding microvascular complications,[6] and that oral therapy should be used before insulin in patients with primary diet failure.[7]

In order to minimise the dose of insulin required, and any risks it may entail, it has been suggested that insulin therapy in type 2 diabetes should be combined with other measures including oral hypoglycaemic drugs.[8] There has long been debate about the value of combined therapy, but a meta-analysis indicated that glycaemic control was better, and insulin requirements lower, in type 2 diabetics who received insulin with a sulfonylurea.[9] For evidence that the insulin analogues insulin lispro and insulin aspart have no advantage over regular insulin in type 2 patients see Insulin Analogues, above.

For further discussion of the management of type 2 diabetes mellitus see p.431.

Diagnosis and testing. ***PITUITARY FUNCTION.*** Insulin-induced hypoglycaemia has been used to provide a stressful stimulus in order to assess hypothalamic-pituitary function. The insulin stress or insulin-tolerance test has been used as a standard test for assessment of growth hormone or corticotropin deficiency. However, it is unpleasant, expensive, and not without risk, and is contra-indicated in patients with angina, heart failure, cerebrovascular disease, or epilepsy; some recommend its use only when results of alternative tests are equivocal,[1-3] and it should only be performed in specialist units under strict surveillance.[4]

Hyperkalaemia. Insulin promotes the intracellular uptake of potassium. It is therefore used in the management of moderate to severe hyperkalaemia, when it is given with glucose (see p.1669).

Liver disorders. There have been reports[1,2] of benefit from the use of insulin and glucagon in the treatment of liver disorders, based on their reported hepatotrophic effect. However, randomised studies have found no benefit from insulin and glucagon infusions in fulminant hepatic failure[3] and acute alcoholic hepatitis.[4]

Myocardial infarction. Discussions on the effects of insulin with glucose and potassium in the ischaemic heart, including its effect in reducing blood free fatty acids, have emphasised its potential benefits in left ventricular failure and cardiogenic shock.[1,2] A meta-analysis[3] of randomised controlled studies performed before the widespread use of thrombolytics found a reduction in mortality in recipients of glucose-insulin-potassium solutions. However, although a pilot study[4] that included patients undergoing reperfusion (thrombolysis or percutaneous coronary intervention) reported benefit, this was not confirmed in larger randomised studies using standard glucose-insulin-potassium infusions.[5,6] A further study[7] found that routine use of such infusions in patients undergoing reperfusion had no effect on myocardial salvage, although some improvement was reported in diabetics.

Intensive glucose control, with insulin-glucose infusion followed by multiple daily subcutaneous insulin injections has been reported to reduce mortality in diabetics who suffered a myocardial infarction.[8,9] A similar study[10] of treatment after myocardial infarction included only patients with type 2 diabetes mellitus who were treated with routine care, or insulin-glucose infusion followed by either long-term subcutaneous insulin or standard glucose control. The study was stopped early due to slow patient recruitment, but results did suggest that although glucose concentration was a strong independent predictor of long-term mortality, the use of long-term insulin treatment did not improve survival compared with conventional treatment at similar levels of glucose control. An observational study[11] in non-diabetics with hyperglycaemia suggested that intensive glucose control also improved outcomes in this population, but another study[12] found no benefit. However, the glucose control achieved in this study was similar in both the intensive and the conventional treatment groups and an analysis based on blood glucose concentrations suggested that strict glucose control was beneficial.[12]

Neonatal hyperglycaemia. Hyperglycaemia is common in very immature neonates because of delayed or reduced insulin production. It can be treated by glucose restriction until glucose tolerance improves. However, this may not provide enough glucose to meet basal metabolic needs, and the use of an insulin infusion can allow sufficient glucose to be given. It has been suggested that insulin is best given intravenously in a separate, easily titratable solution because of the frequent fluctuations of requirement in these infants.[1]

1. Ditzenberger GR, *et al.* Continuous insulin intravenous infusion therapy for VLBW infants. *J Perinat Neonatal Nurs* 1999; **13:** 70–82.

Overdosage with calcium-channel blockers. High-dose insulin, with glucose and potassium as required to maintain normal plasma concentrations of these, has been reported to be of value in the treatment of overdosage with calcium-channel blockers that has not been adequately managed with conventional therapy (which is described under Treatment of Adverse Effects under Nifedipine, p.1352). A review[1] of 13 reported cases found that various dosage regimens had been tried. These included bolus doses of insulin 10 to 20 units, and continuous infusions of 0.1 to 1 unit/kg per hour. The authors of one report[2] have proposed a regimen that includes an initial intravenous bolus dose of insulin 1 unit/kg, followed by a continuous infusion of 0.5 units/kg per hour; this may be increased to 1 unit/kg per hour if necessary.

Metformin Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de metformina; LA-6023 (metformin or metformin hydrochloride); Metformiinihydrokloridi; Metformin Hidroklorür; Metformin hydrochlorid; Metformine, chlorhydrate de; Metformin-hidroklorid; Metforminhydroklorid; Metformini hydrochloridum; Metformino hidrochloridas. 1,1-Dimethylbiguanide hydrochloride.

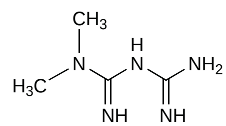
Метформина Гидрохлорид

$C_4H_{11}N_5,HCl = 165.6.$

CAS — 657-24-9 (metformin); 1115-70-4 (metformin hydrochloride).

ATC — A10BA02.

ATC Vet — QA10BA02.



(metformin)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Metformin Hydrochloride). White or almost white crystals. Freely soluble in water; slightly soluble in alcohol; practically insoluble in acetone and in dichloromethane.

USP 31 (Metformin Hydrochloride). A white crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in acetone and in dichloromethane.

Adverse Effects, Treatment, and Precautions

As for biguanides in general, p.437.

Breast feeding. Based on *animal* studies the UK and US licensed product information warns that metformin may be distributed into breast milk, and that the possible effects on the infant should be considered if women wish to breast feed while receiving the drug. However, a study in 7 breast-feeding women receiving metformin at a median dose of 1.5 g daily found the concentrations in milk to be about a third of those in maternal plasma, resulting in a mean calculated dose to the infants of 40 micrograms/kg daily. Blood samples were taken from 4 of the infants: metformin concentrations were undetectable in 2, and were very low (10 to 15% of maternal values) in the others. Given these results the authors considered that women receiving metformin need not be discouraged from breast feeding.[1] Similar results from 3 other studies[2,3] that included 13 women have provided further evidence that metformin is distributed into breast milk, that concentrations in milk are less than those in maternal plasma, and that breast-fed infants would be exposed to a very small percentage of the maternal dose. Six infants were breast-fed with no adverse effects that could be attributed to metformin. A prospective study[4] of weight, height, and motor-social development over 6 months, in infants of women taking metformin (1.5 to 2.55 g daily) for polycystic ovary syndrome, found no difference between 61 infants who were breast-fed and 50 who were formula-fed.

4. Glueck CJ, *et al.* Growth, motor, and social development in breast- and formula-fed infants of metformin-treated women with polycystic ovary syndrome. *J Pediatr* 2006; **148:** 628–32.

Fasting. For the view that metformin could be used with little risk of hypoglycaemia in fasting Muslim patients during Ramadan, and suggestions for modifying the timing of doses, see under Precautions of Insulin, p.448.

Pregnancy. Insulin is generally preferred for treatment of diabetes during pregnancy. However, there are limited data to suggest that metformin does not increase the risk of congenital abnormalities[1,2] and does not adversely affect pregnancy outcome in diabetic women.[2] A controlled study comparing insulin with metformin in gestational diabetes is underway.[3]

The use of metformin to improve ovulation in polycystic ovary syndrome (PCOS) is increasing. There is growing evidence to suggest that metformin used before and during pregnancy in these women does not increase the risk of congenital abnormalities,[1,4-6] and may reduce first trimester spontaneous abortion,[4,6] which is common in women with PCOS.

Interactions

As for biguanides in general, p.438.

Pharmacokinetics

Metformin hydrochloride is slowly and incompletely absorbed from the gastrointestinal tract; the absolute bioavailability of a single 500-mg dose is reported to be about 50 to 60%, although this is reduced somewhat if taken with food. Once absorbed, protein binding in plasma is negligible; the drug is excreted unchanged in the urine. The plasma elimination half-life is reported to range from about 2 to 6 hours after oral doses. Metformin crosses the placenta and is distributed into breast milk in small amounts.

Uses and Administration

Metformin hydrochloride is a biguanide antidiabetic (p.437). It is given orally in the treatment of type 2 diabetes mellitus (p.431), and is the drug of first choice in overweight patients. Initial dosage is 500 mg two or three times daily or 850 mg once or twice daily with or after meals, gradually increased if necessary, at intervals of at least 1 week, to 2 to 3 g daily; doses of 3 g daily are associated with an increased incidence of gastrointestinal adverse effects. Gastrointestinal effects are also common on beginning therapy, and the *BNF* recommends starting therapy more gradually with 500 mg at breakfast for at least 1 week, then increasing to 500 mg twice daily for at least 1 week, with further increases as required, up to a usual maximum of 2 g daily in 3 divided doses with meals. A modified-release preparation is also available, which is given in an initial dose of 500 mg once daily and may be increased in increments of 500 mg, at intervals of at least 1 week, to a maximum of 2 g once daily with the evening meal. If glycaemic control is not adequate the dose may be divided to give 1 g twice daily with meals. If doses above 2 g daily are required, they should be given as the standard preparation. For doses used in children and adolescents, see below.

Metformin is also used as the chlorophenoxyacetate and as the embonate.

Action. A review of the action of metformin[1] considered that although a number of possible mechanisms have been suggested (see Uses and Administration of Biguanide Antidiabetics, p.438), the major action of metformin lay in increasing glucose transport across the cell membrane in skeletal muscle. There is also some evidence *in vitro* that it can inhibit the formation of advanced glycosylation end-products.[2]

Administration in children. In children aged 10 years and older with type 2 diabetes mellitus, oral metformin hydrochloride may be used in a starting dose of 500 mg or 850 mg once daily, or 500 mg twice daily, given with or after a meal. It may be gradually increased if needed, at intervals of at least 1 week, to a maximum of 2 g daily given in 2 or 3 divided doses. Modified-release preparations are generally not licensed for use in children.

Although rare, the incidence of type 2 diabetes is increasing in children and adolescents, related in part to the increase in obesity occurring particularly in westernised countries. A small placebo-controlled study[1] of patients aged 10 to 17 years with type 2 diabetes found that metformin improved glycaemic control and that adverse effects were similar to those in adults. In obese children and adolescents with hyperinsulinaemia, who are at risk of developing type 2 diabetes, small studies[2,3] of metformin use have reported improvements in body composition and fasting insulin concentrations. There has also been some interest in the use of metformin as an adjunct to insulin in adolescents with type 1 diabetes; improvements in glycaemic control[4,5] and reductions in insulin doses[4] have been reported.

Diabetes mellitus. Results of the United Kingdom Prospective Diabetes Study (UKPDS) showed that intensive blood glucose control with metformin reduces the risk of diabetic complications and death in overweight patients with type 2 diabetes.[1] The study also generated some concern regarding intensive therapy with metformin plus a sulfonylurea (see under Interactions, p.462) but this was not borne out on further analysis and such combinations are widely used. Metformin is also used with the thiazolidinediones,[2-5] or with insulin[6] in patients requiring combined or more intensive therapy. Metformin has also been investigated for the prevention of type 2 diabetes in patients at high risk. Although metformin treatment for an average 2.8 years reduced the incidence of type 2 diabetes by 31% in a study[7] of patients with impaired glucose tolerance, intensive lifestyle modification was actually more effective (58% reduction). Lifestyle modification was also more effective than metformin in reducing cardiovascular risk factors[8] and the development of the metabolic syndrome.[9] The durability of these effects is unknown but follow-up of this study is ongoing.

There is some interest in using oral hypoglycaemics as adjuncts to insulin therapy in patients with type 1 diabetes. Short-term results from small studies have suggested that metformin may be beneficial, in this context, in adolescents with pubertal insulin resistance (see also Administration in Children, above) and perhaps in adults who are overweight or otherwise at risk of reduced insulin sensitivity.[10]

Polycystic ovary syndrome. It has been suggested that hyperinsulinism may play a pathogenetic role in stimulating the abnormal androgen production from the ovary seen in women with polycystic ovary syndrome (PCOS, p.2080). Most early studies of metformin in PCOS were small, observational, and of short duration, with mixed results. Although there were reports of reduced insulin levels, increased insulin sensitivity, and improved androgen concentrations, other studies failed to confirm these effects.[1] Later randomised studies were also small, but some were of longer duration. These reported weight reductions of obese patients,[2] reductions in insulin levels[2-4] and increased sensitivity,[5] improved androgen and other hormonal measures,[2,3,5] improved menstrual patterns,[2,4,5] and reduced hirsutism,[2] but again, not consistently. Metformin has also been reported to increase the rate of spontaneous ovulation,[6,7] and may improve the outcome of IVF procedures.[8] Combination of metformin with clomifene appeared to improve ovulatory response, compared with clomifene alone, in studies of women with PCOS,[6,9] though there is also a report of no apparent benefit.[10] Furthermore, 2 large, placebo-controlled studies have found that metformin, either alone or with clomifene, did not improve the rate of ovulation, pregnancy, or live births in women with polycystic ovary syndrome.[11,12]

Some consider that current evidence supports a trial of metformin in patients with anovulation, androgen excess, and vascular risk factors, but because of the lack of data on long-term safety such use should be supervised by an endocrinologist or a physician with suitable expertise.[1]

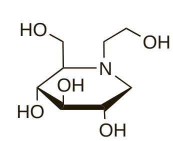
Miglitol *(BAN, USAN, pINN)*

Bay-m-1099; Miglitoli; Miglitolum. (2*R*,3*R*,4*R*,5*S*)-1-(2-Hydroxyethyl)-2-(hydroxymethyl)piperidine-3,4,5-triol.

Миглитол

$C_8H_{17}NO_5$ = 207.2.
CAS — 72432-03-2.
ATC — A10BF02.
ATC Vet — QA10BF02.



Adverse Effects and Precautions
As for alpha-glucosidase inhibitors in general (see Acarbose, p.436). Skin rash may occur. Miglitol should be used with caution in patients with renal impairment.

Interactions
As for alpha-glucosidase inhibitors in general (see Acarbose, p.436). Miglitol may reduce the bioavailability of propranolol and ranitidine.

Pharmacokinetics
Miglitol is completely absorbed at a dose of 25 mg, but only 50 to 70% is absorbed at a dose of 100 mg. It is not metabolised, and is excreted unchanged in the urine with a plasma elimination half-life of about 2 hours.

Uses and Administration
Miglitol is an alpha-glucosidase inhibitor similar in action to acarbose (p.436). It is given orally in the management of type 2 diabetes mellitus (p.431), alone or with a sulfonylurea. Usual initial doses are 25 mg three times daily with meals, increased if necessary to a maximum of 100 mg three times daily.

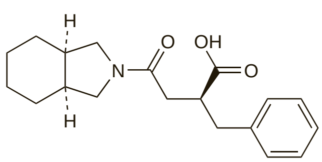
Mitiglinide *(rINN)*

Mitiglinida; Mitiglinidum. (−)-(2*S*,3a,7a-*cis*)-α-Benzylhexahydro-γ-oxo-2-isoindolinebutyric acid.

Митиглинид

$C_{19}H_{25}NO_3 = 315.4.$

CAS — 145375-43-5 (mitiglinide); 145525-41-3 (anhydrous mitiglinide calcium); 207844-01-7 (mitiglinide calcium dihydrate).



Profile
Mitiglinide is a meglitinide antidiabetic that is under investigation in the treatment of type 2 diabetes mellitus.

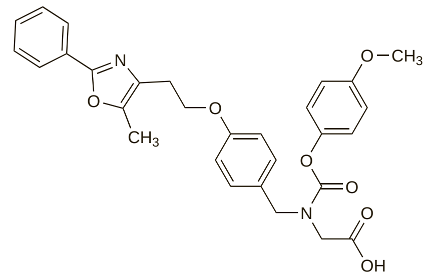
Muraglitazar *(USAN, rINN)*

BMS-298585; Muraglitazarum. {[(4-Methoxyphenoxy)carbonyl]{4-[2-(5-methyl-2-phenyl-1,3-oxazol-4-yl)ethoxy]benzyl}amino}acetic acid.

Мураглитазар

$C_{29}H_{28}N_2O_7 = 516.5.$

CAS — 331741-94-7.



Profile
Muraglitazar is a dual alfa/gamma peroxisome proliferator-activated receptor (PPAR) activator. It has been investigated in the treatment of type 2 diabetes mellitus.

Adverse effects. A review of data from 5 studies suggested that muraglitazar may be associated with an increased risk of adverse cardiovascular events and heart failure.[1]

1. Nissen SE, *et al.* Effect of muraglitazar on death and major adverse cardiovascular events in patients with type 2 diabetes mellitus. *JAMA* 2005; **294:** 2581–6.

Nateglinide *(USAN, rINN)*

A-4166; AY-4166; DJN-608; Nateglinid; Nateglinida; Natéglinide; Nateglinidi; Nateglinidum; SDZ-DJN-608; Senaglinide; YM-026. (−)-*N*-[(*trans*-4-Isopropylcyclohexyl)carbonyl]-D-phenylalanine.

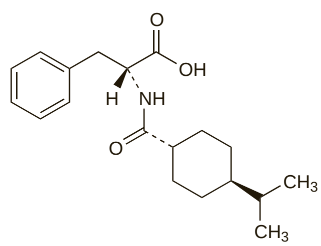
Натеглинид

$C_{19}H_{27}NO_3 = 317.4.$

CAS — 105816-04-4.

ATC — A10BX03.

ATC Vet — QA10BX03.



Adverse Effects and Precautions
As for Repaglinide, p.457.

Overdosage. A blood-glucose concentration of 2.0 mmol/litre was measured 1 hour after ingestion of nateglinide 3.42 g in a 30-year-old woman.[1] She was able to walk unaided, but seemed drowsy. The hypoglycaemic effect of nateglinide lasted for 6 hours and was treated with intravenous glucose (total dose 100 g).

1. Nakayama S, *et al.* Hypoglycemia following a nateglinide overdose in a suicide attempt. *Diabetes Care* 2005; **28:** 227–8.

Renal impairment. A single-dose pharmacokinetic study[1] found that moderate to severe renal impairment (creatinine clearance 15 to 50 mL/minute per 1.73 m^2) and haemodialysis did not significantly affect the pharmacokinetics of nateglinide. However, the metabolite M1 has been found to accumulate in patients with renal impairment requiring haemodialysis after repeated doses of nateglinide, but it may be removed by haemodialysis.[2] M1 is a major metabolite that has modest hypoglycaemic activity compared with nateglinide. An analysis[3] of pooled study data found that efficacy and tolerability of nateglinide in elderly diabetic patients were not significantly affected by renal impairment (mean creatinine clearance 50.9 mL/minute per 1.73 m^2). Nevertheless, a 56-year-old diabetic woman whose renal failure was managed with haemodialysis experienced severe hypoglycaemia with nateglinide; the reaction was attributed to the accumulation of M1.[4] Licensed product information in the UK and USA suggest that no dosage adjustment is necessary in renal impairment, although UK information suggests that dose adjustment might be required in patients on haemodialysis.

2. Inoue T, *et al.* Pharmacokinetics of nateglinide and its metabolites in subjects with type 2 diabetes mellitus and renal failure. *Clin Nephrol* 2003; **60:** 90–5.
3. Del Prato S, *et al.* Treatment of patients over 64 years of age with type 2 diabetes: experience from nateglinide pooled database retrospective analysis. *Diabetes Care* 2003; **26:** 2075–80.
4. Nagai T, *et al.* Hypoglycemia due to nateglinide administration in diabetic patient with chronic renal failure. *Diabetes Res Clin Pract* 2003; **59:** 191–4.

Interactions
As with other oral antidiabetics, the efficacy of nateglinide may be affected by drugs independently increasing or decreasing blood glucose concentrations (see Sulfonylureas, p.461).

1. Scheen AJ. Drug-drug and food-drug pharmacokinetic interactions with new insulinotropic agents repaglinide and nateglinide. *Clin Pharmacokinet* 2007; **46:** 93–108.

Antibacterials. In a study[1] of healthy subjects, *rifampicin* reduced the plasma concentrations and half-life of nateglinide, probably by induction of its metabolism by the cytochrome P450 isoenzyme CYP2C9. The glucose-lowering effect of nateglinide was not affected, but there was a marked interindividual variation in the pharmacokinetic changes, and the authors suggested that some diabetic patients could be affected.

1. Niemi M, *et al.* Effect of rifampicin on the pharmacokinetics and pharmacodynamics of nateglinide in healthy subjects. *Br J Clin Pharmacol* 2003; **56:** 427–32.

Antifungals. In a study[1] of healthy subjects, *fluconazole* raised the plasma concentrations and prolonged the half-life of nateglinide, probably by inhibition of its metabolism by the cytochrome P450 isoenzyme CYP2C9. The glucose-lowering effect of nateglinide was not affected, but a low dose of nateglinide had been used and the authors suggested that in diabetic patients fluconazole may enhance and prolong the effects of nateglinide.

1. Niemi M, *et al.* Effect of fluconazole on the pharmacokinetics and pharmacodynamics of nateglinide. *Clin Pharmacol Ther* 2003; **74:** 25–31.

Lipid regulating drugs. A study[1] investigating the effects of the *gemfibrozil* and *itraconazole* combination on the pharmacokinetics of nateglinide showed only a limited interaction. Nateglinide plasma concentrations were raised moderately and the blood glucose response to nateglinide was not significantly changed. This is in contrast to the substantial interaction of gemfibrozil with repaglinide (p.458).

1. Niemi M, *et al.* Coadministration of gemfibrozil and itraconazole has only a minor effect on the pharmacokinetics of the CYP2C9 and CYP3A4 substrate nateglinide. *Br J Clin Pharmacol* 2005; **60:** 208–17.

Pharmacokinetics
Nateglinide is rapidly absorbed after oral doses, with peak plasma concentrations occurring within one hour and an absolute bioavailability of 73%. Nateglinide is 98% bound to plasma proteins. It is mainly metabolised by cytochrome P450 isoenzyme CYP2C9, and to a lesser extent by CYP3A4. Major metabolites include M1 which is less potent than nateglinide. The parent drug and metabolites are mainly excreted in the urine but about 10% is eliminated in the faeces. The elimination half-life is about 1.5 hours.

3. McLeod JF. Clinical pharmacokinetics of nateglinide: a rapidly-absorbed, short-acting insulinotropic agent. *Clin Pharmacokinet* 2004; **43:** 97–120.

Uses and Administration
Nateglinide, like repaglinide (p.458), is a meglitinide antidiabetic used in the treatment of type 2 diabetes mellitus (p.431). It is given within the 30 minutes before meals in oral doses of 60 or 120 mg three times daily. This may be increased to 180 mg three times daily if necessary. Nateglinide is also given in similar doses with metformin or a thiazolidinedione in type 2 diabetes not adequately controlled by these drugs alone.

Although dose adjustment is not generally required in renal impairment, hypoglycaemia has been attributed to accumulation of the metabolite M1 (see above).

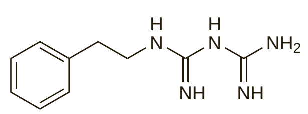
ATC — A10BA01.

ATC Vet — QA10BA01.



(phenformin)

Pharmacopoeias. In *Chin.*

Profile

Phenformin hydrochloride is a biguanide antidiabetic (p.437). Although it is generally considered to be associated with an unacceptably high incidence of lactic acidosis, often fatal, it is still available in some countries for the treatment of type 2 diabetes mellitus.

Phenformin was implicated in the controversial reports of excess cardiovascular mortality associated with oral hypoglycaemic therapy (see under Sulfonylureas, Effects on the Cardiovascular System, p.461).

Preparations

Proprietary Preparations (details are given in Part 3)

Pioglitazone Hydrochloride

(BANM, USAN, rINNM)

AD-4833 (pioglitazone); Hidrocloruro de pioglitazona; Pioglitazone, Chlorhydrate de; Pioglitazoni Hydrochloridum; U-72107A; U-72107E (pioglitazone). (±)-5-{*p*-[2-(5-Ethyl-2-pyridyl)-ethoxy]benzyl}-2,4-thiazolidinedione hydrochloride.

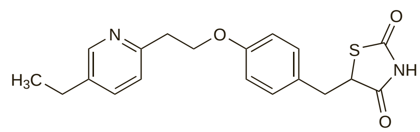
Пиоглитазона Гидрохлорид

$C_{19}H_{20}N_2O_3S,HCl = 392.9.$

CAS — 111025-46-8 (pioglitazone); 112529-15-4 (pioglitazone hydrochloride).

ATC — A10BG03.

ATC Vet — QA10BG03.



(pioglitazone)

Adverse Effects and Precautions

As for Rosiglitazone Maleate, p.458. The effects of pioglitazone on serum lipid concentrations appear to differ from those of rosiglitazone, see below. Other adverse effects reported include upper respiratory-tract infections, haematuria, and visual disturbances. Liver function should be monitored periodically as there have been isolated reports of liver dysfunction, and the drug should be used with caution in patients with hepatic impairment (see below).

An increased incidence of bladder cancer has been seen in *rats* but not in *mice* treated with pioglitazone.

Use is contra-indicated in patients with diabetic ketoacidosis. For precautions and contra-indications to the use of thiazolidinediones in heart failure see Effects on the Heart, under Rosiglitazone Maleate, p.459.

Effects on lipids. Thiazolidinediones are reported to affect serum concentrations of lipids. Compared with placebo,[1,2] pioglitazone has been found to reduce triglycerides, increase high-density lipoprotein (HDL)-cholesterol, and have little or no effect on low-density lipoprotein (LDL)- and total cholesterol. In a study[3] of patients being transferred from troglitazone to either pioglitazone or rosiglitazone, there were decreases in concentrations of triglycerides, LDL- and total cholesterol, and an increase in HDL-cholesterol in those patients on pioglitazone, whereas the opposite occurred for rosiglitazone. Whether these effects of pioglitazone reduce cardiovascular risk in patients with type 2 diabetes is yet to be fully established, but the large prospective PROactive study did suggest that it could reduce the risk of macrovascular events in patients with evidence of macrovascular disease, although the risk of heart failure appears to be *increased* (see Diabetic Complications, below, and Effects on the Heart, under Rosiglitazone Maleate, p.459).

3. Gegick CG, Altheimer MD. Comparison of effects of thiazolidinediones on cardiovascular risk factors: observations from a clinical practice. *Endocr Pract* 2001; **7:** 162–9.

Effects on the liver. There have been isolated reports of hepatocellular injury in patients receiving pioglitazone.[1-5]

The UK and US licensed product information recommends that liver enzymes should be checked before starting therapy with pioglitazone; patients with aminotransferase (ALT) concentrations more than 2.5 times the upper limit of normal should not be given pioglitazone. ALT concentrations should then be monitored periodically during treatment. If ALT concentrations rise to more than 3 times the upper limit of normal and remain so after retesting then treatment with pioglitazone should be stopped; treatment should also be stopped if jaundice develops.

5. Farley-Hills E, *et al.* Fatal liver failure associated with pioglitazone. *BMJ* 2004; **329:** 429.

Interactions

When pioglitazone was given with gemfibrozil, an inhibitor of the cytochrome P450 isoenzyme CYP2C8, there was a threefold increase in the area under the concentration-time curve (AUC) of pioglitazone, and a decrease in pioglitazone dose may be needed if it is given with gemfibrozil or similar CYP2C8 inhibitors. Equally, rifampicin, a potent inducer of cytochrome P450, halves the AUC of pioglitazone when both are given, and pioglitazone dose may need to be increased.

Antibacterials. For a report of hypoglycaemia when *gatifloxacin* was given to a patient already receiving oral hypoglycaemics such as pioglitazone, see p.281.

Pharmacokinetics

Pioglitazone is rapidly absorbed after oral doses. Peak plasma concentrations occur within 2 hours and bioavailability exceeds 80%. Pioglitazone is more than 99% bound to plasma proteins. It is extensively metabolised, primarily by the cytochrome P450 isoenzyme CYP2C8 to both active and inactive metabolites. It is excreted in urine and faeces and has a plasma half-life of up to 7 hours. The active metabolites have a half-life of up to 24 hours.

Uses and Administration

Pioglitazone is a thiazolidinedione oral antidiabetic similar to rosiglitazone (p.458). It is used in the management of type 2 diabetes mellitus (p.431). It is given as pioglitazone hydrochloride but doses are expressed in terms of the base; pioglitazone hydrochloride 1.1 mg is equivalent to about 1 mg of pioglitazone. It is given orally as monotherapy, particularly in patients who are overweight and for whom metformin is contra-indicated or not tolerated. Pioglitazone may also be added to metformin or a sulfonylurea or both, or to insulin, when single-agent therapy is inadequate (but see Administration, below). The usual dose is 15 or 30 mg once daily. This may be increased to a maximum of 45 mg once daily if necessary. Pioglitazone may be taken with or without food.

Administration. Although pioglitazone is licensed for use with other antidiabetic drugs, the specifics of licensing and use may vary from country to country. In the UK, use of pioglitazone with insulin was originally considered to be contra-indicated, because of an increased risk of heart failure, although this was subsequently amended to permit dual therapy in patients who could not be given insulin plus metformin. Furthermore, although pioglitazone is licensed for use with metformin or a sulfonylurea (or both if necessary) in patients who do not respond to these drugs, NICE recommends this only in patients unsuited to combination therapy with metformin plus a sulfonylurea.[1] However, in the USA, pioglitazone has always been licensed for use with insulin (with appropriate monitoring), metformin, or a sulfonylurea in any patient in whom single agent therapy is inadequate.

Diabetic complications. It has been suggested that, in addition to their hypoglycaemic effect, thiazolidinediones may have beneficial effects in the prevention of macrovascular diabetic complications (p.433). Studies[1,2] in patients with type 2 diabetes mellitus have shown that pioglitazone may slow the progression of carotid intima-media thickness, an indicator for cardiovascular risk. A study[3] of secondary prevention found that, compared with placebo (in addition to usual medications for glucose control), pioglitazone reduced death from any cause, myocardial infarction, and stroke. There was also a reduced need to add insulin for glucose control. However, there was no significant difference between the groups when the end-point was broader and also included acute coronary syndrome, leg amputation, and coronary or leg revascularisation. Subgroup analysis[4] also found that pioglitazone reduced the risk of fatal and non-fatal myocardial infarction and acute coronary syndrome in patients with a history of myocardial infarction. A meta-analysis[5] that included the results of this study with cardiovascular outcome data from studies of glycaemic control found that pioglitazone significantly reduced the risk of death, myocardial infarction, and stroke in a diverse population of patients with type 2 diabetes. However, the risk of serious heart failure was increased (see also Effects on the Heart, p.459).

It is unclear whether other thiazolidinediones might have similar effects and whether patients at lower risk might benefit.[6] Rosiglitazone and pioglitazone are known to have different effects on lipids (above) and there is some evidence that rosiglitazone may have adverse cardiovascular effects (p.459).

Hepatitis. A small proof-of-concept study has suggested that pioglitazone 45 mg daily with a hypocaloric diet for 6 months produces greater metabolic and histological improvement in patients with nonalcoholic steatohepatitis than diet alone.[1]

1. Belfort R, *et al.* A placebo-controlled trial of pioglitazone in subjects with nonalcoholic steatohepatitis. *N Engl J Med* 2006; **355:** 2297–2307.

Malignant neoplasms. For references to the experimental use of pioglitazone with rofecoxib and trofosfamide as anti-angiogenic therapy for malignant neoplasms see Trofosfamide, p.783.

Psoriasis. It has been suggested that by binding to peroxisome proliferator-activated receptor gamma, pioglitazone may have an anti-inflammatory effect in conditions such as chronic plaque psoriasis (p.1583) and psoriatic arthritis (see Spondyloarthropathies, p.13). In a small open-label study,[1] oral doses of 30 mg daily were reported to improve moderate chronic plaque psoriasis in 4 of 5 patients, with definite improvement seen 1 to 3 months after starting therapy. Treatment was stopped in 1 other patient because of fluid retention. In a double-blind study,[2] 70 patients with moderate to severe disease were treated for 10 weeks with daily doses of pioglitazone 15 mg, 30 mg, or placebo. Greater improvements were reported with pioglitazone than with placebo, and the dose of 30 mg appeared to be slightly more effective than 15 mg. There has also been a report[3] of improvements in tender and swollen joints in a small group of patients with psoriatic arthritis who were given a high dose of pioglitazone (30 mg twice daily) for 12 weeks. Fluid retention was also reported.

Pramlintide *(BAN, USAN, rINN)*

AC-137; AC-0137 (pramlintide or pramlintide acetate); Pramlintida; Pramlintidum; Tripro-amylin.

Прамлинтид

$C_{171}H_{267}N_{51}O_{53}S_2 = 3949.4.$

CAS — 151126-32-8.

Pramlintide Acetate *(BANM, USAN, rINNM)*

AC-0137 (pramlintide or pramlintide acetate); Acetato de pramlintida; Pramlintide, Acétate de; Pramlintidi Acetas. 25-L-Proline-28-L-proline-29-L-prolineamylin (human) acetate hydrate.

Прамлинтида Ацетат

$C_{171}H_{267}N_{51}O_{53}S_2, xC_2H_4O_2, yH_2O.$

CAS — 196078-30-5.

Incompatibility. Pramlintide should not be mixed in the same syringe with insulin because of reported changes in the pharmacokinetic parameters of pramlintide.

Adverse Effects and Precautions

Pramlintide alone does not cause hypoglycaemia, but increases the risk associated with insulin use, particularly in type 1 diabetes mellitus; severe hypoglycaemia may occur within 3 hours of pramlintide injection. Blood-glucose concentrations must be closely monitored, both before and after meals, and the dose of insulin should be halved when pramlintide therapy is started (see Uses and Administration, below).

Other adverse effects of pramlintide include nausea, vomiting, anorexia, headache, reactions at the injection site, and hypersensitivity. Nausea commonly occurs at the beginning of therapy and decreases with time; incidence and severity are reduced if pramlintide is gradually titrated to the maintenance dose. Pramlintide is contra-indicated in patients with gastroparesis.

Interactions

Pramlintide has the potential to delay the absorption of oral medication; in cases where the rapid onset of action from an oral drug is critical, it should be given at least 1 hour before or 2 hours after pramlintide. Also, pramlintide may interfere with drugs given to alter gastrointestinal motility or absorption.

Pramlintide increases the risk of insulin-induced hypoglycaemia (see Adverse Effects and Precautions, above).

Pharmacokinetics

The bioavailability of pramlintide is about 30 to 40% from a subcutaneous injection. It is metabolised by the kidneys and has a half-life of about 48 minutes in healthy subjects.

Uses and Administration

Pramlintide is a synthetic analogue of amylin, a pancreatic peptide hormone thought to play a role in the regulation of glucose homoeostasis. It differs from amylin by replacement with proline at positions 25 (alanine), 28 (serine), and 29 (serine). Pramlintide slows the rate of gastric emptying, prevents the postprandial rise in glucagon concentrations, and reduces appetite. It is used in the management of diabetes mellitus (p.431) that is not adequately controlled by mealtime insulin therapy. Pramlintide is given as the acetate, but doses are expressed in terms of the base.

In patients with type 1 diabetes mellitus, an initial dose of pramlintide 15 micrograms is given subcutaneously immediately before major meals. The dose of any rapid-acting or short-acting insulins given before meals should be halved. The pramlintide dose may be increased in increments of 15 micrograms to a maintenance dose of 30 or 60 micrograms when no clinically significant nausea has occurred for at least 3 days. Once the maintenance dose of pramlintide has been achieved, the dose of insulin should be further adjusted for optimum glycaemic control.

In patients with type 2 diabetes mellitus who are using insulin, the initial dose of pramlintide is 60 micrograms, subcutaneously, immediately before major meals. The dose may be increased to 120 micrograms when no nausea has occurred for 3 to 7 days. The dose of insulin therapy should be adjusted as described for patients with type 1 diabetes mellitus (above).

Proprietary Preparations (details are given in Part 3)

USA: Symlin.

Repaglinide *(BAN, USAN, rINN)*

AG-EE-6232W; AG-EE-623-ZW; Repaglinid; Repaglinida; Repaglinidas; Répaglinide; Repaglinidi; Repaglinidum. (+)-2-Ethoxy-α-{[(S)-α-isobutyl-*o*-piperidinobenzyl]carbamoyl}-*p*-toluic acid; (*S*)-2-Ethoxy-4-{[1-(*o*-piperidinophenyl)-3-methylbutyl]carbamoyl-methyl}benzoic acid.

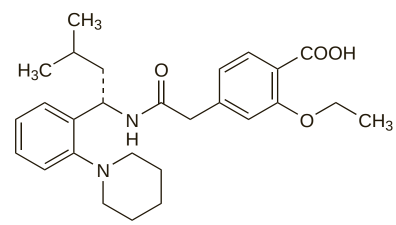
Репаглинид

$C_{27}H_{36}N_2O_4 = 452.6.$

CAS — 135062-02-1.

ATC — A10BX02.

ATC Vet — QA10BX02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Repaglinide). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; freely soluble in dichloromethane and in methyl alcohol. Protect from light.

USP 31 (Repaglinide). A white to off-white solid. Soluble in methyl alcohol. Store in airtight containers.

Adverse Effects and Precautions

Repaglinide may cause gastrointestinal adverse effects including abdominal pain, diarrhoea, constipation, nausea, and vomiting. Hypoglycaemia (usually mild), back and joint pain, hypersensitivity reactions including pruritus, rashes and urticaria, and elevated liver enzyme values may occur. There have been rare cases of transient visual disturbances attributed to changes in blood glucose concentrations associated with starting repaglinide treatment. There have also been rare reports of myocardial infarction in patients who were treated with repaglinide and isophane insulin; the combination is not recommended.

Precautions are similar to those which apply with the shorter-acting sulfonylurea hypoglycaemics (p.461). Repaglinide should be given with caution to patients with hepatic impairment (consideration should be given to extending the interval between doses), and possibly avoided in severe impairment.

Effects on the liver. Hepatotoxic reactions have been reported for repaglinide[1,2] including cholestatic hepatitis and jaundice with pruritus.

1. Nan DN, *et al.* Acute hepatotoxicity caused by repaglinide. *Ann Intern Med* 2004; **141:** 823.
2. López-García F, *et al.* Cholestatic hepatitis associated with repaglinide. *Diabetes Care* 2005; **28:** 752–3.

Fasting. For mention that nateglinide or repaglinide can probably be used with low risk of hypoglycaemia in fasting Muslim patients during Ramadan see under Precautions of Insulin, p.448.

Hypoglycaemia. Mild hypoglycaemia has been reported in patients receiving repaglinide,[1] although in a study comparing flexible repaglinide dosing with fixed glibenclamide dosing, all hypoglycaemic events recorded were in the glibenclamide group.[2] Other studies have found rates of hypoglycaemia in patients receiving repaglinide to be less than, or similar to, sulfonylureas.[3] The risk of hypoglycaemia may be reduced as patients can omit a dose of repaglinide if a meal is missed.

2. Damsbo P, *et al.* A double-blind randomized comparison of meal-related glycemic control by repaglinide and glyburide in well-controlled type 2 diabetic patients. *Diabetes Care* 1999; **22:** 789–94.
3. Culy CR, Jarvis B. Repaglinide: a review of its therapeutic use in type 2 diabetes mellitus. *Drugs* 2001; **61:** 1625–60.

Pregnancy. Insulin is generally preferred to oral antidiabetics in the treatment of diabetes mellitus during pregnancy. Repaglinide has been used in 3 women during the first 6 to 7 weeks of gestation;[1,2] treatment was then changed to insulin for the rest of the pregnancy. Their babies were delivered at term, with adequate weight for birth age and no congenital malformations.

2. Mollar-Puchades MA, *et al.* Use of repaglinide on a pregnant woman during embryogenesis. *Diabetes Obes Metab* 2007; **9:** 146–7.

Interactions

As with other oral antidiabetics, the efficacy of repaglinide may be affected by drugs independently increasing or decreasing blood glucose concentrations (see Sulfonylureas, p.461).

Drugs that affect the cytochrome P450 isoenzymes CYP2C8 and CYP3A4 may alter the metabolism of repaglinide. Use of repaglinide with the CYP2C8 inhibitor gemfibrozil has resulted in marked reduction in repaglinide clearance, and severe hypoglycaemia; UK licensed product information contra-indicates concomitant use.

Antibacterials. A study[1] in healthy subjects found that the plasma concentration of a single dose of repaglinide was reduced, and its half-life shortened, when it was given 12.5 hours after the last dose of a 5-day course of *rifampicin*. This effect was attributed to the induction of the cytochrome P450 isoenzyme CYP3A4 by rifampicin. In another study[2] repaglinide was given either with the last dose of a 7-day course of rifampicin or 24 hours later, and the effects on repaglinide were found to be greater on day 8 than day 7. The authors suggested that rifampicin acted as both an inducer and an inhibitor of CYP3A4 and possibly CYP2C8, and that after rifampicin was stopped its inductive effect lasted longer, thereby having a greater effect 24 hours later.

A study[3] in healthy subjects reported that *clarithromycin* can increase the plasma concentrations and prolong the elimination half-life of repaglinide, probably by inhibition of CYP3A4. *Telithromycin*, another inhibitor of CYP3A4, also increased plasma concentrations of repaglinide in a study of healthy subjects, although the elimination half-life of repaglinide was not significantly affected.[4] *Trimethoprim*[5] can have a similar effect by the inhibition of CYP2C8.

For a report of hypoglycaemia when *gatifloxacin* was given to a patient already receiving repaglinide, see p.281.

1. Niemi M, *et al.* Rifampin decreases the plasma concentrations and effects of repaglinide. *Clin Pharmacol Ther* 2000; **68:** 495–500.
2. Bidstrup TB, *et al.* Rifampicin seems to act as both an inducer and an inhibitor of the metabolism of repaglinide. *Eur J Clin Pharmacol* 2004; **60:** 109–14.
3. Niemi M, *et al.* The cytochrome P4503A4 inhibitor clarithromycin increases the plasma concentrations and effects of repaglinide. *Clin Pharmacol Ther* 2001; **70:** 58–65.
4. Kajosaari LI, *et al.* Telithromycin, but not montelukast, increases the plasma concentrations and effects of the cytochrome P450 3A4 and 2C8 substrate repaglinide. *Clin Pharmacol Ther* 2006; **79:** 231–42.
5. Niemi M, *et al.* The CYP2C8 inhibitor trimethoprim increases the plasma concentrations of repaglinide in healthy subjects. *Br J Clin Pharmacol* 2004; **57:** 441–7.

Ciclosporin. Ciclosporin markedly increased plasma concentrations of repaglinide in healthy subjects;[1] there is a possibly increased risk of hypoglycaemia if these 2 drugs are taken together.

1. Kajosaari LI, *et al.* Cyclosporine markedly raises the plasma concentrations of repaglinide. *Clin Pharmacol Ther* 2005; **78:** 388–99.

Grapefruit juice. Grapefruit juice increased the bioavailability of repaglinide in a study of healthy subjects.[1] The half-life of repaglinide was not affected, suggesting that grapefruit juice inhibited its presystemic metabolism by the cytochrome P450 isoenzyme CYP3A4 in the gut wall. Blood-glucose concentrations were not affected.

1. Bidstrup TB, *et al.* The impact of CYP2C8 polymorphism and grapefruit juice on the pharmacokinetics of repaglinide. *Br J Clin Pharmacol* 2006; **61:** 49–57.

Lipid regulating drugs. A study[1] in healthy subjects found that *gemfibrozil* significantly increased the plasma concentrations of repaglinide and enhanced and prolonged its glucose-lowering effect. Use of this combination should be avoided. Another study[2] in healthy subjects found, however, that repaglinide was not affected by *bezafibrate* or *fenofibrate*.

1. Niemi M, *et al.* Effects of gemfibrozil, itraconazole, and their combination on the pharmacokinetics and pharmacodynamics of repaglinide: potentially hazardous interaction between gemfibrozil and repaglinide. *Diabetologia* 2003; **46:** 347–51.
2. Kajosaari LI, *et al.* Lack of effect of bezafibrate and fenofibrate on the pharmacokinetics and pharmacodynamics of repaglinide. *Br J Clin Pharmacol* 2004; **58:** 390–6.

Pharmacokinetics

Repaglinide is rapidly absorbed from the gastrointestinal tract, with peak plasma concentrations occurring within 1 hour. The mean bioavailability is about 60%. Repaglinide is highly bound to plasma proteins, and has a plasma elimination half-life of about 1 hour. It undergoes almost complete hepatic metabolism involving the cytochrome P450 isoenzymes CYP2C8 and CYP3A4. The metabolites, which are inactive, are excreted in the bile. Higher plasma concentrations and prolonged half-life of repaglinide may occur in patients with renal impairment (creatinine clearance less than 40 mL/minute) or chronic liver disease.

Uses and Administration

Repaglinide is a meglitinide antidiabetic used for the treatment of type 2 diabetes mellitus (p.431). It has a chemical structure different from that of the sulfonylureas, but appears to have a similar mode of action.

Repaglinide is given up to 30 minutes before meals, in usual initial oral doses of 0.5 mg; initial doses of 1 or 2 mg are usually given to patients who have had previous hypoglycaemic treatment. The dose may be adjusted, at intervals of 1 to 2 weeks, up to a maximum of 4 mg before meals; a total of 16 mg daily should not be exceeded. Repaglinide is also given with metformin or a thiazolidinedione in type 2 diabetes not adequately controlled by monotherapy.

Administration in renal impairment. Although repaglinide is cleared mainly by hepatic metabolism, small pharmacokinetic studies have reported that exposure to repaglinide may be increased in patients with renal impairment.[1,2] A larger open-label study[3] that included 151 patients with normal renal function and 130 patients with varying degrees of renal impairment found that the incidence of adverse effects was not influenced by renal function. However, at the end of the 3-month maintenance treatment period, there was a trend towards lower effective doses of repaglinide with increasing degree of renal impairment.

Rosiglitazone Maleate

(BANM, USAN, rINNM)

BRL-49653-C; Maleato de rosiglitazona; Rosiglitazone, Maléate de; Rosiglitazoni Maleas; Roziglitazon Maleat. (±)-5-{*p*-[2-(Methyl-2-pyridylamino)ethoxy]benzyl}-2,4-thiazolidinedione maleate (1:1).

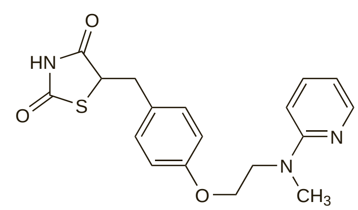
Розиглитазона Малеат

$C_{18}H_{19}N_3O_3S,C_4H_4O_4 = 473.5.$

CAS — 122320-73-4 (rosiglitazone); 155141-29-0 (rosiglitazone maleate); 316371-84-3 (rosiglitazone potassium).

ATC — A10BG02.

ATC Vet — QA10BG02.



(rosiglitazone)

Adverse Effects and Precautions

Rosiglitazone may cause hypoglycaemia, headache, weight gain, and anaemia. It may also cause dizziness, gastrointestinal disturbances, muscle cramps and myalgia, dyspnoea, paraesthesia, pruritus, and hypercholesterolaemia. Very rarely angioedema and urticaria have been reported. Rosiglitazone can also increase the risk of bone fracture in women.

Rosiglitazone can cause oedema, which may worsen or precipitate heart failure. It should therefore be used with caution in patients with oedema, and should not be used in those with a history of heart failure (see also below). Renal impairment may increase the risk of fluid retention and heart failure. There have been very rare reports of new onset and worsening diabetic macular oedema with decreased visual acuity (see Effects on the Eyes, below). There is some evidence to suggest that rosiglitazone might increase the risk of myocardial ischaemia; until further data become available, UK licensed product information advises that rosiglitazone is not recommended in patients with ischaemic heart disease or peripheral arterial disease (see also below). Liver function should be monitored periodically as there have been isolated reports of liver dysfunction, and the drug should be used with caution in patients with hepatic impairment (see Effects on the Liver, below).

In women who are anovulatory because of insulin resistance, rosiglitazone therapy may result in a resumption of ovulation.

Effects on the bones. Use of thiazolidinediones such as pioglitazone or rosiglitazone has been associated with decreases in bone mineral density and increased risk of fractures in female patients. Analysis of data from a comparative study[1] of glycaemic control with rosiglitazone, metformin, or glibenclamide involving 4360 randomised patients found that the risk of fracture in female patients in these 3 groups was 9.3%, 5.1%, and 3.5% respectively;[2] the risk in male patients was not significantly different in the 3 groups at around 3.4 to 3.95%. Analysis of data from another large ongoing study was also consistent with an increased fracture risk with rosiglitazone,[2] and data from the manufacturer of pioglitazone involving over 8100 treated patients also revealed an increased risk of fracture in women given the drug;[3] the excess risk was calculated to be 0.8 per 100 patient years of use. The pattern of fractures seems to differ from that associated with postmenopausal osteoporosis, being mainly in the upper arm, hand, or foot, rather than hip or spine, but an observational study has suggested that thiazolidinedione use is associated with ongoing loss of whole-body bone mineral density.[4]

Effects on the cardiovascular system. It has been suggested that, in addition to their hypoglycaemic effect, thiazolidinediones may have beneficial effects in the prevention of macrovascular diabetic complications, and there is some evidence that pioglitazone may improve some cardiovascular outcomes (see Diabetic Complications, p.457). However, a meta-analysis[1] of 42 studies found that, compared with either placebo or other antidiabetic drugs, rosiglitazone was associated with a significant increase in the risk of myocardial infarction, and an increase of borderline significance in death from cardiovascular causes. There were limitations to this analysis as the studies were not primarily intended to examine cardiovascular outcomes, and many were small and short-term. Another meta-analysis[2] that was restricted to 4 long-term studies (at least 12 months of treatment) that had specified an intention to evaluate cardiovascular adverse effects also found an increased risk of myocardial infarction with rosiglitazone use, without a significant increase in the risk of cardiovascular mortality.

Studies with no recorded cardiovascular events were excluded from the larger meta-analysis,[1] and this has been questioned. An alternative analysis[3] that incorporated these excluded studies, with appropriate analysis adjustment, found odds ratios for myocardial infarction and cardiovascular death that were not statistically significant, and concluded that neither increased nor decreased risk could be established.

In response to concerns raised by the initial meta-analysis, an unplanned interim analysis of an ongoing open-label study designed to assess cardiovascular outcomes has been published (rosiglitazone added to either metformin or a sulfonylurea compared with metformin plus a sulfonylurea).[4] The data, however, were insufficient to determine whether there was an increased risk of myocardial infarction, and the findings were inconclusive regarding any effect on overall risks of hospitalisation or death from cardiovascular causes.

For the risks of heart failure associated with thiazolidinediones, see Effects on the Heart, below.

Effects on the eyes. The manufacturers in the USA and Canada (*GSK*) have received postmarketing reports of the development or worsening of diabetic macular oedema in patients treated with rosiglitazone-containing products; in most cases the patients also reported peripheral oedema or fluid retention.[1,2] In some cases visual impairment improved or resolved after stopping the drug. Rosiglitazone should be used with caution in patients with pre-existing diabetic retinopathy or macular oedema, and should be stopped, and ophthalmological consultation sought, if visual impairment develops while using the drug.[2]

Effects on the heart. Both pioglitazone and rosiglitazone can cause peripheral and pulmonary oedema, which can worsen or precipitate heart failure; a number of cases have been described.[1-6] A large retrospective cohort study[7] also found that the use of thiazolidinediones increased the risk of heart failure. The incidence of peripheral oedema with monotherapy has been reported[8] to range from 3 to 5%, and this increases slightly when a thiazolidinedione is used with another oral antidiabetic. The incidence is about 15% when a thiazolidinedione is used with insulin. The incidence of heart failure is generally lower, but has been reported to be 2 to 3% when a thiazolidinedione is used with insulin; however, a large prospective study,[9] which was intended to examine the cardiovascular benefits of pioglitazone in preventing secondary macrovascular events in diabetic patients with pre-existing macrovascular disease, reported a 6% incidence of heart failure, compared with 4% in the placebo group. Mortality rates from heart failure did not differ between groups. These figures were confirmed on re-analysis.[10]

The American Heart Association and American Diabetes Association have recommended[8] that patients with risk factors for heart disease or a depressed ejection fraction but without symptoms, and patients with NYHA class I or II heart failure, should start with a low dose of a thiazolidinedione that is only increased gradually as necessary and with careful monitoring. Patients with more severe heart failure (class III and IV) should not receive these drugs. These recommendations are reflected in US licensed product information. UK licensed product information contra-indicates the use of pioglitazone or rosiglitazone in patients with heart failure or any history of heart failure, even of class I or II.

Effects on lipids. Rosiglitazone and pioglitazone have different effects on serum lipids—see p.456.

Effects on the liver. Several cases of hepatotoxicity have been described[1-5] in patients receiving rosiglitazone. Most of these occurred within a few weeks or months of starting rosiglitazone therapy. However, the causality of some of these cases has been debated[6,7] because of coexisting disease and concomitant medication.

Licensed product information recommends that liver enzymes should be checked before starting therapy with rosiglitazone; patients with aminotransferase (ALT) concentrations more than 2.5 times the upper limit of normal should not be given rosiglitazone. ALT concentrations should then be monitored periodically. If ALT concentrations rise to more than 3 times the upper limit of normal and remain so after retesting then treatment with rosiglitazone should be stopped; treatment should also be stopped if jaundice develops.

Fasting. For mention that glitazones can probably be used with low risk of hypoglycaemia in fasting Muslim patients during Ramadan see under Precautions of Insulin, p.448.

Interactions

Gemfibrozil, ketoconazole, and trimethoprim, can increase plasma concentrations of rosiglitazone. Conversely, rifampicin can reduce rosiglitazone concentrations. These drugs should be given with caution to patients taking rosiglitazone, and glycaemic control should be monitored.

Use of NSAIDs or insulin with rosiglitazone may increase the risk of oedema and heart failure (see also Effects on the Heart, above, and Administration, below).

Antibacterials. *Rifampicin* significantly reduced the plasma concentration and elimination half-life of rosiglitazone in studies[1,2] of healthy subjects, probably by induction of the cytochrome P450 isoenzyme CYP2C8. Conversely, *trimethoprim* can inhibit CYP2C8, and was found to increase the concentration and half-life of rosiglitazone modestly.[2,3]

1. Park J-Y, *et al.* Effect of rifampin on the pharmacokinetics of rosiglitazone in healthy subjects. *Clin Pharmacol Ther* 2004; **75:** 157–62.
2. Niemi M, *et al.* Effects of trimethoprim and rifampin on the pharmacokinetics of the cytochrome P450 2C8 substrate rosiglitazone. *Clin Pharmacol Ther* 2004; **76:** 239–49.
3. Hruska MW, *et al.* The effect of trimethoprim on CYP2C8 mediated rosiglitazone metabolism in human liver microsomes and healthy subjects. *Br J Clin Pharmacol* 2005; **59:** 70–9.

Antifungals. In a study[1] of healthy subjects, *ketoconazole* increased the plasma concentration and elimination half-life of rosiglitazone, probably by inhibition of the cytochrome P450 isoenzyme CYP2C8 and to a lesser extent CYP2C9.

1. Park J-Y, *et al.* Effect of ketoconazole on the pharmacokinetics of rosiglitazone in healthy subjects. *Br J Clin Pharmacol* 2004; **58:** 397–402.

Lipid regulating drugs. *Gemfibrozil* increased the plasma concentration and about doubled the half-life of rosiglitazone in a study[1] of healthy subjects, probably by inhibiting its metabolism. The authors suggested that these drugs should not be used together, or that the dose of rosiglitazone should be at least halved if gemfibrozil treatment is started.

1. Niemi M, *et al.* Gemfibrozil considerably increases the plasma concentrations of rosiglitazone. *Diabetologia* 2003; **46:** 1319–23.

Pharmacokinetics

Rosiglitazone is well absorbed from the gastrointestinal tract after oral dosing. Peak plasma concentrations occur within 1 hour and the bioavailability is 99%. It is 99.8% bound to plasma proteins. Rosiglitazone is extensively metabolised, almost exclusively by the cytochrome P450 isoenzyme CYP2C8. It is excreted in the urine and faeces, and has a half-life of 3 to 4 hours.

Uses and Administration

Rosiglitazone is a thiazolidinedione oral antidiabetic that improves insulin sensitivity and is used for the treatment of type 2 diabetes mellitus (p.431). It is usually given as rosiglitazone maleate but doses are expressed in terms of the base; rosiglitazone maleate 1.32 mg is equivalent to about 1 mg of rosiglitazone. The potassium salt is used in some countries. Rosiglitazone is given orally as monotherapy, particularly in patients who are overweight and for whom metformin is contra-indicated or not tolerated. It may also be added to metformin, a sulfonylurea (or a combination of the two), or to insulin, when such therapy is inadequate (but see Administration, below). The usual initial dose is 4 mg daily, given in a single dose or two divided doses. The dose may be increased to a maximum of 8 mg daily if necessary after 8 to 12 weeks in patients receiving monotherapy or combination oral therapy. Rosiglitazone may be taken with or without food.

Administration. Although rosiglitazone is licensed for use with other antidiabetic drugs the specifics of licensing and use may vary from country to country. In both the UK and USA, rosiglitazone (*Avandia; GSK*) is licensed for use with metformin or a sulfonylurea, or both if necessary, in patients in whom single or dual agent therapy is inadequate. In the UK, however, NICE recommends dual therapy only in patients who cannot be given combination therapy with metformin plus a sulfonylurea.[1]

The combination of rosiglitazone with insulin is now generally avoided because of an increased risk of heart failure and other cardiac adverse events (see also Effects on the Heart, above), although licensed product information may not necessarily contraindicate the combination. In the UK, licensed product information for rosiglitazone warns that insulin should only be added to established rosiglitazone therapy in exceptional cases and under close supervision. In the USA, the combination of rosiglitazone and insulin is not recommended.

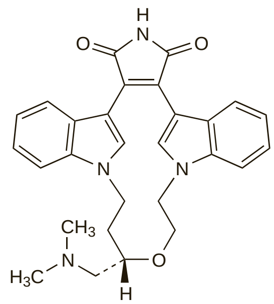
Ruboxistaurin *(rINN)*

LY-333531; LY-341684 (ruboxistaurin mesilate); Ruboxistaurina; Ruboxistaurine; Ruboxistaurinum. (9*S*)-9-[(Dimethylamino)methyl]-6,7,10,11-tetrahydro-9*H*,19*H*-5,21:12,17-dimethenodibenzo[*e*,*k*]pyrrolo[3,4-*h*][1,4,13]oxadiazacyclohexadecene-18,20-dione.

Рубоксистаурин

$C_{28}H_{28}N_4O_3$ = 468.5.

CAS — 169939-94-0 (ruboxistaurin); 169939-93-9 (ruboxistaurin hydrochloride); 202260-21-7 (ruboxistaurin mesilate).



Profile

Ruboxistaurin is an oral inhibitor of the β-isoform of the enzyme protein kinase C, which is thought to play a role in the development of diabetic microvascular complications (p.433). It is under investigation as an adjunct in the treatment of diabetic retinopathy.

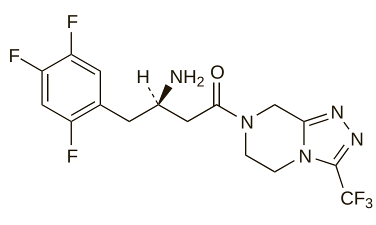
Sitagliptin Phosphate *(USAN, rINNM)*

Fosfato de sitagliptina; MK-431; MK-0431; Ono-5435; Sitagliptine, Phosphate de; Sitagliptini Phosphas. 7-[(3*R*)-3-Amino-4-(2,4,5-trifluorophenyl)butanoyl]-3-(trifluoromethyl)-5,6,7,8-tetrahydro-1,2,4-triazolo[4,3-a]pyrazinemonophosphate monohydrate.

Ситаглиптина Фосфат

$C_{16}H_{15}F_6N_5O,H_3O_4P,H_2O$ = 523.3.

CAS — 486460-32-6 (sitagliptin); 654671-78-0 (sitagliptin phosphate); 654671-77-9 (sitagliptin phosphate monohydrate).



(sitagliptin)

Profile

Like vildagliptin (p.464), sitagliptin is an inhibitor of the enzyme dipeptidylpeptidase-4, an enzyme responsible, among other roles, for the degradation of the incretin hormone glucagon-like peptide-1 (GLP-1; insulinotropin), which plays a role in regulating insulin secretion. It is used in the treatment of type 2 diabetes mellitus (p.431), as monotherapy or as dual therapy with metformin, a sulfonylurea, or a thiazolidinedione. Triple therapy using sitagliptin with metformin and a sulfonylurea may be given if dual therapy is inadequate. Sitagliptin is given as the phosphate, but doses are in terms of the base; 128.5 mg of sitagliptin phosphate is equivalent to about 100 mg of sitagliptin. The usual oral dose is the equivalent of 100 mg of sitagliptin once daily, as monotherapy or in combination. When given with metformin in a combination preparation, sitagliptin may be given in 2 divided doses. The dose of sulfonylurea may need to be lowered when used with sitagliptin. Sitagliptin may be taken with or without food. Dosage should be adjusted in patients with renal impairment (see below).

Adverse effects reported with sitagliptin include upper respiratory-tract infections, headache, and nasopharyngitis. Hypersensitivity reactions including anaphylaxis, angioedema, urticaria, rash, and Stevens-Johnson syndrome have also been reported.

Administration in renal impairment. US licensed product information suggests the following oral doses of sitagliptin in patients with renal impairment, based on creatinine clearance (CC):
- mild impairment (CC 50 mL/minute or more): no adjustment necessary, 100 mg daily
- moderate impairment (CC 30 to less than 50 mL/minute): 50 mg daily
- severe impairment (CC less than 30 mL/minute): 25 mg daily. It may be given without regard to the timing of haemodialysis

Sulfonylurea Antidiabetics

Antidiabéticos sulfonilureas; Sulphonylurea Antidiabetics.

Adverse Effects

Gastrointestinal disturbances such as nausea, vomiting, heartburn, anorexia, diarrhoea, and a metallic taste may occur with sulfonylureas and are usually mild and dose-dependent; increased appetite and weight gain may occur. Skin rashes and pruritus may occur and photosensitivity has been reported. Rashes are usually hypersensitivity reactions and may progress to more serious disorders (see below). Facial flushing may develop in patients receiving sulfonylureas, particularly chlorpropamide, when alcohol is consumed (see under Interactions, below).

Mild hypoglycaemia may occur; severe hypoglycaemia is usually an indication of overdosage and is relatively uncommon. Hypoglycaemia is more likely with long-acting sulfonylureas such as chlorpropamide and glibenclamide, which have been associated with severe, prolonged, and sometimes fatal hypoglycaemia.

Other severe effects may be manifestations of a hypersensitivity reaction. They include altered liver enzyme values, hepatitis and cholestatic jaundice, leucopenia, thrombocytopenia, aplastic anaemia, agranulocytosis, haemolytic anaemia, erythema multiforme or the Stevens-Johnson syndrome, exfoliative dermatitis, and erythema nodosum.

The sulfonylureas, particularly chlorpropamide, occasionally induce a syndrome of inappropriate secretion of antidiuretic hormone (SIADH) characterised by water retention, hyponatraemia, and CNS effects. However, some sulfonylureas, such as glibenclamide, glipizide, and tolazamide are also stated to have mild diuretic actions.

Work on tolbutamide has suggested that the sulfonylureas might be associated with an increase in cardiovascular mortality; this has been the subject of considerable debate (see Effects on the Cardiovascular System, below).

Effects on the cardiovascular system. A multicentre study carried out under the University Group Diabetes Program (UGDP) reported an increased incidence in mortality from cardiovascular complications in diabetic patients given tolbutamide as compared with those treated with diet alone or insulin;[1] a similar increase was also noted in patients given phenformin.[2] The reports from the UGDP aroused prolonged controversy which was not entirely settled by detailed reassessment of relevant studies.[3] Eventually in 1984 the FDA made it a requirement that sulfonylurea oral antidiabetics be labelled with a specific warning about the possibility of increased cardiovascular mortality associated with the use of these drugs.[4] Subsequently the cardiovascular effects of the sulfonylureas were reviewed.[5] It has been hypothesised that the action of the sulfonylureas in preventing the opening of ATP-sensitive potassium channels in the myocardium may abolish adaptive changes (ischaemic preconditioning) that protect the heart against ischaemic insult.[6] A recent retrospective cohort study has also found that, among patients newly treated for type 2 diabetes, sulfonylurea monotherapy was associated with an increased mortality compared with metformin therapy.[7] However, results from the UK Prospective Diabetes Study did not demonstrate any adverse cardiovascular effects associated with sulfonylurea therapy.[8]

Effects on the eyes. When a diabetic patient who had experienced bilateral visual loss for several months and who had been taking chlorpropamide for one year stopped treatment, visual acuity improved and colour vision rapidly returned.[1] A 5-day challenge with chlorpropamide resulted in a mild decrease in acuity followed by return to baseline values when treatment was again stopped. Drug-induced optic neuropathy was considered to have occurred. There is also a report of a patient with type 2 diabetes mellitus who developed myopia two days after starting treatment with glibenclamide 10 mg daily.[2] Visual difficulties resolved a few days after stopping glibenclamide.

2. Teller J, *et al.* Accommodation insufficiency induced by glybenclamide. *Ann Ophthalmol* 1989; **21:** 275–6.

Effects on the kidneys. The nephrotic syndrome has been reported in a patient treated with chlorpropamide.[1] Serological testing and renal biopsy showed that the glomerular lesions were of an immune-complex nature. Both the nephrotic syndrome and the glomerulonephritis resolved after treatment was stopped. The patient also developed a skin eruption, hepatitis, and eosinophilia.

1. Appel GB, *et al.* Nephrotic syndrome and immune complex glomerulonephritis associated with chlorpropamide therapy. *Am J Med* 1983; **74:** 337–42.

Effects on the liver. Chlorpropamide was implicated[1] in 8 of 53 cases of drug-induced acute liver disease admitted to a hospital in Jamaica over the years 1973 to 1988. Hepatocanalicular cholestasis occurred in 5 cases and diffuse necrosis in 3. One patient with massive hepatic necrosis died. Intrahepatic cholestasis,[2-4] an acute hepatitis-like syndrome,[5] and a combination of both[6] have been described in patients receiving glibenclamide.

Effects on the thyroid. See under Precautions, below.

Hypoglycaemia. Severe hypoglycaemia may occur in any patient treated with any sulfonylurea; this potentially life-threatening complication requires prolonged and energetic treatment.[1] Sulfonylureas with a prolonged duration of action such as chlorpropamide and glibenclamide appear to cause severe hypoglycaemia more often than shorter-acting drugs such as tolbutamide. Experience with newer drugs is limited.

A review of 1418 cases of drug-induced hypoglycaemia reported since 1940 showed that sulfonylureas (especially chlorpropamide and glibenclamide), either alone or with a second antidiabetic or potentiating agent, accounted for 63% of all cases.[2] A study of sulfonylurea use in nearly 14,000 patients aged 65 years or older confirmed that chlorpropamide and glibenclamide were associated with hypoglycaemia. However, glipizide caused significantly fewer cases than glibenclamide.[3]

An analysis,[4] of 185 children reported to 10 regional poison centres in the USA after ingesting sulfonylureas found that hypoglycaemia developed only in 56. A lack of hypoglycaemia during the first 8 hours after ingestion was predictive of a benign outcome, and it was recommended that suspected cases be observed for 8 hours with frequent blood glucose monitoring. Children who developed signs of hypoglycaemia, or in whom blood glucose fell below 3.3 mmol/litre could be given intravenous glucose if necessary.

Treatment of Adverse Effects

In acute poisoning with sulfonylureas, if the patient is conscious and presents within 1 hour of ingestion, the stomach should be emptied and/or activated charcoal given. Hypoglycaemia should be treated with urgency; the general management of hypoglycaemia is described under insulin (see p.447). The patient should be observed over several days in case hypoglycaemia recurs. Octreotide has been used in the treatment of severe refractory cases of sulfonylurea-induced hypoglycaemia.

3. Carr R, Zed PJ. Octreotide for sulfonylurea-induced hypoglycemia following overdose. *Ann Pharmacother* 2002; **36:** 1727–32.

Precautions

Sulfonylureas should not be used in type 1 diabetes mellitus. Use in type 2 diabetes mellitus is contra-indicated in patients with ketoacidosis and in those with severe infection, trauma, or other severe conditions where the sulfonylurea is unlikely to control the hyperglycaemia; insulin should be used in such situations.

Insulin is also preferred for therapy during pregnancy.

Sulfonylureas with a long half-life such as chlorpropamide or glibenclamide are associated with an increased risk of hypoglycaemia. They should therefore be avoided in patients with impairment of renal or hepatic function, and a similar precaution would tend to apply in other groups with an increased susceptibility to this effect, such as the elderly, debilitated or malnourished patients, and those with adrenal or pituitary insufficiency. Irregular mealtimes, missed meals, changes in diet, or prolonged exercise may also provoke hypoglycaemia. Where a sulfonylurea needs to be used in patients at increased risk of hypoglycaemia, a short-acting drug such as tolbutamide or gliclazide may be preferred; these 2 sulfonylureas, being principally inactivated in the liver, are perhaps particularly suitable in renal impairment, although careful monitoring of blood-glucose concentration is essential.

Abuse. Severe hypoglycaemia, at first thought to be due to insulinoma but later found to be due to nesidioblastosis [proliferation of the islet cells], was reported in a woman covertly taking chlorpropamide.[1]

1. Rayman G, *et al.* Hyperinsulinaemic hypoglycaemia due to chlorpropamide-induced nesidioblastosis. *J Clin Pathol* 1984; **37:** 651–4.

Administration. It has been suggested that continuously high plasma concentrations of sulfonylureas may lead to the development of tolerance, and that therefore the maximum recommended doses should be reduced.[1]

1. Melander A, *et al.* Is there a concentration-effect relationship for sulphonylureas? *Clin Pharmacokinet* 1998; **34:** 181–8.

Breast feeding. Some sulfonylureas are distributed into breast milk and the class of drugs should be avoided during breast feeding.

Driving. In the UK, patients with diabetes mellitus treated with insulin or oral hypoglycaemics are required to notify their condition to the Driver and Vehicle Licensing Agency, who then assess their fitness to drive. Patients treated with oral hypoglycaemics are generally allowed to retain standard driving licences; those treated with insulin receive restricted licences which must be renewed (with appropriate checks) every 1 to 3 years. Patients should be warned of the dangers of hypoglycaemic attacks while driving, and should be counselled in appropriate management of the situation (stopping driving as soon as it is safe to do so, taking carbohydrate immediately, and quitting the driving seat and removing the ignition key from the car) should such an event occur. Patients who have lost hypoglycaemic awareness, or have frequent hypoglycaemic episodes, should not drive. In addition, eyesight must be adequate (field of vision of at least 120°) for a licence to be valid. Patients treated with diet or oral hypoglycaemics are normally allowed to hold vocational driving licences for heavy goods vehicles or passenger carrying vehicles; those treated with insulin may not drive such vehicles, and are restricted in driving some other vehicles such as small lorries and minibuses.

Fasting. For the suggestion that sulfonylureas should be used with caution in fasting Muslim patients during Ramadan, and that chlorpropamide is contra-indicated in this group, see under Precautions of Insulin, p.448.

Porphyria. Sulfonylureas have been associated with acute attacks of porphyria and are considered unsafe in porphyric patients.

Thyroid disorders. There are conflicting reports concerning the effects of sulfonylureas on thyroid function, with some studies suggesting an increased incidence of thyroid dysfunction in patients treated with tolbutamide or chlorpropamide,[1] while other suggest no antithyroid action.[2,3] Some licensed product information consequently recommends that chlorpropamide should be avoided in patients with impaired thyroid function. Changes in thyroid function may conversely affect glycaemic control—for mention of the possible effects of thyroid hormones on antidiabetic drug requirements see under Interactions, below.

3. Feely J, *et al.* Antithyroid effect of chlorpropamide? *Hum Toxicol* 1983; **2:** 149–53.

Interactions

Many interactions have been reported with the sulfonylureas, largely representing either pharmacokinetic interactions (due to the displacement of the antidiabetic from plasma proteins or alteration in its metabolism or excretion) or pharmacological interactions with drugs having an independent effect on blood glucose. In the former class most reports concern older sulfonylureas such as chlorpropamide and tolbutamide, although the possibility of such reactions with newer drugs should be borne in mind.

A diminished hypoglycaemic effect, possibly requiring an increased dose of sulfonylurea, has been seen or might be expected on theoretical grounds with adrenaline, aminoglutethimide, chlorpromazine, corticosteroids, diazoxide, oral contraceptives, rifamycins, thiazide diuretics, and thyroid hormones.

An increased hypoglycaemic effect has occurred or might be expected with ACE inhibitors, alcohol, allopurinol, some analgesics (notably azapropazone, phenylbutazone, and the salicylates), azole antifungals (fluconazole, ketoconazole, and miconazole), chloramphenicol, cimetidine, clofibrate and related compounds, coumarin anticoagulants, fluoroquinolones, heparin, MAOIs, octreotide (although this may also produce hyperglycaemia), ranitidine, sulfinpyrazone, sulfonamides (including co-trimoxazole), tetracyclines, and tricyclic antidepressants.

Beta blockers have been reported both to increase hypoglycaemia and to mask the typical sympathetic warning signs. There are sporadic and conflicting reports of a possible interaction with calcium-channel blockers, but overall any effect seems to be of little clinical significance.

In addition to producing hypoglycaemia alcohol can interact with chlorpropamide to produce an unpleasant flushing reaction. Such an effect is rare with other sulfonylureas and alcohol.

ACE inhibitors. There are sporadic reports of marked hypoglycaemia developing in patients taking a sulfonylurea who are given an ACE inhibitor (mainly *captopril* or *enalapril*),[1-3] and 2 case-control studies have indicated that the combination is associated with an increased risk of developing severe hypoglycaemia.[4,5] However, other studies have failed to find much evidence of a problem.[6-9]

Alcohol. Sulfonylurea-induced alcohol intolerance is seen mainly but not exclusively with chlorpropamide; this is similar to the disulfiram-alcohol interaction, although it is not clear whether the mechanism is the same. Since the main symptom of the reaction (facial flushing) appears to occur more commonly in diabetic than non-diabetic subjects, it has been proposed that this symptom could be used as a diagnostic test for a certain subset of patients with type 2 diabetes mellitus.[1,2] However, some have not considered the test to be sufficiently specific[3-6] and despite a great deal having been published on the chlorpropamide-alcohol flushing test (CPAF), its value remains poorly defined. Alcohol, as well as provoking a flushing reaction with chlorpropamide, has been reported both to increase and to decrease the half-life of tolbutamide depending on whether the alcohol administration was acute or chronic.[7] Alcohol may also have a variable effect of its own on blood-glucose concentrations; there is a general tendency to increased hypoglycaemia when alcohol and sulfonylureas are taken concurrently.[6]

Analgesics. *Phenylbutazone*[1,2] and related drugs such as *azapropazone*[3] have been associated with acute hypoglycaemic episodes when given to patients receiving sulfonylureas (in most reports, tolbutamide). Other analgesics may enhance the hypoglycaemic effect of sulfonylureas, including *indobufen*,[4] *fenclofenac*,[5] and the *salicylates*.[6,7] Although a study in healthy subjects found no interaction,[7] there has been a report of hypoglycaemia with *ibuprofen* in a diabetic patient who had been stabilised on glibenclamide.[8]

Antibacterials. *Chloramphenicol* markedly inhibits the metabolism of tolbutamide and increases its half-life,[1] which can result in hypoglycaemia. Sulfonamides,[2] including *co-trimoxazole*,[3-5] may also enhance the hypoglycaemic effects of the sulfonylureas. There have been rare reports of elevated glibenclamide concentrations and hypoglycaemia when *ciprofloxacin* was given to patients who were on stable glibenclamide therapy.[6] For reports of hypoglycaemia when *gatifloxacin* was given to patients already receiving a sulfonylurea (glimepiride in one case, and glibenclamide plus pioglitazone in another), see p.281. There have also been a few cases of severe hypoglycaemia when *clarithromycin* was added to glibenclamide or glipizide; renal impairment may have played a role in these cases.[7] *Rifampicin* (and probably other rifamycins) can enhance the metabolism and decrease the effect of tolbutamide, chlorpropamide,[8,9] and glibenclamide[10] and dosage of the hypoglycaemic drug may need to be increased. The effects on glipizide[10] and glimepiride[11] appear to be less pronounced.

Anticoagulants. *Dicoumarol* increases serum concentrations and therefore the hypoglycaemic effects of tolbutamide, and possibly chlorpropamide. In addition, sulfonylureas may affect anticoagulant function (p.1428).

Antiepileptics. For references to *phenytoin* toxicity when tolbutamide or tolazamide was given, see under Phenytoin p.498.

Antifungals. Increased plasma concentrations of tolbutamide have been reported when *fluconazole* was given,[1] but there was no evidence of hypoglycaemia, and no hypoglycaemic symptoms were seen in 29 women receiving gliclazide or glibenclamide who were given fluconazole or *clotrimazole* for vulvovaginitis.[2] A study in healthy subjects found that fluconazole increased plasma concentrations of glimepiride, but again there was no significant effect on glucose concentrations.[3] However, there are reports of hypoglycaemia in a patient who took fluconazole with glipizide,[4] and another who took fluconazole and co-trimoxazole with gliclazide.[5] Similar interactions have been reported for *ketoconazole* (with tolbutamide, in healthy subjects)[6] and *miconazole* (with tolbutamide, in a diabetic),[7] suggesting that such combinations should be regarded with caution.

Ciclosporin. For the effect of glibenclamide on blood concentrations of ciclosporin see Hypoglycaemic Drugs, p.1828.

Metformin. Results apparently suggesting increased mortality in patients who received intensive drug therapy with metformin and a sulfonylurea were reported by the UK Prospective Diabetes Study.[1] This was considered to be artefactual, since it was not confirmed by epidemiological analysis, and such combinations are widely used in practice, but some concern remains and further study is needed.

1. UK Prospective Diabetes Study Group. Effect of intensive blood-glucose control with metformin on complications in overweight patients with type 2 diabetes (UKPDS 34). *Lancet* 1998; **352:** 854–65. Correction. *ibid.*; 1558.

Thyroid hormones. It has been suggested that starting thyroid replacement therapy may increase the requirement for insulin or oral antidiabetic drugs in diabetic patients, which would not seem unreasonable given the stimulant effects of thyroid hormones on metabolic function. For a discussion of the mooted effects of sulfonylureas on thyroid function, see under Precautions, above.

Pharmacokinetics

◊ Reviews.

3. Harrower AD. Pharmacokinetics of oral antihyperglycaemic agents in patients with renal insufficiency. *Clin Pharmacokinet* 1996; **31:** 111–19.

Uses and Administration

The sulfonylurea antidiabetics are a class of oral antidiabetic drugs used in the treatment of type 2 diabetes mellitus (p.431). They are given to supplement treatment by diet modification when such modification has not proved effective on its own, although metformin is preferred in patients who are obese.

Sulfonylureas appear to have several modes of action, apparently mediated by inhibition of ATP-sensitive potassium channels. Initially, secretion of insulin by functioning islet beta cells is increased. However, insulin secretion subsequently falls again but the hypoglycaemic effect persists and may be due to inhibition of hepatic glucose production and increased sensitivity to any available insulin; this may explain the observed clinical improvement in glycaemic control. The duration of action of sulfonylureas is variable; drugs such as tolbutamide are relatively short-acting (about 6 to 12 hours) while chlorpropamide has a prolonged action (over 24 hours).

Sulfonylurea therapy may be combined with metformin or other oral hypoglycaemics in patients who fail to respond to a single type of drug; such combination therapy is usually tried (in the absence of contra-indications) before considering the addition of, or transfer to, insulin therapy.

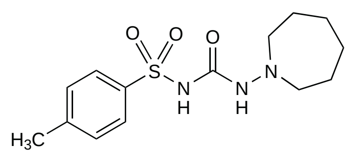
Tolazamide *(BAN, USAN, rINN)*

NSC-70762; Tolatsamidi; Tolazamid; Tolazamida; Tolazamidum; U-17835. 1-(Perhydroazepin-1-yl)-3-tosylurea; 1-(Perhydroazepin-1-yl)-3-*p*-tolylsulphonylurea.

Толазамид

$C_{14}H_{21}N_3O_3S$ = 311.4.
CAS — 1156-19-0.
ATC — A10BB05.
ATC Vet — QA10BB05.



Pharmacopoeias. In *Br., Jpn,* and *US.*

BP 2008 (Tolazamide). A white or almost white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; soluble in acetone; freely soluble in chloroform.

USP 31 (Tolazamide). A white or off-white crystalline powder, odourless or having a slight odour. Very slightly soluble in water; slightly soluble in alcohol; soluble in acetone; freely soluble in chloroform.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460.

Porphyria. Tolazamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for sulfonylureas in general, p.461.

Pharmacokinetics

Tolazamide is slowly absorbed from the gastrointestinal tract, peak plasma concentrations occurring 4 to 8 hours after a dose by mouth, and is extensively bound to plasma proteins. It has a half-life of about 7 hours. It is metabolised in the liver to metabolites with some hypoglycaemic activity. About 85% of an oral dose is excreted in the urine, chiefly as metabolites.

Uses and Administration

Tolazamide is a sulfonylurea antidiabetic (p.460). It is given orally in the treatment of type 2 diabetes mellitus (p.431) and has a duration of action of at least 10 hours and sometimes up to 20 hours. The usual initial dose is 100 to 250 mg daily given as a single dose with breakfast. Dosage may be increased if necessary at weekly intervals by 100 to 250 mg, usually to a maximum of 1 g daily; no further benefit is likely to be gained with higher doses. Doses of more than 500 mg daily may be given in divided doses.

Preparations

BP 2008: Tolazamide Tablets;
USP 31: Tolazamide Tablets.

Proprietary Preparations (details are given in Part 3)

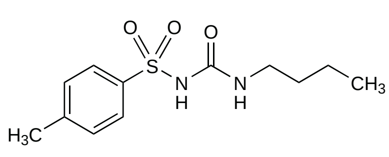
Tolbutamide *(BAN, rINN)*

Butamidum; Tolbutamid; Tolbutamida; Tolbutamidas; Tolbutamidi; Tolbutamidum; Tolglybutamide. 1-Butyl-3-tosylurea; 1-Butyl-3-*p*-tolylsulphonylurea.

Тольбутамид

$C_{12}H_{18}N_2O_3S$ = 270.3.
CAS — 64-77-7 (tolbutamide); 473-41-6 (tolbutamide sodium).
ATC — A10BB03; V04CA01.
ATC Vet — QA10BB03; QV04CA01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Tolbutamide). A white or almost white, crystalline powder. Practically insoluble in water; soluble in alcohol and in acetone. It dissolves in dilute solutions of alkali hydroxides.

USP 31 (Tolbutamide). A white or practically white, practically odourless, crystalline powder. Practically insoluble in water; soluble in alcohol and in chloroform.

Adverse Effects, Treatment, and Precautions

As for sulfonylureas in general, p.460. Tolbutamide was implicated in the controversial reports of excess cardiovascular mortality associated with oral hypoglycaemic therapy (see under Sulfonylureas, Effects on the Cardiovascular System, p.461).

Thrombophlebitis with thrombosis has occurred after the intravenous injection of tolbutamide sodium, but this is usually painless and the vein gradually recovers. Rapid injection may cause a transient mild pain or sensation of heat in the vein.

The *BNF* has suggested that tolbutamide may be suitable for use in patients with renal impairment, but that careful monitoring of blood-glucose concentration is essential. UK licensed product information recommends that it should not be used in patients with severe renal impairment.

Breast feeding. Tolbutamide is distributed into breast milk in relatively low quantities.[1] The American Academy of Pediatrics[2] states that, although usually compatible with breast feeding, use of tolbutamide by breast-feeding mothers may possibly result in jaundice in the infant.

1. Moiel RH, Ryan JR. Tolbutamide orinase in human breast milk. *Clin Pediatr (Phila)* 1967; **6:** 480.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/07/04)

Porphyria. Tolbutamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for sulfonylureas in general, p.461.

Pharmacokinetics

Tolbutamide is readily absorbed from the gastrointestinal tract and is extensively bound to plasma proteins; the half-life is generally within the range of 4 to 7 hours but may be considerably longer. Tolbutamide is metabolised in the liver by hydroxylation mediated by the cytochrome P450 isoenzyme CYP2C9. It is excreted in the urine chiefly as metabolites with little hypoglycaemic activity. Tolbutamide has been detected in breast milk.

Uses and Administration

Tolbutamide is a sulfonylurea antidiabetic (p.460). It is given orally in the treatment of type 2 diabetes mellitus (p.431) and has a duration of action of about 10 hours.

The usual initial dose in type 2 diabetes mellitus may range from 1 to 2 g daily, given either as a single dose with breakfast or, more usually, in divided doses. Maintenance doses usually range from 0.25 to 2 g daily. Although it is unlikely that the response will be improved by increasing the dose further, daily doses of 3 g have been given.

Tolbutamide sodium ($C_{12}H_{17}N_2NaO_3S$ = 292.3) has sometimes been used in the diagnosis of insulinoma as well as other pancreatic disorders including diabetes mellitus. The equivalent of 1 g of tolbutamide is given by intravenous injection as a 5% solution usually over 2 to 3 minutes. Tolbutamide sodium 1.08 g is equivalent to about 1 g of tolbutamide.

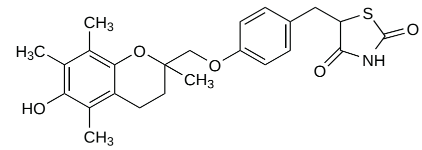
ATC Vet — QA10BG01.



Adverse Effects and Precautions

Troglitazone has been associated with severe hepatic reactions, sometimes fatal, which has led to its withdrawal in most countries. Regular monitoring of liver function during therapy, and withdrawal of the drug in any patient who develops jaundice or signs of liver dysfunction, is required. It should not be given to patients with pre-existing moderate or severe elevations of liver enzyme values, or active liver disease. Increased plasma volume has been reported in healthy subjects given troglitazone: it should be used with caution in patients with heart failure. Other adverse effects reported in patients receiving troglitazone include dizziness, headache, fatigue, musculoskeletal pain, and nausea and vomiting. There is no evidence of hypoglycaemia associated with the use of troglitazone alone.

Effects on the liver. The UK CSM[1] was aware of over 130 cases of hepatic reactions to troglitazone worldwide as of December 1997, although only 1 had been in the UK. There had been 6 deaths. The average time to the onset of the reaction was 3 months, but the frequency of these reactions, and the existence of risk factors predisposing to them, were unclear. The manufacturers had voluntarily withdrawn the drug in the UK.

The US manufacturer and the FDA recommended[2] a schedule for routine monitoring of liver function in November 1997 and revised this again in December 1997. It was estimated that 2% of patients treated with troglitazone would have elevated liver enzyme values necessitating discontinuation of the drug. The FDA[3] had received 560 reports of troglitazone-associated hepatotoxicity by June 1998. There were 24 cases of hepatic failure which were likely to have been caused by the drug; 21 patients died and 3 patients received transplants. More intensive liver function monitoring recommendations were made by the US manufacturer again in July 1998 and in June 1999. Subsequently the manufacturer withdrew the drug in Australia, Japan, and the USA in March 2000. The clinical details of 94 cases of liver failure associated with troglitazone, which were reported to the FDA, have been reviewed.[4]

Interactions

Troglitazone may enhance the hypoglycaemic effects of sulfonylureas; dosage adjustment may be necessary. There is a possibility that troglitazone may enhance the metabolism of drugs metabolised by cytochrome P450 isoenzyme CYP3A4, including some oral contraceptives and terfenadine.

Ciclosporin. For the effect of troglitazone on blood concentrations of ciclosporin see Hypoglycaemic Drugs, p.1828.

Colestyramine. Colestyramine markedly impaired the absorption of troglitazone.[1]

Pharmacokinetics

Troglitazone is rapidly absorbed after oral doses, with peak plasma concentrations 1 to 3 hours after a dose. Bioavailability is about 53%; absorption is markedly increased in the presence of food. In the body, troglitazone is more than 99% bound to plasma albumin. It is extensively metabolised in the liver and excreted largely in faeces as metabolites; small amounts of metabolites are excreted in urine. Plasma elimination half-life ranges from 10 to 39 hours.

Uses and Administration

Troglitazone is a thiazolidinedione oral antidiabetic (see Rosiglitazone Maleate, p.458). It has been given orally for the treatment of type 2 diabetes mellitus (p.431) although as mentioned above it has been withdrawn in most countries owing to hepatotoxicity.

Preparations

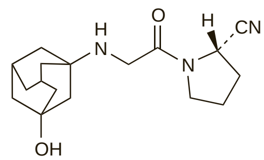
Proprietary Preparations (details are given in Part 3)
Mex.: Rezulin†.

Vildagliptin *(rINN)*

LAF-237; NVP-LAF-237; Vildagliptina; Vildagliptine; Vildagliptinum. (2*S*)-{[(3-Hydroxyadamantan-1-yl)amino]acetyl}pyrrolidine-2-carbonitrile.

Вильдаглиптин

$C_{17}H_{25}N_3O_2$ = 303.4.
CAS — 274901-16-5.
ATC — A10BH02.
ATC Vet — QA10BH02.



Profile

Vildagliptin is an inhibitor of the enzyme dipeptidylpeptidase-4, an enzyme responsible, among other roles, for the degradation of the incretin hormone glucagon-like peptide-1 (GLP-1; insulinotropin), which plays a role in regulating insulin secretion. Vildagliptin is used in the treatment of type 2 diabetes mellitus (p.431); it may be added to metformin, a sulfonylurea, or a thiazolidinedione, when monotherapy with these is insufficient. It is given orally in a dose of 50 mg twice daily when given with metformin or a thiazolidinedione, and in a dose of 50 mg once daily in the morning when given with a sulfonylurea. A total daily dose of more than 100 mg of vildagliptin is not recommended, and in patients taking a combination of vildagliptin with a sulfonylurea, a dose of vildagliptin 100 mg daily is no more effective than vildagliptin 50 mg daily. Vildagliptin may be given with or without food.

Adverse effects of vildagliptin may include dizziness, headache, peripheral oedema, constipation, nasopharyngitis, upper respiratory-tract infection, and arthralgia. Rare cases of hepatic dysfunction, including hepatitis, have been reported. Vildagliptin should not be used in patients with hepatic impairment; liver function should be tested before starting the drug, and monitored during therapy (every 3 months in the first year and periodically thereafter). Vildagliptin should be stopped if there is a persistent increase of 3 or more times the upper limit of normal in alanine aminotransferase (ALT) or aspartate aminotransferase (AST), or if the patient develops jaundice or other signs of liver dysfunction; in such cases, it should not be restarted.

This chapter describes drugs whose chief use is in the management of epilepsy, status epilepticus, and other convulsive disorders.

Epilepsy

Epilepsy is a common neurological disorder. An individual's lifetime risk of developing epilepsy is between 3 and 5%; neonates, children, and the elderly are at the highest risk of developing the disorder.

Definitions and classification. An epileptic seizure has been defined as a paroxysmal discharge of cerebral neurones accompanied by clinical phenomena apparent to the patient or to an observer. The phenomena can be motor, sensory, or autonomic and there may also be impairment or complete loss of consciousness. Motor disturbances may include convulsions—which are involuntary, violent, and spasmodic—or prolonged contraction of skeletal muscles. The word 'fit' is often used colloquially to describe an epileptic seizure. Epilepsy is defined as a condition characterised by a recurrence of such seizures. A patient should not be described as having epilepsy until a second non-febrile seizure occurs.

The following is a broad account of the classification of seizures, epilepsies, and epileptic syndromes based on the views of the International League Against Epilepsy (ILAE) in 1981[1] and 1989.[2] A later proposed revision of the classification[3] does not yet seem to have been widely adopted.

- **Partial seizures** or **focal seizures** (localisation-related seizures) are epileptic seizures in which the initial neuronal discharges are localised in one area of the brain. The phenomena associated with such a seizure depend on the site of origin of the discharge. If there is no loss of consciousness, the seizure has been known as a *simple partial seizure* and includes Jacksonian epilepsy, which may be associated with motor or sensory disturbances. If there is impaired consciousness the seizure has been referred to as a *complex partial seizure*. Partial seizures were formerly referred to as psychomotor epilepsy or temporal lobe epilepsy, but the terms are not synonymous and should be avoided. Partial seizures may become *secondarily generalised seizures* if the neuronal discharge spreads to involve the entire brain
- **Generalised seizures** are characterised by neuronal discharges involving both cerebral hemispheres simultaneously from the outset. Subclassifications are based on the presence or absence of different types of convulsions.

  Absences (petit mal) are generalised seizures, usually occurring in children, characterised by a sudden loss of consciousness lasting for a few seconds. There is usually accompanying motor activity which may vary in degree from eyelid blinking to more extensive clonic body movements. *Atypical absence seizures* are those with a slower onset and longer duration.

  Myoclonic seizures are epileptic seizures in which the motor manifestation is myoclonus (see below).

  Clonic seizures are characterised by loss of consciousness, autonomic symptoms, and rhythmic clonic contractions of all muscles.

  Tonic seizures are also associated with loss of consciousness and autonomic symptoms accompanied by tonic contractions of the limbs. *Tonic-clonic seizures* (grand mal) are characterised by disordered contraction of muscles. During the tonic phase, all the muscles go into spasm followed up to a minute later by rhythmic clonic contractions. Finally, the patient enters a deep stupor followed by a period of confusion as consciousness is regained.

  Atonic seizures are characterised by loss of postural tone; the head sags or the patient falls down.

Within the categories of partial and generalised epilepsies, seizures have also been classified as **idiopathic, symptomatic** (in which the seizures are associated with diagnosable underlying disorders), or **cryptogenic** or **probably symptomatic** (in which the epilepsies are known or suspected to be symptomatic but the cause is not clear).

Partial **syndromes** include Rolandic and occipital epilepsies (both idiopathic), while generalised idiopathic syndromes include childhood absence epilepsies, juvenile myoclonic epilepsy, and the cryptogenic or symptomatic generalised syndromes include infantile spasms (as for example in West's syndrome), Lennox-Gastaut syndrome, and epilepsy with myoclonic absences. A third unclassified category covers undetermined epilepsies and epileptic syndromes. **Special syndromes** include conditions such as febrile convulsions (see below) in which seizures are related to specific situations.

It has been suggested that classification based on seizure type is the most useful in choice of antiepileptic drug whereas the syndrome classification has more benefits in deciding an overall therapeutic strategy and assessing long-term prognosis.

Status epilepticus has previously been defined as a seizure lasting more than 30 minutes or several distinct episodes without restoration of consciousness in between (but see below).

Other convulsive disorders include alcohol withdrawal syndrome, eclampsia and pre-eclampsia, myoclonus, neonatal seizures, and porphyria, and are discussed below.

Starting antiepileptic therapy. A single seizure does not constitute epilepsy and therefore does not necessarily warrant immediate treatment with antiepileptics. The decision to start antiepileptic therapy should be based on whether the risks of further seizures outweigh the risks of treatment.

- Starting antiepileptic therapy *too early* means that the patient may be unnecessarily exposed to the adverse effects of the drugs used, and may have social implications if erroneously diagnosed, such as the loss of a patient's driving licence
- However, the implications of *delaying* treatment must also be considered. Although there has long been concern that seizures may damage the brain and intellectual capabilities, or even cause death, there are insufficient data to support these claims. Status epilepticus, rather than individual or frequent seizures, may be the factor associated with brain injury or death, but the risks of a newly diagnosed epileptic patient developing status epilepticus are unknown. The most compelling reasons for treatment are risk of personal injury or causing injury to others during a seizure, and the psychosocial consequences of untreated epilepsy such as low self-esteem, anxiety, and domestic and employment difficulties

There has been a long-held belief that seizures beget seizures. This is not necessarily borne out by epidemiological studies,[4] and there is evidence in children[5] and adults[6] that the risk of recurrence after a first unprovoked seizure may be 50% or less. Furthermore, a decelerating disease process with successively longer intervals between seizures has been shown[7] in untreated children with newly diagnosed tonic-clonic seizures followed up for 2 years. Results from another study[8] suggested that seizure control or the prospects for and success of eventual withdrawal of therapy is little influenced by the number of pretreatment seizures up to 10 seizures; above this number there was a reduced chance of completely controlling seizures. Similarly, although patients treated immediately after a first seizure have a lower 2-year risk of recurrence than patients whose treatment is deferred, immediate treatment does not affect the probability of achieving longer-term seizure control.[6,9,10]

However, epilepsy is a heterogeneous disorder and there is some experimental evidence[11] that certain seizure types can have a detrimental effect on prognosis. Differences in reported risks in seizure recurrence may be attributable to differences in methodology as well as different important risk factors in the populations studied; also, few studies have followed up patients for more than 2 to 4 years.

Whether antiepileptic therapy should be started early to improve prognosis or delayed or avoided altogether therefore remains contentious.[12-14] Some neurologists do not advise treatment of a first seizure but prefer to wait for evidence of recurrence unless clinical features such as more than one seizure type or a neurological deficit predispose to poor seizure control. However, a first non-convulsive seizure may go undetected.[14] Furthermore, as single partial seizures appear to occur less frequently than single generalised tonic-clonic seizures, many neurologists assume that the first detected attack of a non-convulsive seizure is in fact one of multiple seizures and begin treatment. UK guidelines[15,16] suggest that antiepileptic therapy should be offered to patients after a first tonic-clonic seizure if a previous myoclonic, absence, or partial seizure has occurred, if the EEG shows unequivocal epileptic discharges, if congenital neurological deficits are present, or if the risk of recurrence is unacceptable to the patient.

Choice of antiepileptic. Once a decision to treat has been made, the choice of antiepileptic is determined mainly by its effectiveness against the type of seizures experienced and its potential adverse effects.[15-28]

In recent years many newer drugs have been licensed and added to the classical treatments for epilepsy. The role of these drugs relative to the classical agents is only slowly becoming established, and evidence of relative efficacy on which to base a choice is limited. Many new drugs have been promoted on the basis of superior tolerance and quality of life for epileptic patients, but even this is not always well established, and will, in any case, vary from patient to patient, as individuals will differ in the symptoms they find intolerable. In consequence, guidelines have often reserved their use for situations in which the older drugs are less suitable.

Certain principles of management are, however, well established.

- monotherapy is preferable to a multiple-drug regimen and treatment is therefore begun with a single drug, increasing the dose gradually until seizures are brought under control or adverse effects become unacceptable
- if treatment with the first drug fails, it is preferable to try alternative single first-line antiepileptics before giving combinations of drugs. It has been suggested that for practical purposes a patient should be considered to have refractory epilepsy if seizure control is not obtained with consecutive trials of 2 well tolerated antiepileptics[26]
- the change-over from one antiepileptic to another should be made cautiously, withdrawing the first drug only when the new regimen has been largely established
- if combinations are necessary in intractable cases, regimens should avoid the inclusion, where possible, of sedating drugs such as the barbiturates or benzodiazepines
- drugs with different modes of action should be selected for combined therapy, to reduce the risk that adverse effects will be additive
- many antiepileptics interact with each other through complex mechanisms and dosage adjustments may be necessary to maintain plasma concentrations within the therapeutic range; plasma monitoring may be advisable with combination therapy. (UK guidelines[16] recommend regular monitoring of antiepileptic drug concentrations only when clinically indicated, e.g. to manage pharmacokinetic interactions, or in cases of suspected toxicity or non-adherence)
- if trials of combination therapy do not produce worthwhile benefits, treatment should revert to the regimen (monotherapy or combination) that has provided the most acceptable balance of seizure control and adverse effects

Around 60% of patients with newly diagnosed epilepsy will respond to monotherapy with the first- or second-choice antiepileptic without developing intolerable adverse effects. The remaining 30 to 40% will have epilepsy that is difficult to control from the start, although some of these patients will respond to combination therapy.[26] Patients who fail to respond to adequate medical treatment may be considered for resective surgery; vagus nerve stimulation by means of an implanted device has also proved effective in those with severe intractable epilepsy who experience an aura before the onset of a seizure.[17,18] UK guidelines recommend consideration of the adjunctive use of vagus nerve stimulation in patients refractory to drug therapy but unsuitable for resective surgery.[15,16]

Partial seizures with or without **secondary generalisation** may be treated with *carbamazepine* or *valproate*, or with the newer drugs *lamotrigine* or *oxcarbazepine*.[15,16,29] *Topiramate* is also used, as monotherapy or as an adjunct to other treatments (in the UK, it is considered a first-line option in some circumstances[16,22]). Other second-line drugs are *phenytoin*, *clobazam*, or the newer antiepileptics *gabapentin*, *levetiracetam*, *tiagabine*, or *zonisamide*,[16,23,29] but whether these are recommended for monotherapy or adjunctive treatment may vary from country to country. Other drugs that have been used[16] include *acetazolamide*, *clonazepam*, and the barbiturates *phenobarbital* or *primidone*, although the latter in particular are little used now because of the problems of sedation. *Vigabatrin* is licensed in the UK for adjunctive use in patients in whom all other combinations have failed.

The response rate is somewhat lower for partial seizures than for tonic-clonic seizures associated with primary generalised epilepsy (see below). There is some evidence in favour of carbamazepine rather than valproate in the treatment of partial seizures.[30] More recently, some evidence was found in favour of lamotrigine rather than carbamazepine,[31,32] and of oxcarbazepine rather than phenytoin,[33] in terms of tolerability and time to treatment failure. However, there is no evidence of any significant difference between phenytoin and carbamazepine[34] or valproate[35] in partial seizures.

Calcium-channel blockers such as *flunarizine* have been studied with equivocal results in patients with refractory epilepsy, particularly those with partial seizures.[36]

The drugs used most often to treat **generalised** tonic-clonic seizures are *carbamazepine*, *lamotrigine*, or *valproate*. For tonic-clonic seizures as part of the syndrome of primary generalised epilepsy, valproate is the drug of choice, although systematic reviews were unable to establish evidence for this.[30,35] *Topiramate* is also considered a first choice in patients in whom the other older drugs are unsuitable or ineffective.[16,22] More recently, valproate was found to be better tolerated than topiramate and more effective than lamotrigine in generalised and unclassified epilepsy.[37] Second-line drugs in UK guidelines are *clobazam*, *levetiracetam*, and *oxcarbazepine*, while other drugs that may be considered include *acetazolamide*, *clonazepam*, *phenobarbital*, *phenytoin*, or *primidone*.[16] *Tiagabine* or *vigabatrin* should be avoided as they may worsen the seizures.[16]

The drugs of choice for **absence seizures** are *ethosuximide*, *valproate*, or, where these are unsuitable, *lamotrigine*,[16,23,38] although the evidence base to support this use is weak.[39] Second-choice drugs include *clobazam*, *clonazepam*, and *topiramate*, but *carbamazepine*, *gabapentin*, *oxcarbazepine*, *phenytoin*, *tiagabine*, and *vigabatrin* should be avoided as they may worsen seizures.[16,38] Since absence seizures occur primarily in children the precautions concerning valproate hepatotoxicity apply. However, where absence seizures are associated with tonic-clonic seizures valproate is the drug of choice since it is effective in both conditions; valproate is also preferred for atypical absence seizures. *Levetiracetam* may be used as an alternative for the syndrome of juvenile absence epilepsy.[16]

Valproate is normally the drug of choice for **myoclonic seizures**, including those associated with juvenile myoclonic epilepsy.[40,41] *Lamotrigine* may also be used in juvenile myoclonic epilepsy,[16,41] although some forms of myoclonus may be exacerbated;[16,40] *topiramate* may be considered, particularly for severe myoclonic epilepsy of infancy (in which *stiripentol* may also be effective), and second-line drugs also include *clobazam* and *clonazepam*, and adjunctive *levetiracetam* or *piracetam*.[16] *Zonisamide*[41] has also been used, as has *ethosuximide*.

The classical antiepileptics may not be particularly effective for **atonic** or **tonic** seizures, which are often associated with specific epileptic syndromes or with cerebral damage or mental retardation. UK guidelines suggest *valproate* or *lamotrigine* as first-line drugs; *clobazam*, *clonazepam*, *levetiracetam*, or *topiramate* are possible second-line drugs, and others that have been tried include *acetazolamide* and the barbiturates such as *phenobarbital*, while *phenytoin* may be considered for tonic seizures.[16]

In **catamenial epilepsy** (epilepsy associated with menstruation) seizures can be predicted and intermittent therapy with *clobazam* may be useful. Hormonal manipulation has also been tried using *progestogens*, *gonadorelin analogues*, and *clomifene*.[42]

The **Lennox-Gastaut syndrome** begins in early childhood and is particularly difficult to treat because multiple seizure types co-exist; seizures rarely remit entirely. *Valproate* is most frequently used[43] because of its broad spectrum of activity; UK guidelines consider *lamotrigine* or *topiramate* as alternative first-line drugs if valproate is unsuitable; second-line choices include *clobazam*, *clonazepam*, *ethosuximide*, or *levetiracetam*.[16] *Felbamate* has also been used. The optimum treatment remains uncertain, but monotherapy with any drug has not been shown to be particularly effective.[44]

The classical antiepileptics are often ineffective in **infantile spasms** (as for example in **West's syndrome**).[45] UK guidelines recommend treatment with *corticotropin* or a *corticosteroid*, or else with *vigabatrin*;[16] in the USA, however, the American Academy of Neurology considers that the evidence does not support the use of corticosteroids, although corticotropin or vigabatrin appear to be of benefit.[46] *Vigabatrin* is effective either as adjunctive treatment or monotherapy. Many consider that, despite the risk of visual field defects,[47] it should replace corticotropin or corticosteroids as the treatment of choice,[48-54] although others disagree.[55,56] However, vigabatrin may offer the best first option in the treatment of infantile spasms due to tuberous sclerosis.[54,57,58] In some countries, *valproate*, alone or with *clonazepam* and/or *pyridoxine*, has been tried for initial management of infantile spasms.[59] Other second-line drugs include *clobazam* and *topiramate*;[16] *nitrazepam*,[16,48] *felbamate*,[45,60] and *lamotrigine*[45,60] have also been used. It is unclear to what extent treatment improves long-term outcome.[38,46,58]

Choice of antiepileptics in children. The use of antiepileptics in general in children has been reviewed.[38,60-67] Again, appropriate treatment depends on seizure type, but there is a lack of evidence to support many therapeutic choices,[62,67-69] in part because of the difficulties in undertaking studies in this population. In addition, children may be particularly susceptible to some adverse effects, including effects on behaviour, cognition, and development; behavioural problems have been associated particularly with phenobarbital.[67,70] Nonetheless the principles of pharmacological management are similar to those in adults (above) although UK guidelines recommend that treatment should only be begun by a specialist.[16] Dietary modification (the ketogenic diet) may also be tried.[67,71-74]

Withdrawal of antiepileptic therapy. Concern over the potential adverse effects of antiepileptic therapy clearly makes withdrawal attractive in patients who achieve prolonged seizure-free periods; however, the practical and social consequences of seizure recurrence may be considerable (for example, loss of driving licence and restricted employment prospects). The incidence of relapse after withdrawal has been variously estimated to range from 12% to over 60%.[75,76] Many studies have been carried out in children; data in adults is more scanty and given the differences between the populations, extrapolation of results in children to adults may be invalid.[75] A meta-analysis[77] that included 25 studies and 5354 patients (children and adults) found the overall rate of relapse in seizure-free patients after stopping antiepileptic therapy was 25% at 1 year and 29% at 2 years. There was a higher risk for relapse in adolescent- and adult-onset epilepsy compared with childhood-onset epilepsy. A more recent longitudinal population-based study[78] following 148 patients long-term from the onset of epilepsy in childhood found that of 90 patients in whom antiepileptic therapy was stopped, 33 relapsed and although in most cases relapse took place within 3 years, in one case it occurred 28 years after withdrawal.

Although these findings indicate that it is often possible to withdraw therapy successfully, it is more difficult to offer an individual *prognosis*. It has been suggested that adult patients whose livelihood or lifestyle depends on being seizure-free would be generally ill advised to contemplate drug withdrawal.[79] Several strategies for predicting the likely outcome after withdrawal of antiepileptic therapy in individuals have been published.[80-82] Recognising that epilepsy is a heterogeneous disorder, scoring systems to allow for various risk factors have been devised.[80,81]

Prognostic risk factors (some of which are likely to be surrogate measures for the underlying condition) may include:

- the *aetiology* of the condition.[75,83] Patients classified as having symptomatic or cryptogenic epilepsy generally fare less well than those with idiopathic epilepsy with regard to seizure control, and withdrawal is less likely to be successful
- the *seizure type* and *syndrome*.[75,76,83] A number of studies have identified an increased risk of relapse in patients with particular seizure types; in particular, patients with partial, generalised tonic-clonic, and mixed seizure types seem to be at increased risk. However, it has been pointed out that increased risk has been associated with almost all seizure types other than generalised absence seizures, which seem to have a favourable prognosis; the context in which the seizure arises, such as the associated epilepsy syndrome and the aetiology, is more important than the type alone when considering withdrawal.[75] Examples of syndromes associated with a favourable outcome for withdrawal include benign childhood epilepsy with centrotemporal spikes, childhood absence epilepsy, and benign neonatal convulsions. However, withdrawal is inappropriate in juvenile myoclonic epilepsy, despite its good response to treatment, as relapse occurs in over 90% of patients
- the presence of accompanying *neurological* or *mental deficits*.[75] Some studies have suggested that mental retardation or other neurological deficits are associated with a poorer prognosis on withdrawal; these are probably surrogate markers for symptomatic epilepsy. However, mental retardation is not a contra-indication to withdrawal, and these patients may benefit from the elimination of any sedative effects if other risk factors are absent[75]
- the *age at onset*.[75,76,83] Several studies have identified a markedly increased risk of relapse on withdrawal in patients with seizure onset in adolescence or adulthood, whereas those with onset before 10 to 12 years of age have a generally more favourable prognosis. This is probably a surrogate marker for particular epileptic syndromes or aetiologies
- the *duration of remission*.[75,76,83,84] There is evidence in children that waiting for at least 2 seizure-free years before attempting withdrawal is associated with less risk of relapse than doing so earlier. However, the 2-year period was chosen arbitrarily, and the true optimum timing is unknown.[84] There is little evidence to guide the timing of withdrawal in adults.[84] However, in practice most support a requirement of at least 2 years free from seizures before drug withdrawal[75,76,83]
- the *response to therapy*.[75] Refractory epilepsy, as indicated by the occurrence of seizures once therapy has been begun, or the need for adjunctive or combination therapy to control seizures, is a poor prognostic sign for withdrawal. Patients with a history of multiple seizures before beginning therapy are also at increased risk on withdrawal

There is less agreement about the prognostic significance of some other factors:

- it is unclear whether the *type of drug* used to control seizures affects the risk of recurrence on withdrawal. It has been suggested that patients taking phenobarbital or benzodiazepines may be at increased risk of relapse, but there is little supportive evidence.[75] A poorer prognosis for patients taking valproate has also been reported;[85] a study in patients given combination therapy noted an increased risk when the carbamazepine component of the regimen was withdrawn.[86] It should be borne in mind that withdrawal of an enzyme-inducing antiepileptic may alter the serum concentrations of other drugs in the regimen[87]
- there is also controversy about the prognostic value of the *EEG* for the success of withdrawal.[75-77,83] Although an abnormal EEG before withdrawal was a negative prognostic factor in many studies, EEG abnormalities are not present in all epileptic patients, and some antiepileptic drugs suppress EEG abnormalities and can lead to false-negative results[75]

When a decision to withdraw is made, it is agreed that the *withdrawal regimen* should be gradual to reduce the risk of provoking withdrawal seizures. Drugs should be withdrawn one at a time but there is no agreement on the order or the optimum rate of withdrawal for individual drugs. It has been suggested that tapering therapy over less than 6 months increases the relapse rate.[75] However, one study in children indicated no significant difference in seizure recurrence rate when various antiepileptics, including barbiturates, were withdrawn over 6 weeks or 9 months.[88] Nonetheless, it has been pointed out that relapses tended to occur earlier in the group tapered more rapidly, and in practice it is rarely necessary to withdraw medication more rapidly than over a 6-month period.[75] It may be possible to withdraw phenytoin or valproate quickly (over a few days in hospital) if necessary.

If seizures recur on withdrawal it is almost always possible to restore good control by *re-instituting therapy*, and morbidity, mortality, and incidence of status epilepticus are reported to be low in the setting of prescribed antiepileptic drug withdrawal.[75] However, in a very small number of patients intractable seizures may develop.[89]

Epilepsy and breast feeding. Antiepileptics are generally distributed into breast milk (although this information is not always known for the newer ones), but for most of the older established drugs, the concentrations are lower than in maternal plasma, and breast feeding is considered to be safe for these antiepileptics when given in usual doses.[1-9] The American Academy of Pediatrics[10] also considers that most of the older antiepileptics, specifically *carbamazepine*, *ethosuximide*, *phenytoin*, and *valproate*, are usually compatible with breast feeding; however, they also recommend that *phenobarbital* and *primidone* should be used with caution as significant adverse effects have occurred in nursing infants. Problems of neonatal sedation may occur with the *benzodiazepines* and *barbiturates* (including primidone).[1] Ethosuximide is distributed in significant amounts into breast milk; hyperexcitability and poor suckling have been reported in the infant. There is little data for the new antiepileptics regarding breast feeding (the manufacturers and the UK Drugs in Lactation Advisory Service[11] generally recommend that breast feeding should be avoided). *Lamotrigine* may accumulate in breast-fed infants, as the metabolic pathway for lamotrigine may not be fully developed in newborns;[5,12] the American Academy of Pediatrics[10] considers that the use of lamotrigine during breast feeding may be of concern. *Gabapentin*,[13] *levetiracetam*,[14] and *topiramate*[15] are transferred into breast milk in significant amounts, but serum concentrations in breast-fed infants are very low.

Epilepsy, cognition, and mood. Patients with epilepsy are at increased risk of **cognitive** and **behavioural** deficits. These are often multifactorial in origin: the disease itself and its underlying pathology, psychosocial and environmental factors, and the effects of antiepileptic treatment may all play a role.[1-8] Children are particularly vulnerable: recurrent seizures in the immature brain appear to have an adverse effect on the development of brain structure and function;[8] furthermore, behavioural and cognitive deficits may not be detected for a long time, while imposing detrimental effects on development and learning.[4,6] Because of the multifactorial nature of the problem, and the difficulties of assessing often subtle changes in cognition, it has proved difficult to study appropriately, and evidence is often scanty. Many studies have been small, and have had methodological flaws.[4,6] In addition, there is a need for studies in patient populations at greater risk, such as children.[5,6]

There is particular interest in assessing the risks associated with antiepileptic treatment, since it is perhaps the most readily modifiable factor. Strategies such as avoiding unnecessary polytherapy, using the lowest effective dose of an antiepileptic, keeping drug concentrations in therapeutic ranges, and slow titration when doses are increased, have been associated with fewer cognitive adverse effects. However, it should also be borne in mind that appropriate treatment and good seizure control may offset the negative cognitive effects.[4] (There is an interesting suggestion that suppression of interictal discharges in the EEG with lamotrigine may be associated with an improvement in behaviour in children with epilepsy and behavioural problems.[9])

The most common cognitive effects seem to be sedation, somnolence, distractibility, memory impairment, insomnia, and dizziness; adult patients often experience depression (below), whereas in children hyperactivity and aggression may occur.[5] More subtle effects on cognitive function and neuropsychological variables also occur. It has proved difficult, for the reasons mentioned above, to establish the comparative severity of cognitive effects between different antiepileptics. However, it seems to be generally agreed that barbiturate antiepileptics such as *phenobarbital*, and (particularly in the elderly) benzodiazepines such as *clobazam* and *clonazepam*, have the worst profiles, including decreased arousal and deterioration in most areas of cognitive performance;[4] in children, phenobarbital may decrease IQ and impair academic achievement.[5-7] Other standard antiepileptics such as *phenytoin*, *carbamazepine*, and *valproate* seem to have more modest, and broadly comparable, effects.[2,4-6] Most of the newer antiepileptics appear to be better tolerated; however, *topiramate*, and to some extent *zonisamide*, do produce impairment. There is also limited evidence that *gabapentin*, *lamotrigine*, and *vigabatrin* may enhance cognitive function. However, further data are required for the newer antiepileptics before a definitive assessment can be made.[1-7]

In view of the potential effect of antiepileptics on cognition, the recommendations of the Committee on Drugs of the American Academy of Pediatrics[10] include:

- the relative influence of each antiepileptic on cognitive and behavioural function should be considered along with all other potential adverse effects
- the child's behaviour and academic progress should be monitored through routine questioning of parents and teachers as well as by the physician's own observations of cognitive function, mood, and behaviour
- should behavioural or cognitive changes occur in relation to starting antiepileptic therapy, the need for medication and/or possible alteration of medication must be reassessed

For comment on the potential effects of maternal antiepileptic therapy on fetal neurodevelopment, see Epilepsy and Pregnancy, below.

Epilepsy is also associated with a greater prevalence of mood disorders, particularly **depression**, than is seen in the general population.[11-14] There have been concerns that antiepileptic drugs may play a significant role in exacerbating these. A review[15] has suggested that the commoner antiepileptics could be classified by the risk of associated depression as follows:

- highest risk (about 10% of patients):
  - barbiturate antiepileptics such as phenobarbital
  - topiramate
  - vigabatrin
  - zonisamide (associated with mood disorders in about 7% of those taking high doses)
- intermediate risk (4% or less):
  - felbamate
  - levetiracetam
  - tiagabine
- lower risk (less than 1%; some might actually have positive effects on mood):
  - carbamazepine
  - ethosuximide
  - gabapentin
  - lamotrigine
  - oxcarbazepine
  - phenytoin
  - pregabalin
  - valproate

In January 2008, the FDA issued an alert[16] after analysis of 199 placebo-controlled studies of antiepileptic drugs in the management of not only epilepsy but also psychiatric disorders (including bipolar disorder and depression) and other conditions such as migraine and neuropathic pain. This analysis, which involved 27 863 drug-treated patients and 16 029 controls, found that the risk of suicidal ideation or behaviour was about twice as great in the drug treatment groups (0.43%) as in those given placebo (0.22%). The relative risk was greater in patients with epilepsy than in those with other disorders. Drugs implicated by this analysis were carbamazepine, felbamate, gabapentin, lamotrigine, levetiracetam, oxcarbazepine, pregabalin, tiagabine, topiramate, valproate, and zonisamide. However, the FDA considered that the increased risk was a class effect that would be shared by *all* antiepileptics. It was recommended that prescribers and patients and their families should be aware of the risk, and should be alert for behavioural changes and other warning signs that might signal suicidal ideation. Similar advice has been issued in the EU.[17]

Epilepsy and driving. Driving by patients with epilepsy is generally regulated[1,2] and restricted to those whose seizures are adequately controlled. Also, antiepileptic drugs may produce CNS-related adverse effects, including dizziness and drowsiness, that could impair a patient's ability to drive a vehicle or operate machinery, particularly during the initial stages of therapy.

In the UK,[3] patients suffering from epilepsy may drive a motor vehicle (but not a heavy goods or public service vehicle) provided that they have had a seizure-free period of 1 year, or, if subject to attacks only while asleep, have established a 3-year period without awake attacks. It is recommended that patients should not drive during withdrawal of antiepileptic drugs, or for 6 months afterwards.

Epilepsy and pregnancy. The management of epilepsy during pregnancy may present problems for both the mother and the fetus.[1-9]

The outcome of pregnancy in women with epilepsy is generally recognised to be poorer than that in the general population. Still-births and neonatal loss are increased, and maternal deaths are more common;[5,7] there is also an increased incidence of preterm delivery and low birth-weight at term.[6] In addition, there is a clearly increased risk of fetal malformation. The factors responsible for this poorer outcome are complex, and may include the disease itself, seizure frequency during pregnancy, and socio-economic factors, as well as the effects of antiepileptic drugs.[1-3,5-7,10-12]

A single generalised seizure does not usually pose clinical problems for the fetus, but both mother and fetus are at risk of serious trauma from maternal falls, and intra-uterine deaths have been reported. It is widely considered that status epilepticus is associated with significant mortality in mother and fetus.

The frequency of seizures may increase during pregnancy in some women; this might be related to hormonal or other factors such as lack of sleep, but one of the main reasons is likely to be decreased plasma-antiepileptic concentrations due to changes in drug clearance and binding as pregnancy progresses (and some[13,14] have recommended therapeutic drug monitoring in at-risk patients). However, analysis[15] of 1956 pregnancies of 1882 epileptic women recorded in an international antiepileptic drugs and pregnancy registry (EURAP) found that 58.3% were seizure-free throughout pregnancy. Seizures occurred during delivery in 3.5%, most commonly in those who had seizures earlier during pregnancy, and status epilepticus occurred in 1.8%, with one case of still-birth and none of miscarriage or maternal mortality. The authors noted that publication bias favoured the reporting of adverse outcomes in pregnancy.

As with many other aspects of epilepsy, it is difficult to disentangle the potential adverse effects of therapy from those of the disease. However, although the risk of **major malformations** such as congenital heart defects, neural tube defects, urogenital defects, and orofacial clefts is somewhat increased in offspring of all women with epilepsy,[3,7] there is clear evidence that in children of women treated with antiepileptic drugs it is 2 to 3 times that in the general population, and the risk is higher in women taking multiple drugs or in those who take antiepileptics during the first trimester.[7]

Despite this, evidence linking specific drugs with particular patterns of malformation is limited and often unclear. There appears to be strong evidence for a dose-related increased risk of major malformation with *valproate*,[7,10-12,16-20] and increased risk has been reported for *carbamazepine*, *phenobarbital*, and *primidone*.[7,10,11] The rate of major abnormality with *phenytoin* does not seem to be higher than in the general population.[7] However, a well established **fetal antiepileptic syndrome** (FAS) has been reported with phenytoin, as with other antiepileptic drugs,[6] including some older drugs such as *trimethadione*. Although early reports associated syndromes with specific drugs, such as fetal hydantoin syndrome (phenytoin), or fetal valproate syndrome, there is considerable overlap in the reported effects and recent reviews consider these as manifestations of a single condition, FAS.[6,11] The dysmorphic facial changes characteristic of FAS can be quite subtle, and may become less apparent as the child grows.[7]

Evidence for any effect of the newer antiepileptics on the fetus is particularly scanty. It is unclear if *oxcarbazepine* is associated with an increased risk in major malformation,[7] and limited data have not so far suggested a significant increase in risk with *lamotrigine*[11,19,21] and *levetiracetam*.[22] There are reports suggestive of an increased risk with *topiramate*[7] and licensed product information for this drug, and also *pregabalin* and *zonisamide* advises against use in pregnancy on the basis of animal studies and lack of human data. Caution is also advised with *tiagabine* and *vigabatrin*. There appears to be little evidence of teratogenic potential for *felbamate* or *gabapentin* in *animal* studies to date, although cases of malformation have been seen in pregnancies exposed to gabapentin.[7]

In a study[23] of the UK Epilepsy and Pregnancy Register, which examined the outcome of 3607 pregnancies in mothers with epilepsy, the overall rate of major congenital malformations was 3.5% in those untreated with antiepileptics and 4.2% in those given antiepileptics during pregnancy, with rates of 3.7% and 6.0% in those given monotherapy or polytherapy respectively. For monotherapy the malformation rates for individual drugs were topiramate (7.1%), valproate (6.2%), phenytoin (3.7%), gabapentin (3.2%), lamotrigine (3.2%), and carbamazepine (2.2%). For polytherapy, those regimens containing valproate had a significantly higher risk of major congenital malformations than valproate-free combinations. For monotherapy a relationship between malformations and dose was seen for lamotrigine and although the trend with valproate dosage did not reach statistical significance infants exposed to more than 1000 mg valproate daily had the highest rate of malformations for any monotherapy. The authors also noted that for lamotrigine the risk with doses more than 200 mg daily was no different to that associated with 1000 mg or less of valproate daily.

There is evidence that antiepileptic therapy is associated with lower birth-weight at term, presumably due to drug-induced **intra-uterine growth retardation**; the effect may be seen largely in women taking multiple antiepileptic drugs.[7]

Additional problems that may occur in the immediate post-partum period include the potential for neonatal **sedation** and **dependence** with drugs such as phenobarbital or *benzodiazepines*, if given close to term. Evidence of withdrawal symptoms has also been reported in infants exposed to sodium valproate or phenytoin. Some antiepileptics induce hepatic enzymes and may also increase the risk of vitamin K deficiency and **neonatal bleeding**.[6,7]

There is also increasing concern about the possibility of long-term **impairment of neurodevelopment** in children exposed to antiepileptic drugs *in utero*.[5,7,10,11,24,25] A population-based cohort study[26] in young men with epileptic mothers found lower IQ scores and shorter adult heights than in those born to mothers without epilepsy, although information on fetal exposure to individual antiepileptic drugs was unavailable. Again, most evidence implicates valproate;[7,10,11] some consider that there is also evidence for phenytoin and carbamazepine,[7,10,11] and perhaps phenobarbital,[10] although a systematic review could not find evidence to implicate any individual antiepileptic,[24] and a study involving 182 children exposed to carbamazepine monotherapy could not find evidence of a reduction in verbal and nonverbal IQ scores.[27]

Patients with epilepsy should be offered **pre-conception advice** and treatment should be individualised.[1,3,4,6,7] Women should be advised to plan their pregnancies, and informed of the potential risks of seizures to mother and baby as well as the risks of antiepileptics;[7] fatalities have been associated with the mother stopping her antiepileptic regimen inappropriately.[5] It should be borne in mind that some antiepileptics may reduce the effectiveness of oral contraception and increase the risk of unplanned pregnancy.[6,11] Equally, there is some evidence that a degree of sexual dysfunction and impaired fertility may occur in both women[6,11] and men[28,29] with epilepsy.

In women with epilepsy who intend to become pregnant, certain guidelines and principles are widely followed.

- Withdrawal of antiepileptic therapy may be an option if the patient has been seizure-free for at least 2 years (for further details of drug withdrawal, see above); resumption of therapy may be considered after the end of the first trimester.
- If antiepileptics are to be continued throughout pregnancy, monotherapy is preferred using the lowest possible effective dose, although doses may have to be increased in response to changes in drug disposition during pregnancy, with the necessary readjustments being made after delivery.
- High daily doses of valproate (more than 1 g daily) should be avoided if possible, and peak plasma concentrations may be reduced by dividing the daily dose into 3 or 4 parts or by giving a modified-release preparation.
- Since there is a risk of fetal malformations with all the established antiepileptics, and a lack of data for the newer ones, it is generally considered that as long as there is good seizure control there is little to be gained from changing a pregnant patient's antiepileptic.

For those patients who first present when **already pregnant** there is probably little to be gained in altering potentially teratogenic antiepileptics as the time for intervention has almost certainly passed.[3,4,7] If a patient becomes pregnant while taking carbamazepine, phenytoin, or valproate she should be counselled regarding the risk of neural tube and other defects and should be offered antenatal screening. Adequate supplementation of folic acid is advised before pregnancy and during the first trimester to counteract the risk of neural tube defects; it has been suggested that women taking antiepileptics should be given folic acid in similar doses to those used in women who have previously given birth to an infant with neural tube defects (for further details, see Neural Tube Defects under Folic Acid, p.1942). Although folic acid can reduce serum-phenytoin concentrations this does not appear to be a problem in practice (see Vitamins, p.500).

To counteract the risk of neonatal bleeding associated with enzyme-inducing antiepileptics it is particularly important that the neonate be given vitamin K after delivery[6-8] (for further details, see under Vitamin K deficiency bleeding, p.1997). Some have advocated oral doses for the mother in the last 4 weeks of pregnancy,[6] but the justification of prophylactic maternal dosage has been challenged[30] in the face of available evidence.

Patients with epilepsy have also a higher risk of preterm delivery and antenatal corticosteroid therapy may, therefore, be warranted. High doses of corticosteroid may be required in those women receiving enzyme-inducing antiepileptics.[3]

Status epilepticus during pregnancy should be treated in the same way as for the general population (see below). First seizures occurring during the second half of pregnancy may be part of eclampsia (see below) and should be differentiated from epilepsy.

Status epilepticus

Although status epilepticus has been defined as continuous or repeated seizure activity lasting 30 minutes or more without any regaining of normal consciousness, current definitions generally consider it to be any continuous seizure of more than 5 minutes, or 2 or more seizures without regaining normal consciousness.[1-8] Although status may occur with any seizure type, generalised convulsive status is the most common clinical presentation,[4] with an estimated mortality rate of about 20%; it is most frequent in young children and the elderly.[2,3,9] It is a medical emergency, and the longer seizures continue, the more difficult they are to control and the higher the morbidity and mortality; permanent neuronal damage can occur after 30 minutes of seizure activity.[7]

Management of status epilepticus varies slightly between centres and countries, but the general principles seem to be fairly well established.[1-11]

- In **initial management**, it is important to secure the airway and give oxygen as required, assess cardiac and respiratory function, and establish intravenous access. Blood glucose should be assessed and any hypoglycaemia corrected with glucose; intravenous thiamine should be given if there is any suggestion of alcohol abuse or inadequate nutrition.[3-6,8,11]
- Initial antiepileptic treatment is usually with a benzodiazepine. Although *diazepam* has been widely used in the past, intravenous *lorazepam* is now preferred for first-line treatment in most protocols,[1-6,8-12] as it appears to be more effective and has a longer duration of antiepileptic action.[6,8,12] Rectal diazepam or buccal *midazolam* may be used in the home setting or where intravenous access is not available.[4,5,13] (Rectal diazepam may also have a role in this setting to treat acute repetitive seizures,[14] which may evolve into status epilepticus.) Both midazolam[15,16] and lorazepam[17] have also been given intranasally
- For sustained control in patients with established epilepsy their usual antiepileptic regimen may be given orally or by nasogastric tube once immediate control is established, or if necessary, for those drugs with an intravenous formulation, parenterally.[4,5]
- In other patients, or in patients with **established status** not abolished by the benzodiazepine, additional treatment with one of several first-line antiepileptics is normally required. The choice is usually between intravenous *phenytoin*, *fosphenytoin*, or *phenobarbital*,[3-5,7,8] all of which are effective. Repeat doses may need to be given. Although there is some evidence that phenobarbital is more effective than phenytoin in abolishing seizures,[18] many favour the use of the barbiturate only in patients who do not respond to phenytoin or fosphenytoin,[1-3,9,10] because of the risk of severe respiratory depression. ECG monitoring is required in patients given intravenous phenytoin or fosphenytoin.[4]
- Other antiepileptics have been used for established status. Some have found intravenous *valproate* to be useful in this situation,[7,19-21] and have incorporated it into local protocols. Other alternatives have included *paraldehyde* rectally or by deep intramuscular injection, and intravenous *clomethiazole edisilate* was formerly available. The *BNF* notes that rectal paraldehyde causes little

respiratory depression and may therefore be useful where facilities for resuscitation are poor. Another option is to give *lidocaine* intravenously.[3] *Pyridoxine* may be tried in children under 3 years of age with established convulsive status epilepticus, in case the seizures are pyridoxine dependent or responsive.[1]

- Once seizures have continued for 60 to 90 minutes despite treatment with a benzodiazepine and one of the first-line antiepileptics, the patient is considered to have **refractory status epilepticus**.[3,5] At this point general anaesthesia should be instituted. The usual choice is between treatment with *propofol, midazolam*, or a short-acting barbiturate anaesthetic such as *pentobarbital* or *thiopental*.[3-10,22] The anaesthetic should be continued for 12 to 24 hours after the last clinical or electrographic seizure and the dose then gradually reduced.[5] Some consider that all patients unresponsive to first-line therapy with a benzodiazepine should be considered refractory and proceed to treatment with propofol or midazolam.[6]
- Other drugs tried in refractory status include the inhalational anaesthetics *desflurane* and *isoflurane*.[23] *Tiagabine* and *ketamine* have also been suggested,[6] as has *valproate*,[7,22] and there are a few reports of responses to *levetiracetam*[24] and *topiramate*.[25-27]

Evidence to support the management of **nonconvulsive** forms of status epilepticus (NCSE) is scanty. The *BNF* recommends that usual oral antiepileptics should initially be continued or restarted in patients with incomplete loss of awareness. Otherwise, it has been suggested that management should be as for convulsive status,[6] albeit less aggressive,[28] with intravenous benzodiazepines the first choice for initial management.[4-6,11,28] Subsequent management will probably be influenced by the drugs known to be effective in the given seizure type. The prognosis depends on the aetiology and level of consciousness: comatose patients with refractory NCSE have a poorer prognosis and general anaesthesia may be appropriate.[6] Conscious patients generally have a more favourable outcome and termination of status is considered less urgent; general anaesthetics should thus be used more cautiously.[11,28]

Other convulsive disorders

Disorders that feature convulsions or epileptic seizures but are not considered to be forms of epilepsy are described below.

Alcohol withdrawal syndrome. For a discussion of the management of seizures associated with alcohol withdrawal syndrome, see p.1626.

Eclampsia and pre-eclampsia. Pre-eclampsia is a hypertensive disorder occurring in pregnancy that entails increased blood pressure together with proteinuria, and sometimes abnormal coagulation, liver dysfunction, and oedema; rarely the disorder may progress to eclampsia, which is a convulsive phase. It is difficult to identify those patients who will have eclamptic seizures. The treatment of pre-eclampsia and eclampsia is primarily aimed at reducing hypertension (see Hypertension in Pregnancy, under Hypertension, p.1171) and treating or preventing resultant seizures. However, the treatment of the hypertension alone may not be sufficient to prevent the progression of pre-eclampsia to eclampsia.

Eclampsia in the UK was traditionally **treated** with *diazepam, clomethiazole*, or *phenytoin*. *'Lytic cocktails'* consisting of chlorpromazine, pethidine, and/or promethazine have also been used in some countries in the management of pre-eclampsia and imminent eclampsia but they result in heavy sedation and the use of phenothiazines is generally not recommended late in pregnancy. *Magnesium sulfate* is now the drug of choice for the treatment of eclampsia;[1-3] it has been the preferred treatment of eclampsia in the USA for many years, on the grounds that it is more effective and causes fewer adverse effects than other antiepileptics. A meta-analysis[4] of 9 randomised studies involving 2390 patients with pre-eclampsia and 1743 patients with eclampsia concluded that magnesium sulfate was more effective than phenytoin or no therapy in prevention of seizures in pre-eclamptic patients. In eclamptic patients, magnesium sulfate was superior to phenytoin, diazepam, or a lytic cocktail in terms of seizure recurrence, a result that was confirmed in subsequent systematic reviews.[5-7]

Until recently there has been insufficient evidence to establish the benefits and hazards of antiepileptics in the **prevention** of eclampsia in pre-eclamptic patients although it was considered that magnesium sulfate was the best choice if an antiepileptic was needed.[8,9] Some commentators suggested,[10] in the light of evidence of possible neonatal toxicity, that magnesium sulfate should be restricted to use in more severe pre-eclampsia or eclampsia. However, the significant benefits of magnesium sulfate in the prevention of eclampsia were confirmed in a large, international trial,[11] and follow-up studies found that magnesium sulfate was not associated with an increased risk of death or disability in the children at 18 months[12] and in the mothers at 2 years.[13]

Febrile convulsions. Febrile convulsions have been defined[1] as epileptic seizures occurring between the ages of 6 months to 5 years and associated with a fever arising from an infectious illness outside the CNS. They usually occur during the rising phase of fever early in the course of the infection and are not considered to be a form of epilepsy.[2,3]

Febrile convulsions are considered to be benign if limited to a single tonic or tonic-clonic seizure lasting less than 15 minutes without any focal characteristics.[2] About one-third of children who have a benign febrile convulsion will have a recurrence.[1,2,4] Risk factors for recurrence include a young onset age, a history of epilepsy or febrile seizures in a first-degree relative, subsequent episodes of fever, and a first complex febrile seizure.[4] The risk of developing epilepsy is low, but nevertheless it is 2 to 3 times greater than the risk in the population as a whole.[2] Unless they are recurrent, benign febrile convulsions need only simple treatment to lower body temperature[1,2] such as that described under Fever and Hyperthermia, p.10.

Prolonged febrile convulsions lasting longer than 15 minutes and associated with some focal characteristics are not considered to be benign and further increase the risk of developing epilepsy.[2,3] When they are prolonged or recurrent they are treated with *diazepam* intravenously, or as a rectal solution, to prevent possible brain damage resulting from continued seizure activity, although any such effect appears to be rare.[5]

The prophylactic use of *antiepileptics* in children thought to be at risk of recurrence of febrile convulsions remains controversial. Many consider that even if recurrences can be prevented there is no evidence that the risk of developing epilepsy is reduced.[1,2,4] A working group of the Royal College of Physicians and the British Paediatric Association considered that pooled analyses of studies of the prophylactic use of *phenobarbital* or *sodium valproate* showed that long-term prophylaxis was rarely indicated.[1] Although some have found that intermittent prophylaxis with phenobarbital or diazepam[6] given at the onset of and during fever could prevent recurrence of febrile convulsions, the working group did not recommend their routine use in this way.[1] Other workers have found that giving paracetamol as an antipyretic and diazepam for intermittent prophylaxis failed to prevent recurrences of febrile convulsions.[7] A later meta-analysis[8] concluded that neither continuous nor intermittent prophylaxis could be recommended as the benefits did not outweigh the potential adverse effects, a view endorsed by the American Academy of Pediatrics.[9]

Myoclonus. Myoclonus consists of brief, involuntary, jerky movements of sudden onset which may be focal, segmental, or generalised, and are caused by muscular contractions (positive myoclonus) or inhibitions/pauses (negative myoclonus). The term 'myoclonus' is non-specific and classification is important in order to decide on treatment:[1-4]

- physiological (in normal subjects)
- essential (no known cause)
- epileptic (seizures dominate)
- symptomatic (encephalopathy dominates—causes include storage diseases, neurodegenerative syndromes, toxic and drug-induced syndromes, and hypoxia)

In epileptic myoclonus, epileptic seizures (myoclonic seizures in which the motor manifestation is myoclonus) dominate. Their treatment is discussed under Epilepsy, above. Essential myoclonus may benefit from *clonazepam*. *Botulinum toxin* has been used successfully for spasmodic movements in some forms of myoclonus.

Myoclonus may also be subdivided into cortical, reticular, or spinal forms. Cortical myoclonus is considered to be a subset of epilepsy and responds best to antiepileptics, usually *valproate* and/or clonazepam; *piracetam* or *levetiracetam* are also used, usually as adjunctive therapy. Reticular myoclonus is usually caused by anoxia or acute encephalopathy and may be treated with clonazepam; *serotonin* or serotonergic agonists have also been tried. Posthypoxic myoclonus occurring after hypoxic coma may respond to *oxitriptan* or serotonin combined with *carbidopa*; antiepileptics may help.

Neonatal seizures. Neonatal seizures differ from epilepsy, and the definitions in the 1989 international classification of epilepsy and epileptic syndromes (see above) may be of little value; (a study[1] has suggested that the proposed 2001 classification may be more helpful). They are frequently subtle and difficult to recognise.[2] Causes include asphyxia, glucose or electrolyte imbalance, infection, CNS or cerebrovascular lesions, inborn errors of metabolism, and drug withdrawal or intoxication.[3-5]

Neonatal seizures represent a neurological emergency in the newborn and rapid diagnosis and treatment is essential.[3-7] Infusion of glucose or electrolytes may be of benefit.[4,5] Current practice involves giving antiepileptic drugs to control seizures, although there is no consensus on, nor good evidence for, their use.[2,7] *Phenobarbital* and *phenytoin* are the most widely used.[3-6] Traditionally, phenobarbital has been considered to be the mainstay of treatment for all types of seizures in neonates; however response rates are variable.[6-8] If seizures persist, phenytoin may be added to therapy.[8] Other drugs that have been tried include *carbamazepine*, *levetiracetam*,[9] *benzodiazepines*,[3-5,8,10,11] *lidocaine*,[3,8,10] and *primidone*.[4,5] Pyridoxine-dependent seizures can be abolished by regular large doses of the vitamin[4,5] (see p.1979).

Porphyria. Convulsions may occur at the peak of an attack of acute porphyria (p.1448) but usually disappear as the attack resolves and therapy should be aimed at the underlying disease. However, some patients continue to have convulsions while in remission and their management poses a major therapeutic problem as all the first-line antiepileptics have been associated with acute attacks.[1,2] Barbiturates (*phenobarbital*, *primidone*), hydantoins *(phenytoin, ethotoin)*, and *carbamazepine* are considered unsafe, as is *sultiame*. There is limited evidence that the *benzodiazepines*, *sodium valproate*, and probably *valpromide* are porphyrinogenic but status epilepticus has been treated successfully with intravenous *diazepam*. Seizure prophylaxis may be undertaken as a calculated risk using valproate or *clonazepam* if considered essential. *Magnesium sulfate* is safe. *Clomethiazole* is also probably safe. *Gabapentin* and *vigabatrin* have each been tried in a few patients without ill-effect, although there has been a report of a bullous skin eruption in a patient with porphyria cutanea tarda given vigabatrin.[3] Of the other newer antiepileptics, *oxcarbazepine* was used successfully in one patient whilst *lamotrigine* was associated with an acute porphyric attack in another; *tiagabine* and *topiramate* have been found to increase hepatic and urinary porphobilinogen concentrations.[2] Other antiepileptics such as the succinimides *(ethosuximide, mesuximide, phensuximide)* and oxazolidinediones *(trimethadione)* are considered to be unsafe.

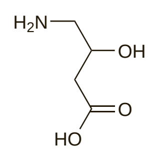
4-Amino-3-hydroxybutyric Acid

Ácido 4-amino-3-hidroxibutírico; γ-Amino-β-hydroxybutyric acid; Buxamin; Gabob; Gamma-amino-beta-hydroxybutyric acid.

4-Амино-3-оксимасляная Кислота

$C_4H_9NO_3$ = 119.1.
CAS — 352-21-6.



Profile

Aminohydroxybutyric acid has been claimed to be of value in a variety of neurological disorders including use as an adjunct in the treatment of epilepsy. It has also been promoted as a dietary supplement for its supposed beneficial effects on the CNS and growth hormone. It should be distinguished from its isomer 3-amino-4-hydroxybutyric acid (GOBAB), which is reported to possess anti-inflammatory and antifungal activity.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Gabimex; ***Braz.:*** Gamibetal†; ***Ital.:*** Gamibetal; ***Mex.:*** Gamibetal; ***Port.:*** Gabomade; Gamibetal†.

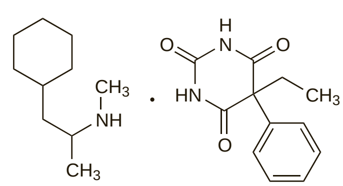
Multi-ingredient: ***Arg.:*** Gabimex Plus; ***Braz.:*** Gamibetal Complex†; ***Ital.:*** Gamibetal Complex; Gamibetal Plus; Parvisedil; ***Mex.:*** Gamibetal Complex; ***Port.:*** Gabisedil†; Gamibetal Compositum†; ***Spain:*** Cefabol; Dorken; Gamalate B6; Redutona.

Barbexaclone *(rINN)*

Barbeksaklon; Barbexaclona; Barbexaclonum. Compound of (−)-*N*,α-Dimethylcyclohexaneethylamine with 5-ethyl-5-phenylbarbituric acid .

Барбексаклон

$C_{12}H_{12}N_2O_3,C_{10}H_{21}N$ = 387.5.
CAS — 4388-82-3.
ATC — N03AA04.
ATC Vet — QN03AA04.



Profile

Barbexaclone is a compound of levopropylhexedrine (see under Propylhexedrine, p.2163) with phenobarbital (p.492). It is used in the treatment of various types of epilepsy (p.465). Usual adult doses are 200 to 400 mg daily given by mouth in divided doses.

Preparations

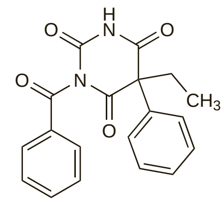
Proprietary Preparations (details are given in Part 3)
Austria: Maliasin; ***Braz.:*** Maliasin; ***Gr.:*** Maliasin; ***Ital.:*** Maliasin; ***Switz.:*** Maliasin; ***Turk.:*** Maliasin.

Benzobarbital *(rINN)*

Benzobarbitalum; Benzobarbitone; Benzonal; Benzonalum. 1-Benzoyl-5-ethyl-5-phenylbarbituric acid.

Бензобарбитал

$C_{19}H_{16}N_2O_4$ = 336.3.
CAS — 744-80-9.



NOTE. The name benzonal has also been used as a proprietary name for benzonatate (p.1552).

Pharmacopoeias. In *Int.*

Profile

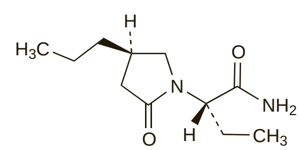
Benzobarbital is a barbiturate used in the treatment of epilepsy.

Brivaracetam *(USAN, rINN)*

Brivaracétam; Brivaracetamum; UCB-34714. (2*S*)-2-[(4*R*)-2-Oxo-4-propylpyrrolidin-1-yl]butanamide.

Бриварацетам

$C_{11}H_{20}N_2O_2$ = 212.3.
CAS — 357336-20-0.



Profile

Brivaracetam is under investigation for the treatment of various types of epilepsy including progressive myoclonic epilepsy and refractory partial seizures.

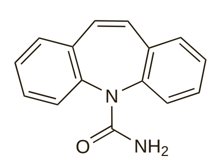
Carbamazepine *(BAN, USAN, rINN)*

Carbamazepina; Carbamazépine; Carbamazepinum; G-32883; Karbamatsepiini; Karbamazepin; Karbamazepinas; Karbamazepinum. 5*H*-Dibenz[*b*,*f*]azepine-5-carboxamide.

Карбамазепин

$C_{15}H_{12}N_2O$ = 236.3.
CAS — 298-46-4.
ATC — N03AF01.
ATC Vet — QN03AF01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Carbamazepine). A white or almost white crystalline powder. It exhibits polymorphism. Very slightly soluble in water; sparingly soluble in alcohol and in acetone; freely soluble in dichloromethane. Store in airtight containers.

USP 31 (Carbamazepine). A white or off-white powder. Practically insoluble in water; soluble in alcohol and in acetone. Store in airtight containers.

Incompatibility. Carbamazepine suspension should be mixed with an equal volume of diluent before nasogastric use as undiluted suspension is adsorbed onto PVC nasogastric tubes.[1]

The FDA have received a report of a patient who passed an orange rubbery mass in his faeces the day after taking a carbamazepine suspension (*Tegretol*; *Novartis, USA*) followed immediately by chlorpromazine solution (*Thorazine*; *GSK, USA*). Subsequent testing showed that mixing the same carbamazepine suspension with a thioridazine hydrochloride solution (*Mellaril*; *Novartis, USA*) also resulted in the precipitation of a rubbery orange mass.

1. Clark-Schmidt AL, *et al.* Loss of carbamazepine suspension through nasogastric feeding tubes. *Am J Hosp Pharm* 1990; **47:** 2034–7.

Stability. FDA studies indicate that carbamazepine tablets could lose up to one-third of their effectiveness if stored in humid conditions.[1] This appears to be due to formation of a dihydrate form which leads to hardening of the tablet and poor dissolution and absorption.[2,3] As the dihydrate has also been detected after storage under ambient conditions some suggest that storage with silica gel sachets may be necessary to avoid physical deterioration of carbamazepine tablets.[2]

3. Wang JT, *et al.* Effects of humidity and temperature on in vitro dissolution of carbamazepine tablets. *J Pharm Sci* 1993; **82:** 1002–5.

Adverse Effects

Fairly common adverse effects of carbamazepine, particularly in the initial stages of therapy, include dizziness, drowsiness, and ataxia. Gastrointestinal disturbances, such as nausea and vomiting, and mild skin reactions are also common. These effects may be minimised by starting therapy with a low dose. Drowsiness and disturbances of cerebellar and oculo-motor function (with ataxia, nystagmus, and diplopia) are also symptoms of excessive plasma concentrations of carbamazepine, and may disappear spontaneously with continued treatment or at reduced or divided dosage.

Although rare, generalised erythematous rashes can be severe and treatment may have to be withdrawn. Photosensitivity reactions, urticaria, alopecia, exfoliative dermatitis, toxic epidermal necrolysis, erythema multiforme and Stevens-Johnson syndrome, and SLE (but see below) have also been reported.

Transient leucopenia is common and usually resolves with continued therapy; however, rarer blood disorders reported include agranulocytosis, aplastic anaemia, eosinophilia, persistent leucopenia, leucocytosis, thrombocytopenia, and purpura. Lymphadenopathy, splenomegaly, pneumonitis, abnormalities of liver and kidney function, hepatitis, and cholestatic jaundice have occurred. Some or all of these symptoms as well as fever and rashes may represent a generalised hypersensitivity reaction to carbamazepine.

Gastrointestinal symptoms reported to be less common include dry mouth, abdominal pain, anorexia, and diarrhoea or constipation. Hyponatraemia, and sometimes oedema, have occurred. Other adverse effects reported include paraesthesia, headache, arrhythmias and heart block, heart failure, impotence, male infertility, gynaecomastia, galactorrhoea, and dystonias and dyskinesias with asterixis. Rectal use has resulted in local irritation.

Overdosage may be manifested by many of the adverse effects listed above, especially those on the CNS, and may result in stupor, coma, convulsions, respiratory depression, and death.

In rare cases, carbamazepine has been reported to exacerbate seizures in patients suffering from mixed-type epilepsy—see Precautions, below.

Congenital malformations have been reported in infants born to women given carbamazepine during pregnancy.

Effects on the blood. Occasional reports of fatal haematological reactions associated with carbamazepine led the manufacturers to recommend extensive blood monitoring during therapy. However, because of the rarity of such reactions these recommendations were questioned and the manufacturers subsequently modified their guidelines (see Precautions, below).

Case reports and studies of carbamazepine's haematological effects have been reviewed.[1] The incidence of haematological reactions to carbamazepine has been estimated to range between 1:10 800 and 1:38 000 per year while one group reported the rate of bone marrow suppression to be between 1:10 000 and 1:50 000 cases. The incidence of aplastic anaemia has been calculated to be 1:200 000 per year. Another investigator indicated that 2.2 deaths per million exposures were associated with aplastic anaemia and agranulocytosis. However, of 27 reports of aplastic anaemia (16 fatal) associated with carbamazepine many were found to have had co-incidental disease or were receiving multiple-drug therapy. Benign or clinically insignificant leucopenia has occurred, usually during the first 3 months of treatment, in about 12% of children and 7% of adults but in most patients this resolved despite continuation of therapy. Mild transient thrombocytopenia has occurred in about 2% of patients; transient eosinophilia has also occurred.

The reviewers[1] suggested that all patients should have blood and platelet counts before treatment. Patients with low white cell and neutrophil counts were at risk of developing leucopenia and should be monitored every 2 weeks for the first 1 to 3 months. If counts fell further the dose should be reduced or treatment stopped. It should be noted that the *BNF* doubts the practical value of routine monitoring: in particular, aplastic anaemia, agranulocytosis, and thrombocytopenia have a rapid onset and are best monitored by instructing the patient to report warning symptoms (see Precautions, below).

For a discussion of the effects of antiepileptics, including carbamazepine, on serum folate, see Folic Acid Deficiency, under Phenytoin, p.495.

1. Sobotka JL, *et al.* A review of carbamazepine's hematologic reactions and monitoring recommendations. *DICP Ann Pharmacother* 1990; **24:** 1214–19.

Effects on bone. For the effects of antiepileptics including carbamazepine on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on electrolytes. There have been reports of *hyponatraemia* or *water intoxication* in patients receiving carbamazepine.[1-7] One review[8] states that although hyponatraemia occurs in 10 to 15% of patients taking carbamazepine, it is seldom symptomatic or severe enough to cause fluid retention. However, care should be taken to distinguish the confusion, dizziness, nausea and headache of water intoxication from the central and gastrointestinal effects of the drug.[2] The mechanism is uncertain; although some studies suggest an increase in secretion of antidiuretic hormone in subjects given carbamazepine,[3,4,6] others indicate the reverse,[5,9] and the fact that the hyponatraemic effects of carbamazepine can be partly reversed by demeclocycline[5] is cited as evidence for an effect on the kidney, either directly upon the distal tubule or by increasing sensitivity to the effects of antidiuretic hormone. Risk factors for developing carbamazepine-induced hyponatraemia include age of over 40 years, use of sodium-depleting drugs, and low pre-treatment plasma-sodium concentrations; it is unclear whether this adverse effect is dose-related.[7]

Effects on the endocrine system. Carbamazepine may reduce serum concentrations of *thyroid* hormones through enzyme induction—see under Interactions of Levothyroxine, p.2172.

For mention of the effects of antiepileptics on *sexual function* in male epileptic patients, see under Phenytoin, p.496.

Effects on the eyes. On rare occasions lenticular opacities have been associated with carbamazepine.[1] Retinotoxicity associated with long-term carbamazepine use has been reported[2] in 2 patients. After stopping the drug visual function and retinal morphological changes improved. A review[3] of the effect of antiepileptics on the eyes noted that despite reports of colour vision disturbances and impaired contrast sensitivity associated with carbamazepine therapy, studies in healthy subjects had shown conflicting results.

1. Anonymous. Adverse ocular effects of systemic drugs. *Med Lett Drugs Ther* 1976; **18:** 63–4.

3. Hilton EJR, *et al.* The effect of antiepileptic drugs on visual performance. *Seizure* 2004; **13:** 113–28.

Effects on the heart. A review[1] of reports of cardiac effects associated with carbamazepine revealed that patients could be divided into 2 distinct groups based on their symptoms. One group consisted mainly of young patients with non life-threatening sinus tachycardia after carbamazepine overdosage while the other group was composed of older female patients with potentially life-threatening bradycardia or AV block associated with therapeutic or modestly raised blood concentrations of carbamazepine. However, there has been a report of fatal syncope, probably due to ventricular asystole, in a 20-year-old patient.[2] Carbamazepine should be avoided in patients who develop conduction abnormalities, or who have conditions such as myotonic dystrophy in which conduction abnormalities are likely.[1]

Elevation of ventricular and atrial stimulation thresholds was reported in a 59-year-old man with a permanent dual-chamber pacemaker, 5 days after starting carbamazepine for mania.[3]

For a report of carbamazepine producing fatal eosinophilic myocarditis, see under Hypersensitivity, below.

Effects on the immune system. There have been reports of hypogammaglobulinaemia associated with carbamazepine.[1-4] The authors of one report[2] stated that this was a recognised but rare adverse effect of carbamazepine and noted that the UK CSM had 9 reports on file of hypogammaglobulinaemia or gammaglobulin abnormalities related to the use of carbamazepine.

4. Tamada T, *et al.* Secondary bronchiolitis obliterans organising pneumonia in a patient with carbamazepine-induced hypogammaglobulinemia. *Thorax* 2007; **62:** 100.

Effects on the liver. A report in 1990 commented that of 499 reports of unwanted effects of carbamazepine on the liver about half comprised only abnormal results from liver function tests;[1] however, deaths have occurred from liver failure[1,2] or hepatic necrosis.[3] Reversible vanishing bile duct syndrome has been associated with long-term use of carbamazepine.[4]

Hepatotoxicity may form part of the antiepileptic hypersensitivity syndrome reported with carbamazepine (see below).

4. Ramos AMO, *et al.* Reversible vanishing bile duct syndrome induced by carbamazepine. *Eur J Gastroenterol Hepatol* 2002; **14:** 1019–22.

Effects on mental function. Carbamazepine therapy has been associated in a few patients with the development of acute psychotic and paranoid symptoms[1-3] and with phobias[2] and mood disturbances, including mania[4] and melancholia.[5] One case of acute paranoid psychosis was associated with the addition of carbamazepine to long-term sodium valproate therapy in a patient subsequently diagnosed as having a schizotypal personality.[3] For nonconvulsive status epilepticus associated with carbamazepine presenting as psychiatric disorders, see under Effects on the Nervous System, below. The problems of antiepileptic therapy adversely affecting cognition and the risk of mood disorders, including suicidal ideation, are discussed on p.468.

Effects on the nervous system. *ASEPTIC MENINGITIS.* Aseptic meningitis has developed in a patient with Sjögren's syndrome given carbamazepine. It abated when the drug was withdrawn and symptoms recurred on rechallenge.[1] Aseptic meningitis has also been associated with carbamazepine in patients without Sjögren's syndrome.[2-4]

4. Dang CT, Riley DK. Aseptic meningitis secondary to carbamazepine therapy. *Clin Infect Dis* 1996; **22:** 729–30.

ENCEPHALOPATHY. Carbamazepine-induced encephalopathy with symptoms resembling Creutzfeldt-Jakob disease was reported in a 71-year-old man; the cognitive decline, bradykinesia, tremor, and abnormal EEG improved on stopping carbamazepine.[1]

1. Horvath J, *et al.* Carbamazepine encephalopathy masquerading as Creutzfeldt-Jakob disease. *Neurology* 2005; **65:** 650–1.

EXTRAPYRAMIDAL EFFECTS. Although carbamazepine has been associated with extrapyramidal adverse effects,[1-4] it has also been tried in the treatment of movement disorders—see under Uses and Administration, below.

1. Schwartzman MJ, Leppik IE. Carbamazepine-induced dyskinesia and ophthalmoplegia. *Cleve Clin J Med* 1990; **57:** 367–72.

STATUS EPILEPTICUS. Nonconvulsive status epilepticus, misdiagnosed as behavioural and psychiatric disorders, was reported[1] to have been precipitated by carbamazepine in 2 patients; seizure control and behaviour improved when carbamazepine was stopped and replaced with valproate.

1. Marini C, *et al.* Nonconvulsive status epilepticus precipitated by carbamazepine presenting as dissociative and affective disorders in adolescents. *J Child Neurol* 2005; **20:** 693–6.

Effects on the skin. Rashes occurring with carbamazepine may form part of an antiepileptic hypersensitivity syndrome (see below). In a report,[1] erythema multiforme occurred when a generic formulation was given instead of a proprietary brand of carbamazepine. Skin lesions resolved when the patient stopped taking the generic formulation and did not recur when the proprietary brand was restarted. In another report, a 6-year-old boy developed Stevens-Johnson syndrome 5 weeks after carbamazepine was added to valproic acid, which he had been taking as sole antiepileptic therapy for several weeks.[2] Carbamazepine was stopped and the patient eventually made a full recovery; valproic acid was continued because it was not thought to be the causative agent (but see under Valproate, p.509). Fatal toxic epidermal necrolysis has been seen when carbamazepine was given to a patient who had previously had Stevens-Johnson syndrome during carbamazepine treatment.[3] Pseudo mycosis fungoides with lymphoid cell infiltration of the dermis and raised liver enzymes has been reported[4] in a 54-year-old man who was taking carbamazepine for seizures; symptoms resolved within about 2 weeks of stopping therapy.

For a warning that severe skin reactions may be more likely in patients of certain genotypes, see Skin Reactions, under Precautions, below. For the relative incidence of skin reactions to different antiepileptics, see under Phenytoin, p.496.

Hypersensitivity. An antiepileptic hypersensitivity syndrome, comprising fever, rash, and lymphadenopathy and less commonly hepatosplenomegaly and eosinophilia, has been associated with some antiepileptic drugs including carbamazepine.[1-3] Although a literature search[1] was only able to find 20 published cases to 1986, 22 cases had been reported to the Australian Adverse Drug Reactions Advisory Committee between 1975 and 1990. Some have estimated the incidence at 1 in 1000 to 1 in 10 000 new exposures to aromatic anticonvulsants,[2,3] but the true incidence is uncertain due to variations in presentation and reporting. Most reactions occurred within 30 days of the start of carbamazepine treatment,[1] although symptoms may occur anywhere between 1 and 8 weeks after exposure.[2] In previously sensitised individuals the reactions may occur within 1 day of rechallenge. The potential for cross-reactivity between carbamazepine, phenobarbital, and phenytoin is approximately 75%, and patients who develop the syndrome, and their close relatives, should be warned of the risk associated with use of these antiepileptics.[2]

Carbamazepine antibodies were detected in an 8-year-old child who developed symptoms of serum sickness including fever, skin rash, oedema, and lymphadenopathy during treatment with carbamazepine.[4] Hypersensitivity to carbamazepine with multisystem effects clinically resembling a mononucleosis syndrome was reported in a 15-year-old boy 2 weeks after starting monotherapy with carbamazepine;[5] all symptoms resolved on stopping carbamazepine and giving prednisone. There have been other cases[6-8] of an infectious mononucleosis syndrome associated with hypersensitivity to carbamazepine, leading the authors to suggest that reactivation of human herpesvirus 6 or 7 infection is a cofactor and an early manifestation of carbamazepine hypersensitivity syndrome; however, further studies are warranted.

A hypersensitivity reaction producing fatal eosinophilic myocarditis has been reported in a 13-year-old patient; initial symptoms mimicked scarlet fever.[9] A 21-year-old woman developed fatal fulminant hepatic failure after taking carbamazepine for about 2 months; she had presented with initial symptoms of fever, breathlessness, bloody diarrhoea, and a spreading rash.[10]

Generalised erythroderma with renal, hepatic, and bone-marrow failure (characterised by hypercellularity and dyserythropoiesis) has been reported[11] in an 81-year-old man 50 days after starting carbamazepine therapy. Symptoms recurred following an inadvertent rechallenge. The presence of underlying lymphoproliferative disease may have potentiated the severe drug-induced reaction.

If the antiepileptic hypersensitivity syndrome develops, immediate withdrawal of carbamazepine is recommended. In most cases this is all that is required and does not seem to precipitate an increase in seizures, compared with gradual withdrawal.[12]

Successful desensitisation to carbamazepine was reported[13] in a 12-year-old boy who was sensitive to carbamazepine, sodium valproate, and phenytoin. Starting with a low dose of carbamazepine 100 micrograms daily the dose was doubled, generally every 2 days, up to 100 mg daily. The dose was then gradually increased over 4 weeks to a maintenance dose of 200 mg twice daily. The same technique was used to desensitise 7 patients, all of whom developed dramatic skin rashes when first exposed to carbamazepine.[14] Carbamazepine therapy in full doses was achieved without problem in about 6 weeks. Some[2] consider that desensitisation is not to be recommended in patients with full-blown antiepileptic hypersensitivity syndrome.

Sudden unexplained death in epilepsy. Sudden unexplained death in epilepsy (SUDEP), a common cause of seizure-related mortality in patients with chronic epilepsy, has been reviewed.[1,2] Risk factors may include early onset of epilepsy, frequent generalised tonic-clonic seizures, intractability, frequent medication changes, and polytherapy. *Carbamazepine* use has also been implicated but the evidence was considered to be tenuous although frequent dose change resulting in plasma-carbamazepine levels outside the therapeutic range was found to be an independent risk factor. Although the FDA in the USA had required data about the specific risk of SUDEP to be included in the prescribing information for the newer antiepileptic drugs *gabapentin, lamotrigine, tiagabine, topiramate,* and *zonisamide*, some commentators[3] consider that none of these antiepileptics have shown an associated change in the risk of SUDEP. It has been suggested[2,3] that the incidence of SUDEP is related to the disease rather than a specific drug effect.

Systemic lupus erythematosus. A review[1] of 80 cases of SLE-like syndromes associated with carbamazepine that had been reported to the manufacturer suggested that the frequency of reports (less than 0.001%) was below that for idiopathic lupus. There have been subsequent reports[2-4] of late-onset SLE occurring after up to 8 years of carbamazepine therapy without previous adverse effects. The symptoms due to carbamazepine usually resolved on stopping treatment.

Treatment of Adverse Effects

In the treatment of carbamazepine overdosage repeated doses of activated charcoal may be given orally to adults and children who have ingested more than 20 mg/kg; the aim is not only to prevent absorption but also to aid elimination. Gastric lavage may be considered if undertaken within 1 hour of ingestion. Supportive and symptomatic therapy alone may then suffice, with particular attention to correcting hypoxia and hypotension; haemoperfusion has been suggested for severe poisoning. If there is doubt about the diagnosis, or if multiple-dose oral activated charcoal is being considered, then monitoring plasma-carbamazepine concentration can be useful; it may also help determine when carbamazepine therapy should be restarted. See also Overdosage, below.

Hypersensitivity reactions. For reference to successful desensitisation in patients sensitive to carbamazepine, see Hypersensitivity under Adverse Effects, above.

Overdosage. Carbamazepine poisoning and its management has been reviewed.[1] Management is primarily supportive, with prompt attention to airway management and seizure control. Activated charcoal should be given; although multiple-dose activated charcoal has been recommended for carbamazepine overdosage, care must be taken to protect the airway since carbamazepine inhibits intestinal motility and there is a significant risk of aspiration. In patients with seizures unresponsive to benzodiazepines phenobarbital should be used; phenytoin is not a drug of choice in this situation. Hypotension is rare, and should be managed with fluid and vasopressor support; hypotension with refractory seizures should be treated aggressively as it has led to permanent neurological disability and death.

Haemodialysis or haemoperfusion may be warranted in patients with unstable cardiac status or status epilepticus complicated by bowel hypomotility and unresponsive to more conventional therapy. However, a report[2] of the use of plasmapheresis in the treatment of an acute overdose of carbamazepine concluded that plasmapheresis removed a very small percentage of the total body load of carbamazepine and could not be recommended. As carbamazepine is highly protein-bound, albumin-enhanced continuous venovenous haemodialysis was tried and found to be effective in the treatment of a 10-year-old child after ingestion of 1.4 g of carbamazepine.[3]

For a further review of the features and management of poisoning with some antiepileptics, including carbamazepine, see under Phenytoin, p.497.

3. Askenazi DJ, *et al.* Management of a severe carbamazepine overdose using albumin-enhanced continuous venovenous hemodialysis. *Pediatrics* 2004; **113:** 406–9.

Precautions

Carbamazepine should be avoided in patients with AV conduction abnormalities. It should not be given to patients with a history of bone marrow depression. Carbamazepine should be given with caution to patients with a history of blood disorders or haematological reactions to other drugs, or of cardiac, hepatic, or renal disease. Patients or their carers should be told how to recognise signs of blood, liver, and skin toxicity and they should be advised to seek immediate medical attention if symptoms such as fever, sore throat, rash, mouth ulcers, bruising, or bleeding develop. Carbamazepine should be withdrawn, if necessary under cover of a suitable alternative antiepileptic, if severe, progressive, or symptomatic leucopenia develops, or if symptoms suggestive of Stevens-Johnson syndrome or toxic epidermal necrolysis occur. Licensed product information recommends blood counts and hepatic and renal-function tests before starting carbamazepine therapy and periodically during treatment, but the *BNF* considers the evidence of practical value unsatisfactory. Clinical monitoring is of primary importance throughout treatment. Some patients of Asian ancestry may be at increased risk of severe skin reactions; for recommendations that such patients' genotype should be tested before beginning carbamazepine see Skin Reactions, below.

Care is required in identifying patients with mixed seizure disorders that include generalised absence or atypical absence seizures, who may be at risk of an increase in generalised seizures if given carbamazepine. Carbamazepine may also exacerbate absence and myoclonic seizures.

Care is required when withdrawing carbamazepine therapy—see also Uses and Administration, below.

Since carbamazepine has mild antimuscarinic properties caution should be observed in patients with glaucoma or raised intra-ocular pressure; scattered punctate lens opacities occur rarely with carbamazepine and it has been suggested that patients should be examined periodically for eye changes.

Abuse. Overdosage requiring hospital admission has been reported after abuse of carbamazepine.[1]

1. Crawford PJ, Fisher BM. Recreational overdosage of carbamazepine in Paisley drug abusers. *Scott Med J* 1997; **42:** 44–5.

Breast feeding. The American Academy of Pediatrics considers[1] that carbamazepine is usually compatible with breast feeding, although there have been reports[2] of transient cholestatic hepatitis in breast-fed infants.

For further comment on antiepileptic therapy and breast feeding, see p.467.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 09/06/08)

Driving. For comment on antiepileptic drugs and driving, see p.468.

Multiple sclerosis. Exacerbation of symptoms of multiple sclerosis has been reported[1] in 5 patients on starting carbamazepine therapy for paroxysmal neurological symptoms and pain. There was a close temporal association between starting carbamazepine and worsening of symptoms, followed by resolution when it was stopped. A 3-year follow-up observational study[2] found that out of 36 multiple sclerosis patients who received carbamazepine therapy, 12 developed neurological adverse effects that mimicked a relapse. The authors concluded that carbamazepine was associated with higher rates of adverse effects and stopping therapy than gabapentin or lamotrigine.

2. Solaro C, *et al.* Antiepileptic medications in multiple sclerosis: adverse effects in a three-year follow-up study. *Neurol Sci* 2005; **25:** 307–10.

Porphyria. Carbamazepine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

There is an increased risk of neural tube defects in infants exposed *in utero* to antiepileptics including carbamazepine; syndromes such as craniofacial and digital abnormalities and, less commonly, cleft lip and palate have also been described. Exposure to carbamazepine has been calculated to carry a 1% risk of spina bifida.[1] A 'carbamazepine syndrome' characterised by facial dysmorphic features and mild mental retardation has been described;[2] such syndromes are now often seen as aspects of a single 'fetal antiepileptic syndrome'. There is also a risk of neonatal bleeding.

1. Rosa FW. Spina bifida in infants of women treated with carbamazepine during pregnancy. *N Engl J Med* 1991; **324:** 674–7.
2. Ornoy A, Cohen E. Outcome of children born to epileptic mothers treated with carbamazepine during pregnancy. *Arch Dis Child* 1996; **75:** 517–20.

Skin reactions. The FDA has issued a warning[1] that severe and potentially fatal skin reactions such as Stevens-Johnson syndrome and toxic epidermal necrolysis are significantly more common in patients with the HLA allele HLA-B*1502, which occurs almost exclusively in persons of Asian ancestry. They recommend that patients with such ancestry should be screened for the presence of this allele before beginning therapy with carbamazepine, and if present the risks and benefits of therapy should be considered with particular care; those who have already taken carbamazepine for more than a few months without developing skin reactions are, however, at low risk of them ever developing, regardless of genotype. Similar recommendations have since been issued in the UK by the MHRA.[2]

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy.

The metabolism of carbamazepine is reported to be less susceptible to inhibition by other drugs than that of phenytoin but a few drugs are reported to inhibit its metabolism by the cytochrome P450 isoenzyme CYP3A4, resulting in raised plasma concentrations and associated toxicity. Conversely, drugs that induce CYP3A4 may increase the metabolism of carbamazepine, leading to reduced plasma concentrations and potentially a decrease in therapeutic effect. Licensed product information advises that, in such situations, the dose of carbamazepine should be adjusted accordingly and/or the plasma concentrations monitored.

Carbamazepine is itself a hepatic enzyme inducer, and induces its own metabolism as well as that of a number of other drugs including some antibacterials (notably, doxycycline), anticoagulants, and sex hormones (notably, oral contraceptives). Carbamazepine and phenytoin may also mutually enhance one another's metabolism. The metabolism of carbamazepine is similarly enhanced by enzyme inducers such as phenobarbital.

Anthelmintics. For the effect of carbamazepine on *mebendazole* and *praziquantel*, see p.149 and p.154, respectively.

Antibacterials. The antimycobacterial *isoniazid*[1,2] and macrolides[3] such as *clarithromycin*, *erythromycin*, and *troleandomycin* have been reported to cause substantial elevations of serum concentrations of carbamazepine and symptoms of carbamazepine toxicity. Clarithromycin has also been reported to have caused hyponatraemia when added to carbamazepine therapy in a 30-year-old epileptic woman.[4] *Rifampicin* and isoniazid decreased the serum concentrations of carbamazepine in a 44-year-old woman being treated for bipolar disorder and suspected tuberculosis, resulting in hypomania.[5]

Use of carbamazepine with isoniazid may increase the risk of isoniazid-induced hepatotoxicity.

Anticoagulants. For the effect of carbamazepine on *warfarin*, see p.1429.

Antidepressants. As with all antiepileptics, antidepressants may antagonise the antiepileptic activity of carbamazepine by lowering the convulsive threshold.

Antidepressants such as *desipramine*,[1] *fluoxetine*,[2] *fluvoxamine*,[3] *nefazodone*[4] (and perhaps *trazodone*[5]), and *viloxazine*[6] increase plasma concentrations of carbamazepine and may induce carbamazepine toxicity. A toxic serotonin syndrome (see p.416) has been reported in a patient who received fluoxetine with carbamazepine.[7] Severe neurotoxicity reported during therapy with *lithium* and carbamazepine[8,9] may be due to a synergistic effect as reports indicate that either drug was tolerated when not given with the other and measured plasma concentrations did not indicate overdosage.[9] However, toxic serum concentrations of lithium have also been reported, due to carbamazepine-induced acute renal failure (see p.404).

Because of the structural similarity to tricyclic antidepressants licensed product information suggests that carbamazepine should not be given to patients taking an *MAOI* or within 14 days of stopping such treatment.

St John's wort has been shown to induce several drug metabolising enzymes (see p.423) and consequently it has been suggested that it might reduce the blood concentrations of carbamazepine leading to an increased risk of seizure.[10] However, a multiple-dose study[11] in healthy subjects reported that St John's wort had no significant effect on the pharmacokinetics of carbamazepine or its active epoxide metabolite.

For the effect of carbamazepine on antidepressants, see Bupropion (p.384), Fluoxetine (p.396), Mianserin (p.409), Nefazodone (p.413), and Amitriptyline (p.380).

Antiepileptics. Interactions of varying degrees of clinical significance have been reported between carbamazepine and other antiepileptics.

Serum concentrations of carbamazepine are reported to be reduced by *phenobarbital*, but without loss of seizure control;[1,2] this reduction is probably due to induction of carbamazepine metabolism.

The interaction with *phenytoin* is somewhat more complex and the consequences vary. There is evidence of a lowering of serum-carbamazepine concentrations, presumably due to induction of metabolism by phenytoin;[1-3] in return carbamazepine has been reported both to lower and increase serum phenytoin—see p.498. Again, these reports do not indicate a loss of seizure control or toxicity resulting from the interaction, although the possibility presumably exists. Gradually withdrawing phenytoin from 2 patients who had been receiving carbamazepine and phenytoin resulted in a dramatic increase in plasma-carbamazepine concentrations;[4] one patient exhibited neurotoxic symptoms. The authors recommended that plasma-carbamazepine monitoring should be carried out whenever phenytoin is withdrawn in patients taking these two drugs together.

Valproic acid produces an increase in serum concentrations of the active epoxide metabolite of carbamazepine. This is usually attributed to inhibition of its hydrolysis by epoxide hydrolase, although an additional proposed mechanism[5] is inhibition of the glucuronidation of carbamazepine-10,11-trans-diol, the compound to which the epoxide is converted under normal circumstances. Adverse effects may be a problem if unusually high epoxide concentrations arise but, in general, this interaction is of limited clinical significance. However, *valpromide*, the amide derivative, is a much more powerful inhibitor of epoxide hydrolase than valproic acid,[6-8] and therefore produces greater increases in epoxide plasma concentrations with clinical signs of toxicity.[7] Switching from sodium valproate to valpromide has resulted in toxicity in patients also receiving carbamazepine.[7] Neither valproic acid nor valpromide have any significant effect on plasma concentrations of the parent drug, carbamazepine. *Valnoctamide*, an isomer of valpromide, appears to be at least as potent as valpromide in inhibiting the elimination of the epoxide metabolite of carbamazepine.[9] Valnoctamide has been used as an anxiolytic, although it does appear to possess some antiepileptic activity. For a report of acute psychosis associated with the combination of carbamazepine and sodium valproate, see Effects on Mental Function under Adverse Effects, above. For the effects of carbamazepine on valproate, see p.511.

Of the other antiepileptics *stiripentol*[10,11] has been reported to inhibit carbamazepine metabolism, while *felbamate* causes a significant fall in plasma-carbamazepine concentrations which may require an increase in the dose of carbamazepine.[12] However, another study[13] has shown a significant increase in plasma-concentrations of the active epoxide metabolite, which may counteract the effect of the decrease in plasma concentrations of the parent compound. Neurotoxicity has been seen after use of carbamazepine with *lamotrigine*.[14] The suggestion that this was due to raised concentrations of carbamazepine epoxide was not confirmed in a controlled study in which the 2 drugs were used together safely and effectively.[15] Toxic epidermal necrolysis occurred[16] when lamotrigine was added to carbamazepine therapy in a patient who had been taking carbamazepine for 3 years; symptoms resolved progressively when both drugs were stopped. Symptoms of carbamazepine toxicity have been reported[17] when *levetiracetam* was added to carbamazepine therapy; this interaction appeared to be due to a pharmacodynamic mechanism as blood levels of carbamazepine and its epoxide metabolite were not altered. There have also been reports[18] of carbamazepine toxicity when *topiramate* was added to carbamazepine therapy; symptoms resolved when the dose of carbamazepine was reduced. Fulminant liver failure has been reported[19] after an increase in adjunctive topiramate dose in a patient maintained on carbamazepine for 2 years without any signs of hepatotoxicity. The GABA agonist *progabide* has increased plasma concentrations of the epoxide metabolite, probably due to inhibition of microsomal epoxide hydrolase.[20] *Vigabatrin* is reported[21] to increase the clearance of carbamazepine by about 35%.

For the effects of carbamazepine on *ethosuximide*, see p.480, on *lamotrigine*, see p.486, on *oxcarbazepine*, see p.491, on *primidone*, see p.503, on *tiagabine*, see p.505, and on *topiramate*, see p.506. For interactions with benzodiazepines, see below.

Antifungals. Malaise, myoclonus, and trembling were reported[1] to have developed in a patient receiving carbamazepine after the addition of *miconazole* to therapy. *Ketoconazole* was associated with a significant increase in plasma-carbamazepine concentrations in 8 epileptic patients stabilised on carbamazepine;[2] plasma concentrations of the epoxide metabolite were unchanged. A threefold increase in serum-carbamazepine concentrations, reported[3] in a patient after addition of *fluconazole* to carbamazepine therapy, was asymptomatic; however, carbamazepine toxicity has been reported[4,5] in 2 patients stabilised on carbamazepine who were given fluconazole. *Terbinafine* has also been reported[6] to cause possible carbamazepine toxicity.

For the effect of carbamazepine on *itraconazole*, see p.537.

6. Baath NS, *et al.* Possible carbamazepine toxicity with terbinafine. *Can J Clin Pharmacol* 2006; **13:** e228–e231.

Antihistamines. *Terfenadine* and carbamazepine are both highly protein bound and therefore may compete for protein binding sites. An 18-year-old woman receiving carbamazepine as an antiepileptic experienced symptoms of neurotoxicity shortly after starting treatment with terfenadine for rhinitis.[1] The concentration of free carbamazepine in the plasma was higher than normal and returned to normal on stopping terfenadine.

1. Hirschfeld S, Jarosinski P. Drug interaction of terfenadine and carbamazepine. *Ann Intern Med* 1993; **118:** 907–8.

Antimalarials. *Chloroquine* and *mefloquine* may antagonise the antiepileptic activity of carbamazepine by lowering the convulsive threshold.

Antiprotozoals. A patient receiving carbamazepine for bipolar disorder developed dizziness, diplopia, and nausea 4 days after the addition of *metronidazole* for diverticulitis.[1]

1. Patterson BD. Possible interaction between metronidazole and carbamazepine. *Ann Pharmacother* 1994; **28:** 1303–4.

Antipsychotics. As with all antiepileptics, antipsychotics may antagonise the antiepileptic activity of carbamazepine by lowering the convulsive threshold.

Increased plasma concentrations of carbamazepine epoxide have been reported to occur during therapy with carbamazepine and *loxapine*[1] or *quetiapine*,[2] possibly due to induction of carbamazepine metabolism or inhibition of metabolism of the epoxide. Raised serum concentrations of carbamazepine have also been reported in patients receiving *haloperidol*.[3]

For the effect of carbamazepine on antipsychotics, see under Chlorpromazine, p.974.

1. Collins DM, *et al.* Potential interaction between carbamazepine and loxapine: case report and retrospective review. *Ann Pharmacother* 1993; **27:** 1180–3.

3. Iwahashi K, *et al.* The drug-drug interaction effects of haloperidol on plasma carbamazepine levels. *Clin Neuropharmacol* 1995; **18:** 233–6.

Antivirals. *Ritonavir* inhibits several microsomal liver enzymes and therefore may potentially increase plasma concentrations of carbamazepine. Licensed product information for ritonavir advises that such combinations may require monitoring. Carbamazepine toxicity has been reported[1,2] after interaction with ritonavir. In one report,[2] the patient was also taking *nelfinavir* and *lopinavir*, both of which are substrates and inhibitors of CYP450 isoenzymes.

For the effect of carbamazepine on HIV-protease inhibitors, see p.883.

Anxiolytics. For a discussion of the potential interaction between carbamazepine and the anxiolytic *valnoctamide*, an isomer of the antiepileptic valpromide, see Antiepileptics, above.

See also Benzodiazepines, below.

Benzodiazepines. The metabolism of benzodiazepines may be enhanced by induction of hepatic drug-metabolising enzymes in patients who have received long-term therapy with carbamazepine; benzodiazepine plasma concentrations are reduced, half-life is shorter, and clearance is increased[1,2] (see also Antiepileptics, under Interactions of Diazepam, p.990).

Some benzodiazepines may also affect carbamazepine. One group of workers reported that after addition of *clobazam* to carbamazepine therapy a dose reduction for the latter was required due to increased blood concentrations.[3] In a later study[4] it appeared that clobazam could produce a moderate increase in the metabolism of carbamazepine. The plasma ratio of metabolites of carbamazepine, including carbamazepine-10,11-epoxide, to parent compound was increased in patients taking clobazam and carbamazepine.

4. Muñoz JJ, *et al.* The effect of clobazam on steady state plasma concentrations of carbamazepine and its metabolites. *Br J Clin Pharmacol* 1990; **29:** 763–5.

Calcium-channel blockers. Six patients with steady-state carbamazepine concentrations had symptoms of neurotoxicity consistent with carbamazepine intoxication within 36 to 96 hours of the first dose of *verapamil*.[1] In 5 patients, in whom plasma concentrations were measured, there was a mean increase of 46% in total carbamazepine and 33% in free carbamazepine; no effect on the plasma protein binding of carbamazepine was seen. The results suggested that verapamil inhibits the metabolism of carbamazepine to an extent likely to have important clinical repercussions. There has also been a report[2] of a patient in whom *diltiazem*, but not *nifedipine*, precipitated carbamazepine neurotoxicity.

For the effect of carbamazepine on dihydropyridine calcium-channel blockers, see under Nifedipine, p.1353.

2. Brodie MJ, Macphee GJA. Carbamazepine neurotoxicity precipitated by diltiazem. *BMJ* 1986; **292:** 1170–1.

Ciclosporin. For the effect of carbamazepine on ciclosporin, see p.1826.

Corticosteroids. For the effect of carbamazepine on corticosteroids, see p.1494.

Danazol. Use of danazol with carbamazepine has been reported to increase the half-life and decrease clearance of carbamazepine,[1] resulting in increases in plasma-carbamazepine concentrations of up to 100%[1,2] and resultant toxicity in a number of patients.[2]

2. Zielinski JJ, *et al.* Clinically significant danazol-carbamazepine interaction. *Ther Drug Monit* 1987; **9:** 24–7.

Dermatological drugs. Addition of *isotretinoin* to regular carbamazepine therapy appeared to reduce plasma concentrations of the latter and its active epoxide metabolite.[1] However, no adverse events were noted during a 6-week period of treatment with isotretinoin. Nonetheless, licensed product information for carbamazepine recommends that the levels of carbamazepine are monitored if both are used together.

1. Marsden JR. Effect of isotretinoin on carbamazepine pharmacokinetics. *Br J Dermatol* 1988; **119:** 403–4.

Diuretics. There has been a report of symptomatic hyponatraemia associated with use of carbamazepine and a diuretic (*hydrochlorothiazide* or *furosemide*—see under Interactions of Furosemide, p.1293). Carbamazepine serum concentrations are increased by *acetazolamide*.[1]

1. McBride MC. Serum carbamazepine levels are increased by acetazolamide. *Ann Neurol* 1984; **16:** 393.

Gastrointestinal drugs. *Cimetidine* is reported to produce a transient increase in plasma-carbamazepine concentrations, with a return to pre-cimetidine values within about a week;[1] some increase in adverse effects was seen. *Ranitidine* does not appear to affect plasma-carbamazepine concentrations.[2] Neurotoxicity has been seen in a patient receiving carbamazepine and *metoclopramide*.[3]

3. Sandyk R. Carbamazepine and metoclopramide interaction: possible neurotoxicity. *BMJ* 1984; **288:** 830.

Grapefruit juice. The bioavailability and plasma concentrations of carbamazepine have been reported[1] to be increased by grapefruit juice.

1. Garg SK, *et al.* Effect of grapefruit juice on carbamazepine bioavailability in patients with epilepsy. *Clin Pharmacol Ther* 1998; **64:** 286–8.

Levothyroxine. For the effect of carbamazepine on levothyroxine, see p.2172.

Neuromuscular blockers. For the effect of carbamazepine on *suxamethonium*, see p.1911 and on *competitive neuromuscular blockers*, see under Atracurium, p.1904.

Sex hormones. For the effect of carbamazepine on *oral contraceptives*, see p.2068 and for the possible effect on *tibolone*, see p.2134.

See also Danazol, above

Theophylline. A decrease in serum-carbamazepine concentrations of about 50% was reported[1] in an epileptic patient given theophylline. The patient experienced seizures and the proposed mechanism was that theophylline had increased the metabolism of carbamazepine.

For the effect of carbamazepine on theophylline, see p.1143.

1. Mitchell EA, *et al.* Interaction between carbamazepine and theophylline. *N Z Med J* 1986; **99:** 69–70.

Vitamins. The plasma concentration of carbamazepine was increased in 2 patients given *nicotinamide*.[1]

For the effect of antiepileptics, including carbamazepine, on *vitamin D* concentrations, see Effects on Bone under the Adverse Effects of Phenytoin, p.496.

1. Bourgeois BFD, *et al.* Interactions between primidone, carbamazepine, and nicotinamide. *Neurology* 1982; **32:** 1122–6.

Pharmacokinetics

Carbamazepine is slowly and irregularly absorbed from the gastrointestinal tract and has a bioavailability of 85 to 100%. It is extensively metabolised in the liver, notably by the cytochrome P450 isoenzymes CYP3A4 and CYP2C8. One of its primary metabolites, carbamazepine-10,11-epoxide, is also active. Carbamazepine is excreted in the urine almost entirely in the form of its metabolites; some are also excreted in faeces. Elimination of carbamazepine is reported to be more rapid in children and accumulation of the active metabolite may often be higher than in adults.

Carbamazepine is widely distributed throughout the body and is about 70 to 80% bound to plasma proteins. It induces its own metabolism so that the plasma half-life may be considerably reduced after repeated dosage. The mean plasma half-life of carbamazepine on repeated dosage is about 12 to 24 hours; it appears to be considerably shorter in children than in adults.

Moreover, the metabolism of carbamazepine is readily induced by drugs that induce hepatic microsomal enzymes (see Interactions, above).

Monitoring of plasma concentrations may be performed when clinically indicated and the therapeutic range of total plasma-carbamazepine is usually quoted as being about 4 to 12 micrograms/mL (17 to 50 micromoles/litre), although this is subject to considerable variation. It has been suggested by some, but not all investigators, that measurement of free carbamazepine concentrations in plasma may prove more reliable, and concentrations in saliva or tears, which contain only free carbamazepine, have also been measured.

Carbamazepine crosses the placental barrier and is distributed into breast milk.

The pharmacokinetics of carbamazepine are affected by use with other antiepileptics (see under Interactions, above).

Uses and Administration

Carbamazepine is a dibenzazepine derivative with antiepileptic and psychotropic properties. It is used to control secondarily generalised tonic-clonic seizures and partial seizures, and in some primary generalised seizures. Carbamazepine is also used in the treatment of trigeminal neuralgia and has been tried with variable success in glossopharyngeal neuralgia and other severe pain syndromes associated with neurological disorders such as tabes dorsalis and multiple sclerosis. Another use of carbamazepine is in the management of bipolar disorder unresponsive to lithium.

In the treatment of **epilepsy**, the dose of carbamazepine should be adjusted to the needs of the individual patient to achieve adequate control of seizures; this usually requires total plasma-carbamazepine concentrations of about 4 to 12 micrograms/mL (17 to 50 micromoles/litre). A low initial dose of carbamazepine is recommended to minimise adverse effects. The suggested initial oral dose is 100 to 200 mg once or twice daily gradually increased by increments of up to 200 mg daily every week to a usual maintenance dose of 0.8 to 1.2 g daily in divided doses; up to 2 g daily may occasionally be necessary. For details of doses in children, see below.

Oral carbamazepine is usually given in divided doses 2 to 4 times daily. A twice-daily regimen may be associated with improved compliance but can produce widely fluctuating plasma-carbamazepine concentrations that lead to intermittent adverse effects. Twice-daily dosage may nonetheless be suitable for patients receiving carbamazepine monotherapy; modified-release formulations can minimise fluctuations in plasma concentration and may also allow effective twice-daily use. Different preparations vary in bioavailability and it may be prudent to avoid changing the formulation.

The time and manner of taking carbamazepine should be standardised for the patient since variations might affect absorption with consequent fluctuations in the plasma concentrations.

Carbamazepine may be given by the rectal route in doses up to a maximum of 250 mg every 6 hours to patients for whom oral treatment is temporarily not possible. The dosage should be increased by about 25% when changing from an oral formulation to suppositories, and it is recommended that the rectal route should not be used for longer than 7 days.

As with other antiepileptics, withdrawal of carbamazepine therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

The treatment of **trigeminal neuralgia** is typically begun with low oral doses, such as 100 mg of carbamazepine twice daily (although up to 200 mg twice daily has been suggested in the UK), and increased gradually as needed to maintain freedom from pain. This is usually at maintenance doses of 400 to 800 mg in divided doses; up to 1.2 g daily is considered standard maintenance in the USA, while UK licensed product information considers that up to 1.6 g daily may be needed in some patients. When pain relief has been obtained attempts should be made to reduce, and if possible stop, therapy, until another attack occurs.

For the management of **bipolar disorder**, carbamazepine is given in an initial oral dose of 400 mg daily in divided doses, increased gradually as necessary up to a maximum of 1.6 g daily; the usual maintenance dose range is 400 to 600 mg daily.

Administration. A modified-release formulation of carbamazepine can reduce fluctuations in carbamazepine concentrations,[1] and tolerability and seizure control in patients with epilepsy may be improved.[2,3] Such formulations should be considered in patients receiving high doses who suffer intermittent adverse effects, and might also permit a reduction to twice- or even, in some patients, once-daily dosage.[2,4] However, bioavailability appears to be slightly less than conventional preparations and dosage adjustments may be required when changing between formulations.[1]

3. Ryan SW, *et al.* Slow release carbamazepine in treatment of poorly controlled seizures. *Arch Dis Child* 1990; **65:** 930–5.
4. McKee PJW, *et al.* Double dummy comparison between once and twice daily dosing with modified-release carbamazepine in epileptic patients. *Br J Clin Pharmacol* 1993; **36:** 257–61.

Administration in children. In the UK, the usual recommended oral dose of carbamazepine for generalised tonic-clonic and partial seizures in children is 10 to 20 mg/kg daily in divided doses. Alternatively the daily dose may be given according to age as follows:

- up to 1 year: 100 to 200 mg
- 1 to 5 years: 200 to 400 mg
- 5 to 10 years: 400 to 600 mg
- 10 to 15 years: 0.6 to 1 g

As with adults, children should be started on a low initial dose of carbamazepine to minimise adverse effects; the *BNFC* suggests that those aged 1 month to 12 years may initially be given 5 mg/kg at night or 2.5 mg/kg twice daily, increasing by 2.5 to 5 mg/kg every 3 to 7 days as necessary to a usual maintenance dose of 5 mg/kg 2 or 3 times daily. Older children may be given the usual adult dose (see above) although a maximum of 1.8 g daily has been suggested.

The *BNFC* also states that these doses may be used for the treatment of neuropathic pain and some movement disorders, and for mood stabilisation.

Carbamazepine may be given rectally to children in whom oral treatment is temporarily not possible; the *BNFC* suggests this route may be used from 1 month of age. Doses should be about 25% greater than the corresponding oral dose, to a maximum of 250 mg, and given up to 4 times daily.

Bipolar disorder. Carbamazepine may be given as an alternative to lithium or valproate in patients with bipolar disorder (p.372). Studies of its efficacy have been conflicting; although clearly effective in some patients, at least one early study suggested that short-term benefit was not sustained in the longer term.[1] More recent results[2,3] have suggested that lithium or valproate are generally more effective, but that carbamazepine may conceivably have a role in patients with nonclassical features. Carbamazepine has also been used with lithium, particularly in patients unresponsive to either drug alone; although there are suggestions that the combination may be more effective than monotherapy, particularly in patients with a history of rapid cycling,[4] it is associated with a potential risk of serious neurotoxicity—see Antidepressants, under Interactions, above. While some commentators have suggested that carbamazepine is falling out of favour with specialists prescribing for bipolar disorder,[5] a more recent literature review[6] concluded that it was still a feasible treatment option.

1. Frankenburg FR, *et al.* Long-term response to carbamazepine: a retrospective study. *J Clin Psychopharmacol* 1988; **8:** 130–2.
2. Kleindienst N, Greil W. Differential efficacy of lithium and carbamazepine in the prophylaxis of bipolar disorder: results of the MAP study. *Neuropsychobiology* 2000; **42** (suppl 1): 2–10.
3. Vasudev K, *et al.* Carbamazepine and valproate monotherapy: feasibility, relative safety and efficacy, and therapeutic drug monitoring in manic disorder. *Psychopharmacology (Berl)* 2000; **150:** 15–23.
4. Denicoff KD, *et al.* Comparative prophylactic efficacy of lithium, carbamazepine, and the combination in bipolar disorder. *J Clin Psychiatry* 1997; **58:** 470–8.

6. Stoner SC, *et al.* Historical review of carbamazepine for the treatment of bipolar disorder. *Pharmacotherapy* 2007; **27:** 68–88.

Depression. Carbamazepine has been tried[1-3] for the augmentation of antidepressant therapy in the treatment of resistant depression (p.373). However, such combined therapy may lead to interactions—see also Antidepressants under Interactions, above.

1. De la Fuente JM, Mendlewicz J. Carbamazepine addition in tricyclic antidepressant-resistant unipolar depression. *Biol Psychiatry* 1992; **32:** 369–74.
2. Otani K, *et al.* Carbamazepine augmentation therapy in three patients with trazodone-resistant depression. *Int Clin Psychopharmacol* 1996; **11:** 55–7.

Diabetes insipidus. Cranial diabetes insipidus is usually treated by replacement therapy with antidiuretic hormone (ADH) in the form of desmopressin (see p.2179). Carbamazepine is one of a variety of other drugs that have been tried to promote ADH secretion, although some consider that it is usually ineffective and has unwanted effects.[1,2] Doses of 200 to 400 mg daily by mouth have been given. See also Effects on Electrolytes under Adverse Effects, above.

2. Singer I, *et al.* The management of diabetes insipidus in adults. *Arch Intern Med* 1997; **157:** 1293–1301.

Epilepsy. Carbamazepine is one of the drugs of choice for partial seizures with or without secondary generalisation (see p.465). It has been used for generalised tonic-clonic seizures (although valproate is the drug of choice where these occur in primary generalised epilepsy), but it may exacerbate absence and myoclonic seizures.

Hemifacial spasm. Carbamazepine has been reported to have been of help in the treatment of hemifacial spasm (p.1892).

Hiccup. For the management of intractable hiccups see under Chlorpromazine, p.976. Carbamazepine may be of value for the treatment of neurogenic hiccups such as those that occur in multiple sclerosis.[1] Carbamazepine has also been reported to have been of benefit in 3 patients with diaphragmatic flutter,[2] a rare disorder associated with involuntary contractions of the diaphragm.

1. McFarling DA, Susac JO. Hoquet diabolique: intractable hiccups as a manifestation of multiple sclerosis. *Neurology* 1979; **29:** 797–801.
2. Vantrappen G, *et al.* High-frequency diaphragmatic flutter: symptoms and treatment by carbamazepine. *Lancet* 1992; **339:** 265–7.

Hyperactivity. When drugs are indicated for attention deficit hyperactivity disorder (p.2148) initial treatment is usually with a central stimulant but meta-analysis of a small number of trials has provided evidence that carbamazepine may be effective.[1]

1. Silva RR, *et al.* Carbamazepine use in children and adolescents with features of attention-deficit hyperactivity disorder: a meta-analysis. *J Am Acad Child Adolesc Psychiatry* 1996; **35:** 352–8.

Lesch-Nyhan syndrome. The severe self-mutilation that occurs in patients with Lesch-Nyhan syndrome (p.976) has been reported to improve in those given antiepileptics such as carbamazepine.[1]

1. Roach ES, *et al.* Carbamazepine trial for Lesch-Nyhan self-mutilation. *J Child Neurol* 1996; **11:** 476–8.

Movement disorders. Carbamazepine is one of many drugs that have been tried in the symptomatic treatment of *chorea* (p.953); there have been anecdotal reports of benefit in both non-hereditary[1,2] and hereditary choreas.[3] Carbamazepine is also among the drugs that have been tried in the treatment of *dystonias* that have not responded to levodopa or antimuscarinics (p.809). Although some patients may benefit from carbamazepine, it is not generally recommended because of a relatively low success rate and the possibility of adverse effects.[4] Carbamazepine therapy has also been associated with movement disorders—see Effects on the Nervous System: Extrapyramidal Effects under Adverse Effects, above.

Carbamazepine has also been used in resistant cases of *tardive dyskinesia* (see under Extrapyramidal Disorders, p.971).

Although not licensed in the UK for movement disorders in children, the *BNFC* suggests that carbamazepine may be tried in disorders such as *paroxysmal kinesigenic choreoathetosis* in doses similar to those used for the treatment of epilepsy (see Administration in Children, above).

4. Anonymous. Dystonia: underdiagnosed and undertreated? *Drug Ther Bull* 1988; **26:** 33–6.

Neonatal seizures. Carbamazepine has been tried in the management of neonatal seizures (p.471).

Neuropathic pain. As well as being used to ease the pain of trigeminal neuralgia (see below) carbamazepine may be of use in other neuropathic pain including that associated with diabetic neuropathy (p.6). A systematic review[1] concluded that about two-fifths of patients who take carbamazepine for neuropathic pain will achieve moderate pain relief, but this was based on small studies. The authors found no evidence that carbamazepine was effective for acute pain.

Carbamazepine has also been tried in an attempt to prevent the painful sensory neuropathy associated with oxaliplatin treatment (p.758); results of preliminary studies have been conflicting.[2,3]

Although not licensed in the UK for neuropathic pain in children, the *BNFC* suggests that carbamazepine may be tried in doses similar to those used for the treatment of epilepsy (see Administration in Children, above).

3. Wilson RH, *et al.* Acute oxaliplatin-induced peripheral nerve hyperexcitability. *J Clin Oncol* 2002; **20:** 1767–74.

Nocturnal enuresis. Carbamazepine has been reported to be of benefit in the treatment of primary nocturnal enuresis; a dose of 200 mg at night for 15 nights markedly decreased the frequency of bed-wetting episodes in 8 children.[1]

For the conventional management of nocturnal enuresis see p.2180.

1. Al-Waili NS, *et al.* Effect of carbamazepine on urinary volume and osmolality, water clearance, and serum osmolality in patients with primary enuresis. *Eur Urol* 2006; **50:** 844–9.

Psychiatric disorders. Carbamazepine has psychotropic properties and has been tried in the management of several psychiatric disorders, particularly in patients with *bipolar disorder* (see above). Carbamazepine has also been used with mixed results in various disorders for the control of symptoms such as agitation, aggression, and rage[1-4] (see Disturbed Behaviour, p.954). It may produce modest benefit when used as an adjunct to antipsychotics in the management of refractory *schizophrenia* (p.955) but any improvement appears to be related to its mood stabilising effect.[5] However, a more recent systematic review,[6] albeit based on small studies, found carbamazepine to have no significant benefit either as monotherapy or as an adjunct to antipsychotics; the authors considered that further randomised studies may be warranted. Carbamazepine also has the potential to reduce serum concentrations of antipsychotics, resulting in clinical deterioration (see under Interactions for Chlorpromazine, p.974). Carbamazepine has also been tried[7] in *post-traumatic stress disorder* (p.953).

1. Mattes JA. Comparative effectiveness of carbamazepine and propranolol for rage outbursts. *J Neuropsychiatr Clin Neurosci* 1990; **2:** 159–64.

6. Leucht S, *et al.* Carbamazepine for schizophrenia. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2007 (accessed 09/06/08).
7. Wolf ME, *et al.* Posttraumatic stress disorder in Vietnam veterans: clinical and EEG findings; possible therapeutic effects of carbamazepine. *Biol Psychiatry* 1988; **23:** 642–4.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p.958) is obscure and treatment has been largely empirical. In a double-blind study involving 174 patients carbamazepine appeared to be more effective than placebo.[1] Oxcarbazepine has been reported[2] to be of benefit in restless legs syndrome induced by paroxetine.

1. Telstad W, *et al.* Treatment of the restless legs syndrome with carbamazepine: a double blind study. *BMJ* 1984; **288:** 444–6.
2. Öztürk Ö, *et al.* Oxcarbazepine treatment for paroxetine-induced restless leg syndrome. *Gen Hosp Psychiatry* 2006; **28:** 264–5.

Tinnitus. Treatment of tinnitus (p.1866) is difficult, and many drugs have been tried. Although carbamazepine has been reported to be effective in some patients, it is rarely used because of its adverse effects.

Trigeminal neuralgia. Carbamazepine is the drug of choice in the treatment of the acute stages of trigeminal neuralgia (p.9). Satisfactory pain relief may be achieved in 70% or more of patients, although increasingly larger doses may be required and adverse effects can be troublesome.

Withdrawal syndromes. Carbamazepine has been tried in the prophylaxis and treatment of various withdrawal syndromes. Reduction in *cocaine use* associated with carbamazepine treatment was found in one short-term controlled study,[1] although a systematic review[2] of data from later studies concluded that there was no evidence to support the use of carbamazepine in the treatment of cocaine dependence (p.1860). It has been reported[3,4] to be of benefit in some patients during *benzodiazepine withdrawal* but such adjunct therapy is not usually indicated (see p.987). Carbamazepine has been shown[5,6] to be effective in the treatment of symptoms of the *alcohol withdrawal syndrome* (p.1626) but as there are limited data on its efficacy in preventing associated delirium tremens and seizures it is usually recommended that it should only be used as an adjunct to benzodiazepine therapy. Carbamazepine has also been studied[7] as an aid in the treatment of alcohol dependence.

Clobazam *(BAN, USAN, rINN)*

Clobazamum; H-4723; HR-376; Klobatsaami; Klobazam; Klobazamas; LM-2717. 7-Chloro-1,5-dihydro-1-methyl-5-phenyl-1,5-benzodiazepine-2,4(3*H*)-dione.

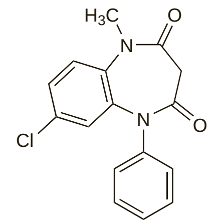
Клобазам

$C_{16}H_{13}ClN_2O_2$ = 300.7.

CAS — 22316-47-8.

ATC — N05BA09.

ATC Vet — QN05BA09.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Clobazam). A white or almost white crystalline powder. Slightly soluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane.

Dependence and Withdrawal

As for Diazepam, p.987.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

Breast feeding. Benzodiazepines, such as clobazam, given to the mother may cause neonatal sedation and breast feeding should be avoided. For comments on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Effects on menstruation. Occasionally the use of clobazam before menstruation for catamenial epilepsy appeared to delay the period.[1]

1. Feely M. Prescribing anticonvulsant drugs 3: clonazepam and clobazam. *Prescribers' J* 1989; **29:** 111–15.

Effects on mental function. For a review of the effects of antiepileptic therapy, including clobazam, on *cognition* and *mood*, including risk of suicidal ideation, see p.468.

Effects on the skin. Report[1] of toxic epidermal necrolysis that developed in light-exposed areas in a patient being treated with clobazam.

1. Redondo P, *et al.* Photo-induced toxic epidermal necrolysis caused by clobazam. *Br J Dermatol* 1996; **135:** 999–1002.

Porphyria. Clobazam is considered to be unsafe in patients with porphyria although there is conflicting evidence of porphyrinogenicity.

For comments on the use of benzodiazepines in porphyria, see p.471.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

As for Diazepam, p.989.

Antiepileptics. For reference to the interactions of clobazam with *felbamate* and *stiripentol*, see under Diazepam, p.990.

Pharmacokinetics

Clobazam is well absorbed from the gastrointestinal tract and peak plasma concentrations are reached 1 to 4 hours after oral doses. It is about 85% bound to plasma proteins. Clobazam is highly lipophilic and rapidly crosses the blood-brain barrier. It is metabolised in the liver by demethylation and hydroxylation but unlike the 1,4-benzodiazepines such as diazepam, clobazam, a 1,5-benzodiazepine, is hydroxylated at the 4-position rather than the 3-position (see also Metabolism under Diazepam, p.992). Clobazam is excreted unchanged and as metabolites mainly in the urine. Mean half-lives of 18 hours and 42 hours have been reported for clobazam and its main active metabolite *N*-desmethylclobazam, respectively.

◊ References.

Uses and Administration

Clobazam is a long-acting 1,5-benzodiazepine with uses similar to those of diazepam (a 1,4-benzodiazepine; see p.992). It may be used as an adjunct in the treatment of epilepsy with other antiepileptics, although its use may be limited by the development of tolerance or sedation (but see below). It is also used in the short-term treatment of acute anxiety.

As an adjunct in **epilepsy** usual oral doses in the UK are 20 to 30 mg daily, increased if necessary to a maximum of 60 mg daily.

For doses in children, see below.

As with other antiepileptics, withdrawal of clobazam therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465 and under Clonazepam, below.

For the short-term management of acute **anxiety** usual oral doses of 10 to 30 mg daily may be taken in divided doses or as a single dose at night; up to 80 mg daily has been used in hospitalised patients with severe anxiety states. Low initial doses and cautious increments to a usual daily dose of 10 to 20 mg are recommended in elderly or debilitated patients.

Administration in children. In the UK, clobazam is licensed for use as an adjunct in epilepsy in children over 3 years of age; no more than half the adult dose (see above) should be given. Alternatively, the *BNFC* suggests the following oral doses according to age:

- 1 month to 12 years: initially 125 micrograms/kg twice daily, increased every 5 days to a usual maintenance dose of 250 micrograms/kg twice daily. The maximum dose is 500 micrograms/kg twice daily and should not exceed 15 mg twice daily
- 12 to 18 years: initially 10 mg twice daily, increased every 5 days to a usual maintenance dose of 10 to 15 mg twice daily. The dose should not exceed 30 mg twice daily

The *BNFC* also suggests that clobazam may be given for cluster seizures and as monotherapy under specialist supervision for catamenial seizures (usually for 7 to 10 days each month just before and during menstruation).

Epilepsy. Benzodiazepines are sometimes used in the management of epilepsy (p.465), but their long-term use is limited by problems of sedation, dependence, and tolerance to the antiepileptic effects.

Clobazam, a 1,5-benzodiazepine, is considered to be somewhat better tolerated than conventional benzodiazepines, and has been widely used for adjunctive oral therapy in patients with epilepsy.[1,2] Clobazam is active against partial and generalised seizures in epilepsy of widely differing aetiology in patients of all ages and has also been used for short-term cover in patients with intermittent seizures, including in women with catamenial epilepsy (seizures associated with menstruation) or patients whose epileptic attacks occur in clusters. Clobazam has also been tried with some success in children, including those with refractory epilepsy[3-5] and epileptic encephalopathy.[6] However, a recent systematic review[7] concluded that although clobazam may reduce seizure frequency and may be most effective in partial onset seizures, it was not clear who would best benefit from its use and over what time-frame.

Neuropathic pain. There has been a mention[1] of the complete relief of *phantom limb pain* (p.9) refractory to other therapy in an elderly patient given clobazam 10 mg three times daily.

1. Rice-Oxley CP. The limited list: clobazam for phantom limb pain. *BMJ* 1986; **293:** 1309.

Preparations

BP 2008: Clobazam Capsules.

Proprietary Preparations (details are given in Part 3)

Arg.: Karidium; ***Austral.:*** Frisium; ***Austria:*** Frisium; ***Belg.:*** Frisium; ***Braz.:*** Frisium; Urbanil; ***Canad.:*** Frisium; ***Chile:*** Frisin†; Grifoclobam; ***Cz.:*** Frisium; ***Denm.:*** Frisium; ***Fin.:*** Frisium; ***Fr.:*** Urbanyl; ***Ger.:*** Frisium; ***Gr.:*** Frisium; ***Hong Kong:*** Frisium; ***Hung.:*** Frisium; ***India:*** Frisium; ***Indon.:*** Asabium; Clobium; Frisium; Proclozam; ***Irl.:*** Frisium; ***Israel:*** Frisium; ***Ital.:*** Frisium; ***Malaysia:*** Frisium; ***Mex.:*** Frisium; ***Neth.:*** Frisium; ***NZ:*** Frisium; ***Pol.:*** Frisium; ***Port.:*** Castilium; Urbanil†; ***S.Afr.:*** Urbanol; ***Singapore:*** Frisium†; ***Spain:*** Noiafren; ***Switz.:*** Urbanyl; ***Thai.:*** Frisium; ***UK:*** Frisium; ***Venez.:*** Frisium.

Clonazepam *(BAN, USAN, rINN)*

Clonazépam; Clonazepamum; Klonatsepaami; Klonazepám; Klonazepam; Klonazepamas; Ro-5-4023. 5-(2-Chlorophenyl)-1,3-dihydro-7-nitro-1,4-benzodiazepin-2-one.

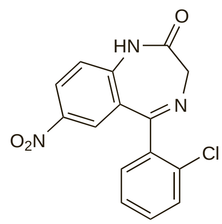
Клоназепам

$C_{15}H_{10}ClN_3O_3$ = 315.7.

CAS — 1622-61-3.

ATC — N03AE01.

ATC Vet — QN03AE01.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of clonazepam:

K-Pins; Klondike Bars; Klonnies; Klons; La Roche; Pins; R2; R-2; Roaches; Roachies; Roche.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Clonazepam). A slightly yellowish, crystalline powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol. Protect from light.

USP 31 (Clonazepam). A light yellow powder having a faint odour. Insoluble in water; slightly soluble in alcohol and in ether; sparingly soluble in acetone and in chloroform. Store in airtight containers. Protect from light.

Sorption. Significant loss of clonazepam (up to 50% over 24 hours) has been reported[1] from solutions infused through PVC tubing; the effect was concentration dependent. The authors recommended that non-PVC tubing should always be used.

1. Schneider JJ, *et al.* Effect of tubing on loss of clonazepam administered by continuous subcutaneous infusion. *J Pain Symptom Manage* 2006; **31:** 563–7.

Dependence and Withdrawal

As for Diazepam, p.987.

Withdrawal. A study[1] of the withdrawal of clonazepam therapy in 40 epileptic children found that 19 had withdrawal symptoms of increased seizure frequency, either alone or with other symptoms but that this effect was transient. Withdrawal seizures and status might become an obstacle to the removal of useless or even deleterious therapy with clonazepam because the transient nature of these effects was not always recognised. Clonazepam should not be used for more than 3 to 6 months and should be stopped if clear and lasting therapeutic benefit could not be shown.

See also Uses and Administration, below.

1. Specht U, *et al.* Discontinuation of clonazepam after long-term treatment. *Epilepsia* 1989; **30:** 458–63.

Adverse Effects, Treatment, and Precautions

As for Diazepam, p.987.

The principal adverse effect of clonazepam is drowsiness, which occurs in about 50% of all patients when starting therapy. Salivary or bronchial hypersecretion may cause respiratory problems in children. Thrombophlebitis has been associated with intravenous use and may be avoided by injection into a large vein at a rate not exceeding 500 micrograms/minute. Respiration and blood pressure should also be monitored.

Care is required when withdrawing clonazepam therapy—see above.

Breast feeding. Benzodiazepines, such as clonazepam, given to the mother may cause neonatal sedation and breast feeding should be avoided. For comments on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Effects on the endocrine system. Precocious development of secondary sexual characteristics occurred in a 15-month-old girl 2 months after starting treatment with clonazepam 500 micrograms twice daily for convulsions.[1] Symptoms regressed upon withdrawal of clonazepam.

1. Choonara IA, *et al.* Clonazepam and sexual precocity. *N Engl J Med* 1985; **312:** 185.

Effects on mental function. For a review of the effects of antiepileptic therapy, including clonazepam, on *cognition* and mood, including the risk of suicidal ideation, see p.468.

Effects on the mouth. A 52-year-old woman developed burning mouth syndrome after starting clonazepam;[1] some improvement was noted when the dose was reduced but symptoms were still intolerable and clonazepam was withdrawn. Subsequently, symptoms resolved within 3 weeks.

1. Culhane NS, Hodle AD. Burning mouth syndrome after taking clonazepam. *Ann Pharmacother* 2001; **35:** 874–6.

Effects on sexual function. Sexual dysfunction was reported[1] in 18 of 42 male patients receiving clonazepam for the treatment of post-traumatic stress disorder; symptoms resolved when therapy was changed to diazepam in 17 patients and lorazepam in the remaining patient.

1. Fossey MD, Hamner MB. Clonazepam-related sexual dysfunction in male veterans with PTSD. *Anxiety* 1994-95; **1:** 233–6.

Extrapyramidal disorders. For reference to extrapyramidal disorders associated with the use of benzodiazepines including clonazepam, see Effects on the Nervous System in Diazepam, p.988. However, clonazepam is also used in the treatment of some extrapyramidal disorders as discussed under Uses and Administration, below.

Porphyria. Clonazepam is considered to be unsafe in patients with porphyria although there is conflicting evidence of porphyrinogenicity.

For comments on the use of benzodiazepines in porphyria, see p.471.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

As for Diazepam, p.989.

Antiepileptics. For reference to possible interactions between clonazepam and other antiepileptics, see under Diazepam, p.990 and Benzodiazepines under Interactions of Phenytoin, p.499.

Pharmacokinetics

Clonazepam is quickly absorbed after oral doses with a bioavailability of about 90%; peak plasma concentrations are reached between 1 and 4 hours after ingestion. It is extensively metabolised in the liver, its principal metabolite being 7-aminoclonazepam, which has no antiepileptic activity; minor metabolites are the 7-acetamido- and 3-hydroxy-derivatives. It is excreted mainly in the urine almost entirely as its metabolites in free or conjugated form. It is about 85% bound to plasma proteins and estimations of its elimination half-life range from about 20 to 40 hours, and occasionally more.

A therapeutic range of plasma concentrations has not been established.

Clonazepam crosses the placental barrier and is distributed into breast milk.

The pharmacokinetics of clonazepam may be affected by use with other antiepileptics (see under Interactions, above).

◊ A single-dose pharmacokinetic study[1] in healthy subjects found that absorption of clonazepam was slower and intersubject variability was greater after intramuscular injection than after an oral dose. The pharmacokinetics of a modified-release subcutaneous injection have also been studied in healthy subjects;[2] plasma-clonazepam concentrations were sustained and elimination occurred slowly over 13 days.

1. Crevoisier C, *et al.* Comparative single-dose pharmacokinetics of clonazepam following intravenous, intramuscular and oral administration to healthy volunteers. *Eur Neurol* 2003; **49:** 173–7.
2. Greenblatt DJ, *et al.* Clonazepam pharmacokinetics: comparison of subcutaneous microsphere injection with multiple-dose oral administration. *J Clin Pharmacol* 2005; **45:** 1288–93.

Bioavailability. It has been suggested, on the basis of anecdotal evidence,[1] that there may be differences in bioavailability, and hence in clinical effect, between formulations of clonazepam tablets.

1. Rapaport MH. Clinical differences between the generic and non-generic forms of clonazepam. *J Clin Psychopharmacol* 1997; **17:** 424.

Uses and Administration

Clonazepam is a benzodiazepine derivative similar to diazepam (p.992), with marked antiepileptic properties.

It may be used in the treatment of all types of epilepsy and seizures (p.465), including status epilepticus (p.469), but its usefulness in chronic treatment is sometimes limited by the development of tolerance and by sedation, and other antiepileptics are often preferred. It may also be used in myoclonus (p.470) and associated abnormal movements, and for the treatment of panic disorder (see Psychiatric Disorders, below).

For **epilepsy** and **myoclonus** treatment is started with small doses that are progressively increased to an optimum dose according to response. Total daily doses may initially be taken in 3 or 4 divided doses; however, once the maintenance dose has been reached, the daily amount may be given as a single dose at night. In the UK the initial oral dose is 1 mg (500 micrograms in the elderly) at night for 4 nights gradually increased over 2 to 4 weeks to a usual maintenance dose of 4 to 8 mg daily; it is recommended that the total dose should not exceed 20 mg daily. Dosage recommendations in the USA are generally similar although initial doses of up to 1.5 mg daily are permitted and dosage increments of 0.5 to 1 mg every 3 days are recommended. There is little value in routinely monitoring plasma-clonazepam concentrations.

Clonazepam may be an alternative to other benzodiazepines in the emergency management of **status epilepticus**. The usual dose is 1 mg given by slow intravenous injection over at least 2 minutes or by intravenous infusion, repeated if necessary to a maximum total dose of 20 mg.

For doses in children, see below.

As with other antiepileptics, withdrawal of clonazepam therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465 and above.

In the treatment of **panic disorder**, clonazepam is given in an initial oral dose of 250 micrograms twice daily. This may be increased after 3 days to a total of 1 mg daily; a few patients may benefit from further increases, up to a maximum of 4 mg daily. In order to minimise drowsiness, clonazepam may be taken as a single dose at bedtime. Withdrawal should again be gradual.

Administration. Serum concentrations of clonazepam after buccal, intranasal, or intravenous dosage were measured in a crossover study[1] in 7 healthy males. The results showed that intranasal clonazepam may offer an alternative to buccal use in patients with serial seizures but the initial concentrations were too low to recommend its use as an alternative to intravenous clonazepam in the management of status epilepticus. The nasal formulation used in this study contained dimethyl-β-cyclodextrin as a solubiliser and absorption enhancer.

1. Schols-Hendriks MWG, *et al.* Absorption of clonazepam after intranasal and buccal administration. *Br J Clin Pharmacol* 1995; **39:** 449–51.

Administration in children. For **epilepsy** and **myoclonus** treatment with clonazepam is started with small doses that are progressively increased to an optimum dose according to response. Total daily doses are taken in 3 divided doses; however, once the maintenance dose has been reached, the daily amount may be given as a single dose at night. Alternatively, the *BNFC* suggests giving the initial dose at night for 4 nights and gradually increasing it over 2 to 4 weeks. In the UK, the recommended initial oral daily dose is up to 250 micrograms for infants and children aged up to 5 years, or up to 500 micrograms for older children. The following usual maintenance doses are given according to age:

- neonate to 1 year (although the BNFC recommends a minimum age of 1 month): 0.5 to 1 mg daily
- 1 to 5 years: 1 to 3 mg daily
- 5 to 12 years: 3 to 6 mg daily

Older children may be given the usual adult dose (see above).

If control of childhood epilepsy ceases to be adequate with clonazepam, the dose may be increased, or treatment interrupted for 2 or 3 weeks. The *BNFC* states that the UK injection formulation (*Rivotril; Roche, UK*) can be given orally if necessary; this may not apply to other injection formulations available elsewhere.

In the USA, doses may be given according to body weight. Infants and children aged up to 10 years or weighing up to 30 kg may be given an initial daily dose of 10 to 30 micrograms/kg (maximum 50 micrograms/kg) in 2 or 3 divided doses. This may be increased by a total of 250 to 500 micrograms every 3 days to a maintenance dose of 100 to 200 micrograms/kg daily given in 3 divided doses.

In the emergency management of **status epilepticus**, clonazepam is used as an alternative to other benzodiazepines. The usual dose in children is 500 micrograms given by slow intravenous injection or by intravenous infusion. Alternatively, the *BNFC* suggests giving the following doses by slow intravenous injection over at least 2 minutes according to age:

- neonates: 100 micrograms/kg, repeated if necessary after 24 hours
- 1 month to 12 years: 50 micrograms/kg (maximum 1 mg), repeated if necessary

Older children may be given the usual adult dose.

In children aged over 1 month, these doses by injection may be followed by an intravenous infusion of 10 micrograms/kg per hour, adjusted according to response to a maximum of 60 micrograms/kg per hour.

Extrapyramidal disorders. Clonazepam may be of benefit in some extrapyramidal disorders. It has been tried in the management of patients with *tic disorders* such as *Tourette's syndrome* (p.954) but evidence of efficacy from controlled studies is limited.[1] Some use clonazepam in preference to haloperidol[2] since it does not carry the risk of tardive dyskinesia associated with such antipsychotics and a case report[3] described the successful use of clonazepam for haloperidol-induced tardive Tourette's syndrome in an adult patient. There is also limited evidence of benefit with clonazepam in antipsychotic-induced *akathisia*[4,5] and *tardive dyskinesia*[6,7] (see under Extrapyramidal Disorders, p.971), and of improvement in *dysarthria* in a study in patients with parkinsonism.[8]

8. Biary N, *et al.* A double-blind trial of clonazepam in the treatment of parkinsonian dysarthria. *Neurology* 1988; **38:** 255–8.

Hiccup. For the management of intractable hiccups see under Chlorpromazine, p.976. Clonazepam may also be of value, especially in neurogenic hiccups.

Neuropathic pain. The management of *phantom limb pain* (p.9) can be difficult, and tricyclic antidepressants and antiepileptics are used for the neuropathic components of the pain. Rapid and marked pain relief was achieved in 2 patients with lancinating phantom limb pain after treatment with clonazepam with or without amitriptyline.[1]

Although carbamazepine is the drug of choice in the treatment of *trigeminal neuralgia* (p.9), clonazepam may be used in carbamazepine-intolerant patients.

1. Bartusch SL, *et al.* Clonazepam for the treatment of lancinating phantom limb pain. *Clin J Pain* 1996; **12:** 59–62.

Psychiatric disorders. Although the risk of dependence with benzodiazepines may outweigh their benefits in panic disorder (p.952), clonazepam has been used for the treatment of panic disorder with or without agoraphobia, and reported benefit in such patients[1] suggests a similar action to alprazolam. A literature review[2] evaluated the use of clonazepam in a range of psychiatric disorders and found that it may also be effective in the treatment of social anxiety disorder (see Phobic Disorders, p.953) although further studies are warranted. There was evidence to suggest that clonazepam may be useful in acute mania (p.372) and for the augmentation of antidepressant therapy with SSRIs in depression (p.373). A study[3] found that augmentation was significantly more effective with a daily dose of 3 mg of clonazepam than with lower doses.

3. Morishita S, Aoki S. Clonazepam in the treatment of prolonged depression. *J Affect Disord* 1999; **53:** 275–8.

Sleep-associated movement disorders. Treatment of sleep-associated movement disorders (p.958) including sleep behaviour disorder, restless legs syndrome, and periodic limb movements in sleep is largely empirical, but benzodiazepines such as clonazepam are often used.[1] Small studies have provided some evidence for benefit with clonazepam therapy in these disorders,[2-4] including bruxism.[5]

1. Schenck CH, Mahowald MW. Long-term, nightly benzodiazepine treatment of injurious parasomnias and other disorders of disrupted nocturnal sleep in 170 adults. *Am J Med* 1996; **100:** 333–7.

4. Saletu M, *et al.* Restless legs syndrome (RLS) and periodic limb movement disorder (PLMD): acute placebo-controlled sleep laboratory studies with clonazepam. *Eur Neuropsychopharmacol* 2001; **11:** 153–61.
5. Saletu A, *et al.* On the pharmacotherapy of sleep bruxism: placebo-controlled polysomnographic and psychometric studies with clonazepam. *Neuropsychobiology* 2005; **51:** 214–25.

Stiff-man syndrome. Clonazepam has been used as an alternative to diazepam in the management of stiff-man syndrome (see under Muscle Spasm, p.993) and is reported[1] to be effective for familial startle disease, a rare congenital form of stiff-man syndrome.

1. Ryan SG, *et al.* Startle disease, or hyperekplexia: response to clonazepam and assignment of the gene (STHE) to chromosome 5q by linkage analysis. *Ann Neurol* 1992; **31:** 663–8.

Tinnitus. Clonazepam is one of many drugs that have been tried in tinnitus (p.1866), but although it has been reported to be effective in some patients it is rarely used because of problems with adverse effects.

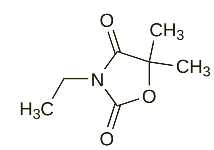
Ethadione

Etadiona. 3-Ethyl-5,5-dimethyl-2,4-oxazolidinedione.

Этадион

$C_7H_{11}NO_3$ = 157.2.
CAS — 520-77-4.
ATC — N03AC03.
ATC Vet — QN03AC03.



Profile

Ethadione is an oxazolidinedione antiepileptic that has been given orally to treat epilepsy in patients with absence seizures resistant to other therapy.

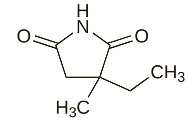
Preparations

Ethosuximide *(BAN, USAN, rINN)*

CI-366; CN-10395; Ethosuximid; Éthosuximide; Ethosuximidum; Etosüksimid; Etosuksimidas; Etosuksimidi; Etosuksymid; Etosuximid; Etosuximida; Etoszuximid; NSC-64013; PM-671. 2-Ethyl-2-methylsuccinimide.

Этосуксимид

$C_7H_{11}NO_2$ = 141.2.
CAS — 77-67-8.
ATC — N03AD01.
ATC Vet — QN03AD01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Ethosuximide). A white or almost white powder or waxy solid. It exhibits polymorphism. Freely soluble in water;

The symbol † denotes a preparation no longer actively marketed

very soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Ethosuximide). A white to off-white crystalline powder or waxy solid, having a characteristic odour. Freely soluble in water and in chloroform; very soluble in alcohol and in ether; very slightly soluble in petroleum spirit. Store in airtight containers.

Adverse Effects and Treatment

Gastrointestinal adverse effects including nausea, vomiting, diarrhoea, anorexia, gastric upset, and abdominal pain occur quite often with ethosuximide. Other effects that may occur include headache, fatigue, lethargy, drowsiness, dizziness, ataxia, hiccup, and mild euphoria.

More rarely dyskinesias, personality changes, depression, psychosis, sleep disturbances including night terrors, skin rashes, erythema multiforme or Stevens-Johnson syndrome, SLE, photophobia, gum hypertrophy, tongue swelling, myopia, increased libido, and vaginal bleeding have been reported. There are a few reports of blood disorders including eosinophilia, leucopenia, agranulocytosis, thrombocytopenia, pancytopenia, and aplastic anaemia; fatalities have occurred.

Abnormal renal and liver function values have been recorded.

Effects on mental function. For the effects of antiepileptic therapy on cognition and mood, including the risk of suicidal ideation, see p.468.

Precautions

Ethosuximide should be used with caution in patients with impaired hepatic or renal function. Licensed product information recommends regular hepatic and renal-function tests (and some suggest blood counts) during treatment with ethosuximide, although the practical value of such monitoring has been questioned. Patients or their carers should be told how to recognise signs of blood toxicity and they should be advised to seek immediate medical attention if symptoms such as fever, sore throat, mouth ulcers, bruising, or bleeding develop.

Care is required when withdrawing ethosuximide therapy—see also Uses and Administration, below.

Breast feeding. Ethosuximide is distributed in significant amounts into breast milk; hyperexcitability and poor suckling have been reported in the infant. Although licensed product information recommends that breast feeding should be avoided, the American Academy of Pediatrics[1] considers that ethosuximide is usually compatible with breast feeding.

For further comment on antiepileptic therapy and breast feeding, see p.467.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 09/06/08)

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Porphyria. Ethosuximide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy.

Antibacterials. *Isoniazid* raises the plasma concentration of ethosuximide and increases the risk of toxicity. Psychotic behaviour has been reported[1] in a patient stabilised on ethosuximide and sodium valproate, after the introduction of isoniazid. Serum-ethosuximide concentrations rose substantially until both ethosuximide and isoniazid were stopped.

1. van Wieringen A, Vrijlandt CM. Ethosuximide intoxication caused by interaction with isoniazid. *Neurology* 1983; **33:** 1227–8.

Antidepressants. As with all antiepileptics, antidepressants may antagonise the antiepileptic activity of ethosuximide by lowering the convulsive threshold.

Antiepileptics. Since ethosuximide has a limited spectrum of antiepileptic action, patients with mixed seizure syndromes may require addition of other antiepileptics. *Carbamazepine*, *phenobarbital*, and *phenytoin* have all been shown[1] to increase the clearance of ethosuximide and thus reduce plasma concentrations. This interaction is likely to be clinically relevant and higher ethosuximide dosages may be necessary to achieve therapeutic drug levels. The effect of *valproic acid* on ethosuximide concentrations is unclear. One study[2] showed a marked increase in serum ethosuximide concentrations once valproate was added to combination therapies; increases in ethosuximide concentrations have also been noted in healthy subjects when taken with valproic acid.[3] Conversely, other studies have reported reductions[4] or no significant changes in serum ethosuximide concentrations[5,6] with valproic acid. For the effect of ethosuximide on valproic acid, see p.511.

Antipsychotics. As with all antiepileptics, antipsychotics may antagonise the antiepileptic activity of ethosuximide by lowering the convulsive threshold.

Pharmacokinetics

Ethosuximide is readily absorbed from the gastrointestinal tract and extensively hydroxylated in the liver to its principal metabolite which is reported to be inactive. Ethosuximide is excreted in the urine mainly in the form of its metabolites, either free or conjugated, but about 12 to 20% is also excreted unchanged.

Ethosuximide is widely distributed throughout the body, but is not significantly bound to plasma proteins. A half-life of about 40 to 60 hours has been reported for adults with a shorter half-life of about 30 hours in children.

Monitoring of plasma concentrations has been suggested as an aid in assessing control and the therapeutic range of ethosuximide is usually quoted as being 40 to 100 micrograms/mL (about 300 to 700 micromoles/litre); concentrations in saliva and tears have also been measured.

Ethosuximide crosses the placental barrier, and is distributed into breast milk.

The pharmacokinetics of ethosuximide are affected by use with other antiepileptics (see under Interactions, above).

Uses and Administration

Ethosuximide is a succinimide antiepileptic used in the treatment of absence seizures (below). It may also be used for myoclonic seizures. Ethosuximide is ineffective against tonic-clonic seizures and may unmask them if given alone in mixed seizure types.

A plasma-ethosuximide concentration of 40 to 100 micrograms/mL (about 300 to 700 micromoles/litre) appears to be generally necessary. The initial dose is 500 mg daily by mouth. The dosage is then adjusted in steps of 250 mg every 4 to 7 days, according to response. Control of seizures is usually produced with a daily dose of 1 to 1.5 g, although some patients may require doses of up to 2 g; strict supervision is necessary when the dose exceeds 1.5 g. Daily doses at the higher end of the range should be given in 2 divided doses.

For doses in children, see below.

As with other antiepileptics, withdrawal of ethosuximide therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Administration in children. Ethosuximide may be used in the treatment of absence (petit mal) seizures and for myoclonic seizures in infants and children. In the UK, the following recommended oral doses are given according to age:

- up to 6 years of age: an initial dose of 250 mg daily, increased gradually in small steps every few days to a usual dose of 20 mg/kg daily; licensed information for one product (*Emeside; Chemidex, UK*) recommends that the dose should not exceed 1 g. (Similar dosages are recommended in the USA for children aged between 3 to 6 years). The *BNFC* suggests giving the daily dose as 2, or if necessary 3, divided doses
- aged 6 years and above: usual adult doses (see above)

Epilepsy. Ethosuximide is a drug of choice in the treatment of absence seizures; it may also be used for myoclonic, atonic, and tonic seizures but is ineffective in other forms of epilepsy (p.465). Ethosuximide may be given with other antiepileptics in the treatment of mixed-seizure syndromes that include absences. It has been suggested that ethosuximide may provoke tonic-clonic seizures, but there is not a great deal of evidence for this. One early report indicated that 22 of 85 patients receiving a regimen of ethosuximide, mesuximide, and trimethadione for absence seizures developed tonic-clonic seizures[1] and another of similar vintage reported exacerbation of mixed-seizure types in 7 patients receiving ethosuximide.[2] However, it is recognised that patients with absence seizures have a high incidence of generalised tonic-clonic seizures[3] and it would presumably be difficult to distinguish such attacks from any putative effect of ethosuximide. Furthermore, ethosuximide is not effective against tonic-clonic seizures, and in patients with mixed-seizure types it might be expected to unmask the non-absence components of the disease.

Ethosuximide has also been tried in the management of absence status epilepticus (p.469).

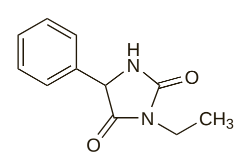
Ethotoin *(BAN, rINN)*

Éthotoïne; Ethotoinum; Etotoiini; Etotoin; Etotoína. 3-Ethyl-5-phenylhydantoin.

Этотоин

$C_{11}H_{12}N_2O_2$ = 204.2.
CAS — 86-35-1.
ATC — N03AB01.
ATC Vet — QN03AB01.



Pharmacopoeias. In *US.*

USP 31 (Ethotoin). A white crystalline powder. Insoluble in water; freely soluble in dehydrated alcohol and in chloroform; soluble in ether. Store in airtight containers.

Profile

Ethotoin is a hydantoin antiepileptic with actions similar to those of phenytoin (p.495), but it is reported to be both less toxic and less effective and is not commonly used in epilepsy (p.465).

Ethotoin is given orally for tonic-clonic and complex partial seizures in initial doses of up to 1 g daily, increased gradually at intervals of several days to 2 to 3 g daily, given in 4 to 6 divided doses after meals.

Administration. A study[1] of the pharmacokinetics of ethotoin given at more convenient intervals of every 8 hours.

1. Browne TR, Szabo GK. A pharmacokinetic rationale for three times daily administration of ethotoin (Peganone). *J Clin Pharmacol* 1989; **29:** 270–1.

Porphyria. Ethotoin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

USP 31: Ethotoin Tablets.

Proprietary Preparations (details are given in Part 3)
USA: Peganone.

Felbamate (*USAN, rINN*)

AD-03055; Felbamato; Felbamatum; W-554. 2-Phenyl-1,3-propanediol dicarbamate.

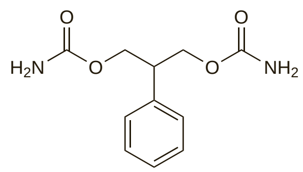
Фелбамат

$C_{11}H_{14}N_2O_4$ = 238.2.

CAS — 25451-15-4.

ATC — N03AX10.

ATC Vet — QN03AX10.



Adverse Effects

The most frequently reported adverse effects with felbamate are anorexia, weight loss, nausea and vomiting, rash, insomnia, headache, dizziness, somnolence, and diplopia. Aplastic anaemia or acute liver failure, sometimes fatal, have occurred rarely, and there have been reports of Stevens-Johnson syndrome.

Effects on the kidneys. A 15-year-old boy receiving up to 3 g of felbamate daily developed urethral obstruction due to formation of urethral stones composed of felbamate.[1] Records revealed that unidentified urinary crystals had been found in the patient's urine 2 years before presentation with acute urolithiasis.

For reports of crystalluria associated with felbamate overdosage, see below.

1. Sparagana SP, *et al.* Felbamate urolithiasis. *Epilepsia* 2001; **42:** 682–5.

Effects on mental function. For the effects of antiepileptic therapy on cognition and mood, including the risk of suicidal ideation, see p.468

Effects on the skin. Toxic epidermal necrolysis has been reported[1] in a patient 16 days after she started monotherapy with felbamate for partial complex seizures.

1. Travaglini MT, *et al.* Toxic epidermal necrolysis after initiation of felbamate therapy. *Pharmacotherapy* 1995; **15:** 260–4.

Overdosage. A 20-year-old woman presented with slurred speech and nausea 4 hours after ingesting 18 g of felbamate and 12 to 25 g of sodium valproate.[1] Over the next 4 to 5 hours she became combative, uncooperative, and progressively obtunded and eventually required endotracheal intubation and assisted ventilation. Peak plasma concentrations of 200 micrograms/mL for felbamate and 470 micrograms/mL for sodium valproate occurred 12 and 14 hours respectively after ingestion. Large quantities of macroscopic crystals, identified as containing felbamate, were noted in the urine 18 hours after ingestion and the patient developed renal failure. The crystalluria and renal failure responded to parenteral hydration. In another case report,[2] a 3-year-old child ingested 232 mg/kg of felbamate resulting in ataxia, vomiting, crystalluria, haematuria, and mild tachycardia. The plasma concentration of felbamate 15 hours after ingestion was 138 micrograms/mL. She was successfully treated with an infusion of sodium chloride 0.9% and intravenous metoclopramide; no renal impairment was seen.

2. Meier KH, *et al.* Acute felbamate overdose with crystalluria. *Clin Toxicol* 2005; **43:** 189–92.

Precautions

Felbamate is contra-indicated in patients with a history of blood disorders or hepatic impairment. It should be used only in the treatment of severe epilepsy refractory to other antiepileptics because of the risk of fatal aplastic anaemia or acute liver failure. Patients or their carers should be advised of the symptoms of aplastic anaemia and be told to report immediately should any such symptoms develop. Complete blood counts should be carried out before the patient starts treatment and regularly during treatment (but see Epilepsy, under Uses and Administration, below). Aplastic anaemia may occur after felbamate has been stopped so patients should continue to be monitored for some time. Liver function tests are also recommended before starting and regularly (at 1- to 2-week intervals) during treatment. Felbamate should be stopped if there is any evidence of bone marrow depression or liver abnormalities.

Felbamate should be used with caution in patients with renal impairment. Felbamate may cause photosensitivity reactions and patients should be advised to take protective measures against exposure to UV radiation.

Care is required when withdrawing felbamate therapy—see also Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

The elderly. Felbamate may need to be given with care in elderly patients (see Administration in the Elderly, below).

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. The metabolism of felbamate is enhanced by enzyme inducers such as phenytoin, phenobarbital, or carbamazepine. In contrast, the half-life of felbamate may be prolonged by gabapentin. Felbamate inhibits or enhances the metabolism of several other antiepileptics and care is required when it is added to therapy.

Anticoagulants. For the effect of felbamate on *warfarin*, see p.1429.

Antiepileptics. For some references to the effect of felbamate on other antiepileptics, see under *Carbamazepine*, p.474, *Phenobarbital*, p.493, *Phenytoin*, p.498, and *Valproate* p.511.

Sex hormones. For the effect of felbamate on *oral contraceptives* see p.2068 and also under Gestodene, p.2105.

Pharmacokinetics

Felbamate is well absorbed from the gastrointestinal tract and peak plasma concentrations have been reported 1 to 6 hours after oral doses. Protein binding is reported to be about 22 to 25%. It is partly metabolised in the liver by hydroxylation and conjugation to inactive metabolites. Felbamate is excreted mainly in the urine as metabolites and unchanged drug (40 to 50%); less than 5% appears in the faeces. The terminal half-life is reported to be between 16 and 23 hours. Felbamate is distributed into breast milk.

The pharmacokinetics of felbamate are reported to be linear at the doses used clinically. Therapeutic plasma concentrations have been reported to be between 30 and 80 micrograms/mL.

The pharmacokinetics of felbamate are affected by use with other antiepileptics (see Interactions, above).

◊ See under Uses and Administration (below) for mention of pharmacokinetic studies of felbamate in the elderly and in patients with renal impairment.

Uses and Administration

Felbamate is a carbamate structurally related to meprobamate (p.1006). It is used in the treatment of epilepsy (see below); however, because of its toxicity, it should only be used in severe cases unresponsive to other drugs.

Felbamate is given orally as monotherapy or adjunctive therapy for refractory partial seizures with or without secondary generalisation. It is used in children as adjunctive therapy in controlling the seizures associated with the Lennox-Gastaut syndrome (see below).

The initial dose of felbamate when given as *monotherapy* is 1.2 g daily in 3 or 4 divided doses. The daily dose should be increased gradually under close supervision; increments of 600 mg every 2 weeks are given according to response, up to 2.4 g daily. Thereafter doses may be further increased to a maximum of 3.6 g daily if necessary.

Similar initial doses are given as *adjunctive* therapy, but the doses of the other antiepileptics should be decreased as necessary. This adjunctive dose may be increased by 1.2 g at weekly intervals, up to a maximum of 3.6 g.

As with other antiepileptics, withdrawal of felbamate therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

◊ References.

Administration in children. As an adjunct in Lennox-Gastaut syndrome, the initial oral dose of felbamate in children aged 2 to 14 years is 15 mg/kg daily in 3 to 4 divided doses. This may be increased gradually in increments of 15 mg/kg at weekly intervals to a maximum of 45 mg/kg daily; the doses of other antiepileptics should be decreased as necessary.

Those aged 14 years and over may be given the usual adult dose (see above) as monotherapy or adjunctive therapy for refractory partial seizures with or without secondary generalisation.

Administration in the elderly. The elderly may require lower initial doses of felbamate and slower dose titration. After single doses of felbamate, plasma concentrations and half-lives were greater and mean clearance lower in elderly than in young subjects, whereas pharmacokinetic parameters after multiple dosing schedules were similar.[1]

1. Richens A, *et al.* Single and multiple dose pharmacokinetics of felbamate in the elderly. *Br J Clin Pharmacol* 1997; **44:** 129–34.

Administration in renal impairment. A single-dose pharmacokinetic study[1] indicated that in patients with renal impairment the initial dose of felbamate may need to be lower and increases made more cautiously than in patients with normal renal function (licensed product information suggests halving initial and maintenance doses).

1. Glue P, *et al.* Single-dose pharmacokinetics of felbamate in patients with renal dysfunction. *Br J Clin Pharmacol* 1997; **44:** 91–3.

Epilepsy. Although felbamate was well tolerated in clinical studies, rare but serious adverse effects were noted during early postmarketing use.[1,2] Aplastic anaemia and serious hepatotoxic reactions, sometimes with fatal outcomes, developed in some patients. Patients taking felbamate should have frequent blood counts and monitoring of liver enzymes. However there is no evidence that such monitoring will prevent adverse outcomes; in addition, the risk of aplastic anaemia is thought to decrease after the first year of therapy, and the need for ongoing blood counts is still less clear.[3] Even if detected early, aplastic anaemia and hepatic impairment may not be reversible.[1] Usage in the USA is restricted to patients with refractory partial seizures with or without secondary generalisation or for adjunctive therapy for children with Lennox-Gastaut syndrome. Guidelines on appropriate use have been issued.[3]

The overall management of epilepsy is discussed on p.465.

Adverse Effects and Precautions

As for Phenytoin, p.495.

Severe cardiovascular reactions, sometimes fatal, have been reported after intravenous doses of fosphenytoin. Therefore, continuous monitoring of ECG, blood pressure, and respiratory function is recommended during the infusion, and the patient should be kept under observation for at least 30 minutes after the end of the infusion. Hypotension may occur with recommended doses and rates of infusion; a reduction in the infusion rate or stopping therapy may be necessary. Fosphenytoin is contra-indicated in patients with sinus bradycardia, sino-atrial block, second- or third-degree AV block, or Stokes-Adams syndrome.

Burning, itching, and paraesthesia, particularly in the groin area, have also been reported after intravenous fosphenytoin; reducing the rate of, or temporarily stopping, the infusion may relieve the discomfort.

Caution should be exercised when giving fosphenytoin to patients in whom phosphate restriction is necessary. The rate of metabolism of fosphenytoin to phenytoin may be increased in patients with hepatic or renal disease, or in those with hypoalbuminaemia, and consequently there is an increased risk of adverse effects in such patients.

Effects on the cardiovascular system. The UK CSM[1] stated in May 2000 that worldwide there had been reports of 21 cases of asystole, ventricular fibrillation, or cardiac arrest associated with intravenous use of fosphenytoin. Of these, 5 cases had received doses or infusion rates greater than recommended. There had also been 34 reports of hypotension, 15 of bradycardia, and 10 of varying degrees of heart block. Most reactions had occurred within 30 minutes of the infusion. A review[2] of adverse events associated with fosphenytoin infusion received by the FDA Adverse Event Reporting System between 1997 and 2002 identified 29 of adverse cardiac events, including 10 fatalities. Of these reports, 5 were of sinus arrest, 4 of AV block, and 8 of asystole. The authors acknowledged that the majority of patients had serious confounders including renal failure, stroke, acute cardiac ischaemia or failure, overdose, or infection.

ECG changes consistent with hypocalcaemia have occurred in a patient who received 1500 mg-equivalents of phenytoin over 85 minutes as an intravenous infusion of fosphenytoin.[3] The patient had initially been normocalcaemic and it was suggested that the effect may have been due to acute inorganic phosphate toxicity.

3. Keegan MT, *et al.* Hypocalcemia-like electrocardiographic changes after administration of intravenous fosphenytoin. *Mayo Clin Proc* 2002; **77:** 584–6.

Porphyria. Phenytoin is considered unsafe in porphyric patients; it would be prudent to assume that this consideration also applied to its prodrug, fosphenytoin.

Interactions

As for Phenytoin, p.497.

Pharmacokinetics

Plasma concentrations of fosphenytoin are maximal at the end of intravenous infusion and about 30 minutes after intramuscular injection. Protein binding of fosphenytoin is high (95 to 99%), mainly to albumin, and is saturable. Fosphenytoin displaces phenytoin from protein binding sites which increases the fraction of unbound phenytoin to up to 30% for about half to one hour post-infusion. Fosphenytoin is rapidly and completely hydrolysed to phenytoin with a conversion half-life of about 15 minutes; one mmol of fosphenytoin yields one mmol of phenytoin, and the same of phosphate and formate. Metabolites of phenytoin are excreted in the urine. For the pharmacokinetics of phenytoin, see p.500.

◊ References.

1. Fischer JH, *et al.* Fosphenytoin: clinical pharmacokinetics and comparative advantages in the acute treatment of seizures. *Clin Pharmacokinet* 2003; **42:** 33–58.

Uses and Administration

Fosphenytoin is a prodrug of phenytoin (p.495) used similarly as part of the emergency treatment of status epilepticus (p.469). It is also used for the prevention and treatment of post-traumatic seizures (p.501) associated with neurosurgery or head trauma and as a short-term parenteral substitute for oral phenytoin in the management of epilepsy (p.465).

Fosphenytoin is given as the sodium salt and doses of fosphenytoin sodium are expressed as phenytoin sodium equivalents (PSE); therefore no adjustment in dosage is necessary when substituting fosphenytoin for phenytoin or vice versa. Fosphenytoin may be given by intramuscular injection or intravenous infusion; only the intravenous route is recommended in children.

The maximum rate of intravenous infusion in PSE is 150 mg/minute and should not be exceeded. Continuous monitoring of ECG, blood pressure, and respiratory function is recommended during intravenous infusion. Patients should also be observed for at least 30 minutes after the end of infusion.

In the treatment of tonic-clonic status epilepticus a benzodiazepine such as diazepam or lorazepam is usually given initially intravenously or rectally followed by fosphenytoin. In the UK, the loading dose in PSE is 15 mg/kg given as a single dose by intravenous infusion at a rate of 100 to 150 mg/minute. The intramuscular route is not appropriate for the management of status epilepticus because peak phenytoin concentrations will not be reached quickly enough. The loading dose for seizures other than in status epilepticus is 10 to 15 mg/kg given as a single dose by intramuscular injection or by intravenous infusion at a rate of 50 to 100 mg/minute. Initial maintenance doses for status epilepticus and other seizures are 4 to 5 mg/kg daily given in 1 or 2 divided doses by intramuscular injection or by intravenous infusion at a rate of 50 to 100 mg/minute. Subsequent doses are dependent on patient response and trough plasma-phenytoin concentrations.

Fosphenytoin given intramuscularly or by intravenous infusion at a rate of 50 to 100 mg/minute may be substituted for oral phenytoin at the same equivalent total daily dose for up to 5 days.

In the USA, loading doses in PSE of up to 20 mg/kg are permitted, and initial maintenance doses are 4 to 6 mg/kg daily.

For doses in children, see below.

A lower loading dose and/or infusion rate, and lower or less frequent maintenance dosing may be necessary for elderly patients; UK licensed product information suggests a reduction in dose or rate of 10 to 25%. Similar reductions are suggested for patients with renal or hepatic impairment (see also below) or in those with hypoalbuminaemia, except in the treatment of status epilepticus.

Administration in children. In the UK, fosphenytoin sodium may be given to children over 5 years of age for the emergency treatment of status epilepticus, the prevention and treatment of post-traumatic seizures associated with neurosurgery or head trauma, and as a short-term parenteral substitute for oral phenytoin in the management of epilepsy. It is given by intravenous infusion and doses are expressed as phenytoin sodium equivalents (PSE).

In the treatment of tonic-clonic status epilepticus, the loading dose in PSE is 15 mg/kg given as a single dose at a rate of 2 to 3 mg/kg per minute; however, the *BNFC* allows up to 20 mg/kg. In the treatment or prophylaxis of seizures other than in status epilepticus, the loading dose in PSE is 10 to 15 mg/kg given as a single dose at a rate of 1 to 2 mg/kg per minute. The maximum rate of infusion of loading doses is 3 mg/kg per minute or 150 mg/minute and should not be exceeded. Initial maintenance doses in PSE for status epilepticus and other seizures are 4 to 5 mg/kg daily given in 1 to 4 divided doses at a rate of 1 to 2 mg/kg per minute, not exceeding 100 mg/minute. Subsequent doses are dependent on patient response and trough plasma-phenytoin concentrations.

Fosphenytoin given at a rate of 1 to 2 mg/kg per minute, not exceeding 50 to 100 mg/minute, may be substituted for oral phenytoin at equivalent total daily doses for up to 5 days.

Similar precautions to those in adults apply to the monitoring of clinical parameters and plasma-phenytoin concentrations in children (see above).

Administration in hepatic or renal impairment. The rate and extent of conversion of fosphenytoin to phenytoin in patients with hepatic cirrhosis or renal impairment requiring dialysis was not found to be significantly different from those for healthy controls.[1] However, there was a trend towards an increase in fosphenytoin clearance and a decrease in the time to peak phenytoin concentrations in those with hepatic or renal impairment. Consequently, the authors recommended that fosphenytoin may need to be given at lower doses or infused more slowly (see above for the licensed product recommendations).

Gabapentin *(BAN, USAN, rINN)*

CI-945; Gabapentiini; Gabapentina; Gabapentine; Gabapentinum; GOE-3450. 1-(Aminomethyl)cyclohexaneacetic acid.

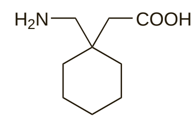
Габапентин

$C_9H_{17}NO_2$ = 171.2.

CAS — 60142-96-3.

ATC — N03AX12.

ATC Vet — QN03AX12.



Pharmacopoeias. In *US.*

USP 31 (Gabapentin). A white to off-white, crystalline solid. Freely soluble in water and in alkaline and acidic solutions. A 2% solution in water has a pH of 6.5 to 8.0.

Adverse Effects and Precautions

The most commonly reported adverse effects associated with gabapentin are somnolence, dizziness, ataxia, and fatigue. Nystagmus, tremor, diplopia, amblyopia, pharyngitis, rhinitis, dysarthria, nausea and vomiting, weight gain, oedema, dyspepsia, amnesia, weakness, paraesthesia, arthralgia, purpura, leucopenia, anxiety, and urinary-tract infection may occur less frequently. Rarely, pancreatitis, altered liver function tests, erythema multiforme, Stevens-Johnson syndrome, myalgia, headache, and blood glucose fluctuations in diabetics have been reported. Common psychiatric effects include confusion, depression, and nervousness, and, more rarely, hallucinations and psychoses. Other adverse effects include acute renal failure, allergic reactions, alopecia, angioedema, chest pain, hepatitis, jaundice, movement disorders such as choreoathetosis, dyskinesia and dystonia, palpitations, thrombocytopenia, and tinnitus.

Gabapentin should be used with caution in patients with renal impairment and in those undergoing haemodialysis. False positive readings have been reported with some urinary protein tests in patients taking gabapentin.

Care is required when withdrawing gabapentin therapy—see also Uses and Administration, below.

Incidence of adverse effects. A postmarketing surveillance study[1] of 3100 patients taking gabapentin identified drowsiness or sedation as the most frequent adverse effect, occurring in about 6.7%. The incidences of other adverse effects were: headache, 3.6%; fatigue, 3.5%; nausea and vomiting, 2.6%; and dizziness, 2.4%. Less common adverse events included rash, visual defect, and ataxia. Overall, adverse effects were reported as the reason for stopping treatment in about 10% of patients. In the 136 children aged under 12 years whose data were included in the study, the most frequently reported treatment-related adverse events were eczema, rash, and vomiting. In this study, none of the 11 infants born to mothers taking gabapentin throughout pregnancy had congenital abnormalities.

1. Wilton LV, Shakir S. A postmarketing surveillance study of gabapentin as add-on therapy for 3,100 patients in England. *Epilepsia* 2002; **43:** 983–92.

Breast feeding. For mention of the pharmacokinetics of gabapentin during pregnancy and breast feeding, see under Pharmacokinetics, below.

For comment on antiepileptic therapy and breast feeding, see p.467.

Carcinogenicity. It had been reported[1] that studies on gabapentin had been temporarily stopped in 1990 when pancreatic tumours were seen in *rodent* studies. However, the tumours were benign, occurred only with large doses, and were not thought to relate to humans.

Effects on mental function. For a review of the effects of antiepileptic therapy including gabapentin on *cognition*, and on *mood* (including the risk of suicidal ideation), see p.468.

Effects on the skin. For a suggestion that skin reactions are less common with gabapentin than with some other antiepileptics see under Phenytoin, p.496.

Overdosage. A 16-year-old girl complained of dizziness 6 hours after ingesting 48.9 g of gabapentin and was lethargic but arousable 2 hours later.[1] Her gabapentin plasma concentration was 62 micrograms/mL 8.5 hours after ingestion. By 18 hours she was alert and had no further complaints of lethargy or dizziness. In another report[2] a patient with renal failure inadvertently received inappropriately high doses of gabapentin for 3 weeks and had a serum gabapentin concentration of 85 micrograms/mL without serious adverse effects. However, a patient with end-stage renal disease who twice took extra doses of gabapentin between haemodialysis sessions developed marked somnolence and hypoxia severe enough to require intubation on both occasions; haemodialysis produced rapid improvement.[3] A prospective observational study[4] of gabapentin exposures reported to 3 poison centers has described a case series of 20 patients who took from 50 mg to 35 g of gabapentin alone. Of these, 12 experienced clinical symptoms including drowsiness, dizziness, gastrointestinal disturbance, hypotension, and mild tachycardia. These effects developed in under 5 hours and lasted for less than 24 hours; toxicity was generally mild and there were no fatalities.

4. Klein-Schwartz W, *et al.* Characterization of gabapentin overdose using a poison center case series. *J Toxicol Clin Toxicol* 2003; **41:** 11–15.

Pregnancy. For mention of the pharmacokinetics of gabapentin during pregnancy and breast feeding, see under Pharmacokinetics, below.

For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

The absorption of gabapentin from the gastrointestinal tract is reduced by antacids containing aluminium with magnesium; it is recommended that gabapentin is taken at least 2 hours after any such antacid. Morphine has been reported to reduce the clearance of gabapentin; patients receiving both drugs should be monitored for signs of CNS depression and doses should be reduced accordingly. Cimetidine has also been reported to reduce the renal clearance of gabapentin but licensed product information does not consider this to be of clinical importance. For references to possible interactions with other antiepileptics, see under Phenytoin, p.498 and under Felbamate, p.481.

Pharmacokinetics

Gabapentin is absorbed from the gastrointestinal tract by means of a saturable mechanism. After multiple dosing peak plasma concentrations are usually achieved within 2 to 3 hours of a dose and steady state achieved within 1 to 2 days. Gabapentin is not appreciably metabolised and most of a dose is excreted unchanged in the urine with the remainder appearing in the faeces. Gabapentin is widely distributed throughout the body but binding to plasma proteins is minimal. The elimination half-life has been reported to be about 5 to 7 hours. Gabapentin is distributed into breast milk.

Children. A study[1] of the pharmacokinetics of single doses of gabapentin in healthy children aged 1 month to 12 years found that peak plasma concentrations occurred 2 to 3 hours after the dose in all age groups but that the mean value was higher in those older than 5 years than in younger children, and the exposure was calculated to be about 30% less in the younger age group. As a result it was suggested that the initial dose of gabapentin in studies of safety and efficacy should be 40 mg/kg daily in children aged from 1 month up to 5 years, and 30 mg/kg daily in children aged 5 to 12 years. (For licensed doses, see Administration in children, below.) A pharmacokinetics study[2] in children with uncontrolled seizures (aged from 3 to about 15 years) also found a markedly higher mean oral clearance of gabapentin when compared with adults.

2. Tallian KB, *et al.* Pharmacokinetics of gabapentin in paediatric patients with uncontrolled seizures. *J Clin Pharm Ther* 2004; **29:** 511–15.

Pregnancy and breast feeding. The pharmacokinetics of gabapentin were studied[1] in 6 women, and in their offspring, during pregnancy, delivery, and breast feeding. Findings suggested that gabapentin is actively transported across the placenta and accumulates in the fetus although its effect was unclear. All the deliveries, including one preterm, were uneventful and all of the infants were healthy, apart from one who became cyanosed and mildly hypotonic 8 hours after birth.

The distribution of gabapentin into breast milk was extensive and neonates were found to have a lower capacity to eliminate gabapentin than adults, with an elimination half-life of about 14 hours. However, the plasma concentrations in the breast-fed infants appeared to be low and the relative infant dose was estimated to be 1.3 to 3.8% of the mothers' weight-adjusted dose at 0.2 to 1.3 mg/kg daily. No adverse effects were reported in the infants, and the authors considered that gabapentin was generally safe during breast feeding.

Uses and Administration

Gabapentin is an antiepileptic used as monotherapy or adjunctive therapy in the treatment of partial seizures with or without secondary generalisation. It is not generally considered effective for absence seizures. Although gabapentin is an analogue of gamma-aminobutyric acid (GABA), it is neither a GABA agonist nor antagonist and its mechanism of action is unknown. Gabapentin is also used in the treatment of neuropathic pain.

In the UK, the initial oral dose of gabapentin for the treatment of **epilepsy** is 300 mg on the first day of treatment, 300 mg twice daily on the second day, and 300 mg three times daily on the third day; thereafter the dose may be increased in increments of 300 mg every 2 to 3 days until effective antiepileptic control is achieved, which is usually within the range of 0.9 to 3.6 g daily. Higher doses up to a maximum of 4.8 g daily have been reported to be well tolerated. Similar doses are used in the USA. The total daily dose should be taken in three equally divided doses and the maximum dosage interval should not exceed 12 hours.

For details of doses in children, see below.

In the treatment of **neuropathic pain**, doses should be titrated to a usual maximum of 1.8 g daily in three divided doses, in a similar manner to that recommended above for the treatment of epilepsy. Higher doses have sometimes been given.

As with other antiepileptics, withdrawal of gabapentin therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. Licensed product information recommends reducing the dose gradually over at least 7 days. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Dosage of gabapentin should be reduced in patients with renal impairment (see below).

Gabapentin enacarbil (XP-13512) has been investigated as a prodrug of gabapentin.

Administration in children. In the UK, for the treatment of partial seizures with or without secondary generalisation, gabapentin is licensed for use as adjunctive therapy in children aged 6 years and over and as monotherapy in those aged 12 years and over. As *adjunctive therapy,* gabapentin may be given in an initial oral dose of 10 to 15 mg/kg daily, titrated over a period of about 3 days until effective antiepileptic control is achieved, which is usually within the range 25 to 35 mg/kg daily. Higher doses up to a maximum of 50 mg/kg daily have been reported to be well tolerated. Although not licensed for use in younger children, the *BNFC* suggests that similar initial doses may be used in those aged 2 to 12 years; maintenance doses of 10 to 20 mg/kg 3 times daily (up to 900 mg daily for children weighing 36 kg or under, or 1.2 g daily for those over 36 kg) are also recommended. Older children may be given the usual adult dosage regimen (see above) titrated to a maximum of 2.4 g daily. When used as *monotherapy,* the usual adult dosage regimen is given.

In the USA, gabapentin is licensed for *adjunctive* use in children aged 3 years and over. Initial doses are as for the UK; the maintenance dose for children aged 3 to 4 years is 40 mg/kg daily, and for those aged 5 years and over is 25 to 35 mg/kg daily. Children aged 12 years and over may be given the usual adult dosage regimen (see above).

The total daily dose should be taken in 3 equally divided doses and the maximum dosage interval should not exceed 12 hours.

For a pharmacokinetic study suggesting that initial doses in younger children should be proportionately higher than in older ones, see above.

Administration in renal impairment. Reduced doses of gabapentin are recommended for patients with renal impairment or those undergoing haemodialysis. Licensed UK product information recommends the following maintenance doses based on creatinine clearance (CC) and given as 3 divided doses:

- CC 50 to 79 mL/minute: 600 to 1800 mg daily
- CC 30 to 49 mL/minute: 300 to 900 mg daily
- CC 15 to 29 mL/minute: 300 mg on alternate days to 600 mg daily
- CC less than 15 mL/minute: 300 mg on alternate days to 300 mg daily

For those undergoing haemodialysis who have never received gabapentin, the recommended loading dose is 300 to 400 mg followed by 200 to 300 mg after each 4 hours of haemodialysis. On dialysis-free days no doses of gabapentin should be given (see also Overdosage, above).

Ciguatera poisoning. Gabapentin has relieved some of the neurological symptoms associated with ciguatera poisoning (see Mannitol, p.1331).

Epilepsy. Gabapentin is used in epilepsy (p.465) as adjunctive therapy for partial seizures with or without secondary generalisation in patients refractory to standard antiepileptics. In double-blind placebo-controlled studies[1-4] in such patients seizure frequency was reduced when gabapentin was added to treatment. Long-term efficacy has been encouraging,[5-7] and its lack of potential for interactions with other antiepileptics is considered to make it particularly suitable for adjunctive treatment. Dosage is adjusted against clinical response rather than by monitoring blood concentrations. Gabapentin is also used as monotherapy in partial epilepsy;[8-10] its efficacy as adjunctive treatment in generalised seizures remains to be determined.

Gabapentin has been found to be effective as adjunctive therapy in children with refractory partial seizures.[11]

Headache. Benefit has been reported[1] from the use of gabapentin in the prophylaxis of *migraine* (p.616). Gabapentin may also be effective[2,3] in the management of *cluster headache* (p.616), and has been tried[4] in the prophylaxis of *chronic daily headache*.

Hot flushes. Gabapentin appears to be of benefit in the management of hot flushes associated with treatment of breast cancer (p.661); a study involving 420 women with breast cancer experiencing hot flushes (excluding women on active chemotherapy, but most of whom were receiving adjuvant endocrine therapy), found that a dose of 900 mg daily in three divided doses for 8 weeks was effective, although a dose of 300 mg daily was not.[1]

There is also evidence of benefit[2,3] from gabapentin in the same dose (900 mg daily) in women experiencing hot flushes as a symptom of the menopause (p.2077). Another randomised placebo-controlled study[4] found gabapentin 2.4 g daily to be as effective as conjugated oestrogens 625 micrograms daily in the treatment of hot flushes in postmenopausal women.

4. Reddy SY, *et al.* Gabapentin, estrogen, and placebo for treating hot flushes: a randomized controlled trial. *Obstet Gynecol* 2006; **108:** 41–8.

Lesch-Nyhan syndrome. The severe self-mutilation that occurs in patients with Lesch-Nyhan syndrome (p.976) has been reported to improve in those given antiepileptics such as gabapentin.[1]

1. McManaman J, Tam DA. Gabapentin for self-injurious behavior in Lesch-Nyhan syndrome. *Pediatr Neurol* 1999; **20:** 381–2.

Motor neurone disease. Interest has been shown in gabapentin as a potential therapy for amyotrophic lateral sclerosis (see Motor Neurone Disease, p.2380) because it may inhibit glutamate formation. Results from an early study[1] demonstrated a trend towards a beneficial effect; however, a randomised trial[2] failed to confirm any benefit from gabapentin on disease progression or symptoms.

Neuropathic pain. Antiepileptics are among the drugs used to manage neuropathic pain, which is often insensitive to opioid analgesics (see Choice of Analgesic, p.2). Although carbamazepine appears to be the usual choice, gabapentin is also given in the treatment of neuropathic pain,[1-3] including central pain[4] (see p.6), complex regional pain syndrome (see p.6), postherpetic neuralgia[5-7] (see p.9), trigeminal neuralgia (see p.9), and painful diabetic neuropathy[8,9] (see p.6).

Parkinsonism. While some overall ratings of Parkinson's disease (p.791) appeared to be improved by gabapentin in a double-blind study involving 19 patients with advanced parkinsonism, improvements in individual signs and symptoms were not significant.[1] It was also reported that 5 of 6 other patients with progressive supranuclear palsy had experienced worsening of their disease when given gabapentin. Another study[2] in 15 patients with motor complications failed to find any clinically significant benefit from gabapentin therapy.

2. Van Blercom N, *et al.* Effects of gabapentin on the motor response to levodopa: a double-blind, placebo-controlled, crossover study in patients with complicated Parkinson disease. *Clin Neuropharmacol* 2004; **27:** 124–8.

Postoperative pain. There is growing interest in the use of analgesic adjuvants including antiepileptics such as gabapentin to modulate opioid dosage and efficacy for postoperative pain (see p.4).[1] A systematic review considered that evidence of benefit for gabapentin in acute pain was lacking, and noted that more effective analgesics for this indication were available.[2] However, a later systematic review found that perioperative use of gabapentin effectively reduced opioid consumption and postoperative pain; further studies were considered warranted.[3] It has been suggested that perioperative use of gabapentin may have other benefits, including pre-operative anxiolysis, attenuation of the haemodynamic response to intubation, and reduction in postoperative nausea and vomiting.[4]

Psychiatric disorders. Gabapentin has psychotropic properties and has been tried in the management of several psychiatric disorders, including as an adjunct in the treatment of resistant *depression*[1] (p.373) and in the treatment of *post-traumatic stress disorder*[2] (p.953). Although early open studies[3] found that gabapentin may be of benefit in patients with *bipolar disorder* (p.372) randomised controlled trials have so far failed to confirm this effect.[4-6] Gabapentin is under investigation for the treatment of *social anxiety disorder* (see under Phobic Disorders, p.953).

1. Yasmin S, *et al.* Adjunctive gabapentin in treatment-resistant depression: a retrospective chart review. *J Affect Disord* 2001; **63:** 243–7.

3. Maidment ID. Gabapentin treatment for bipolar disorders. *Ann Pharmacother* 2001; **35:** 1264–9.
4. Pande AC, *et al.* Gabapentin in bipolar disorder: a placebo-controlled trial of adjunctive therapy. *Bipolar Disord* 2000; **2:** 249–55.
5. Frye MA, *et al.* A placebo-controlled study of lamotrigine and gabapentin monotherapy in refractory mood disorders. *J Clin Psychopharmacol* 2000; **20:** 607–14.
6. Vieta E, *et al.* A double-blind, randomized, placebo-controlled, prophylaxis study of adjunctive gabapentin for bipolar disorder. *J Clin Psychiatry* 2006; **67:** 473–7.

Restless legs syndrome. The aetiology of restless legs syndrome (see Sleep-associated Movement Disorders, p.958) is obscure and treatment has been largely empirical. Two small randomised double-blind crossover studies[1,2] found 6 weeks of treatment with gabapentin to produce improvement in symptoms; in patients undergoing haemodialysis the effects were seen with a dose of 300 mg after each of the 3 dialysis sessions per week,[1] although in patients with idiopathic disease the mean effective dose was 1.855 g daily.[2]

A prodrug of gabapentin, gabapentin enacarbil, is reported to be under investigation for the treatment of restless legs syndrome.

2. Garcia-Borreguero D, *et al.* Treatment of restless legs syndrome with gabapentin: a double-blind, cross-over study. *Neurology* 2002; **59:** 1573–9.

Soft-tissue rheumatism. Gabapentin may be of benefit in some patients with fibromyalgia (p.13). In a randomised controlled study treatment with oral gabapentin 1.2 to 2.4 g daily in 75 patients produced a greater improvement in mean pain score over 12 weeks than placebo in 75 controls.[1] Sleep problems were also improved, but there was no difference between the groups in a depression rating scale. The drug was generally well tolerated.

1. Arnold LM, *et al.* Gabapentin in the treatment of fibromyalgia: a randomized, double-blind, placebo-controlled, multicenter trial. *Arthritis Rheum* 2007; **56:** 1336–44.

Stiff-man syndrome. Gabapentin may improve the symptoms of stiff-man syndrome (see under Muscle Spasm in Uses of Diazepam, p.993) in patients unable to tolerate benzodiazepine therapy.

Tremor. A beta blocker is often the first drug used in patients with essential tremor who require regular treatment (p.1231); however, gabapentin has also been tried with some success.[1-3]

Lacosamide *(USAN, rINN)*

ADD-234037; Erlosamida; Erlosamide; Erlosamidum; Harkoseride; Lacosamida; Lacosamidum; SPM-927. (2*R*)-2-(Acetylamino)-*N*-benzyl-3-methoxypropanamide.

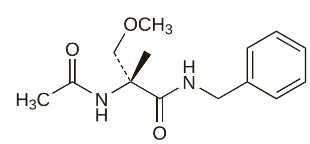
Эрлозамид

$C_{13}H_{18}N_2O_3$ = 250.3.

CAS — 175481-36-4.

ATC — N03AX18.

ATC Vet — QN03AX18.



Profile

Lacosamide is an antiepileptic drug that is under investigation for adjunctive therapy in partial seizures. It is also being studied for use in diabetic neuropathic pain, fibromyalgia, osteoarthritis, and migraine.

Lamotrigine *(BAN, USAN, rINN)*

BW-430C; Lamotrigiini; Lamotrigin; Lamotrigina; Lamotriginum; Lamotrijin. 6-(2,3-Dichlorophenyl)-1,2,4-triazine-3,5-diyldiamine.

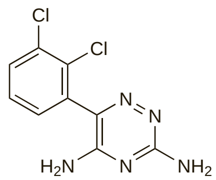
Ламотригин

$C_9H_7Cl_2N_5$ = 256.1.

CAS — 84057-84-1.

ATC — N03AX09.

ATC Vet — QN03AX09.



Adverse Effects and Treatment

Skin rashes may occur during therapy with lamotrigine; severe skin reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported, especially in children, and usually occur within 8 weeks of starting lamotrigine (see Effects on the Skin, below). Symptoms such as fever, malaise, flu-like symptoms, drowsiness, lymphadenopathy, facial oedema and, rarely, hepatic dysfunction have been reported. Blood dyscrasias such as leucopenia, neutropenia, and thrombocytopenia have also been reported, sometimes with rashes as part of a hypersensitivity syndrome.

Movement disorders such as tics, ataxia, nystagmus, and tremor have occurred; lamotrigine may worsen symptoms in patients with pre-existing Parkinson's disease. Other adverse effects include angioedema, photosensitivity, diplopia, blurred vision, conjunctivitis, dizziness, drowsiness, insomnia, headache, tiredness, nausea and vomiting, irritability and aggression, hallucinations, agitation, and confusion. Very rarely, lupus-like reactions and increases in seizure frequency have been reported.

◊ Licensed product information states that there have been rare instances of death after a rapidly progressive illness involving status epilepticus, multi-organ dysfunction, and disseminated intravascular coagulation in patients taking multiple antiepileptics including lamotrigine, although the role of lamotrigine remains to be established. It has been suggested[1] that multi-organ failure and disseminated intravascular coagulation, with associated rhabdomyolysis, are complications of severe convulsive seizures rather than of lamotrigine therapy. However, there has been a report[2] of a patient with no history of generalised seizures who developed a syndrome of disseminated intravascular coagulation, rhabdomyolysis, renal failure, maculopapular rash, and ataxia 14 days after lamotrigine was added to her antiepileptic regimen. Two cases of disseminated intravascular coagulation were found in a cohort of 11 316 patients involved in prescription-event monitoring of lamotrigine therapy in general practice.[3]

3. Mackay FJ, *et al.* Safety of long-term lamotrigine in epilepsy. *Epilepsia* 1997; **38:** 881–6.

Effects on the blood. Septic shock secondary to leucopenia occurred in a patient when lamotrigine was added to therapy with sodium valproate.[1] There has also been a report of agranulocytosis in a child started on high-dose lamotrigine monotherapy.[2] The fall in the blood count was noted several days after lamotrigine had been stopped due to skin rash. The UK CSM subsequently reported[3] that 7 cases of aplastic anaemia, 12 of bone-marrow depression, and 20 of pancytopenia associated with lamotrigine had been received worldwide. Given the extensive usage of lamotrigine the CSM considered the risk of aplastic anaemia to be small and routine blood monitoring was not recommended. However, prescribers were warned to be alert for symptoms and signs suggestive of bone-marrow depression.

Effects on bone. For the effects of antiepileptics including lamotrigine on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on the liver. Fatal fulminant hepatic failure has been reported[1] in a patient after addition of lamotrigine to antiepileptic therapy with sodium valproate and carbamazepine. Another fatal case was reported[2] in a patient who was given lamotrigine for bipolar disorder; she was also taking other drugs for pain and insomnia. Reversible eosinophilic hepatitis occurred[3] as part of a hypersensitivity syndrome in a patient given lamotrigine for seizures.

3. Fix OK, *et al.* Eosinophilic hepatitis caused by lamotrigine. *Clin Gastroenterol Hepatol* 2006; **4:** xxvi.

Effects on the lungs. Interstitial pneumonitis with pulmonary infiltrates occurred when lamotrigine was added to antiepileptic therapy in a 57-year-old woman; the condition resolved when lamotrigine was stopped.[1]

1. Saravanan N, *et al.* Interstitial pneumonitis during lamotrigine therapy. *Br J Clin Pharmacol* 2005; **60:** 666–7.

Effects on mental function. Acute *psychosis* was reported[1] in 6 out of about 1400 patients when lamotrigine was added to antiepileptic therapy and/or when the dose of lamotrigine was increased. Symptoms resolved when lamotrigine was stopped, and recurred in 1 case of rechallenge.

For a review of the effects of antiepileptic therapy including lamotrigine on *cognition,* and on *mood* (including the risk of suicidal ideation), see p.468.

1. Brandt C, *et al.* Development of psychosis in patients with epilepsy treated with lamotrigine: report of six cases and review of the literature. *Epilepsy Behav* 2007; **11:** 133–9.

Effects on the nervous system. Of 93 patients with idiopathic generalised epilepsy who were treated with lamotrigine, 5 adults experienced *de novo* or exacerbated myoclonic jerks.[1] In each case, symptoms resolved when the dose of lamotrigine was reduced by 25 to 50% or stopped altogether. In another report, a 17-year-old girl with idiopathic Rolandic epilepsy experienced a sudden increase in seizure frequency when lamotrigine was added to therapy with sodium valproate; other adverse effects included emotional lability, headaches, and drowsiness.[2] Again symptoms resolved when lamotrigine was stopped.[2]

Overdose of lamotrigine has been known to cause seizures (see below).

2. Cerminara C, *et al.* Lamotrigine-induced seizure aggravation and negative myoclonus in idiopathic rolandic epilepsy. *Neurology* 2004; **63:** 373–5.

Effects on the skin. Rashes account for withdrawal from therapy in about 2% of those given lamotrigine,[1,2] and serious skin reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis occur in about 1 in 1000 adult patients.[3,4] The majority of rashes resolve once lamotrigine has been stopped; however, some patients have developed permanent scarring and there have been rare reports of fatalities. The main risk factors appear to be use with valproate, exceeding the recommended initial dose of lamotrigine or the recommended rate of dose escalation, and a history of antiepileptic-induced rash. The risk appears to be greater in children[1,4-6] and has been estimated to be between 1 in 300 and 1 in 50. These skin reactions usually occur within 8 weeks of starting therapy with lamotrigine, but onset as early as the first day and as late as 2 years has been noted.[7] After continuing reports of serious skin reactions in children, UK recommended dosage regimens for children have been revised to further reduce the risk of such reactions.[8] For the relative incidence of rash with different antiepileptics see under Phenytoin, p.496.

Overdosage. An evaluation[1] of 493 cases of lamotrigine-only overdoses reported to the American Association of Poison Control Centers over a 2-year period found that 52.1% of patients had no toxic effects. The most commonly reported adverse effects were drowsiness, nausea, vomiting, and ataxia. Serious effects such as seizures, coma, and respiratory depression were reported in 0.6 to 1.2% of cases; no deaths were reported.

No serious toxicity was seen in a patient who deliberately took an overdose of 1.35 g of lamotrigine and was subsequently treated with gastric lavage and activated charcoal.[2] Symptoms at presentation one hour after ingestion had included nystagmus and muscle hypertonicity. ECG monitoring had revealed widening of the QRS interval. Low-grade fever, erythema, and periorbital oedema suggestive of a hypersensitivity syndrome developed in another patient who inadvertently received lamotrigine 2.7 g daily for 4 days.[3] The patient recovered after corticosteroid treatment and stopping lamotrigine. Generalised tonic-clonic seizures, tremor, muscle weakness, ataxia, and hypertonia were reported[4] in a 2-year-old child after ingestion of 800 mg of lamotrigine. Symptoms resolved within 24 hours after treatment with gastric lavage and activated charcoal, midazolam, and fluids. Plasma-lamotrigine concentrations were in the high adult therapeutic range (3.8 micrograms/mL) with a slow elimination rate. Generalised seizures also occurred[5] after an unknown quantity of lamotrigine was ingested by a 19-month-old child who had no history of seizures; other presenting symptoms included tachycardia and vomiting. The serum-lamotrigine concentration measured 1 hour post ingestion was 20.3 mg/L. Symptoms resolved within 24 hours after treatment with trimethobenzamide and activated charcoal.

For a further review of the features and management of poisoning with some antiepileptics, including lamotrigine, see under Phenytoin, p.497.

Precautions

Lamotrigine should be given with caution to patients with hepatic or renal impairment. All patients should be warned to see their doctor immediately if rashes or symptoms associated with hypersensitivity develop. To minimise the risk of developing serious skin reactions, dosage recommendations should not be exceeded. Particular care is needed in patients also receiving valproate—see Interactions, below.

Withdrawal of lamotrigine should be considered if rash, fever, flu-like symptoms, drowsiness, or worsening of seizure control occurs. Care is required when withdrawing lamotrigine therapy—see also under Uses and Administration, below. Abrupt withdrawal should be avoided unless serious skin reactions have occurred. Lamotrigine should not be restarted in patients with previous hypersensitivity.

Breast feeding. The American Academy of Pediatrics[1] considers that the use of lamotrigine by mothers during breast feeding may be of concern, since there is the potential for therapeutic serum concentrations to occur in the infant. A report in 4 breast-fed infants whose mothers were taking lamotrigine found that although serum concentrations of the drug 10 days after birth were about 30% of maternal concentrations in 3 infants, no short-term adverse effects were seen; the drug was undetectable in the fourth.[2] A study[3] in 6 mothers taking lamotrigine found that the relative dose in their breast-fed infants was 7.6% (mean absolute dose: 450 micrograms/kg daily) and infant plasma concentrations were 18% of maternal concentrations; no adverse effects were reported. The authors also noted that no adverse effects were reported in 12 previous cases.

For further comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Hepatic impairment. The pharmacokinetics of lamotrigine were not significantly altered in patients with moderate cirrhosis;[1] however, those with severe cirrhosis showed significantly lower oral clearance and longer elimination half-lives than those in healthy subjects.

The recommended licensed doses in patients with hepatic impairment are given under Uses and Administration, below.

1. Marcellin P, *et al.* Influence of cirrhosis on lamotrigine pharmacokinetics. *Br J Clin Pharmacol* 2001; **51:** 410–14.

Intellectual impairment. Aggressive behaviour has been reported in intellectually impaired patients given lamotrigine.[1] Of 19 such patients given lamotrigine, aggressive behaviour developed in 9; the drug was stopped in 5, and stopped but reintroduced in a further 2, together with psychiatric management. One patient responded to a reduction in lamotrigine dosage.

1. Beran RG, Gibson RJ. Aggressive behaviour in intellectually challenged patients with epilepsy treated with lamotrigine. *Epilepsia* 1998; **39:** 280–2.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468. For reference to alteration of lamotrigine pharmacokinetics in pregnancy, see under Pharmacokinetics, below.

There is a theoretical risk of teratogenicity with lamotrigine because, like valproate, it is a folate antagonist. In 2002 the manufacturer of lamotrigine, *GlaxoSmithKline*, reported[1] that it had follow-up information on 395 outcomes of pregnancies exposed to lamotrigine between September 1992 and September 2001 from the International Lamotrigine Pregnancy Registry. Major birth defects were found in 13 infants but no distinctive pattern of abnormalities suggestive of a common cause could be identified. Of the 168 who had been exposed to lamotrigine monotherapy during the first trimester, birth defects were reported in 3 (1.8%). The frequency of major birth defects in pregnancies exposed to polytherapy containing lamotrigine with valproate was 10% compared with 4.3% in lamotrigine polytherapy without valproate. Although it was considered that the sample sizes were too small to rule out a small increase in the frequency of major birth defects, it was noted that the frequency of malformations after lamotrigine monotherapy did not differ from that reported in the literature for women with epilepsy receiving antiepileptic monotherapy. Updated results from 785 pregnancies up to March 2004 included 414 first-trimester exposures to lamotrigine monotherapy, of which 12 were associated with a major abnormality.[2] As of March 2006, the registry had recorded 802 first-trimester exposures to lamotrigine monotherapy with major abnormalities occurring in 22; there was no evidence to suggest a dose-response relationship with daily doses of up to 400 mg.[3]

In August 2006, the manufacturer[4] reported that data from the North American Antiepileptic Drug Pregnancy Registry suggested an association between lamotrigine and an increased risk of oral clefts. Of 564 first-trimester exposures to lamotrigine monotherapy, 5 cases of oral clefts were reported giving an incidence rate of 8.9 per 1000 compared with 0.37 per 1000 in the reference population. Again, however, no increase in the overall risk of major malformations was found. Analysis of data from other pregnancy registries found 4 additional cases of oral clefts in about 2200 first-trimester exposures to lamotrigine monotherapy.

4. GlaxoSmithKline, Canada. Association of Lamictal® (lamotrigine) with an increased risk of non-syndromic oral clefts (issued 1st August, 2006). Available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/lamictal_2_hpc-cps-eng.pdf (accessed 01/09/08)

Renal impairment. Results from a pharmacokinetic study[1] indicated that impaired renal function was likely to have little effect on plasma concentrations of lamotrigine. The drug is mainly cleared by metabolism and although the glucuronide metabolite accumulates it is inactive. Nevertheless, there is limited clinical experience with lamotrigine in such patients and caution was recommended.

1. Wootton R, *et al.* Comparison of the pharmacokinetics of lamotrigine in patients with chronic renal failure and healthy volunteers. *Br J Clin Pharmacol* 1997; **43:** 23–7.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. The metabolism of lamotrigine is enhanced by the enzyme inducers carbamazepine, phenytoin, phenobarbital, and primidone, and inhibited by valproate (see below).

Analgesics. *Paracetamol* affects the metabolic disposition of lamotrigine but the clinical significance of this interaction remains to be determined.[1] Paracetamol reduced the area under the plasma concentration-time curve for lamotrigine, reduced lamotrigine's half-life, and increased the percentage of lamotrigine recovered in the urine.

1. Depot M, *et al.* Kinetic effects of multiple oral doses of acetaminophen on a single oral dose of lamotrigine. *Clin Pharmacol Ther* 1990; **48:** 346–55.

Antibacterials. Use with *rifampicin* significantly increased the clearance of lamotrigine.[1] The total urinary excretion of lamotrigine and the amount excreted as glucuronide were significantly higher compared with placebo.

1. Ebert U, *et al.* Effects of rifampicin and cimetidine on pharmacokinetics and pharmacodynamics of lamotrigine in healthy subjects. *Eur J Clin Pharmacol* 2000; **56:** 299–304.

Antidepressants. An epileptic patient maintained on lamotrigine 200 mg daily complained[1] of increasing confusion and cognitive impairment after starting *sertraline* 25 mg daily for post-traumatic disorder; after 6 weeks her lamotrigine blood concentrations had risen from 2.5 to 5.1 micrograms/mL during this period. The adverse effects cleared and blood concentrations of lamotrigine fell to 3.1 micrograms/mL within 3 weeks of changing the daily dosage to lamotrigine 100 mg and sertraline 50 mg. A patient, with poorly controlled epilepsy, who initially had been taking lamotrigine 450 mg and sertraline 75 mg together daily for 6 weeks without adverse effects had marked sedation, fatigue, and decreased cognition 6 weeks after the daily dosage of lamotrigine was increased to 600 mg. Her lamotrigine blood concentration was 19.3 micrograms/mL. The patient was subsequently stabilised on lamotrigine 800 mg and sertraline 50 mg daily and had less sedation and fatigue and clearer cognition; blood concentrations of lamotrigine fell to 9.8 micrograms/mL.

1. Kaufman KR, Gerner R. Lamotrigine toxicity secondary to sertraline. *Seizure* 1998; **7:** 163–5.

Antiepileptics. *Valproate* can inhibit the metabolism of lamotrigine resulting in increased concentrations of lamotrigine. This effect can be beneficial in the control of certain seizures, although careful monitoring is required as toxicity may occur. Disabling tremor occurred in 3 patients taking such a combination which resolved when the dose of lamotrigine or valproate was reduced.[1] Other reports of toxicity, resolving on reduction of the lamotrigine dose, were marked by sedation, ataxia, and fatigue,[2] or delirium.[3] Symptoms of neurotoxicity were reported in 3 patients on lamotrigine therapy who were given valproate, intravenously then orally, for absence status epilepticus. Serum concentrations of lamotrigine in these patients were raised about three- to sevenfold.[4] Reversible encephalopathy has been reported[5] when sodium valproate was substituted for phenytoin in a patient also taking lamotrigine, although her clinical condition had been satisfactory on this new regimen for several months. Symptoms improved when the doses of both valproate and lamotrigine were reduced. Pharmacokinetic studies[6,7] in healthy adults have attempted to elucidate the mechanism of the interaction between lamotrigine and valproate. The clearance of lamotrigine was found to be reduced, and exposure and elimination half-life increased when valproate was also given. Renal elimination was not affected and the investigators[6] suggested that there was hepatic competition for glucuronidation between valproate and lamotrigine. However, there was no substantial alteration in the linear kinetics of lamotrigine in the presence of therapeutic plasma concentrations of valproate.[7] Similar observations were made when lamotrigine was added to existing antiepileptic regimens in children,[8] although the clinical relevance of the influence of age on the pharmacokinetics remains to be determined. Both young age and use with valproate are risk factors for lamotrigine-induced dermatological toxicity—see Effects on the Skin, above.

For details of dosage reductions required for lamotrigine used with valproate, see Uses and Administration, below.

Other antiepileptics also affect plasma concentrations of lamotrigine. In contrast to valproate, *carbamazepine*, *phenytoin*, or *phenobarbital* all markedly induced the elimination of lamotrigine.[9] Others have confirmed a reduction in plasma-lamotrigine concentrations when given with phenytoin and other enzyme-inducing antiepileptics,[10] but analysis of results from another study[11] suggested that the increase in lamotrigine clearance by phenytoin and carbamazepine was of minimal clinical significance. *Oxcarbazepine* has also been reported[12] to decrease serum-lamotrigine concentrations (although to a lesser extent than carbamazepine). However, a study[13] in healthy subjects found that oxcarbazepine did not affect the pharmacokinetics of lamotrigine, although adverse effects occurred more frequently when they were used together (for a report of severe toxicity associated with such use see p.491). *Mesuximide* was found[12,14] to have a marked inducing effect on the metabolism of lamotrigine. In one study,[14] plasma-lamotrigine concentrations were significantly reduced when given together.

For reports of an interaction between lamotrigine and carbamazepine, see p.474. For the effect of lamotrigine on clonazepam concentrations, see p.990.

Antipsychotics. An apparent interaction between lamotrigine and *aripiprazole*, resulting in Stevens-Johnson syndrome, has been reported[1] in 2 patients with schizophrenia after the introduction of lamotrigine; both patients recovered with supportive treatment.

1. Shen Y-C, *et al.* Concomitant use of lamotrigine and aripiprazole increases risk of Stevens-Johnson syndrome? *Int Clin Psychopharmacol* 2007; **22:** 247–8.

Antivirals. A study[1] in healthy subjects found that ritonavir-boosted lopinavir decreased the steady-state minimum plasma concentration of lamotrigine by about 55%; doubling the dose of lamotrigine achieved concentrations similar to those with lamotrigine alone.

1. van der Lee MJ, *et al.* Lopinavir/ritonavir reduces lamotrigine plasma concentrations in healthy subjects. *Clin Pharmacol Ther* 2006; **80:** 159–68.

Sex hormones. Studies in patients taking lamotrigine have indicated that *combined oral contraceptives*[1,2] may halve plasma concentrations of the antiepileptic. Other studies[3,4] have also found a significant increase in lamotrigine-plasma concentrations within one week of stopping contraceptive therapy; however, wide interpatient variability was noted in one study.[3] Significant adjustments in maintenance doses of lamotrigine may be needed if combined contraceptives are started or stopped (see below), and patients should be warned not to make changes in their contraceptive therapy without consulting their physician.[5] However, in a study,[6] progestogen-only contraceptives did not appear to affect lamotrigine concentrations. Licensed drug information recommends that, when starting treatment with combined oral contraceptives, the dose of lamotrigine may need to be increased by as much as twofold in those women not taking drugs known to induce cytochrome P450-mediated metabolism of lamotrigine; conversely, the dose of lamotrigine may need to be halved when stopping contraceptive therapy in women not taking enzyme inducers. Dosage adjustment may not be necessary when starting or stopping combined oral contraceptive therapy in women taking lamotrigine with known enzyme inducers.

Adjustments may also be needed if other hormonal preparations are taken with lamotrigine.

Some reduction in plasma concentrations of levonorgestrel, and to a lesser extent ethinylestradiol, may also occur with lamotrigine, and there have been reports of breakthrough bleeding and unexpected pregnancies.[5]

Pharmacokinetics

Lamotrigine is rapidly absorbed from the gastrointestinal tract with an absolute bioavailability of 98%. Peak plasma concentrations occur about 2.5 hours after oral doses. It is widely distributed in the body and is reported to be about 55% bound to plasma proteins. It is extensively metabolised in the liver and excreted almost entirely in urine, principally as an inactive glucuronide conjugate. It slightly induces its own metabolism and the mean elimination half-life is reported to be 24 to 35 hours. Clearance is reported to be higher in children aged up to 12 years than in adults, with the highest values occurring in those under 5 years of age. Lamotrigine is distributed into breast milk.

The pharmacokinetics of lamotrigine are affected by other antiepileptics (see Interactions, above).

Renal impairment. See under Precautions, above.

Therapeutic drug monitoring. A literature review[1] concluded that a clear relationship between lamotrigine concentrations and toxicity or antiepileptic efficacy has not been demonstrated. Routine therapeutic drug monitoring was therefore not recommended and clinical end-points rather than plasma concentrations remained the best guide for dosage adjustment of lamotrigine.

Uses and Administration

Lamotrigine, a phenyltriazine compound, is an antiepileptic used mainly for monotherapy or adjunctive treatment of partial seizures and primary and secondarily generalised tonic-clonic seizures. It may be used for seizures associated with the Lennox-Gastaut syndrome and for the maintenance treatment of bipolar disorder.

The doses given below for the use of lamotrigine in **epilepsy** are those licensed in the UK; similar doses are given in the USA although the use of lamotrigine is more limited than in the UK.

- The initial oral dose for use as *monotherapy* is 25 mg once daily for 2 weeks followed by 50 mg once daily for 2 weeks; thereafter the dose is increased by a maximum of 50 to 100 mg every 1 to 2 weeks to usual maintenance doses of 100 to 200 mg daily, given as a single dose or in 2 divided doses. Some patients have required up to 500 mg daily
- The initial oral dose of lamotrigine for use as an *adjunct* to therapy with enzyme-inducing antiepileptics (but *not with valproate*) is 50 mg once daily for 2 weeks followed by 50 mg twice daily for 2 weeks; thereafter the dose is increased by a maximum of 100 mg every 1 to 2 weeks to usual maintenance doses of 200 to 400 mg daily given in 2 divided doses. Some patients have required up to 700 mg daily
- In those *taking valproate* the initial oral dose of lamotrigine is 25 mg every other day for 2 weeks followed by 25 mg once daily for 2 weeks; thereafter the dose is increased by a maximum of 25 to 50 mg every 1 to 2 weeks to usual maintenance doses of 100 to 200 mg daily given as a single dose or in 2 divided doses
- In those *taking oxcarbazepine* but no enzyme-inducing or -inhibiting antiepileptics the dosage regimen of adjunctive lamotrigine is as for monotherapy

If the potential for interaction with adjunctive antiepileptics is unknown, treatment with lamotrigine should be started with lower doses such as those used with valproate. For comment on the need to modify maintenance doses when starting or stopping oral contraceptives see Sex Hormones, under Interactions, above.

For doses in children, see below.

In the management of **bipolar disorder**, the target dose of lamotrigine is 200 mg daily as *monotherapy*; for patients *taking valproate* the target dose is 100 mg daily and in those taking enzyme-inducing drugs (but *not with valproate*) the target dose is 400 mg daily. Lamotrigine should be started at a reduced dose and increased gradually to the target dose in a regimen similar to that used in the treatment of epilepsy (see above).

Doses should be reduced in patients with hepatic impairment regardless of indication (see below).

As with other antiepileptics, withdrawal of lamotrigine therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465. Licensed drug information recommends that regardless of indication the withdrawal of lamotrigine should be tapered over at least 2 weeks.

Administration in children. Lamotrigine is used as an adjunct in the treatment of partial seizures and primary and secondarily generalised tonic-clonic seizures in children aged 2 years and over; it is used as monotherapy in those over 12 years of age. Lamotrigine may also be used for seizures associated with the Lennox-Gastaut syndrome.

The doses given below are those licensed in the UK; similar doses are given in the USA although the use of lamotrigine is more limited than in the UK.

- In those taking enzyme-inducing antiepileptics (but *not with valproate*) the initial oral dose of lamotrigine is 600 micrograms/kg daily in 2 divided doses for 2 weeks followed by 1.2 mg/kg daily for 2 weeks; thereafter the dose is increased by a maximum of 1.2 mg/kg every 1 to 2 weeks to usual maintenance doses of 5 to 15 mg/kg daily given in 2 divided doses
- In those *taking valproate* the initial oral dose of lamotrigine is 150 micrograms/kg once daily for 2 weeks followed by 300 micrograms/kg once daily for 2 weeks; thereafter the dose is increased by a maximum of 300 micrograms/kg every 1 to 2 weeks to usual maintenance doses of 1 to 5 mg/kg daily, given as a single dose or in 2 divided doses
- In those taking *oxcarbazepine* but no enzyme-inducing or -inhibiting antiepileptics the initial oral dose of lamotrigine, given as a single dose or in 2 divided doses, is 300 micrograms/kg daily for 2 weeks, followed by 600 micrograms/kg daily for 2 weeks; thereafter the dose is increased by a maximum of 600 micrograms/kg every 1 to 2 weeks to usual maintenance doses of 1 to 10 mg/kg daily, to a maximum of 200 mg daily.

If the calculated daily dose of lamotrigine lies between 1 and 2 mg, then 2 mg may be given on alternate days for the first 2 weeks of therapy. Lamotrigine should not be given if the calculated daily dose is less than 1 mg.

Children over 12 years of age may be given the adult dosage regimen for monotherapy and adjunctive therapy (see above).

Administration in hepatic impairment. UK licensed product information for lamotrigine recommends that doses should be reduced by about 50% in patients with moderate hepatic impairment (Child-Pugh category B), and by about 75% in severe impairment (Child-Pugh category C). US licensed product information recommends that doses should be reduced by about 25% in patients with moderate to severe hepatic impairment without ascites, and by about 50% in those with severe hepatic impairment with ascites.

Anxiety disorders. Small studies have suggested that lamotrigine may relieve some of the symptoms of post-traumatic stress disorder (p.953).

Bipolar disorder. In a multicentre placebo-controlled study involving 195 patients, lamotrigine 50 or 200 mg daily by mouth produced dose-related improvement in patients with bipolar disorder (p.372) experiencing a major depressive episode.[1] Further data from randomised controlled studies[2-8] have confirmed benefit for depressive symptoms (although not for mania), and reviews[9-13] have generally favoured its use, although some have queried the strength of the evidence.[14] Guidelines for the treatment of bipolar disorder now recommend lamotrigine as a first-line option for bipolar depression, and it is licensed for such use in a number of countries (see also Uses and Administration, above).

Epilepsy. Lamotrigine is used in the treatment of epilepsy (p.465). It is used in partial seizures with or without secondary generalisation, and in generalised tonic-clonic seizures, although valproate is the drug of choice in the latter where these are associated with the syndrome of primary generalised epilepsy. It is also recommended in absence seizures, although the evidence base is not particularly strong, and may be used in juvenile myoclonic epilepsy and tried in tonic or atonic seizures.

As monotherapy for partial seizures with or without secondary generalisation, lamotrigine was found to be better than carbamazepine (the established first-line drug) in terms of time to treatment failure and tolerability.[1] In patients with newly-diagnosed partial seizures with or without secondary generalisation, lamotrigine had a similar efficacy to carbamazepine, but again was better tolerated.[2] A systematic review[3] of randomised, placebo-controlled studies concluded that lamotrigine is also effective in reducing the seizure frequency when added to current antiepileptic regimens in patients with refractory partial seizures.

As monotherapy for primary generalised and unclassifiable seizures lamotrigine was found[4] to be significantly inferior to valproate (the established first-line drug) in terms of seizure control, with almost twice the failure rate; valproate was also significantly more effective for achieving 12-month remission and prolonging the time to first seizure. Benefit was seen with adjunctive lamotrigine when compared with placebo in children[5] and adults[6] for treatment-resistant primary generalised seizures; it was also suggested[6] that lamotrigine therapy may be appropriate when determination of the type of epilepsy in these patients is not possible.

Lamotrigine appears to be an effective adjunctive treatment in children with the Lennox-Gastaut syndrome.[7,8]

It has also been found to be effective and well tolerated as adjunctive therapy in paediatric patients with refractory epilepsy including those with developmental impairment;[9] it was particularly effective in absence and atypical seizures in this open-label study. (Evidence for the use of lamotrigine to treat absence seizures, as for the other common alternatives ethosuximide and valproate, is, however, generally poor.[10])

Motor neurone disease. Lamotrigine has been tried as a potential therapy for amyotrophic lateral sclerosis (see Motor Neurone Disease, p.2380) but with disappointing results.[1]

1. Ryberg H, *et al.* A double-blind randomized clinical trial in amyotrophic lateral sclerosis using lamotrigine: effects on CSF glutamate, aspartate, branched-chain amino acid levels and clinical parameters. *Acta Neurol Scand* 2003; **108:** 1–8.

Movement disorders. Symptomatic improvement and a trend towards decreased chorea was reported[1] with lamotrigine in a double-blind, placebo-controlled study of 64 patients with Huntington's chorea (p.953) with motor signs of less than 5 years' duration. There was, however, no clear evidence that lamotrigine retarded the progression of early Huntington disease over a period of 30 months.

1. Kremer B, *et al.* Influence of lamotrigine on progress of early Huntington disease: a randomized clinical trial. *Neurology* 1999; **53:** 1000–11.

Neuropathic pain. There is growing evidence that lamotrigine is of use in the management of neuropathic pain.[1] It was effective when used with carbamazepine or phenytoin in the treatment of refractory *trigeminal neuralgia*[2] (p.9), and has also shown promise in the treatment of pain associated with *HIV-related distal sensory neuropathy*[3] (p.857). Some benefit has been found[4] in the treatment of *diabetic neuropathy* (see p.6). Case reports[5] and a placebo-controlled trial[6] have also indicated that lamotrigine may be effective in *central post-stroke pain* (p.6). More recently, the use of lamotrigine in neuropathic pain has been reviewed.[7,8] Based on the same studies, one review[7] concluded that lamotrigine is an effective treatment for various types of neuropathic pain and that further studies are warranted while another[8] concluded that it is unlikely to be of benefit and that further studies are probably not justified.

Schizophrenia. Lamotrigine has been tried as adjunctive therapy in treatment-resistant schizophrenic patients[1] and a benefit has been reported in few studies,[2-4] although patient numbers have been small. However, a systematic review[5] of the use of lamotrigine in schizophrenia concluded that the evidence for its use was poor, although it was suggestive of a positive effect on symptoms.

Levetiracetam *(BAN, USAN, rINN)*

S-Etiracetam; Lévétiracétam; Levetiracetamum; Levetirasetam; SIB-S1; UCB-22059; UCB-L059. (*S*)-2-(2-Oxopyrrolidin-1-yl)butanamide.

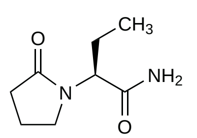
Леветирацетам

$C_8H_{14}N_2O_2$ = 170.2.

CAS — 102767-28-2.

ATC — N03AX14.

ATC Vet — QN03AX14.



Adverse Effects and Precautions

The most commonly reported adverse effects associated with levetiracetam are somnolence, weakness, and dizziness. Anorexia, diarrhoea, dyspepsia, nausea, weight gain or loss, myalgia, ataxia, headache, amnesia, depression, emotional lability, insomnia, nervousness, tremor, vertigo, diplopia, and rash may occur less frequently. Other adverse effects include paraesthesia, pancreatitis, hepatic failure, and hepatitis. A raised incidence of mild infections, such as the common cold and upper respiratory-tract infections, has been reported. Alopecia may also develop; in some cases, stopping levetiracetam has resulted in regrowth of hair.

Other adverse effects reported include abnormal behaviour, aggression, anger, anxiety, confusion, hallucinations, irritability, and psychotic disorders; these adverse effects may be more common in children than in adults. Blood dyscrasias such as neutropenia, pancytopenia, and thrombocytopenia may develop.

Levetiracetam should be used with caution in patients with renal impairment, and/or severe hepatic impairment.

Care is required when withdrawing levetiracetam therapy—see also Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Effects on the endocrine system. Hyponatraemia developed[1] in a patient given levetiracetam in whom carbamazepine had previously caused the syndrome of inappropriate antidiuretic hormone secretion; symptoms resolved on stopping levetiracetam and recurred on rechallenge.

1. Nasrallah K, Silver B. Hyponatremia associated with repeated use of levetiracetam. *Epilepsia* 2005; **46:** 972–3.

Effects on the lungs. Diffuse interstitial lung disease developed[1] after a dose increase of levetiracetam in a 9-year-old girl who had been taking the drug for 2 years. The condition resolved when levetiracetam was stopped and treatment with corticosteroids was given.

1. Newsome SD, *et al.* Levetiracetam-induced diffuse interstitial lung disease. *J Child Neurol* 2007; **22:** 628–30.

Effects on mental function. For a review of the effects of antiepileptic therapy on *cognition*, and the effects of levetiracetam on *mood* (including the risk of suicidal ideation), see p.468.

Effects on the skin. For a suggestion that skin reactions are less common with levetiracetam than with some other antiepileptics see under Phenytoin, p.496.

Movement disorders. Levetiracetam has been associated with symptoms of parkinsonism including resting tremor, bradykinesia, and rigidity when used to treat Huntington's chorea in a 58-year-old man;[1] symptoms resolved within 7 days of stopping levetiracetam. The patient was also taking a number of other drugs at the time and the authors suggested that these symptoms might have been caused by a drug interaction. However, levetiracetam has been tried in the treatment of some movement disorders as discussed under Uses and Administration, below.

1. Zesiewicz TA, *et al.* Levetiracetam-induced parkinsonism in a Huntington disease patient. *Clin Neuropharmacol* 2005; **28:** 188–90.

Overdosage. A 38-year-old woman who ingested 30 g of levetiracetam vomited 4 hours later and presented with hypoxia, hypotension, and respiratory depression 6 hours after ingestion; peak plasma-levetiracetam concentration was 400 micrograms/mL.[1] The patient recovered without sequelae over 48 hours with symptomatic treatment.

1. Barrueto F, *et al.* A case of levetiracetam (Keppra) poisoning with clinical and toxicokinetic data. *J Toxicol Clin Toxicol* 2002; **40:** 881–4.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

The UK Epilepsy and Pregnancy Register[1] provided data as of July 2005 from 117 first-trimester exposures to levetiracetam with 39 to monotherapy and 78 to adjunctive therapy. In the former group, 4 infants had a low birth-weight and 4 were born at 37 weeks of gestation or less. In the latter, 10 had a low birth-weight, 18 were born at 37 weeks of gestation or less, and 3 had major congenital malformations.

1. Hunt S, *et al.* Levetiracetam in pregnancy: preliminary experience from the UK Epilepsy and Pregnancy Register. *Neurology* 2006; **67:** 1876–9.

Interactions

Evidence of significant interactions between levetiracetam and other antiepileptics is mostly lacking. However, for the effects of levetiracetam on carbamazepine, see p.474.

Pharmacokinetics

Levetiracetam is readily absorbed from the gastrointestinal tract with a bioavailability of almost 100%; peak plasma concentrations are usually achieved within 1.3 hours of oral doses and steady state achieved after 2 days. Plasma protein binding is minimal at less than 10%. Levetiracetam is not extensively metabolised; about 25% of a dose is metabolised by hydroxylation to inactive metabolites. Around 95% of a dose is excreted as unchanged drug and metabolites in the urine. The plasma elimination half-life has been reported to be about 7 hours in adults and children aged 12 years and over; the half-life may be shorter in younger children. Levetiracetam is distributed into breast milk.

Uses and Administration

Levetiracetam is an analogue of piracetam (p.368). It is used as an adjunct in the treatment of partial seizures with or without secondary generalisations in adults and children aged 4 years and over; in the UK, adults and adolescents aged 16 years and over may also be given levetiracetam as monotherapy for this indication. In addition, levetiracetam is licensed for adjunctive use in the treatment of myoclonic seizures in adults and children aged 12 years and over with juvenile myoclonic epilepsy. It is also licensed for use as an adjunct in the treatment of primary generalised tonic-clonic seizures in adults and children with idiopathic generalised epilepsy; for this indication, in the UK, licensed use is restricted to children aged 12 years and over, whereas in the USA, it is licensed from 6 years of age.

The daily oral dose of levetiracetam is given in two divided doses.

- The initial adult dose when used *as an adjunct* is 1 g on the first day of treatment; thereafter, the daily dose may be increased in steps of 1 g every 2 to 4 weeks until effective antiepileptic control is achieved, up to a maximum dose of 3 g daily.

  The initial dose in children weighing less than 50 kg is 20 mg/kg daily which may be increased in steps of 20 mg/kg every 2 weeks to a maximum of 60 mg/kg daily.

  Children and adolescents weighing 50 kg or more should be given the usual adult dose (see above).

  When used as *monotherapy*, the initial dose of levetiracetam is 500 mg daily, increased after 2 weeks to 1 g daily. Further increases may be made in steps of 500 mg every 2 weeks up to a maximum of 3 g daily.

When oral use is not feasible, levetiracetam may be given by intravenous infusion over 15 minutes in doses similar to those used orally; as with the oral formulation, details of licensed uses and ages may vary from country to country. UK licensed product information states that there has been no experience with the use of intravenous levetiracetam for more than 4 days.

Reduced doses are recommended in renal and severe hepatic impairment (see below).

As with other antiepileptics, withdrawal of levetiracetam therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. UK licensed product information recommends reducing the daily dose in adults by 1 g every 2 to 4 weeks; in children, the dose reduction should not exceed 20 mg/kg every 2 weeks. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Administration in children. Licensed indications and doses of levetiracetam in children vary from country to country, see Uses and Administration, above. It is mainly used for partial and myoclonic seizures, and in idiopathic generalised epilepsy, often as an adjunct. A retrospective review[1] of 122 children aged from 1 month to 2 years given levetiracetam either as monotherapy (48 patients) or adjunctive therapy (74 patients) found that 70 achieved seizure remission. Of these, a longer duration of remission was seen in those receiving less than 30 mg/kg daily of levetiracetam. A case series[2] of 3 infants aged from 2 days to 3 months reported that levetiracetam 30 mg/kg daily was effective in the treatment of refractory neonatal seizures.

1. Perry MS, Benatar M. Efficacy and tolerability of levetiracetam in children younger than 4 years: a retrospective review. *Epilepsia* 2007; **48:** 1123–7.
2. Shoemaker MT, Rotenberg JS. Levetiracetam for the treatment of neonatal seizures. *J Child Neurol* 2007; **22:** 95–8.

Administration in hepatic impairment. No dose adjustment is needed in patients with mild to moderate hepatic impairment. In patients with severe hepatic impairment, creatinine clearance (CC) may underestimate concomitant renal impairment, and UK licensed product information recommends that the usual adult maintenance dose (see above) should be reduced by 50% in those with a CC of less than 70 mL/minute.

Administration in renal impairment. Reduced doses of levetiracetam are recommended for patients with renal impairment. Suitable daily doses according to UK and US licensed product information, based on creatinine clearance (CC) and given in 2 divided doses, are:

- CC 50 to 79 mL/minute: 1 to 2 g
- CC 30 to 49 mL/minute: 500 mg to 1.5 g
- CC less than 30 mL/minute: 500 mg to 1 g

Patients receiving dialysis may be given a loading dose of 750 mg when starting levetiracetam followed by doses of 500 mg to 1 g once daily; a supplemental dose of 250 to 500 mg is recommended after dialysis.

Doses may be given orally or intravenously, as necessary.

See also above for dosage recommendations in those patients with severe hepatic impairment and concomitant renal impairment.

Epilepsy. Levetiracetam is used in epilepsy (p.465) as an adjunct or monotherapy in the management of partial seizures with or without secondary generalisation.[1-6] It is also used as an adjunct in myoclonic seizures[7-9] and for generalised tonic-clonic seizures,[10] although valproate is the drug of choice in the latter where these are associated with the syndrome of primary generalised epilepsy. Levetiracetam may be considered as second-line drug for atonic or tonic seizures, and has been tried in Lennox-Gastaut syndrome and in juvenile absence epilepsy.[11] In children, levetiracetam has also been tried as adjunctive therapy for nonconvulsive status epilepticus,[12] in infantile spasms,[13] and in severe myoclonic epilepsy of infancy,[14] and as monotherapy in partial and generalised epilepsy.[15]

Movement disorders. Levetiracetam may be of benefit in some movement disorders. It has been tried in antipsychotic-induced *tardive dyskinesia*[1-3] and with equivocal benefit in levodopa-induced tardive dyskinesia[4,5] (see under Extrapyramidal Disorders on p.971). There is also limited evidence of benefit with levetiracetam for the treatment of *chorea* (p.953) in Huntington's disease[6,7] and in *paroxysmal kinesigenic choreoathetosis*.[8]

1. Konitsiotis S, *et al.* Levetiracetam in tardive dyskinesia: an open label study. *Mov Disord* 2006; **21:** 1219–21.

8. Chatterjee A, *et al.* Levetiracetam in the treatment of paroxysmal kinesiogenic choreoathetosis. *Mov Disord* 2002; **17:** 614–15.

Muscle spasm. Levetiracetam has been tried with some success in *Meige's syndrome*,[1] and *hemifacial spasm*.[2] For use in *stiff-man syndrome* see below.

1. Yardimci N, *et al.* Levetiracetam in Meige's syndrome. *Acta Neurol Scand* 2006; **114:** 63–6.
2. Deleu D. Levetiracetam in the treatment of idiopathic hemifacial spasm. *Neurology* 2004; **62:** 2134–5.

Psychiatric disorders. Levetiracetam has psychotropic properties and has been tried in the management of *anxiety disorders*[1] (p.952) including *social anxiety disorder*[2] (see Phobic Disorders, p.953), *post-traumatic stress disorder*[3] (p.953), and *panic disorder*[4] (p.952). There is also limited evidence[5] from case reports and small open-label studies that levetiracetam may be of benefit in the treatment of *bipolar disorder* (p.372).

1. Kinrys G, *et al.* Levetiracetam as adjunctive therapy for refractory anxiety disorders. *J Clin Psychiatry* 2007; **68:** 1010–13.
2. Simon NM, *et al.* An open-label study of levetiracetam for the treatment of social anxiety disorder. *J Clin Psychiatry* 2004; **65:** 1219–22.
3. Kinrys G, *et al.* Levetiracetam for treatment-refractory posttraumatic stress disorder. *J Clin Psychiatry* 2006; **67:** 211–14.
4. Papp LA. Safety and efficacy of levetiracetam for patients with panic disorder: results of an open-label, fixed-flexible dose study. *J Clin Psychiatry* 2006; **67:** 1573–6.
5. Muralidharan A, Bhagwagar Z. Potential of levetiracetam in mood disorders: a preliminary review. *CNS Drugs* 2006; **20:** 969–79.

Restless legs syndrome. Levetiracetam has been reported to be of benefit in the treatment of refractory restless legs syndrome (see Sleep-associated Movement Disorders, p.958).[1]

1. Della Marca G, *et al.* Levetiracetam can be effective in the treatment of restless legs syndrome with periodic limb movements in sleep: report of two cases. *J Neurol Neurosurg Psychiatry* 2006; **77:** 566–7.

Status epilepticus. Levetiracetam has been tried, with some success, in the management of nonconvulsive status epilepticus[1] and refractory status epilepticus.[2] For the conventional management of status epilepticus see p.469.

1. Rupprecht S, *et al.* Levetiracetam as a treatment option in nonconvulsive status epilepticus. *Epilepsy Res* 2007; **73:** 238–44.
2. Patel NC, *et al.* The use of levetiracetam in refractory status epilepticus. *Seizure* 2006; **15:** 137–41.

Stiff-man syndrome. In a report[1] of a patient with stiff-man syndrome, substitution of levetiracetam for previous valproate therapy (because of suspected valproate-induced parkinsonism) resulted in complete suppression of paroxysmal spasms; benefit was sustained with continued therapy over 2 years of follow-up.

1. Rüegg SJ, *et al.* Levetiracetam improves paroxysmal symptoms in a patient with stiff-person syndrome. *Neurology* 2004; **62:** 338.

Tremor. A beta blocker is often the first drug used in patients with essential tremor who require regular treatment (p.1231); however, levetiracetam has also been tried with some success.[1] Benefit was also reported[2] with levetiracetam in the treatment of tremor secondary to multiple sclerosis.

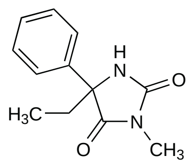
CAS — 50-12-4.

ATC — N03AB04.

ATC Vet — QN03AB04.



Pharmacopoeias. In *US.*

USP 31 (Mephenytoin). Store in airtight containers.

Profile

Mephenytoin is a hydantoin antiepileptic with actions similar to those of phenytoin (p.495), but it is more toxic. Because of its potential toxicity it is not one of the main drugs used in the treatment of epilepsy (p.465) and is given only to patients unresponsive to other treatment. Some of the adverse effects of mephenytoin may be due to the metabolite, 5-ethyl-5-phenylhydantoin (also termed nirvanol). Like phenytoin the rate of metabolism of mephenytoin is subject to genetic polymorphism.

Mephenytoin is given in an initial oral daily dose of 50 to 100 mg for 1 week; thereafter the daily dose is increased by 50 to 100 mg at weekly intervals until the optimum dose is reached, which is usually between 200 and 600 mg daily for an adult and 100 and 400 mg daily for a child; daily maintenance doses are usually taken in 3 divided doses.

Porphyria. Mephenytoin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

USP 31: Mephenytoin Tablets.

Proprietary Preparations (details are given in Part 3)
Austria: Epilan; ***Cz.:*** Epilan†.

Mesuximide *(BAN, rINN)*

Mesuksimidi; Mesuximid; Mesuximida; Mésuximide; Mesuximidum; Methsuximide; PM-396. *N*,2-Dimethyl-2-phenylsuccinimide.

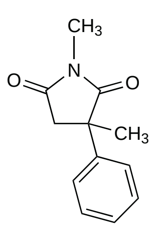
Мезуксимид

$C_{12}H_{13}NO_2$ = 203.2.

CAS — 77-41-8.

ATC — N03AD03.

ATC Vet — QN03AD03.



Pharmacopoeias. In *US.*

USP 31 (Methsuximide). A white to greyish-white crystalline powder. Is odourless or has a slight odour. Soluble 1 in 350 of water, 1 in 3 of alcohol, 1 in less than 1 of chloroform, and 1 in 2 of ether. Store in airtight containers.

Profile

Mesuximide is a succinimide antiepileptic with actions similar to those of ethosuximide (p.479) that is used in the treatment of absence seizures; although it also has some activity in complex partial seizures it is reported to be less well tolerated than ethosuximide, and is usually only given to patients unresponsive to other antiepileptic treatment. It is thought to owe its activity to its major metabolite *N*-desmethylmesuximide.

The usual initial oral dosage is a single dose of 300 mg daily for the first week, and this is increased by 300 mg at weekly intervals to an optimum dosage, according to response. The suggested maximum daily dose is 1.2 g in divided doses.

Epilepsy. Mesuximide is used for absence seizures that are refractory to less toxic antiepileptics such as ethosuximide or valproate, which are the usual first-line drugs (see p.465). Mesuximide has also been tried in complex partial seizures and myoclonic seizures.

Methylphenobarbital *(BAN, rINN)*

Enphenemalum; Mephobarbital; Methylfenobarbital; Méthylphénobarbital; Methylphenobarbitalum; Methylphenobarbitone; Metilfenobarbitál; Metilfenobarbital; Metilfenobarbitalis; Metylfenobarbital; Metyylifenobarbitaali; Phemitone. 5-Ethyl-1-methyl-5-phenylbarbituric acid.

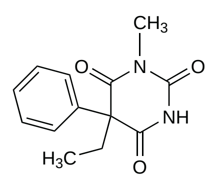
Метилфенобарбитал

$C_{13}H_{14}N_2O_3$ = 246.3.

CAS — 115-38-8.

ATC — N03AA01.

ATC Vet — QN03AA01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Methylphenobarbital). A white or almost white, crystalline powder or colourless crystals. Practically insoluble in water; very slightly soluble in dehydrated alcohol. It forms water-soluble compounds with alkali hydroxides and carbonates, and with ammonia.

USP 31 (Mephobarbital). A white, odourless, crystalline powder. Slightly soluble in water, in alcohol, and in ether; soluble in chloroform and in solutions of fixed alkali hydroxides and carbonates. Its saturated solution in water is acid to litmus.

Dependence and Withdrawal, Adverse Effects, Treatment, and Precautions

As for Phenobarbital, p.492.

Interactions

As for Phenobarbital, p.493.

Pharmacokinetics

Methylphenobarbital is incompletely absorbed from the gastrointestinal tract. It is demethylated to phenobarbital (p.494) in the liver.

Uses and Administration

Methylphenobarbital is used similarly to phenobarbital (p.494) in the treatment of epilepsy (p.465). It is given in oral doses of up to 600 mg daily. It has also been used as a sedative in a usual dose of 50 mg 3 or 4 times daily.

Preparations

BP 2008: Methylphenobarbital Tablets;
USP 31: Mephobarbital Tablets.

Proprietary Preparations (details are given in Part 3)
Austral.: Prominal†; ***USA:*** Mebaral.

Multi-ingredient: *Arg.:* Cumatil L; ***Ital.:*** Dintoinale; Metinal-Idantoina; Metinal-Idantoina L.

Oxcarbazepine *(BAN, USAN, rINN)*

GP-47680; KIN-493; Okskarbatsepiini; Okskarbazepin; Oxcarbazepin; Oxcarbazepina; Oxcarbazépine; Oxcarbazepinum. 10,11-Dihydro-10-oxo-5*H*-dibenz[*b,f*]azepine-5-carboxamide.

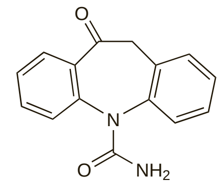
Окскарбазепин

$C_{15}H_{12}N_2O_2$ = 252.3.

CAS — 28721-07-5.

ATC — N03AF02.

ATC Vet — QN03AF02.



Adverse Effects, Treatment, and Precautions

As for Carbamazepine, p.472.

Hypersensitivity reactions such as skin rashes (see also under Carbamazepine, p.473) occur less frequently with oxcarbazepine than with carbamazepine. However, cross-sensitivity does occur and about 25 to 30% of patients hypersensitive to carbamazepine may experience such reactions with oxcarbazepine. Reductions in plasma-sodium levels have also been observed with oxcarbazepine (see Hyponatraemia, below). Patients with cardiac insufficiency and secondary heart failure should be weighed regularly to detect fluid retention. Oxcarbazepine may, very rarely, impair cardiac conduction and patients with pre-existing conduction disorders should be carefully monitored. Very rarely, oxcarbazepine treatment has been associated with pancreatitis.

Dosage reductions are recommended in renal impairment.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Effects on the blood. Although it would appear that oxcarbazepine is less likely than carbamazepine to cause blood dyscrasias such as leucopenia, individual cases have been reported. In one such case leucopenia and hyponatraemia developed in a 57-year-old woman while taking oxcarbazepine;[1] she recovered after treatment with filgrastim. It was noted that the patient had experienced a similar reaction when taking carbamazepine. Oxcarbazepine has also been associated with reversible pancytopenia[2] in a 40-year-old woman, and reversible thrombocytopenia[3] in a 63-year-old woman.

3. Mahmud J, *et al*. Oxcarbazepine-induced thrombocytopenia. *Psychosomatics* 2006; **47:** 73–4.

Effects on mental function. For a review of the effects of antiepileptic therapy on *cognition*, and the effects of oxcarbazepine on *mood* (including the risk of suicidal ideation), see p.468.

Effects on sexual function. For mention of the effects of antiepileptics including oxcarbazepine on sexual function in male epileptic patients, see Effects on the Endocrine System, under Phenytoin, p.496.

Hyponatraemia. Hyponatraemia appears to be more pronounced at clinical doses of oxcarbazepine than with carbamazepine. Hyponatraemia was reported[1] in 12 of 15 patients in whom oxcarbazepine was substituted for carbamazepine therapy. The fall in plasma-sodium concentrations appeared to be related to the dose of oxcarbazepine. In another report[2] hyponatraemia occurred in 23% of 350 patients whose serum-sodium concentrations were monitored. The manufacturers state that in 14 controlled studies sodium levels of less than 125 mmol/litre occurred in 2.5% of 1524 patients treated with oxcarbazepine compared to no such patients in the control groups. Most patients remain asymptomatic but some may experience drowsiness, increase in seizure frequency, and impaired consciousness.[3] In a later study[4] in 97 patients taking oxcarbazepine and 451 taking carbamazepine, hyponatraemia occurred in 29 (12 severe) of the former and in 61 (13 severe) of the latter. The authors failed to find a correlation between high doses of oxcarbazepine and the occurrence of hyponatraemia.

It has been suggested that serum-sodium concentrations should be measured before the start of therapy but routine monitoring, may be indicated only in elderly patients or if a high dosage is used.[5] Licensed product information recommends that monitoring be considered in those with pre-existing conditions associated with low sodium levels and in those taking other medications known to interfere with sodium levels, for example NSAIDs and diuretics.

Severe hyponatraemia has been reported[6] in a 12-year-old child during treatment with oxcarbazepine. A review of 48 other children who had received oxcarbazepine in the same centre, found that 9 had hyponatraemia, and the authors suggested that sodium levels should be monitored in paediatric patients. In another case,[7] a 7-year old boy developed a reversible coma caused by oxcarbazepine-induced hyponatraemia.

Overdosage. A 36-year-old man[1] who ingested 30.6 g of oxcarbazepine showed no serious signs of toxicity. Serum concentrations of oxcarbazepine were 31.6 mg/litre 2 hours after ingestion; corresponding serum concentrations of the active monohydroxy metabolite were 37.2 mg/litre, which later peaked at 59.0 mg/litre 7 hours after ingestion. The patient remained conscious, though somnolent, and had fully recovered within 2 days.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. Plasma concentrations of the active monohydroxy metabolite of oxcarbazepine may be reduced by strong inducers of cytochrome P450 isoenzymes, such as carbamazepine, phenytoin, or phenobarbital. Oxcarbazepine appears to induce hepatic enzymes to a lesser extent than carbamazepine. However, oxcarbazepine and its active metabolite do inhibit the cytochrome P450 isoenzyme CYP2C19, and in high doses may raise plasma concentrations of phenobarbital or phenytoin. Oxcarbazepine and its metabolite also have the capacity to induce CYP3A4 and CYP3A5 with the possibility of reducing plasma concentrations of drugs such as carbamazepine (but see below), dihydropyridine calcium-channel blockers, and oral contraceptives.

Antiepileptics. In a study[1] of epileptic patients the area under the concentration-time curve (AUC) seen with monotherapy of *carbamazepine, phenytoin,* or *valproate* was unchanged when oxcarbazepine was added to treatment; only carbamazepine affected the pharmacokinetics of oxcarbazepine, producing a reduction in the AUC for the active metabolite hydroxycarbazepine. It was considered that there was unlikely to be any clinically relevant pharmacokinetic interaction if oxcarbazepine was used with any of these antiepileptics, including carbamazepine. However, increases in plasma-phenytoin concentration have been reported after use with oxcarbazepine (see p.498).

There is a case-report of severe toxicity occurring with concomitant use of oxcarbazepine and *lamotrigine.*[2] For the effect of oxcarbazepine on lamotrigine concentrations, see p.486.

2. Alving J. Case of severe acute intoxication with oxcarbazepine combined with lamotrigine. *Epilepsia* 1994; **35** (suppl 7): 72.

Pharmacokinetics

Oxcarbazepine is completely absorbed from the gastrointestinal tract. It is rapidly and extensively metabolised in the liver to the principal metabolite 10,11-dihydro-10-hydroxy-carbamazepine, often referred to as MHD, which also possesses antiepileptic activity. The monohydroxy metabolite is widely distributed in the body and is about 40% bound to plasma proteins, mainly albumin. The plasma half-life has been reported to be about 2 hours for oxcarbazepine, and about 9 hours for the monohydroxy metabolite; consequently the latter provides most of the antiepileptic activity. Clearance of the monohydroxy metabolite is reported to be about 40% higher in children aged 4 to 12 years, and about 80% higher in those aged 2 to 4 years, than in adults. Oxcarbazepine is excreted in the urine mainly as metabolites; less than 1% is excreted as unchanged drug.

Oxcarbazepine and its monohydroxy metabolite cross the placental barrier and are distributed into breast milk.

The pharmacokinetics of oxcarbazepine and its monohydroxy metabolite are affected by use with other antiepileptics (see Interactions, above).

Pregnancy. Clearance of the active monohydroxy metabolite of oxcarbazepine was reported to increase[1,2] during pregnancy and to decrease[2] after delivery; one study[1] reported a reduction in plasma concentrations of about 36% during the third trimester. However, sample sizes in both studies were small.

Uses and Administration

Oxcarbazepine is a derivative of carbamazepine (p.476) with similar actions. It is used as monotherapy or adjunctive therapy in the treatment of partial seizures with or without secondary generalisation. The initial oral dose for monotherapy and adjunctive therapy is 600 mg daily, given in 2 divided doses. The daily dose may be increased thereafter, if necessary, in maximum increments of 600 mg at approximately weekly intervals until the desired clinical response has been achieved. Maintenance doses are usually in the range of 600 mg to 1.2 g daily or up to 2.4 g daily if given as adjunctive therapy or in refractory patients switched from other antiepileptics.

For doses in children, see below.

Reduced initial doses are recommended in patients with renal impairment (see below).

As with other antiepileptics, withdrawal of oxcarbazepine therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Administration in children. Oxcarbazepine is used in children as monotherapy or adjunctive therapy in the treatment of partial seizures with or without secondary generalisation. In the UK, the recommended initial oral dose for monotherapy and adjunctive therapy in those aged 6 years and over is 8 to 10 mg/kg daily, given in 2 divided doses. The daily dose may be increased thereafter, if necessary, in maximum increments of 10 mg/kg at approximately weekly intervals to a maximum dose of 46 mg/kg daily; usual maintenance doses in adjunctive therapy are around 30 mg/kg daily. In the USA, similar doses are recommended for adjunctive therapy in children aged 2 years and over (the initial dose may be doubled in those weighing under 20 kg), and for monotherapy in those aged 4 years and over; a maximum daily dose of 60 mg/kg is permitted for adjunctive therapy.

Administration in renal impairment. Initial doses of oxcarbazepine for adult patients with a creatinine clearance of less than 30 mL/minute should be 300 mg daily (half the usual starting dose, above), increased at weekly intervals or longer.

Bipolar disorder. Like the related drug carbamazepine (p.476), oxcarbazepine has antimanic properties and has been tried in the management of patients with bipolar disorder (p.372). Reviews[1,2] have suggested that it may be useful in treating acute mania and in patients with refractory disease; however, the evidence base is weak[3] and further studies are needed.

Epilepsy. Oxcarbazepine is used in the treatment of epilepsy (p.465) and may be a useful alternative in patients unable to tolerate carbamazepine.

In a double-blind study[1] involving newly diagnosed adult patients, oxcarbazepine was of similar efficacy and tolerability to valproate for partial or generalised tonic-clonic seizures. Oxcarbazepine was of similar efficacy to phenytoin, but was better tolerated in adults and children with newly diagnosed partial or generalised tonic-clonic seizures.[2,3] Further randomised controlled studies and 2 small systematic reviews[4,5] have also confirmed the efficacy and tolerability of oxcarbazepine as adjunctive therapy[4,6] or monotherapy[5,7-9] in refractory partial seizures in children and adults.

Neuropathic pain. Antiepileptics are among the drugs used to manage neuropathic pain, which is often insensitive to opioid analgesics (see Choice of Analgesic, p.2). Carbamazepine appears to be the antiepileptic most frequently used, but oxcarbazepine has also been tried in various neuropathic pain syndromes[1] including painful diabetic neuropathy[2-4] (see p.6), postherpetic neuralgia[5,6] (p.9), complex regional pain syndrome[7] (p.6), glossopharyngeal neuralgia,[8] oxaliplatin-induced neuropathy[9] (see p.758), and trigeminal neuralgia (p.9).

Psychiatric disorders. Case reports[1,2] in children and adolescents and a randomised, placebo-controlled study[3] in adults have indicated some benefit from oxcarbazepine in the treatment of *aggression* and *disturbed behaviour*(p.954). A retrospective review[4] of 14 children and adolescents with various psychiatric and behavioural disorders found moderate symptomatic improvement in 50% after the addition of oxcarbazepine. Oxcarbazepine has also been tried in the treatment of *schizophrenia*[5] (p.955) and *post-traumatic stress disorder*[6] (p.953). For use in *bipolar disorder* see above.

Withdrawal syndromes and abstinence. Oxcarbazepine has been tried in the prophylaxis and treatment of various withdrawal syndromes. Although it was not found[1] to be superior to placebo in the treatment of symptoms of the *alcohol withdrawal syndrome* (p.1626), oxcarbazepine has been reported[2-4] to be of benefit in relapse prevention; further studies are considered warranted. It has also been tried[5] during *benzodiazepine withdrawal* but such adjunct therapy is not usually indicated (see p.987).

Preparations

Proprietary Preparations (details are given in Part 3)

Arg.: Atoxecar†; Aurene; Oxca; Oxcazen†; Rupox; Trileptal; ***Austral.:*** Trileptal; ***Austria:*** Trileptal; ***Belg.:*** Trileptal; ***Braz.:*** Auram; Oleptal; Oxcarb; Trileptal; ***Canad.:*** Trileptal; ***Chile:*** Alox†; Oxicodal; Trileptal; ***Cz.:*** Trileptal; ***Denm.:*** Apydan; Trileptal; ***Fin.:*** Apydan; Trileptal; ***Fr.:*** Trileptal; ***Ger.:*** Timox; Trileptal; ***Gr.:*** Trileptal; ***Hong Kong:*** Trileptal; ***Hung.:*** Apydan; Trileptal; ***India:*** Oxcarb; Oxrate; ***Indon.:*** Barzepin; Prolepsi; Trileptal; ***Irl.:*** Trileptal; ***Israel:*** Trileptin; ***Ital.:*** Tolep; ***Malaysia:*** Trileptal; ***Mex.:*** Actinium; Deprectal; Oxetol; Trileptal; ***Neth.:*** Trileptal; ***Norw.:*** Trileptal; ***NZ:*** Trileptal; ***Philipp.:*** Trileptal; ***Pol.:*** Apydan; Trileptal; ***Port.:*** Epilfarmo; Proaxen; Zigabal; ***Rus.:*** Trileptal (Трилептал); ***S.Afr.:*** Trileptal; ***Spain:*** Trileptal; ***Swed.:*** Trileptal; ***Switz.:*** Trileptal; ***Thai.:*** Trileptal; ***Turk.:*** Trileptal; ***UK:*** Trileptal; ***USA:*** Trileptal; ***Venez.:*** Trileptal.

Pheneturide *(BAN, rINN)*

Ethylphenacemide; Feneturida; Phénéturide; Pheneturidum; S-46. (2-Phenylbutyryl)urea.

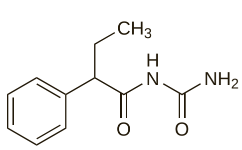
Фенетурид

$C_{11}H_{14}N_2O_2$ = 206.2.

CAS — 90-49-3.

ATC — N03AX13.

ATC Vet — QN03AX13.



Profile

Pheneturide is an acetylurea antiepileptic used in the treatment of complex partial seizures with or without secondary generalisation (p.465). It is given in usual oral daily doses of 300 to 600 mg in 2 or 3 divided doses, up to a maximum of 1.2 g daily.

Preparations

Proprietary Preparations (details are given in Part 3)

Belg.: Laburide.

Phenobarbital *(BAN, rINN)*

Ácido feniletilbarbitúrico; Fenobarbitaali; Fenobarbitál; Fenobarbital; Fenobarbitalis; Fenobarbitona; Phenemalum; Phénobarbital; Phenobarbitalum; Phenobarbitone; Phenylethylbarbituric Acid; Phenylethylmalonylurea. 5-Ethyl-5-phenylbarbituric acid.

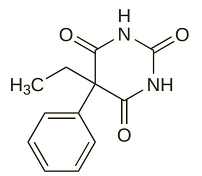
Фенобарбитал

$C_{12}H_{12}N_2O_3$ = 232.2.

CAS — 50-06-6.

ATC — N03AA02.

ATC Vet — QN03AA02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of phenobarbital: Feenies; Phennies; Phenos.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Phenobarbital). A white or almost white, crystalline powder or colourless crystals. Very slightly soluble in water; freely soluble in alcohol. It forms water-soluble compounds with alkali hydroxides and carbonates, and with ammonia.

USP 31 (Phenobarbital). White, odourless, glistening, small crystals or a white crystalline powder. It may exhibit polymorphism. Soluble 1 in 1000 of water and 1 in 10 of alcohol; sparingly soluble in chloroform; soluble in ether and in solutions of fixed alkali hydroxides and carbonates. A saturated solution in water has a pH of about 5.

Phenobarbital Sodium *(BANM, rINN)*

Fenobarbitaalinatrium; Fenobarbital sódico; Fenobarbital sodná sůl; Fenobarbital sodowy; Fenobarbitalio natrio druska; Fenobarbitalnatrium; Fenobarbitál-nátrium; Natrii Phenobarbitalum; Phenemalnatrium; Phénobarbital sodique; Phenobarbitalum natricum; Phenobarbitone Sodium; Sodium Phenylethylbarbiturate; Soluble Phenobarbitone. Sodium 5-ethyl-5-phenylbarbiturate.

Натрий Фенобарбитал

$C_{12}H_{11}N_2NaO_3$ = 254.2.

CAS — 57-30-7.

ATC — N03AA02.

ATC Vet — QN03AA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *US.*

Ph. Eur. 6.2 (Phenobarbital Sodium). A white or almost white, hygroscopic, crystalline powder. Freely soluble in carbon dioxide-free water (a small amount may be insoluble); soluble in alcohol; practically insoluble in dichloromethane. A 10% solution in water has a pH not greater than 10.2. Store in airtight containers.

USP 31 (Phenobarbital Sodium). Flaky crystals, or white crystalline granules, or a white powder. It is odourless and hygroscopic. Very soluble in water; soluble in alcohol; practically insoluble in chloroform and in ether. pH of a 10% solution in water is between 9.2 and 10.2. Solutions decompose on standing. Store in airtight containers.

Incompatibility. Phenobarbital sodium is incompatible with many other drugs and phenobarbital may be precipitated from mixtures containing phenobarbital sodium. This precipitation is dependent upon the concentration and the pH, and also on the presence of other solvents.

Stability. Extemporaneous oral preparations of phenobarbital 10 mg/mL in a 1:1 mixture of *Ora-Plus* and either *Ora-Sweet* or *Ora-Sweet SF* (*Paddock, USA*) were found[1] to be stable for at least 115 days in amber plastic bottles stored at room temperature.

1. Cober MP, Johnson CE. Stability of an extemporaneously prepared alcohol-free phenobarbital suspension. *Am J Health-Syst Pharm* 2007; **64:** 644–6.

Dependence and Withdrawal

As for the barbiturates (see Amobarbital, p.962).

Adverse Effects

The most frequent adverse effect associated with phenobarbital is sedation, but this often becomes less marked with continued use. Like some of the other antiepileptics, phenobarbital may produce subtle mood changes and impairment of cognition and memory that may not be apparent without testing. Depression may occur.

Prolonged use can occasionally result in folate deficiency; rarely, megaloblastic anaemia has been reported. There is some evidence that phenobarbital interferes with vitamin D metabolism.

At high doses nystagmus and ataxia may occur and the typical barbiturate-induced respiratory depression may become severe. Overdosage can prove fatal; toxic effects include coma, severe respiratory and cardiovascular depression, with hypotension and shock leading to renal failure. Hypothermia may occur, with associated pyrexia during recovery. Skin blisters (bullae) reportedly occur in about 6% of patients with barbiturate overdose.

Sodium salts of barbiturates have a very high pH in solution, and necrosis has followed subcutaneous injection or extravasation. Intravenous injections can be hazardous and cause hypotension, shock, laryngospasm, and apnoea, especially if given too rapidly.

Hypersensitivity reactions occur in a small proportion of patients; skin reactions are reported in 1 to 3% of patients taking phenobarbital, and are most commonly maculopapular, morbilliform, or scarlatiniform rashes. More severe reactions such as exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis are extremely rare. Hepatitis and disturbances of liver function have been reported.

Paradoxical excitement, restlessness, and confusion may sometimes occur in the elderly, and irritability and hyperactivity may occur in children.

Neonatal drug dependence and symptoms resembling vitamin K deficiency have been reported in infants born to mothers who received phenobarbital during pregnancy. Congenital malformations have been reported in children of women who received phenobarbital during pregnancy but the causal role of the drug is a matter of some debate.

Effects on the blood. For the effects of antiepileptics including phenobarbital on serum folate, see under Phenytoin, p.495.

Effects on bone. For the effects of antiepileptics including phenobarbital on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on connective tissue. The use of phenobarbital and primidone has been associated with the development of Dupuytren's contracture, frozen shoulder, Ledderhose's syndrome, Peyronie's disease, fibromas, and general joint pain.[1]

1. Mattson RH, *et al.* Barbiturate-related connective tissue disorders. *Arch Intern Med* 1989; **149:** 911–14.

Effects on the endocrine system. For mention of the effects of antiepileptics on *sexual function* in male epileptic patients, see under Phenytoin, p.496.

Barbiturates may reduce serum concentrations of *thyroid* hormones through enzyme induction—see under Interactions of Levothyroxine, p.2172.

Effects on the liver. For mention of the effects of phenobarbital on the liver, see under Phenytoin, p.496.

Effects on mental function. For a review of the effects of antiepileptics, including phenobarbital, on *cognition* and *mood* (including the risk of suicidal ideation), see p.468.

DEPRESSION. Follow-up of 28 patients aged 6 to 16 who had received phenobarbital or carbamazepine for epilepsy indicated that the rate of major depression was significantly higher in those receiving phenobarbital.[1] It was recommended that treatment with phenobarbital should be avoided particularly in patients with a personal or family history of an affective disorder; patients who do receive it should be monitored for symptoms of depression.

1. Brent DA, *et al.* Phenobarbital treatment and major depressive disorder in children with epilepsy: a naturalistic follow-up. *Pediatrics* 1990; **85:** 1086–91.

DISTURBED BEHAVIOUR. Disturbed behaviour is a recognised adverse effect of phenobarbital, especially in children and the elderly; however, no excess in behavioural adverse effects was seen[1] on follow-up for up to 12 months in 40 children who took phenobarbital when compared with 45 who took carbamazepine.

1. Banu SH, *et al.* Side effects of phenobarbital and carbamazepine in childhood epilepsy: randomised controlled trial. Abridged version: *BMJ* 2007; **334:** 1207–10. Full version: http://www.bmj.com/cgi/reprint/334/7605/1207 (accessed 09/06/08)

Hypersensitivity. An antiepileptic hypersensitivity syndrome, comprising fever, rash, and lymphadenopathy and less commonly lymphocytosis, and liver and other organ involvement, has been associated with some antiepileptics including phenobarbital.[1,2] Some have estimated the incidence at 1 in 1000 to 1 in 10 000 new exposures to aromatic anticonvulsants,[1,2] but the true incidence is unknown due to variations in presentation and reporting. The syndrome occurs most frequently on first exposure to the drug, with initial symptoms starting anywhere between 1 and 8 weeks after exposure. In previously sensitised individuals the reaction may occur within 1 day of rechallenge. The potential for cross-reactivity between carbamazepine, phenobarbital, and phenytoin is about 75%, and patients who develop the syndrome, and their close relatives, should be warned of the risk associated with use of these antiepileptics.[1]

2. Bessmertny O, *et al.* Antiepileptic hypersensitivity syndrome in children. *Ann Pharmacother* 2001; **35:** 533–8.

Treatment of Adverse Effects

In the treatment of phenobarbital overdosage repeated oral doses of activated charcoal may be helpful after recent ingestion of doses above 10 mg/kg; the aim is not only to prevent absorption but also aid elimination. Care should be taken to protect the airway. The prime objectives of management are then intensive symptomatic and supportive therapy with particular attention being paid to the maintenance of cardiovascular, respiratory, and renal functions and to the maintenance of electrolyte balance.

Charcoal haemoperfusion may be considered for patients with severe refractory poisoning; other methods aimed at the active removal of phenobarbital include haemodialysis and urine alkalinisation, although the latter appears to be less effective than multiple doses of activated charcoal.

Precautions

Phenobarbital and other barbiturates should be used with care in children and in elderly or debilitated patients, in those in acute pain, and in those with depressive disorders. Phenobarbital should be used with caution in patients with impaired hepatic, renal, or respiratory function; its use is contra-indicated in those with severe respiratory depression.

Breast feeding. The American Academy of Pediatrics[1] considers that phenobarbital should be given with caution to breast-feeding mothers, since there have been significant adverse effects including sedation and methaemoglobinaemia in nursing infants. The *BNF* recommends that phenobarbital should be avoided where possible during breast feeding. Both authorities make similar recommendations for primidone.

For further comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Neonates. Care should be taken when giving phenobarbital orally as the elixir to neonates because regular dosing could result in alcohol toxicity [the BP 2008 formulation contains 38% v/v alcohol].[1] Aqueous preparations are more readily made using the sodium salt than the acid.[2]

1. Colquhoun-Flannery W, Wheeler R. Treating neonatal jaundice with phenobarbitone: the inadvertent administration of significant doses of ethyl alcohol. *Arch Dis Child* 1992; **67:** 152.
2. Leach F. Treating neonatal jaundice with phenobarbitone: the inadvertent administration of significant doses of ethyl alcohol. *Arch Dis Child* 1992; **67:** 152.

Porphyria. Phenobarbital has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Congenital craniofacial and digital abnormalities and, less commonly, cleft lip and palate have been described with antiepileptics including phenobarbital. *In utero* exposure to phenobarbital might result in neonatal sedation and drug dependence and also in neonatal bleeding due to vitamin K deficiency.

Interactions

There are complex interactions between antiepileptics, and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. Valproate and phenytoin have been reported to cause rises in phenobarbital (and primidone) concentrations in plasma.

The effects of phenobarbital and other barbiturates are enhanced by other CNS depressants including alcohol.

Phenobarbital and other barbiturates may reduce the activity of many drugs by increasing the rate of metabolism through induction of drug-metabolising enzymes in liver microsomes.

Analgesics. *Dextropropoxyphene* 65 mg given three times daily to 4 epileptic patients stabilised on phenobarbital therapy increased serum-phenobarbital concentration by 8 to 29% but this was not considered of major importance in the light of the normally accepted therapeutic range for phenobarbital.[1]

For the effect of phenobarbital on *fenoprofen*, *methadone*, and *pethidine*, see p.55, p.84, and p.114, respectively. Enzyme-inducing antiepileptics such as phenobarbital also affect the threshold for the use of antidote in the treatment of *paracetamol* poisoning, see p.110.

1. Hansen BS, *et al.* Influence of dextropropoxyphene on steady state serum levels and protein binding of three anti-epileptic drugs in man. *Acta Neurol Scand* 1980; **61:** 357–67.

Antiarrhythmics. For the effect of phenobarbital on *disopyramide*, *lidocaine*, and *quinidine*, see p.1270, p.1863, and p.1384, respectively.

Antibacterials. Serum concentrations of phenytoin and phenobarbital in a previously stabilised patient were increased when he took *chloramphenicol*.[1] Subsequent monitoring revealed a similar effect when chloramphenicol was taken with phenobarbital alone. In turn, phenobarbital may affect serum concentrations of chloramphenicol (see p.240).

Barbiturates such as phenobarbital and primidone may enhance the metabolism of *doxycycline*.[2]

1. Koup JR, *et al.* Interaction of chloramphenicol with phenytoin and phenobarbital. *Clin Pharmacol Ther* 1978; **24:** 571–5.
2. Neuvonen PJ, *et al.* Effect of antiepileptic drugs on the elimination of various tetracycline derivatives. *Eur J Clin Pharmacol* 1975; **9:** 147–54.

Anticoagulants. For the effect of barbiturates such as phenobarbital and primidone on *warfarin* and other coumarins, see p.1429.

Antidepressants. As with all antiepileptics, antidepressants may antagonise the antiepileptic activity of phenobarbital by lowering the convulsive threshold.

St John's wort has been shown to induce several drug metabolising enzymes (see p.423) and so might reduce the blood concentrations of phenobarbital, and increase the seizure risk.[1]

For the effect of phenobarbital on antidepressants, see under the monographs for *amitriptyline* (under Barbiturates, p.380), *bupropion* (p.384), *fluoxetine* (p.396), *lithium* (p.404), and *mianserin* (p.409).

Inhibition of drug-metabolising enzymes by *MAOIs* may enhance the effects of barbiturates.

1. Committee on Safety of Medicines/Medicines Control Agency. Reminder: St John's wort (Hypericum perforatum) interactions. *Current Problems* 2000; **26:** 6–7. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007462&RevisionSelectionMethod=LatestReleased (accessed 09/06/08)

Antiepileptics. Interactions may occur if phenobarbital is given with other antiepileptics, of which probably the most significant is the interaction with *valproate*. Valproate increases plasma-phenobarbital concentration by a reported 17 to 48%,[1] and it may be necessary to reduce the dose of phenobarbital in some patients.[1,2] The mechanism for the increase appears to be inhibition of the metabolism of phenobarbital, resulting in reduced clearance;[2,3] valproate appears to inhibit both the direct *N*-glucosidation of phenobarbital and the *O*-glucuronidation of *p*-hydroxyphenobarbital.[4] However, phenobarbital reciprocally increases the clearance of valproate, and the valproate dose may also need to be adjusted.[5]

A similarly complex interaction exists between phenobarbital and *phenytoin.* Phenytoin can increase plasma concentrations of phenobarbital in some patients[6] since the two drugs compete for metabolism by the same enzyme system, but other evidence suggests that where this occurs it is rarely of significant magnitude.[7] Similarly, although phenobarbital induces the metabolism of phenytoin it is also, as stated, a competitive inhibitor and in practice the two effects appear to balance out, with rarely any need for dose adjustment.[7-9] However, dosage adjustment of phenobarbital may be crucial for some patients.[10] Measurement of serum concentrations of phenytoin and phenobarbital in one patient[10] showed that, in her case, large increases in serum-phenobarbital concentrations resulted from use with phenytoin; the increases were concentration-dependent.

The GABA-agonist, *progabide* has also been reported to cause a significant increase in phenobarbital concentrations when the two were given together to healthy subjects.[11]

Neurotoxicity, attributed to an increase in plasma concentrations of phenobarbital, has been seen[12] in one patient taking phenobarbital and sodium valproate when *felbamate* was added to treatment. The dosage of phenobarbital had already been reduced before treatment with felbamate was started. Data from a pharmacokinetic study[13] indicated that the interaction may result from the inhibition of phenobarbital hydroxylation by felbamate.

Vigabatrin has been reported to lower plasma concentrations of phenobarbital in some patients,[14] although dosage changes were not necessary in these patients.

High dose of *oxcarbazepine* may increase the plasma concentrations of phenobarbital but this was thought unlikely to be clinically significant;[15] conversely phenobarbital may reduce the plasma concentrations of the active metabolite of oxcarbazepine (p.491).

For the effect of phenobarbital on the metabolism of other antiepileptics, see under *Carbamazepine*, p.474, *Diazepam*, p.990, *Ethosuximide*, p.480, *Lamotrigine*, p.486, *Tiagabine*, p.505, and *Zonisamide*, p.515.

Antifungals. For the effect of phenobarbital on *griseofulvin*, see p.536, and on *itraconazole*, see p.537.

Antineoplastics. For the effect of phenobarbital on *teniposide*, see p.778.

Antiprotozoals. For the effect of phenobarbital on *metronidazole*, see p.838.

Antipsychotics. As with all antiepileptics, antipsychotics may antagonise the antiepileptic activity of phenobarbital by lowering the convulsive threshold.

For the effect of phenobarbital on antipsychotics, see under Chlorpromazine, p.974.

Antivirals. A patient stabilised on phenobarbital 100 mg daily had an episode of seizures 4 weeks after starting HAART therapy with abacavir, didanosine, ritonavir-boosted tipranavir, and enfuvirtide.[1] The patient's phenobarbital plasma concentrations had fallen from 16 to 8 micrograms/mL and an increase in the phenobarbital dosage to 150 mg daily was required to restore concentrations. The tipranavir/ritonavir component of HAART therapy was considered to be responsible.

For the possible effect of phenobarbital on *HIV-protease inhibitors*, see p.883.

Levothyroxine. For the effects of barbiturates on levothyroxine, see p.2172.

Montelukast. For the effect of phenobarbital on montelukast, see p.1126.

Sex hormones. For the effect of phenobarbital on sex hormones in *oral contraceptives*, see p.2068.

Theophylline. For the effect of phenobarbital on theophylline, see p.1143.

Vaccines. *Influenza vaccination* can cause prolonged rises in serum-phenobarbital concentrations in some patients.[1]

1. Jann MW, Fidone GS. Effect of influenza vaccine on serum anticonvulsant concentrations. *Clin Pharm* 1986; **5:** 817–20.

Vitamins. *Pyridoxine* reduced serum-phenobarbital concentrations in 5 patients.[1] Plasma concentrations of phenobarbital and primidone are possibly reduced by *folic acid* and *folinic acid*. For the effect of antiepileptics, including phenobarbital, on *vitamin D* concentrations, see Effects on Bone under Adverse Effects of Phenytoin, p.496.

1. Hansson O, Sillanpaa M. Pyridoxine and serum concentration of phenytoin and phenobarbitone. *Lancet* 1976; **i:** 256.

Pharmacokinetics

Like other barbiturates phenobarbital is readily absorbed from the gastrointestinal tract, although it is relatively lipid-insoluble; peak concentrations are reached in about 2 hours after oral doses and within 4 hours of intramuscular doses.

Phenobarbital is about 45 to 60% bound to plasma proteins and is only partly metabolised in the liver. About 25% of a dose is excreted in the urine unchanged at normal urinary pH. The plasma half-life is about 75 to 120 hours in adults but is greatly prolonged in neonates, and shorter (about 21 to 75 hours) in children. There is considerable interindividual variation in phenobarbital kinetics.

Monitoring of plasma concentrations has been performed as an aid in assessing control and the therapeutic range of plasma-phenobarbital has been quoted as 15 to 40 micrograms/mL or around 60 to 180 micromoles/litre.

Phenobarbital crosses the placental barrier and is distributed into breast milk.

The pharmacokinetics of phenobarbital are affected if given with other antiepileptics (see under Interactions, above).

Uses and Administration

Phenobarbital is a barbiturate that may be used as an antiepileptic to control partial and generalised tonic-clonic seizures. It is also used as part of the emergency management of acute seizures including status epilepticus.

The dose should be adjusted to the needs of the individual patient to achieve adequate control of seizures; this usually requires plasma concentrations of 15 to 40 micrograms/mL or around 60 to 180 micromoles/litre. In the UK, the usual oral dose is 60 to 180 mg daily, taken at night. In the USA, total daily doses of up to 300 mg have been given.

Phenobarbital sodium may be given parenterally as part of the emergency management of acute seizures including status epilepticus. Doses of 200 mg have been given by intramuscular injection, repeated after 6 hours if necessary. Doubts have been expressed about the efficacy of the intramuscular route owing to the delay in achieving adequate blood concentrations, and the subcutaneous route may cause tissue necrosis. In the UK, for the control of status epilepticus, doses of 10 mg/kg to a maximum of 1 g may be given intravenously. The *BNF* recommends that an intravenous injection solution containing 200 mg/mL should be diluted 1 in 10 and given at a rate not exceeding 100 mg/minute.

For doses in children, see below.

As with other antiepileptics, withdrawal of phenobarbital therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Phenobarbital has also been used as a hypnotic and sedative but drugs such as the benzodiazepines are preferred.

Phenobarbital stimulates the enzymes in hepatic microsomes responsible for the metabolism of some drugs and normal body constituents including bilirubin, and for this reason it has been used to reduce hyperbilirubinaemia in neonatal jaundice.

Phenobarbital magnesium and phenobarbital diethylamine have also been used.

Tetrabamate is a complex of phenobarbital, difebarbamate, and febarbamate but its use has been associated with the development of hepatitis.

Administration in children. Phenobarbital may be used in children as an antiepileptic to control partial and generalised tonic-clonic seizures. It is also used as part of the emergency management of status epilepticus. The doses given below for all indications are those recommended by the *BNFC* in the UK.

For treatment of epilepsy, the following doses are given orally, unless stated otherwise, according to age:

- neonates: an initial dose of 20 mg/kg by slow intravenous injection, then 2.5 to 5 mg/kg once daily by slow intravenous injection or orally, adjusted according to response
- 1 month to 12 years: an initial dose of 1 to 1.5 mg/kg twice daily, increased by 2 mg/kg daily if necessary to a usual maintenance dose of 2.5 to 4 mg/kg once or twice daily
- 12 to 18 years: 60 to 180 mg daily

For status epilepticus, an intravenous injection solution containing 200 mg/mL should be diluted 1 in 10 and given by intravenous injection over 20 minutes, at a rate not exceeding 1 mg/kg per minute, in the following doses according to age:

- neonate to 12 years: an initial dose of 20 mg/kg, followed by 2.5 to 5 mg/kg once or twice daily
- 12 to 18 years: an initial dose of 20 mg/kg (to a maximum of 1 g), followed by 300 mg twice daily

Alcohol withdrawal syndrome. Phenobarbital is used in some centres for the management of alcohol withdrawal syndrome (p.1626), but has a lower safety profile than benzodiazepines (the treatment of choice) and creates the potential for multiple drug interactions. Additionally, a lack of well-defined studies make its role difficult to assess.[1]

1. Rodgers JE, Crouch MA. Phenobarbital for alcohol withdrawal syndrome. *Am J Health-Syst Pharm* 1999; **56:** 175–8.

Cerebral malaria. Phenobarbital has been used to prevent convulsions in patients with cerebral malaria (p.594) but a systematic review[1] concluded that, although it was an effective anticonvulsant, it should not be given routinely to patients with cerebral malaria as it might increase mortality. The optimal dose, particularly in children, has yet to be confirmed. In an early study[2] a single intramuscular injection of phenobarbital sodium 3.5 mg/kg, or 200 mg in patients over 60 kg was effective. A dose of 10 to 15 mg/kg was later suggested.[3] Although a single intramuscular dose of phenobarbital 20 mg/kg markedly reduced seizure frequency in young children with cerebral malaria, it was also associated with a doubling of mortality.[4] The frequency of respiratory arrest was higher in the phenobarbital group than in controls given placebo, and mortality was greatly increased in those given phenobarbital who required 3 or more doses of diazepam. Intravenous use has also been tried, and a study[5] suggested giving a loading dose of phenobarbital 15 mg/kg by intravenous infusion followed by 2.5 mg/kg 24 and 48 hours later. WHO recommends[6] that a dose of 20 mg/kg should not be given without respiratory support but states that it is unknown whether ventilation would prevent the increase in mortality; it is also unknown whether lower doses are effective and safer.

Epilepsy. Phenobarbital is used in the treatment of epilepsy (p.465) for partial seizures with or without secondary generalisation and for primary generalised tonic-clonic seizures. It may also be tried for atypical absence, atonic, and tonic seizures but is not effective in absence seizures. However, the usefulness of phenobarbital is limited by problems of sedation in adults and paradoxical excitement in children. There is also concern about its effects on behaviour and cognition in children. Phenobarbital is therefore usually reserved for use in cases unresponsive to other antiepileptics, although some have suggested that its low cost and broad efficacy make it a suitable first-line drug in developing countries.

Febrile convulsions. Phenobarbital has been used prophylactically in children thought to be at risk of recurrence of febrile convulsions (p.470), but routine use of antiepileptics is no longer recommended.

Neonatal abstinence syndrome. For reference to the use of phenobarbital for the treatment of neonates with opioid abstinence syndrome, see p.102.

Neonatal intraventricular haemorrhage. Phenobarbital is one of several drugs that has been tried to prevent the development of neonatal intraventricular haemorrhage (p.1050). Initial studies[1-3] of antenatal use in the mother were promising, but a larger randomised study[4] in 610 women failed to show any effect of antenatal phenobarbital on incidence or severity of intraventricular haemorrhage. An assessment of surviving infants that could be traced at about 20 months of age also found that antenatal phenobarbital had no apparent effect on neurodevelopmental outcome.[5] A systematic review[6] of these and other studies concluded that giving phenobarbital before preterm birth cannot be recommended for routine clinical practice; strategies for future studies were suggested to improve methodology. Studies of use in neonates have also shown inconsistent results. A systematic review[7] of studies of phenobarbital for prophylaxis of intraventricular haemorrhage in preterm neonates concluded that postnatal use cannot be recommended either, and is associated with an increased need for mechanical ventilation.

Neonatal seizures. Some consider phenobarbital to be the mainstay of treatment for all types of neonatal seizures (p.471). In a study[1] in 120 neonates with clinical seizure activity of varying aetiology, 48 were controlled by an initial intravenous loading dose of phenobarbital 15 to 20 mg/kg over 10 to 15 minutes, and a further 37 were controlled by sequential bolus doses of phenobarbital 5 to 10 mg/kg every 20 to 30 minutes up to a serum concentration of 40 micrograms/mL. Of the remaining 35 neonates only 7 responded when the serum-phenobarbital concentration was increased to 100 micrograms/mL, 13 required addition of a second antiepileptic (phenytoin or lorazepam) and 4 were controlled by addition of a third drug. Phenobarbital alone can effectively control seizures in the majority of neonates with recurrent seizure activity.

Phenobarbital given prophylactically as a single dose of about 40 mg/kg intravenously over one hour has also been shown to be effective in reducing the incidence of seizures in 15 infants with severe perinatal asphyxia compared with a control group who only received phenobarbital if there was clinical evidence of seizures.[2] Subsequent follow-up over 3 years suggested that prophylactic phenobarbital might also improve later neurological outcome.[2] However, a later retrospective cohort study[3] found no significant difference in the rate of seizure recurrence and developmental outcome between infants who were discharged with prophylactic phenobarbital (33 patients) and those who were discharged without any antiepileptics (99).

Status epilepticus. Phenobarbital given intravenously is an alternative to intravenous phenytoin in the management of status epilepticus (p.469). It should not be used in patients who have recently received oral phenobarbital or primidone.

Although one study[1] suggested that phenobarbital might be at least as effective, safe, and practical as diazepam with phenytoin for the initial treatment of convulsive status epilepticus, it tends to be reserved for patients who do not respond to benzodiazepines or phenytoin.

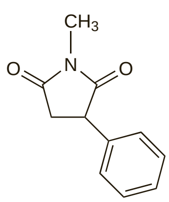
Phensuximide *(BAN, rINN)*

Fensuksimidi; Fensuximid; Fensuximida; Phensuximidum. *N*-Methyl-2-phenylsuccinimide.

Фенсуксимид

$C_{11}H_{11}NO_2$ = 189.2.
CAS — 86-34-0.
ATC — N03AD02.
ATC Vet — QN03AD02.



Pharmacopoeias. In *US.*

USP 31 (Phensuximide). A white to off-white crystalline powder. Is odourless or has not more than a slight odour. Slightly soluble in water; soluble in alcohol; very soluble in chloroform. Store in airtight containers.

Profile

Phensuximide is a succinimide antiepileptic with actions similar to those of ethosuximide (p.479), but it is reported to be less effective.

Porphyria. Phensuximide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

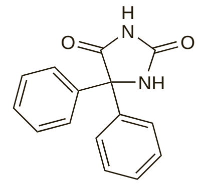
USP 31: Phensuximide Capsules.

Phenytoin *(BAN, USAN, rINN)*

Difenilhidantoína; Diphenylhydantoin; Fanantina; Fenantoína; Fenitoin; Fenitoína; Fenitoinas; Fenytoiini; Fenytoin; Fenytoina; Phenantoinum; Phénytoïne; Phenytoinum. 5,5-Diphenylhydantoin; 5,5-Diphenylimidazolidine-2,4-dione.

Фенитоин

$C_{15}H_{12}N_2O_2$ = 252.3.
CAS — 57-41-0.
ATC — N03AB02.
ATC Vet — QN03AB02.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Phenytoin). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; very slightly soluble in dichloromethane. It dissolves in dilute solutions of alkali hydroxides.

USP 31 (Phenytoin). A white, odourless powder. Practically insoluble in water; soluble in hot alcohol; slightly soluble in cold alcohol, in chloroform, and in ether. Store in airtight containers.

Phenytoin Sodium *(BANM, rINNM)*

Diphenin; Fenitoin Sodyum; Fenitoína sódica; Fenitoin-nátrium; Fenitoino natrio druska; Fenytoiininatrium; Fenytoin sodná sůl; Fenytoina sodowa; Fenytoinnatrium; Natrii Phenytoinum; Phénytoïne sodique; Phenytoinum natricum; Soluble Phenytoin.

Натрий Фенитоин

$C_{15}H_{11}N_2NaO_2$ = 274.2.
CAS — 630-93-3.
ATC — N03AB02.
ATC Vet — QN03AB02.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Phenytoin Sodium). A white or almost white, slightly hygroscopic, crystalline powder. Soluble in water and in alcohol; practically insoluble in dichloromethane. Store in airtight containers.

USP 31 (Phenytoin Sodium). A white, odourless powder. Is somewhat hygroscopic and on exposure to air gradually absorbs carbon dioxide. Freely soluble in water, the solution usually being somewhat turbid due to partial hydrolysis and absorption of carbon dioxide; soluble in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers.

Incompatibility. Phenytoin sodium only remains in solution when the pH is considerably alkaline (about 10 to 12) and there have been reports of loss of clarity or precipitation of phenytoin crystals when solutions of phenytoin sodium for injection have been mixed with other drugs[1-6] or added to intravenous infusion fluids,[7-10] while binding has been reported after addition to enteral nutrition solutions.[11] A phenytoin precipitate has blocked implanted central venous access devices after the inadvertent admixture of phenytoin sodium with glucose 5% or glucose in sodium chloride (pH 4);[12,13] the blockage can be successfully cleared by the local instillation of sodium bicarbonate 8.4% to increase the pH of the medium.

Adverse Effects

Adverse effects are fairly frequent in patients receiving phenytoin, but some remit with dose reduction or continued use. Often reported are CNS-related effects (such as headache, dizziness, tremor, transient nervousness, and insomnia), and gastrointestinal disturbances including nausea, vomiting, and constipation. Tenderness and hyperplasia of the gums often occur, particularly in younger patients. Acne, hirsutism, and coarsening of the facial features may be associated with phenytoin therapy, and may be particularly undesirable in adolescents and women.

Phenytoin toxicity may be manifested as a syndrome of cerebellar, vestibular, and ocular effects, notably nystagmus, diplopia, slurred speech, and ataxia. Mental confusion, sometimes severe, may occur, and dyskinesias and exacerbations of seizure frequency have been noted. Hyperglycaemia has been associated with toxic concentrations.

Overdosage may result in hypotension, coma, and respiratory depression. Hypotension and CNS depression may also follow intravenous dosage, if too rapid, as may cardiac arrhythmias and impaired cardiac conduction. Solutions for injection are very alkaline and may result in irritation at the injection site or phlebitis. A syndrome of distal limb oedema, discoloration, and pain ('purple glove syndrome') has been reported occasionally.

Prolonged therapy may produce subtle effects on mental function and cognition, especially in children. In addition there is some evidence that phenytoin interferes with vitamin D and folate metabolism. Rickets and osteomalacia have occurred in a few patients not exposed to adequate sunlight, although the causal role of phenytoin is debatable. A proportion of patients develop peripheral neuropathies, usually mild, and occasional cases of megaloblastic anaemia have been seen.

Mild hypersensitivity reactions are common, with skin rashes, often morbilliform, sometimes accompanied by fever. Bullous, exfoliative, or purpuric rashes may be symptoms of rare but severe reactions such as lupus erythematosus, erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis. Eosinophilia, lymphadenopathy, hepatitis, polyarteritis nodosa, and blood disorders such as aplastic anaemia, leucopenia, thrombocytopenia, and agranulocytosis, have occurred rarely; some of these conditions may also represent hypersensitivity reactions.

Hypoprothrombinaemia of the newborn after use of phenytoin during pregnancy has been reported. Congenital malformations have been seen in the offspring of mothers receiving phenytoin during pregnancy (see under Precautions, below).

Effects on the blood. ***AGRANULOCYTOSIS.*** Fatal agranulocytosis has been reported[1] in a patient 17 years after starting therapy with phenytoin and primidone. In the report it was stated that since 1963 the UK CSM had received reports of 3 previous cases of fatal agranulocytosis associated with phenytoin and none associated with primidone. The most likely cause was considered to be a direct toxic effect of phenytoin although other possible mechanisms included the ability of both drugs to produce folate deficiency. For a discussion of the effect of antiepileptics on serum folate, see below.

1. Laurenson IF, *et al.* Delayed fatal agranulocytosis in an epileptic taking primidone and phenytoin. *Lancet* 1994, **344:** 332–3.

FOLIC ACID DEFICIENCY. Antiepileptic therapy has long been associated with folate deficiency: early studies suggested that more than half of all patients on long-term therapy with drugs such as phenytoin, phenobarbital, and primidone had subnormal serum-folate concentrations.[1,2] Megaloblastic haematopoiesis is often present,[3] but clinical megaloblastic anaemia appears to be rare.

The relative importance of individual antiepileptics in causing folate deficiency and macrocytosis has been difficult to establish, because of the tendency to use combination regimens; with greater emphasis on single drug therapy there is evidence that monotherapy may produce less significant changes.[4,5] Despite suggestions that carbamazepine has relatively little effect on folic acid concentrations, its effects have been found to be comparable with those of phenytoin;[5] however, valproate had little or no effect on red cell folate concentrations.

The mechanism by which phenytoin and similar antiepileptics reduce serum folate is uncertain; there is good evidence for a reduction in absorption of glutamate both *in vitro*[6] and *in vivo*,[7] but the drugs associated with subnormal serum folate are all enzyme inducers and it has been suggested that enzyme induction and enhanced folate metabolism may also play a role.[2,5,8] Adverse blood changes also result from hypersensitivity (see below).

Effects on bone. The effects of phenytoin and other antiepileptics on the skeletal system are a matter of some debate. There are numerous reports indicating effects on bone and on calcium and vitamin D metabolism. Therapy with *carbamazepine*, *phenobarbital*, or *phenytoin* has been associated with reduction in serum-calcium concentration to hypocalcaemic values, significant reduction in 25-hydroxycholecalciferol concentrations, and elevated alkaline phosphatase.[1] In this study, involving 226 outpatients with epilepsy, the association was not seen with *valproate*. The effects were significantly greater in the group of patients receiving polytherapy, and there was limited evidence that these biochemical changes were exacerbated by reduced exposure to sunlight. In contrast, measurements of bone mineral density (BMD) found that children treated for epilepsy have reduced BMD during the first 1 to 5 years of therapy and that this progressively deteriorates thereafter.[2] Studies[3-5] of children receiving antiepileptic monotherapy revealed a reduction in density in those taking *valproate*; no reduction was found with *carbamazepine*.[3,4] The authors of one study[5] concluded that longer duration of therapy and higher doses resulted in lower BMD, and that this effect appeared to be more prominent in children under 5 years of age. A study[6] in 54 male patients followed for 12 to 29 months revealed that treatment with antiepileptics was associated with bone loss at the hip in the absence of vitamin D deficiency. There was no evidence that any particular drug produced more bone loss than another. Risk factors appear to include treatment duration of more than 2 years, age of over 40 years, and use of enzyme-inducing antiepileptics; the greatest rate of bone loss occurred in those with a combination of risk factors.[7] In a large cohort study[8] of women aged 65 years and older, continuous use of antiepileptics, particularly *phenytoin*, almost doubled the rate of bone loss.

A review[9] stated that there have been no significant reports of altered bone metabolism associated with the newer antiepileptics (*gabapentin*, *lamotrigine*, *topiramate*, and *vigabatrin*). However, short stature, low BMD, and reduced bone formation have been reported with long-term *lamotrigine* treatment, particularly when used with *valproate*;[10] further study is needed. *Oxcarbazepine* was found to have[11] similar effects on bone and vitamin D metabolism to *carbamazepine*; both drugs were associated with a reduction in 25-hydroxycholecalciferol serum concentrations and an increased bone turnover.

A more recent literature review[12] considered that most studies to date have been limited by factors such as small sample size, possible selection bias, lack of appropriate controls, and not adjusting for potential confounders. Nevertheless, long-term antiepileptic therapy was found to have an adverse effect on BMD and to increase fracture risk in some patients; there was little information regarding the relative risk with different types of antiepileptics. The authors suggested monitoring indices of bone health, optimising lifestyle factors, maintaining vitamin D and calcium status, and preventing falls in patients on long-term therapy.

Despite these alterations in bone metabolism reports of clinical osteomalacia associated with antiepileptics are rare.[13] A study in 20 epileptic outpatients who had received antiepileptic therapy for a mean of 14⁄ years failed to show any clinical evidence of osteomalacia although there was some evidence of altered calcium metabolism.[14] Similarly osteomalacia was seen in only 1 of 19 elderly inpatients in another study,[15] a rate similar to that previously seen in elderly patients with acute illness not receiving antiepileptic therapy.

Effects on the endocrine system and metabolism. Although it may be difficult to separate from the effects of the disease itself, there is some evidence that antiepileptics can diminish *sexual potency* and *fertility* in male epileptics. Phenytoin is excreted in human semen in small quantities and might affect sperm morphology and motility. Reduced plasma concentrations of free testosterone have been detected in male epileptic patients receiving one or more of the following: carbamazepine, phenytoin, primidone, and sodium valproate.[1] There is, however, some evidence[2] that some of the changes in sex hormone concentrations induced by antiepileptics in men and women are reversible. A higher frequency of sperm abnormalities has been found[3] in men given carbamazepine, oxcarbazepine, or valproate monotherapy when compared with healthy controls; those on valproate also had reduced testicular volume. Women may also have altered reproductive function and impaired fertility associated with antiepileptic therapy, particularly with the enzyme-inducing antiepileptics and valproate.[4]

Gynaecomastia has been reported[5] in 5 men receiving long-term antiepileptic treatment; one also complained of impotence but libido was stated to be normal in all 5. Phenytoin was a component of therapy in all patients and was the sole drug used in one.

Phenytoin may cause reversible *hyperglycaemia* at toxic doses but it does not appear to produce long-term effects on glucose tolerance when used in therapeutic doses.[6] Paradoxically, phenytoin has also been reported to improve insulin resistance in some patients. There has been a case report[7] of severe *hypoglycaemia* in a patient who was given intravenous phenytoin for the treatment of status epilepticus; symptoms resolved when glucose 5% was infused and no further episodes of hypoglycaemia occurred after phenytoin infusion was stopped.

Phenytoin may reduce serum concentrations of *thyroid* hormones through enzyme induction—see under Interactions of Levothyroxine, p.2172.

Effects on the liver. There have been occasional reports of liver damage, probably due to hypersensitivity, associated with phenobarbital and phenytoin; the authors of an early study suggested that such drugs need not be withdrawn if there were merely transient elevations in transaminase values,[1] but care is needed to distinguish such effects from the early symptoms of the antiepileptic hypersensitivity syndrome (see below).

1. Aiges HW, *et al.* The effects of phenobarbital and diphenylhydantoin on liver function and morphology. *J Pediatr* 1980; **97:** 22–6.

Effects on the lungs. Pulmonary eosinophilia and acute respiratory failure requiring mechanical ventilation have been reported[1] in a patient receiving phenytoin; other pulmonary symptoms associated with phenytoin were reviewed.

1. Mahatma M, *et al.* Phenytoin-induced acute respiratory failure with pulmonary eosinophilia. *Am J Med* 1989; **87:** 93–4.

Effects on mental function. For a review of the effects of antiepileptic therapy including phenytoin on *cognition* and *mood* (including the risk of suicidal ideation), see p.468.

Effects on the skin. A retrospective analysis involving 1890 outpatients taking antiepileptics found that rates of skin reactions associated with treatment varied with different drugs, the risk being greatest with carbamazepine, lamotrigine, and phenytoin, and lowest with gabapentin, levetiracetam, and valproate.[1] Overall, the rate of skin reactions in this study was 2.8%, but as also mentioned in Hypersensitivity, below (where more details on phenytoin-associated skin reactions are given), there appeared to be cross-sensitivity; risk in this study was increased to 8.8% in those who had previously experienced rash with another antiepileptic drug.

Rare, but severe reactions such as Stevens-Johnson syndrome and toxic epidermal necrolysis have also occurred.

For reference to cutaneous manifestations of zinc deficiency, possibly due to chelation with phenytoin, see under Valproate, p.509.

1. Arif H, *et al.* Comparison and predictors of rash associated with 15 antiepileptic drugs. *Neurology* 2007; **68:** 1701–9.

Gingival hyperplasia. Gingival hyperplasia, characterised by inflammation and a marked fibrotic response, may affect up to 50% of patients receiving phenytoin. It usually becomes apparent within the first few months of therapy and occurs more frequently in children; there is no increase in alveolar bone loss. The mechanism underlying its development is unknown, although the main metabolite of phenytoin, 5-(4-hydroxyphenyl)-5-phenylhydantoin, has been implicated.[1-3]

3. Zhou LX, *et al.* Metabolism of phenytoin by the gingiva of normal humans: the possible role of reactive metabolites of phenytoin in the initiation of gingival hyperplasia. *Clin Pharmacol Ther* 1996; **60:** 191–8.

Hypersensitivity. An antiepileptic hypersensitivity syndrome, comprising fever, rash, and lymphadenopathy and less commonly lymphocytosis, and liver and other organ involvement, has been associated with some antiepileptic drugs including phenytoin.[1-3] Clinical manifestations may include interstitial nephritis, anaemia, interstitial pulmonary infiltrates, thrombocytopenia, eosinophilia, myopathy, and diffuse intravascular coagulation.[1,2] Some have estimated the incidence at 1 in 1000 to 1 in 10 000 new exposures to aromatic antiepileptics,[2,3] but the true incidence is unknown due to variations in presentation and reporting. The syndrome occurs most frequently on first exposure to the drug, with initial symptoms starting anywhere between 1 and 8 weeks after exposure. The mean interval to onset is 17 to 21 days with phenytoin. In previously sensitised individuals the reaction may occur within 1 day of rechallenge. The potential for cross-reactivity between carbamazepine, phenobarbital, and phenytoin is approximately 75%, and patients who develop the syndrome, and their close relatives, should be warned of the risk associated with use of these antiepileptics.[2] An early review[1] of the syndrome in patients taking phenytoin commented that it occurred mainly in black male patients and should not be confused with more common mild general hypersensitivity reactions. More recent evidence does not suggest that ethnic origin predicts differences in risk.[2]

Most cases resolve spontaneously on withdrawal of the drug and symptomatic management. The use of corticosteroids in the management of severe cases remains controversial in the absence of controlled studies of their effectiveness.[1,2]

Phenytoin-induced pseudolymphoma mimicking cutaneous T-cell lymphoma has also been reported.[2,4] In most cases, symptoms resolve within 7 to 14 days of stopping the drug, and the condition is not considered premalignant.[2] However, in one report[4] the cutaneous eruption and lymphadenopathy persisted after withdrawal of phenytoin for one year when the patient eventually became asymptomatic.

In a prospective study[5] of 306 patients given phenytoin there was an overall incidence of 8.5% of morbilliform rash, but there was a marked seasonal incidence with most reactions occurring during the summer months. The results did not appear to be due to photosensitivity and might represent seasonal alterations in the immune system.

Peripheral neuropathies. Electrophysiological abnormalities after prolonged phenytoin treatment are common, but clinically significant peripheral neuropathy is rare.[1] The neuropathy usually involves sensory nerves and lesions are generally mild and asymptomatic.[2] Much of the reported clinical neuropathy has been associated with multiple drug therapy of epilepsy and with exposure to toxic concentrations of phenytoin.[1,3] Although an association with folate deficiency has been suggested, a study in 52 patients on long-term antiepileptic therapy failed to find any convincing evidence of a relationship between serum-folate concentration and peripheral neuropathy.[4]

Treatment of Adverse Effects

Treatment of poisoning with phenytoin tends to be supportive. Repeated doses of activated charcoal may be given orally to adults and children who have ingested more than 20 mg/kg; the aim is not only to prevent absorption but also to aid elimination. Gastric lavage may be considered if a very large amount has been taken within 1 hour.

◊ Multiple oral doses of activated charcoal may reduce the absorption of phenytoin[1,2] but the degree of clinical benefit is unclear.[3] The value of charcoal haemoperfusion in the management of phenytoin overdosage is debatable. A review of haemoperfusion included data from 2 patients who ingested phenytoin[4] but, although it was suggested that haemoperfusion should contribute significantly to drug removal, results are difficult to evaluate in these patients who had also ingested phenobarbital. An evaluation in a patient who had also taken primidone[5] suggested that, although initial clearance of phenytoin was promising, the system rapidly became saturated and there was little overall benefit. A review[3] of the features and management of phenytoin poisoning concluded that supportive care is the mainstay of treatment. Gastric lavage and multiple-dose activated charcoal should not be used routinely, although they might be considered for life-threatening ingestion. They were most effective when used within 1 hour of ingestion; the airway should be secured first. Extracorporeal methods of elimination (e.g. haemodialysis, haemoperfusion, peritoneal dialysis, or plasmapheresis) had not been shown to be of benefit;[3] however, some such procedures may be beneficial in patients with renal failure[3] or hypoalbuminaemia[6] in whom free phenytoin concentrations are raised.

Precautions

Phenytoin is metabolised in the liver and should be given with care to patients with impaired liver function. Caution is also advocated in diabetic patients because of the potential effects of phenytoin on blood sugar.

Protein binding may be reduced in certain disease states such as uraemia, and in certain patient populations such as neonates, pregnant women, and the elderly. Although phenytoin is extensively protein bound this may be of little clinical significance in itself, provided that hepatic function is not impaired, because the concentration of free (pharmacologically active) drug in the plasma often remains more or less unchanged, due to distribution, metabolism, and excretion. Thus, an alteration in protein binding would not necessarily require a change in dosage of phenytoin to be made although, when plasma concentrations are being monitored, relatively lower total plasma-phenytoin concentrations will be found to be effective since there is less bound (pharmacologically inactive) phenytoin available for measurement.

Intravenous phenytoin must be given slowly and extravasation and intra-arterial injection must be avoided. Phenytoin should not be given intravenously to patients with sinus bradycardia, heart block, or Stokes-Adams syndrome, and should be used with caution in patients with hypotension, heart failure, or myocardial infarction; monitoring of blood pressure and the ECG is recommended during intravenous use.

Patients or their carers should be told how to recognise signs of blood or skin toxicity and they should be advised to seek immediate medical attention if symptoms such as fever, sore throat, rash, mouth ulcers, bruising, or bleeding develop. Phenytoin should be stopped, if necessary under cover of a suitable alternative antiepileptic, if leucopenia which is severe, progressive, or associated with clinical symptoms develops. It should also be stopped if a skin rash develops; in the case of mild rashes phenytoin may be reintroduced cautiously, but should be stopped immediately and permanently if the rash recurs.

Care is required when withdrawing phenytoin therapy—see also Uses and Administration, below.

Phenytoin may interfere with some tests of thyroid function as it can reduce free and circulating concentrations of levothyroxine, mainly by enhanced conversion to tri-iodothyronine, and it may also produce lower than normal values for dexamethasone and metyrapone suppression tests.

Breast feeding. The American Academy of Pediatrics[1] considers that phenytoin is usually compatible with breast feeding, although there had been an early case report of methaemoglobinaemia in a breast-fed infant.

For further comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For comment on antiepileptic drugs and driving, see p.468.

Infections. A 52-year-old woman previously well-controlled on phenytoin 400 mg daily suffered phenytoin toxicity after a viral infection;[1] her plasma-phenytoin concentration had increased from 16 to 51 micrograms/mL. Six weeks later she had recovered and was re-stabilised on phenytoin 400 mg daily.

1. Levine M, Jones MW. Toxic reaction to phenytoin following a viral infection. *Can Med Assoc J* 1983; **128:** 1270–1.

AIDS. Renal abnormalities or hypoalbuminaemia associated with AIDS may increase the risk of elevated free phenytoin concentrations and subsequent toxicity. Altered protein binding resulted in marked phenytoin toxicity, with lethargy and seizure-like activity, in an HIV-positive patient with profound hypoalbuminaemia and moderate renal insufficiency.[1] Therapeutic drug monitoring in 21 patients with AIDS indicated that although total serum concentrations of phenytoin were lower than in a reference population, the fraction of unbound drug was higher.[2] These changes might be attributed to hypoalbuminaemia and it was suggested that free rather than total phenytoin concentrations should be measured in HIV-infected patients with hypoalbuminaemia.

Phenytoin itself was associated with reversible hypogammaglobulinaemia in an HIV-positive patient who previously had borderline hypergammaglobulinaemia.[3]

3. Britigan BE. Diphenylhydantoin-induced hypogammaglobulinemia in a patient infected with human immunodeficiency virus. *Am J Med* 1991; **90:** 524–7.

Porphyria. Phenytoin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

There is an increased risk of neural tube defects in infants exposed *in utero* to antiepileptics including phenytoin, and a variety of syndromes such as craniofacial and digital abnormalities and, less commonly, cleft lip and palate have been described. Specific syndromes such as the 'fetal hydantoin syndrome' with phenytoin have been linked to individual antiepileptics. However, there is overlap between the effects seen with different antiepileptics and these are now often seen as aspects of a single 'fetal antiepileptic syndrome'. There is also a risk of neonatal bleeding with phenytoin.

Interactions

There are complex interactions between antiepileptics, and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy.

Since phenytoin is extensively bound to plasma proteins it can be displaced by drugs competing for protein-binding sites, thus liberating more free (pharmacologically active) phenytoin into the plasma. However, elevation of free phenytoin is reported to be of little clinical significance provided hepatic function is not impaired (see Precautions, above). A potentially more serious type of interaction may occur because phenytoin metabolism is saturable: toxic concentrations of phenytoin can develop in patients given drugs that inhibit phenytoin metabolism even to quite a minor degree. Phenytoin itself is also a potent enzyme inducer, and induces the metabolism of a number of drugs, including some antibacterials, anticoagulants, corticosteroids, quinidine, and sex hormones (notably, oral contraceptives).

The hypotensive properties of dopamine and the cardiac depressant properties of drugs such as lidocaine may be dangerously enhanced by intravenous phenytoin.

◊ General references.

Anaesthetics. A 10-year-old girl with epilepsy who had been treated with phenytoin 100 mg three times daily for 5 years and who had lateral nystagmus developed symptoms of phenytoin intoxication after anaesthesia with *halothane*.[1] The plasma concentration of phenytoin 72 hours after anaesthesia was 41 microgram/mL. It was suggested that temporary liver dysfunction was responsible for impaired metabolism of phenytoin.

1. Karlin JM, Kutt H. Acute diphenylhydantoin intoxication following halothane anesthesia. *J Pediatr* 1970; **76:** 941–4.

Analgesics. *Aspirin* is reported to displace phenytoin from plasma binding[1,2] but there is no evidence of any effect on metabolism and effects are unlikely to be clinically significant.[3,4] *Paracetamol* is reported to have no significant effect on serum-phenytoin concentrations.[4] (However, enzyme-inducing antiepileptics such as phenytoin affect the threshold for use of antidote in the treatment of paracetamol poisoning, see p.110.) Alterations of the pharmacokinetics of phenytoin have been reported with *bromfenac*, but it was thought unlikely that a change in phenytoin dose would be necessary.[5]

Other analgesic and anti-inflammatory drugs may have clinically significant effects. *Phenylbutazone* has been reported to cause an initial decrease in serum phenytoin, followed by an increase;[4] in addition to effects on protein binding it inhibits phenytoin metabolism[6] and severe phenytoin toxicity may result.[7] *Azapropazone* appears to be a competitive inhibitor of phenytoin metabolism and has also been implicated in interactions resulting in toxicity.[8,9] Substantial increases in serum phenytoin have been found in healthy subjects given the analgesic and muscle relaxant *fenyramidol*,[10] indicating a potential for toxicity. There is a single report of toxicity in a patient receiving *ibuprofen* with phenytoin[11] but in a study in 9 healthy subjects, ibuprofen had no effect on the pharmacokinetics of phenytoin.[12] In another report, phenytoin toxicity developed[13] in a patient who was also taking *celecoxib*.

The opioid analgesic *dextropropoxyphene* has also been reported to affect phenytoin metabolism, with the resultant development of toxic blood-phenytoin concentrations;[14] however, the patient in this case was taking relatively high doses of dextropropoxyphene (650 mg daily). For the effect of phenytoin on *methadone* and *pethidine*, see p.84 and p.114, respectively.

2. McGovern B, *et al.* Possible interaction between amiodarone and phenytoin. *Ann Intern Med* 1984; **101:** 650.

Antibacterials. Interactions, some clinically significant, may occur between phenytoin and various antibacterials. Giving *chloramphenicol* with phenytoin has resulted in moderate[1] to marked[2] elevation of serum-phenytoin concentrations due to inhibition of phenytoin metabolism;[2] toxicity has resulted.[3,4] In turn, phenytoin may affect serum concentrations of chloramphenicol (see p.240).

Phenytoin may enhance the metabolism of *doxycycline*.[5]

There is limited evidence that *erythromycin* decreases phenytoin clearance[6] but this was subject to considerable interindividual variation and is of unknown clinical significance. Results from another study[7] suggested that *clarithromycin* might also raise phenytoin levels.

The interaction with *isoniazid* is well documented and potentially significant in slow acetylators of isoniazid who may develop raised phenytoin concentrations and signs of toxicity;[8,9] in at least one case, death has resulted.[10] Plasma-isoniazid concentrations may become sufficiently raised in slow acetylators of isoniazid to produce marked inhibition of the hepatic microsomal enzymes responsible for the metabolism of phenytoin.

There have been conflicting reports of the effect of *ciprofloxacin* on serum concentrations of phenytoin. While some report no effect[11] others have reported reduced[12-16] or increased[17,18] concentrations of phenytoin in patients given ciprofloxacin. A fall in serum-phenytoin concentrations, and resultant loss of seizure control has been reported in a patient in whom *nitrofurantoin* was added to therapy.[19] The mechanism of this interaction is unknown although a combination of impaired absorption and increased metabolism of the phenytoin was suggested. Something similar was reported in a patient given *oxacillin* in whom plasma-phenytoin concentrations dropped markedly and status epilepticus developed.[20] This effect was thought to be due to impaired phenytoin absorption.

Rifampicin can also reduce plasma-phenytoin concentrations and markedly increase its clearance;[21,22] this is in marked contrast to the effects of isoniazid, and when given together it overrides the effects of isoniazid on phenytoin, even in slow acetylators.[22]

Various sulfonamides are reported to interact with phenytoin, reducing clearance and prolonging half-life: *sulfaphenazole* is reportedly the strongest inhibitor of phenytoin metabolism but *sulfamethizole* also inhibits phenytoin metabolism and the latter has been implicated in producing phenytoin toxicity.[23] *Co-trimoxazole* reportedly inhibits phenytoin metabolism to a modest degree; a case of phenytoin toxicity in a child given co-trimoxazole has been reported[24] but the role of the co-trimoxazole is uncertain since the patient was also receiving sultiame. Fatal acute fulminant hepatic failure in a 60-year-old patient was suggested[25] to be due to phenytoin-induced hepatitis exacerbated by addition of co-trimoxazole to her drug regimen.

Anticoagulants. Serum-phenytoin concentrations have been reported to be markedly elevated by *dicoumarol*[1,2] and elevated to a lesser extent by *phenprocoumon*;[2] however, although *warfarin* has been implicated in a report of phenytoin toxicity,[3] other evidence suggests that it has no effect on serum-phenytoin concentrations in most patients.[2]

For the effect of phenytoin on anticoagulants such as dicoumarol and warfarin, see p.1429.

3. Rothermich NO. Diphenylhydantoin intoxication. *Lancet* 1966; **ii:** 640.

Antidepressants. As with all antiepileptics, antidepressants may antagonise the antiepileptic activity of phenytoin by lowering the convulsive threshold.

Plasma-phenytoin concentrations rose in 2 epileptic patients also receiving *imipramine* 75 mg daily for about 3 months for depression.[1] In one patient the concentration gradually increased over several weeks to more than twice the pretreatment figure and he showed mild signs of phenytoin intoxication, which remitted after imipramine was stopped. Increased serum-phenytoin concentration and phenytoin toxicity possibly precipitated by addition of *trazodone* has been described;[2] licensed product information for trazodone recommends monitoring serum-phenytoin concentrations in patients receiving these two drugs. Elevated plasma-phenytoin concentrations, in some cases accompanied by signs and symptoms of phenytoin toxicity, have also been reported with *fluoxetine*,[3] *fluvoxamine*,[4,5] *sertraline*,[6] and *viloxazine*.[7] Product information for *mianserin* also recommends that plasma concentrations of phenytoin should be monitored carefully when both are given.

St John's wort has been shown to induce several drug metabolising enzymes (see p.423) and consequently it might reduce the blood concentrations of phenytoin leading to an increased risk of seizure.[8] Some licensed product information for phenytoin in the UK therefore recommends that phenytoin should not be used with St John's wort and warns that the effects of St John's wort may persist for at least 2 weeks after it was last used.

For the effects of phenytoin on antidepressants, see under Amitriptyline (p.380), Fluoxetine (p.396), and Lithium (p.404).

Antidiabetics. Transient rises in the amount of non-protein-bound phenytoin were observed in 17 patients when *tolbutamide* was given in addition to phenytoin, but none developed signs of intoxication.[1] Toxic symptoms were reported in another patient given phenytoin with tolbutamide, although she had tolerated this combination on a previous occasion.[2]

Symptoms of phenytoin toxicity are known to have occurred[1] in one patient receiving *tolazamide* and phenytoin.

1. Wesseling H, Mols-Thürkow I. Interaction of diphenylhydantoin (DPH) and tolbutamide in man. *Eur J Clin Pharmacol* 1975; **8:** 75–8.
2. Beech E, *et al.* Phenytoin toxicity produced by tolbutamide. *BMJ* 1988; **297:** 1613–14.

Antiepileptics. Interactions may occur when phenytoin is used with other antiepileptics, but these are often variable in their effect and difficult to predict.

For a discussion of the effect of *benzodiazepines* on plasma concentrations of phenytoin, see Benzodiazepines, below.

Carbamazepine has been generally reported to lower serum-phenytoin concentrations,[1,2] although reports exist of elevated serum-phenytoin concentrations when the two were given concurrently.[3] It should be noted that phenytoin also reduces serum-carbamazepine values—see p.474. These studies have not indicated any loss of seizure control due to this interaction.

For the effects of phenytoin on *ethosuximide*, see p.480.

Felbamate has caused increases in serum-phenytoin concentrations, and in some cases toxicity requiring a reduction in phenytoin dose.[4,5]

Increased plasma concentrations of phenytoin with symptoms of toxicity have been reported in a patient receiving phenytoin, carbamazepine, and clobazam after *gabapentin* was added to treatment.[6]

Phenytoin reduces plasma concentrations of *lamotrigine* as described on p.486.

Phenytoin plasma concentrations may be increased by high doses of *oxcarbazepine*;[7] licensed product information for oxcarbazepine suggests that doses of phenytoin may need to be reduced when high doses of oxcarbazepine are given.

Phenobarbital both induces the metabolism of phenytoin and competes with it for metabolism by the same enzyme system; in practice there is rarely sufficient alteration for a change in phenytoin dosage to be necessary.[8-10] For the effect of phenytoin on phenobarbital, see p.493. Phenytoin has also been reported to enhance the metabolism of *primidone* to phenobarbital, see p.503.

The GABA agonist *progabide* increased blood-phenytoin concentrations[11] and *stiripentol* appears to produce a dose-dependent reduction in phenytoin clearance.[12]

Sultiame causes substantial increases in plasma-phenytoin concentrations, in some cases resulting in phenytoin toxicity;[13] the dose of phenytoin may therefore require adjustment if these drugs are given together.

Modest increases in plasma-phenytoin concentrations have been observed in some patients when *topiramate* was added to therapy, but it was considered that dosage adjustments were unlikely to be necessary.[14] For the effect of phenytoin on topiramate, see p.506.

The interaction between phenytoin and *valproate* is complex. Valproate displaces phenytoin from serum binding sites and may inhibit its metabolism;[15] the former effect increases the concentration of free drug but reduces total serum phenytoin.[16,17] Most studies seem to suggest that the dose of phenytoin need only rarely be adjusted, but the possibility of loss of seizure control, or phenytoin toxicity, does exist.[15] Interestingly there is some evidence that the interactions may be affected by circadian variations in valproate concentrations.[18] Total plasma-phenytoin concentrations rose significantly in 9 of 11 patients, 2 of whom developed toxic symptoms, when the formulation of sodium valproate that they were taking with phenytoin was changed from a standard tablet to a slow-release form.[19] The authors hypothesised that reduced diurnal fluctuations in plasma-valproate concentrations due to the use of slow-release tablets reduced the displacement interaction between phenytoin and valproate, thereby increasing total plasma-phenytoin concentrations. Phenytoin may also cause a fall in serum concentrations of valproate—see p.511.

Gradual or delayed reductions in plasma-phenytoin concentrations have been seen in several studies in patients given *vigabatrin*;[20] a review[20] states that concentrations have been reduced by 20 to 30%. The manufacturer of vigabatrin considers that this is unlikely to be of clinical significance although in a study the reduction was considered to compromise seizure control.[21]

Antifungals. There have been several reports of interactions, sometimes resulting in phenytoin toxicity, between imidazole antifungals and phenytoin. The drug most frequently implicated is *miconazole*.[1-3] The related triazole antifungals *fluconazole*[4-6] and *voriconazole*[7] are also reported to interact with phenytoin,[4-6] possibly due to dose-related inhibition of cytochrome P450 isoenzymes by these antifungals.[4,7]

Phenytoin can decrease plasma concentrations of azole antifungals such as *ketoconazole*, voriconazole, and *itraconazole*.

Antigout drugs. Licensed product information for *sulfinpyrazone* states that it displaces phenytoin from its protein-binding sites, and also inhibits microsomal liver enzymes. The net result is an increase in plasma-phenytoin concentrations and a prolonged half-life, which is potentially hazardous.

Reduced doses of phenytoin were necessary to avoid toxicity when *allopurinol* was added to the therapy of a child with the Lesch-Nyhan syndrome.[1] Although the authors thought caution was advisable in using these two drugs together, they did emphasise that overgeneralisation may be dangerous since the child also received other antiepileptics and the role his disease may have played was unknown.

1. Yokochi K, *et al.* Phenytoin-allopurinol interaction: Michaelis-Menten kinetic parameters of phenytoin with and without allopurinol in a child with Lesch-Nyhan syndrome. *Ther Drug Monit* 1982; **4:** 353–7.

Antihistamines. A young woman developed drowsiness, ataxia, diplopia, tinnitus, and episodes of occipital headaches associated with vomiting after taking phenytoin sodium and *chlorphenamine*.[1] Chlorphenamine might have delayed the hepatic metabolism of phenytoin thereby increasing the plasma concentrations.

1. Pugh RNH, *et al.* Interaction of phenytoin with chlorphenamine. *Br J Clin Pharmacol* 1975; **2:** 173–5.

Antihypertensives. In 2 patients with hypoglycaemia associated with hyperinsulinism, therapeutic serum-phenytoin concentrations could not be achieved while they were also receiving *diazoxide*.[1] It was suggested that an increased rate of metabolism, and possibly a decreased binding, of phenytoin induced by diazoxide might have been responsible.

1. Roe TF, *et al*. Drug interaction: diazoxide and diphenylhydantoin. *J Pediatr* 1975; **87:** 480–4.

Antimalarials. Antimalarials may antagonise the antiepileptic activity of phenytoin by lowering the convulsive threshold.

Antineoplastics. There have been reports of decreased plasma-phenytoin concentrations associated with cancer chemotherapy,[1-4] resulting in some cases in loss of seizure control.[2-4] The effect appears to be due to impaired absorption of phenytoin arising from antineoplastic damage to the gastrointestinal mucosa. In a patient a mean of 32% of an oral dose of phenytoin was absorbed after therapy with *cisplatin*, *vinblastine*, and *bleomycin*; this compared with a reported oral bioavailability of 80% or more.[3] *Trabectedin* may also reduce phenytoin absorption leading to an exacerbation of seizures.

Licensed product information for *levamisole* reports that increased plasma-phenytoin concentrations have been seen in patients taking phenytoin with levamisole given as an adjuvant to *fluorouracil* therapy. Treatment with fluorouracil (alone or with folinic acid) has also led to phenytoin toxicity in patients on long-term antiepileptic therapy.[5-7] Similar interactions have occurred with *doxifluridine*[8] and *capecitabine*[7] (both prodrugs of fluorouracil), and a combination preparation containing *tegafur* (a prodrug of fluorouracil) with *uracil* . However, a decrease in phenytoin serum concentrations has been seen when such a preparation was given with folinic acid to a patient receiving the antiepileptic.[9] For the effect of phenytoin on *busulfan* see Effects on the Nervous System under Adverse Effects of Busulfan, p.690. For the effect of phenytoin on the use of *streptozocin* and on *teniposide* see p.771 and p.778, respectively.

9. Veldhorst-Janssen NML, *et al.* Oral tegafur/folinic acid chemotherapy decreases phenytoin efficacy. *Br J Cancer* 2004; **90:** 745.

Antiprotozoals. Conflicting results have been reported with *metronidazole*: while one study has suggested only minimal effects on phenytoin concentrations and metabolism,[1] another has indicated inhibition of the metabolism of phenytoin.[2] For the effect of phenytoin on metronidazole, see p.838.

2. Blyden GT, *et al.* Metronidazole impairs clearance of phenytoin but not of alprazolam or lorazepam. *Clin Pharmacol Ther* 1986; **39:** 181.

Antipsychotics. As with all antiepileptics, antipsychotics may antagonise the antiepileptic activity of phenytoin by lowering the convulsive threshold. Two cases of phenytoin toxicity and elevated plasma-phenytoin concentrations associated with the phenothiazine *thioridazine* have been reported;[1] but another study indicated that *thioridazine*, *chlorpromazine*, or *mesoridazine* reduced serum-phenytoin concentrations.[2]

The non-phenothiazine antipsychotic *loxapine* has also been implicated as producing a fall in serum-phenytoin concentration.[3]

For the effect of phenytoin on antipsychotics in general, see under Chlorpromazine, p.974. For the effect of phenytoin on *clozapine*, see p.984.

Antivirals. *Zidovudine* may possibly reduce or increase plasma concentrations of phenytoin. There has been a report[1] of markedly decreased serum-phenytoin concentrations resulting in a recurrence of seizure activity in an epileptic patient after starting *nelfinavir* as part of antiretroviral therapy. Serum concentrations of phenytoin and valproate decreased[2,3] in 2 reports in children after the addition of *aciclovir. Ritonavir-boosted lopinavir* was reported[4] to increase the clearance of phenytoin in healthy subjects, probably due to hepatic enzyme induction; phenytoin similarly increased the clearance of the protease inhibitor. A case report[5] described the inhibition of phenytoin clearance by *efavirenz* resulting in elevated phenytoin plasma concentrations, and subtherapeutic levels of efavirenz resulting from hepatic enzyme induction by phenytoin.

For the possible effect of phenytoin on HIV-protease inhibitors, see p.883.

Anxiolytics. See Benzodiazepines, below.

Benzodiazepines. The metabolism of benzodiazepines may be enhanced as a result of induction of hepatic drug-metabolising enzymes after long-term use of phenytoin. In comparison with healthy subjects, half-lives have been shorter and clearance increased.[1,2]

There are sporadic reports of interactions between phenytoin and benzodiazepines, but the evidence is conflicting. Elevated plasma concentrations of phenytoin have been reported in patients given *diazepam*[3,4] or *chlordiazepoxide*[3] but, in contrast, another study suggested that these drugs produced a significant fall in serum-phenytoin concentrations.[5] It has been suggested that phenytoin intoxication could result from the impaired metabolism associated with the combination[3,4,6] but in practice this seems to be uncommon. There are similar conflicting reports for *clonazepam*.[7-9]

Calcium-channel blockers. Raised serum-phenytoin concentration with phenytoin toxicity developed in a patient who had been taking *nifedipine* in addition to phenytoin for 3 weeks;[1] symptoms resolved completely after nifedipine withdrawal. The mechanism of interaction appeared to be complex. Similar effects have been reported with *diltiazem*[2] and *isradipine*.[3]

For the effect of phenytoin on dihydropyridine calcium-channel blockers, see under Nifedipine, p.1353, and on verapamil, see p.1422.

Dermatological drugs. For the effect of phenytoin on *methoxsalen*, see p.1606.

Disulfiram. A well-documented interaction exists between phenytoin and disulfiram, which may result in clinical phenytoin toxicity.[1,2] The effect appears to be due to non-competitive inhibition of the metabolism of phenytoin by disulfiram,[2] which results in a substantial increase in phenytoin half-life and a decrease in its clearance.[3]

Dopaminergics. For the effect of phenytoin on *levodopa*, see p.807.

Enteral and parenteral nutrition. Therapeutic plasma concentrations of phenytoin may be difficult to achieve in patients receiving enteral or total parenteral nutrition.[1,2] Incompatibility studies indicate that phenytoin probably binds to components of the feed (see Incompatibility, above), which might explain this interaction when both are given together nasogastrically, but the same effect has also been reported when they were given separately by the intravenous route.[2] A review[3] of case reports and studies concluded that the exact role of enteral feeding in this interaction still remained unclear because of a lack of prospective, randomised, controlled studies performed in patients, rather than in healthy subjects. However, because of the amount of literature describing such a phenomenon, it was considered unlikely to occur just by chance. Monitoring of serum-phenytoin concentrations to guide therapy was recommended, and measures such as staggering phenytoin and enteral feeding might be considered to minimise the occurrence of this reaction.

Gastrointestinal drugs. Evidence for an interaction between phenytoin and *antacids* is conflicting. Some studies have shown a decrease in the bioavailability of phenytoin given with various antacid mixtures[1,2] but others have failed to find any evidence of reduced absorption.[3] Furthermore even those studies that recorded decreased absorption varied in their results with regard to particular drugs, suggesting for example that calcium carbonate both does[1] and does not[2] reduce phenytoin bioavailability. The clinical significance of this data is uncertain but it has been suggested that if antacids and phenytoin are both needed, doses should be spaced several hours apart.[4,5] *Sucralfate* is also reported to reduce phenytoin absorption.[6]

A well documented interaction exists between phenytoin and *cimetidine*, which produces a dose-dependent reduction in phenytoin clearance[7] and a significant elevation of serum-phenytoin concentration.[8] There are reports of phenytoin toxicity when cimetidine was given to epileptic patients[9,10] including a report of severe granulocytopenia.[11] Although some studies have found that neither *ranitidine*[12] nor *famotidine*[13] appear to affect the pharmacokinetics of phenytoin significantly, there have been isolated reports of raised plasma concentrations of phenytoin associated with use of ranitidine[14-16] or famotidine.[17]

Omeprazole 40 mg daily can decrease the plasma clearance of phenytoin[18] and increase the area under the serum-phenytoin concentration-time curve,[19] but one study[20] suggests that the dosage of 20 mg daily usually used for peptic ulcer disease is unlikely to produce a clinically significant effect on the steady-state plasma concentrations of phenytoin in patients with epilepsy.

Ginkgo biloba. A fatal breakthrough seizure occurred[1] in a 55-year-old man who was taking phenytoin and valproate semisodium for a seizure disorder; he was also taking numerous non-prescription supplements, such as vitamin preparations and herbal medicines including ginkgo biloba extract, without the knowledge of his physician. Autopsy revealed subtherapeutic plasma concentrations of both antiepileptics. Although the exact cause was unclear, the authors postulated that hepatic enzyme induction by ginkgo biloba might have increased the clearance of phenytoin and valproate semisodium.

1. Kupiec T, Raj V. Fatal seizures due to potential herb-drug interactions with ginkgo biloba. *J Anal Toxicol* 2005; **29:** 755–8.

Immunosuppressants. Increased plasma-phenytoin concentrations were reported[1] in one patient when *tacrolimus* was added to existing therapy. Phenytoin was stopped until values were within the therapeutic range and then restarted at a lower dose, tacrolimus therapy continuing throughout; phenytoin levels remained stable thereafter.

For the effect of phenytoin on *ciclosporin*, see p.1826.

1. Thompson PA, Mosley CA. Tacrolimus-phenytoin interaction. *Ann Pharmacother* 1996; **30:** 544.

Levothyroxine. For the effects of phenytoin on levothyroxine, see p.2172.

Muscle relaxants. An increase in serum concentrations of phenytoin has been reported[1] in a patient when *tizanidine* was added to therapy.

1. Ueno K, *et al.* Phenytoin-tizanidine interaction. *DICP Ann Pharmacother* 1991; **25:** 1273.

Sex hormones. For the effect of phenytoin on *oral contraceptives*, see p.2068. Similar effects may also be noted in patients receiving *HRT*, see p.2076.

Stimulants and anorectics. Although there has been a report of elevated phenytoin and primidone serum concentrations in a 5-year-old after addition of *methylphenidate* to therapy[1] there was no similar elevation in 2 other children receiving phenobarbital and phenytoin in the same report, nor in 11 patients of varying ages given methylphenidate with antiepileptic therapy as part of a controlled study.[2] The likelihood of an interaction seems small in the majority of patients.

2. Kupferberg HJ, *et al.* Effect of methylphenidate on plasma anticonvulsant levels. *Clin Pharmacol Ther* 1972; **13:** 201–4.

Theophylline. Although most reports of an interaction between phenytoin and theophylline concern effects on theophylline concentrations, one study in 14 healthy subjects suggested that treatment with both could lower serum-phenytoin concentrations, with a subsequent rise in concentration on stopping theophylline.[1] The mechanism was suggested to be enzyme induction by the xanthine resulting in increased phenytoin metabolism.

For the effect of phenytoin on theophylline, see p.1143.

1. Taylor JW, *et al.* The interaction of phenytoin and theophylline. *Drug Intell Clin Pharm* 1980; **14:** 638.

Ticlopidine. Acute phenytoin toxicity has been reported in a well-stabilised 44-year-old patient on introduction of ticlopidine to prevent restenosis after placement of a coronary stent.[1] The patient also took metoprolol, aspirin, and for a short period lovastatin, but inhibition of the cytochrome P450 isoenzyme CYP2C19 by ticlopidine was considered the most likely cause of the patient's elevated serum phenytoin. A later report[2] by the same authors found that ticlopidine inhibited the clearance of phenytoin in 6 patients on phenytoin monotherapy; the involvement of CYP2C19 was also supported. The authors recommended that dosage adjustment of phenytoin should be considered if ticlopidine is also given.

A similar interaction occurred in a 72-year-old patient,[3] and the authors postulated that, since steady-state plasma concentrations of ticlopidine are almost twofold higher in elderly patients than those in younger patients, the higher ticlopidine concentrations may have played a role in this drug interaction.

3. Klaassen SL. Ticlopidine-induced phenytoin toxicity. *Ann Pharmacother* 1998; **32:** 1295–8.

Vaccines. Contradictory results have been reported for the effects of *influenza vaccine* on serum-phenytoin concentrations. A significant elevation in total phenytoin concentration has been reported[1] after vaccination, and was suggested to be due to interferon induction and inhibition of the cytochrome P450 enzyme system. In contrast, other reports have suggested that any increase in serum-phenytoin concentration was temporary and not significant overall[2] or even that there was a slight fall in serum-phenytoin concentration.[3] One study reported a significant increase in total phenytoin concentration two days after vaccination, followed by a return to previous values but this was accompanied by evidence of a gradual and prolonged fall in free phenytoin concentrations.[4] The possibility of either phenytoin toxicity or loss of seizure control may exist in some epileptic patients given influenza vaccine during phenytoin therapy.[5]

Vitamins. *Pyridoxine* given in large doses produced a reduction in serum-phenytoin concentrations in 7 patients,[1] perhaps reflecting increased activity by pyridoxal phosphate-dependent enzymes involved in phenytoin metabolism.

Correction of antiepileptic-associated folate deficiency with *folic acid* has been reported to result in a decrease in serum-phenytoin concentrations and an increase in seizure frequency.[2-4] The effect has been reported to be most marked in subjects with high initial serum-phenytoin concentrations[5] and is associated with an increased phenytoin metabolism.[4,6] However, in the majority of patients the effect is unlikely to assume clinical significance,[2,5] and there is some evidence that very low doses of folic acid may be used to maintain normal serum-folate values without an increase in seizure frequency.[3] Information regarding the dual and interdependent interaction between phenytoin and folic acid has been reviewed.[7] Although limited numbers of patients and healthy subjects were involved, evaluation of the data suggested that starting phenytoin and folic acid at the same time prevents decreased folate levels and steady-state concentrations of phenytoin are reached sooner. Plasma concentrations of phenytoin are also possibly reduced by *folinic acid* (see also Antineoplastics, above).

For the effect of antiepileptics, including phenytoin, on *vitamin D* concentrations, see Effects on Bone under Adverse Effects, above.

Pharmacokinetics

Phenytoin is slowly but almost completely absorbed from the gastrointestinal tract. It is largely insoluble at the acid pH of the stomach, most being absorbed from the upper intestine; the rate of absorption is variable and is reported to be affected by the presence of food. Absorption after intramuscular injection is slower than that from the gastrointestinal tract.

Phenytoin is extensively metabolised in the liver to inactive metabolites, chiefly 5-(4-hydroxyphenyl)-5-phenylhydantoin. The rate of metabolism appears to be subject to genetic polymorphism and may also be influenced by racial characteristics; it is reported to be increased during pregnancy and menstruation and to decrease with age. Phenytoin hydroxylation is saturable and is therefore readily inhibited by drugs that compete for its metabolic pathways; this is also the reason why small increments in dose may produce large rises in plasma concentration. Phenytoin undergoes enterohepatic recycling and is excreted in the urine, mainly as its hydroxylated metabolite, in either free or conjugated form.

Phenytoin is widely distributed throughout the body. It is about 90% bound to plasma proteins, although this may be reduced in certain disease states and in certain patient populations (see Precautions, above). It has a very variable, dose-dependent half-life, but the mean plasma half-life appears to be about 22 hours at steady state; because phenytoin inhibits its own metabolism it may sometimes be several weeks before a steady-state plasma-phenytoin concentration is attained.

Monitoring of plasma concentrations may be performed as an aid in assessing control, and the therapeutic range of total plasma-phenytoin concentrations is usually quoted as 10 to 20 micrograms/mL (40 to 80 micromoles/litre); some patients, however, achieve control at concentrations outside this range. It has been suggested that, because of differences in protein binding, measurement of free phenytoin concentrations in plasma may prove more reliable; measurement of concentrations in saliva, which contains only free phenytoin, has also been performed.

Phenytoin crosses the placental barrier and small amounts are distributed into breast milk.

The pharmacokinetics of phenytoin are affected by other antiepileptics (see Interactions, above).

Uses and Administration

Phenytoin is a hydantoin antiepileptic used to control partial and generalised tonic-clonic seizures. It is also used as part of the emergency treatment of status epilepticus and has been used for the prevention and treatment of seizures associated with neurosurgery or severe traumatic injury to the head. Phenytoin has also been used in the treatment of trigeminal neuralgia. It is a class Ib antiarrhythmic and has been used to treat cardiac arrhythmias.

Doses may be expressed in terms of phenytoin or phenytoin sodium; although phenytoin 92 mg is equivalent to about 100 mg of phenytoin sodium these molecular equivalents are not necessarily biologically equivalent. In the UK an oral suspension of phenytoin 90 mg in 15 mL may be considered about equivalent in therapeutic effect to capsules or tablets containing phenytoin sodium 100 mg. In the USA a suspension containing phenytoin 125 mg in 5 mL is available.

For **epilepsy** the dose of phenytoin should be adjusted to the needs of the individual patient to achieve adequate control of seizures, preferably with monitoring of plasma concentrations; in many patients control requires total plasma-phenytoin concentrations of 10 to 20 micrograms/mL (40 to 80 micromoles/litre), but some are controlled at concentrations outside this range. A suggested initial oral dose of phenytoin or phenytoin sodium given as a single dose or in divided doses is 3 to 4 mg/kg daily or 150 to 300 mg daily progressively increased with care to 600 mg daily if necessary; the suggested minimum interval between increments has ranged from about 7 to 10 days. Particular care is needed at higher doses, where saturation of metabolism may mean that a small increment produces a large rise in plasma concentrations. A usual maintenance dose is 200 to 500 mg daily.

The practice of starting phenytoin therapy with initial small doses means that more than a week may be required before therapeutic plasma concentrations are attained; it has been reported that it may even be several weeks before a steady-state concentration is established. An initial loading dose may therefore be given, with the usual maintenance dosage being instituted 24 hours after the loading dose. Once the patient is stabilised the long half-life of phenytoin may permit the total daily dose to be given in two daily divisions or as a single dose, usually at night.

Although clinical evidence is lacking, different brands of phenytoin, as well as different formulations from the same manufacturer, may vary in their bioavailability and patients may need to be restabilised in the event of a change.

In order to lessen gastric irritation, phenytoin should be taken with or after food. The time and manner of taking phenytoin should be standardised for the patient since variations might affect absorption with consequent fluctuations in the plasma concentrations.

As with other antiepileptics, withdrawal of phenytoin therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Treatment of tonic-clonic **status epilepticus** is usually begun with a benzodiazepine such as diazepam or lorazepam given intravenously or rectally, and followed by phenytoin sodium intravenously. A suggested dose of phenytoin sodium is 10 to 15 mg/kg given by slow intravenous injection or by intermittent infusion at a uniform rate of not more than 50 mg/minute. Thereafter maintenance doses of 100 mg orally or intravenously are given every 6 to 8 hours; the rate and dose should be reduced according to body-weight. For doses in children, see below.

Deaths have been caused by the over-rapid intravenous injection of phenytoin sodium and continuous monitoring of the ECG and blood pressure is recommended whenever phenytoin sodium is given intravenously.

Phenytoin sodium is absorbed slowly and erratically from the intramuscular site and therefore intramuscular injections are not appropriate for the emergency arrest of status epilepticus. They may, however, be used in certain situations to maintain or establish therapeutic plasma concentrations of phenytoin in patients who are unconscious or otherwise unable to take phenytoin orally. Owing to the slower absorption of phenytoin from intramuscular sites, patients stabilised on the oral route require an increase in the intramuscular dose of about 50%; it is recommended that, if possible, intramuscular injections of phenytoin sodium should not be continued for longer than one week. On transfer back to the oral route the patient should receive 50% of the original oral dose for the same period of time as intramuscular injections were given, to allow for continued absorption of the residual phenytoin in the intramuscular sites. For the **prevention and treatment of seizures associated with neurosurgery** in patients who have not previously taken phenytoin sodium, a suggested intramuscular dose is 100 to 200 mg given at 4-hourly intervals during surgery and continued postoperatively for 48 to 72 hours. Thereafter, the dose should be reduced to a maintenance dose of 300 mg and adjusted according to plasma-phenytoin concentrations.

Administration in children. Phenytoin may be given to children for the control of partial and generalised tonic-clonic seizures. It is also used as part of the emergency treatment of status epilepticus and has been used for the prevention and treatment of seizures associated with neurosurgery or severe traumatic injury to the head.

For **epilepsy** the dose of phenytoin should be adjusted to the needs of the individual patient to achieve adequate control of seizures, preferably with monitoring of plasma concentrations; young children may require a higher dose per kg body-weight than adults due to more rapid metabolism. In many patients control requires total plasma-phenytoin concentrations of 10 to 20 micrograms/mL (40 to 80 micromoles/litre), but some are controlled at concentrations outside this range; the *BNFC* suggests concentrations of 6 to 15 micrograms/mL (25 to 60 micromoles/litre) in neonates and those aged up to 3 months. The recommended initial oral dose for children is 5 mg/kg daily in 2 or 3 divided doses up to a maximum of 300 mg daily; the usual maintenance dose is 4 to 8 mg/kg daily in divided doses. Alternatively, the *BNFC* suggests the following doses given according to age:

- neonates: an initial loading dose of 18 mg/kg by slow intravenous injection, over 20 to 30 minutes, followed by oral doses of 2.5 to 5 mg/kg twice daily adjusted as necessary to a usual maximum of 7.5 mg/kg twice daily
- 1 month to 12 years: an initial oral dose of 1.5 to 2.5 mg/kg twice daily followed by 2.5 to 5 mg/kg twice daily adjusted as necessary to a usual maximum of 7.5 mg/kg twice daily or 300 mg daily
- 12 years and older: usual adult doses (see above)

For **status epilepticus** and for the **prevention and treatment of seizures associated with neurosurgery or trauma** an initial loading dose of 15 to 20 mg/kg given by slow intravenous injection may be followed by usual adult doses (see above). Alternatively, the *BNFC* suggests the following doses given by slow intravenous injection or infusion according to age:

- neonates and children up to 12 years: a loading dose of 18 mg/kg followed by 2.5 to 5 mg/kg twice daily
- 12 to 18 years: a loading dose of 18 mg/kg followed by up to 100 mg 3 or 4 times daily

Intravenous injections and infusions of phenytoin should be given at a rate not exceeding 1 mg/kg per minute (a maximum of 50 mg per minute).

A comparison of methods[1] for the prediction of required phenytoin dosage in paediatric patients indicated that all methods produced a sizeable number of predictions with an error of more than 10% and that close monitoring of serum concentrations and clinical status was recommended regardless of the method chosen to adjust dosage. Similar conclusions have been made regarding the need to monitor plasma concentrations of phenytoin in the newborn and young infants.[2]

1. Yuen GJ, *et al.* Phenytoin dosage predictions in paediatric patients. *Clin Pharmacokinet* 1989; **16:** 254–60.
2. Loughnan PM, *et al.* Pharmacokinetic observations of phenytoin disposition in the newborn and young infant. *Arch Dis Child* 1977; **52:** 302–9.

Administration in the elderly. Pharmacokinetic studies in elderly patients have shown reduced binding to plasma proteins which was not itself an indication for dosage change,[1] but a study showing a decreased metabolism[2] did indicate that elderly patients may need lower doses of phenytoin than younger adults to maintain similar serum concentrations.

1. Patterson M, *et al.* Plasma protein binding of phenytoin in the aged: in vivo studies. *Br J Clin Pharmacol* 1982; **13:** 423–5.
2. Bauer LA, Blouin RA. Age and phenytoin kinetics in adult epileptics. *Clin Pharmacol Ther* 1982; **31:** 301–4.

Cardiac arrhythmias. Phenytoin has been given intravenously in the treatment of ventricular arrhythmias (p.1160), especially those caused by overdosage with cardiac glycosides. Although this use now appears to be obsolete, in the UK the licensed dose of phenytoin sodium is 3.5 to 5 mg/kg given by slow intravenous injection at a uniform rate of not more than 50 mg/minute, repeated once if necessary.

Eclampsia and pre-eclampsia. Phenytoin has been used for eclampsia but now treatment with magnesium sulfate is preferred, see p.470.

Epidermolysis bullosa. There have been reports[1-3] of a favourable but variable clinical response to phenytoin in patients with some variants of epidermolysis bullosa (p.1579), a condition for the severe forms of which there is no truly effective treatment. However, a double-blind placebo-controlled study[4] concluded that phenytoin was not an effective treatment for the recessive dystrophic variant, and offered no overall benefit when compared with placebo.

1. Bauer EA, *et al.* Phenytoin therapy of recessive dystrophic epidermolysis bullosa. *N Engl J Med* 1980; **303:** 776–81.
2. Cooper TW, Bauer EA. Therapeutic efficacy of phenytoin in recessive dystrophic epidermolysis. *Arch Dermatol* 1984; **120:** 490–5.

4. Caldwell-Brown D, *et al.* Lack of efficacy of phenytoin in recessive dystrophic epidermolysis bullosa. *N Engl J Med* 1992; **327:** 163–7.

Epilepsy. Phenytoin has long been used in the treatment of partial seizures with or without secondary generalisation and in primarily generalised tonic-clonic seizures, although other drugs may be better tolerated and easier to use (see p.465). It is also effective in other forms of epilepsy with the exception of absence and myoclonic seizures.

Hiccup. Phenytoin may be of value for the treatment of intractable hiccups,[1] especially those of neurogenic origin. For the management of intractable hiccups see under Chlorpromazine, p.976.

1. Petroski D, Patel AN. Diphenylhydantoin for intractable hiccups. *Lancet* 1974; **i:** 739.

Myotonia. A review[1] of myotonia congenita, a hereditary muscular disorder characterised by symptoms of muscle stiffness especially after rest and on starting to move. Where treatment is necessary it is usually with phenytoin or procainamide, the former being preferred as being better tolerated.

1. Gutmann L, *et al.* Myotonia congenita. *Semin Neurol* 1991; **11:** 244–8.

Neonatal seizures. Phenytoin is one of the antiepileptics that may be used in the management of neonatal seizures (p.471).

Neuropathic pain. Phenytoin is used alone or added to treatment in trigeminal neuralgia (p.9) in patients unresponsive to or intolerant of carbamazepine. It has also been used in the treatment of painful diabetic neuropathy (p.6).

Post-traumatic seizures. About 12% of patients with severe traumatic brain injury develop seizures and the rate may be more than 50% for those with penetrating missile injuries.[1] The use of antiepileptics to treat such seizures is standard but there has been some debate about prophylactic use. Evidence suggests that prophylaxis with phenytoin (and perhaps carbamazepine) is effective in preventing early seizures (arbitrarily defined as those occurring up to 7 days after trauma), but prophylaxis with these or other antiepileptics such as phenobarbital valproate, has not been shown to be effective for preventing late seizures, disability, or death.[1-6] Guidelines and recommendations for such use have been issued.[1,7,8] Children with severe, acute neurotrauma were found to have markedly altered protein binding and phenytoin metabolism, and therefore may require increased doses.[9]

9. Stowe CD, *et al.* Altered phenytoin pharmacokinetics in children with severe, acute traumatic brain injury. *J Clin Pharmacol* 2000; **40:** 1452–61.

Status epilepticus. A benzodiazepine is the usual choice to abort an attack of status epilepticus (p.469). If this fails to control the seizures or the seizures recur, then intravenous phenytoin may be given.

Once seizures have been brought under control, maintenance antiepileptic therapy may be started.

Syndrome of inappropriate ADH secretion. Phenytoin has been used occasionally to inhibit pituitary antidiuretic hormone (ADH) secretion in patients with the syndrome of inappropriate ADH secretion (SIADH), the management of which is discussed on p.2182.

Tinnitus. Phenytoin is one of many drugs that have been tried in tinnitus (p.1866), but although it has been reported to be effective in some patients it is rarely used because of problems with adverse effects.

Withdrawal syndromes. Phenytoin has little place in the management of seizures associated with the *alcohol withdrawal syndrome* (p.1626). Prophylaxis with phenytoin has been shown[1,2] to be ineffective for prevention of recurrent alcohol-related seizures and therefore drugs such as the benzodiazepines or clomethiazole, which are effective both for the treatment and prophylaxis of such seizures, are preferred.

Results from a double-blind study[3] indicated that phenytoin was associated with a reduction in *cocaine abuse* compared with placebo. The abuse of cocaine is discussed on p.1858 and treatment of cocaine withdrawal on p.1860.

3. Crosby RD, *et al.* Phenytoin in the treatment of cocaine abuse: a double-blind study. *Clin Pharmacol Ther* 1996; **59:** 458–68.

Wounds and ulcers. Phenytoin has been used to promote wound healing (p.1585). Topical application of phenytoin has produced encouraging results in the healing of various types of ulcers[1-7] and large abscess cavities.[8] It has been suggested that phenytoin may reduce bacterial colonisation by changing the pH or by a direct antibacterial effect.[2] The enhanced wound healing may also be due to increased fibroblast proliferation and increased collagen content.[2] Limited absorption from the wound site may occur[9,10] and patients may need to be monitored for signs of toxicity. A systematic review,[11] which included some of these studies, found evidence to support the use of phenytoin in the treatment of leg ulcers, leprosy wounds, chronic wounds, and diabetic foot ulcers despite the poor methodological quality in the majority of studies.

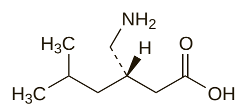
Pregabalin *(BAN, USAN, rINN)*

CI-1008; PD-144723; Pregabalina; Prégabaline; Pregabalinum.
(*S*)-3-(Aminomethyl)-5-methylhexanoic acid.
Прегабалин
$C_8H_{17}NO_2$ = 159.2.
CAS — 148553-50-8.
ATC — N03AX16.
ATC Vet — QN03AX16.



Adverse Effects and Precautions

The most common adverse effects reported during therapy with pregabalin are dizziness and somnolence. Other common adverse effects include blurred vision, diplopia, increased appetite and weight gain, dry mouth, constipation, vomiting, flatulence, euphoria, confusion, reduced libido, erectile dysfunction, irritability, vertigo, ataxia, tremor, dysarthria, paraesthesia, fatigue, and oedema. Disturbances of attention, memory, coordination, and gait also occur frequently. Syncope and congestive heart failure have been reported less frequently. Reversible renal failure, elevation of creatine kinase concentration, and rhabdomyolysis have been reported rarely. Hypersensitivity reactions have occurred shortly after starting pregabalin therapy; symptoms include rash, blisters, urticaria, dyspnoea, and wheezing. Stevens-Johnson syndrome has also been reported. An increased incidence of haemangiosarcoma was observed in *mice* that had been given high doses of pregabalin.

Licensed product information states that care is required when withdrawing pregabalin therapy, regardless of the indication—see also Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Effects on mental function. For a review of the effects of antiepileptic therapy on *cognition*, and the effects of pregabalin on *mood* (including the risk of suicidal ideation), see p.468.

Hypersensitivity reactions. The Australian Adverse Drug Reactions Advisory Committee[1] stated in December 2007 that 13% of all pregabalin adverse reaction reports in its database were hypersensitivity reactions. Presenting symptoms included anaphylaxis, skin rash, and angioedema. Of the 22 reports received, 6 women developed symptoms within hours of their first dose and pregabalin was the sole suspected drug in 14.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Reports of hypersensitivity reactions to pregabalin. *Aust Adverse Drug React Bull* 2007; **26:** 23. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0712.pdf (accessed 09/06/08)

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Pharmacokinetics

Pregabalin is rapidly absorbed after oral doses and peak plasma concentrations are achieved within 1.5 hours. Oral bioavailability is about 90%. The rate but not the extent of absorption is reduced if given with food but this is not clinically significant. Steady state is achieved after 1 to 2 days. Pregabalin is not bound to plasma proteins and undergoes negligible metabolism. About 98% of a dose is excreted in the urine as unchanged drug. The mean elimination half-life is 6.3 hours. Pregabalin is removed by haemodialysis.

Distribution into milk has been found in studies in *rats*.

Renal impairment. References.

1. Randinitis EJ, *et al.* Pharmacokinetics of pregabalin in subjects with various degrees of renal function. *J Clin Pharmacol* 2003; **43:** 277–83.

Uses and Administration

Pregabalin is an antiepileptic used as an adjunct in the treatment of partial seizures with or without secondary generalisation. It is also used in the treatment of generalised anxiety disorder, neuropathic pain, and fibromyalgia.

Pregabalin is given orally in 2 or 3 divided doses daily.

The initial dose in the treatment of **epilepsy** is 150 mg daily increased after 1 week according to response to 300 mg daily and then to 600 mg daily after another week.

In the treatment of **generalised anxiety disorder**, the initial dose is 150 mg daily; this may be increased at weekly intervals in steps of 150 mg, to a maximum of 600 mg daily.

For **neuropathic pain** the initial dose in the UK is 150 mg daily increased after 3 to 7 days according to response to 300 mg daily and then to 600 mg daily after another 7 days. Similar doses are licensed in the USA for the treatment of neuropathic pain in diabetic neuropathy and postherpetic neuralgia, although a maximum daily dose of 300 mg is recommended in diabetic neuropathy.

For **fibromyalgia** the initial dose is 150 mg daily increased after 1 week according to response to 300 mg daily and then to 450 mg daily if necessary.

Dosage of pregabalin should be reduced in patients with renal impairment (see below).

As with other antiepileptics, withdrawal of pregabalin therapy in epilepsy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465. Licensed drug information states that if pregabalin therapy has to be stopped, this should be done gradually over a minimum of 1 week, regardless of indication.

Administration in renal impairment. The dose of pregabalin for patients with renal impairment should be reduced according to creatinine clearance (CC):

- CC 30 to less than 60 mL/minute: starting daily dose: 75 mg; maximum daily dose: 300 mg; daily dose given in 2 or 3 divided doses
- CC 15 to less than 30 mL/minute: starting daily dose: 25 to 50 mg; maximum daily dose: 150 mg; daily dose given in 2 divided doses or once daily
- CC less than 15 mL/minute: starting daily dose: 25 mg; maximum daily dose: 75 mg; daily dose given as one dose
- haemodialysis patients should receive in addition to the daily dose a supplementary dose of 25 to 100 mg immediately after each 4-hour haemodialysis session

Anxiety disorders. Pregabalin is used for the treatment of generalised anxiety disorder (p.952); it has also been tried in social anxiety disorder (see Phobic Disorders, p.953).

Neuropathic pain. Antiepileptics are among the drugs used to manage neuropathic pain, which is often insensitive to opioid analgesics (see Choice of Analgesic, p.2). Although carbamazepine appears to be the antiepileptic most frequently used, pregabalin is also given in the treatment of peripheral neuropathic pain[1] including postherpetic neuralgia[2,3] (p.9) and painful diabetic neuropathy[4,5] (p.6). Pregabalin may also be used in central neuropathic pain[6,7] (p.6).

Soft-tissue rheumatism. Three large, multicentre controlled studies[1-3] have shown that pregabalin in oral doses of between 300 and 600 mg daily is effective in reducing pain and other core symptoms of fibromyalgia (see Soft-tissue Rheumatism, p.13) such as sleep disturbance and fatigue. The drug was reported to be generally well tolerated, dizziness and somnolence being the most common adverse effects. Pain relief appears to be largely independent of reduction in anxiety or depression scores.[4]

Primidone *(BAN, rINN)*

Desoxifenobarbitona; Hexamidinum; Primaclona; Primaclone; Primidon; Primidona; Primidonas; Primidoni; Primidonum; Prymidon. 5-Ethyl-5-phenylperhydropyrimidine-4,6-dione.

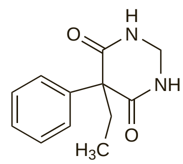
Примидон

$C_{12}H_{14}N_2O_2$ = 218.3.

CAS — 125-33-7.

ATC — N03AA03.

ATC Vet — QN03AA03.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Primidone). A white or almost white, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol. It dissolves in alkaline solutions.

USP 31 (Primidone). A white, odourless, crystalline powder. Soluble 1 in 2000 of water and 1 in 200 of alcohol; very slightly soluble in most organic solvents.

Adverse Effects, Treatment, and Precautions

As for Phenobarbital, p.492.

Adverse effects may be more frequent than with phenobarbital. Most patients rapidly develop tolerance to the adverse effects of primidone, including ataxia, dizziness, drowsiness, headache, nausea and vomiting, nystagmus, skin rashes, and visual disturbances.

Care is required when withdrawing primidone therapy—see also Uses and Administration, below.

Effects on the blood. For a report of delayed agranulocytosis in a patient treated with phenytoin and primidone, see p.495.

Effects on the endocrine system. For mention of the effects of antiepileptics on *sexual function* in male epileptic patients, see under Phenytoin, p.496.

Overdosage. Crystalluria has been reported[1] after acute overdosage of primidone and 7 other reported cases were also reviewed. Based on these few reports, crystalluria appears to be associated with serum-primidone concentrations in excess of 80 micrograms/mL. There is evidence from 2 reports of renal damage associated with crystal formation *in vivo*. Vigorous hydration is recommended in patients at risk, in order to lessen the potential for renal toxicity and improve elimination.

1. Lehmann DF. Primidone crystalluria following overdose: a report of a case and an analysis of the literature. *Med Toxicol* 1987; **2:** 383–7.

Porphyria. Primidone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Tremor. It was noted that patients receiving primidone for essential tremor have a high incidence of acute adverse reactions after small initial doses.[1] This could be due to the absence of induced hepatic enzymes in these patients previously not exposed to antiepileptics.

1. Findley LJ, *et al.* Primidone in essential tremor of the hands and head: a double blind controlled clinical study. *J Neurol Neurosurg Psychiatry* 1985; **48:** 911–15.

Interactions

Primidone is metabolised in the body in part to phenobarbital, and interactions recorded for phenobarbital (p.493) might potentially occur in patients receiving primidone. In addition, enzyme-inducing drugs enhance this metabolism and have the potential to produce elevated phenobarbital concentrations.

Antiepileptics. Both *phenytoin*[1] and *carbamazepine*[2] have been reported to enhance the metabolism of primidone to phenobarbital and when primidone was combined with phenytoin there have been instances of phenobarbital toxicity.[3] *Vigabatrin* has been reported[4] to lower plasma concentrations of primidone in some patients, although it is unlikely that dosage changes would be necessary. *Valproate* may increase plasma concentrations of primidone and phenobarbital, but patient response seems to be inconsistent.[5-7]

Pharmacokinetics

Primidone is readily absorbed from the gastrointestinal tract and is reported to have a plasma half-life ranging from 10 to 15 hours, which is shorter than those of its principal metabolites phenylethylmalonamide and phenobarbital, both of which are active. Therapeutic plasma concentrations of primidone have been suggested to be between 5 and 12 micrograms/mL. It is excreted in urine as unchanged drug (40%) and metabolites.

Primidone is widely distributed but is only partially bound to plasma proteins; it has been suggested that it exhibits variable binding of up to about 20%. It crosses the placenta and is distributed into breast milk.

The pharmacokinetics of primidone may be affected by use with other antiepileptics (see under Interactions, above).

Uses and Administration

Primidone is an antiepileptic that is partially metabolised to phenobarbital (p.494), but is also considered to have some antiepileptic activity in its own right. It may be given to control partial and generalised tonic-clonic seizures. Primidone is also used in the management of essential tremor.

In the treatment of **epilepsy** the dose of primidone should be adjusted according to response; a limited correlation with plasma concentrations has suggested that concentrations of 5 to 12 micrograms/mL (23 to 55 micromoles/litre) are usually necessary, but the *BNF* recommends monitoring of phenobarbital concentrations instead.

Recommended initial oral doses in the UK are 125 mg at bedtime increased, if necessary, by 125 mg every 3 days to a total of 500 mg daily given in 2 divided doses. If necessary, the daily dose may be increased further every 3 days by 250 mg up to a maximum of 1.5 g daily given in divided doses. Usual maintenance doses are 0.75 to 1.5 g daily; maintenance doses are usually given as 2 divided doses. Dosage recommendations in the USA are generally similar although a maximum daily dose of 2 g is permitted.

For doses in children, see below.

As with other antiepileptics, withdrawal of primidone or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

For **essential tremor** primidone is usually started at daily oral doses of 50 mg as the syrup or 62.5 mg as the tablet, increased gradually over 2 to 3 weeks if necessary, to a maximum of 750 mg daily.

Administration in children. Children may be given primidone to control partial and generalised tonic-clonic seizures. Recommended initial oral doses in the UK are 125 mg at bedtime, increased if necessary, by 125 mg every 3 days to the following usual maintenance daily doses (given in 2 divided doses) according to age:

- up to 2 years: 250 to 500 mg
- 2 to 5 years: 500 to 750 mg
- 6 to 9 years: 750 to 1000 mg

Children aged over 9 years may be given the usual adult dose (see above).

In the USA, a lower initial oral dose of 50 mg daily is recommended. This is doubled every 3 days, to reach a maintenance dose of 125 to 250 mg 3 times daily (10 to 25 mg/kg daily in divided doses) after 10 or more days. Children over 8 years of age may be given the usual adult dose as above.

Epilepsy. Primidone, like its metabolite phenobarbital, is used in the treatment of epilepsy (p.465) for partial seizures with or

The symbol † denotes a preparation no longer actively marketed

without secondary generalisation and for primary generalised tonic-clonic seizures. However, because of problems of sedation, it is usually reserved for use in cases unresponsive to other antiepileptics. It has been suggested that it may be suitable for use in patients with QT-interval prolongation.[1]

1. Christidis D, *et al.* Is primidone the drug of choice for epileptic patients with QT-prolongation? A comprehensive analysis of literature. *Seizure* 2006; **15:** 64–6.

Neonatal apnoea. Results from a preliminary study suggested that adjunctive treatment with primidone[1] might be of value in neonatal apnoea resistant to first-line therapy with xanthines alone, but subsequent confirmatory studies seem to be lacking.

1. Miller CA, *et al.* The use of primidone in neonates with theophylline-resistant apnea. *Am J Dis Child* 1993; **147:** 183–6.

Neonatal seizures. Primidone has been tried in the management of neonatal seizures (p.471).

Tremor. A beta blocker is often the first drug used in patients with essential tremor who require regular treatment (p.1231) but primidone[1] may also be tried. A high incidence of acute adverse reactions has been reported after initial doses (see Tremor, under Adverse Effects, above). There has been concern that long-term use may produce tolerance to primidone's effects, although a small study has found a reduced response in only a few patients.[2] A later study[3] found a dose of 250 mg daily to be as or more effective than 750 mg daily without there being evidence of loss of efficacy during a 12-month follow-up.

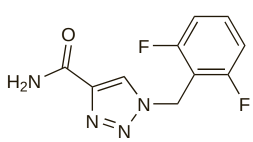
Rufinamide *(BAN, USAN, rINN)*

60231/4; CGP-33101; E-2080; RUF-331; Rufinamida; Rufinamidum. 1-(2,6-Difluorobenzyl)-1*H*-1,2,3-triazole-4-carboxamide.

Руфинамид

$C_{10}H_8F_2N_4O$ = 238.2.
CAS — 106308-44-5.
ATC — N03AF03.
ATC Vet — QN03AF03.



Adverse Effects and Precautions

The most common adverse effects with rufinamide include headache, dizziness, fatigue, somnolence, nausea, and vomiting. Other reported adverse effects include anorexia, weight loss, anxiety, insomnia, vertigo, nystagmus, tremor, dyspepsia, constipation, and diarrhoea. Convulsions, including status epilepticus, have occurred. Lymphadenopathy, abnormal liver function tests, and haematuria, as well as fever and rash, have been reported as part of a hypersensitivity syndrome.

Rufinamide can reduce the QT interval and should be used with caution in those with a shortening of their QT interval or with a family history of congenital short QT syndrome.

Care is required when withdrawing rufinamide therapy—see Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics, and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. Rufinamide plasma concentrations are reportedly decreased by carbamazepine, phenobarbital, phenytoin, vigabatrin, or primidone. In contrast, significant increases in rufinamide plasma concentrations can occur with valproate and dosage adjustments may be necessary (see Uses and Administration, below).

Rufinamide induces the cytochrome P450 isoenzyme CYP3A4 and may be expected to decrease plasma concentrations of drugs metabolised by this route, such as oral contraceptives. Rufinamide reportedly increases steady-state plasma concentrations of phenytoin.

Pharmacokinetics

Rufinamide is well absorbed after oral doses; peak plasma concentrations are reached after about 6 hours. Food increases the bioavailability of rufinamide by about 34 to 40%. It is 34% bound to serum proteins, mainly to albumin.

Rufinamide is hydrolysed to an inactive metabolite and has a plasma elimination half-life of about 6 to 10 hours, although clearance in children is reported to be slower. It is mainly excreted in urine as the inactive metabolite.

◊ References

1. Cardot JM, *et al.* The influence of food on the disposition of the antiepileptic rufinamide in healthy volunteers. *Biopharm Drug Dispos* 1998; **19:** 259–62.

Uses and Administration

Rufinamide is an antiepileptic used as an adjunct in the treatment of seizures associated with the Lennox-Gastaut syndrome (p.465) in patients aged 4 years and over. Rufinamide is given orally in 2 divided doses daily with food. The initial daily dose in patients weighing less than 30 kg is 200 mg, increased according to response in increments of 200 mg every 2 days to a usual maximum of 1 g daily; the recommended maximum dose in those taking *valproate* is 600 mg daily. In patients weighing more than 30 kg, the initial daily dose is 400 mg, increased according to response in increments of 400 mg every 2 days to a maximum daily dose of 1.8 g in those weighing up to 50 kg, 2.4 g in those weighing up to 70 kg, and 3.2 g in those over 70 kg.

As with other antiepileptics, withdrawal of rufinamide therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. UK licensed product information recommends reducing the daily dose by about 25% every 2 days. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Rufinamide has also been investigated as adjunctive therapy in the treatment of partial and primary generalised tonic-clonic seizures.

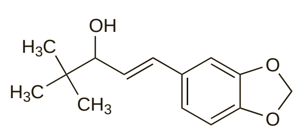
Stiripentol *(USAN, rINN)*

BCX-2600; Estiripentol; Stiripentolum. 4,4-Dimethyl-1-[(3,4-methylenedioxy)phenyl]-1-penten-3-ol.

Стирипентол

$C_{14}H_{18}O_3$ = 234.3.
CAS — 49763-96-4.
ATC — N03AX17.
ATC Vet — QN03AX17.



Adverse Effects and Precautions

The most common adverse effects of stiripentol include anorexia, weight loss, insomnia, drowsiness, ataxia, hypotonia, and dystonia. Other common adverse effects include nausea, vomiting, and aggressiveness, and other mood or behavioural disorders. Neutropenia is also reported to be common; persistent severe neutropenia usually resolves spontaneously when stiripentol is stopped. Photosensitivity, rash, and urticaria have occurred. Patients may exhibit altered liver enzyme values.

Growth rates, blood counts, and hepatic function should be monitored periodically in patients given stiripentol.

Interactions

Stiripentol is a potent inhibitor of several cytochrome P450 isoenzymes, including CYP1A2, CYP2C19, and CYP3A4, and may markedly reduce clearance of drugs metabolised by these enzymes. The possibility of an effect on stiripentol metabolism by other inhibitors or inducers of these enzymes should also be borne in mind.

For interactions of stiripentol with other antiepileptics, see under Carbamazepine, p.474, Diazepam, p.990, and Phenytoin, p.498.

Uses and Administration

Stiripentol is used with clobazam and valproate as adjunctive therapy in the treatment of refractory generalised tonic-clonic seizures in severe myoclonic epilepsy in infancy. It is thought to be less potent than some conventional antiepileptics, but may reduce their adverse effects when used adjunctively.

Stiripentol is given orally and should be started at a low dose, gradually increased over 3 days, to the recommended dose of 50 mg/kg daily given in 2 or 3 divided doses with food (but not with dairy products, carbonated drinks, fruit juice, or food and drinks that contain caffeine or theophylline). After starting adjunctive stiripentol therapy, the daily dose of clobazam may be reduced by 25% every week if there are signs of adverse effects or overdosage with clobazam. The daily dose of valproate is not usually adjusted, however, it may be reduced by 30% every week if there are signs of gastrointestinal adverse effects.

Epilepsy. A 24-week study[1] in 10 children found that stiripentol might be effective as adjunctive therapy for the treatment of atypical absence seizures (p.465). Further studies suggested benefit from adjunctive use in children with partial epilepsy[2] and severe myoclonic epilepsy.[2-4]

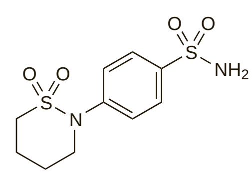
Sultiame *(BAN, rINN)*

Riker-594; Sulthiame *(USAN)*; Sultiaami; Sultiam; Sultiamo; Sultiamum. 4-(Tetrahydro-2*H*-1,2-thiazin-2-yl)benzenesulphonamide *S,S*-dioxide.

Сультиам

$C_{10}H_{14}N_2O_4S_2$ = 290.4.
CAS — 61-56-3.
ATC — N03AX03.
ATC Vet — QN03AX03.



Pharmacopoeias. In *Jpn.*

Profile

Sultiame is a carbonic anhydrase inhibitor that has been used as an antiepileptic in most forms of epilepsy (p.465) except absence seizures. It has usually been given with other antiepileptics and it is believed that much of its activity is due to the inhibition of metabolism of the other drugs.

Sultiame has been given orally in initial doses of 100 mg twice daily or 50 mg three times daily gradually increased according to response to 200 mg three times daily. A dose of 5 to 10 mg/kg daily, adjusted according to response, has been recommended in Rolandic epilepsy.

Interactions. For the effect of sultiame on *phenytoin*, see p.498.

Porphyria. Sultiame has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Tiagabine Hydrochloride

(BANM, USAN, rINNM)

Abbott-70569.1; ABT-569; Hidrocloruro de tiagabina; NNC-05-0328; NO-05-0328; Tiagabine, Chlorhydrate de; Tiagabini Hydrochloridum. (–)-(*R*)-1-[4,4-Bis(3-methyl-2-thienyl)-3-butenyl]-nipecotic acid hydrochloride.

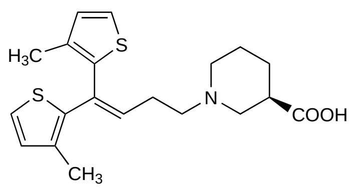
Тиагабина Гидрохлорид

$C_{20}H_{25}NO_2S_2,HCl = 412.0.$

CAS — 115103-54-3 (tiagabine); 145821-59-6 (tiagabine hydrochloride).

ATC — N03AG06.

ATC Vet — QN03AG06.



(tiagabine)

Pharmacopoeias. In *US.*

USP 31 (Tiagabine Hydrochloride). A white to off-white powder. Sparingly soluble in water; freely soluble in alcohol and methyl alcohol; soluble in isopropyl alcohol; very slightly soluble in chloroform; practically insoluble in *n*-heptane. Store in airtight containers at a temperature not exceeding 30°. Protect from light.

Stability. An extemporaneously prepared suspension containing tiagabine hydrochloride 1 mg/mL in a mixture of simple syrup and 1% methylcellulose was found,[1] when stored in plastic amber bottles, to be stable for 6 weeks at 25° or 13 weeks at 4°. When prepared in a 1:1 mixture of *Ora-Plus* and *Ora-Sweet* (*Paddock, USA*), the suspension was stable for 10 weeks at 25° or 13 weeks at 4°.

1. Nahata MC, Morosco RS. Stability of tiagabine in two oral liquid vehicles. *Am J Health-Syst Pharm* 2003; **60:** 75–7.

Adverse Effects

The most common adverse effects include dizziness, nervousness, tiredness, somnolence, and tremor. Other reported adverse effects include irritability, confusion, depression, psychosis, difficulties in concentration, diarrhoea, abdominal pain, nausea, ataxia, emotional lability, and nystagmus. Bruising, rashes, speech difficulties, and a flu-like syndrome of chills, fever, myalgia, and headache have also been reported. Visual field defects have been reported rarely and decreased white blood cell counts have been noted at routine screenings.

Incidence of adverse effects. A systematic review[1] considered 5 double-blind studies involving about 1000 patients of whom 675 were receiving tiagabine as adjunctive therapy for refractory partial seizures. Withdrawal due to adverse effects was infrequent and occurred in 15% of patients receiving tiagabine compared with 5% receiving placebo. Adverse effects were usually associated with dose titration, and were generally mild to moderate in severity, and transient. Another review[2] by the same author on data from all clinical studies (52 studies involving nearly 3100 patients) reported that in 21% of patients receiving tiagabine had the drug stopped for adverse effects, mostly during the first 6 months of therapy. Sub-analysis showed that figures for placebo-controlled, adjunctive studies were similar to those of the earlier review.

1. Leppik IE. Tiagabine: the safety landscape. *Epilepsia* 1995; **36** (suppl 6): S10–S13.
2. Leppik IE, *et al.* Safety of tiagabine: summary of 53 trials. *Epilepsy Res* 1999; **33:** 235–46.

Effects on the eyes. Unlike vigabatrin, which is associated with visual field defects (see p.513), studies of visual function in patients taking tiagabine, another GABAergic antiepileptic, have been generally reassuring. However, in a case report[1] a 39-year-old patient was noted to have visual field defects while receiving long-term tiagabine therapy for bipolar disorder. The defects reversed after tiagabine was withdrawn.

1. Kaufman KR, *et al.* Visual fields and tiagabine: a quandary. *Seizure* 2001; **10:** 525–9.

Effects on mental function. For a review of the effects of antiepileptic therapy on *cognition*, and the effects of tiagabine on *mood* (including the risk of suicidal ideation) see p.468.

Effects on the nervous system. Acute dystonic reactions occurred in 3 patients when tiagabine was added to their existing carbamazepine treatment;[1] the reactions were associated with an increase in the dose of tiagabine to 20 mg or more. In all cases the dystonias disappeared despite continuing tiagabine therapy at the same dose, although in one patient carbamazepine was withdrawn.

There have been case reports of nonconvulsive status epilepticus,[2-4] associated with tiagabine. The authors of one such report[2] noted that, in placebo-controlled studies, the incidence of such an event was no higher in the tiagabine group than in the placebo group. However, a retrospective analysis[5] of inpatients with refractory localised epilepsy found that non convulsive status epilepticus occurred more frequently in patients treated with tiagabine (6.7%) than in those who were not (1.1%).

The FDA has warned of the risk of seizures with tiagabine when used in *non-epileptic patients* for unlicensed indications;[6] it had received over 30 reports of new-onset seizures or status epilepticus in such patients. Predisposing factors may include the use of other drugs known to lower the seizure threshold, and probably the dose. Although some cases were noted after doses as low as 4 mg daily, licensed doses in patients with epilepsy take into account the customary use of other enzyme-inducing antiepileptics which can roughly halve the plasma levels of tiagabine by inducing its metabolism. For reports of status epilepticus occurring in non-epileptic patients after tiagabine overdosage, see below.

Overdosage. A 30-year-old man who took 320 mg of tiagabine in overdose together with 400 mg of phenytoin showed no serious signs of toxicity other than significantly depressed levels of consciousness from which he quickly recovered.[1] Plasma concentrations of tiagabine measured 4 hours after ingestion were 30 times higher than those seen with therapeutic doses; phenytoin concentrations just exceeded the therapeutic range. A 46-year-old woman[2] who ingested about 72 mg of tiagabine exhibited facial grimacing, rigid flexure posturing of the upper extremities, and dilated pupils. She was uncommunicative and unresponsive to commands. Treatment with benzodiazepines was given, and symptoms resolved within 12 hours of admission.

Seizures, including status epilepticus, are a recognised adverse effect of tiagabine (see above); there have been reports of status epilepticus occurring in non-epileptic patients after overdosage, including non convulsive status epilepticus[3] in a 14-year-old girl who took about 180 mg of tiagabine, and myoclonic status epilepticus[4] in an 18-year-old man who took 120 mg of tiagabine with 400 mg of lamotrigine.

A retrospective review[5] of 57 overdoses with tiagabine reported to several poison centres in the USA found that the most common adverse effects were lethargy (in 56%), seizures (37%, including status epilepticus in 5%), agitation (32%), confusion (30%), and coma (28%). Other adverse effects included tachycardia, respiratory depression, tremor, and hallucinations; no deaths were reported. The mean onset and duration of symptoms were 1.3 and 9.1 hours, respectively. The lowest dose associated with seizures was 96 mg.

Precautions

Hepatic metabolism of tiagabine is reduced in patients with hepatic impairment, and dosage should therefore be reduced and/or the intervals between doses increased. It should not be used in patients with severely impaired hepatic function.

Use of tiagabine in non-epileptic patients may be associated with an increased risk of seizures— see Effects on the Nervous System, above.

Care is required when withdrawing tiagabine therapy—see Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For comment on antiepileptic drugs and driving, see p.468.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. The hepatic metabolism of tiagabine is accelerated by antiepileptics that induce enzymes of the cytochrome P450 system such as carbamazepine, phenobarbital, phenytoin, or primidone. Plasma concentrations of tiagabine may be reduced up to threefold by use with these drugs.

Pharmacokinetics

Tiagabine is readily absorbed after oral doses, with a bioavailability of 89%. Food reduces the rate but not the extent of absorption. The absorption and elimination pharmacokinetics of tiagabine are linear within the therapeutic dosage range.

Tiagabine is widely distributed throughout the body and plasma protein binding is 96%.

Tiagabine is extensively metabolised in the liver and excreted as metabolites in the faeces or, to a lesser extent, in the urine; less than 2% of a dose is eliminated as unchanged drug. The plasma-elimination half-life is 7 to 9 hours, although this may be reduced to 2 to 3 hours by liver enzyme-inducing drugs (see also Interactions, above).

Uses and Administration

Tiagabine is a nipecotic acid derivative used in the treatment of epilepsy (p.465) as adjunctive therapy for refractory partial seizures with or without secondary generalisation. It inhibits the uptake of GABA into neuronal and glial cells, and therefore increases the availability of GABA at receptor sites.

UK licensing information states that tiagabine hydrochloride is given as the monohydrate, but doses are described in terms of tiagabine; dose forms providing the equivalent of 5, 10, and 15 mg of tiagabine are available. In the USA, however, the licensed product is stated to contain anhydrous tiagabine hydrochloride, and doses are described in terms of this substance; dose forms providing 2, 4, 12, and 16 mg are available. As a result, the doses in the UK and US literature may not be directly comparable.

In the UK, the initial oral daily dose as adjunctive therapy in adults and children over 12 years of age is the equivalent of tiagabine 5 to 10 mg as a single dose or in 2 divided doses, increased weekly as necessary by increments of 5 to 10 mg. The usual maintenance dose is 30 to 45 mg daily, in 2 or 3 divided doses, in patients receiving enzyme-inducing antiepileptics; in patients *not* taking enzyme-inducing drugs an initial maintenance dosage of 15 to 30 mg daily is suggested. Lower initial doses of the hydrochloride are recommended in the USA. Doses should be taken with food to avoid rapid rises in plasma concentrations, thereby reducing the incidence of adverse effects. Reduced doses should be given in hepatic impairment—see below.

As with other antiepileptics, withdrawal of tiagabine therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. UK licensed product information recommends gradual withdrawal over a period of 2 to 3 weeks. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Administration in hepatic impairment. The initial daily maintenance dosage of tiagabine in patients with mild to moderate hepatic impairment (Child-Pugh score 5 to 9) should be reduced to 5 to 10 mg given as a single dose or in 2 divided doses. Tiagabine should not be given to patients with severe hepatic impairment.

Epilepsy. Tiagabine is one of a number of drugs that may be used as adjunctive therapy in patients with partial seizures (with or without secondary generalisation) refractory to standard treatment (p.465). It appears to be reasonably well tolerated. For the suggestion that it might be tried in refractory status epilepticus, see p.469.

Pain. Antiepileptics are among the drugs used to manage pain (see Choice of Analgesic, p.2); tiagabine has been tried in chronic pain[1] and was found to be effective.

1. Todorov AA, *et al.* Tiagabine and gabapentin for the management of chronic pain. *Clin J Pain* 2005; **21:** 358–61.

Psychiatric disorders. Tiagabine has been tried for the treatment of *generalised anxiety disorder*[1,2] (p.952) and *major depressive disorder* with anxiety[3] (p.373), with variable results. It has also been tried in *post-traumatic stress disorder* (p.953) with some success in a case series[4] and a small open-label study[5] although a later multicentre placebo-controlled study[6] found no significant difference between tiagabine and placebo; further studies are considered warranted. A preliminary study[7] suggested that tiagabine may be effective and generally well tolerated as augmentation therapy in patients with anxiety disorders.

Topiramate *(BAN, USAN, rINN)*

KW-6485; McN-4853; RWJ-17021; Topiramaatti; Topiramat; Topiramato; Topiramatum. 2,3:4,5-Di-*O*-isopropylidene-β-D-fructopyranose sulphamate.

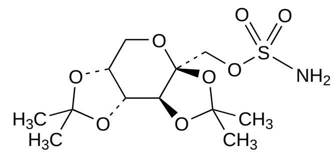
Топирамат

$C_{12}H_{21}NO_8S = 339.4.$

CAS — 97240-79-4.

ATC — N03AX11.

ATC Vet — QN03AX11.



Pharmacopoeias. In *US.*

USP 31 (Topiramate). A white to off-white powder. Freely soluble in dichloromethane. Store in airtight containers at a temperature of 20° to 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

Adverse effects associated with topiramate therapy include ataxia, impaired concentration, confusion, dizziness, fatigue, paraesthesia or hypoaesthesia, drowsiness, and difficulties with memory or cognition. Agitation, anxiety, nervousness, emotional lability, and mood disorders may also occur. Other reported adverse effects include abdominal pain, anorexia, asthenia, diplopia, leucopenia, nausea, nystagmus, insomnia, psychomotor retardation, impaired speech, altered taste, visual disturbances, and weight loss. The risk of developing renal calculi is increased, especially in predisposed patients. Reduced sweating with hyperthermia has occurred particularly in children. Rare cases of acute myopia with secondary angle-closure glaucoma have been reported.

Effects on bone. For the effects of antiepileptics, including topiramate, on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on electrolytes. Metabolic acidosis has been associated with topiramate treatment. Data from clinical trials estimate that the incidence of persistently decreased serum bicarbonate concentrations ranges from 23 to 67% with topiramate compared with 1 to 10% with placebo;[1] children, in particular, may be at a greater risk than adults.[1,2] A retrospective cohort study also found that 48% of adult patients developed decreased serum bicarbonate concentrations while receiving topiramate.[3] Generally, the decreases in serum bicarbonate are mild to moderate and occur soon after starting topiramate. Clinical signs such as hyperventilation may develop.

Some sources such as the US licensed product information recommend that baseline and periodic serum bicarbonate levels should be monitored during topiramate treatment. If metabolic acidosis develops or persists, it may be necessary to reduce the dose or stop topiramate although, in some cases, correcting the acidosis with alkali therapy may be more appropriate.

Effects on the eyes. There have been rare reports of acute myopia with or without secondary angle-closure glaucoma in adults and children receiving topiramate:[1-3] as of April 2002 the UK CSM was aware of 23 cases worldwide occurring with secondary angle-closure glaucoma.[4] Symptoms include decreased visual acuity and ocular pain which generally appear within one month of starting treatment; hyperaemia and raised intra-ocular pressure may be present with or without mydriasis. Choroidal effusions resulting in anterior displacement of lens and iris have been reported. Appropriate measures to reduce intra-ocular pressure should be taken, and topiramate stopped as rapidly as is clinically feasible.[4] A later review[5] of 115 reports of ocular adverse effects associated with topiramate described 83 cases of bilateral and 3 cases of unilateral acute angle-closure glaucoma; of these, 7 sustained permanent loss of vision. Onset of glaucoma was between 1 and 49 days after starting topiramate therapy, with 85% of cases occurring within the first 2 weeks. Also reported were cases of acute bilateral myopia (17 patients), suprachoroidal effusions (9), scleritis (4), blepharospasm (2), oculogyric crisis (2), and myokymia (1). Diplopia and nystagmus were reported with daily doses of at least 200 to 400 mg topiramate.

5. Fraunfelder FW, *et al.* Topiramate-associated acute, bilateral, secondary angle-closure glaucoma. *Ophthalmology* 2004; **111:** 109–11.

Effects on the liver. For reports of hepatotoxicity associated with the addition of topiramate to therapy with carbamazepine or valproate see Interactions, Antiepileptics, on p.474 and p.511 respectively.

Effects on mental function. For a review of the effects of antiepileptic therapy including topiramate on *cognition* and *mood* (including the risk of suicidal ideation), see p.468.

Effects on the nervous system. Hyperthermia was reported in 10.5% of patients taking topiramate compared with 0.15% of patients taking other antiepileptic drugs in one centre.[1] Children under the age of 6 years, patients on daily doses of 6 mg/kg or more, and those exposed to high ambient temperatures were most at risk. Licensed product information recommends that children should be monitored closely for decreased sweating and hyperthermia, especially during warm or hot weather. Caution is also advised when giving topiramate with other drugs known to cause similar effects, for example, carbonic anhydrase inhibitors and antimuscarinics.

Hemiparesis that resolved on withdrawal of topiramate has been reported[2] in 2 patients, although both already had compromised neurological function.

2. Sun C, *et al.* Reversible anorgasmia with topiramate therapy for headache: a report of 7 patients. *Headache* 2006; **46:** 1450–3.

Precautions

Topiramate should be used with caution in patients with renal or hepatic impairment. Adequate hydration is recommended to reduce the risk of developing renal calculi, especially in predisposed patients.

Care is required when withdrawing topiramate therapy—see also Uses and Administration, below.

Breast feeding. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Pregnancy. For comments on the management of epilepsy during pregnancy, see p.468.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy.

Pharmacokinetics

Topiramate is readily absorbed after oral doses, with peak plasma concentrations achieved after about 2 hours. Bioavailability is not affected by the presence of food. Protein binding is about 9 to 17%. The volume of distribution in women is about half that in men. Topiramate crosses the placental barrier and is distributed into breast milk.

In healthy subjects topiramate is not extensively metabolised; however, up to 50% of a dose may undergo metabolism in the liver in patients also receiving enzyme-inducing drugs. It is eliminated chiefly in urine, as unchanged drug and metabolites; mean plasma elimination half-life is about 21 hours. Steady-state concentrations are achieved after about 4 to 8 days in patients with normal renal function. Clearance is decreased in patients with impaired renal or hepatic function, and steady-state plasma concentrations may not be achieved for 10 to 15 days in the former. Children exhibit a higher clearance and shorter elimination half-life than adults.

The pharmacokinetics of topiramate may be affected by use with other antiepileptics (see under Interactions, above).

Uses and Administration

Topiramate, a sulfamate-substituted monosaccharide, is an antiepileptic used as adjunctive therapy in refractory partial seizures with or without secondary generalisation, seizures associated with the Lennox-Gastaut syndrome, and primary generalised tonic-clonic seizures. It may also be used as monotherapy in patients with newly diagnosed epilepsy who have generalised tonic-clonic seizures or partial seizures. Topiramate is also used for the prophylaxis of migraine.

In the UK, for both adjunctive and monotherapy of **epilepsy**, the initial oral dose of topiramate is 25 mg at night for 1 week increased thereafter by increments of 25 or 50 mg at intervals of 1 to 2 weeks until the effective dose is reached. Daily doses of more than 25 mg should be taken in 2 divided doses. The usual daily dose for *adjunctive therapy* is 200 to 400 mg although some patients may require up to 800 mg daily. When used as *monotherapy*, usual doses range from 100 mg daily to a maximum of 400 mg daily. Similar target doses are also used in the USA for both adjunctive and monotherapy although higher initial doses of 50 mg daily with weekly increases thereafter are recommended in the licensed product information.

For doses in children, see below.

As with other antiepileptics, withdrawal of topiramate therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465. The UK product information suggests decreasing the daily dose by 50 to 100 mg at weekly intervals.

In the prophylaxis of **migraine**, topiramate is given orally in initial doses of 25 mg at night for 1 week, increased by 25-mg increments every week, to a usual dose of 50 mg twice daily. UK product information suggests decreasing the daily dose by 25 to 50 mg at weekly intervals when withdrawing topiramate therapy.

Smaller increments or longer intervals between increments may be necessary if patients cannot tolerate the above regimens; US product information suggests that doses should be halved in patients with moderate to severe renal impairment regardless of indication (see also below).

Administration in children. Topiramate is used as adjunctive therapy in children for refractory partial seizures with or without secondary generalisation, seizures associated with the Lennox-Gastaut syndrome, and primary generalised tonic-clonic seizures. It may also be used as monotherapy in those with newly diagnosed epilepsy who have generalised tonic-clonic seizures or partial seizures.

In the UK, the initial oral dose for *adjunctive* therapy in children from 2 years of age is 25 mg. This is given as a single dose at night for 1 week, then increased by 1 to 3 mg/kg every 1 to 2 weeks until the effective dose is reached; these higher daily doses are divided and given twice daily. About 5 to 9 mg/kg daily is usually required, although up to 30 mg/kg has been given.

For *monotherapy*, in children from 6 years of age, the initial daily oral dose is 0.5 to 1 mg/kg at night for the first week, increased thereafter by 0.5 to 1 mg/kg every 1 or 2 weeks, to a usual dose of 3 to 6 mg/kg daily in 2 divided doses; up to 16 mg/kg daily has been used.

The adult dose (above) is recommended in those over 16 years of age.

In the USA, licensed doses for adjunctive therapy are similar to those in the UK; however, monotherapy, which is limited to those 10 years of age and over, is given at usual adult doses.

Administration in renal impairment. Patients with moderate to severe renal impairment take longer to reach steady-state plasma concentrations of topiramate than patients with normal renal function (see Pharmacokinetics, above) and the dosage regimen may need adjusting; US licensed product information recommends that usual adult doses (see above) be halved in such patients.

In patients undergoing haemodialysis a supplemental dose equal to about one-half of the daily dose should be given in divided doses (at the start and finish of the procedure).

Alcohol withdrawal and abstinence. Topiramate may be of use as an adjunct in achieving and maintaining abstinence in patients with alcohol dependence[1,2] (p.1626).

1. Johnson BA, *et al.* Oral topiramate for treatment of alcohol dependence: a randomised controlled trial. *Lancet* 2003; **361:** 1677–85.
2. Johnson BA, *et al.* Topiramate for treating alcohol dependence: a randomized controlled trial. *JAMA* 2007; **298:** 1641–51.

Bipolar disorder. Mood-stabilising antiepileptics such as carbamazepine and valproate are alternatives to lithium in the management of bipolar disorder (p.372). Topiramate has also been investigated after favourable case reports,[1,2] but randomised controlled studies[3,4] have produced disappointing results and a systematic review[5] found insufficient evidence for its use as monotherapy or adjunctive therapy.

5. Vasudev K, *et al.* Topiramate for acute affective episodes in bipolar disorder. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2006 (accessed 09/06/08).

Epilepsy. Topiramate is used[1-5] in epilepsy (p.465) for refractory partial seizures, for primary generalised tonic-clonic seizures,[6] and in patients with the Lennox-Gastaut syndrome;[7] in the UK, it may be a first-line option in some circumstances. Starting topiramate therapy gradually improves tolerability without delaying therapeutic response.[8]

Topiramate has also been investigated in children with infantile spasms (as for example in West's syndrome),[9] severe myoclonic epilepsy,[10] and juvenile myoclonic epilepsy;[11] it has been tried as a second-line drug in absence seizures and for tonic or atonic seizures. A retrospective review[12] and later studies[13,14] of the use of topiramate in such drug-resistant childhood epilepsies have concluded that it is efficacious and well tolerated.

Topiramate has also been investigated as an alternative antiepileptic in the management of refractory status epilepticus (p.469).[15,16]

Headache. Topiramate is used for the prophylaxis of *migraine* (p.616). Results from placebo-controlled studies[1-5] have shown a significant reduction in frequency of migraines in those patients receiving prophylactic topiramate.

Topiramate has been tried for prophylaxis of *cluster headache* attacks[6] (p.616) and chronic *tension-type headache*[7] (p.617). It has also been used to control headache due to *raised intracranial pressure* (see p.1181).

Hyperhidrosis. Reduced sweating has been associated with topiramate therapy (see Effects on the Nervous System under Adverse Effects, above). There have been 2 case reports[1,2] of the use of topiramate in the treatment of hyperhidrosis.

1. Owen DB, Meffert JJ. The suppression of primary palmar-plantar hyperhidrosis by topiramate. *Br J Dermatol* 2003; **148:** 826–7.
2. Hoehn-Saric R. Facial hyperhidrosis-induced social fear alleviated with topiramate. *J Clin Psychiatry* 2006; **67:** 1157.

Motor neurone disease. Topiramate has been tried as a potential therapy for amyotrophic lateral sclerosis (see Motor Neurone Disease, p.2380) but with disappointing results.[1]

1. Cudkowicz ME, *et al.* A randomized, placebo-controlled trial of topiramate in amyotrophic lateral sclerosis. *Neurology* 2003; **61:** 456–64.

Neuropathic pain. Although carbamazepine is the drug of choice in the treatment of *trigeminal neuralgia* (p.9), topiramate has also been tried successfully.[1] It has also been tried[2,3] in the treatment of *diabetic neuropathy* (p.6) and of *phantom limb pain*[4] (p.9).

1. Zvartau-Hind M, *et al.* Topiramate relieves refractory trigeminal neuralgia in MS patients. *Neurology* 2000; **55:** 1587–8.
2. Raskin P, *et al.* Topiramate vs placebo in painful diabetic neuropathy: analgesic and metabolic effects. *Neurology* 2004; **63:** 865–73.
3. Donofrio PD, *et al.* Safety and effectiveness of topiramate for the management of painful diabetic peripheral neuropathy in an open-label extension study. *Clin Ther* 2005; **27:** 1420–31.
4. Harden RN, *et al.* Topiramate for phantom limb pain: a time-series analysis. *Pain Med* 2005; **6:** 375–8.

Obesity. Weight loss has been associated with topiramate therapy (see Adverse Effects, above) and it has been tried as an adjunct in the treatment of obesity (p.2149) and in overweight patients; topiramate appears to be reasonably well tolerated. It has also been tried in binge eating (see below).

Psychiatric disorders. Topiramate has been tried in several psychiatric disorders, including *schizophrenia*[1] (p.955), *disturbed behaviour*[2] (p.954), *post-traumatic stress disorder*[3] (p.953), and *social anxiety disorder*[4] (see Phobic Disorders, p.953). It has also been tried in *binge eating*.[5-7] For its use in *bipolar disorder* see above.

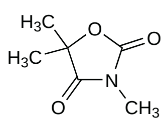
Trimethadione *(BAN, rINN)*

Trimetadion; Trimetadiona; Trimetadionas; Trimetadioni; Trimethadion; Triméthadione; Trimethadionum; Trimethinum; Troxidone. 3,5,5-Trimethyl-1,3-oxazolidine-2,4-dione.

Триметадион

$C_6H_9NO_3$ = 143.1.
CAS — 127-48-0.
ATC — N03AC02.
ATC Vet — QN03AC02.



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Jpn.*
Ph. Eur. 6.2 (Trimethadione). Colourless or almost colourless crystals. Soluble in water; very soluble in alcohol. Protect from light.

Profile

Trimethadione is an oxazolidinedione antiepileptic that has been given in the treatment of absence seizures refractory to other antiepileptics. However, because of its potential toxicity, other antiepileptics are preferred (see under Epilepsy, p.465).

Porphyria. Trimethadione has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Characteristic congenital malformations, termed the fetal trimethadione syndrome, have been associated with the use of trimethadione in pregnancy.

For comments on the management of epilepsy during pregnancy, see p.468.

Preparations

Valproate

Valproato.
Вальпроат

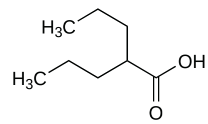
NOTE. Valproate is a generic term applied to valproic acid and its salts and esters.

Valproic Acid *(BAN, USAN, rINN)*

Abbott-44089; Acide valproïque; Ácido dipropilacético; Ácido valproico; Acidum valproicum; Kyselina valproová; Valproiinihappo; Valproik Asit; Valproinė rūgštis; Valproinsav; Valproinsyra. 2-Propylvaleric acid; 2-Propylpentanoic acid.

Вальпроевая Кислота

$C_8H_{16}O_2$ = 144.2.
CAS — 99-66-1.
ATC — N03AG01.
ATC Vet — QN03AG01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Valproic Acid). A colourless or very slightly yellow, slightly viscous, clear liquid. Very slightly soluble in water; miscible with alcohol and with dichloromethane. It dissolves in dilute solutions of alkali hydroxides. Store in airtight containers.
USP 31 (Valproic Acid). A colourless to pale yellow, slightly viscous, clear liquid having a characteristic odour. Slightly soluble in water; freely soluble in alcohol, in acetone, in chloroform, in ether, in methyl alcohol, in benzene, in *n*-heptane, and in 1N sodium hydroxide; slightly soluble in 0.1N hydrochloric acid. Store in airtight glass, stainless steel, or polyethylene containers.

Sodium Valproate *(BANM, rINNM)*

Abbott-44090; Natrii valproas; Natrio valproatas; Natriumvalproaatti; Natriumvalproat; Nátrium-valproát; Natrium-valproát; NIK-240; Sodium, valproate de; Sodyum Valproat; Valproate de Sodium; Valproate Sodium *(USAN)*; Valproato sódico. Sodium 2-propylvalerate; Sodium 2-propylpentanoate.

Натрий Вальпроат

$C_8H_{15}NaO_2$ = 166.2.
CAS — 1069-66-5.
ATC — N03AG01.
ATC Vet — QN03AG01.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn.*, and *US.*
Ph. Eur. 6.2 (Sodium Valproate). A white or almost white, hygroscopic, crystalline powder. Very soluble in water; slightly to freely soluble in alcohol. Store in airtight containers.
USP 31 (Divalproex Sodium). A white to off-white powder. Soluble in acetone; practically insoluble in acetonitrile; very soluble in chloroform; freely soluble in ethyl ether and in methyl alcohol. Store in airtight containers.

Valproate Pivoxil *(rINN)*

CHF-1504; Valproato de pivoxilo; Valproate pivoxilo; Valproatum Pivoxilum. Hydroxymethyl 2-propylvalerate pivalate.

Вальпроат Пивоксил

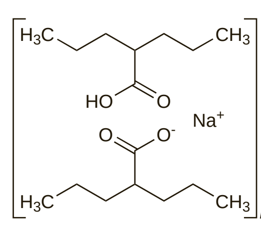
$C_{14}H_{26}O_4$ = 258.4.
CAS — 77372-61-3.
ATC — N03AG01.
ATC Vet — QN03AG01.

Valproate Semisodium *(rINN)*

Abbott-50711; Divalproex Sodium *(USAN)*; Semisodium Valproate *(BAN)*; Valproate Semisodique; Valproato semisódico; Valproatum Seminatricum. 2-Propylvaleric acid—Sodium 2-propylvalerate (1:1); Sodium hydrogen bis(2-propylvalerate) oligomer.

Вальпроат Семинатрий

$C_{16}H_{31}NaO_4$ = 310.4.
CAS — 76584-70-8.
ATC — N03AG01.
ATC Vet — QN03AG01.



Valpromide *(rINN)*

Dipropilacetamida; Dipropylacetamide; Valpromida; Valpromidum. 2-Propylvaleramide.

Вальпромид

$C_8H_{17}NO$ = 143.2.
CAS — 2430-27-5.
ATC — N03AG02.
ATC Vet — QN03AG02.

Adverse Effects

The most frequently reported adverse effects associated with valproate therapy are gastrointestinal disturbances, particularly at the start of therapy; enteric-coated formulations, taking doses with meals, and starting with low doses may minimise symptoms. There may be increased appetite, and weight gain is common.

Less common adverse effects include oedema, headache, reversible prolongation of bleeding time, and thrombocytopenia. Leucopenia and bone marrow depression have been reported. Neurological adverse effects including ataxia, tremor, sedation, lethargy, confusion, and more rarely encephalopathy and coma, have occasionally been reported, although these are often associated with too high a starting dose, increasing doses too rapidly, or use with other antiepileptics. Very rare cases of extrapyramidal symptoms or reversible dementia associated with cerebral atrophy have been reported. Increased alertness may occur, which is generally considered beneficial, but occasionally aggression, hyperactivity, and behavioural disturbances have been reported. Hearing loss has been noted. There may occasionally be rashes, and, rarely, hirsutism, acne, toxic epidermal necrolysis and Stevens-Johnson syndrome or erythema multiforme. Transient hair loss, sometimes with regrowth of curly hair, has occurred. Irregular periods, amenorrhoea, and gynaecomastia have been reported rarely.

Liver dysfunction including hepatic failure has occasionally been reported, usually in the first few months of treatment, and requires valproate withdrawal; there have been fatalities. Elevation of liver enzyme values is common but normally transient and dose-related. Hyperammonaemia has occurred, even in the absence of overt hepatic failure, and is sometimes associated with neurological symptoms; hyperglycinaemia has also been reported. Pancreatitis has also been reported rarely, and fatalities have occurred; plasma amylase should be measured if there is acute abdominal pain, although the value of serum amylase as a diagnostic tool has been questioned—see Effects on the Pancreas, below. In a few patients there have been reports of reversible defects in renal tubular function (Fanconi's syndrome).

Congenital malformations have been reported in infants born to women who had received antiepileptics including valproate during pregnancy.

Inflammatory reactions and pain have been reported at the injection site after intravenous doses.

Incidence of adverse effects. Adverse effects were present in 71 of 88 children receiving sodium valproate monotherapy[1] and, although average doses in these patients were significantly higher than in the 17 with no adverse effects, no difference in the plasma concentrations was observed between the 2 groups.

- Behavioural alterations seen in 56 included irritability, longer and deeper sleep, superficial sleep, hyperactivity, being more alert, lassitude, drowsiness, being more sociable, calmness, being happier, absent mindedness, being sadder, aggressiveness, being more skillful, and docility; it was emphasised that stimulatory reactions were as frequent as depressant effects
- Digestive disorders occurred in 43 children with anorexia, abdominal pain, and nausea and vomiting being the most frequent; diarrhoea, constipation, an increase in appetite, and a gain in weight also occurred. With the exception of a temporary increase in plasma transaminase concentrations in 2 patients, hepatic or pancreatic dysfunction was not seen
- Neurological changes in the form of tremor, paraesthesia, or ataxia, occurring in only 4 patients, were less frequent than either behavioural or digestive reactions
- Miscellaneous reactions including polydipsia, polyuria, diaphoresis, enuresis, hair loss, change in hair colour or texture, and rash were seen in 23 children

- Of the 71 children experiencing reactions, therapy continued unchanged in 56, was changed in 3 either by altering the pharmaceutical formulation (syrup, tablets, granules), by changing the frequency of dosing, or by reducing the dose in 6, and in the remaining 9 children valproate therapy was stopped

1. Herranz JL, *et al*. Side effects of sodium valproate in monotherapy controlled by plasma levels: a study in 88 pediatric patients. *Epilepsia* 1982; **23:** 203–14.

Carnitine deficiency. Carnitine deficiency may occasionally arise during long-term use of valproate; although it is unclear whether carnitine supplementation (p.1933) of value in children receiving valproate, some neurologists consider it justified in selected cases, including those with, or at risk of, valproate-induced hepatotoxicity.[1,2]

Effects on the blood. A number of reports have implicated valproate as a cause of occasional neutropenia,[1-3] leucopenia,[4] and thrombocytopenia.[2] A 1-year prospective study involving 45 patients found that absolute neutropenia developed in 12 and thrombocytopenia in 15, but that the disorders were transient and self-limiting.[2] However, neutropenia has occasionally been sufficiently severe to warrant withdrawal of valproate.[5] Red cell aplasia has also been associated with valproate therapy.[6,7] A study[8] involving 30 children indicated that valproate might produce symptoms similar to those of von Willebrand's disease; 19 of the 30 had a history of minor haemorrhage during therapy, and 7 had abnormal bleeding times. Factor VIII therapy might need to be given in patients receiving valproate who underwent surgery or in whom bleeding was severe.

For a discussion of the effects of antiepileptics, including valproate, on serum folate, see under Phenytoin, p.495.

Effects on bone. For the effects of antiepileptics including valproate on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on the endocrine system. An early study[1] reported that menstrual disturbances were associated more often with valproate than with other antiepileptics among 238 women with epilepsy; 80% of those treated with valproate before 20 years of age had polycystic ovaries or hyperandrogenism. A later study[2] found that the occurrence of polycystic ovaries in 105 epileptic women taking carbamazepine or valproate was no greater than that in the general population, although valproate appeared to increase glucose-stimulated pancreatic insulin secretion. Subsequent studies[3-5] and reviews[6-9] support the association between valproate therapy and reproductive endocrine disorders and metabolic disturbances in female patients with epilepsy. However, a causal link could not be established since epilepsy itself affects the endocrine system. Symptoms such as hyperandrogenism, menstrual disturbances, polycystic ovaries, weight gain, and insulin resistance have been attributed to the development of polycystic ovary syndrome (p.2080) in some patients. Other adverse effects of valproate on the endocrine system include dyslipidaemia, hypocalcaemia, and hypothyroidism.

For mention of the effects of antiepileptics, including valproate, on *sexual function* in male epileptic patients, see under Phenytoin, p.496.

Effects on the liver. An early review[1] of the hepatotoxicity of valproate included an analysis of 42 cases with fatal hepatitis, 3 cases with a Reye's-like syndrome, and 22 instances of hyperammonaemia:

- In 19 studies the incidence of *abnormal serum aminotransferase* activity ranged from 0 to 44% with an overall incidence of 11% in the 1197 patients monitored; in the non-fatal cases activity was usually between one and three times the upper limit of normal and was not usually, except in the most severe cases, accompanied by rises in serum bilirubin or alkaline phosphatase
- In the 42 cases of *hepatitis* with a fatal outcome the age at presentation ranged from 2.5 months to 34 years with 69% aged 10 years or less. Below the age of 15 years the proportion of males was 62.5% but above this age it was 30%; the disproportionate vulnerability of young individuals, particularly boys, did not appear to be a reflection of prescribing habits in that age group. In more than two-thirds of these patients with a fatal outcome, prodromal symptoms comprised anorexia and vomiting, loss of epilepsy control, impaired consciousness, and ataxia; in about one-third there were signs of liver damage with fever, jaundice, ascites, peripheral oedema, and easy bruising. In all of the patients hepatic coma developed. In 36 patients on whom data were available the onset of hepatic illness in one-third occurred between 1 and 2 months and in only 2 patients did the onset occur after more than 5 months. Of these 42 patients with fatal hepatotoxicity 36 were also given other drugs, mostly antiepileptics
- The 3 children with a *Reye's-like syndrome* all died within 3 weeks of the first occurrence of symptoms as a result of cerebral oedema (2) or aspiration pneumonia (1)
- In the 22 patients with symptomatic *hyperammonaemia*, characterised usually by impaired consciousness and ataxia, but without overt liver disease, withdrawal of valproate resulted in all becoming asymptomatic and biochemical abnormalities returned to normal. Hyperammonaemia has also been reported in asymptomatic patients

Hyperammonaemia and encephalopathy may also be precipitated when valproate is used with certain drugs (see under Antibacterials, p.510 and Antiepileptics, p.511, in Interactions).

Various hypotheses for the cause of valproate hepatotoxicity have been discussed in detail.[2]

Analysis of deaths in the USA attributed to valproate liver toxicity identified a decline in the incidence of fatalities as use in young children and use with other antiepileptics declined.[3] However, occasional reports still occur in some countries.[4]

Effects on mental function. For a review of the effects of antiepileptic therapy including valproate on *cognition* and *mood* (including the risk of suicidal ideation), see p.468.

Effects on the nervous system. An *extrapyramidal* syndrome of tremor and rigidity, unresponsive to benzatropine or trihexyphenidyl, developed in a 52-year-old man with schizophrenia given a therapeutic trial of sodium valproate 1 to 2 g daily.[1] Giving sodium valproate to a man with dystonic movements of the neck and spine produced a severe subjective and objective deterioration in his symptoms, which returned to their previous severity on withdrawal of the drug.[2] There have also been reports[3,4] of *parkinsonism* associated with valproate antiepileptic therapy; onset was usually insidious and progressive, occurring after several years of good tolerability. A case series[4] also reported *cognitive impairment* in 6 of 10 patients who developed parkinsonism. In most cases symptoms improved on stopping valproate.

Spasmodic dysphonia associated with valproate has been reported;[5] symptoms resolved when the dose of valproate was reduced.

A *stuporous state* associated with EEG abnormalities has been described[6,7] during valproate therapy for complex partial or mixed seizure types and it was suggested that in certain forms of epilepsy valproate may exhibit a paradoxical epileptogenic effect. Other findings[8] have argued against an epileptic origin for valproate-induced stupor.

Effects on the pancreas. An early report of 4 cases of pancreatitis associated with valproic acid therapy also reviewed 10 previously published cases.[1] None of the 14 patients, 2 of whom died, suffered other symptoms of a toxic reaction to valproic acid. Pancreatitis was not dose-related and had developed as early as one week and as late as 4.5 years after the introduction of therapy. Symptoms recurred on rechallenge in 6 of 7 patients. However, routine monitoring of serum-amylase concentrations in asymptomatic patients did not seem necessary. In February 1994 the UK CSM commented[2] in a review of drug-induced pancreatitis that they had received 29 reports of pancreatitis, including 2 fatalities, associated with sodium valproate. A later review[3] of 22 children who developed pancreatitis while taking valproate (2 of whom died) found that duration of therapy, dose, serum concentrations, and polytherapy were not risk factors. The authors advised against rechallenge as the rate of relapse is high. Serum amylase concentrations were found to be nondiagnostic in 39% of these patients, and the authors considered that serum lipase concentrations were far more likely to be elevated.

Effects on the skin, hair, and nails. Five of 250 patients developed curly hair during treatment with sodium valproate 1 g daily;[1] in 3 patients this effect followed temporary alopecia. Another report of hair curling in a patient who received sodium valproate in doses up to 3 g daily for 30 months commented that her hair started to revert to the former straight style 9 months after stopping the drug.[2]

Valproate-induced nicotinic-acid deficiency with an associated pellagra-like syndrome has been reported in a young boy;[3] the condition responded dramatically to treatment with nicotinamide.

Reduced serum-zinc concentrations and cutaneous manifestations of zinc deficiency were found in 2 patients receiving antiepileptic drugs.[4] It was thought that deficiency resulted from chelation by sodium valproate, and possibly phenytoin, in association with malabsorption and that, in one case, malabsorption was triggered by valproate.

Cutaneous vasculitis has been reported[5] in 2 patients taking sodium valproate. The reaction recurred on rechallenge.

Very rarely, skin rashes occurring with valproate may form part of an antiepileptic hypersensitivity syndrome (see below). Valproate might share the same order of risk as other antiepileptics for the development of Stevens-Johnson syndrome and toxic epidermal necrolysis,[6] although it had previously been regarded as safer in this respect. For a suggestion that skin reactions are less common with valproate than with some other antiepileptics see under Phenytoin, p.496.

Reversible yellow nail pigmentation has been reported[7] in a woman who was taking valproate semisodium.

Enuresis. Nocturnal enuresis associated with sodium valproate therapy has been reported[1] in 2 children. Remission of the enuresis was achieved either by reducing or redistributing the doses. Several studies have recorded enuresis as an adverse effect of valproate in children,[2] the frequency being between 1 and 7%. The most likely explanations are that either it is secondary to a central effect on the thirst centre resulting in polydipsia or it is a consequence of the increased depth of sleep associated with valproate.

2. Choonara IA. Sodium valproate and enuresis. *Lancet* 1985; **i:** 1276.

Hypersensitivity. An antiepileptic hypersensitivity syndrome, comprising fever, rash, and lymphadenopathy and less commonly lymphocytosis, and liver and other organ involvement, has been associated with some aromatic antiepileptic drugs; however, there have also been case reports[1-3] associated with valproate, a non-aromatic compound. In one case[1] a patient developed these symptoms with carbamazepine but they resolved when the drug was stopped; however, when valproate was started 2 weeks later the symptoms reappeared. Another report[2] described a fatal case occurring in a 2-year-old girl who developed fulminant hepatitis.

Overdosage. A cohort study[1] of valproate poisonings reported to a regional toxicology centre between January 1991 and November 2001 reported 79 cases. Of these, valproate was the only drug taken in 15 cases with a median dose of 15 g; symptoms were mild and included drowsiness (2 patients), vomiting (4), and tachycardia (5). The authors concluded that overdoses of more than 400 mg/kg could cause severe, potentially life-threatening toxicity, but these were uncommon. Symptoms of severe toxicity include significant CNS depression, respiratory insufficiency, and multi-organ failure; fatalities have been reported.[2] Children younger than 2 years of age are considered to be at significant risk for developing fatal valproate-induced hepatotoxicity in overdose; there has been a report of a 26-day-old neonate who died 42 hours after receiving a dose of 75 mg/kg.[3]

3. Unal E, *et al.* Fatal valproate overdose in a newborn baby. *Hum Exp Toxicol* 2007; **26:** 453–6.

Treatment of Adverse Effects

The value of gastric decontamination for overdose is uncertain since valproic acid and its salts are rapidly absorbed. Activated charcoal may be given orally to adults and children who present within 1 hour of ingesting more than 100 mg/kg; alternatively gastric lavage may be considered in adults within 1 hour of a potentially life-threatening overdose. Supportive therapy alone may then suffice although haemodialysis should be considered in very severe poisoning.

◊ A variety of active treatments including forced diuresis, whole bowel irrigation, naloxone, and haemodialysis or haemoperfusion have been advocated for valproate overdose;[1,2] however, supportive measures provided sufficient treatment for a patient who had taken 25 g of sodium valproate.[1] For a further review of the features and management of poisoning with some antiepileptics such as valproate, see under Phenytoin, p.497.

Precautions

Valproate is contra-indicated in patients with pre-existing liver disease or a family history of severe hepatic dysfunction. Children under 3 years of age and those with congenital metabolic or degenerative disorders, organic brain disease, or severe seizure disorders associated with mental retardation may be at particular risk of hepatotoxicity and the drug should be used with particular caution in these groups. Use with other antiepileptics, which may also increase the risks of liver damage, should be avoided if possible. Liver function tests should be carried out, particularly in those most at risk, before and during the first 6 months of therapy. Raised liver enzymes are not uncommon during treatment and are usually transient or respond to reduction in dosage, but patients should be reassessed clinically and liver function, including prothrombin time, monitored until they return to normal. An abnormally prolonged prothrombin time, particularly in association with other relevant abnormalities, requires treatment to be stopped. If given with salicylates, these should also be stopped. Treatment should also be stopped if pancreatitis is diagnosed.

Patients or their carers should be told how to recognise signs of blood and liver toxicity or pancreatitis, and they should be advised to seek immediate medical attention if symptoms develop.

Patients should be monitored for potential bleeding complications before major elective surgery; some licensed product information suggests regular monitoring before and during therapy.

Valproate should be used with caution if the patient is at risk of SLE.

Patients should be warned of the risk of weight gain and appropriate strategies adopted to minimise the effect.

Care is required when withdrawing valproate therapy—see also Uses and Administration, below.

The protein binding of valproate is saturable and thus shows concentration dependency; significant increases in free drug occur at high total plasma concentrations.

Because valproate is partly excreted in the form of ketone bodies, it may cause false positives in urine tests for diabetes mellitus.

Dosage adjustments may be necessary in severe renal impairment in accordance with free serum valproate levels.

Breast feeding. Thrombocytopenic purpura and anaemia occurred in a breast-fed infant whose mother was being treated with valproic acid.[1] The baby recovered when breast feeding was stopped. Low serum-valproate levels were detected[2] in 6 breast-fed infants whose mothers had been taking valproate semisodium post partum; no adverse effects were seen in the infants. Similar results have previously been obtained for patients taking sodium valproate[3] or valproic acid.[4] The American Academy of Pediatrics considers[5] that valproate is, therefore, usually compatible with breast feeding.

For further comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

HIV infection and AIDS. Limited data from several small *in-vitro* studies have found that valproic acid may induce viral replication of HIV;[1] some clinicians have therefore suggested increased monitoring of viral load in HIV-positive patients treated with valproic acid. For the use of this effect to reduce latent viral load see under Uses and Administration, below.

1. Jennings HR, Romanelli F. The use of valproic acid in HIV-positive patients. *Ann Pharmacother* 1999; **33:** 1113–16.

Porphyria. Valproate is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems. There is conflicting evidence of the porphyrinogenicity of valpromide, although it has also been shown to be porphyrinogenic in *in-vitro* systems.

For comments on the use of valproate in porphyria, see p.471.

Pregnancy. For comments on the management of epilepsy during pregnancy see p.468.

There is an increased risk of neural tube defects in infants exposed *in utero* to antiepileptics including valproate and craniofacial and digital abnormalities and, less commonly, cleft lip and palate have been described, which may form part of a fetal antiepileptic syndrome.[1] In an unselected series[2] of 17 infants whose epileptic mothers had received valproate during pregnancy, 9 had minor abnormalities and of these 5 also had major abnormalities, including congenital heart defect in 4. In another series,[3] involving 149 women whose offspring were exposed to valproate monotherapy in the first trimester, 16 infants with major malformations were identified (a relative risk calculated at about 7 times that in the population at large). The abnormalities reported included craniosynostosis, spina bifida, and pulmonary atresia. A population-based study[4] of 2350 births to epileptic women between 1991 and 2000 found that the offspring of mothers who were given valproate, as mono- or polytherapy, in the first trimester had a fourfold increase in risk for congenital malformations compared with untreated mothers; the risk was tenfold in those who were given daily doses of more than 1.5 g. The risk of malformations was not increased in the offspring of mothers taking carbamazepine, oxcarbazepine, or phenytoin as mono- or polytherapy without valproate.

Neonatal bleeding, attributed to fibrinogen depletion and sometimes fatal, has been reported after exposure *in utero* to valproate.[5,6] Hypoglycaemia was recorded[7] in 13 of 22 neonates whose mothers had taken valproate during pregnancy. Valproate-withdrawal symptoms, including irritability, jitteriness, hypertonia, seizures, and feeding problems were also noted.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. Caution is recommended when giving valproate with other drugs liable to interfere with blood coagulation, such as aspirin or warfarin. Use with other hepatotoxic drugs should be avoided. Use of highly protein bound drugs with valproate may increase free valproate plasma concentrations.

Analgesics. The free fraction of valproate was increased eightfold in a 76-year-old man[1] who was also given *aspirin* 325 mg daily, resulting in signs of clinical toxicity. Aspirin displaces valproate from plasma protein binding sites, as well as inhibiting its metabolism by inhibition of beta-oxidation. Similarly, the valproic acid free fraction was reported to be increased, as was the half-life, when aspirin was given in a study in 6 epileptic children.[2] Furthermore, salicylates have been associated with an increased risk of Reye's syndrome (p.22) in children, and combination with another hepatotoxic drug such as valproate is clearly undesirable. In addition, both aspirin and valproate affect blood coagulation and platelet function.

Naproxen has also been reported to produce a slight displacement of protein-bound valproic acid but the effect is probably not sufficiently marked for it to have a clinical effect.[3]

Antibacterials. Raised valproate blood concentrations and symptoms consistent with valproate toxicity have been reported in a patient also given *erythromycin*.[1]

There is a theoretical possibility that carnitine deficiency may be increased in patients receiving *pivampicillin* and valproate. Hyperammonaemic encephalopathy developed in a 72-year-old woman who had been taking valproate for 10 months when she was given *pivmecillinam* for a urinary-tract infection. It was suggested that valproate's propensity to produce hyperammonaemia had been exacerbated by a secondary hyperammonaemia induced by both drugs reducing carnitine concentrations.[2]

Decreases in plasma concentrations of valproate to subtherapeutic levels (and sometimes with loss of seizure control) have been noted in patients during therapy with antibacterial treatment containing *ertapenem*,[3] *imipenem*,[4] or *meropenem*.[4-8] Marked reductions in valproate concentrations have also been reported in 3 children given *panipenem* (with betamipron).[9]

Increased serum-valproate concentrations resulting in signs of valproate toxicity occurred in a child after beginning therapy with *isoniazid*;[10] the child was a slow acetylator of isoniazid and valproate dosage had to be reduced by about 60% to maintain satisfactory concentrations. When isoniazid was subsequently stopped, valproate dosage had to be increased to its previous value in order to maintain a therapeutic effect.

Antidepressants. As with all antiepileptics, antidepressants may antagonise the antiepileptic activity of valproate by lowering the convulsive threshold.

There have been conflicting reports of the effect of *fluoxetine* on serum concentrations of valproate. While some reported an increase,[1-3] others have reported a decrease[4] in valproate-serum concentrations when the 2 drugs were used together.

For the effect of valproate on *amitriptyline*, see p.380.

4. Droulers A, *et al.* Decrease of valproic acid concentration in the blood when coprescribed with fluoxetine. *J Clin Psychopharmacol* 1997; **17:** 139–40.

Antiepileptics. The barbiturate antiepileptic *phenobarbital* is reported to decrease serum-valproate concentrations when given together,[1] apparently by induction of valproate metabolism.[2] This effect is overshadowed, however, by the marked increase in serum-phenobarbital concentrations caused by valproate inhibition of phenobarbital metabolism—see p.493. It has been suggested that phenobarbital may also increase the risk of valproate-induced hyperammonaemic encephalopathy.[3]

Carbamazepine and *phenytoin* are also enzyme-inducing drugs and, as might be expected, are reported to increase the metabolism and decrease the serum concentration of valproate.[4-6] The effect may be clinically significant.[7] The reciprocal effects of valproate on both drugs are complex, with conflicting effects on metabolism and protein binding, and the clinical outcome is difficult to predict. For more details see under Carbamazepine, p.474 and Phenytoin, p.498.

Serum concentrations of valproic acid were reduced, with considerable interpatient variability, when *ethosuximide*[8] or *mesuximide*[9] was added to the antiepileptic therapy of some patients.

Raised serum concentrations of valproic acid have been reported in patients given *felbamate*.[10]

Reversible hepatic impairment has been reported[11,12] when *topiramate* was added to valproate therapy in patients who had previously tolerated valproate well. Use of valproate with topiramate has also been associated with hyperammonaemia and encephalopathy.[13]

Valproate inhibits the metabolism of *lamotrigine* which may result in serious toxic reactions—see p.486. There is limited evidence that valproic acid may affect the metabolism of *ethosuximide* in some patients—see p.480. Valproate reduces the half-life of *zonisamide*—see p.515.

Antimalarials. Low serum concentrations of valproate have been reported[1] in patients taking *mefloquine.* Also, mefloquine and *chloroquine* may antagonise the antiepileptic activity of valproate by lowering the convulsive threshold.

1. Anonymous. Mefloquine for malaria. *Med Lett Drugs Ther* 1990; **32:** 13–14.

Antineoplastics. A marked reduction in serum-valproate concentration occurred in a 6-year-old child after a high-dose 24-hour infusion of *methotrexate*.[1]

1. Schrøder H, Østergaard JR. Interference of high-dose methotrexate in the metabolism of valproate? *Pediatr Hematol Oncol* 1994; **11:** 445–9.

Antipsychotics. As with all antiepileptics, antipsychotics may antagonise the antiepileptic activity of valproate by lowering the convulsive threshold. Although a study[1] found that *risperidone* had no significant effect on the pharmacokinetics of valproate, 2 earlier case reports showed conflicting results; one[2] described increased serum-valproate concentrations, and the other[3] decreased concentrations, when risperidone was added to valproate therapy. For the effect of valproate on *clozapine*, see p.984.

1. Ravindran A, *et al.* Risperidone does not affect steady-state pharmacokinetics of divalproex sodium in patients with bipolar disorder. *Clin Pharmacokinet* 2004; **43:** 733–40.

3. Bertoldo M. Valproic acid and risperidone. *J Am Acad Child Adolesc Psychiatry* 2002; **41:** 632.

Antivirals. There have been 2 reports that describe a reduction in plasma-valproate concentrations in HIV-positive patients who were taking valproate for bipolar disorder and were given *efavirenz* in one case[1] and *ritonavir-boosted lopinavir* in another,[2] resulting in mania. However, an earlier study[3] in a small number of HIV-positive patients did not find any clinically significant interactions between these drugs and valproic acid. For the effect of *aciclovir* on valproate, see under Interactions of Phenytoin, p.499.

For the effect of valproate on *zidovudine*, see p.915.

Anxiolytics. For interactions between valproate and *benzodiazepines*, see under Diazepam, p.990. For an interaction between valproate and *zolpidem*, see p.1038.

Calcium-channel blockers. For the effect of sodium valproate on *nimodipine*, see under Nifedipine, p.1353.

Colestyramine. Colestyramine may decrease the absorption of valproate.

Gastrointestinal drugs. Use with an *antacid* (aluminium and magnesium hydroxides) significantly increased the bioavailability of a valproic acid preparation in healthy subjects;[1] other antacids in this study (calcium carbonate and an aluminium magnesium trisilicate mixture) had a lesser, insignificant effect.

Cimetidine significantly increased the half-life and decreased the clearance of sodium valproate in another study;[2] *ranitidine* had no effect on valproate pharmacokinetics.[2]

These interactions have not been reported to be of clinical significance, although the possibility must exist, particularly in patients on high-dose therapy.

2. Webster LK, *et al.* Effect of cimetidine and ranitidine on carbamazepine and sodium valproate pharmacokinetics. *Eur J Clin Pharmacol* 1984; **27:** 341–3.

Ginkgo biloba. For a report of a fatal breakthrough seizure occurring when phenytoin and valproate semisodium were used with ginkgo biloba, see under Phenytoin, p.500.

Sex hormones. A 26-year-old woman who was taking valproate for epilepsy and a combined *oral contraceptive* had lower serum-valproate concentrations and an increase in seizure frequency during the active pill phase when compared with the inactive pill phase.[1] A subsequent study[2] in 9 epileptic women who were taking valproate and a combined oral contraceptive found that the apparent oral clearance of total and unbound valproic acid increased during contraceptive intake compared with the pill-free interval; the authors suggested that this effect was due to the induction of glucuronidation of valproate by ethinylestradiol.

1. Herzog AG, *et al.* Serum valproate levels with oral contraceptive use. *Epilepsia* 2005; **46:** 970–1.
2. Galimberti CA, *et al.* Increased apparent oral clearance of valproic acid during intake of combined contraceptive steroids in women with epilepsy. *Epilepsia* 2006; **47:** 1569–72.

Pharmacokinetics

Valproic acid and its salts are rapidly and completely absorbed from the gastrointestinal tract; the rate, but not the extent, of absorption is delayed if given with or after food.

Valproic acid is extensively metabolised in the liver, a large part by glucuronidation and the rest by a variety of complex pathways. It does not appear to enhance its own metabolism, but metabolism may be enhanced by other drugs that induce hepatic microsomal enzymes. It is excreted in the urine almost entirely in the form of its metabolites; small amounts are excreted in faeces and expired air.

Valproic acid is extensively bound to plasma proteins. The extent of protein binding is concentration dependent and is stated to be about 90 to 95% at total concentrations of 50 micrograms/mL, falling to about 80 to 85% at 100 micrograms/mL. Reported half-lives for valproic acid have ranged from about 5 to 20 hours; the shorter half-lives have generally been recorded in epileptic patients receiving multiple drug therapy. Clearance is usually higher in children than in adults.

The 'target' range of total plasma-valproic acid is usually quoted as being 40 to 100 micrograms/mL (280 to 700 micromoles/litre) but routine monitoring of plasma concentrations is not generally considered to be of use as an aid to assessing control.

Valproic acid crosses the placental barrier and small amounts are distributed into breast milk.

Valpromide is an amide derivative of valproic acid and its absorption is slower and its bioavailability somewhat less than that of valproic acid. Valpromide is rapidly and almost completely metabolised in the liver to valproic acid.

The pharmacokinetics of valproate are affected by other antiepileptics (see under Interactions, above).

Uses and Administration

Valproate is an antiepileptic used particularly in the treatment of primary generalised seizures, has notable benefit in absence and myoclonic seizures, and is also used for partial seizures. Its actions are complex and its mode of action in epilepsy is not fully understood. Valproate is also used to treat the acute manic phase of bipolar disorder and for the prophylaxis of migraine.

Forms used include the sodium salts (valproate semisodium and sodium valproate), the amide derivative (valpromide), and valproic acid. Magnesium valproate has also been tried as has calcium valproate. Valproate should preferably be taken with or after food.

In the treatment of **epilepsy** the dose should be adjusted to the needs of the individual patient to achieve adequate control of seizures. Plasma concentrations of valproate (see Pharmacokinetics, above) are not considered to be a useful index of efficacy and thus their routine monitoring is generally not helpful.

- A suggested initial *oral* daily dose of ***sodium valproate*** is 600 mg given in 2 divided doses. The daily dose may be increased by 200 mg every 3 days to a usual range of 1 to 2 g daily (20 to 30 mg/kg daily); up to a maximum of 2.5 g daily may be necessary if adequate control has not been achieved.

  When oral dosage is not possible, sodium valproate may be given *intravenously* to start therapy or to continue therapy previously given orally. A suggested dose to *begin* therapy is up to 10 mg/kg by intravenous injection over 3 to 5 minutes followed by intravenous infusion, as necessary, up to a maximum of 2.5 g daily. To *continue* therapy intravenously, doses are the same as the patient's previous oral dose. In the USA, intravenous sodium valproate is given in doses equivalent to those used orally for valproic acid (see below).

- A suggested initial oral dose of ***valproic acid*** is 10 to 15 mg/kg daily increased at one-week intervals by 5 to 10 mg/kg. The maximum recommended dose of valproic acid in the UK is 30 mg/kg daily whereas in the USA it is 60 mg/kg daily. Valproic acid may be given in 2 to 4 divided doses.
- ***Valproate semisodium*** is given orally in doses equivalent to those used for oral valproic acid (see above).
- The amide derivative of valproic acid, ***valpromide***, is also used in some countries. Usual oral doses have ranged from 600 mg to 1.8 g daily, in divided doses.

For details of valproate doses in children, see below.

As with other antiepileptics, withdrawal of valproate or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

In the treatment of acute manic episodes of **bipolar disorder**, the initial oral dose of ***valproate semisodium*** is the equivalent of valproic acid 750 mg daily in 2 to 3 divided doses. Thereafter, the dose is increased as rapidly as possible to achieve the optimal response, up to a maximum of 60 mg/kg daily. Patients receiving doses higher than 45 mg/kg daily should be carefully monitored. ***Valpromide*** has also been used in some countries for bipolar disorder in doses similar to those for epilepsy (see above).

In the prophylaxis of **migraine** valproate semisodium is given orally in a dose equivalent to valproic acid 250 mg twice daily; up to 1 g daily may be necessary in some patients.

Action. The actions of valproate are complex and not well understood. As well as enhancing central GABAergic neurotransmission and inhibiting neuronal sodium channels, it affects cellular signalling systems such as the Wnt/β-catenin and extracellular signal-regulated kinase (ERK) pathways, and has actions on inositol and arachidonate metabolism. In addition it has potent effects on transcription of a number of genes, mediated at least in part by its action as a direct histone deacetylase inhibitor. It is probable that its clinical effects in different disorders depend on a combination of such properties.[1]

1. Rosenberg G. The mechanisms of action of valproate in neuropsychiatric disorders: can we see the forest for the trees? *Cell Mol Life Sci* 2007; **64:** 2090–2103.

Administration in children. Valproate is used as an antiepileptic in children in the treatment of primary generalised seizures, notably for absence and myoclonic seizures, and also for partial seizures. Available forms include the sodium salts (valproate semisodium and sodium valproate) or as valproic acid. The *BNFC* suggests that sodium valproate may also be used for infantile spasms.

A suggested initial *oral* dose of ***sodium valproate*** for children weighing over 20 kg is 400 mg daily (irrespective of weight) in 2 divided doses. This may be gradually increased to a usual dose of 20 to 30 mg/kg daily; up to a maximum of 35 mg/kg daily may be necessary if adequate control has not been achieved. Children weighing under 20 kg may be given 20 mg/kg daily in 2 divided doses, which may be increased to 40 mg/kg daily or more if necessary (but see below). Alternatively the *BNFC* suggests the following *oral* or *rectal* doses, given according to age:

- neonates: initially 20 mg/kg once daily followed by a usual maintenance dose of 10 mg/kg twice daily
- 1 month to 12 years: initially 5 to 7.5 mg/kg twice daily followed by a usual maintenance dose of 12.5 to 15 mg/kg twice daily; up to 30 mg/kg twice daily may be given for infantile spasms (but see below)
- over 12 years: usual adult doses (see above)

When used rectally, the *BNFC* recommends that sodium valproate oral solution may be used and retained for 15 minutes; dilution with water may be required, if necessary.

When oral dosage is not possible, sodium valproate is licensed for use *intravenously* to start therapy or to continue therapy previously given orally. The usual dose is in the range of 20 to 30 mg/kg daily by intravenous injection over 3 to 5 minutes or by infusion; up to 40 mg/kg daily or more may be necessary if adequate control is not achieved (but see below). When switching from oral to intravenous therapy, the intravenous dose should be the same as the established oral dose.

Alternatively, the *BNFC* suggests giving neonates, children, and adolescents up to 18 years of age 10 mg/kg twice daily by intravenous injection; those aged from 1 month to 12 years may also be given 10 mg/kg initially by intravenous injection, followed by continuous infusion of 20 to 40 mg/kg daily, and older children may be given the usual adult doses (see above).

When a dose over 20 mg/kg daily is given, regardless of route, it is recommended that plasma-valproate concentrations should be monitored. If the dose exceeds 40 mg/kg daily, the patient's clinical chemistry and haematological parameters should also be monitored.

The *BNFC* states that children of all ages may be given ***valproic acid*** in doses as for sodium valproate (see above). In the USA, valproic acid is only licensed for children aged 10 years and older, who may be given the adult dose.

In the USA, ***valproate semisodium*** may also be given to children aged 10 years and over in the usual adult doses (see above) for the treatment of epilepsy.

Bipolar disorder. Valproate, usually as valproate semisodium, is increasingly being used as an alternative to lithium in patients with bipolar disorder (p.372).[1-9] Most guidelines consider it to be a first-line alternative to lithium particularly in those who have rapid cycling disease with 4 or more affective episodes a year or in those with mixed or dysphoric states. However, a study[9] failed to show particular benefit in rapid cycling disease, and systematic reviews considered that any shift in prescribing practice in favour of valproate was not based on reliable evidence of efficacy,[10] although it was effective in acute mania.[8]

Cushing's syndrome. Sodium valproate has been used in the management of Cushing's syndrome (p.2344).

Epilepsy. Valproate is one of the drugs of choice in partial seizures, primary generalised tonic-clonic seizures, absence seizures, and myoclonic seizures (see p.465), although evidence for some of these is lacking. It is also the drug of choice in epileptic syndromes such as the Lennox-Gastaut syndrome because of its wide therapeutic spectrum, and it may be useful in tonic or atonic seizures and infantile spasms.

Extrapyramidal disorders. Valproate is one of several drugs with GABAergic action that has been tried in the management of tardive dyskinesia (see under Extrapyramidal Disorders on p.971).

Febrile convulsions. Sodium valproate has been used prophylactically in children thought to be at risk of recurrence of febrile convulsions (p.470), but routine use of antiepileptics is no longer recommended.

Headache. Valproate, as valproate semisodium, may be used for the prophylaxis of *migraine* (p.616) in patients refractory to drugs such as propranolol.[1-7] Valproate has also been shown to be effective and well-tolerated for the prophylaxis of migraine in children aged between 7 and 16 years.[8,9] Intravenous valproate has been tried in the treatment of acute migraine but a review[10] concluded that its use could not be recommended. To date, published studies had mostly been small, open-label, and non-placebo controlled and had used variable doses. Valproate had not been shown to be superior to other antimigraine drugs and had been inferior to prochlorperazine in one study.

Valproate has also been tried in the prophylaxis of persistent chronic daily headache including *tension-type headache* (p.617) unresponsive to other drugs.[11]

It has also been tried for prevention of *cluster headache* (p.616).

Hiccup. Valproic acid may be of value in the treatment of intractable hiccups,[1] especially those of neurogenic origin. For the management of intractable hiccups see under Chlorpromazine, p.976.

1. Jacobson PL, *et al.* Treatment of intractable hiccups with valproic acid. *Neurology* 1981; **31:** 1458–60.

HIV infection and AIDS. As mentioned under Precautions, above, valproate appears to induce replication of HIV, and this effect has been used to reduce latent, and therefore treatment-resistant, HIV-infection in resting CD4+ T-cells. In a preliminary study,[1] 4 HIV-positive patients on HAART were started on the fusion inhibitor enfuvirtide to intensify their HIV treatment and prevent viral spread due to valproate; oral valproic acid (500 to 750 mg twice daily) was then introduced a few weeks later and continued for 3 months. In 3 of these patients, the frequency of latent infection in resting T-cells significantly declined after enfuvirtide and valproate treatment when compared with pretreatment values. However, a later study[2] found the levels of latently infected T-cells in 9 HIV-positive patients receiving HAART and oral valproic acid for at least 3 months to be similar to those of patients receiving HAART alone. A case report[3] also described rapid rebound viraemia occurring in a 54-year-old man when HAART and sodium valproate were stopped after more than 2 years of therapy, suggesting little benefit in eradicating latent infection.

Malignant neoplasms. Valproate appears to have anti-tumour activity, thought to be mediated through the inhibition of cellular histone deacetylase. It has been tried[1-6] usually as an adjunct to other antineoplastics in the treatment of various malignancies, with some reported benefit.

Migraine. See under Headache, above.

Muscle spasm. The mainstay of management of *spasticity* is physiotherapy and an antispastic drug (see p.1887). Valproate has been tried for its GABAergic activity and case reports[1] of 4 patients with spastic conditions of various aetiologies indicated that the addition of valproate to the existing regimen of antispastic drugs might produce improvements in spasticity and pain; further studies are warranted.

Valproate has also been tried[2] in the management of *stiff-man syndrome* (see under Muscle Spasm, p.993) unresponsive to diazepam.

1. Zachariah SB, *et al.* Positive response to oral divalproex sodium (Depakote) in patients with spasticity and pain. *Am J Med Sci* 1994; **308:** 38–40.
2. Spehlmann R, *et al.* Improvement of stiff-man syndrome with sodium valproate. *Neurology* 1981; **31:** 1162–3.

Myoclonus. Valproate is used alone or in combination with clonazepam for cortical myoclonus (see p.470).

Neuropathic pain. Although carbamazepine is the drug of choice in the treatment of *trigeminal neuralgia* (p.9), sodium valproate is an alternative antiepileptic that may be used in carbamazepine-intolerant patients. Valproate has also been tried, with some success, in painful *diabetic neuropathy*[1] (p.6), *postherpetic neuralgia*[2] (p.9), and neuropathic *cancer pain*[3] (p.5). However, a placebo-controlled study[4] did not find any benefit with valproate therapy in the treatment of pain in diabetic and nondiabetic polyneuropathy.

4. Otto M, *et al.* Valproic acid has no effect on pain in polyneuropathy: a randomized, controlled trial. *Neurology* 2004; **62:** 285–8.

Psychiatric disorders. Valproate has psychotropic properties and has been used in the management of bipolar disorder (see above) and in some countries as a mood stabiliser for augmentation of antidepressant therapy in the treatment of resistant depression (p.373). Valproate has also been tried in various disorders for the control of symptoms such as agitation, aggression, and rage[1,2] (see Disturbed Behaviour, p.954). However, a systematic review of the use of valproate for agitation in dementia found no convincing evidence of efficacy at low doses, and adverse effects may be unacceptable at higher doses.[3] Valproate has also been reported[4,5] to be efficacious as adjunctive therapy to antipsychotics, but again, systematic review[6] has thrown doubt upon its effectiveness. It has also been tried in anxiety disorders such as panic disorder[7-9] (p.952), and post-traumatic stress disorder[10,11] (p.953).

Status epilepticus. Valproate has been used in *absence* status epilepticus once the initial attack has been brought under control with intravenous benzodiazepines[1] and has been considered to be the drug of choice to prevent its recurrence.[2] Its place in the management of *convulsive* status epilepticus (p.469) is less clear, but it has been tried, mainly as a second- or third-line drug in benzodiazepine-refractory patients,[3-12] and some centres have included it in management protocols.[5]

BP 2008 (Vigabatrin). A white to almost white powder. Very soluble in water.

Adverse Effects, Treatment, and Precautions

About half of all patients experience adverse effects with vigabatrin. The most common are drowsiness and fatigue, although in children excitation and agitation occur more frequently. The incidence of these effects is generally higher at the start of therapy and decreases over time. Other CNS-related adverse effects include dizziness, headache, ataxia, paraesthesia, tremor, impaired concentration, confusion, and memory disturbances. Other reported adverse effects include weight gain, gastrointestinal disturbances, oedema, alopecia, angioedema, urticaria, and skin rash. Haemoglobin and liver enzyme values may be decreased. Rarely marked sedation, stupor and confusion, together with other symptoms suggestive of encephalopathy, have occurred.

About one-third of all patients receiving vigabatrin have developed irreversible visual field defects, ranging from mild to severe and usually occurring after months or years of therapy. Blurred vision, diplopia, or nystagmus are somewhat less common. Retinal disorders such as peripheral retinal atrophy, or very rarely optic neuritis or atrophy have also been reported (see also below). Visual field function should be assessed before beginning treatment and during routine follow-up (ideally at 6-month intervals), and patients should be warned to report any new visual symptoms that develop during therapy. Vigabatrin should not be used in patients with pre-existing visual field defects.

Psychiatric reactions such as agitation, aggression, irritability, nervousness, depression, and paranoid reactions have occurred in patients with or without a psychiatric history; psychosis, hypomania, or mania have been reported rarely. Patients receiving vigabatrin should be observed carefully for any signs of adverse effects on neurological function. Caution is warranted in patients with a history of psychosis, depression, or behavioural problems.

Vigabatrin may exacerbate myoclonic or absence seizures.

Vigabatrin should be given with caution to the elderly and patients with renal impairment.

Care is required when withdrawing vigabatrin therapy—see also Uses and Administration, below.

Breast feeding. Licensed product information states that breast feeding is not recommended in women receiving vigabatrin. For comment on antiepileptic therapy and breast feeding, see p.467.

Driving. For a comment on antiepileptic drugs and driving, see p.468.

Particular care should be taken in view of the possible effects of vigabatrin on visual acuity.

Effects on bone. For the effects of antiepileptics, including vigabatrin, on bone and on calcium and vitamin D metabolism, see under Phenytoin, p.496.

Effects on the eyes. A report of 3 patients who developed bilateral severely constricted visual fields 2 to 3 years after vigabatrin was added to their antiepileptic regimens[1] prompted publication of similar anecdotal reports.[2-5] Peripheral retinal atrophy rather than optic nerve damage appeared to be the cause. Symptoms showed no improvement on stopping the drug, although there was no further deterioration. At that time (1997) the manufacturers replied[6] stating that it was a rare occurrence (less than 0.1%) and was being monitored in further clinical studies. The UK CSM subsequently stated[7] (in March 1998) that it had received 41 reports of visual field defects since December 1989, which persisted in most cases despite stopping treatment. The evidence suggested that the onset of symptoms varied from 1 month to several years after starting vigabatrin. In most cases, visual field defects have persisted despite stopping vigabatrin.[8,9] Interim results of a Prescription Event Monitoring Study[10] in the UK stated that vigabatrin was considered to be probably or possibly associated with objective evidence of a visual field defect in 0.2% of patients. However, subsequent evidence appears to have confirmed that the incidence of visual field defects is much higher;[11-14] revised product literature issued in late 1999 indicated that visual field defects occurred in about one-third of all patients receiving vigabatrin. Male patients appear to be at an increased risk of developing defects.[15,16] Whether cumulative dose may be considered a risk factor remains unclear.[16,17]

The CSM considered[14] that vigabatrin should only be prescribed by a specialist, and only where all other combination therapies have failed. Ophthalmological consultation and visual field assessment should be undertaken before starting vigabatrin and visual field screening repeated at 6-monthly intervals during treatment. Conventional perimetry is unsuitable in patients under 9 years of age, in whom alternative methods should be employed. Opinion amongst some paediatricians[18] was that the risk of developing visual field defects had to be weighed against the potential benefit of seizure control. In very young patients, in whom monitoring of vision was impossible, the benefits of vigabatrin in the treatment of infantile spasms were felt by some to outweigh this risk.[19]

Vigabatrin should not be used in patients with pre-existing visual field defects.[14,18]

Effects on the liver. Vigabatrin has demonstrated *in-vivo* and *in-vitro* inhibition of plasma-alanine transaminase activity, which may mask signs of early underlying hepatic disease if only transaminase levels are evaluated.[1]

1. Richens A, *et al.* Evidence for both in vivo and in vitro interaction between vigabatrin and alanine transaminase. *Br J Clin Pharmacol* 1997; **43:** 163–8.

Effects on mental function. *Behavioural disturbances* ranging from irritability and confusion to psychotic reactions have been reported in patients receiving vigabatrin.[1-7] An analysis[8] of adverse effect reports from double-blind controlled studies found that the incidence of psychotic reactions was about 2.5% in vigabatrin-treated patients; however, the most common psychiatric reaction was depression, which occurred in 8 to 12% of patients. Symptoms of psychiatric disturbance were often relatively mild. Psychiatric reactions are generally reversible when doses are reduced or gradually stopped. In 2 patients[9,10] psychosis developed after sudden withdrawal of vigabatrin; mental state improved when the drug was reinstated. It is not clear whether patients with a history of previous psychiatric disturbances are at greater risk when given vigabatrin.[8,11] Also, using low doses of vigabatrin to start therapy did not reduce the incidence of disturbances.[11]

The problems of antiepileptic therapy adversely affecting *cognition* and *mood* (including the risk of suicidal ideation) are discussed on p.468.

Effects on the nervous system. Two patients developed disturbances of motor behaviour associated with the addition of vigabatrin to therapy for intractable seizures.[1]

Acute encephalopathy was reported[2] in two patients after starting vigabatrin in addition to carbamazepine; symptoms of stupor, dysphoria, and irritability were present in both and their EEG background activity was slowed. Clinical symptoms could not be related to intoxication with carbamazepine or its epoxide but it was not known whether an interaction between carbamazepine and vigabatrin had caused the acute encephalopathy. Acute encephalopathy was also reported[3] when vigabatrin was given to a 6-month-old girl who was also receiving phenobarbital. Symptoms resolved when vigabatrin was stopped. In another report[4] vigabatrin was associated with the development of encephalopathy in 3 patients already receiving a variety of antiepileptic drugs other than carbamazepine; withdrawal of vigabatrin led to full recovery. The authors suggested that acute encephalopathy after vigabatrin may be related to a pre-existing cerebral abnormality. Other predisposing factors suggested by licensed product information include higher than recommended initial doses, faster dose increases at greater increments than those recommended, and renal failure.

Overdosage. For a review of the features and management of poisoning with some antiepileptics such as vigabatrin, see under Phenytoin, p.497.

Porphyria. For comment on the use of vigabatrin in porphyria, see p.471.

Pregnancy. For comments on the management of epilepsy in pregnancy, see p.468.

Little is known of the effects of newer antiepileptics such as vigabatrin on the fetus, although congenital anomalies have been reported in the offspring of some mothers using vigabatrin during pregnancy.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy.

Antiepileptics. For the effect of vigabatrin on plasma concentrations of other antiepileptics, see *Carbamazepine*, p.474; *Phenobarbital*, p.493; *Phenytoin*, p.498; and *Primidone*, p.503.

Pharmacokinetics

Vigabatrin is well absorbed after oral doses of the racemate; the inactive *R*(–)-enantiomer is reported to be present at much higher plasma concentrations than the active *S*(+)-enantiomer, perhaps indicating a difference in bioavailability. About 60 to 80% of an oral dose is excreted in urine as unchanged drug. The elimination half-life is reported to be 5 to 8 hours. Vigabatrin is not significantly bound to plasma proteins.

There does not appear to be any correlation between plasma concentrations of vigabatrin and its efficacy or toxicity. Children exhibit a lower area under the concentration-time curve than adults and may need higher doses to achieve therapeutic plasma concentrations.

Vigabatrin crosses the placenta and is distributed into breast milk.

Uses and Administration

Vigabatrin is an analogue of gamma-aminobutyric acid (GABA) that acts as an irreversible inhibitor of GABA-transaminase, the enzyme responsible for the catabolism of GABA. It is used as an adjunctive antiepileptic in patients with resistant partial epilepsy with or without secondary generalisation, unresponsive to other therapy. It is also used as monotherapy for infantile spasms (as for example in West's syndrome).

The recommended initial oral dose of vigabatrin as adjunctive therapy is 1 g daily, increased, according to response and tolerability, in increments of 500 mg at weekly intervals to a maximum of 3 g daily.

Doses may be divided and given twice daily or taken as a single daily dose. Dosage reductions may be required in the elderly and in patients with renal impairment, particularly those with a creatinine clearance of less than 60 mL/minute.

For details of doses in children, see below.

As with other antiepileptics, withdrawal of vigabatrin therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465. Licensed product information recommends that the dose of vigabatrin should be gradually reduced over 2 to 4 weeks.

Administration in children. Vigabatrin is used as an adjunctive antiepileptic in children with resistant partial epilepsy with or without secondary generalisation, unresponsive to other therapy. It is also used as monotherapy for infantile spasms (as for example in West's syndrome).

The recommended initial oral dose of vigabatrin as *adjunctive therapy* is 40 mg/kg daily, as a single dose or in 2 divided doses. Maintenance doses are given according to body-weight as follows:

- 10 to 15 kg: 0.5 to 1 g daily
- 15 to 30 kg: 1 to 1.5 g daily
- 30 to 50 kg: 1.5 to 3 g daily
- over 50 kg: 2 to 3 g daily

Alternatively, the *BNFC* suggests giving the following oral doses according to age:

- neonates to 12 years: initially 15 to 20 mg/kg twice daily, increased over 2 to 3 weeks to a usual maintenance dose of 30 to 40 mg/kg twice daily; maximum 150 mg/kg daily
- 12 to 18 years: initially 1 g twice daily, increased over 2 to 3 weeks to a usual maintenance dose of 1 to 1.5 g twice daily

Vigabatrin has been given rectally; in the UK, the *BNFC* has suggested that children over 1 month old may be given the same rectal doses, calculated by age, as those used orally (see above). The commercially available oral powder should be dissolved in a small amount of water before use.

For *monotherapy* in infantile spasms, the recommended initial oral dose of vigabatrin is 50 mg/kg daily, adjusted according to response. Up to 150 mg/kg daily has been used. The *BNFC* suggests starting with 15 to 25 mg/kg twice daily, adjusted according to response over 7 days; the usual maintenance dose is 40 to 50 mg/kg twice daily (maximum of 75 mg/kg twice daily) for neonates and children up to 2 years of age.

Epilepsy. Vigabatrin is used in the treatment of epilepsy (p.465) as adjunctive therapy for refractory seizures. Reviews[1-3] of vigabatrin have considered it to be most effective in the treatment of complex partial seizures with or without secondary generalisation; it may, however, exacerbate myoclonic or absence seizures. Efficacy as adjunctive therapy in refractory partial seizures was shown by 2 multicentre studies[4,5] involving 228 patients (including 46 children) and a study[6] involving 52 patients being assessed for epilepsy surgery. However, in a follow-up study[7] of 120 patients who had participated in an open-label study of vigabatrin as adjunctive therapy for refractory epilepsy 6 to 8 years earlier, it was considered that vigabatrin had had only marginal benefit on the long-term prognosis of severe refractory epilepsy, despite favourable results from the original trial.

Vigabatrin is also of value in infantile spasms (as for example in West's syndrome). In an assessment of vigabatrin as monotherapy in 192 infants with infantile spasms who were followed up for an average of 7.6 months,[8] there was complete cessation of spasms in 131 patients, a decrease in cluster frequency in 37, and no improvement in 24 (including deterioration in 1 infant). A crossover study comparing vigabatrin with corticotropin in 42 infants found that both drugs produced some benefit;[9] a larger multicentre comparison of treatment with prednisolone and tetracosactide versus vigabatrin found that the former produced better initial control, but that the treatments were equivalent after more prolonged follow-up to 12 to 14 months of age.[10] A review of the literature suggested that vigabatrin was particularly effective in infantile spasms associated with tuberous sclerosis;[11] the authors considered that its efficacy might be less in other forms of infantile spasm.[11] A later guideline[12] also tentatively concluded that vigabatrin was effective in the short-term treatment of infantile spasms including those associated with tuberous sclerosis.

Metabolic disorders. Vigabatrin, an irreversible inhibitor of GABA-transaminase, has been tried in GABA metabolic disorders, with or without concurrent epilepsy,[1-5] with ambivalent results. Data from 23 case reports of patients with succinic semialdehyde dehydrogenase deficiency indicated that vigabatrin was clinically beneficial in only about one-third of patients.[4]

Zonisamide *(BAN, USAN, rINN)*

AD-810; CI-912; PD-110843; Zonisamida; Zonisamidum. 1-(1,2-Benzoxazol-3-yl)methanesulphonamide.

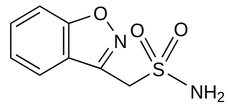
Зонизамид

$C_8H_8N_2O_3S = 212.2.$

CAS — 68291-97-4.

ATC — N03AX15.

ATC Vet — QN03AX15.



Adverse Effects

The most common adverse effects with zonisamide have included anorexia, gastrointestinal disturbances such as abdominal pain, diarrhoea, and nausea, somnolence, dizziness, headache, ataxia, depression, and agitation or irritability. Severe, sometimes fatal, skin reactions including Stevens-Johnson syndrome and toxic epidermal necrolysis have occurred rarely. There have been isolated reports of aplastic anaemia, agranulocytosis, thrombocytopenia, leucopenia, pancytopenia, and leucocytosis.

Other adverse effects have included renal calculi (see below), renal impairment, pancreatitis, rhabdomyolysis, abnormal liver function tests, psychosis, psychomotor slowing, reduced concentration, speech or language difficulties, paraesthesia, nystagmus, diplopia, weight loss, and fatigue. Reduced sweating with hyperthermia has occurred in children (see below).

Effects on mental function. For a review of the effects of antiepileptic therapy including zonisamide on *cognition* and *mood* (including the risk of suicidal ideation), see p.468.

Hyperthermia. Decreased sweating and hyperthermia have been reported in patients given zonisamide. By the end of December 2001 the manufacturers in the USA were aware of 40 such cases; of these, 38 had occurred in the first 11 years of marketing in Japan and 2 in the first year of marketing in the USA. Many cases were reported after exposure to high ambient temperatures and some progressed to heat stroke, but none had led to death.

The manufacturer noted that children appeared to be at an increased risk of developing these adverse reactions and should be monitored closely for such effects especially during warm or hot weather. Caution was also advised when zonisamide was given with other drugs known to cause similar effects, for example, carbonic anhydrase inhibitors and antimuscarinics.[1]

Renal calculi. Patients treated with zonisamide in the USA and Europe may have had a higher incidence of renal calculi than those treated in Japan. In one US study,[1] 4 of 113 patients (3.5%) receiving long-term treatment with zonisamide developed renal calculi, but a familial relationship was found for 2. In pooled data[2] from earlier studies, renal calculi had been reported in 13 of 700 patients (1.9%) treated in the USA and Europe compared with 2 of 1008 patients (0.2%) in Japan. Another review,[3] involving information from more than 750 patients, considered the risk of renal calculi in zonisamide-treated patients to be 5 to 9 times greater than that in the general population. However, a later study[4] that evaluated all safety data available at the time (from the US and European clinical trial programme and the manufacturer's postmarketing surveillance database) found the prevalence of symptomatic renal calculi to be low. There has been a report[5] of 3 patients who developed renal calculi associated with zonisamide but were able to continue therapy with hydration and/or citrate supplementation.

Precautions

Zonisamide is a sulfonamide derivative and is therefore contra-indicated in patients with a history of hypersensitivity to sulfonamides.

It should be used with care in patients with renal impairment; there is no data on safety in those with hepatic impairment. Zonisamide should be used with caution in patients who have risk factors for nephrolithiasis; adequate hydration is recommended to increase urine output, to try to reduce the risk of developing renal calculi, especially in predisposed patients.

Pancreatic lipase and amylase levels should be monitored in patients who develop pancreatitis and consideration should be given to withdrawing zonisamide. Patients who develop severe muscle pain or weakness, with or without fever, should have their serum creatine phosphokinase and aldolase levels assessed; if these are elevated, zonisamide may need to be withdrawn. A dietary supplement or increased food intake may be appropriate in patients who are losing weight or are underweight with zonisamide; withdrawing zonisamide may be warranted in those with substantial undesirable weight loss. Consideration should be given to withdrawing zonisamide in patients who develop unexplained rash.

Care is required when withdrawing zonisamide therapy—see also Uses and Administration below.

Breast feeding. Zonisamide is distributed into breast milk;[1] in view of the potential for serious adverse effects in infants from zonisamide, licensed product information recommends that it should only be used in nursing mothers if the benefits outweigh the risks. It is also recommended that breast feeding must not be resumed until 1 month after stopping zonisamide therapy. For comment on antiepileptic therapy and breast feeding, see p.467.

Interactions

There are complex interactions between antiepileptics and toxicity may be enhanced without a corresponding increase in antiepileptic activity. Such interactions are very variable and unpredictable and plasma monitoring is often advisable with combination therapy. Use with drugs that induce or inhibit the cytochrome P450 isoenzyme CYP3A4 may alter plasma concentrations of zonisamide. Carbamazepine, phenytoin, or phenobarbital reduce the half-life of zonisamide; reductions have also been noted with valproate but to a lesser degree.

The use of zonisamide with other drugs that cause nephrolithiasis should be avoided because of the increased risk of developing renal calculi (see under Adverse Effects, above). Caution is advised when zonisamide is used with other drugs known to cause heat-related disorders because of the increased risk of developing hyperthermia (see Adverse Effects, above).

◊ References.

Pharmacokinetics

Zonisamide is almost completely absorbed from the gastrointestinal tract and peak plasma concentrations are achieved within 2 to 6 hours of oral doses. Bioavailability is essentially complete; the presence of food does not affect the bioavailability of zonisamide but the time to reach peak plasma concentrations is delayed. Steady-state concentrations are achieved within 14 days. It is widely distributed into body tissues. Plasma protein binding is low (40 to 50%) but zonisamide is extensively bound to erythrocytes. The plasma elimination half-life is about 63 hours.

Zonisamide undergoes acetylation to *N*-acetylzonisamide and reduction mediated by the cytochrome P450 isoenzyme CYP3A4 to 2-sulfamoylacetylphenol (SMAP); both metabolites are inactive. Excretion is mainly in the urine; about 15 to 30% appearing as

The symbol † denotes a preparation no longer actively marketed

unchanged drug, 15% as *N*-acetylzonisamide, and 50% as the glucuronide of SMAP.

Zonisamide crosses the placenta and is distributed into breast milk.

The pharmacokinetics of zonisamide are affected by use with other antiepileptics (see under Interactions, above).

Uses and Administration

Zonisamide, a benzisoxazole derivative, is used as an adjunctive antiepileptic in the treatment of partial seizures, with or without secondary generalisation.

In the UK, the usual initial oral dose in adults over 18 years of age is 50 mg daily in 2 divided doses, increased after 1 week to 100 mg daily. Thereafter, the dose may be further increased at weekly intervals by increments of up to 100 mg, to a usual dose of 300 to 500 mg daily, although some patients may respond to lower doses. Dose increments at intervals of 2 weeks should be considered in patients with hepatic or renal impairment and in patients who are not receiving CYP3A4 inducers (see also Interactions, above). Zonisamide may be given as a single dose or in 2 divided doses after the titration phase.

In the USA, the usual initial oral dose in patients over 16 years of age is 100 mg daily, increased after at least 2 weeks to 200 mg daily, given as a single dose or in 2 divided doses. Thereafter, if necessary, the dose may be further increased at intervals of at least 2 weeks by increments of 100 mg, to a dose of 400 mg daily. Doses up to 600 mg daily have been used, but there is no current evidence of an increase in response above 400 mg daily; many of the adverse effects of zonisamide are reported to be more frequent at doses of 300 mg daily and above.

As with other antiepileptics, withdrawal of zonisamide therapy or transition to or from another type of antiepileptic therapy should be made gradually to avoid precipitating an increase in the frequency of seizures; UK licensed product information has suggested that the dose may be decreased in steps of 100 mg at weekly intervals. For a discussion on whether or not to withdraw antiepileptic therapy in seizure-free patients, see p.465.

Bipolar disorder. Zonisamide may have psychotropic properties, and has been tried in the management of bipolar disorder (p.372).

Epilepsy. Zonisamide is used in the treatment of refractory epilepsy (p.465). Many studies have been conducted in Japan where clinical experience demonstrated its efficacy mainly in the treatment of partial seizures with or without secondary generalisation.[1,2] Data from studies[3-6] conducted outside Japan have confirmed the efficacy of zonisamide as an adjunct in the treatment of partial epilepsies. Efficacy in primary generalised and mixed-seizure epilepsies appears to be more variable, although it may be of value in refractory myoclonic seizures[7] and absence seizures.[8] Retrospective cohort studies[9,10] have also found that zonisamide may have efficacy as monotherapy. Zonisamide might also be of use in the treatment of epileptic syndromes such as Lennox-Gastaut syndrome,[11] and infantile spasms (as for example in West's syndrome), although only a small number of patients with the latter condition have been studied.[12,13]

Obesity. Anorexia and weight loss have been associated with zonisamide therapy (see Adverse Effects, above) and it has been tried, with some success, as an adjunct in the treatment of obesity[1,2] (p.2149); it has also been tried in binge-eating disorder associated with obesity.[3] Combination with bupropion (p.383) is under investigation.[2]

This chapter describes the drugs that are used mainly in the treatment and prophylaxis of fungal infections (mycoses). They include:

- the azole derivatives, including:
  - imidazoles (such as ketoconazole)
  - triazoles (such as fluconazole, itraconazole, posaconazole, and voriconazole)
- the allylamines (naftifine and terbinafine)
- the echinocandins (such as caspofungin and micafungin)
- several polyene antibiotics (including amphotericin B and nystatin)
- other antifungal antibiotics (for example griseofulvin)
- other compounds such as amorolfine, ciclopirox olamine, flucytosine, haloprogin, tolnaftate, and undecenoic acid and its salts.

Choice of Antifungal

Fungi may be classified as yeasts or moulds according to their appearance and means of growth. Examples of yeasts are *Candida* and *Cryptococcus* spp., while moulds include *Aspergillus* spp., the dermatophytes, and the Mucorales fungi. Some fungi are termed dimorphic as they appear to be yeast-like in the host, but grow as moulds *in vitro*. Blastomycosis, chromoblastomycosis, coccidioidomycosis, histoplasmosis, paracoccidioidomycosis, and sporotrichosis are examples of diseases caused by dimorphic fungi.

Most fungi that are pathogenic in humans are saprophytic in nature, but cause infection when airborne spores reach the lungs or paranasal sinuses or are inoculated accidentally into the skin or cornea. Most fungal infections are therefore not transmissible between patients, with the exception of ringworm of the scalp. Endemic mycoses such as blastomycosis, coccidioidomycosis, histoplasmosis, and paracoccidioidomycosis are true pathogens and can cause disease in otherwise healthy persons. Other fungi, such as *Aspergillus*, *Candida*, *Cryptococcus*, and *Pneumocystis jirovecii* are of low pathogenicity and require an alteration in the normal defence mechanisms for disease to occur; such disease is called opportunistic. Fungal diseases are classified into 3 groups: the superficial, subcutaneous, and deep or systemic mycoses. **Superficial** infections are confined to the skin, hair, nails, or mucous membranes. **Subcutaneous** infections are largely limited to the subcutaneous tissue but may spread to surrounding bone and skin. **Deep or systemic** infections may involve organs such as the lung, spleen, or brain, or may affect the body as a whole, and tend to occur more frequently in immunocompromised patients. Fungal infections may also be described as **local** when they are restricted to one body area, as **invasive** when there is spread into the tissues, or as **disseminated** when the infection has spread from the primary site to other organs throughout the body.

Ideally antifungal treatment should be chosen after the infecting organism has been identified, but it is often necessary to start empirical treatment before the pathogen can be cultured and identified, especially in immunocompromised patients in whom infections are often rapidly progressive.

The choice of treatment for the important fungal diseases is described below.

Aspergillosis

Aspergillosis is an infection caused by fungi of the genus *Aspergillus*, usually *A. fumigatus*, although *A. flavus*, *A. nidulans*, *A. niger*, and *A. terreus* may occasionally be encountered. Aspergillosis is usually acquired by inhalation and most commonly causes non-invasive disease of the respiratory tract. Other sites of infection include the eye after trauma or cataract surgery. Tissue invasion adjacent to the site of infection and dissemination to distant organs may occur, predominantly in immunocompromised patients. In severely immunocompromised patients aspergillosis usually presents as a severe acute rapidly progressive lung disease. Other organs affected may include the heart (particularly damaged or prosthetic valves), kidneys, bone, brain, liver, and skin.

In general the response of **invasive** aspergillosis to treatment is poor and starting treatment early is essential. Surgical excision may be necessary. High intravenous doses of amphotericin B have traditionally been the antifungal of choice.[1] However, the overall response rate to conventional amphotericin B is reported to be only 30 to 35%; this may be improved by the use of liposomal amphotericin B.[2,3] Studies have shown voriconazole to be superior[4-6] to amphotericin B for the treatment of invasive aspergillosis and comparable[7] as empirical therapy for patients with persistent fever and neutropenia. Favourable responses with caspofungin have been reported in those with invasive disease[8] as well as in patients with persistent fever and neutropenia.[9] Intravenous or oral voriconazole is now the recommended treatment for invasive pulmonary aspergillosis.[1,10,11] Drugs that may be used for salvage therapy include itraconazole, posaconazole, caspofungin, micafungin, and lipid formulations of amphotericin B. Salvage therapy may also include combination therapy with the initial antifungal drug or combination therapy with antifungal drugs from classes other than that used in the initial treatment regimen.[11] A retrospective review of patients given salvage therapy with voriconazole plus caspofungin or voriconazole alone reported that 3-month survival was greater for the combination than for voriconazole alone.[12] Successful treatment for invasive aspergillosis was also described in 2 patients who received a combination of caspofungin and itraconazole.[13] Treatment for invasive pulmonary aspergillosis should be given for a minimum of 6 to 12 weeks; in immunosuppressed patients, it should be continued throughout the period of immunosuppression and until the lesions have cleared.[11]

In neutropenic patients with prolonged fever despite broad-spectrum antibacterial therapy, empirical treatment with amphotericin B or its lipid formulations, itraconazole, voriconazole, or caspofungin is recommended.[11]

Antifungal prophylaxis with posaconazole is recommended for haematopoietic stem cell transplant recipients with graft-versus-host disease and in patients with acute myeloid leukaemia or myelodysplastic syndromes who are at high risk for invasive aspergillosis. Itraconazole may be useful, but it is not well tolerated.[1,11,14]

Non-invasive forms of aspergillosis include allergic bronchopulmonary aspergillosis, a hypersensitivity reaction to *Aspergillus* usually occurring in asthmatic patients, and aspergilloma, a fungal mass or ball developing within a pre-existing pulmonary cavity or paranasal sinus. **Allergic bronchopulmonary aspergillosis** is usually treated with corticosteroids and oral itraconazole.[11,15] A systematic review[16] has concluded that itraconazole modifies the immunological activation associated with allergic bronchopulmonary aspergillosis in asthmatic patients and improves clinical outcome in the first 4 months of treatment. The treatment of **aspergilloma** depends on the severity of symptoms, and includes conservative management, antifungal therapy, or surgical resection. Treatment with itraconazole, voriconazole, and possibly also posaconazole are considered to have some benefit. Surgical resection and direct intracavitary instillation of antifungals may also be useful in selected patients with a single aspergilloma.[11]

Chronic necrotising pulmonary aspergillosis (CNPA or subacute invasive pulmonary aspergillosis)[17] is a subacute infection seen in patients with an underlying lung disease or systemic risk factors for immunosuppression. Various antifungals have been tried in the treatment of CNPA. Case reports have shown amphotericin B to be successful in about 50% of the patients and clinical benefit has also been achieved with intracavitary amphotericin B. Flucytosine has been used with or without amphotericin B. Itraconazole has a reported success rate of 70 to 90%. Treatment needs to be prolonged, so oral antifungals are preferred to parenteral antifungal therapy. Current evidence supports the use of itraconazole, with voriconazole and possibly also posaconazole as alternatives, for the treatment of CNPA.[11]

Aspergillosis of the **eye**, like other fungal eye infections, is difficult to treat; antifungals are generally not well absorbed after topical application and infections extending into the vitreous or anterior chamber require subconjunctival, intra-ocular, and/or systemic treatment. Systemic treatment is necessary for ocular manifestations of disseminated disease. Intravenous and intravitreal amphotericin B are recommended for the treatment of *Aspergillus* endophthalmitis; intravitreal or systemic voriconazole may be given as an alternative. For the management of *Aspergillus* keratitis topical antifungal therapy plus systemic antifungal therapy with either amphotericin B, voriconazole, or itraconazole is recommended.[11] For superficial eye infections a number of drugs including natamycin, amphotericin B, azoles, and sulfadiazine silver have been applied topically alone or as an adjunct to systemic therapy. Surgical excision of infected tissue may be necessary in severe infections.

Blastomycosis

Blastomycosis (not to be confused with South American blastomycosis, see Paracoccidioidomycosis, below) is an infection caused by the fungus *Blastomyces dermatitidis*, which is endemic to much of North America. Inhalation of spores results in pulmonary infection which may be followed in 25 to 40% of patients by dissemination; the skin, skeleton, and genito-urinary system may become infected. While blastomycosis may affect anyone living in an endemic area, disseminated disease (including CNS involvement) is more common in immunocompromised patients.

Acute pulmonary infection may be mild and self-limiting in immunocompetent patients, but treatment should be considered in patients presenting with clinical symptoms. All patients with moderate to severe pneumonia or disseminated disease, and all immunocompromised patients require treatment.[1]

In immunocompetent patients, mild to moderate disease is treated with oral itraconazole; the duration of treatment is at least 6 months for pulmonary disease and 12 months for bone disease. Ketoconazole or fluconazole are less effective alternatives (and ketoconazole is more toxic); the role of voriconazole or posaconazole is not clear, although they may be effective. Patients unable to tolerate azoles or in whom disease progresses should be switched to amphotericin B. Life-threatening disease (either pulmonary or extrapulmonary) should be treated intravenously with a lipid or conventional formulation of amphotericin B; patients are usually switched to oral itraconazole once stabilised. All patients with CNS disease should be given a lipid formulation of amphotericin B intravenously for 4 to 6 weeks, followed by an oral azole; the options for the latter include fluconazole, itraconazole, or voriconazole. Oral treatment should be continued for at least 12 months and until resolution of abnormalities in the CSF.

In patients who are immunosuppressed, the recommended initial treatment is a lipid formulation of amphotericin B given intravenously for 1 to 2 weeks, or until improvement is noted. Once the patient has responded to this initial treatment they may be switched to oral itraconazole, which is continued until at least 12 months of therapy has been given. Life-long itraconazole treatment may be needed in patients in whom immunosuppression cannot be reversed, or in those who relapse despite appropriate therapy (a well-documented phenomenon in immunosuppressed patients).

In pregnant patients presenting with blastomycosis a lipid formulation of amphotericin B is recommended; azoles should be avoided because of possible teratogenicity. If the neonate shows signs of infection, treatment with a conventional (deoxycholate) formulation of amphotericin B is recommended. Children may be treated with amphotericin B or oral itraconazole, depending on the severity of infection; in general, they tolerate conventional amphotericin B better than adults, and lipid formulations may not be needed.

Candidiasis

Candida spp. are commensal fungi commonly found in the gastrointestinal tract, mouth, and vagina; they may become pathogenic when natural defence mechanisms are impaired. *C. albicans* is the species most commonly associated with infection although infections with other *Candida* spp., notably *C. glabrata* (*Torulopsis glabrata*), *C. krusei*, *C. lusitaniae*, *C. parapsilosis*, and *C. tropicalis*, also occur and together are commonly referred to as non-*albicans* species. Predisposing factors for candidiasis include antibacterial therapy, skin or mucosal breach, abdominal surgery, debility, diabetes mellitus, pregnancy, and neutropenia and T-cell immunodeficiency; candidiasis often occurs in patients with HIV infection.

Candidiasis (or candidosis) may be classified as mucocutaneous or superficial, invasive (deep-organ), or disseminated. **Mucocutaneous** candidiasis includes infections of the oropharynx, genital organs, and skin. Oropharyngeal and vulvovaginal candidiasis are commonly termed thrush. Most superficial infections may be effectively treated with topical antifungals, although the rare chronic mucocutaneous candidiasis syndrome usually requires systemic treatment. The choice of antifungal should be guided by the availability of an appropriate formulation for the site of infection, toxicity, and the duration of treatment.

Oropharyngeal candidiasis may be treated with topical clotrimazole, miconazole, or nystatin, or oral fluconazole. Alternatives are oral itraconazole or amphotericin B. Topical therapy may not be adequate in severely immunocompromised patients and oral azole therapy should be considered in these patients.[1-3] Intravenous amphotericin B or caspofungin are usually effective but only indicated in patients with refractory disease.[1-3] Oral posaconazole was found to be as effective as oral fluconazole in the treatment of oropharyngeal candidiasis in HIV-infected persons, but more effective than fluconazole is sustaining clinical benefit after treatment was stopped.[4]

Oesophageal infections are not normally accessible to topical therapy and oral or intravenous fluconazole or itraconazole are considered to be the drugs of choice. Severe or refractory disease may be treated with voriconazole, either intravenously or orally, or intravenous caspofungin or amphotericin B.[1-3,5]

Genital candidiasis responds well to topical antifungal treatment with creams or pessaries. Uncomplicated vaginitis responds to short-course topical therapy with azoles such as butoconazole, clotrimazole, econazole, fenticonazole, isoconazole, miconazole, terconazole, or tioconazole, to topical nystatin, or to oral therapy with fluconazole or itraconazole.[6,7] Complicated disease, which occurs in up to 10% of cases, requires at least 7 to 14 days of treatment with topical antifungals or an oral dose of fluconazole repeated 72 hours later.[1,6] Vulvovaginal candidiasis with non-*albicans* species may not respond to topical azoles, in which case topical boric acid or topical flucytosine are often effective.[1] In pregnancy, topical azoles are recommended[6,7] and appear to be more effective than nystatin;[8] treatment is given for 7 days. Recurrent vaginal candidiasis should be treated for at least 6 months.[6,7] In the USA,[6] initial treatment with a topical or oral azole is recommended. Some suggest that the duration of therapy be increased to 7 to 14 days for the topical products and that the oral dose of fluconazole may be repeated every 72 hours for a total of 3 doses. Recommended maintenance therapy is with oral fluconazole once weekly; alternative regimens are topical clotrimazole 200 mg twice weekly or 500 mg once weekly, or other topical treatments used intermittently. UK guidelines[7] recommend initial treatment with fluconazole 150 mg every 72 hours for 3 doses followed by maintenance treatment of 150 mg once weekly. Alternatively initial treatment may be with a topical azole product for 10 to 14 days, followed by maintenance with topical clotrimazole 500 mg once weekly, oral fluconazole 100 mg once weekly, or daily oral itraconazole or ketoconazole. Yogurt preparations containing *Lactobacillus* spp. have been used in the treatment and prevention of vaginal candidiasis in an attempt to restore the natural vaginal flora but evidence to support their use is limited.

Infection involving the **nails** and surrounding tissue is difficult to treat. Chronic paronychia (infection affecting the tissue around the nails) is often resistant to treatment but may respond to prolonged application of topical imidazoles or nystatin. Onychomycosis (infection affecting the nail itself) usually only responds to systemic antifungals. Treatment with oral itraconazole appears to be the most appropriate, although oral terbinafine has also been used.[1]

Primary *prophylaxis* against mucocutaneous candidiasis is not recommended for patients with advanced HIV infection since this may select for resistant *Candida* spp.[9] Due to similar concerns, secondary prophylaxis in immunocompromised patients with mucocutaneous candidiasis is largely restricted to those with frequent or severe recurrences, or those at risk of developing invasive disease, in which case oral fluconazole or itraconazole may be considered.[1,9]

Invasive and **disseminated** candidiasis require systemic antifungal treatment. Intravenous amphotericin B, with or without flucytosine, has traditionally been regarded as the standard initial treatment in most infections but flucytosine is now infrequently used because of concerns over its bone-marrow toxicity in AIDS patients. Fluconazole, caspofungin, and a combination of amphotericin B (for 5 to 6 days) and fluconazole have been shown to be effective and now offer alternatives for initial antifungal therapy. Fluconazole may be used as first-line for clinically stable patients with uncomplicated candidaemia who have not recently received treatment with an azole and is preferred for infections with *C. lusitaniae*. Amphotericin B is used for other non-*albicans* infections, although there is some evidence of resistance developing in *C. krusei* and *C. glabrata*. However, these species are susceptible to voriconazole and caspofungin and voriconazole may also be used as an alternative for fluconazole-resistant invasive *Candida* infections.[1] Neonates with disseminated candidiasis are usually best treated with amphotericin B, although fluconazole may also be effective.[1,10]

Empirical antifungal therapy may be appropriate for neutropenic patients. Drugs that may be considered include amphotericin B, itraconazole, or voriconazole. Fluconazole is unsuitable because of its restricted antifungal spectrum. The role of caspofungin is uncertain.[1] Treatment should generally be continued until signs and symptoms have resolved and the patient is no longer neutropenic. For empirical antifungal treatment in non-neutropenic patients, amphotericin B or fluconazole may be considered.[1]

Although antifungal *prophylaxis* is generally not routinely recommended for non-neutropenic patients, some would consider it appropriate in patients who are at high risk of infection such as patients who are critically ill, neutropenic, or receiving solid organ or bone marrow transplants.[1,11]

Chromoblastomycosis

Chromoblastomycosis (chromomycosis) is a chronic fungal infection that affects skin and subcutaneous tissue. It occurs worldwide but is more common in tropical and subtropical climates. Chromoblastomycosis may result from traumatic inoculation of a number of fungal species including *Fonsecaea compacta* (*Phialophora compacta*), *F. pedrosoi* (*P. pedrosoi*), *Exophiala spinifera*, *E. jeanselmei*, *Phialophora verrucosa*, *Cladosporium carrionii*, and *Rhinocladiella aquaspersa*. In its early stages, when lesions are small, surgical excision or cryotherapy are the treatments of choice, although there is some risk of dissemination during surgery. Many antifungals have been tried but itraconazole and terbinafine, often in high doses and for prolonged periods, have been the most successful. However, recurrence and drug resistance has been a problem with monotherapy. Itraconazole and terbinafine (given daily on alternate weeks or daily concomitantly for up to 9 months) have been shown to be effective in selected cases of chromoblastomycosis that were unresponsive to monotherapy. Local heat treatment aids healing and may be a useful adjunct.

Coccidioidomycosis

Coccidioidomycosis is an infection caused by inhalation of the spores of *Coccidioides immitis*, a fungus found in the soil in arid and semi-desert areas mainly of North, Central, and South America. Common names for the infection include valley fever, desert fever, and desert rheumatism. In endemic areas, coccidioidomycosis is a common opportunistic infection in immunocompromised patients.

Patients with coccidioidomycosis may experience acute or chronic lung infections, meningitis, and disseminated disease although many infections are subclinical. In immunocompetent individuals, acute pulmonary disease is usually mild and self-limiting and in 60% of cases resolves without specific chemotherapy. In some patients the infection progresses to chronic pulmonary coccidioidomycosis with granulomatous lesions, fibrosis, and cavitation. Less than 1% of patients develop acute progressive pneumonia (which is commonly fatal if untreated) or disseminated disease (usually involving the skin, bone, meninges, and joints). Severe pulmonary and disseminated infections are more likely in pregnant women, males, certain ethnic groups, diabetics, and immunocompromised patients.

Treatment is usually reserved for severe, progressive, or disseminated infections or for patients with concurrent risk factors, especially immunosuppression.[1,2] If antifungal therapy is given, it is preferably with an oral azole as initial therapy or with intravenous amphotericin B;[1,3] itraconazole and fluconazole are used most often, while voriconazole has been reported to be effective in some patients who have not responded to fluconazole.[4] Amphotericin B is generally used for rapidly progressive disease while azoles are generally preferred for chronic disease.[1,2] Although combination therapy with an azole and amphotericin B has been used, there is no evidence that it is superior to a single antifungal drug.[1] Diffuse pneumonia is most often seen in immunocompromised patients and treatment is initially with an azole or amphotericin B followed by maintenance treatment with an azole for a year or more. In immunocompromised patients it is advisable to continue treatment indefinitely.[4] Fluconazole is effective in meningeal infections and is the most frequently recommended antifungal for this indication,[1,2,4] although itraconazole has also produced beneficial responses; intrathecal amphotericin B may also be used, especially in aggressive infections.[1,2,5] Due to the high incidence of relapse, indefinite suppressive therapy with fluconazole or itraconazole is recommended for patients with coccidioidal meningitis or diffuse pulmonary coccidioidomycosis.[1] Patients with HIV infection and solid organ transplant recipients who have completed induction therapy should subsequently receive lifelong suppressive fluconazole or itraconazole.[2,6,7] It may, however, be possible to stop therapy in patients with CD4+ lymphocyte counts above 250 cells/microlitre (except in those with meningitis) if there is clinical evidence that the coccidioidal infection is controlled.[1] Primary prophylaxis for HIV-infected patients living in coccidioidomycosis-endemic areas is not routinely recommended.[1,6] However, primary prophylaxis may be considered for solid organ transplant recipients who are at risk of coccidioidal infection.[1,7]

Cryptococcosis

Cryptococcosis is an infection caused by inhalation of the fungus *Cryptococcus neoformans*. It is rare in immunocompetent individuals, but is an important life-threatening disease in immunocompromised patients, especially those with AIDS, in whom it occurs principally as cryptococcal meningitis.

Mild infections in immunocompetent patients may resolve without treatment, but oral fluconazole is usually effective if treatment is necessary.[1] Itraconazole is a suitable alternative in patients unable to take fluconazole. In either case, treatment should continue for several months. For more severe disease, amphotericin B may be given alone, or, if there is CNS involvement, with flucytosine. Patients may be switched to oral fluconazole after 2 weeks of induction therapy with amphotericin B and flucytosine or may continue on amphotericin B and flucytosine for 6 to 10 weeks.[1]

Cryptococcosis in immunocompromised patients other than those with HIV infection should be treated as for CNS infections in immunocompetent patients.[1]

HIV-infected patients who develop cryptococcosis always require treatment. Those with isolated pulmonary or urinary-tract disease may be treated with oral fluconazole or, if fluconazole is not an option, itraconazole.[1] A further alternative is combined treatment with fluconazole and flucytosine for 10 weeks followed by maintenance with fluconazole, although the toxicity of this regimen limits its usefulness. Those with more severe disease may be given intravenous amphotericin B until symptoms are controlled and then switched to oral fluconazole.[1-3] Patients with HIV infection who develop cryptococcal meningitis should receive induction therapy with intravenous amphotericin B and intravenous flucytosine.[1-3] Amphotericin B may be given alone in patients unable to tolerate flucytosine. In refractory cases, amphotericin B may be given intrathecally or intraventricularly. Oral fluconazole and intravenous flucytosine is an alternative to the use of amphotericin B but carries a high risk of toxicity. After induction, oral fluconazole should be given as consolidation therapy; if fluconazole cannot be given, itraconazole is a suitable though less effective alternative.[1-3]

Immunocompetent patients with CNS disease and immunocompromised patients (without HIV infection) may require 6 to 12 months of suppressive therapy with oral fluconazole after a primary course of antifungal therapy.[1] HIV-infected patients should generally receive lifelong maintenance therapy,[1-4] although it may be possible to stop secondary prophylaxis in patients who exhibit a sustained response to highly active antiretroviral therapy and who remain asymptomatic with regard to cryptococcosis. US guidelines[4] recommend restarting secondary prophylaxis if the CD4+ T lymphocyte count falls below 100 to 200 cells/microlitre.

Primary prophylaxis in patients with HIV infection is not generally recommended since it has not been shown to be more beneficial than treating cryptococcal infections when they occur and may increase the risk of resistance.[4]

Dermatophytoses

See under Skin Infections, below.

Endocarditis

Infective endocarditis caused by fungi such as *Aspergillus* or *Candida* is much less common than that caused by bacteria (p.168).

Mortality due to fungal endocarditis is high. Patients should be treated with antifungal therapy and in many cases surgical removal of an infected heart valve. Amphotericin B was most commonly used, usually alone but in some cases combined with flucytosine.[1-4] Alternatives for endocarditis caused by *Candida* spp. are fluconazole or caspofungin. Voriconazole may now be the drug of choice for endocarditis caused by *Aspergillus* spp.[4] Since relapse rates of up to 40% have been reported after stopping therapy, secondary prophylaxis is recommended with fluconazole, itraconazole, posaconazole, or voriconazole (depending on the susceptibilities of the infecting organism) for a minimum of 2 years and in some cases for life. Lifelong suppressive therapy is also given to patients who are not suitable candidates for valve replacement.[1-3,5]

Eye infections

Fungal infections of the eye are less common than infections with bacteria or viruses, but are usually severe and may lead to loss of vision. Diagnosis may be delayed due to a gradual onset of symptoms and empirical treatment with antibacterials. Patients with impaired host resistance such as diabetics or immunocompromised patients are particularly at risk. The most common fungi causing eye infections are *Aspergillus, Candida,* and *Fusarium*; others include *Blastomyces*, *Cryptococcus*, and *Sporothrix*. Corneal infection (keratitis) occurs most frequently, but the orbit, eyelids, lachrymal sacs, conjunctiva, sclera, and intraocular structures may also become infected. Infections of the orbit rarely occur spontaneously but are more common with systemic fungal infection or may spread from the adjacent paranasal sinus tissue, as seen in mucormycosis or aspergillosis.[1,2] Ocular fungal infections are difficult to treat. Diagnosis may be delayed due to a gradual onset of symptoms and empirical treatment with topical antibacterials or corticosteroids. Topical natamycin is generally considered the drug of choice for fungal keratitis due to filamentous fungi, while topical amphotericin B is an alternative. Topical amphotericin B with or without topical flucytosine, is preferred for yeast infections. Azoles exhibit a wide spectrum of activity and clotrimazole, fluconazole, itraconazole, ketoconazole, and miconazole are all used topically. Topical antifungals are not well absorbed and infections extending into the eye require subconjunctival, intra-ocular, or systemic therapy. Systemic treatment may also be indicated when there is a poor response to topical agents, for fungal endophthalmitis, or for ocular manifestations of disseminated fungal disease. When systemic treatment is indicated intravenous amphotericin B is usually given. Azoles may be given for less severe infections or as adjunctive therapy in severe infections. Oral fluconazole and ketoconazole have better penetration into the cornea, aqueous humour, and vitreous humour than itraconazole. Intravitreal injections may be required in infections unresponsive to systemic antifungals.[3,4] Surgical debridement or excision may be necessary if the infection progresses despite appropriate antifungal therapy.[1,2]

Histoplasmosis

Histoplasmosis is a systemic infection caused by *Histoplasma capsulatum*, a fungus found in the soil in endemic areas, particularly at sites with heavy accumulations of bird or bat excrement. Infection is by inhalation of spores. Two types of histoplasmosis occur:

- American histoplasmosis, due to infection with *H. capsulatum* var. *capsulatum*
- African histoplasmosis, due to infection with *H. capsulatum* var. *duboisii*

H. capsulatum var. *capsulatum* is endemic in the central USA where 50 to 90% of the population is infected. Mild infections are generally asymptomatic. However, acute pulmonary infection can occur. Massive infection can be fatal. Chronic pulmonary histoplasmosis can result in lung fibrosis and cavitation. Acute or chronic disseminated infection involving widespread infiltration of the reticuloendothelial system, is mainly seen in immunodeficient or immunocompromised patients.

Histoplasma capsulatum var. *duboisii* is found in Africa and may cause a chronic disseminated form of histoplasmosis with focal lesions predominantly in skin and bone.

Antifungal therapy for histoplasmosis is necessary in patients with severe acute pulmonary infections, chronic pulmonary disease, or disseminated infection. Infections which are not life-threatening but not resolving spontaneously may be treated with an oral azole in both immunocompetent and immunocompromised patients.[1,2] Itraconazole is the preferred drug.[1,2] Ketoconazole is moderately effective but more toxic. Fluconazole is less effective than either itraconazole or ketoconazole.[2-4] Patients with chronic cavitary pulmonary histoplasmosis should be treated with oral itraconazole for a minimum of 1 year.[1] Patients with moderately severe to severe acute pulmonary histoplasmosis may be treated with intravenous liposomal amphotericin B for 1 to 2 weeks followed by oral itraconazole for a total of 12 weeks. Conventional intravenous amphotericin B may be given as an alternative. The same treatment regimen is recommended for those with progressive disseminated disease; oral itraconazole in these patients should be continued for 12 months.[1] Immunocompromised patients, including those with HIV infection, may need to continue maintenance therapy indefinitely, with itraconazole daily or amphotericin B weekly,[1-3,5] if immunosuppression cannot be reversed.[1] Patients with CNS histoplasmosis should be given intravenous liposomal amphotericin B for 4 to 6 weeks, followed by oral itraconazole for a minimum of 1 year.[1] Primary prophylaxis with itraconazole is not recommended routinely but may be considered for patients with advanced AIDS at especially high risk of infection due to occupational exposure or residence in a hyperendemic area.[5]

Infections in immunocompromised patients

Immunocompromised patients are at increased risk of infections, including those caused by fungi. Fungi most commonly affecting AIDS patients include *Cryptococcus neoformans*, *Pneumocystis jirovecii* and *Candida albicans* while those associated with immunosuppressive therapy and cancer are mainly *Aspergillus* and *Candida* spp. Immunocompromised patients are also at increased risk of endemic mycoses, such as coccidioidomycosis, histoplasmosis, and *Penicillium marneffei* as well as a growing number of uncommon fungi reported to cause invasive infections, including *Fusarium*, *Scedosporium*, and *Trichosporon* species.

Fungal infections in immunocompromised patients are often invasive or disseminated and treatment should start as early as possible. A fungal cause of infection should be considered in patients with persistent febrile neutropenia who have not responded to broad spectrum antibacterials. If the infection has not been identified, empirical treatment should be started. Conventional intravenous amphotericin B has been considered first-line empirical therapy and is no less effective than lipid formulations. Fluconazole, itraconazole, voriconazole, and caspofungin appear at least as effective as amphotericin B. For patients with renal impairment lipid formulation of amphotericin B or voriconazole may be given. For patients not responding to an amphotericin B formulation voriconazole, itraconazole, or caspofungin are alternatives. Fluconazole may be considered for low risk patients infected with susceptible *Candida* species.

The benefit and role of primary prophylaxis in the management of fungal infections associated with HIV, cancer, and organ transplants is controversial as this may select for resistant isolates and species not susceptible to the antifungals used. This is of particular concern with fluconazole (see Resistance, p.533), one of the drugs most widely used for this purpose. Fluconazole has been shown to be effective as primary prophylaxis against invasive candidiasis but not aspergillosis. Itraconazole or voriconazole are preferred for patients at risk of invasive aspergillosis, such as patients being treated for graft-versus-host disease or cytomegalovirus disease.

Long term suppressive therapy has been recommended for immunocompromised patients with proven or probable invasive aspergillosis or candidiasis. Secondary prophylaxis may be stopped when patients are no longer profoundly neutropenic.

Antifungals are also used in selective digestive tract decontamination (see Intensive Care, p.175).

Treatment and prophylaxis of specific fungal infections in immunocompromised patients is discussed under the appropriate headings—see Aspergillosis, Candidiasis, Coccidioidomycosis, Cryptococcosis, and Histoplasmosis (above), and Pneumocystis Pneumonia (below).

Meningitis

Fungal diseases associated with meningitis include aspergillosis, candidiasis, coccidioidomycosis, cryptococcosis, and histoplasmosis (see above), although many disseminated fungal infections can involve the CNS, especially in immunocompromised patients. The treatment of each infection is discussed under the appropriate heading, but in general the initial drug of choice in fungal meningitis is intravenous amphotericin B, sometimes with flucytosine.

Mucormycosis

Mucormycosis,[1-5] a rare but invasive and rapidly progressive infection caused by Mucorales fungi, is a form of zygomycosis, a term that is sometimes used synonymously. Mucormycosis usually acquired by inhalation of spores, although trauma and ingestion may also be routes of infection. It usually occurs in poorly controlled diabetic patients or in immunocompromised patients. Patients given desferrioxamine may also be at increased risk of infection (see p.1440). Infections of the mucosa of the respiratory tract or gastrointestinal tract, or of abraded skin, usually with *Rhizopus* or *Rhizomucor* spp., can result in local invasion of deeper tissues including bone and the CNS, with extensive tissue destruction. Disseminated disease may also occur.

The treatment of mucormycosis includes a combination of antifungal therapy, surgical debridement when possible, and management of the underlying disease. The standard antifungal therapy is relatively high doses of intravenous amphotericin B or lipid formulations of amphotericin B. Fluconazole, itraconazole, ketoconazole, voriconazole, or the echinocandins are not considered to have a role in the treatment of mucormycosis, although the newer triazoles, posaconazole and ravuconazole, have reported *in-vitro* activity against zygomycetes and posaconazole has been tried in patients with refractory disease. Invasive or disseminated disease is difficult to treat and is usually fatal.

Mycetoma

Mycetoma[1-4] has a worldwide distribution, but is most commonly encountered in the tropics and subtropics. It may affect subcutaneous tissue, bone, and skin. The foot is most often affected (70 to 80% of cases), less often hand (12%), legs, and knee joints. The term Madura foot is used for mycetoma affecting the foot. Infection mainly results from trauma to the skin, and may spread locally through the lymphatic system to surrounding tissues, progressively destroying connective tissue and bone. Mycetomas caused by fungi such as *Madurella mycetomatis*, *M. grisea*, or *Pseudallescheria boydii* are called eumycetomas. Those caused by the filamentous bacteria, actinomycetes, are called actinomycetomas and are discussed on p.180. Eumycetomas do not heal spontaneously and are poorly responsive to treatment. They often require both surgical excision and antifungal therapy. Itraconazole or ketoconazole are recommended as first-line antifungals for eumycetomas and the duration of treatment depends on the severity of the infection and ranges from a few months to years. Itraconazole has resulted in good clinical responses and low recurrence rates. Treatment with antifungals before surgery results in lesions that are localised and encapsulated and easier to excise during surgery.[1,2]

Nail infections

See under Skin Infections, below.

Paracoccidioidomycosis

Paracoccidioidomycosis (South American blastomycosis) is caused by an infection with the fungus *Paracoccidioides brasiliensis*. The disease occurs mainly in inhabitants of Central and South America. Infection is thought to be by inhalation and may remain dormant for long periods. While most primary infections are subclinical, some may be progressive and severe, particularly in immunocompromised patients. Paracoccidioidomycosis usually presents as a chronic infection affecting the lungs. Disseminated disease may affect the skin, mucous membranes, gastrointestinal tract, reticuloendothelial system, and adrenals, and may be acute or chronic. Relatively mild cases may be treated with oral ketoconazole or itraconazole for 6 to 12 months or longer. Itraconazole allows shorter treatment courses and lower doses than ketoconazole; relapse rates are also lower. A small open-label study reported that oral voriconazole was as effective as oral itraconazole for long-term treatment of paracoccidioidomycosis.[1] More severe infections or those not responding to azoles are treated with intravenous amphotericin B followed by maintenance azole therapy.[2] Sulfonamides are now rarely used since more effective drugs are available. Terbinafine has been used successfully when access to azoles was not possible.[3]

Peritonitis

Fungal peritonitis may be a complication of continuous ambulatory peritoneal dialysis, abdominal surgery, or trauma. It is usually caused by yeasts such as *Candida* and rarely moulds such as *Aspergillus*. Amphotericin B is often used to treat fungal peritonitis;[1-3] intravenous dosage has been preferred to intraperitoneal use since the latter route is painful,[4] but intravenous use may lead to poor penetration into the peritoneum.[3] There is some evidence that early removal of the peritoneal catheter reduces the risk of death.[3] Fluconazole, voriconazole, caspofungin, or flucytosine may also be effective.[3,5] Oral continuation therapy with flucytosine and fluconazole has been given after removal of the catheter.[3] However, fungal peritonitis may be difficult to treat and causes substantial morbidity and mortality.[4]

Pityriasis versicolor

See under Skin Infections, below.

Pneumocystis pneumonia

Pneumocystis pneumonia (PCP) is caused by the organism *Pneumocystis jirovecii* (previously named *Pneumocystis carinii* f. sp. *hominis* and at one time considered to be a protozoan). It is an opportunistic pathogen and infection is acquired by inhalation. In persons with normally functioning immune systems infection rarely produces disease, but in immunocompromised patients it may produce interstitial pneumonia which, if untreated, is almost always fatal. In patients with AIDS (p.856), Pneumocystis pneumonia is a common occurrence.

The **treatment** of choice for PCP is:

- intravenous or oral co-trimoxazole[1-4]

Alternative regimens are:[1-4]

- intravenous pentamidine
- oral clindamycin and primaquine
- oral atovaquone
- oral trimethoprim and dapsone
- nebulised pentamidine is occasionally suggested for mild to moderate infection but is now generally reserved for prophylaxis.
- intravenous trimetrexate plus folinic acid may be a further option to intravenous co-trimoxazole or pentamidine in patients with moderate to severe disease.

Adjunctive folinic acid with co-trimoxazole has been associated with an increased risk of therapeutic failure and death in AIDS patients.[5] Combination therapy with co-trimoxazole and pentamidine is not more effective and is potentially more toxic than either drug alone.[6]

Adjunctive treatment with glucocorticosteroids should be given to patients with severe infection[1,2] if they are hypoxic, and treatment should be started as soon as antimicrobial treatment is begun.

Primary **prophylaxis** is indicated for all HIV-positive adolescents and adults (including pregnant women and patients on highly active antiretroviral therapy) with CD4+ T lymphocyte counts lower than 200 cells/microlitre, or a history of oropharyngeal candidiasis.[2,7] Infants are at increased risk to PCP during their first year of life and, in infants and young children, PCP may occur at higher CD4+ T lymphocyte counts compared with adults. The WHO/UNAIDS/UNICEF[8] and US guidelines[7] recommend that infants under 18 months born to HIV-positive mothers should be given prophylaxis beginning at 4 to 6 weeks of age. Therapy should continue until breast feeding is stopped and the infant is confirmed to be HIV-negative, or for at least 1 year initially. Infants subsequently confirmed to be HIV-positive should remain on prophylactic therapy. In Europe, some clinicians have tended to have a less aggressive approach and only offer prophylaxis once HIV infection is confirmed or opportunistic infections occur.[9] Recommendations for primary prophylaxis in patients without HIV infection suggest that prophylaxis should be considered for patients with primary immune deficiency, severe protein malnutrition, organ or stem cell transplants, persistent CD4+ T lymphocyte counts lower than 200 cells/microlitre, or patients receiving cytotoxic or immunosuppressive therapy.[2,10,11] Secondary prophylaxis is given to all patients following successful treatment of PCP.[2]

For both primary and secondary prophylaxis[1,4,7] the drug of choice is:

- co-trimoxazole

Alternative prophylactic regimens[1,2,4,7] for patients not able to receive co-trimoxazole are:

- dapsone (alone or with pyrimethamine)
- aerosolised pentamidine
- atovaquone

Other prophylactic regimens include intermittent parenteral administration of pentamidine, pyrimethamine with sulfadoxine, clindamycin with primaquine, and trimetrexate, but are not recommended unless the more usual drugs cannot be used.[7] Co-trimoxazole has the added advantage of also protecting against bacterial infections and toxoplasmosis, a common opportunistic infection in AIDS patients.[7]

In HIV-infected patients, primary and secondary prophylaxis may be discontinued in those who attain a CD4+ T lymphocyte count above 200 cells/microlitre on antiretroviral therapy. Primary and secondary prophylaxis should be restarted in patients whose CD4+ T lymphocyte count falls to below 200 cells/microlitre, and in those in whom PCP recurs at a count of greater than 200 cells/microlitre.[7,12] A study of solid organ transplant recipients[13] suggested that lung transplant recipients are at continued risk of developing PCP and prophylaxis should be continued indefinitely in this group.

Protothecosis

Protothecosis is an infection with algae of the *Prototheca* spp., usually *P. wickerhamii.* Infection occurs rarely in humans but may follow minor trauma or surgery, leading to a chronic skin lesion and occasionally dissemination. Amphotericin B appears to be the most effective antifungal,[1,2] and has been combined with an oral tetracycline.[2] There are also case reports of itraconazole[3,4] being used successfully and fluconazole has been of benefit in a case unresponsive to itraconazole,[5] but azole therapy has also been associated with treatment failure in a number of cases.[2] Azole antifungals and surgery may be considered for patients with more localised disease.[1]

Respiratory-tract infections

Pathogenic fungi may enter the body by inhalation and colonise the respiratory tract. Fungal infections of the respiratory tract include aspergillosis, blastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, and paracoccidioidomycosis (see above). *Pneumocystis jirovecii* is an important cause of pneumonia in HIV-infected patients (see above). Other fungi reported to produce respiratory-tract infections mainly in immunocompromised patients include *Candida* spp., *Fusarium* spp., *Penicillium marneffei*, *Pseudoallescheria boydii*, and Zygomycetes such as *Rhizopus arrhizus.* Acute pulmonary fungal infections in immunocompetent individuals are mostly self-limiting conditions that resolve without treatment. Severe, persistent, or progressive infections, or infections in immunocompromised patients, require treatment. Intravenous amphotericin B is usually the drug of choice but mild to moderate infection can be treated with an oral azole such as fluconazole, itraconazole, or ketoconazole. Pulmonary granulomas may require surgical removal. Chronic suppressive treatment is recommended for patients with ongoing immunosuppression due to HIV infection.

Skin infections

The most common fungal skin infections are the dermatophytoses, pityriasis versicolor, and candidiasis. The first two are described here; for candidiasis, see above. Other fungal skin infections are discussed under the appropriate headings: blastomycosis, chromoblastomycosis, mycetoma, mucormycosis, protothecosis, and sporotrichosis. Fungal infections that may involve the skin by dissemination include aspergillosis, coccidioidomycosis, cryptococcosis, histoplasmosis, and paracoccidioidomycosis. Less common fungi causing skin infections include *Penicillium marneffei.* Sometimes a fungal infection may affect mucous membranes, nails, or subcutaneous tissue, and there can be spread to deeper tissue and dissemination especially in immunosuppressed patients. The term superficial fungal infections includes those involving the skin, nails, and mucous membranes. Antifungal treatment may be topical or systemic.[1,2]

Dermatophytoses (ringworm, tinea) are infections by dermatophytes, a group of fungi which includes soil-dwelling organisms and human and animal pathogens from 3 genera — *Epidermophyton, Microsporum,* and *Trichophyton.* Dermatophytoses are encouraged by hot and humid conditions and poor hygiene and occur throughout tropical and temperate regions of the world.

Dermatophytoses are classified according to the body site affected. They include

- tinea barbae (beard)
- tinea capitis (scalp)
- tinea corporis (body)
- tinea cruris (groin)
- tinea manuum (hand)
- tinea pedis (athlete's foot)
- tinea unguium (nail)

A chronic infection most commonly seen in the tropics is known as favus (tinea favosa) and a variant of tinea corporis known as tinea imbricata (tokelau) is caused by *T. concentricum* and is endemic in parts of the Far East and Central and South America. A severe form of dermatophytosis caused by animal pathogens with deep, suppurant, inflammatory lesions is known as kerion.

Deep infections may occur rarely in immunocompromised patients; they can spread to involve lymph nodes, liver, and brain, and may be fatal.

Mild localised superficial dermatophytoses of hairless skin sites will often respond to *topical* therapy.[3-5] Non-specific agents with a long history of topical use include benzoic acid, methylrosanilinium chloride, selenium sulfide, and salicylic acid. Many of these agents are effective, and while some older preparations such as Compound Benzoic Acid Ointment may be less cosmetically acceptable than modern products, they still have a role in the treatment of minor infections, particularly in the tropics.[6] However, the use of methylrosanilinium chloride is restricted due to fears over possible carcinogenicity (see p.1653). There are a number of specific topical antifungals that are active against dermatophytes. The azoles used topically include clotrimazole, econazole, ketoconazole, and miconazole. Ciclopirox olamine[7] and the allylamine antifungals naftifine and terbinafine[5] are also active, and a systematic review[5] considered that allylamines such as terbinafine were slightly more effective than azoles in the treatment of fungal infections of the foot. Chlorphenesin, tolnaftate, and undecenoic acid salts are all effective in uncomplicated dermatophytoses, but there are few comparative studies of their relative efficacy. Amorolfine has also been shown to be effective in skin infections, although its major application is in nail infections (see below).

Infections of some body sites respond poorly to topical therapy, as do extensive infections or those in heavily keratinised areas.[4,8] *Systemic* therapy may be appropriate in these cases as well as in disseminated disease. Griseofulvin, ketoconazole, and itraconazole have been the drugs most widely used, although terbinafine has been reported to be more effective than itraconazole in some forms of tinea[9,10] and also requires only short-duration therapy.[11,12] However, efficacy of terbinafine is reported to depend on the infecting organism.[13] Griseofulvin has proved to have few major toxic effects during long-term therapy and is useful for tinea capitis, extensive or disseminated infections, and nail infections in selected patients. However, since it has a narrow spectrum of activity largely confined to the dermatophytes, accurate diagnosis is essential, particularly before embarking on a prolonged treatment course when no immediate response is anticipated. Ketoconazole has a broader spectrum of activity, but severe adverse effects can occur on prolonged use. Itraconazole appears to produce a rapid response and thus requires shorter treatment periods.[4] Other azoles such as fluconazole may also be effective.[14] Selenium sulfide and povidone-iodine shampoos may be useful adjuncts to oral therapy for tinea capitis to improve efficacy and limit the spread of infection.[15,16] A suitable topical antifungal is used in individuals suspected of carrying infection.[17]

Infections of the **nails (onychomycoses)** are notoriously difficult to treat.[18] Infections of the fingernails take up to 6 months to respond to oral griseofulvin and those of the toenails, a year or longer, but about 60% of nail infections fail to respond or relapse after the initial treatment course. The oral antifungals terbinafine, itraconazole, and fluconazole produce persistent antifungal concentrations in the nail more rapidly than griseofulvin.[18,19] Terbinafine and itraconazole have been most widely studied. Both are reported to produce clinical and mycological cures in a high proportion of patients more quickly than griseofulvin, generally after 12 weeks of treatment or less. Long-term follow-up has shown that the response to terbinafine is maintained.[20-22] Terbinafine has been reported to be more effective than itraconazole,[23-26] although neither is effective in all patients. Although topical treatments have generally been ineffective in nail infections, ciclopirox nail lacquer has been reported to be effective,[27] but a systematic review[5] noted that cure rates were poor. Amorolfine as a 5% lacquer has also shown benefit,[28] and may be more effective than ciclopirox although evidence is scanty.[5] It has also been applied in combination with oral itraconazole[29] or terbinafine[30] with some success. Topical butenafine may also be of benefit.[5] Another approach has been the dissolution of the nail plate with 40% urea paste, usually in combination with bifonazole.[31] Guidelines for the treatment of onychomycosis have been published in the UK.[32]

Pityriasis versicolor (tinea versicolor) is a superficial infection caused by the commensal yeast *Malassezia furfur (Pityrosporum orbiculare).* It is more common in tropical than in temperate latitudes and sun exposure may trigger the infection. Pityriasis versicolor will often respond to topical treatment with an azole antifungal or with selenium sulfide. Topical terbinafine (but not oral) or ciclopirox are alternatives.[33] Immunocompromised patients, including those receiving corticosteroids, may develop extensive infections. In addition, these fungi have caused septicaemia in patients receiving parenteral nutrition.[34] Severe infections require oral treatment with an azole.[35] Griseofulvin is not effective.

Other infections in which *Malassezia* yeasts are implicated include seborrhoeic dermatitis (p.1584) and pityrosporum folliculitis, both of which may present in a more severe form in patients with AIDS. Topical or systemic azole antifungals are effective in these conditions and are the main drugs used. However, relapses are common.[36]

Sporotrichosis

Sporotrichosis is a disease caused by *Sporothrix schenckii*, a fungus found in soil and vegetation. The infection occurs in the Americas and Africa, and may give rise to cutaneous or extracutaneous disease. The cutaneous form is the more common. It probably follows entry of the organism through skin abrasions and usually presents as a single skin lesion, although infection may spread along lymphatic channels causing a series of skin lesions. Extracutaneous sporotrichosis usually presents as osteoarticular infection. Pulmonary infections are occasionally seen and, rarely, CNS and ocular infections.

Infections rarely heal spontaneously and most patients require treatment. Oral potassium iodide has traditionally been used for cutaneous and lymphocutaneous infections although the mode of action is unclear since potassium iodide does not demonstrate antifungal activity *in vitro*. Oral itraconazole 200 mg daily for 3 to 6 months is also effective[1-3] and is regarded by some[3,4] as the treatment of choice. The dose of itraconazole may be increased to 200 mg twice daily in non-responders; alternatively patients may be given oral terbinafine or a saturated potassium iodide solution taken orally. Oral fluconazole should only be used in patients who cannot tolerate any of the preferred drugs.[4]

For patients with osteoarticular infections, oral itraconazole 200 mg twice daily for at least 12 months is recommended, with either liposomal or conventional amphotericin B given intravenously as alternatives. Oral itraconazole 200 mg twice daily may be given as maintenance therapy once the patient has responded to the amphotericin B treatment.[4]

Patients with life-threatening pulmonary, disseminated, or meningeal disease should receive treatment for at least 12 months. The drug of choice is intravenous liposomal amphotericin B with conventional amphotericin B given intravenously as an alternative. Oral itraconazole 200 mg twice daily may be given as maintenance therapy. Oral itraconazole may be given in non-life-threatening pulmonary infections and for patients who cannot tolerate amphotericin B.[4]

Lifelong maintenance therapy with oral itraconazole 200 mg daily may be beneficial after initial treatment for meningeal or disseminated sporotrichosis in immunocompromised patients, including those with AIDS, if immunosuppression cannot be reversed.[4]

CAS — 78613-38-4.

ATC — D01AE16.

ATC Vet — QD01AE16.

Adverse Effects

Skin irritation, presenting as erythema, pruritus, or a burning sensation, and, rarely, more severe skin reactions have been reported after topical application of amorolfine.

Antimicrobial Action

Amorolfine is a morpholine derivative with antifungal activity. It appears to act by interfering with the synthesis of sterols essential for the functioning of fungal cell membranes.

Amorolfine is active *in vitro* against a wide variety of pathogenic and opportunistic fungi including dermatophytes, *Blastomyces dermatitidis*, *Candida* spp., *Histoplasma capsulatum*, and *Sporothrix schenckii*. It also has variable activity against *Aspergillus* spp. However, despite its *in vitro* activity, amorolfine is inactive when given systemically and this limits its use to topical application for superficial infections.

Uses and Administration

Amorolfine is a morpholine derivative applied topically as the hydrochloride in the treatment of fungal nail and skin infections (p.521). After topical application, systemic absorption of amorolfine is negligible.

For the treatment of nail infections caused by dermatophytes, yeasts, and moulds a lacquer containing the equivalent of 5% amorolfine is painted onto the affected nail once or sometimes twice weekly until the nail has regenerated. Treatment generally needs to be continued for 6 to 12 months.

For skin infections, including dermatophyte infections, a cream containing the equivalent of 0.25% amorolfine is applied once daily for at least 2 to 3 weeks (up to 6 weeks for foot infections) and continued for 3 to 5 days after clinical cure is achieved.

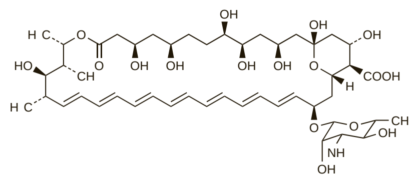
ATC Vet — QA01AB04; QA07AA07; QG01AA03; QJ02AA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Amphotericin B; Amphotericin BP 2008). A mixture of antifungal polyenes produced by the growth of certain strains of *Streptomyces nodosus* or by any other means. It consists largely of amphotericin B. It occurs as a yellow or orange powder. The potency is not less than 750 units per mg with reference to the dried substance. It contains not more than 10% of tetraenes, or not more than 5% if intended for use in parenteral dosage forms. Practically insoluble in water and in alcohol; soluble in dimethyl sulfoxide and in propylene glycol; slightly soluble in dimethylformamide; very slightly soluble in methyl alcohol. Amphotericin B is inactivated at low pH values. Store at 2° to 8° in airtight containers. Protect from light.

USP 31 (Amphotericin B). A yellow to orange, odourless or practically odourless, powder. It contains not less than 750 micrograms of $C_{47}H_{73}NO_{17}$ per mg, and, for material intended for oral or topical use, not more than 15% of amphotericin A, both calculated on the dried substance. Insoluble in water, in dehydrated alcohol, in ether, in benzene, and in toluene; soluble in dimethylformamide, in dimethyl sulfoxide, and in propylene glycol; slightly soluble in methyl alcohol. Store at a temperature not exceeding 8° in airtight containers. Protect from light.

Formulation. Conventional formulations of amphotericin B injection are typically a complex of amphotericin B and deoxycholate with suitable buffers which form a colloidal dispersion when reconstituted. Nonconventional '**lipid**' formulations of amphotericin B for injection include liposomal amphotericin B, a colloidal dispersion of an amphotericin B and sodium cholesteryl sulfate complex, and a phospholipid complex.

Incompatibility. Because of the wide range of incompatibilities reported with conventional and lipid formulations of amphotericin B, it is generally advisable not to mix them with any other drug. Most incompatibilities are caused by precipitation of amphotericin B due to a change in pH or by the disruption of the colloidal suspension. Precipitation can occur if amphotericin B is added to sodium chloride 0.9% or to electrolyte solutions.

Although heparin is generally reported to be compatible with conventional amphotericin B injection, care should be taken if heparin flush solutions, which are diluted with sodium chloride solution, are used to maintain the patency of intravenous lines in patients receiving amphotericin B. Flushing the intravenous line with 5% glucose solution has been suggested.

Mixtures of conventional amphotericin B in commercial lipid emulsions have been reported to be unstable,[1-3] although others have reported satisfactory stability.[4-6] In one study,[6] vigorous agitation of the mixtures enhanced their stability when compared with gentle mixing.

Preparation of solutions for injection. Recommendations from the manufacturers for preparation of amphotericin solutions are:

- *conventional amphotericin B* formulations for injection are prepared by reconstitution of amphotericin B with sterile water for injection without preservatives, then dilution with glucose injection 5% with a pH above 4.2 to the desired final concentration.
- *liposomal amphotericin B*: injections are prepared by reconstitution with sterile water for injection without a preservative; the required reconstituted amount is then withdrawn and injected via a sterile filter into the desired volume of glucose 5%.
- *amphotericin B-sodium cholesteryl sulfate complex*: injections are prepared by rapidly adding the required amount of water for injection, then further diluting with glucose 5% until the desired final concentration is reached.
- *amphotericin B-phospholipid complex*: before infusion the suspension concentrate must be diluted to the required final concentration with glucose 5%. The required amount of concentrate is injected via a sterile filter into the glucose 5%.

CAUTION: Mixture with sodium chloride injection 0.9% would precipitate amphotericin B.

Stability of oral suspensions. An oral suspension of amphotericin B 100 mg/mL, prepared from powder and a cherry-flavoured vehicle and maintained at pH 5.3, was found to be stable at 22 to 25° for 93 days.[1]

Adverse Effects

Amphotericin B for intravenous use was originally only available in a conventional colloidal form; lipid formulations have been developed to reduce toxicity. The following adverse effects apply to the **conventional** form. Common adverse effects which occur during or after intravenous infusion of amphotericin B include headache, nausea, vomiting, chills, fever, malaise, muscle and joint pains, anorexia, diarrhoea, and gastrointestinal cramp. Hypertension, hypotension, cardiac arrhythmias including ventricular fibrillation and cardiac arrest, skin rashes, flushing, anaphylactoid reactions including bronchospasm and dyspnoea, blurred vision, tinnitus, hearing loss, vertigo, gastrointestinal bleeding, liver disorders, peripheral neuropathy, and convulsions have been reported occasionally.

Some degree of nephrotoxicity occurs in almost all patients given amphotericin B intravenously. Both tubular and glomerular damage occur; there may be improvement on cessation of therapy, but there is a risk of permanent renal impairment, particularly in patients given large cumulative doses (over 5 g). Renal tubular acidosis without systemic acidosis may develop. Use of amphotericin B is associated with increased urinary excretion of potassium and magnesium resulting in hypokalaemia and hypomagnesaemia respectively. Uric acid excretion is increased and nephrocalcinosis can occur. Limited data indicate that renal toxicity may be associated with sodium depletion; for strategies to improve sodium load see Nephrotoxicity, under Treatment of Adverse Effects, below.

A reversible, normocytic, normochromic anaemia develops in most patients given amphotericin B, possibly due to a direct suppressive effect on erythropoietin production. There are rare reports of thrombocytopenia, leucopenia, agranulocytosis, eosinophilia, and coagulation defects.

Leukoencephalopathy has been reported rarely in patients also receiving total body irradiation.

Amphotericin B solutions irritate the venous endothelium and may cause pain and thrombophlebitis at the injection site. Extravasation may cause tissue damage.

After intrathecal injection amphotericin B may also cause irritation of the meninges, neuropathy with pain, impaired vision, and retention of urine.

In general, adverse effects of **lipid** formulations have been similar to those of conventional amphotericin B, but are less frequent and less severe. Brief reversible episodes of renal impairment have been observed but these formulations have been considered to be safe enough to use in patients with renal impairment who could not be given conventional amphotericin B. Anaphylaxis has been reported rarely.

Amphotericin applied **topically** may produce local irritation, pruritus, and skin rash.

Effects on the cardiovascular system. Ventricular arrhythmias in 2 patients, resulting in fatal sudden cardiac arrest in 1, were associated with both conventional and liposomal formulations of amphotericin B at conventional doses and infusion rates,[1] but cardiac toxicity is more common with high doses or rapid infusion rates (see Infusion Rate, under Administration, below). Cardiac arrests in 5 infants and children, fatal in 4 cases, were associated[2] with overdoses of conventional amphotericin B of between 3.8 and 40.8 mg/kg. Fatal cardiac toxicity has also been reported in an adult who inadvertently received an overdose (5 mg/kg) of conventional amphotericin B on 2 consecutive days.[3] A case of reversible dilated cardiomyopathy and congestive heart failure has been reported in a 20-year-old male patient after about 2 months of treatment, initially with conventional amphotericin B for 30 days and then with amphotericin B phospholipid complex. Symptoms resolved within 6 weeks of stopping treatment.[4] An increased risk of arrhythmia and cardiac arrest has been reported in patients with evidence of antimony-induced myocardial damage who were switched to amphotericin B treatment for visceral leishmaniasis.[5] A rest period of at least 10 days was advised before beginning amphotericin B in such patients.

Severe hypertension was associated with infusion of phospholipid-amphotericin B complex in 1 patient.[6]

6. Rowles DM, Fraser SL. Amphotericin B lipid complex (ABLC)-associated hypertension: case report and review. *Clin Infect Dis* 1999; **29:** 1564–5.

Effects on the eyes. Rapid loss of vision resulting in permanent bilateral blindness occurred in a patient with lupus erythematosus and cryptococcal meningitis after a 1-mg test dose of amphotericin B.[1] Amphotericin B was considered to be the cause as visual disturbances associated with cryptococcal meningitis are usually progressive in nature and acute blindness with normal funduscopic appearance had not previously been reported.

1. Li PKT, Lai KN. Amphotericin B induced ocular toxicity in cryptococcal meningitis. *Br J Ophthalmol* 1989; **73:** 397–8.

Effects on the liver. Amphotericin B has only rarely been associated with adverse effects on the liver. Fatal hepatic failure was reported in a patient after a total dose of 4.82 g given intermittently over 1 year.[1] The patient had been given a potentially incompatible intravenous admixture of amphotericin B and diphenhydramine.

There have been a few reports of abnormal liver-function tests during amphotericin B therapy;[2,3] in such cases amphotericin B should be stopped. Hyperbilirubinaemia associated with amphotericin B has also been reported.[4] An episode of reversible hepatic and renal toxicity has been reported in a child with cystic fibrosis after a cumulative dose of 84 mg of conventional amphotericin B and 168 mg of liposomal amphotericin B.[5]

Effects on the lungs. Reports implicating use of leucocytes[1] or other blood products[2] in the development of pulmonary reactions in patients receiving amphotericin B have been refuted,[3,4] and a report has indicated that amphotericin B can produce pulmonary toxicity in the absence of blood products.[5] An increased incidence of pulmonary symptoms was noted in patients given amphotericin B in lipid emulsion,[6] including acute respiratory distress after starting the infusion. Chest discomfort, including tightness, pain, dyspnoea, and acute hypoxia, has been reported in 3 patients during one-hour infusions of liposomal amphotericin B. The reactions occurred within 5 to 10 minutes of starting the infusion and resolved on stopping the infusion. A slower rate of infusion was subsequently tolerated in 2 patients.[7]

Effects on potassium homoeostasis. In addition to the hypokalaemia known to be associated with amphotericin B and due to increased urinary excretion of potassium, hyperkalaemia has been reported in a patient with severe renal impairment who received a rapid infusion of amphotericin B (see Infusion Rate, under Administration, below). Hyperkalaemia also occurred in a 2-year-old child with chronic renal failure after a two-hour infusion of conventional amphotericin B. Hyperkalaemia and fatal cardiac arrest were also reported in a 4-year-old child after 3 infusions of amphotericin B lipid complex.[1]

1. Barcia JP. Hyperkalemia associated with rapid infusion of conventional and lipid complex formulations of amphotericin B. *Pharmacotherapy* 1998; **18:** 874–6.

Hypersensitivity. Anaphylactoid reactions have occurred with conventional amphotericin B, but have also been associated with liposomal amphotericin B,[1-3] including reports of patients who subsequently tolerated conventional formulations.[1,3]

3. Vaidya SJ, *et al.* Anaphylactic reaction to liposomal amphotericin B. *Ann Pharmacother* 2002; **36:** 1480–1.

Red man syndrome. Red man syndrome (see Vancomycin, p.359) occurred in a patient on 2 occasions after a 1-mg test dose of amphotericin B.[1]

1. Ellis ME, Tharpe W. Red man syndrome associated with amphotericin B. *BMJ* 1990; **300:** 1468.

Treatment of Adverse Effects

To reduce febrile reactions antipyretics and antihistamines may be given before the intravenous infusion of conventional amphotericin B. Hydrocortisone given intravenously before or during amphotericin B infusion may also reduce febrile reactions. However, corticosteroids should not be given indiscriminately to patients given amphotericin B (see Interactions, below) and dosage should be kept to a minimum. In the UK the advice is to give antipyretics or hydrocortisone prophylactically, but only to patients who have previously had acute adverse reactions and in whom continued treatment with intravenous amphotericin B is essential (see Prophylaxis, below). Pethidine has been given intravenously to treat amphotericin B-induced shaking chills. Antiemetics may also be required. Amphotericin B is not removed by haemodialysis. Hypokalaemia and hypomagnesaemia should be corrected, and adequate hydration and sodium supplements may reduce the severity of renal impairment. Lipid formulations of amphotericin B can be substituted for conventional amphotericin B if the latter cannot be tolerated.

Heparin has been added to conventional amphotericin B infusions to reduce the incidence of thrombophlebitis.

Anaemia. Amphotericin B appears to produce a normochromic, normocytic anaemia by suppression of erythropoietin production.[1,2] Stopping amphotericin B reverses the suppression but if the anaemia is severe, or treatment with amphotericin B cannot be stopped, blood transfusions may be required. Recombinant erythropoietin may prove an alternative to blood transfusions in patients who need to continue treatment with amphotericin B.

2. Lin AC, *et al.* Amphotericin B blunts erythropoietin response to anemia. *J Infect Dis* 1990; **161:** 348–51.

Electrolyte disturbances. It has been suggested[1] that amiloride could ameliorate the hypokalaemia and hypomagnesaemia associated with amphotericin B. However, since amiloride may produce sodium depletion and its own associated renal toxicity this strategy is potentially hazardous. Another report[2] has suggested that spironolactone may be a safe and effective method of preventing hypokalaemia.

1. Wazny LD, Brophy DF. Amiloride for the prevention of amphotericin B-induced hypokalemia and hypomagnesemia. *Ann Pharmacother* 2000; **34:** 94–7.
2. Ural AU. Comment: spironolactone prevents amphotericin B-induced hypokalemia in neutropenic patients. *Ann Pharmacother* 2000; **34:** 1488.

Nephrotoxicity. A review of strategies for limiting the toxicity of amphotericin B concluded that sodium balance should be monitored and sodium replacement implemented if necessary and that, where possible, salt restriction and drugs that potentiate sodium loss or nephrotoxicity should be avoided.[1] Correction of sodium depletion may reverse amphotericin B-induced nephrotoxicity.[2] However, assessment of sodium status and correction of deficiency should precede use of amphotericin B.[3,4] While supplementation with 150 mmol sodium has been recommended for suitable patients,[4] routine prophylactic use of sodium is not advised.[5] However, a randomised study in a small number of patients has suggested that prophylactic sodium supplementation could be beneficial, but that it enhances potassium loss.[6] Diuretics in general should be avoided[7] although there have been suggestions that potassium-sparing diuretics such as amiloride or spironolactone may be useful in preventing hypokalaemia (see Electrolyte Disturbances, above). Use of mannitol as a protective agent is controversial and is not recommended.[3,4,8] Amphotericin B is often given on alternate days although this has never been proven to reduce nephrotoxicity.[3,4]

More recently, lipid formulations have been reported to overcome most problems of chronic nephrotoxicity, even in patients with renal impairment after previous treatment with conventional amphotericin B (see Lipid Formulations, under Administration, below).

Prophylaxis. The value of prophylaxis against generalised reactions to amphotericin B infusion was questioned after a retrospective study in 397 patients.[1] The most commonly used drugs were diphenhydramine, corticosteroids, paracetamol, and heparin. It was concluded that patients who had had an adverse reaction after amphotericin B should be given appropriate premedication before subsequent amphotericin B infusions, but that routine premedication was not justified.

1. Goodwin SD, *et al.* Pretreatment regimens for adverse events related to infusion of amphotericin B. *Clin Infect Dis* 1995; **20:** 755–61.

Precautions

Although anaphylaxis is rare after intravenous amphotericin B, it is advisable to give a test dose and then to observe the patient carefully for about 30 minutes before starting treatment. Patients experiencing acute toxic reactions in whom treatment is essential may be given prophylactic treatment, as mentioned in Treatment of Adverse Effects, above, to ameliorate the reactions. To reduce the risk of vein irritation and infusion-related adverse effects, the rate of intravenous infusion of conventional amphotericin B should be slow (see Infusion Rate, under Administration, below). Patients given any parenteral form of amphotericin B should be monitored for changes in renal function, liver function, serum electrolytes, and haematological status. If the BUN or creatinine concentrations increase to clinically significant levels amphotericin B therapy should be interrupted or the dose reduced until renal function improves. Alternatively, a lipid amphotericin B preparation may be substituted. Treatment should be stopped if liver function tests are abnormal. Acute pulmonary reactions have been noted in patients given amphotericin B during or shortly after leucocyte transfusions. Although the association is contested (see Effects on the Lungs, above), manufacturers of some amphotericin B products consider it advisable to separate the two and to monitor pulmonary function in these patients.

Care should be taken not to confuse the dosage regimens for individual preparations, and in particular those of conventional and lipid formulations.

Pregnancy. There are case reports of conventional amphotericin B having been used successfully to treat fungal infections in pregnant women without any adverse effects on the infant.[1-3] A review[4] of the use of antifungal drugs in pregnancy concluded that parenteral amphotericin B was the drug of first choice in the treatment of serious fungal infections in pregnancy. The safety of the lipid amphotericin formulations in pregnancy is not yet clear, although there has been a report of a series of 5 pregnant women with visceral leishmaniasis who were treated in the first or second trimester with a short course of liposomal amphotericin B without adverse effects on the infant.[5]

Interactions

Most interactions involving amphotericin B have been observed during treatment with conventional formulations. Since lipid formulations appear to be less toxic, it may be anticipated that they will produce fewer serious interactions.

Use of nephrotoxic antibacterials, ciclosporin or other nephrotoxic immunosuppressants, or parenteral pentamidine may lead to an increased risk of nephrotoxicity. If possible, amphotericin B should not be given to patients receiving antineoplastics. Diuretics should generally be avoided in patients taking amphotericin B. If a diuretic has to be given then volume and electrolyte depletion should be monitored carefully. The potassium-depleting effect of amphotericin B may enhance the effects of neuromuscular blocking drugs and may increase the toxicity of digitalis glycosides; corticosteroids may enhance the depletion of potassium and their immunosuppressive effects may be detrimental in patients with severe fungal infections.

Amphotericin B may increase the toxicity of flucytosine, but the combination is nonetheless used in severe infections for its synergistic activity. For information on synergistic and antagonistic effects with other antimicrobials, see under Antimicrobial Action, below. Renal excretion of zalcitabine may be reduced by amphotericin B.

For an increased risk of cardiac arrhythmias and arrest when amphotericin B was given to patients with myocardial damage induced by an antimony compound, see Effects on the Cardiovascular System, under Adverse Effects, above.

Antimicrobial Action

Amphotericin B is a polyene antifungal antibiotic which appears to act mainly by interfering with the permeability of the cell membrane of sensitive fungi by binding to sterols, chiefly ergosterol. It is reported to be fungistatic at concentrations achieved clinically. It is active against *Absidia* spp., *Aspergillus* spp., *Basidiobolus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Conidiobolus* spp., *Cryptococcus neoformans*, *Histoplasma capsulatum*, *Mucor* spp., *Paracoccidioides brasiliensis*, *Rhizopus* spp., *Rhodotorula* spp., and *Sporothrix schenckii*. Other organisms that have been reported to be sensitive to amphotericin B include the algal *Prototheca* spp. and the protozoa *Leishmania* and *Naegleria* spp. It is inactive against bacteria (including rickettsia) and viruses.

Some resistant strains of *Candida* have been isolated from immunocompromised patients given prolonged treatment with amphotericin B.

Microbiological interactions. *Azoles.* Although there have been occasional reports of synergy between amphotericin B and the azole antifungals, greater emphasis has been placed on possible antagonism. Studies *in vitro* have supported theoretical concerns that the action of amphotericin B (which depends on binding to ergosterol in the fungal cell membrane) would be antagonised by azoles (which inhibit ergosterol synthesis).[1,2] *Animal* studies appear to have confirmed antagonism between amphotericin B and the imidazole ketoconazole, but not between amphotericin B and the triazoles fluconazole or itraconazole. Available clinical evidence seems to indicate that azoles given with, or as continuation therapy after, induction therapy with amphotericin B, are effective in severe infections, although reduced plasma concentrations of itraconazole have been reported in some patients while being given amphotericin B.[3] However, strains of *Candida albicans* resistant to both amphotericin B and fluconazole have emerged in patients who have received repeated or prolonged courses of fluconazole.[4,5]

Pharmacokinetics

There is little or no absorption of amphotericin B from the gastrointestinal tract. When given intravenously in the *conventional colloidal form* and in the usual increasing dosage regimens, peak plasma concentrations of 0.5 to 4 micrograms/mL have been reported; the average plasma concentration with maintenance doses of 400 to 600 micrograms/kg daily tends to be 500 nanograms/mL. Amphotericin B is highly bound to plasma proteins and is widely distributed, but passes into the CSF only in small quantities. The plasma half-life is about 24 hours; with long-term use the terminal half-life increases to 15 days.

Unchanged amphotericin B is excreted in small amounts slowly in the urine. Traces are present in the serum and urine several weeks after completion of treatment. Amphotericin B is not removed by haemodialysis.

The pharmacokinetics of the lipid formulations differ considerably from the conventional formulation and from each other:

- at clinical doses of 1 to 7.5 mg/kg, *liposomal amphotericin B* produces peak plasma concentrations of around 8 to 80 micrograms/mL, around 20 times those with conventional formulations
- after doses of 0.5 to 8 mg/kg, *amphotericin B-sodium cholesteryl sulfate complex* produces peak plasma concentrations of about 0.7 to 6.2 micrograms/mL
- at a dose of 5 mg/kg daily, *amphotericin B phospholipid complex* produces maximum plasma concentrations of about 1.7 micrograms/mL

Studies in *animals* have shown that concentrations in the kidney are several times lower after lipid formulations than with conventional ones.

Children and neonates. Serum-amphotericin B concentrations ranged from 0.78 to 10.02 micrograms/mL in 12 children (many with leukaemia) aged 4 months to 14 years after the intravenous infusion of *conventional amphotericin B* 0.25 to 1.5 mg/kg daily. Serum concentrations did not correlate with dose. The elimination half-life was 18.1 ± 6.65 hours. There was an inverse relationship between age and total clearance, suggesting that children older than 9 years may require lower doses.[1]

The pharmacokinetics of amphotericin B have also been studied in a group of 13 neonates with systemic fungal infections.[2] *Conventional amphotericin B* was infused over 4 to 6 hours every 24 hours. Ten of the infants started treatment with 100 micrograms/kg increased over 4 to 6 days to 500 micrograms/kg. Three infants were started on a dose of 800 to 1000 micrograms/kg reduced to 500 micrograms/kg daily. All infants were maintained on 500 micrograms/kg daily; total doses ranged from 17.3 to 28.6 mg/kg. Serum-amphotericin B concentrations were measured after the first dose in 3 infants in the first group and 2 in the second; no serum-amphotericin B could be detected in the 3 infants who had received 100 micrograms/kg. After 5 days of treatment peak serum-amphotericin B concentrations ranged from 0.5 to 4.0 micrograms/mL and this was considered to be the range that could be achieved with the daily maintenance dose of 500 micrograms/kg. The elimination half-life was 14.8 hours. Drug elimination between doses was not detected in 4 of the infants; one was in oliguric renal failure and the other 3 had developed increases in serum-creatinine concentrations. CSF-amphotericin B concentrations in 5 of the neonates ranged from 40 to 90% of simultaneous serum concentrations. It was considered that an initial dose of 500 micrograms/kg was well tolerated and could produce therapeutic serum concentrations more quickly than a regimen which consisted of 100 micrograms/kg on day one increased over 4 to 6 days to 500 micrograms/kg daily.

A comparative study[3] of plasma concentrations of *liposomal amphotericin B* in adults, children, and neonates after a dose of 1 mg/kg daily for 28 days, reported peak concentrations in children and neonates that were significantly lower than in adults. Increases in the mean peak plasma concentrations over days 1 to 28 were: adults, 1.02 to 1.66 micrograms/mL; children aged 1 to 12 years, 0.63 to 1.10 micrograms/mL; and neonates, 0.54 to 0.73 micrograms/mL. This was thought to be due to the greater volume of distribution in the neonates and greater clearance in older children.

The pharmacokinetics of *amphotericin B lipid complex* was studied in a cohort of 6 paediatric cancer patients with hepatosplenic candidiasis receiving a dose of 2.5 mg/kg daily for 6 weeks, to a total dosage of 105 mg/kg.[4] It was noted that the mean plasma concentrations over the dosing interval and area under the curve increased between the first and seventh doses but were similar between doses 7 and 42, suggesting that a steady state was achieved within 1 week of therapy. After the final dose of amphotericin B lipid complex, the mean plasma-amphotericin concentration was noted to be 0.50 micrograms/mL and the maximum concentration in whole blood was 1.69 micrograms/mL.

4. Walsh TJ, *et al.* Safety, tolerance, and pharmacokinetics of amphotericin B lipid complex in children with hepatosplenic candidiasis. *Antimicrob Agents Chemother* 1997; **41:** 1944–8.

Distribution. Amphotericin B concentrations in various organs and tissues were determined in 13 cancer patients who had received conventional amphotericin B before death.[1] Concentrations were determined by high-pressure liquid chromatography (HPLC) and bioassay. Mean recovery by HPLC reported as a percentage of total dose given was liver 27.5%, spleen 5.2%, lungs 3.2%, kidney 1.5%, heart 0.4%, brain 0.3%, and pancreas 0.2%; each organ had a specific accumulation pattern. The mean total recovery was 38.8%. Reported median bile concentration was 7.3 micrograms/mL. The drug concentrations obtained by bioassay were much lower than those measured by HPLC. As the HPLC-determined concentrations of amphotericin B were higher than the MICs for the pathogens in patients with candidiasis or aspergillosis, the poor clinical outcome in these patients suggested that amphotericin B in the tissue lacked antifungal activity.

In another study,[2] amphotericin B was not detected in the CSF of 4 AIDS patients with cryptococcal meningitis on intravenous maintenance conventional doses of 350 to 1890 micrograms/kg given 1 to 7 times weekly. The clinical success of amphotericin B for this indication could not be explained by measurable CSF drug concentrations.

Concentrations of amphotericin B have been measured in fetal-cord serum in an infant and were 37.5% of maternal serum concentration.[3]

3. Ismail MA, Lerner SA. Disseminated blastomycosis in a pregnant woman. *Am Rev Respir Dis* 1982; **126:** 350–3.

Half-life. The terminal half-life for amphotericin B was 15 days in 2 patients on completion of conventional amphotericin B infusion therapy for disseminated histoplasmosis.[1] In another study,[2] the half-life was 21.5 hours (based on the exponential phase of disappearance from the blood) in a 65-year-old patient on a maintenance conventional dose of 500 micrograms/kg infused over 1 hour every other day. Serum concentrations appeared to plateau at about 600 nanograms/mL 36 to 48 hours after each dose. This suggested that alternate-day dosage might be effective.

Uses and Administration

Amphotericin B is a polyene antifungal antibiotic. It is reported to be fungistatic at concentrations achieved clinically. Amphotericin B is given by intravenous infusion in the treatment of severe *systemic* fungal infections including aspergillosis, blastomycosis, candidiasis, coccidioidomycosis, cryptococcosis, histoplasmosis, mucormycosis, paracoccidioidomycosis, and sporotrichosis, and is the usual treatment of choice in fungal endocarditis, meningitis, peritonitis, or severe respiratory-tract infections. Many of these infections are most likely to occur in immunocompromised patients. Amphotericin may be given with flucytosine (p.534) in severe infections.

Amphotericin B is also used for the *local* treatment of superficial candidiasis. It is taken orally for intestinal candidiasis, sometimes as part of regimens for selective decontamination of the digestive tract in patients at special risk of infection, such as those in intensive care (see p.175).

The role of amphotericin B in the treatment of the above systemic and local infections is discussed under Choice of Antifungal, p.517.

Amphotericin B also has antiprotozoal activity. It is used for primary amoebic meningoencephalitis caused by *Naegleria* spp. and for the treatment of visceral and mucocutaneous leishmaniasis.

Administration and dosage. Amphotericin B is given by *intravenous* infusion conventionally as a colloidal complex with sodium deoxycholate. There is also a liposomal form and other complexes of amphotericin B available for use by infusion when conventional amphotericin B is contra-indicated because of toxicity, especially nephrotoxicity. Before starting therapy with any form of intravenous amphotericin B a test dose is usually advised and the patient observed carefully for about 30 minutes.

Details of intravenous administration and dosage vary according to the formulation being used. Therapy has sometimes continued for several months depending on the infection. Doses are expressed in terms of amphotericin B.

- ***Conventional amphotericin B*** (*Fungizone, UK*). After an initial test dose (1 mg infused over 20 to 30 minutes) treatment usually starts with a daily dose of 250 micrograms/kg, increased gradually to a maximum of 1 mg/kg daily; in seriously ill patients up to 1.5 mg/kg daily or on alternate days may be necessary. If treatment is stopped for longer than 7 days, it should be resumed at a dose of 250 micrograms/kg daily and increased gradually. The daily dose is infused over 2 to 4 hours at a concentration of 100 micrograms/mL in glucose 5%. Slower infusion, over up to 6 hours, may be necessary to reduce the incidence of acute toxic effects.
- ***Liposomal amphotericin B*** (*AmBisome, UK*). After an initial test dose (1 mg infused over 10 minutes), the usual dose is 1 mg/kg daily, increased gradually to 3 mg/kg if necessary. The daily dose is infused over 30 to 60 minutes at a concentration of 200 to 2000 micrograms/mL in glucose 5%.
- ***Amphotericin B-sodium cholesteryl sulfate complex*** (*Amphocil, UK*). After an initial test dose (2 mg infused over 10 minutes) the usual dose is 1 mg/kg daily, increased gradually to 3 to 4 mg/kg daily if necessary; doses of up to 6 mg/kg daily have been given. The daily dose is infused at a rate of 1 to 2 mg/kg per hour at a concentration of 625 micrograms/mL in glucose 5%.
- ***Amphotericin B-phospholipid complex*** (*Abelcet, UK*). After an initial test dose (1 mg infused over 15 minutes) the usual dose is 5 mg/kg daily. The daily dose is infused at a rate of 2.5 mg/kg per hour as a diluted suspension containing 1 mg/mL in glucose 5%.

Conventional amphotericin B may be given by *intrathecal* injection to patients with severe meningitis especially when intravenous therapy has been ineffective. Starting with 25 micrograms, the dose is gradually increased to the maximum that can be tolerated without excessive discomfort. The usual dosage is 0.25 to 1 mg given two to four times each week.

Conventional amphotericin B is also used *orally* as 10-mg lozenges or as a suspension containing 100 mg/mL for oral or perioral candidiasis. The suspension is given in a dose of 1 mL four times daily; it should be retained in the mouth for as long as possible before swallowing. The lozenges are intended to be dissolved in the mouth and are given four times daily, increased to 8 lozenges daily if necessary. Doses of 100 to 200 mg are given four times daily as tablets or suspension to suppress intestinal *Candida*.

Conventional amphotericin B has been given for candiduria as a *continuous bladder irrigation* daily at a suggested concentration of 50 mg in 1000 mL of sterile water. Intermittent irrigation has also been tried.

Conventional amphotericin B has also been given into the lung by nebulised solution, into the eye topically or by subconjunctival or intravitreal injection, to the skin by topical application, into body cavities by instillation, and into joint spaces by intra-articular injection.

Administration. *LIPID FORMULATIONS.* A number of lipid formulations of amphotericin B have been developed in an attempt to minimise renal toxicity and acute toxic reactions. Three lipid-based formulations of amphotericin B available commercially in some countries are:

- liposomes (e.g. *AmBisome*)[1]
- a lipid complex with L-α-dimyristoylphosphatidylcholine and L-α-dimyristoylphosphatidylglycerol (e.g. *Abelcet*)
- a colloidal dispersion with sodium cholesteryl sulfate (e.g. *Amphocil*)

The aim of reducing renal toxicity has largely been achieved, and in some cases patients unable to tolerate conventional amphotericin B have subsequently been successfully treated with one of the lipid-based formulations. Experience with these formulations suggests that they also produce fewer acute toxic reactions. Review articles[2-9] on lipid formulations of amphotericin B indicate that clinical studies have generally been encouraging, and that although they differ in their pharmacodynamics, pharmacokinetics, and dosage, they appear to be clinically at least as effective as amphotericin B.[5,6]

INFUSION RATE. Conventional amphotericin B is licensed for use by intravenous infusion over at least 2 hours. A long infusion time is inconvenient for outpatients and often impractical in patients receiving other intravenous medications. This may be overcome by using one of the lipid formulations that can be infused over 30 to 120 minutes. Shorter infusion times have been tried with conventional amphotericin B but although 2 studies[1,2] in small numbers of patients without pre-existing renal impairment found rapid infusion over 1 hour was generally no more toxic than infusion over 4 hours, another[3] found infusion over 45 minutes to be more toxic than a 4-hour infusion during the first 5 to 7 days of treatment. Cardiac toxicity reported in patients receiving rapid infusions includes atrial fibrillation in a patient with pre-existing cardiac disease,[2] ventricular fibrillation associated with hyperkalaemia in a patient with severe renal impairment,[4] and bradycardia[5] and dilated cardiomyopathy[6] in patients without apparent risk factors. Ventricular dysrhythmias were not observed in 27 patients with adequate renal function.[7]

Conversely, continuous infusion of amphotericin B over 24 hours has resulted in fewer adverse effects and a significant reduction in nephrotoxicity compared with infusion over 4 hours.[8] Furthermore, an observational study of 33 patients concluded that a continuous infusion of amphotericin B deoxycholate, started at 1 mg/kg daily and gradually escalated to 2 mg/kg daily was safe and well tolerated by most patients.[9]

Administration in children and neonates. Intravenous doses for conventional and lipid formulations of amphotericin B similar to those in adults have been found to be safe and effective in children and neonates with candidiasis. For neonates with severe disease, dose increments of conventional amphotericin B every 12 hours have been given and daily doses up to 1.5 mg/kg tolerated. For prophylaxis of neonatal intestinal candidiasis conventional amphotericin B solution 100 mg is given orally once daily. Although the most appropriate dose of lipid formulations of amphotericin B for low-birth-weight preterm infants has yet to be firmly established reports suggest that they may be safe and effective at doses similar to those used in adults, relative to body-weight.[1-3]

Leishmaniasis. The treatment of visceral and mucocutaneous leishmaniasis including the use of amphotericin B is described on p.824.

VISCERAL LEISHMANIASIS. Evidence of declining responsiveness to pentavalent antimonials has led to the evaluation of intravenous amphotericin B as an alternative for first-line therapy. WHO has included liposomal amphotericin B 3 mg/kg daily on each of 5 consecutive days and a sixth dose 6 days later among the regimens suggested for first-line therapy of Mediterranean visceral leishmaniasis in immunocompetent patients.[1] Similar doses are recommended by licensed product information for one product (*AmBisome; Gilead, USA*), which recommends 3 mg/kg daily for 5 days with further doses on days 14 and 21. Experience with a short course of 10 mg/kg daily for 2 days was also shown to be effective in 41 immunocompetent children under 14 years, although 1 subsequently relapsed after 5 weeks.[2] Responses to liposomal amphotericin B have been reported to be slower in immunocompromised patients; relapses occurred in 8 of 11 patients despite treatment with liposomal amphotericin B 1.38 to 1.85 mg/kg daily for 21 days.[3] Increasing the dose to 4 mg/kg daily given on 10 days over a 38-day period did not improve the long-term outcome, although initial responses were good[4] and this regimen is now that recommended by the licensed product information above. Due to frequent relapse in these patients secondary prophylaxis with intermittent amphotericin B has been considered. An open-label, multicentre study with amphotericin B lipid complex in doses of 3 mg/kg every 21 days for 12 months[5] was effective in 50% of HIV-infected patients. Another cohort study[6] reported that 80% of HIV-infected patients were relapse free at 12 months after receiving an initial treatment course of liposomal amphotericin B in doses of 4 mg/kg daily for 5 consecutive days and then once weekly for 5 weeks, followed by secondary prophylaxis in doses of 5 mg/kg every 3 weeks. However, at 24 months about 45% of the patients had experienced relapses.

Amphotericin B is also being evaluated in other parts of the world. In India, conventional amphotericin B in modest doses (500 micrograms/kg on alternate days) produced good responses both in patients unresponsive to antimonials[7,8] and as first-line therapy.[9] Experience with a higher dose of 1 mg/kg daily for 20 days achieved a 99% cure rate in 938 patients[10] and a lower dose regimen of 0.75 mg/kg daily for 15 days was also found to be effective.[11] Liposomal amphotericin B 2 mg/kg daily on 3, 5 or 7 days over a 10-day period all produced clinical cures and minimal toxicity,[12] as did single infusions of 7.5 mg/kg or 5 mg/kg, or once-daily infusion of 1 mg/kg for 5 days.[13,14] Amphotericin B lipid complex 1, 2, or 3 mg/kg daily for 5 days,[15] or 5 mg/kg given once or twice (5 days apart),[16] has been used successfully although relapses occurred in some patients taking the lower doses in these latter studies. In Brazil, colloidal amphotericin B with sodium cholesteryl sulfate in a dose of 2 mg/kg daily for 5 days produced cures in 10 patients although 1 subsequently relapsed.[17] A study by WHO[18] suggested that more intensive courses of treatment may be needed in Brazil compared with India and Kenya.

MUCOCUTANEOUS LEISHMANIASIS. Amphotericin B is used in mucocutaneous leishmaniasis unresponsive to antimonials. Successful treatment with liposomal amphotericin B has been reported in immunocompetent[19] and immunocompromised[20] patients.

Primary amoebic meningoencephalitis. Amphotericin B is active *in vitro* against *Naegleria fowleri* and has been recommended for the treatment of primary amoebic meningoencephalitis (see Naegleria Infections, p.822) caused by this amoeba. There have been some case reports[1-7] of survival after the use of intravenous and intrathecal amphotericin B. In all cases amphotericin B was combined with other antimicrobials, notably oral rifampicin.

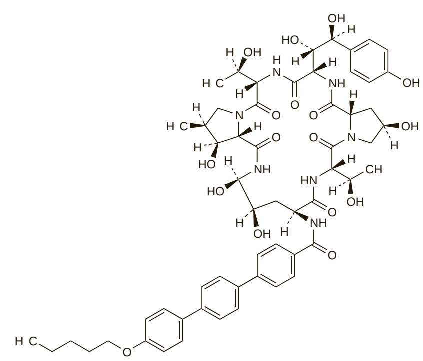
Anidulafungin *(USAN, rINN)*

Anidulafungina; Anidulafungine; Anidulafunginum; LY-303366; V-Echinocandin. (4*R*,5*R*)-4,5-Dihydroxy-*N*[2]-{[4″-(pentyloxy)-*p*-terphenyl-4-yl]carbonyl}-L-ornithyl-L-threonyl-*trans*-4-hydroxy-L-prolyl-(*S*)-4-hydroxy-4-(*p*-hydroxyphenyl)-L-threonyl-L-threonyl-(3*S*,4*S*)-3-hydroxy-4-methyl-L-proline cyclic (6→1)-peptide; 1-((4*R*,5*R*)-4,5-Dihydroxy-*N*[2]-{[4″-(pentyloxy)(1,1′:4′,1″-terphenyl)-4-yl]carbonyl}-L-ornithine)-echinocandin B.

Анидулафунгин

$C_{58}H_{73}N_7O_{17}$ = 1140.2.
CAS — 166663-25-8.
ATC — J02AX06.
ATC Vet — QJ02AX06.



Adverse Effects and Precautions

As for Caspofungin, see p.528.

Dose adjustments are not required in patients with hepatic or renal impairment.

Interactions

Few drug interactions are expected with anidulafungin, as it is not metabolised by the hepatic cytochrome P450 system and almost no renal clearance occurs.

Antimicrobial Action

As for Caspofungin, see p.528.

Pharmacokinetics

Steady state plasma concentrations of anidulafungin are achieved after the first loading dose; systemic clearance is about 1 litre/hour and the terminal elimination half-life is 40 to 50 hours. Anidulafungin is 84% bound to plasma proteins and the volume of distribution is 30 to 50 litres. It is not metabolised, but undergoes slow chemical degradation to inactive peptide degradants. Less than 10% of the intact drug is eliminated in the faeces and less than 1% is excreted in the urine.

2. Benjamin DK, *et al.* Safety and pharmacokinetics of intravenous anidulafungin in children with neutropenia at high risk for invasive fungal infections. *Antimicrob Agents Chemother* 2006; **50:** 632–8.

Uses and Administration

Anidulafungin is an echinocandin antifungal active against *Aspergillus* and *Candida* spp. It is used in the treatment of candidaemia, oesophageal candidiasis, and other forms of invasive candidiasis.

Anidulafungin is given by intravenous infusion, the rate of which should not exceed 1.1 mg/minute. For candidaemia and other invasive candidiasis a loading dose of 200 mg is given on the first day followed by 100 mg daily thereafter. For oesophageal candidiasis the loading dose is 100 mg followed by 50 mg daily.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Bifonazole). A white or almost white crystalline powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in dehydrated alcohol.

Profile

Bifonazole is an imidazole antifungal with a broad spectrum of activity; sensitive fungi include dermatophytes, *Malassezia furfur*, and *Candida* spp. It also has some antibacterial activity.

Bifonazole is mainly used by topical application in the treatment of fungal skin and nail infections (p.521). It is applied once daily as a 1% cream, powder, solution, or gel. Treatment is usually continued for 2 to 4 weeks. More prolonged treatment is necessary for nail infections and bifonazole may be applied initially with a 40% urea paste to soften the nail.

Local reactions including burning and itching have been reported.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

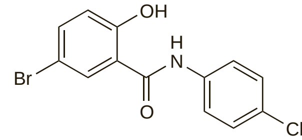
ATC Vet — QD01AE01.



Profile

Bromochlorosalicylanilide is a bromsalan antifungal that has been applied topically. Photosensitivity may occur. See also Bromsalans, p.1632.

Preparations

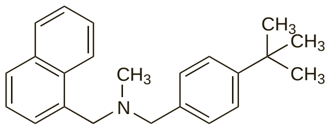
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***India:*** Multifungin H†; Multifungin†.

Butenafine Hydrochloride *(BANM, USAN, rINNM)*

Butenafiinihydrokloridi; Buténafine, Chlorhydrate de; Butenafinhydroklorid; Butenafini Hydrochloridum; Hidrocloruro de butenafina; KP-363. *N*-(*p*-*tert*-Butylbenzyl)-*N*-methyl-1-naphthalenemethylamine hydrochloride; 4-*tert*-Butylbenzyl(methyl)(1-naphthalenemethyl)amine hydrochloride.

Бутенафина Гидрохлорид

$C_{23}H_{27}N,HCl = 353.9.$
CAS — 101828-21-1 (butenafine); 101827-46-7 (butenafine hydrochloride).
ATC — D01AE23.
ATC Vet — QD01AE23.



(butenafine)

Profile

Butenafine is a benzylamine antifungal with actions similar to those of the allylamine antifungal terbinafine (p.546). The hydrochloride is used topically as a 1% cream for the treatment of superficial dermatophyte infections (see Skin Infections, p.521).

◊ Reviews.

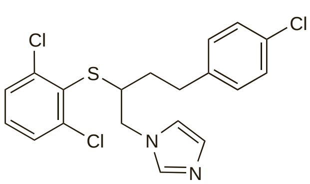
Butoconazole Nitrate *(BANM, USAN, rINNM)*

Butoconazole, Nitrate de; Butoconazoli Nitras; Nitrato de butoconazol; RS-35887; RS-35887-00-10-3. 1-[4-(4-Chlorophenyl)-2-(2,6-dichlorophenylthio)butyl]imidazole mononitrate.

Бутоконазола Нитрат

$C_{19}H_{17}Cl_3N_2S,HNO_3 = 474.8.$
CAS — 64872-76-0 (butoconazole); 64872-77-1 (butoconazole nitrate).
ATC — G01AF15.
ATC Vet — QG01AF15.



(butoconazole)

Pharmacopoeias. In *US.*

USP 31 (Butoconazole Nitrate). A white to off-white crystalline powder. Practically insoluble in water; slightly soluble in acetone, in acetonitrile, in dichloromethane, and in tetrahydrofuran; very slightly soluble in ethyl acetate; sparingly soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

Local reactions including burning and irritation and pelvic or abdominal pain or cramping may occur when butoconazole is applied vaginally.

Intravaginal preparations of butoconazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Effects on the blood. Severe reversible thrombocytopenia was associated with treatment with intravaginal butoconazole.[1] The patient had previously had a drop in white cell count after treatment with intravaginal clotrimazole, suggestive of an idiosyncratic reaction to imidazoles.

1. Maloley PA, *et al.* Severe reversible thrombocytopenia resulting from butoconazole cream. *DICP Ann Pharmacother* 1990; **24:** 143–4.

Antimicrobial Action

Butoconazole is an imidazole antifungal with antimicrobial activity similar to that of ketoconazole (p.539) including activity against *Candida* spp.

Pharmacokinetics

About 5% of a dose of butoconazole is absorbed after vaginal use. The plasma half-life is 21 to 24 hours.

Uses and Administration

Butoconazole is an imidazole antifungal used locally as the nitrate in the treatment of vulvovaginal candidiasis (p.518). It is given intravaginally as a 100-mg pessary or as 5 g of a 2% cream for 3 consecutive nights; a single application of the cream has also been used.

Preparations

USP 31: Butoconazole Nitrate Vaginal Cream.

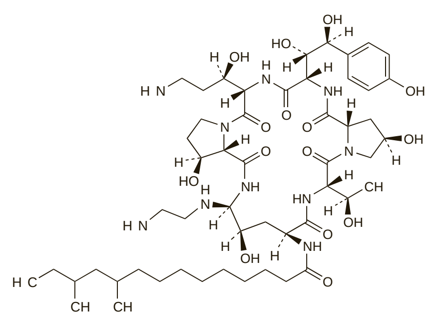
ATC — J02AX04.
ATC Vet — QJ02AX04.



(caspofungin)

Adverse Effects and Precautions

Adverse experiences reported with caspofungin have included anaemia, diarrhoea, nausea and vomiting, flushing, headache, fever, tachycardia, and venous complications around the infusion site. Possible histamine-mediated symptoms have been rash, facial swelling, pruritus, sensation of warmth, or bronchospasm. Anaphylaxis has occurred.

Isolated cases of hepatotoxicity have occurred and patients who develop abnormal liver function tests should be monitored for deterioration in hepatic function. Caspofungin may need to be given in reduced doses to patients with hepatic impairment (see below).

Breast feeding. Caspofungin is excreted in the breast milk of lactating *animals*, but the risk to breast-fed infants is suggested to be low. Recommendations in licensed product information vary: in the UK it recommends against use in women who are breast feeding, while in the USA caution is advised.

Pregnancy. Caspofungin has been shown to cross the placenta in *animal* studies and was shown to be embryotoxic in *rats* and *rabbits*; it was noted that there were no adequate and well-controlled studies in human pregnancy. Caspofungin is generally only recommended in pregnancy if the benefits to the mother are considered to outweigh the risks to the fetus.

Interactions

Although caspofungin is not metabolised by the hepatic cytochrome P450 system, drugs that induce hepatic enzymes may increase its clearance. Such effects have been noted with carbamazepine, dexamethasone, efavirenz, nevirapine, phenytoin, and rifampicin, and an increase in the dose of caspofungin should be considered in patients who are also taking these drugs and who are not clinically responding (see Uses and Administration, below).

When caspofungin has been given with ciclosporin, an increase in the area under the concentration-time curve for caspofungin, as well as increases in hepatic enzymes, were observed and use of the two drugs together is not recommended.

Caspofungin has resulted in decreased blood concentrations of tacrolimus and therapeutic drug monitoring and appropriate dosage adjustments to tacrolimus are recommended.

Antimicrobial Action

Caspofungin inhibits the synthesis of β-1,3-D-glucan, an essential component of the cell wall of many fungi. Caspofungin exhibits *in-vitro* activity against many *Aspergillus* spp. and is fungicidal against *Candida* spp. including non-albicans strains.

Pharmacokinetics

Plasma concentrations of caspofungin decline in a polyphasic manner after intravenous infusion. The initial short α-phase occurs immediately post-infusion and is followed by a β-phase with a half-life of 9 to 11 hours; an additional longer γ-phase also occurs with a half-life of 40 to 50 hours. Plasma clearance is dependent on distribution rather than on biotransformation or excretion. Caspofungin is highly bound to plasma protein. There is slow metabolism of caspofungin by hydrolysis and *N*-acetylation and excretion in faeces and urine.

Uses and Administration

Caspofungin is an echinocandin antifungal used in the treatment of invasive aspergillosis (p.517) in patients who are refractory to, or intolerant of, other therapy. It is also used in the treatment of invasive candidiasis and as empirical therapy for presumed fungal infections in febrile, neutropenic patients.

Caspofungin is used as the acetate but doses are expressed in terms of the base; caspofungin acetate 77.7 mg is equivalent to about 70 mg of caspofungin. It is given by slow intravenous infusion over about 1 hour. A loading dose of 70 mg is given on the first day and is followed by 50 mg daily; in adult patients weighing more than 80 kg, and in patients taking hepatic-enzyme inducing drugs who fail to respond, a daily dose of 70 mg is recommended. Doses may need to be reduced in patients with hepatic impairment (see below).

Administration in children. Caspofungin is not licensed for use in paediatric patients, but has been prescribed.[1] A retrospective study[2] of 25 immunocompromised children with a median age of 9.8 years, given at least one dose of caspofungin, found that it appeared to be safe and well tolerated. Patients weighing less than 50 kg had a dose of 0.8 to 1.6 mg/kg daily, while those over 50 kg were given 50 to 75 mg daily. Another retrospective review[3] of 64 immunocompromised children with a median age of 11.5 years, reported a success rate of 67.7% with caspofungin at a median daily maintenance dose of 1.07 mg/kg, either as monotherapy or with another antifungal. A case series[4] of 10 neonates (9 preterm) with invasive candidiasis not responsive to amphotericin B and/or fluconazole reported that *Candida* spp. were cleared from the blood in all patients in a mean of 4.3 days after starting caspofungin therapy. Nine neonates were given an initial dose of 1 mg/kg daily for the first 2 days followed by 2 mg/kg daily for 15 to 21 days; the other was given a lower dose.

4. Odio CM, *et al.* Caspofungin therapy of neonates with invasive candidiasis. *Pediatr Infect Dis J* 2004; **23:** 1093–7.

Administration in hepatic impairment. Patients with mild hepatic impairment do not require dosage adjustment. In patients with moderate hepatic impairment, a daily dose of caspofungin 35 mg should be used after the initial dose of 70 mg; appropriate doses for patients with severe hepatic impairment have not been established.

Циклопирокс Оламин

$C_{12}H_{17}NO_2,C_2H_7NO = 268.4.$

CAS — 41621-49-2.

ATC — D01AE14; G01AX12.

ATC Vet — QD01AE14; QG01AX12.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Ciclopirox Olamine). A white or pale yellow crystalline powder. It exhibits polymorphism. Slightly soluble in water; very soluble in alcohol and in dichloromethane; slightly soluble in ethyl acetate; practically insoluble in cyclohexane. A 1% solution in water has a pH of 8.0 to 9.0. Protect from light.

USP 31 (Ciclopirox Olamine). A white to slightly yellowish-white, crystalline powder. Slightly soluble in water; very soluble in alcohol and in dichloromethane; practically insoluble in cyclohexane. pH of a 1% solution in water is between 8.0 and 9.0. Store in airtight containers at a temperature of 5° to 25°. Protect from light.

Adverse Effects

Irritation and pruritus have been reported after topical application of ciclopirox.

Antimicrobial Action

Ciclopirox has a wide spectrum of antifungal activity. It inhibits most *Candida*, *Epidermophyton*, *Microsporum*, and *Trichophyton* spp. and is also active against *Malassezia furfur.* It has some antibacterial activity.

Uses and Administration

Ciclopirox is an antifungal that is applied topically in the treatment of fungal skin and nail infections, including cutaneous candidiasis (p.518), dermatophytosis, pityriasis versicolor (see Skin Infections, p.521), and seborrhoeic dermatitis (p.1584). It has also been used in the treatment of vaginal candidiasis.

It is applied twice daily for skin infections, as a cream, gel, suspension, solution, or powder; both the base and the olamine salt have been used, with products containing the equivalent of 0.77% ciclopirox base.

A lacquer containing 8% ciclopirox base is applied once daily for nail infections.

A shampoo containing 1% ciclopirox base is used twice weekly for the treatment of seborrhoeic dermatitis.

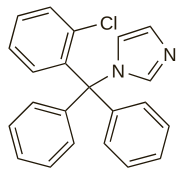
ATC Vet — QA01AB18; QD01AC01; QG01AF02; QJ02AB90.



NOTE. Compounded preparations of clotrimazole may be represented by the following names:

- Co-climasone (*PEN*)—clotrimazole and betamethasone dipropionate.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Clotrimazole). A white or pale yellow crystalline powder. Practically insoluble in water; soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Clotrimazole). A white to pale yellow, crystalline powder. Practically insoluble in water; freely soluble in alcohol, in acetone, in chloroform, and in methyl alcohol. Store in airtight containers.

Adverse Effects and Precautions

Nausea, vomiting, unpleasant mouth sensations, and pruritus have been reported after the use of oral clotrimazole lozenges. Raised liver enzyme values have also occurred. Local reactions including irritation and a burning sensation may occur in patients treated topically; contact allergic dermatitis has been reported.

Intravaginal preparations of clotrimazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

Gastrointestinal disturbance, elevation of liver enzymes, dysuria, and mental depression have been reported after oral clotrimazole (although this route is no longer used). For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Antimicrobial Action

Clotrimazole is an imidazole antifungal with antimicrobial activity similar to that of ketoconazole (p.539).

Pharmacokinetics

When applied topically clotrimazole penetrates the epidermis but there is little if any systemic absorption. Absorption of 3 to 10% of a dose has been reported after vaginal use. Clotrimazole is metabolised in the liver to inactive compounds and excreted in the faeces and urine.

Uses and Administration

Clotrimazole is an imidazole antifungal used topically in superficial candidiasis (p.518), and in the skin infections pityriasis versicolor and dermatophytosis (see Skin Infections, p.521). Clotrimazole may also be used occasionally for symptomatic relief of the protozoal infection trichomoniasis when other drugs are contra-indicated (see p.827).

Clotrimazole is applied topically two or three times daily for 2 to 4 weeks as a 1% cream, lotion, spray, or solution in the treatment of fungal skin infections; a 1% powder may be used with the cream or solution and has been applied to prevent re-infection. The 1% solution is also used topically for fungal otitis externa. Clotrimazole is given as pessaries in dosage regimens of 100 mg for 6 days, 200 mg for 3 days, or a single dose of 500 mg in the treatment of vulvovaginal candidiasis; similar doses are given as a 1, 2, or 10% vaginal cream. It may be necessary to treat balanitis in male partners concurrently.

For the treatment of oropharyngeal candidiasis one 10-mg lozenge of clotrimazole is dissolved in the mouth five times daily for 14 days. For the prophylaxis of oropharyngeal candidiasis in patients receiving immunosuppressant therapy the dose is one 10-mg lozenge three times daily for the duration of the immunosuppressant treatment. Clotrimazole has also been given orally but has now been largely superseded by other azole drugs.

Sickle-cell disease. Oral clotrimazole has been investigated for the treatment of sickle-cell disease (p.1044).[1]

1. Brugnara C, *et al.* Therapy with oral clotrimazole induces inhibition of the Gardos channel and reduction of erythrocyte dehydration in patients with sickle cell disease. *J Clin Invest* 1996; **97:** 1227–34.

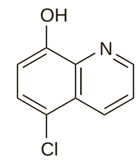
Cloxiquine *(rINN)*

5-Chloro-8-hydroxyquinoline; Cloxiquina; Cloxiquinum; Cloxyquin *(USAN)*. 5-Chloroquinolin-8-ol.

Клоксихин

C_9H_6ClNO = 179.6.

CAS — 130-16-5.



Profile

Cloxiquine has been included in preparations used topically for the treatment of fungal and bacterial skin infections. It is a component of halquinol, p.286.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Austria:*** Decoderm trivalent; ***Indon.:*** Decoderm 3; ***Thai.:*** Supracortin 3†.

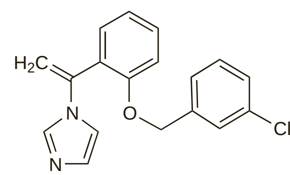
Croconazole Hydrochloride *(rINNM)*

Cloconazole Hydrochloride; Croconazol, Chlorhydrate de; Croconazoli Hydrochloridum; Hidrocloruro de croconazol; 710674-S (croconazole). 1-(1-{*o*-[(*m*-Chlorobenzyl)oxy]phenyl}vinyl)imidazole hydrochloride.

Кроконазола Гидрохлорид

$C_{18}H_{15}ClN_2O,HCl$ = 347.2.

CAS — 77175-51-0 (croconazole).



(croconazole)

Pharmacopoeias. In *Jpn.*

Profile

Croconazole is an imidazole antifungal used topically in the treatment of superficial cutaneous candidiasis, dermatophytosis, and pityriasis versicolor. It is applied as a 1% cream or gel containing the hydrochloride.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Pilzcin; ***Ger.:*** Pilzcin; ***Jpn:*** Pilzcin.

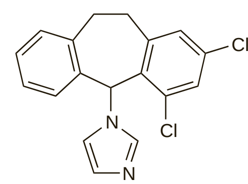
Eberconazole Nitrate *(rINNM)*

Éberconazole, Nitrate de; Eberconazoli Nitras; Nitrato de eberconazol. (±)-1-(2,4-Dichloro-10,11-dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-yl)imidazole nitrate.

Эберконазола Нитрат

$C_{18}H_{14}Cl_2N_2,NO_3$ = 391.2.

CAS — 128326-82-9 (eberconazole).



(eberconazole)

Profile

Eberconazole nitrate is an imidazole antifungal used topically as a 1% cream in the treatment of superficial fungal infections of the skin.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

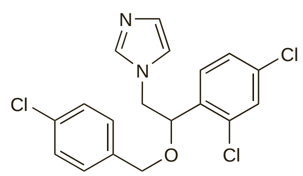
Econazole *(BAN, USAN, rINN)*

Econazol; Éconazole; Econazolum; Ekonatsoli; Ekonazol; Ekonazolas. 1-[2,4-Dichloro-β-(4-chlorobenzyloxy)phenethyl]imidazole.

Эконазол

$C_{18}H_{15}Cl_3N_2O$ = 381.7.
CAS — 27220-47-9.
ATC — D01AC03; G01AF05.
ATC Vet — QD01AC03; QG01AF05.



Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Econazole). A white or almost white powder. M.p. 88° to 92°. Practically insoluble in water; very soluble in alcohol and in dichloromethane. Protect from light.

Econazole Nitrate *(BANM, USAN, rINNM)*

C-C2470; Éconazole, nitrate d'; Econazoli nitras; Ekonatsolinitraatti; Ekonazolnitrat; Ekonazol-nitrát; Ekonazolo nitratas; Nitrato de econazol; R-14827; SQ-13050. (±)-1-[2,4-Dichloro-β-(4-chlorobenzyloxy)phenethyl]imidazole nitrate.

Эконазола Нитрат

$C_{18}H_{15}Cl_3N_2O,HNO_3$ = 444.7.
CAS — 24169-02-6 (econazole nitrate); 68797-31-9 ((±)-econazole nitrate).
ATC — D01AC03; G01AF05.
ATC Vet — QD01AC03; QG01AF05.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*
Ph. Eur. 6.2 (Econazole Nitrate). A white or almost white crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; sparingly soluble in dichloromethane; soluble in methyl alcohol. Protect from light.
USP 31 (Econazole Nitrate). A white or practically white, crystalline powder, with not more than a slight odour. Very slightly soluble in water and in ether; slightly soluble in alcohol; sparingly soluble in chloroform; soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

Local reactions including burning and irritation may occur when econazole nitrate is applied topically. Contact dermatitis has been reported rarely.

Intravaginal preparations of econazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Porphyria. Econazole nitrate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Antimicrobial Action

Econazole is an imidazole antifungal with antimicrobial activity similar to that of ketoconazole (p.539).

Pharmacokinetics

Absorption is not significant when econazole nitrate is applied to the skin or vagina.

Uses and Administration

Econazole is an imidazole antifungal used topically in the treatment of superficial candidiasis (see p.518) and in dermatophytosis and pityriasis versicolor (see Skin Infections, p.521).

Econazole nitrate is applied topically up to 3 times daily as a 1% cream, lotion, powder, or solution in the treatment of fungal skin infections. Treatment is continued for 2 to 4 weeks. It is also used in the treatment of vaginal candidiasis as pessaries of 150 mg once daily at bedtime for 3 consecutive nights; a single dose of 150 mg in a long-acting formulation has also been used. Intravaginal use of 5 g of a 1% cream once daily at night has been given for 2 weeks. A 1% cream may be used concurrently for the treatment of vulval infections or for the treatment of balanitis in a male partner.

In the treatment of fungal infections of the nails, a 1% cream or lotion is applied once daily and covered with an occlusive dressing.

Econazole nitrate has also been used as eye or ear drops.

Econazole sulfosalicylate has also been used.

Preparations

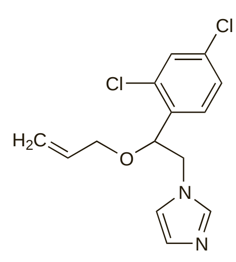
Enilconazole *(BAN, USAN, rINN)*

Enilconazol; Énilconazole; Enilconazolum; Enilkonatsoli; Enilkonazol; R-23979. (±)-1-(β-Allyloxy-2,4-dichlorophenethyl)imidazole.

Энилконазол

$C_{14}H_{14}Cl_2N_2O$ = 297.2.
CAS — 35554-44-0.
ATC Vet — QD01AC90.



Pharmacopoeias. In *Eur.* (see p.vii) for veterinary use only.
Ph. Eur. 6.2 (Enilconazole for Veterinary Use; Enilconazole BP(Vet) 2008). A clear, yellowish, oily liquid or solid mass. Very slightly soluble in water; freely soluble in alcohol, in methyl alcohol, and in toluene. Store in airtight containers. Protect from light.

Profile

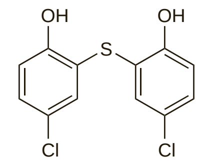
Enilconazole is an imidazole antifungal used topically in veterinary medicine for the treatment of fungal skin infections in cattle, horses, and dogs. It is also used by inhalation for the treatment of aspergillosis in ostriches.

Fenticlor *(BAN, USAN, rINN)*

D-25; Fenticloro; Fenticlorum; HL-1050; NSC-4112; Ph-549; S-7. 2,2′-Thiobis(4-chlorophenol).

Фентиклор

$C_{12}H_8Cl_2O_2S$ = 287.2.
CAS — 97-24-5.



Profile

Fenticlor is an antifungal that has been applied topically in the treatment of dermatophyte infections.

Photosensitivity reactions have been reported.

Preparations

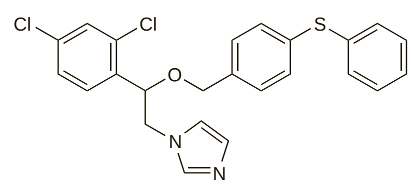
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Spain:*** Dermisdin†.

Fenticonazole Nitrate *(BANM, USAN, rINNM)*

Fenticonazole, nitrate de; Fenticonazoli nitras; Fentikonatsolinitraatti; Fentikonazolnitrat; Fentikonazol-nitrát; Fentikonazolo nitratas; Nitrato de fenticonazol; Rec-15/1476. (±)-1-[2,4-Dichloro-β-{[*p*-(phenylthio)benzyl]oxy}phenethyl]imidazole mononitrate.

Фентиконазола Нитрат

$C_{24}H_{20}Cl_2N_2OS,HNO_3$ = 518.4.
CAS — 72479-26-6 (fenticonazole); 73151-29-8 (fenticonazole nitrate).
ATC — D01AC12; G01AF12.
ATC Vet — QD01AC12; QG01AF12.



(fenticonazole)

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Fenticonazole Nitrate). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in dimethylformamide and in methyl alcohol. Protect from light.

Adverse Effects and Precautions

Burning and itching have been reported after the application of fenticonazole nitrate.

Intravaginal preparations of fenticonazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Antimicrobial Action

Fenticonazole is an imidazole antifungal active against a range of organisms including dermatophyte pathogens, *Malassezia furfur,* and *Candida albicans.*

Uses and Administration

Fenticonazole is an imidazole antifungal used locally as the nitrate in the treatment of vulvovaginal candidiasis (p.518). A 200-mg pessary is inserted into the vagina at bedtime for 3 nights or a 600-mg pessary is inserted once only at bedtime. Fenticonazole nitrate is also applied topically as a 2% cream or solution for the treatment of fungal skin infections.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Lomexin†; ***Austria:*** Lomexin; ***Braz.:*** Fentizol; Lomexin; ***Cz.:*** Lomexin; ***Fr.:*** Lomexin; Terlomexin; ***Ger.:*** Fenizolan; Lomexin; ***Gr.:*** Lomexin; ***Hung.:*** Gynoxin; ***Ital.:*** Falvin; Fentiderm†; Fentigyn†; Lomexin; ***Mex.:*** Lomexin; ***Neth.:*** Gynoxin; ***Pol.:*** Gynoxin; ***Port.:*** Lomexin; ***S.Afr.:*** Lomexin†; ***Singapore:*** Lomexin†; ***Spain:*** Laurimic; Lomexin; Micofulvin; ***Switz.:*** Mycodermil; ***Turk.:*** Gyno-Lomexin; ***UK:*** Lomexin†; ***Venez.:*** Mycofentin.

Fluconazole *(BAN, USAN, rINN)*

Fluconazol; Fluconazolum; Flukonatsoli; Flukonazol; UK-49858. 2-(2,4-Difluorophenyl)-1,3-bis(1*H*-1,2,4-triazol-1-yl)propan-2-ol.

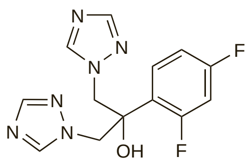
Флуконазол

$C_{13}H_{12}F_2N_6O$ = 306.3.

CAS — 86386-73-4.

ATC — D01AC15; J02AC01.

ATC Vet — QD01AC15; QJ02AC01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Fluconazole). A white or almost white, hygroscopic, crystalline powder. It exhibits polymorphism. Slightly soluble in water; freely soluble in methyl alcohol; soluble in acetone. Store in airtight containers.

USP 31 (Fluconazole). A white or almost white, crystalline powder. Slightly soluble in water; soluble in alcohol and in acetone; sparingly soluble in chloroform and in isopropyl alcohol; freely soluble in methyl alcohol; very slightly soluble in toluene. Store in airtight containers at a temperature below 30°.

Incompatibility and stability. References.

Adverse Effects

Adverse effects reported with fluconazole most commonly affect the gastrointestinal tract and include abdominal pain, diarrhoea, flatulence, nausea and vomiting, and taste disturbance. Other adverse effects include headache, dizziness, leucopenia, thrombocytopenia, hyperlipidaemias, and raised liver enzyme values. Serious hepatotoxicity has been reported in patients with severe underlying disease such as AIDS or malignancy. Anaphylaxis and angioedema have been reported rarely.

Skin reactions are rare but exfoliative cutaneous reactions such as toxic epidermal necrolysis and Stevens-Johnson syndrome have occurred, more commonly in patients with AIDS.

Alopecia. Alopecia has occasionally been reported in patients receiving fluconazole, especially during prolonged use.[1,2]

1. Weinroth SE, Tuazon CU. Alopecia associated with fluconazole treatment. *Ann Intern Med* 1993; **119:** 637.
2. Pappas PG, *et al.* Alopecia associated with fluconazole therapy. *Ann Intern Med* 1995; **123:** 354–7.

Effect on electrolyte balance. Hypokalaemia was associated with fluconazole in 3 patients with acute myeloid leukaemia.[1]

1. Kidd D, *et al.* Hypokalaemia in patients with acute myeloid leukaemia after treatment with fluconazole. *Lancet* 1989; **i:** 1017.

Effects on the heart. Prolonged QT interval and torsade de pointes have been reported rarely in patients receiving fluconazole.[1-5]

1. Wassmann S, *et al.* Long QT syndrome and torsade de pointes in a patient receiving fluconazole. *Ann Intern Med* 1999; **131:** 797.

5. McMahon JH, Grayson ML. Torsades de pointes in a patient receiving fluconazole for cerebral cryptococcosis. *Am J Health-Syst Pharm* 2008; **65:** 619–23.

Effects on the liver. Although severe hepatic reactions to fluconazole are rare they have been reported, especially in patients with severe underlying diseases or hepatic dysfunction.[1,2] Elevated liver enzymes are commonly found and there have been reports of jaundice.[3,4] Hepatic necrosis has been seen rarely post mortem in patients with severe underlying disease who had received fluconazole. In one such patient, hepatotoxicity was concluded to be dose-dependent.[5]

1. Wells C, Lever AML. Dose-dependent fluconazole hepatotoxicity proven on biopsy and rechallenge. *J Infect* 1992; **24:** 111–12.
2. Jacobson MA, *et al.* Fatal acute hepatic necrosis due to fluconazole. *Am J Med* 1994; **96:** 188–90.
3. Holmes J, Clements D. Jaundice in HIV positive haemophiliac. *Lancet* 1989; **i:** 1027.
4. Franklin IM, *et al.* Fluconazole-induced jaundice. *Lancet* 1990; **336:** 565.
5. Bronstein J-A, *et al.* Fatal acute hepatic necrosis due to dose-dependent fluconazole hepatotoxicity. *Clin Infect Dis* 1997; **25:** 1266–7.

Hypersensitivity. Desensitisation has been successfully carried out in a patient with AIDS who exhibited hypersensitivity to both fluconazole and itraconazole.[1] Gradually increasing oral doses of fluconazole (starting at 5 mg daily) were given over 7 days; thereafter dosage was maintained at 400 mg daily. No adverse reactions were noted during the desensitisation period or in the 3 months up to the publication of the report.

1. Takahashi T, *et al.* Desensitization to fluconazole in an AIDS patient. *Ann Pharmacother* 2001; **35:** 642–3.

Precautions

Fluconazole should be used with caution in patients with impaired hepatic or renal function. Abnormalities in haematological, hepatic, and renal-function tests have been observed in patients with serious underlying diseases such as AIDS or malignancy. Cases of torsade de pointes and QT prolongation have been reported rarely and caution is advised when giving fluconazole to patients with proarrhythmic conditions.

Teratogenicity has occurred in *animals* given high doses of fluconazole and its use is not recommended in pregnancy (see under Pregnancy, below).

Breast feeding. Fluconazole is distributed into breast milk, achieving concentrations similar to those found in maternal plasma,[1] and its use in women who are breast feeding is not recommended by licensed product information.

In one report,[2] no untoward effects, other than a slight increase in lactase dehydrogenase level, were seen in an infant who was exposed to fluconazole in breast milk for 6 weeks.

The American Academy of Pediatrics considers that the use of fluconazole is usually compatible with breast feeding.[3]

Pregnancy. High (toxic) doses of *fluconazole*, *itraconazole*, and *ketoconazole* have been reported to be teratogenic in *rodents.* Although there is little information about the use of these drugs in human pregnancy, there is a report of a woman who took fluconazole 400 mg daily throughout pregnancy and who gave birth to an infant with severe craniofacial and limb abnormalities.[1] The abnormalities resembled those associated with the Antley-Bixler syndrome, a genetic disorder, but a teratogenic effect could not be excluded. Although prescription-event-monitoring studies of fluconazole did not reveal adverse effects on the fetus,[2-4] congenital abnormalities have occurred in infants whose mothers were given high doses of fluconazole for 3 months or more. Data collected by the manufacturer,[5] relating to 198 women exposed to itraconazole during the first trimester of pregnancy, indicated that the malformation rate for both exposed women and matched controls was within the expected baseline risk for the general population. Nevertheless, the manufacturers recommend that fluconazole, itraconazole, and ketoconazole should be avoided during pregnancy.

Licensed product information states that doses of *voriconazole* equivalent to those used therapeutically have been shown to be teratogenic and embryotoxic in *rodents*. It therefore recommends that voriconazole should be avoided during pregnancy and that women of child bearing potential should use effective contraception during treatment. Similar recommendations have been made for *posaconazole.*

Other azole antifungals including butoconazole, clotrimazole, econazole, miconazole, sulconazole, terconazole, and tioconazole are reported to be embryotoxic but not teratogenic in *rodents* given high doses. Many of these drugs are used topically or intravaginally and the systemic absorption from these routes of administration varies. While these drugs may not necessarily be contra-indicated in pregnancy, consideration should be given to these potential risks when choosing antifungal therapy for such patients.

Renal impairment. For dose adjustments in renal impairment, see Administration in Renal Impairment, under Uses and Administration, below.

Interactions

In general, fewer interactions are considered to occur with fluconazole than with either itraconazole or ketoconazole.

Use of rifampicin with fluconazole results in reduced plasma concentrations of fluconazole. Use of hydrochlorothiazide and fluconazole has resulted in clinically insignificant increases in plasma-fluconazole concentrations.

Fluconazole may interfere with the metabolism of some other drugs, mainly through inhibition of the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. This may account for the reported increases in plasma concentrations of bosentan, ciclosporin, midazolam, nevirapine, amitriptyline, nortriptyline, phenytoin, rifabutin, sulfonylurea hypoglycaemics and nateglinide, selective cyclo-oxygenase-2-inhibitors such as celecoxib and parecoxib, tacrolimus, triazolam, warfarin, and zidovudine; fluconazole may inhibit the formation of a toxic metabolite of sulfamethoxazole.

Increases in terfenadine concentrations following high doses of fluconazole have been associated with ECG abnormalities. A similar effect may be anticipated with astemizole. Use of fluconazole with cisapride could result in increased cisapride concentrations and associated toxicity. The use of fluconazole with astemizole, cisapride, or terfenadine should therefore be avoided because of the risk of cardiac arrhythmias. Syncope attributed to increased amitriptyline concentrations has occurred when amitriptyline was given with fluconazole.

Fluconazole may also reduce the clearance of theophylline. The concentration of contraceptive steroids has been reported to be both increased and decreased in patients receiving fluconazole and the efficacy of oral contraceptives may be affected.

For further information on interactions between drugs metabolised by the cytochrome P450 isoenzyme CYP3A and azoles, see under Itraconazole, p.537.

Antineoplastics. For the effect of azole antifungals on *cyclophosphamide* metabolism, see p.703.

Fluoroquinolones. Both *levofloxacin* and fluconazole can cause a prolonged QT interval. The simultaneous use of intravenous levofloxacin and fluconazole resulted in an episode of torsade de pointes in a patient on haemodialysis.[1]

1. Gandhi PJ, *et al.* Fluconazole- and levofloxacin-induced torsades de pointes in an intensive care unit patient. *Am J Health-Syst Pharm* 2003; **60:** 2479–83.

Nitrofurans. For a report of pulmonary and hepatic toxicity due to a possible interaction between *nitrofurantoin* and fluconazole, see p.308.

Antimicrobial Action

Fluconazole is a triazole antifungal drug which in sensitive fungi inhibits cytochrome P450-dependent enzymes, resulting in impairment of ergosterol synthesis in fungal cell membranes. It is active against *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Cryptococcus neoformans*, *Epidermophyton* spp., *Histoplasma capsulatum*, *Microsporum* spp., and *Trichophyton* spp.

Resistance has developed in some *Candida* spp. following long-term prophylaxis with fluconazole, and cross-resistance with other azoles has been reported.

Microbiological interactions. A synergistic antifungal effect was seen *in vitro* with terbinafine and fluconazole against strains of *Candida albicans*.[1] For effects on the antifungal activity of fluconazole when given with amphotericin B, see p.525.

1. Barchiesi F, *et al.* In vitro activities of terbinafine in combination with fluconazole and itraconazole against isolates of Candida albicans with reduced susceptibility to azoles. *Antimicrob Agents Chemother* 1997; **41:** 1812–14.

Resistance. The emergence of strains of *Candida* spp. resistant to fluconazole has become increasingly important, particularly in immunocompromised patients receiving long-term prophylaxis with fluconazole.[1,2] In addition to resistance in *C. albicans*,[3-5] infections with *C. dubliniensis*,[5] *C. glabrata*, and *C. krusei*, all of which may be less sensitive to fluconazole than *C. albicans*, have been noted in these patients,[6,7] and secondary resistance of *C. glabrata* has been reported during fluconazole therapy.[8,9] Resistance to fluconazole has been reported to occur more frequently than resistance to either ketoconazole or itraconazole and may be related to the widespread use of this drug.[4,7] Cross-resistance with other azoles[10,11] and with amphotericin B[12,13] has been reported.

Fluconazole resistance has also been reported in *Cryptococcus neoformans*[14] and *Histoplasma capsulatum*.[15] Histoplasmosis developed during treatment with fluconazole in a patient with HIV infection.[16] Fluconazole-resistant *C. neoformans* has been isolated from an immunocompetent patient who had not been exposed to azole antifungals previously.[17]

Pharmacokinetics

Fluconazole is well absorbed after oral doses, bioavailability from the oral route being 90% or more of that from the intravenous route. Mean peak plasma concentrations of 6.72 micrograms/mL have been reported in healthy subjects after a 400-mg oral dose. Peak concentrations are reached within 1 to 2 hours of oral doses. Plasma concentrations are proportional to the dose over a range of 50 to 400 mg. Multiple dosing leads to increases in peak plasma concentrations; steady-state concentrations are reached in 5 to 10 days but may be attained on day 2 if a loading dose is given.

Fluconazole is widely distributed and the apparent volume of distribution is close to that of total body water. Concentrations in breast milk, joint fluid, saliva, sputum, vaginal fluids, and peritoneal fluid are similar to those achieved in plasma. Concentrations in the CSF range from 50 to 90% of plasma concentrations, even in the absence of meningeal inflammation. Protein binding is only about 12%.

About 80% of a dose is excreted unchanged in the urine and about 11% as metabolites. The elimination half-life of fluconazole is about 30 hours and is increased in patients with renal impairment. Fluconazole is removed by dialysis.

Distribution. Salivary concentrations of fluconazole after oral doses should be adequate for the treatment of oropharyngeal and oesophageal candidiasis[1,2] even in patients with AIDS who may have decreased salivation.[3] Treatment failures are more likely to be due to inadequate dosage or resistant organisms than to decreased salivary secretion.[3]

Pharmacologically active concentrations of fluconazole have been detected in scalp hair[4] and nails[5] after oral treatment with conventional daily doses and with once-weekly dosage.

Uses and Administration

Fluconazole is a triazole antifungal used for superficial mucosal (oropharyngeal, oesophageal, or vaginal) candidiasis and for fungal skin infections. It is also given for systemic infections including systemic candidiasis, coccidioidomycosis, and cryptococcosis, and has been tried in blastomycosis, histoplasmosis, and sporotrichosis. The place of fluconazole in the treatment of fungal infections is discussed in the various sections under Choice of Antifungal, p.517.

Fluconazole is given by mouth or intravenous infusion in similar doses. For intravenous infusion it is given as a solution containing 2 mg/mL at a rate of 5 to 10 mL/minute (300 to 600 mL/hour). In the USA, a maximum infusion rate of 100 mL/hour is recommended.

For **superficial mucosal candidiasis** (other than genital candidiasis), the usual dose of fluconazole in the UK is 50 mg daily by mouth, although 100 mg daily may be given if necessary. Treatment usually continues for 7 to 14 days in *oropharyngeal* candidiasis (except in severely immunocompromised patients), for 14 days in *atrophic oral candidiasis* associated with dentures, and for 14 to 30 days in other mucosal candidal infections including *oesophagitis*.

Higher doses are recommended in the USA where an initial dose of fluconazole 200 mg is followed by 100 mg daily and where the minimum treatment period is 14 days for oropharyngeal infection, or a minimum of 21 days and at least 14 days after resolution of symptoms for oesophageal infections; doses of up to 400 mg daily may be used for oesophageal candidiasis if necessary.

Fluconazole 150 mg as a single oral dose may be used for **genital candidiasis** (vaginal candidiasis or candidal balanitis).

Dermatophytosis, pityriasis versicolor, and *Candida* **infections of the skin** may be treated with fluconazole 50 mg daily by mouth for up to 6 weeks.

Systemic candidiasis, **cryptococcal meningitis**, and other **cryptococcal infections** may be treated with fluconazole orally or by intravenous infusion; the initial dose is 400 mg followed by 200 to 400 mg daily. Duration of therapy is based on clinical and mycological response, but is usually at least 6 to 8 weeks in cryptococcal meningitis; in the USA, treatment for 10 to 12 weeks after the CSF cultures become negative is recommended. Fluconazole may also be used in daily doses of 100 to 200 mg orally or intravenously to prevent relapse after a primary course of antifungal treatment for acute cryptococcal meningitis in patients with AIDS.

In *immunocompromised patients* at risk of fungal infections, fluconazole may be given **prophylactically** in a dose of 50 to 400 mg daily orally or by intravenous infusion, although long-term prophylaxis has been associated with the emergence of resistant organisms (see under Intermittent Doses, below).

Doses for **children** over 4 weeks of age are 3 mg/kg daily for superficial infections (a loading dose of 6 mg/kg may be used on the first day if necessary), and 6 to 12 mg/kg daily for systemic infections. For prophylaxis in immunocompromised children, a dose of 3 to 12 mg/kg daily may be given. For infants under 2 weeks of age, all these doses should be given once every 72 hours; for those aged between 2 and 4 weeks, the doses should be given every 48 hours. A maximum dose of 400 mg daily should not be exceeded in children, or 12 mg/kg at appropriate intervals in infants.

Dosage may need to be reduced in patients with **renal impairment** (see below).

◊ Reviews.

1. Grant SM, Clissold SP. Fluconazole: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic potential in superficial and systemic mycoses. *Drugs* 1990; **39:** 877–916. Correction. *ibid.* **40:** 862.

4. Charlier C, *et al.* Fluconazole for the management of invasive candidiasis: where do we stand after 15 years? *J Antimicrob Chemother* 2006; **57:** 384–410.

Administration. *HIGH DOSES.* Doses higher than those recommended by licensed product information for fluconazole have been tried in patients with life-threatening infections caused by *Candida* spp., *Cryptococcus neoformans*, and *Coccidioides immitis*. Dose finding studies have found daily doses of 800 to 1000 mg of fluconazole to be effective and well tolerated.[1-3] In a study of 11 HIV-infected patients who received fluconazole 800 to 1000 mg daily intravenously for 3 weeks then orally until the CSF culture became negative, 6 patients had responded at 10 weeks and another 2 improved clinically.[1] Daily doses of up to 800 mg have been used in blastomycosis[2] and coccidioidomycosis,[3] and doses of 10 mg/kg daily have been tried in disseminated candidiasis.[4]

4. Graninger W, *et al.* Treatment of Candida albicans fungaemia with fluconazole. *J Infect* 1993; **26:** 133–46.

INTERMITTENT DOSES. Concern has been expressed about the increasingly widespread use of fluconazole[1] and, in particular, about the impact of continuous fluconazole therapy in immunocompromised patients on the development of resistance (see under Antimicrobial Action, above). Nevertheless, fluconazole remains popular for primary and secondary prophylaxis.

Some investigators have suggested the use of intermittent doses[2,3] although this could further increase the risk of infections with resistant organisms.

Once-weekly treatment with fluconazole has been tried in onychomycosis[4] and tinea capitis.[5]

5. Gupta AK, *et al.* Once weekly fluconazole is effective in children in the treatment of tinea capitis: a prospective, multicentre study. *Br J Dermatol* 2000; **142:** 965–8.

Administration in renal impairment. Patients with renal impairment may require dosage reduction. Normal loading or initial doses of fluconazole should be given on the first day of treatment and subsequent doses should be adjusted according to creatinine clearance (CC):

- CC more than 50 mL/minute: 100% of the standard recommended dose
- CC less than 50 mL/minute and not receiving dialysis: 50% of the standard recommended dose
- patients on regular haemodialysis: 100% of the standard recommended dose after each dialysis session

No dosage adjustment is needed in patients with renal impairment given single-dose therapy.

Leishmaniasis. Fluconazole has been tried in the treatment of cutaneous leishmaniasis (p.824) caused by *Leishmania major.* In a randomised, double-blind, placebo-controlled study,[1] 80 patients received a six-week course of oral fluconazole 200 mg daily, of whom 63 had complete healing of lesions after 3 months, compared with 22 of 65 patients who received placebo. However, others[2] have reported a response rate not significantly different from placebo.

Flucytosine *(BAN, USAN, rINN)*

5-FC; Flucitosina; Flucitozin; Flucitozinas; Flucytosin; Flucytosinum; Flucytozyna; Flusitozin; Flusytosiini; Ro-2-9915. 5-Fluorocytosine; 4-Amino-5-fluoropyrimidin-2(1*H*)-one.

Флуцитозин

$C_4H_4FN_3O$ = 129.1.

CAS — 2022-85-7.

ATC — D01AE21; J02AX01.

ATC Vet — QD01AE21; QJ02AX01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Flucytosine). A white or almost white crystalline powder. Sparingly soluble in water; slightly soluble in dehydrated alcohol. Protect from light.

USP 31 (Flucytosine). A white to off-white crystalline powder, odourless or with a slight odour. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers. Protect from light.

Stability. A solution of flucytosine for intravenous infusion should be stored between 18° and 25°. Precipitation may occur at lower temperatures and decomposition, with the formation of fluorouracil, at higher temperatures.

Adverse Effects

Adverse effects of flucytosine include nausea, vomiting, diarrhoea, and skin rashes. Less frequently reported adverse effects include confusion, hallucinations, convulsions, headache, sedation, and vertigo, and also allergic reactions, toxic epidermal necrolysis, and cardiotoxicity. Alterations in liver function tests are generally dose-related and reversible; hepatotoxicity may also occur. Hypokalaemia may occur. There have been a few reports of peripheral neuropathy.

Bone-marrow depression, especially leucopenia and thrombocytopenia, is associated with blood concentrations of flucytosine greater than 100 micrograms/mL, with concurrent use of amphotericin B, and with renal impairment. Fatal agranulocytosis and aplastic anaemia have been reported.

Effects on the blood. Bone marrow toxicity associated with flucytosine has been attributed to its conversion to fluorouracil, possibly by intestinal flora.[1] A pilot study[2] of 6 patients given intravenous flucytosine found that the amounts of fluorouracil in serum samples were undetectable, whereas flucytosine could be detected in the samples. This might be because intravenous dosage did not allow the conversion of flucytosine to fluorouracil by intestinal microflora. However, one patient still developed thrombocytopenia and another leucocytopenia and the authors hypothesised that toxicity might be due to flucytosine and not the metabolite.

1. Pirmohamed M, *et al.* The role of active metabolites in drug toxicity. *Drug Safety* 1994; **11:** 114–44.
2. Vermes A, *et al.* 5-fluorocytosine-related bone-marrow depression and conversion to fluorouracil: a pilot study. *Fundam Clin Pharmacol* 2002; **16:** 39–47.

Precautions

Flucytosine should be given with great care to patients with renal impairment, or with blood disorders or bone marrow depression. Renal and hepatic function and blood counts should be monitored during therapy (at least weekly in patients with renal impairment or blood disorders). In patients with renal impairment, doses should be reduced and trough blood concentrations of flucytosine should be checked regularly from blood samples taken just before an injection of flucytosine (see under Uses, below). Care should be taken in patients given radiation therapy or other drugs which depress bone marrow.

Flucytosine is teratogenic in *rats.*

AIDS. Frequent bone marrow toxicity has been reported in patients with AIDS during flucytosine therapy.[1] However, in a study in 381 patients, no additional haematotoxicity was reported in patients given amphotericin B plus flucytosine compared with those given amphotericin B alone.[2] The toxicity could be minimised by monitoring serum concentrations[3] and the British Society for Antimicrobial Chemotherapy has suggested that these should be maintained within 25 to 50 micrograms/mL in patients with AIDS.[4]

4. British Society for Antimicrobial Chemotherapy Working Party. Antifungal chemotherapy in patients with acquired immunodeficiency syndrome. *Lancet* 1992; **340:** 648–51.

Pregnancy. Teratogenicity has been reported in some *animal* models and licensed product information recommends that flucytosine should only be used if the benefit justifies that possible risk to the fetus. The congenital defects are thought to be as a result of the conversion of flucytosine to fluorouracil by the intestinal microflora. However, there are some case reports of pregnant patients receiving flucytosine (with or without amphotericin B) in the second[1-4] and third[5] trimesters with no reports of abnormalities in the infants.

5. Chen C-P, Wang K-G. Cryptococcal meningitis in pregnancy. *Am J Perinatol* 1996; **13:** 35–6.

Interactions

Flucytosine is commonly used with amphotericin B. Amphotericin B can cause a deterioration in renal function, which can result in raised flucytosine blood concentrations and increased toxicity. However, the two drugs are generally regarded as having synergistic antifungal activity. Cytarabine has been claimed to reduce blood concentrations of flucytosine and to antagonise its antifungal activity, although the evidence is limited.

Antimicrobial Action

Flucytosine is a fluorinated pyrimidine antifungal. In susceptible fungi it is converted by cytosine deaminase to fluorouracil which is then incorporated in place of uracil into fungal RNA and disrupts protein synthesis. The activity of thymidilate synthetase is also inhibited and this effect interferes with fungal DNA synthesis.

Flucytosine is active against *Candida* spp., *Cryptococcus neoformans*, *Cladosporium* spp., and *Fonsecaea* spp. Some *Aspergillus* spp. have also been reported to be sensitive. There is synergy between flucytosine and amphotericin B against *Candida* spp. and *Cryptococcus neoformans.*

There is a high incidence of primary resistance to flucytosine among isolates of *Candida* spp. and *Cryptococcus neoformans.* Resistance also develops during treatment with flucytosine and has been reported rarely from combination therapy with flucytosine and amphotericin B.

Pharmacokinetics

Flucytosine is absorbed rapidly and almost completely from the gastrointestinal tract. Bioavailability is 78 to 89%. After oral doses of 37.5 mg/kg every 6 hours, peak plasma concentrations of 70 to 80 micrograms/mL have been achieved within 2 hours; similar concentrations have been achieved but more rapidly, after an intravenous dose. The plasma-flucytosine concentration for optimum response is 25 to 50 micrograms/mL. Flucytosine is widely distributed through the body tissues and fluids; concentrations in the CSF are 65 to 90% of those in serum. About 2 to 4% of flucytosine is protein bound.

About 90% of a dose is excreted unchanged by glomerular filtration; a small amount of flucytosine may be metabolised to fluorouracil. The small amount of an oral dose of flucytosine not absorbed from the gastrointestinal tract is eliminated unchanged in the faeces. The elimination half-life is 2.5 to 6 hours in patients with normal renal function but increases with decreasing renal function. Flucytosine is removed by haemodialysis or peritoneal dialysis.

◊ References[1-3] to the pharmacokinetics of flucytosine. A study[3] reviewing flucytosine concentrations in serum, blood, or plasma from 233 patients, including 33 neonates, found that they were within the therapeutic range in only about 20% of cases; of the remainder, 40% were low (5% undetectable) and 40% were excessive (potentially toxic in about 10% of the samples). The results emphasised the importance of therapeutic drug monitoring.

2. Baley JE, *et al.* Pharmacokinetics, outcome of treatment, and toxic effects of amphotericin B and 5-fluorocytosine in neonates. *J Pediatr* 1990; **116:** 791–7.
3. Pasqualotto AC, *et al.* Flucytosine therapeutic monitoring: 15 years experience from the UK. *J Antimicrob Chemother* 2007; **59:** 791–3.

Uses and Administration

Flucytosine is a fluorinated pyrimidine antifungal used in the treatment of systemic fungal infections, the treatments for which are discussed under Choice of Antifungal, p.517. It is mainly used with amphotericin B or fluconazole in the treatment of severe systemic candidiasis and cryptococcal meningitis. It has also been tried in other infections due to susceptible fungi including chromoblastomycosis.

Flucytosine is given by *intravenous infusion* as a 1% solution over 20 to 40 minutes. The usual dose is 200 mg/kg daily in 4 divided doses; a dose of 100 to 150 mg/kg daily may be sufficient in some patients. Dosage should be adjusted to produce trough plasma concentrations of 25 to 50 micrograms/mL. This is particularly important in patients with AIDS who are at increased risk of bone marrow toxicity. Parenteral treatment is rarely given for more than 7 days, except for cryptococcal meningitis when it is continued for at least 4 months. For intravenous doses to be used in patients with renal impairment, see below.

Flucytosine is given *orally* in usual doses of 50 to 150 mg/kg daily in 4 divided doses. Again, blood concentrations should be monitored and dosage adjusted in patients with renal impairment to avoid accumulation of the drug (see below).

Flucytosine has been used *topically* for azole-refractory vaginitis caused by *Candida* spp., but such use may increase problems of resistance.

◊ Reviews.

3. Vermes A, *et al.* Flucytosine: a review of its pharmacology, clinical indications, pharmacokinetics, toxicity and drug interactions. *J Antimicrob Chemother* 2000; **46:** 171–9.

Administration in renal impairment. Flucytosine is mainly excreted by the kidneys and the dose must be adjusted in patients with renal impairment.

Dose intervals for intravenous flucytosine should be adjusted according to creatinine clearance (CC):

For intravenous use,

- CC 20 to 40 mL/minute: 50 mg/kg every 12 hours
- CC 10 to 20 mL/minute: 50 mg/kg every 24 hours
- CC less than 10 mL/minute: 50 mg/kg then further doses should be based on plasma concentrations which should not exceed 80 micrograms/mL

Initial oral doses should be at the lower end of the recommended range (see above) and dosage should be adjusted subsequently to avoid accumulation.

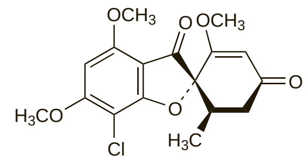
Jpn: Prodif.

Griseofulvin *(BAN, rINN)*

Curling Factor; Griseofulviini; Griseofulvina; Griséofulvine; Griseofulvinum; Grizeofulvin; Grizeofulvinas; Gryzeofulwina. (2*S*,4′*R*)-7-Chloro-2′,4,6-trimethoxy-4′-methylspiro[benzofuran-2(3*H*),3′-cyclohexene]-3,6′-dione.

Гризеофульвин

$C_{17}H_{17}ClO_6$ = 352.8.
CAS — 126-07-8.
ATC — D01AA08; D01BA01.
ATC Vet — QD01AA08; QD01BA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Griseofulvin). An antifungal substance produced by the growth of certain strains of *Penicillium griseofulvum*, or by any other means. It is a white or yellowish-white powder. The particles of the powder are generally up to 5 micrometres in maximum dimension, though larger particles, which may occasionally exceed 30 micrometres, may be present. It contains 97 to 102% of $C_{17}H_{17}ClO_6$, calculated on the dried substance. Practically insoluble in water; slightly soluble in dehydrated alcohol and in methyl alcohol; freely soluble in dimethylformamide and in tetrachloroethane.

USP 31 (Griseofulvin). A white to creamy-white, odourless powder, in which particles of the order of 4 micrometres in diameter predominate. It has a potency of not less than 900 micrograms of $C_{17}H_{17}ClO_6$ per mg. Very slightly soluble in water; sparingly soluble in alcohol; soluble in acetone, in chloroform, and in dimethylformamide. Store in airtight containers.

Adverse Effects

Adverse effects are usually mild and transient and consist of headache, skin rashes and urticaria, dry mouth, an altered sensation of taste, and gastrointestinal disturbances. Angioedema, erythema multiforme, toxic epidermal necrolysis, proteinuria, leucopenia and other blood dyscrasias, oral candidiasis, peripheral neuropathy, photosensitisation, and severe headache have been reported occasionally. Depression, confusion, dizziness, impaired coordination, insomnia, and fatigue have also been reported. Griseofulvin may precipitate or aggravate systemic lupus erythematosus.

There have been a few reports of hepatotoxicity attributed to griseofulvin.

Effects on the skin. Fatal toxic epidermal necrolysis in a 19-year-old woman[1] was attributed to griseofulvin that she had taken for 6 days; she had also taken metronidazole for 1 day. There are also reports[2,3] of erythema multiforme in 4 patients occurring within 10 days of starting griseofulvin. The precipitation or aggravation of systemic lupus erythematosus is a known complication of griseofulvin. Most cases are said to be characterised by prominent skin manifestations and absence of renal disease although the nephrotic syndrome has been described[4] in a 16-year-old male after 2 single doses of griseofulvin taken 3 weeks apart.

1. Mion G, *et al.* Fatal toxic epidermal necrolysis after griseofulvin. *Lancet* 1989; **ii:** 1331.
2. Rustin MHA, *et al.* Erythema multiforme due to griseofulvin. *Br J Dermatol* 1989; **120:** 455–8.
3. Thami GP, *et al.* Erythema multiforme due to griseofulvin with positive re-exposure test. *Dermatology* 2001; **203:** 84–5.
4. Bonilla-Felix M, *et al.* Nephrotic syndrome related to systemic lupus erythematosus after griseofulvin therapy. *Pediatr Nephrol* 1995; **9:** 478–9.

Hypersensitivity. A serum sickness-like reaction has been reported in a 5-year-old child being treated for tinea capitis with griseofulvin.[1] About 3 weeks after starting treatment the child developed fever, rash on his legs and back, swelling of his toes and fingers, and leg pain. Symptoms resolved after griseofulvin was stopped.

1. Colton RL, *et al.* Serum sickness-like reaction associated with griseofulvin. *Ann Pharmacother* 2004; **38:** 609–11.

Precautions

Griseofulvin is contra-indicated in patients with severe liver disease or systemic lupus erythematosus.

Griseofulvin is embryotoxic and teratogenic in *rats* and there have been isolated cases of conjoined twins after its use during the first trimester of pregnancy. It is therefore contra-indicated in pregnancy and women should not become pregnant during, or within 1 month of stopping therapy. Griseofulvin may reduce the effectiveness of oral contraceptives and additional contraceptive precautions should be used during treatment. Data from *in-vitro* and *in-vivo* studies using mammalian cells, which showed aneuploidy, have led to the warning that men taking griseofulvin should not father children within 6 months of treatment.

The symbol † denotes a preparation no longer actively marketed

Griseofulvin may impair the ability to drive or operate machinery, and has been reported to enhance the effects of alcohol.

Porphyria. Griseofulvin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

Phenobarbital has been reported to decrease the gastrointestinal absorption of griseofulvin. Plasma concentrations of griseofulvin have also been reported to be reduced by drugs that induce metabolising enzymes.

Griseofulvin may increase the rate of metabolism and diminish the effects of some drugs such as coumarin anticoagulants and oral contraceptives.

Griseofulvin may enhance the effects of alcohol.

Alcohol. In addition to reports of griseofulvin enhancing the effects of alcohol, a severe disulfiram-like reaction to alcohol has been reported in a patient taking griseofulvin.[1]

1. Fett DL, Vukov LF. An unusual case of severe griseofulvin-alcohol interaction. *Ann Emerg Med* 1994; **24:** 95–7.

Bromocriptine. For a report that griseofulvin can block the response to bromocriptine, see p.800.

Salicylates. Griseofulvin has been reported to reduce plasma concentrations of salicylate in a patient taking aspirin, see p.23.

Antimicrobial Action

Griseofulvin is a fungistatic antibiotic that inhibits fungal cell division by disruption of the mitotic spindle structure. It may also interfere with DNA production. It is active against the common dermatophytes, including some species of *Epidermophyton*, *Microsporum*, or *Trichophyton*.

Pharmacokinetics

Absorption of griseofulvin from the gastrointestinal tract is variable and incomplete, but is enhanced by reducing the particle size or when given with a fatty meal. Peak plasma concentrations are reached within 4 hours and are maintained for 10 to 20 hours.

Griseofulvin is about 84% bound to plasma proteins. It is deposited in keratin precursor cells and is concentrated in the stratum corneum of the skin and in the nails and hair, thus preventing fungal invasion of newly formed cells. Concentrations of 12 to 25 micrograms/g are maintained in skin during long-term use, while plasma concentrations remain at about 1 to 2 micrograms/mL. Griseofulvin has an elimination half-life of 9 to 24 hours, and is metabolised by the liver mainly to 6-demethylgriseofulvin and its glucuronide conjugate which are excreted in the urine. A large amount of a dose of griseofulvin of reduced particle size appears unchanged in the faeces; less than 1% is excreted unchanged in the urine; some is excreted in the sweat.

Uses and Administration

Griseofulvin is an antifungal used orally in the treatment of dermatophyte infections. It is generally given when such infections involve the scalp, hair, nails, and skin and do not respond to topical treatment (see Skin Infections, p.521); infections of the soles of the feet, the palms of the hands, and the nails respond slowly.

The usual dose of griseofulvin has been 0.5 to 1 g daily in single or divided doses; children have been given 10 mg/kg daily. These doses are for preparations of griseofulvin of reduced particle size, sometimes known as microcrystalline or microsize griseofulvin. Doses have been reduced by about one-quarter when preparations, available in some countries, containing ultramicrocrystalline or ultramicrosize griseofulvin are used. Griseofulvin should be given with or after meals.

The duration of treatment depends on the thickness of the keratin layer: 2 to 8 weeks for infections of the hair and skin, up to 6 months for infections of the fingernails, and 12 months or more for infections of the toenails.

Griseofulvin is also used as a 1% topical spray in tinea pedis.

◊ Reviews.

1. Fleece D, *et al.* Griseofulvin versus terbinafine in the treatment of tinea capitis: a meta-analysis of randomized, clinical trials. *Pediatrics* 2004; **114:** 1312–15.
2. Gupta AK, *et al.* Meta-analysis: griseofulvin efficacy in the treatment of tinea capitis. *J Drugs Dermatol* 2008; **7:** 369–72.

Non-infective skin disorders. Lichen planus is usually treated with corticosteroids or retinoids (see p.1580) but griseofulvin has been suggested as an alternative to topical corticosteroids in erosive disease.[1] However, some researchers have found it to be of no value.[2]

Dramatic responses of pigmented purpuric dermatoses to griseofulvin 500 to 750 mg daily have been reported in 5 patients.[3]

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Isoconazole Nitrate). A white or almost white powder. Very slightly soluble in water; slightly soluble in alcohol; soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

Local reactions including burning or itching may occur after application of isoconazole.

Intravaginal preparations of azole antifungals may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Antimicrobial Action

Isoconazole is an imidazole antifungal active against a wide spectrum of fungi including *Candida* spp., dermatophytes, and *Malassezia furfur*. It is also active against some Gram-positive bacteria.

Uses and Administration

Isoconazole is an imidazole antifungal used locally as the nitrate in the treatment of vaginal mycoses, particularly due to *Candida* spp. (p.518) and in fungal skin infections (p.521). For vaginal infections it is usually given as pessaries in a single dose of 600 mg or 300 mg daily for 3 days, or as a 1% vaginal cream daily for 7 days. For skin infections a 1% or 2% cream or other topical formulation has been used.

Preparations

Itraconazole *(BAN, USAN, rINN)*

Itraconazol; Itraconazolum; Itrakonatsoli; Itrakonazol; Itrakonazolas; Oriconazole; R-51211. (±)-2-*sec*-Butyl-4-[4-(4-{4-[(2*R**,4*S**)-2-(2,4-dichlorophenyl)-2-(1*H*-1,2,4-triazol-1-ylmethyl)-1,3-dioxolan-4-ylmethoxy]phenyl}-piperazin-1-yl)phenyl]-2,4-dihydro-1,2,4-triazol-3-one.

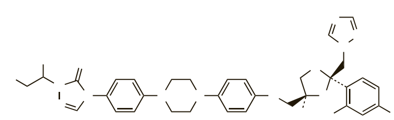
Итраконазол

$C_{35}H_{38}Cl_2N_8O_4$ = 705.6.

CAS — 84625-61-6.

ATC — J02AC02.

ATC Vet — QJ02AC02.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Itraconazole). A white or almost white powder. Practically insoluble in water; very slightly soluble in alcohol; freely soluble in dichloromethane; sparingly soluble in tetrahydrofuran. Protect from light.

Adverse Effects

The most common adverse effects associated with itraconazole include dyspepsia, abdominal pain, nausea, vomiting, constipation, diarrhoea, headache, and dizziness. Others include allergic reactions such as pruritus, rash, urticaria, and angioedema. Isolated cases of the Stevens-Johnson syndrome have been associated with itraconazole.

An increase in liver enzyme values has occurred in some patients and cases of hepatitis and cholestatic jaundice have been observed, especially in those treated for more than one month. There have been rare cases of liver failure and death.

Heart failure and pulmonary oedema have been reported rarely and serious cardiovascular events including arrhythmias and sudden death have been attributed to drug interactions in patients receiving itraconazole (see Interactions, below).

Alopecia, oedema, and hypokalaemia have also been associated with prolonged use. Menstrual disorders and peripheral neuropathy have been reported in a few patients.

Incidence of adverse effects. Itraconazole 50 to 400 mg daily for a median of 5 months was considered to be well tolerated in 189 patients with systemic fungal infections.[1] Of 86 patients with underlying disease, including 49 with AIDS, 16 with diabetes, and 23 with malignancy, nausea and vomiting occurred in 19 patients, hypertriglyceridaemia in 16, hypokalaemia in 11, and elevated liver enzyme values in 13. The role of itraconazole in hypertriglyceridaemia could not be assessed because all the samples were not drawn in the fasting state and hypertriglyceridaemia is a complication of HIV infection. Gynaecomastia occurred in 2 patients, 1 of whom also took spironolactone. Rash occurred in 4 patients.

Of 49 patients taking itraconazole 100 to 400 mg daily for up to 39 months, 23 did not experience adverse effects during treatment,[2] while 6 had nausea and vomiting, 5 developed oedema, and 2 developed hypertension; 3 of the patients who developed oedema and 1 who became hypertensive were diabetic. Three patients stopped itraconazole, 1 due to vomiting, 1 to leucopenia, and 1 to nephrotic syndrome. The patient with nephrotic syndrome had pre-existing oedema and hypertension; the syndrome cleared when itraconazole was stopped.

Effects on the heart. Between September 1992, when itraconazole was approved in the USA, and April 2001, the FDA had received 58 reports of potential cases of heart failure associated with itraconazole.[1] There had been 28 patients admitted to hospital, and 13 had died. However, a causal relationship was difficult to prove. Overall, 43 patients had risk factors or diseases which might confound an association between the use of itraconazole and development of heart failure. Unpublished studies in *dogs* and humans had suggested a negative inotropic effect with intravenous itraconazole.

In August 2001, the UK CSM published a similar alert.[2] By this time, about 67 million patients worldwide had received itraconazole and there had been 75 spontaneously reported cases of suspected heart failure and an additional 63 reports of oedema suggestive of heart failure associated with oral formulations; there had been only 1 report of suspected heart failure in the UK. The CSM considered that the risk of heart failure with itraconazole was low, especially in young healthy patients receiving short courses of treatment (e.g. for vulvovaginal candidiasis). However, the risks appeared to be higher for older patients, patients with pre-existing heart disease or risk factors for heart failure, and for those receiving high doses and longer treatment courses (e.g. for onychomycosis).

The CSM[2] therefore advised caution when prescribing itraconazole to patients at risk of heart failure, whereas the FDA[1] contra-indicated it for the treatment of onychomycosis in patients with evidence of ventricular dysfunction.

Precautions

Itraconazole has caused abnormalities in fetal development in *rodents* and is therefore contra-indicated in pregnancy. For further information, see Pregnancy, under Precautions of Fluconazole, p.532.

Itraconazole should be avoided in patients with hepatic impairment. Liver function should be monitored if treatment lasts more than one month or if there are symptoms suggestive of hepatitis. Treatment should be stopped if abnormal liver function is detected. Plasma-itraconazole concentrations should be monitored in patients with active liver disease and the dosage adjusted if necessary.

Dose adjustments may also be required in some patients with renal impairment. Licensed product information warns that the use of intravenous preparations of itraconazole formulated with hydroxypropylbetadex is contra-indicated in patients with a creatinine clearance of less than 30 mL/minute.

Itraconazole should be stopped if neuropathy develops.

Itraconazole should not be used for the treatment of less severe fungal infections such as onychomycosis in patients with evidence of, or a history of, ventricular dysfunction such as heart failure.

Hypochlorhydria, which may be present in patients with AIDS, can reduce absorption of itraconazole. In this case absorption may be improved by giving itraconazole with an acidic drink, such as a cola beverage.

Breast feeding. Breast feeding while receiving itraconazole is not recommended by the manufacturer although only small amounts of itraconazole are distributed into breast milk.

Interactions

Enzyme-inducing drugs such as carbamazepine, isoniazid, nevirapine, phenobarbital, phenytoin, rifabutin, or rifampicin may *decrease* plasma concentrations of itraconazole sufficiently to reduce its effectiveness. Conversely, enzyme inhibitors such as clarithromycin, erythromycin, HIV-protease inhibitors, including ritonavir-boosted HIV-protease inhibitors, may *increase* plasma concentrations of itraconazole. Use of drugs that reduce stomach acidity, such as antimuscarinics, antacids, proton pump inhibitors, and histamine H_2-receptor antagonists, may reduce the absorption of itraconazole. Like other triazole antifungals, itraconazole is a potent inhibitor of the cytochrome P450 isoenzyme CYP3A4, and may increase plasma concentrations of other drugs reliant upon it for their metabolism. This increases the risk of adverse effects and such combinations should be given with caution and careful monitoring, if at all. Drugs so affected may include:

- *antiarrhythmics* such as dofetilide and quinidine
- *antiepileptics* such as carbamazepine (which in turn decreases the concentration of the antifungal, see above)
- *antihistamines* such as astemizole and terfenadine
- the *antimycobacterial* rifabutin (which again also decreases antifungal concentrations)
- *antineoplastics* such as busulfan, docetaxel, and the vinca alkaloids
- *antipsychotics* such as pimozide and sertindole
- *anxiolytics and sedatives* such as buspirone
- *benzodiazepines* such as alprazolam, diazepam, midazolam, and triazolam
- *calcium channel blockers* such as verapamil, and the dihydropyridines felodipine, nifedipine, and nisoldipine (see also below)
- *cardiac glycosides* such as digoxin
- some *corticosteroids* such as budesonide, dexamethasone, fluticasone and methylprednisolone
- the *coumarin anticoagulant* warfarin
- *ergot alkaloids* such as dihydroergotamine, ergometrine, ergotamine, and methylergometrine
- the *gastrointestinal prokinetic* cisapride
- *HIV-protease inhibitors* such as indinavir, ritonavir, and saquinavir (concentrations of the antifungal may be increased in turn by indinavir, ritonavir, or co-formulated lopinavir-ritonavir, but not by saquinavir)
- *immunosuppressants* such as ciclosporin, sirolimus, and tacrolimus
- *opioids* such as alfentanil and levacetylmethadol
- some *oral hypoglycaemics*
- the *phosphodiesterase inhibitors* sildenafil and vardenafil
- *statins* (HMG Co-A reductase inhibitors) such as atorvastatin, lovastatin, and simvastatin

Where drugs metabolised via CYP3A4 also prolong the QT interval, the risk of serious cardiovascular effects such as torsade de pointes means that the combination should be avoided; this includes astemizole, cisapride, dofetilide, levacetylmethadol, pimozide, quinidine, sertindole, and terfenadine. Care is also required with calcium channel blockers, which may increase the risk of congestive heart failure if given together, and nisoldipine in particular is considered contra-indicated. Use with the statins is also best avoided because of the risk of muscle damage.

Antimicrobial Action

Itraconazole is a triazole antifungal drug that in sensitive fungi inhibits cytochrome P450-dependent enzymes resulting in impairment of ergosterol synthesis in fungal cell membranes. It has a slightly wider spectrum of activity than ketoconazole. It is active against *Aspergillus* spp., *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Cryptococcus neoformans*, *Epidermophyton* spp., *Histoplasma capsulatum*, *Malassezia furfur*, *Microsporum* spp., *Paracoccidioides brasiliensis*, *Sporothrix schenckii*, and *Trichophyton* spp. Itraconazole also has some antiprotozoal activity against *Leishmania* spp.

Acquired resistance to itraconazole is rare but ketoconazole-resistant strains of *Candida albicans* have been found to be cross resistant to itraconazole.

Microbiological interactions. Synergistic antifungal effects were seen *in vitro* with terbinafine and itraconazole against strains of *Candida albicans*[1] and *Scedosporium prolificans*.[2] For effects on the antifungal activity of azoles when given with amphotericin B, see p.525.

1. Barchiesi F, *et al.* In vitro activities of terbinafine in combination with fluconazole and itraconazole against isolates of Candida albicans with reduced susceptibility to azoles. *Antimicrob Agents Chemother* 1997; **41:** 1812–14.
2. Meletiadis J, *et al.* In vitro interaction of terbinafine with itraconazole against clinical isolates of Scedosporium prolificans. *Antimicrob Agents Chemother* 2000; **44:** 470–2.

Resistance. For a discussion of increasing resistance of *Candida* spp. to azoles, see under Antimicrobial Action of Fluconazole, p.533. Decreased susceptibility to itraconazole and cross-resistance to fluconazole has been reported in *C. albicans* isolated from patients with AIDS given long-term prophylaxis with itraconazole.[1] *Aspergillus fumigatus* resistant to itraconazole has also been seen.[2,3]

1. Goldman M, *et al.* Does long-term itraconazole prophylaxis result in in vitro azole resistance in mucosal Candida albicans isolates from persons with advanced human immunodeficiency virus infection? *Antimicrob Agents Chemother* 2000; **44:** 1585–7.

3. Dannaoui E, *et al.* Acquired itraconazole resistance in Aspergillus fumigatus. *J Antimicrob Chemother* 2001; **47:** 333–340.

Pharmacokinetics

Itraconazole is absorbed from the gastrointestinal tract when given orally either as capsules containing itraconazole coated onto sugar spheres or as an oral liquid formulated with hydroxypropylbetadex. Absorption from the capsule formulation is enhanced by an acidic gastric environment and is greatest when doses are taken with food; absorption from the oral liquid is not dependent on an acid environment, and absorption is greatest in the fasting state. Peak plasma concentrations are achieved between 1.5 and 5 hours after a dose of either formulation, and steady state is reached within 15 days during daily dosing. Peak plasma concentrations at steady state of about 2 micrograms/mL have been reported after daily doses of 200 mg.

Bioavailability increases with doses of 100 to 400 mg in such a manner as to suggest that itraconazole undergoes saturable metabolism. Itraconazole is highly protein bound; only 0.2% circulates as free drug. Itraconazole is widely distributed but only small amounts diffuse into the CSF. Concentrations attained in the skin, sebum, pus, and many organs and tissues are several times higher than simultaneous plasma concentrations. Therapeutic concentrations of itraconazole remain in the skin and mucous membranes for 1 to 4 weeks after the drug is stopped. Small amounts are distributed into breast milk.

Itraconazole is metabolised in the liver mainly by cytochrome P450 isoenzyme CYP3A4. The major metabolite, hydroxyitraconazole, has antifungal activity comparable with that of itraconazole. Itraconazole is also excreted as inactive metabolites in the bile or urine; 3 to 18% is excreted in the faeces as unchanged drug. Small amounts are eliminated in the stratum corneum and hair. Itraconazole is not removed by dialysis.

The elimination half-life following a single 100-mg dose has been reported as 20 hours, increasing to 30 to 40 hours with continued use.

Uses and Administration

Itraconazole is a triazole antifungal given orally for the treatment of oropharyngeal and vulvovaginal candidiasis, for pityriasis versicolor, for dermatophytoses unresponsive to topical treatment, for onychomycosis, and for systemic infections including aspergillosis, blastomycosis, candidiasis, chromoblastomycosis, coccidioidomycosis, cryptococcosis, histoplasmosis, paracoccidioidomycosis, and sporotrichosis. It is also given for the prophylaxis of fungal infections in immunocompromised patients. The place of itraconazole in the treatment of fungal infections is discussed in the various sections under Choice of Antifungal, p.517.

Doses of itraconazole oral liquid and capsules are not equivalent and may not be used interchangeably.

In the UK, itraconazole **oral liquid** is licensed for use in oral and oesophageal candidiasis in a dose of 200 mg daily for 1 week; it may be taken as a single daily dose, or, preferably, in 2 divided doses, the liquid being retained in the mouth for 20 seconds before swallowing. If there is no response after a week, treatment may be continued for a further week. In the USA, a similar regimen is licensed for oropharyngeal candidiasis, but in oesophageal candidiasis an alternative regimen of 100 mg daily for at least 3 weeks is preferred, although the dose may be increased to 200 mg daily if necessary.

For patients with fluconazole-resistant infections the dose in the UK is 100 to 200 mg twice daily for 2 weeks; if there is no response, 100 mg twice daily may be given for a further 2 weeks. In the USA the recommended dose is 100 mg twice daily.

Itraconazole oral liquid is also licensed in the UK for prophylaxis of susceptible fungal infections in immunocompromised patients, in doses of 5 mg/kg daily, in 2 divided doses.

The following oral doses all apply to itraconazole **capsules**. The dose in oropharyngeal candidiasis is 100 mg (or 200 mg in patients with AIDS or neutropenia) daily for 15 days. Vulvovaginal candidiasis may be treated with itraconazole 200 mg twice daily for 1 day. Pityriasis versicolor may be treated with itraconazole 200 mg daily for 7 days. For dermatophytoses the dose is 100 mg daily for 15 days or 200 mg daily for 7 days in tinea corporis or tinea cruris; doses are 100 mg daily for 30 days or 200 mg twice daily for 7 days in tinea pedis or tinea manuum. For nail infections the dose is 200 mg daily for 3 months or pulse therapy with 200 mg twice daily for 7 days repeated once (for fingernails) or twice (for toenails) after drug-free intervals of 21 days.

For systemic infections, itraconazole capsules are given in usual doses of 100 to 200 mg once daily, increased to 200 mg twice daily for invasive or disseminated infections, including cryptococcal meningitis. In life-threatening infections a loading dose of 200 mg three times daily for 3 days has been given. A dose of 200 mg daily is used for primary or secondary prophylaxis in neutropenic patients or those with AIDS. Absorption may be impaired in these patients and monitoring of plasma concentrations is advised with an increase in dose to 200 mg twice daily if necessary. This higher dose is recommended routinely by some authorities in the USA such as the *Centers for Disease Control and Prevention*.

Itraconazole may also be given by **intravenous infusion** in a dose of 200 mg given twice daily over 1 hour for two days, then 200 mg daily thereafter.

Administration. ***HIGH DOSES.*** Doses of itraconazole 600 mg daily in two divided doses for 3 to 16 months were used in 8 patients with systemic mycoses resistant to conventional therapy.[1] Two patients with AIDS and cryptococcal meningitis failed to respond and 2 who responded initially later relapsed or developed progressive disease when the dose was reduced. The main adverse effects were hypokalaemia, hypertension, and oedema possibly associated with adrenal suppression.

In a patient with cerebral aspergillosis, itraconazole 800 mg daily for 5 months then 400 mg daily for a further 4 ⁄ months produced complete resolution of cerebral lesions.[2]

1. Sharkey PK, *et al.* High-dose itraconazole in the treatment of severe mycoses. *Antimicrob Agents Chemother* 1991; **35:** 707–13.
2. Sánchez C, *et al.* Treatment of cerebral aspergillosis with itraconazole: do high doses improve the prognosis? *Clin Infect Dis* 1995; **21:** 1485–7.

Administration in children and neonates. Itraconazole has been used in children in the treatment of tinea capitis.[1] Doses were 50 mg daily by mouth for those below 20 kg and 100 mg daily for those weighing 20 kg or more.

A review of the use of itraconazole in children[2] considered oral itraconazole to be safe and effective against most fungal organisms causing superficial infections.

Itraconazole was given to 2 premature infants with disseminated candidiasis in a dose of 10 mg/kg daily in two divided doses for 3 or 4 weeks without adverse effects.[3] Treatment was successful in both infants.

Although itraconazole oral liquid is not licensed for use in children in the UK, and the capsules are only licensed from 12 years of age, the *BNFC* suggests the following daily ***oral*** doses, given as a single dose (unless otherwise specified):

for **oropharyngeal candidiasis**:

- 1 month to 12 years of age, 3 to 5 mg/kg (to a maximum of 100 mg) daily for 15 days; up to 200 mg daily may be given to patients with neutropenia or AIDS
- 12 to 18 years of age, 100 mg (200 mg in those with neutropenia or AIDS) daily for 15 days

for **dermatophyte infections**:

- 1 month to 12 years of age, 3 to 5 mg/kg daily; this is given to a maximum of 200 mg daily for 7 days (pityriasis versicolor), to a maximum of 100 mg daily for 15 days (tinea corporis and tinea cruris), or to a maximum of 100 mg daily for 30 days (tinea pedis and tinea manuum)
- 12 to 18 years of age, 200 mg daily for 7 days (pityriasis versicolor); 100 mg daily for 15 days or as in pityriasis (tinea corporis and tinea cruris); or 100 mg daily for 30 days or 200 mg *twice* daily for 7 days (tinea pedis and tinea manuum)

for **onychomycosis**, from 1 year of age:

- 1 to 12 years, courses of 5 mg/kg daily for 7 days, repeated after intervals of 21 days to a total of 2 courses for infections of the fingernails and 3 courses for toenail infections
- 12 to 18 years, either 200 mg daily for 3 months, or courses of 200 mg *twice* daily for 7 days, repeated after intervals of 21 days to a total of 2 courses for infections of the fingernails and 3 courses for toenail infections

for **histoplasmosis** or for **systemic fungal infections** such as aspergillosis, candidiasis, and cryptococcosis (including cryptococcal meningitis) where other antifungal drugs are inappropriate or ineffective:

- from 1 month of age to 18 years, 5 mg/kg (to a maximum of 200 mg) once or twice daily; the *twice* daily dose should be used in invasive or disseminated disease or cryptococcal meningitis. For intravenous doses see below

for **maintenance in AIDS patients** to prevent relapse of underlying fungal infection, or for **prophylaxis in neutropenia** when standard therapy is inappropriate:

- from 1 month of age to 18 years, 5 mg/kg (to a maximum of 200 mg) daily, increased to *twice* daily if plasma-itraconazole concentrations are low

for **prophylaxis in haematological malignancy or bone-marrow transplantation** (in patients expected to become neutropenic), where standard therapy is inappropriate the *oral liquid* may be given as follows:

- from 1 month of age to 18 years, 2.5 mg/kg *twice* daily, starting before transplantation or chemotherapy and continued until the neutrophil count recovers

Like the oral liquid the intravenous product is not licensed in children in the UK; the *BNFC* suggests the following ***intravenous*** doses by infusion in children with **systemic fungal infections**:

- from 1 month of age to 18 years, 2.5 mg/kg (to a maximum of 200 mg) every 12 hours for 2 days, then the same dose once daily for a maximum of 12 days. Doses should be given by diluting 250 mg as the intravenous concentrate in 50 mL of sodium chloride 0.9% and infusing over 60 minutes

3. Bhandari V, Narang A. Oral itraconazole therapy for disseminated candidiasis in low birth weight infants. *J Pediatr* 1992; **120:** 330.

Amoebic infections. Itraconazole has been suggested for *Acanthamoeba* keratitis (p.822), when it is given orally with topical miconazole.

Leishmaniasis. When systemic therapy is required for the treatment of leishmaniasis (p.824), pentavalent antimonials are most commonly used. The successful use of itraconazole has been reported in a few patients[1-4] with cutaneous disease but infections with *Leishmania aethiopica* may not respond.[5] Although a pilot study[6] in patients with mucocutaneous leishmaniasis reported benefit with itraconazole this was not confirmed in another study[7] where the response was only transient in the majority of patients. Similarly, itraconazole with terbinafine has been found to be ineffective in post kala-azar dermal leishmaniasis.[8]

Ketoconazole *(BAN, USAN, rINN)*

Ketoconazol; Kétoconazole; Ketoconazolum; Ketokonatsoli; Ketokonazol; Ketokonazolas; R-41400. (±)-*cis*-1-Acetyl-4-{4-[2-(2,4-dichlorophenyl)-2-imidazol-1-ylmethyl-1,3-dioxolan-4-yl-methoxy]phenyl}piperazine.

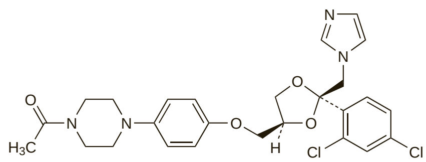
Кетоконазол

$C_{26}H_{28}Cl_2N_4O_4$ = 531.4.

CAS — 65277-42-1.

ATC — D01AC08; G01AF11; J02AB02.

ATC Vet — QD01AC08; QG01AF11; QJ02AB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Ketoconazole). A white or almost white powder. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in dichloromethane; soluble in methyl alcohol. Protect from light.

Adverse Effects

Gastrointestinal disturbances are the most frequently reported adverse effect after the oral use of ketoconazole. Nausea and vomiting have been reported in about 3% of patients, and abdominal pain in about 1%. These adverse effects are dose-related and may be minimised by giving ketoconazole with food. Asymptomatic, transient elevations in serum concentrations of liver enzymes may occur in about 10% of patients. Hepatitis has been reported and the risk appears to increase if treatment with ketoconazole is continued for longer than 2 weeks; it is usually reversible on stopping ketoconazole but fatalities have occurred. Ketoconazole interferes with steroid biosynthesis and adverse endocrine effects include gynaecomastia, oligospermia, menstrual irregularities, and adrenal cortex suppression, especially at high doses.

Other adverse effects include allergic reactions such as urticaria and angioedema, and rare cases of anaphylaxis after the first dose have been reported. Pruritus, rash, alopecia, headache, dizziness, impotence, and somnolence may also occur. Thrombocytopenia, paraesthesia, raised intracranial pressure, and photophobia have been reported rarely.

After topical use of ketoconazole, irritation, dermatitis, or a burning sensation has occurred.

Effects on the blood. A case of fatal aplastic anaemia was reported[1] in a 23-year-old woman who had taken ketoconazole for 4 days for the treatment of vaginal discharge.

Effects on endocrine function. Oral ketoconazole blocks testosterone synthesis and adrenal response to corticotropin, resulting in azospermia and oligospermia, gynaecomastia, impotence and decreased libido, and adrenal insufficiency.[1-8] As an inhibitor of steroid production, ketoconazole is valuable in controlling hypercortisolism and is used therapeutically in some endocrine disorders and prostatic cancer. For further discussion see under Uses and Administration, below.

Effects on the liver. Hepatic adverse reactions to oral ketoconazole are well known.[1-4] Transient minor elevations of liver enzymes without clinical signs or symptoms of hepatic disease occur in about 10% of patients and may occur at any stage of treatment. Although this reaction is not usually clinically important it may signal the onset of more serious hepatic injury and indicates the need for close monitoring of liver function. Symptomatic hepatic reactions are much rarer (less than 0.1% of patients) but are potentially fatal. There is usually a hepatocellular pattern of damage and sometimes cholestasis. Patients at increased risk of hepatic injury include those with a history of liver disease, those aged over 50, especially women, and those requiring prolonged treatment. It is important to monitor liver function during treatment as well as to limit the length of treatment. If liver enzyme values continue to rise or jaundice or hepatitis occur, ketoconazole should be withdrawn immediately since fatalities have occurred in patients who continued treatment after signs of hepatic injury developed.

4. García Rodríguez LA, *et al.* A cohort study on the risk of acute liver injury among users of ketoconazole and other antifungal drugs. *Br J Clin Pharmacol* 1999; **48:** 847–52.

Precautions

Since ketoconazole has been reported to cause hepatotoxicity it should not be given to patients with pre-existing liver disease. Patients given ketoconazole should be monitored for symptoms of hepatitis; also, liver function tests should be performed before starting oral treatment with ketoconazole lasting for more than 14 days and then at least monthly throughout therapy.

Ketoconazole has been shown to be teratogenic in *animal* studies and its use is generally not recommended during pregnancy. For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Hypochlorhydria, which may be present in patients with AIDS, can reduce absorption of ketoconazole. In this case absorption may be improved by giving ketoconazole with an acidic drink, such as a cola beverage.

Breast feeding. Ketoconazole is excreted in breast milk and licensed product information states that oral use should be avoided during breast feeding. However, no adverse effects were seen in a breast-fed infant whose mother was receiving ketoconazole;[1] it was calculated that the infant was exposed to about 0.4% of the usual therapeutic dose of ketoconazole for this age group. The American Academy of Pediatrics considers[2] that use of ketoconazole is therefore usually compatible with breast feeding.

1. Moretti ME, *et al.* Disposition of maternal ketoconazole in breast milk. *Am J Obstet Gynecol* 1995; **173:** 1625–6.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 28/06/05)

Porphyria. Ketoconazole is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Use of drugs that reduce stomach acidity, such as antimuscarinics, antacids, histamine H_2-antagonists, and proton pump inhibitors, may reduce the absorption of ketoconazole. Absorption of ketoconazole may also be reduced by sucralfate. Enzyme-inducing drugs such as rifampicin, isoniazid, efavirenz, nevirapine, or phenytoin may reduce plasma-ketoconazole concentrations. Concentrations of isoniazid and rifampicin may also be reduced by ketoconazole.

Ketoconazole inhibits certain hepatic oxidase enzymes, especially the cytochrome P450 isoenzyme CYP3A4, in a similar way to itraconazole (p.537) and similar care should be taken to avoid adverse effects due to increased plasma concentrations of the interacting drugs.

A disulfiram-like reaction may occur in patients taking ketoconazole after drinking alcohol. The efficacy of oral contraceptives may be reduced.

◊ For reviews of drug interactions with azole antifungals, see Itraconazole, p.537.

Antimicrobial Action

Ketoconazole is an imidazole antifungal that interferes with ergosterol synthesis and therefore alters the permeability of the cell membrane of sensitive fungi. It is reported to be fungistatic at concentrations achieved clinically. Ketoconazole has a wide spectrum of antimicrobial activity including activity against *Blastomyces dermatitidis*, *Candida* spp., *Coccidioides immitis*, *Epidermophyton floccosum*, *Histoplasma capsulatum*, *Malassezia* spp., *Microsporum canis*, *Paracoccidioides brasiliensis*, *Trichophyton mentagrophytes*, and *T. rubrum*. Some strains of *Aspergillus* spp., *Cryptococcus neoformans*, and *Sporothrix schenckii* are sensitive.

Ketoconazole has activity against some Gram-positive bacteria and some antiprotozoal activity against *Leishmania* spp.

There are rare reports of *Candida albicans* acquiring resistance to ketoconazole.

Microbiological interactions. For the effect of imidazoles and amphotericin B on each other's antimicrobial activity, see Amphotericin B, p.525.

Resistance. For a discussion of increasing resistance of *Candida* spp. to azoles see Fluconazole, Antimicrobial Action, p.533.

Pharmacokinetics

The absorption of ketoconazole from the gastrointestinal tract is variable and increases with decreasing stomach pH. Mean peak plasma concentrations of about 3.5 micrograms/mL have been obtained 2 hours after an oral dose of 200 mg. Systemic absorption after topical or vaginal application in healthy subjects is minimal. Ketoconazole is more than 90% bound to plasma proteins, mainly albumin. It is widely distributed and appears in breast milk. Penetration into the CSF is poor. The elimination of ketoconazole is reported to be biphasic, with an initial half-life of 2 hours and a terminal half-life of about 8 hours.

Ketoconazole is metabolised in the liver to inactive metabolites. It is excreted as metabolites and unchanged drug chiefly in the faeces; some is excreted in the urine.

Uses and Administration

Ketoconazole is an imidazole antifungal used topically or orally. It is given orally in chronic mucocutaneous or vaginal candidiasis, in fungal infections of the gastrointestinal tract, in dermatophyte infections of the skin and fingernails not responding to topical treatment, and in systemic infections including blastomycosis, candidiasis, coccidioidomycosis, histoplasmosis, and paracoccidioidomycosis. It has been given for the prophylaxis of fungal infections in immunocompromised patients, although fluconazole or itraconazole are usually preferred. It has been recommended that, because of its erratic absorption and slow therapeutic response, ketoconazole should not be used for the treatment of life-threatening fungal infections, including fungal meningitis, or for severe infections in immunocompromised patients. Also, because of the risk of hepatotoxicity the use of ketoconazole in nonsystemic fungal infections tends to be restricted to serious infections resistant to other treatment.

The place of ketoconazole in the treatment of fungal infections is discussed in the various sections under Choice of Antifungal, p.517.

The usual oral dose for treatment and prophylaxis of fungal infections is 200 mg once daily taken with food. This may be increased to 400 mg daily if an adequate response is not obtained; in some infections even higher doses have been used. Children may be given about 3 mg/kg daily, or 50 mg for those aged 1 to 4 years and 100 mg for children aged 5 to 12 years. Treatment should usually be continued for 14 days and for at least one week after symptoms have cleared and cultures have become negative. Some infections may require several months of treatment and giving ketoconazole for such prolonged periods may increase the risk of hepatotoxicity.

A dose of 400 mg once daily for 5 days is used for the treatment of chronic vaginal candidiasis.

Ketoconazole is applied topically as a 2% cream in the treatment of candidal or dermatophyte infections of the skin, or in the treatment of pityriasis versicolor. It is used once or twice daily and continued for at least a few days after the disappearance of symptoms. A foam containing 2% ketoconazole applied twice daily for 4 weeks may be used in the treatment of seborrhoeic dermatitis. A shampoo containing 1 or 2% ketoconazole is also used; it is applied twice weekly for 2 to 4 weeks (or occasionally longer) in the treatment of dandruff or seborrhoeic dermatitis. The 2% shampoo is used once daily for up to 5 days in pityriasis versicolor. For prophylaxis of seborrhoeic dermatitis the 2% shampoo is used once every 1 to 2 weeks; for prophylaxis of pityriasis versicolor it may be used once daily for a maximum of 3 days before exposure to sunshine.

Acanthamoeba infections. Although there is currently no established treatment for granulomatous amoebic encephalitis, ketoconazole may have some activity against the *Acanthamoeba* spp. responsible for this infection and has been applied topically to skin lesions. Ketoconazole has also been suggested for *Acanthamoeba* keratitis (p.822), when it has been given orally with topical miconazole.

Acute respiratory distress syndrome. In two small double-blind, controlled trials,[1,2] the development of acute respiratory distress syndrome (ARDS—p.1498) and mortality rates were lower in high-risk patients given ketoconazole than in those given placebo. An accompanying editorial[3] commented that adequate blood concentrations appeared to be essential. The mode of action could be associated with inhibition of leukotriene and thromboxane synthesis.[2,3] Nevertheless, in a study in 234 patients,[4] ketoconazole failed to reduce mortality or improve clinical outcomes when given early in the course of ARDS. Some centres have developed guidelines for ketoconazole prophylaxis in patients at risk of ARDS.[5]

Blastomycosis. Ketoconazole has largely been replaced by itraconazole as the azole of choice in the treatment of blastomycosis (p.518) because of its higher incidence of adverse effects, and lower efficacy. If used as an alternative it is given in doses of 400 to 800 mg daily.[1]

1. Chapman SW, *et al.* Clinical practice guidelines for the management of blastomycosis: 2008 update by the Infectious Diseases Society of America. *Clin Infect Dis* 2008; **46:** 1801–12. Also available at: http://www.journals.uchicago.edu/doi/pdf/10.1086/588300 (accessed 03/07/08)

Endocrine disorders and malignant neoplasms. Ketoconazole has been reported to impair steroid hormone synthesis[1] and to blunt the response of cortisone to adrenocorticotrophic hormone (ACTH)[2] and has been tried in the management of a number of endocrine disorders.

In **Cushing's syndrome** (p.2344), ketoconazole in doses of up to 1200 mg daily has been used successfully as an alternative or adjuvant to definitive therapies such as surgery or radiotherapy.[3-6]

Treatment of **hirsutism** is usually with an anti-androgen (see under Cyproterone, p.2089), but ketoconazole has been tried in small numbers of women at a dose of 300 mg daily[7] or 400 mg daily,[8,9] with variable results.

Ketoconazole has been reported to produce a beneficial response in some forms of **precocious puberty** (p.2081) that do not generally respond to gonadorelin analogues; cessation of menstruation and regression of pubertal signs in girls[10] and reduced testosterone secretion and increase in adult height in boys[11-13] has been noted in small numbers of patients studied.

The anti-androgenic effects of ketoconazole have also been found useful in the management of **prostatic cancer** (p.671) in selected patients,[14-18] although there have been some concerns about its tolerability,[17] and it is not generally used as a first-line treatment.

Ketoconazole was ineffective in suppressing **postoperative erection** in patients undergoing penile reconstructive surgery.[19]

Hypercalcaemia. Ketoconazole has been used[1,2] in the treatment of hypercalcaemia (p.1668). It acts to reduce 1,25-dihydroxycholecalciferol concentrations by inhibiting cytochrome P450-dependent 1α-hydroxylation of vitamin D.

1. Yavuz H. Familiar drugs for the treatment of hypercalcemia. *J Pediatr* 1998; **133:** 311.
2. Young C, *et al.* Hypercalcaemia in sarcoidosis. *Lancet* 1999; **353:** 374.

Leishmaniasis. As discussed on p.824, ketoconazole has been tried as an alternative to conventional first- and second-line therapy for visceral leishmaniasis,[1,2] although reports of treatment have not all been favourable.[3,4]

It has also been tried in cutaneous leishmaniasis. A cure rate of 70% was reported in over 100 patients with *Leishmania major* infections treated with oral ketoconazole 200 to 400 mg daily for 4 to 6 weeks. Ketoconazole was not considered to be effective in infections due to *L. tropica*, *L. aethiopica*,[5] or *L. guyanensis*.[6] Ketoconazole 600 mg daily for 28 days has produced similar results to sodium stibogluconate intramuscularly for 20 days in patients with cutaneous leishmaniasis due to *L. panamensis*.[7] A further comparative study[8] of 96 patients being treated for cutaneous leishmaniasis, caused mainly by *L. major* or *L. tropica*, found ketoconazole given in doses of 600 mg in adults or 10 mg/kg in children for 30 days to be more effective than 6 to 8 bi-weekly intralesional injections of meglumine antimonate. In another study,[9] ketoconazole was less effective than sodium stibogluconate when cutaneous leishmaniasis was due to *L. braziliensis*, but more effective when *L. mexicana* was the cause.

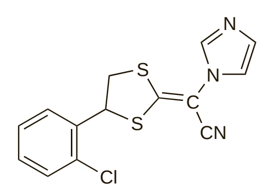
Lanoconazole *(rINN)*

Lanoconazol; Lanoconazolum; Latoconazole; NND-318; TJN-318. (±)-α-[(*E*)-4-(*o*-Chlorophenyl)-1,3-dithiolan-2-ylidene]imidazole-1-acetonitrile.

Ланоконазол

$C_{14}H_{10}ClN_3S_2$ = 319.8.

CAS — 101530-10-3.



Profile

Lanoconazole is an imidazole antifungal used topically in the treatment of fungal skin infections as a 1% cream, ointment, or solution, applied once daily. For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Astat; ***Port.:*** Micoder.

Liranaftate *(rINN)*

Liranaftato; Liranaftatum; M-732; Piritetrate. *O*-5,6,7,8-Tetrahydro-2-naphthyl 6-methoxy-*N*-methylthio-2-pyridinecarbamate.

Лиранафтат

$C_{18}H_{20}N_2O_2S$ = 328.4.

CAS — 88678-31-3.

Profile

Liranaftate is an antifungal related to tolnaftate (p.548) and is applied once daily as a 2% cream or solution in the treatment of superficial dermatophyte infections (p.521).

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Zefnart.

Mepartricin *(BAN, USAN, rINN)*

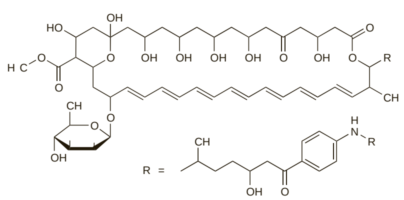
Mepartricina; Mépartricine; Mepartricinum; Methylpartricin; SN-654; SPA-S-160.

Мепартрицин

CAS — 11121-32-7.

ATC — A01AB16; D01AA06; G01AA09; G04CX03.

ATC Vet — QA01AB16; QD01AA06; QG01AA09; QG04CX03.



Mepartricin A: R = CH
Mepartricin B: R = H

Profile

Mepartricin is a mixture of the methyl esters of 2 related polyene antibiotics that may be obtained from a strain of *Streptomyces aureofaciens*. It has antifungal and antiprotozoal activity and has been used in vaginal candidiasis and trichomoniasis as pessaries or as a vaginal cream. A cream is also available for the treatment of superficial candidiasis. An oral form of mepartricin sodium laurilsulfate is also used. Oral mepartricin 40 mg daily is used in the treatment of some prostate disorders.

Prostate disorders. Studies[1,2] have shown that mepartricin given by mouth is effective in the treatment of *benign prostatic hyperplasia* (see p.2178 for the more usual treatments); a dose of 40 mg daily is commonly used.[2] Mepartricin is thought to reduce cholesterol, oestrogen, and androgen binding to the prostate. Similarly, another study[3] has shown that the same dose of mepartricin provides symptomatic improvement in the management of *chronic prostatitis/chronic pelvic pain syndrome* (see Prostatitis, p.2181).

1. Tosto A, *et al.* A double-blind study of the effects of mepartricin in the treatment of obstruction due to benign prostatic hyperplasia. *Curr Ther Res* 1995; **56:** 1270–75.
2. Denis L, *et al.* Double-blind, placebo-controlled trial to assess the efficacy and tolerability of mepartricin in the treatment of BPH. *Prostate* 1998; **37:** 246–52.
3. De Rose AF, *et al.* Role of mepartricin in category III chronic nonbacterial prostatitis/chronic pelvic pain syndrome: a randomized prospective placebo-controlled trial. *Urology* 2004; **63:** 13–16.

Multi-ingredient: ***Braz.:*** Tricangine†.

Micafungin Sodium *(USAN, rINNM)*

FK-463; Micafungina sódica; Micafungine Sodique; Natrii Micafunginum. 5-((1*S*,2*S*)-2-{(2*R*,6*S*,9*S*,11*R*,12*R*,14a*S*,15*S*,16*S*,20*S*,23*S*,25a*S*)-20-[(1*R*)-3-Amino-1-hydroxy-3-oxopropyl]-2,11,12,15-tetrahydroxy-6-[(1*R*)-1-hydroxyethyl]-16-methyl-5,8,14,19,22,25-hexaoxo-9-[(4-{5-[4-(pentyloxy)phenyl]isoxazol-3-yl}benzoyl)amino]tetracosahydro-1*H*-dipyrrolo[2,1-*c*:2′,1′-*l*][1,4,7,10,13,16]hexaazacyclohenicosin-23-yl}-1,2-dihydroxyethyl)-2-hydroxyphenyl sodium sulfate.

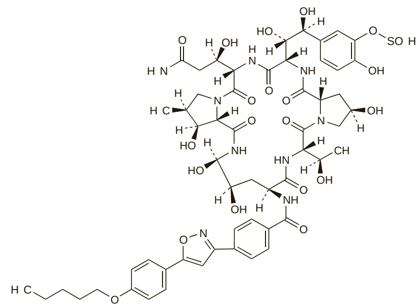
Натрий Микафунгин

$C_{56}H_{70}N_9NaO_{23}S$ = 1292.3.

CAS — 235114-32-6 (micafungin); 208538-73-2 (micafungin sodium).

ATC — J02AX05.

ATC Vet — QJ02AX05.



Adverse Effects

As for Caspofungin, p.528. Isolated cases of renal dysfunction or acute renal failure have also occurred in patients taking micafungin.

Precautions

Patients who develop abnormal liver or renal function tests while taking micafungin should be monitored for deterioration in hepatic or renal function respectively.

Interactions

Micafungin may increase the area under the concentration-time curve for nifedipine and sirolimus.

Antimicrobial Action

As for Caspofungin, p.528.

Pharmacokinetics

Micafungin is absorbed from the gastrointestinal tract after oral doses. It is more than 99% bound to plasma proteins, mainly albumin.

Micafungin is metabolised by arylsulfatase to its catechol form and further metabolised to the methoxy form by catechol-*O*-methyltransferase. Some hydroxylation to micafungin via cytochrome P450 isoenzymes also occurs.

After 28 days about 71% of a dose is recovered in the faeces and 12% in the urine. Mean half-lives of 14.0 to 17.2 hours have been reported.

Uses and Administration

Micafungin is an echinocandin antifungal with general properties similar to those of caspofungin (p.528). It is used for the treatment and prophylaxis of candidiasis and also in the treatment of aspergillosis. It is given as the sodium salt by intravenous infusion in doses of 50 mg once daily for candidiasis. For the treatment of oesophageal candidiasis the recommended dose is 150 mg daily. For aspergillosis 50 to 150 mg is given once daily. Doses up to 300 mg daily have been used in severe or refractory disease. A dose of 50 mg daily is used for prophylaxis of candidiasis in patients undergoing haematopoietic stem cell transplantation.

ATC Vet — QA01AB09; QA07AC01; QD01AC02; QG01AF04; QJ02AB01; QS02AA13.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Miconazole Nitrate). A white or almost white powder. Very slightly soluble in water; slightly soluble in alcohol; sparingly soluble in methyl alcohol. Protect from light.

USP 31 (Miconazole Nitrate). A white or practically white, crystalline powder, with not more than a slight odour. Soluble 1 in 6250 of water, 1 in 312 of alcohol, 1 in 75 of methyl alcohol, 1 in 525 of chloroform, 1 in 1408 of isopropyl alcohol, 1 in 119 of propylene glycol; freely soluble in dimethyl sulfoxide; soluble in dimethylformamide; insoluble in ether. Protect from light.

Adverse Effects

After oral use of miconazole, nausea and vomiting have been reported, and also diarrhoea (usually on long-term treatment). There have been allergic reactions, rarely, and isolated reports of hepatitis.

Local irritation and sensitivity reactions may occur when miconazole nitrate is used topically; contact dermatitis has been reported.

After the intravenous infusion of miconazole, phlebitis, nausea, vomiting, diarrhoea, anorexia, pruritus, rash, febrile reactions, flushes, drowsiness, and hyponatraemia have been reported. Other effects include hyperlipidaemia, aggregation of erythrocytes, anaemia, and thrombocytosis. Transient tachycardia and other cardiac arrhythmias have followed the rapid intravenous injection of miconazole (but see also Effects on the Heart, below). Rare adverse effects include acute psychosis, arthralgia, and anaphylaxis. Many of these adverse effects have been associated with the injection vehicle, which contains polyoxyl castor oil (p.1918).

Effects on the heart. Bradycardia, progressing to fatal ventricular fibrillation and cardiac arrest, occurred in a heart transplant patient during intravenous infusion of miconazole for an invasive fungal infection.[1]

1. Coley KC, Crain JL. Miconazole-induced fatal dysrhythmia. *Pharmacotherapy* 1997; **17:** 379–82.

Overdosage. A report[1] of a generalised tonic-clonic convulsion that occurred in an infant 10 to 15 minutes after the inadvertent infusion of miconazole 500 mg instead of 50 mg.

1. Coulthard K, *et al.* Convulsions after miconazole overdose. *Med J Aust* 1987; **146:** 57–8.

Precautions

Miconazole oral gel should be avoided in patients with hepatic impairment.

Intravaginal preparations of miconazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

Miconazole has been fetotoxic at high doses in *animals* and its use is generally not recommended during pregnancy. For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Porphyria. Miconazole is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Miconazole can inhibit the metabolism of drugs metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP2C9, and may thus have effects similar to those of fluconazole (p.532). Miconazole may enhance the activity of oral anticoagulants, sulfonylurea hypoglycaemics, or phenytoin. Adverse effects have been reported when miconazole was given with carbamazepine.

There is a risk of cardiac arrhythmias if miconazole is used with astemizole, cisapride, or terfenadine and such combinations should be avoided.

Anticoagulants. The anticoagulant activity of coumarin anticoagulants can be potentiated by miconazole given orally,[1] intravaginally,[2] or topically.[3] As of December 2002 the Australian Adverse Drug Reactions Advisory Committee had received 18 reports of significant increases in the INR of patients previously stabilised on warfarin within 1 to 2 weeks of starting treatment with miconazole oral gel.[4]

Antimicrobial Action

Miconazole is an imidazole antifungal with similar antimicrobial activity to that of ketoconazole (p.539). It also has some activity against *Aspergillus* spp., *Cryptococcus neoformans, Pseudallescheria boydii,* and some Gram-positive bacteria including staphylococci and streptococci.

1. Vanden Bossche H, *et al.* Synergism of the antimicrobial agents miconazole and benzoyl peroxide. *Br J Dermatol* 1982; **107:** 343–8.

Pharmacokinetics

Miconazole is incompletely absorbed from the gastrointestinal tract. Peak plasma concentrations of 1 microgram/mL are achieved about 4 hours after a dose of 1 g daily. Over 90% is reported to be bound to plasma proteins.

Miconazole is metabolised in the liver to inactive metabolites. From 10 to 20% of an oral dose is excreted in the urine, mainly as metabolites, within 6 days. About 50% of an oral dose may be excreted unchanged in the faeces. The elimination pharmacokinetics of miconazole have been described as triphasic, with a biological half-life of about 24 hours.

Very little miconazole is removed by haemodialysis.

There is little absorption through skin or mucous membranes when miconazole nitrate is applied topically.

◊ Reviews.

1. Daneshmend TK, Warnock DW. Clinical pharmacokinetics of systemic antifungal drugs. *Clin Pharmacokinet* 1983; **8:** 17–42.

Uses and Administration

Miconazole is an imidazole antifungal used as miconazole base or nitrate in the treatment of superficial candidiasis (p.518), and of the skin infections dermatophytosis and pityriasis versicolor (p.521). It has also been given intravenously by infusion in the treatment of disseminated fungal infections, but other azoles are now more commonly used.

Miconazole may be given orally as a gel containing 20 mg/g (24 mg/mL) for the treatment of oropharyngeal and intestinal candidiasis. The usual adult dose is 5 to 10 mL four times daily (equivalent to a total of about 15 mg/kg daily). Children under the age of 2 years may be given the oral gel in a dose of 2.5 mL twice daily; those aged between 2 and 6 years, 5 mL twice daily; and those aged over 6 years, 5 mL four times daily. For the treatment of oral lesions the oral gel is applied directly.

Miconazole nitrate is usually applied twice daily as a 2% cream, lotion, or powder in the treatment of fungal infections of the skin including candidiasis, dermatophytosis, and pityriasis versicolor. In the treatment of vaginal candidiasis, 5 g of a 2% intravaginal cream is inserted into the vagina once daily for 10 to 14 days or twice daily for 7 days. Miconazole nitrate pessaries may be inserted in dosage regimens of 100 mg once daily for 7 or 14 days, 100 mg twice daily for 7 days, 200 or 400 mg daily for 3 days, or in a single dose of 1200 mg.

Acanthamoeba keratitis. Miconazole has been applied topically in *Acanthamoeba* keratitis (p.822) in combination with systemic treatment with either ketoconazole or itraconazole.

Skin disorders. Topical preparations containing an imidazole such as ketoconazole or miconazole, usually with hydrocortisone, are used in the management of *seborrhoeic dermatitis* (p.1584). A cream containing miconazole nitrate 2% and benzoyl peroxide 5% has been used topically in the treatment of *acne* (p.1577).

Naftifine Hydrochloride *(BANM, USAN, rINNM)*

AW-105-843; Hidrocloruro de naftifina; Naftifin Hidroklorür; Naftifine, Chlorhydrate de; Naftifini Hydrochloridum; Naftifungin Hydrochloride; SN-105-843 (naftifine). (*E*)-*N*-Cinnamyl-*N*-methyl(1-naphthylmethyl)amine hydrochloride.

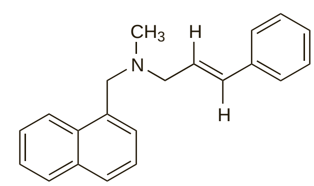
Нафтифина Гидрохлорид

$C_{21}H_{21}N,HCl = 323.9.$

CAS — 65472-88-0 (naftifine); 65473-14-5 (naftifine hydrochloride).

ATC — D01AE22.

ATC Vet — QD01AE22.



(naftifine)

Pharmacopoeias. In *US.*

USP 31 (Naftifine Hydrochloride). Store in airtight containers.

Profile

Naftifine hydrochloride is an allylamine derivative (see Terbinafine, p.546) which is fungicidal against dermatophytes, but only fungistatic against *Candida* spp.

Naftifine hydrochloride 1% is applied topically once or twice daily for fungal skin infections, particularly dermatophytosis (see Skin Infections, p.521).

Local reactions such as burning or stinging may occur.

◊ Reviews.

1. Gupta AK, *et al.* Naftifine: a review. *J Cutan Med Surg* 2008; **12:** 51–8.

Preparations

Natamycin *(BAN, USAN, pINN)*

Antibiotic A-5283; CL-12625; E235; Natamicina; Natamycine; Natamycinum; Natamycyna; Natamysiini; Pimaricin; Pimarisin.

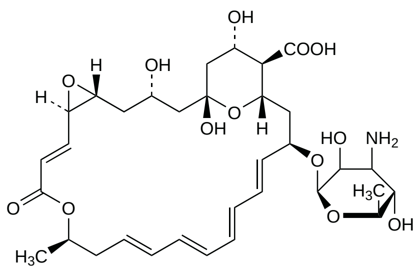
Натамицин

$C_{33}H_{47}NO_{13}$ = 665.7.

CAS — 7681-93-8.

ATC — A01AB10; A07AA03; D01AA02; G01AA02; S01AA10.

ATC Vet — QA01AB10; QA07AA03; QD01AA02; QG01AA02; QS01AA10.



Pharmacopoeias. In *Jpn*, *Pol.*, and *US*.

USP 31 (Natamycin). An off-white to cream-coloured powder. It may contain up to 3 moles of water. Practically insoluble in water; soluble in glacial acetic acid and in dimethylformamide; slightly soluble in methyl alcohol. A 1% suspension in water has a pH of 5.0 to 7.5. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Gastrointestinal disturbances have occurred after oral use of natamycin. Local application has sometimes produced irritation.

Porphyria. Natamycin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Antimicrobial Action

Natamycin is a polyene antifungal active against *Candida* and *Fusarium* spp. In addition it is active against the protozoan *Trichomonas vaginalis*.

Pharmacokinetics

Natamycin is poorly absorbed from the gastrointestinal tract. It is not absorbed through the skin or mucous membranes when applied topically. After ocular use, natamycin is present in therapeutic concentrations in corneal stroma but not in intra-ocular fluid; systemic absorption does not usually occur.

Uses and Administration

Natamycin is a polyene antifungal antibiotic produced by the growth of *Streptomyces natalensis*. It is used for the local treatment of candidiasis (p.518) and fungal keratitis (see Eye Infections, p.519). It has also been used in vaginal trichomoniasis (p.827).

A 5% ophthalmic suspension or a 1% ointment of natamycin is used in the treatment of blepharitis, conjunctivitis, or keratitis due to susceptible fungi, including *Fusarium solani*.

Natamycin lozenges are used for the treatment of oral candidiasis in a dose of 10 mg every 4 to 6 hours. Tablets have been given orally for the treatment of intestinal candidiasis. Natamycin has also been used topically for fungal skin infections and for candidal and trichomonal infections of the vagina.

Preparations

USP 31: Natamycin Ophthalmic Suspension.

Proprietary Preparations (details are given in Part 3)

Nystatin *(BAN, USAN, rINN)*

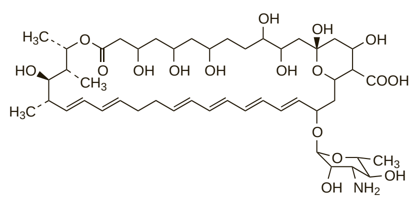
Fungicidin; Nistatin; Nistatina; Nistatinas; Nisztatin; Nystatiini; Nystatine; Nystatinum; Nystatyna.

Нистатин

CAS — 1400-61-9.

ATC — A07AA02; D01AA01; G01AA01.

ATC Vet — QA07AA02; QD01AA01; QG01AA01.



(nystatin A_1)

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Nystatin). An antifungal substance obtained by fermentation using certain strains of *Streptomyces noursei*. It contains mainly tetraenes, the principal component being nystatin A_1. The potency is not less than 4400 units/mg and not less than 5000 units/mg if intended for oral use, calculated with reference to the dried substance. It is a yellow or slightly brownish hygroscopic powder. Practically insoluble in water and in alcohol; freely soluble in dimethylformamide and in dimethyl sulfoxide; slightly soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Nystatin). A substance, or a mixture of two or more substances, produced by the growth of *Streptomyces noursei* (Streptomycetaceae). It has a potency of not less than 4400 units/mg, or, where intended for use in extemporaneous preparation of oral suspensions, not less than 5000 units/mg. A yellow to light tan, hygroscopic powder, with an odour suggestive of cereals; it is affected by long exposure to light, heat, and air. Practically insoluble in water and in alcohol; insoluble in chloroform and in ether; freely soluble in dimethylformamide and in dimethyl sulfoxide; slightly to sparingly soluble in methyl alcohol, in *n*-butyl alcohol, and in *n*-propyl alcohol. A 3% suspension in water has a pH of 6.0 to 8.0. Store in airtight containers. Protect from light.

Adverse Effects

Nausea, vomiting, and diarrhoea have occasionally been reported after oral use of nystatin. Oral irritation or sensitisation may occur. Rashes, including urticaria, have occurred and Stevens-Johnson syndrome has been reported rarely. Irritation may occur rarely after the topical use of nystatin.

Effects on the skin. Generalised pustular eruptions were reported in 3 patients after oral nystatin.[1] Subsequent sensitivity testing revealed delayed (type IV) hypersensitivity to nystatin.

1. Küchler A, *et al.* Acute generalized exanthematous pustulosis following oral nystatin therapy: a report of three cases. *Br J Dermatol* 1997; **137:** 808–11.

Precautions

Some intravaginal preparations of nystatin may damage latex contraceptives and additional contraceptive precautions may be necessary during treatment.

Antimicrobial Action

Nystatin is a polyene antifungal antibiotic that interferes with the permeability of the cell membrane of sensitive fungi by binding to sterols, chiefly ergosterol. Its main action is against *Candida* spp.

Pharmacokinetics

Nystatin is poorly absorbed from the gastrointestinal tract. It is not absorbed through the skin or mucous membranes when applied topically.

Uses and Administration

Nystatin is a polyene antifungal antibiotic used for the prophylaxis and treatment of candidiasis of the skin and mucous membranes (see p.518). It has been used with antibacterials in various regimens to suppress the overgrowth of gastrointestinal flora and as part of selective decontamination regimens (see Intensive Care, p.175).

For the treatment of intestinal or oesophageal candidiasis, nystatin is given in oral doses of 500 000 or 1 000 000 units, as a tablet or capsule, 3 or 4 times daily. In infants and children a dosage of 100 000 units or more may be given 4 times daily, as an oral suspension.

For the treatment of lesions of the mouth, pastilles or a suspension may be given in a dosage of 100 000 units 4 times daily. Higher doses of, for example, 500 000 units 4 times daily, may be needed in immunocompromised patients (but see also Candidiasis, below). The formulation should be kept in contact with the affected area for as long as possible, and patients should avoid taking food or drink for one hour after a dose. In the USA, doses of 400 000 to 600 000 units 4 times daily of the suspension, or 200 000 to 400 000 units 4 or 5 times daily as lozenges, are used.

For prophylaxis of intestinal candidiasis in patients given broad-spectrum antibacterials, tablets to a total dose of 1 000 000 units daily may be given. A prophylactic dose for infants born to mothers with vaginal candidiasis is 100 000 units daily of the oral suspension.

For the treatment of vaginal infections, nystatin is given in a dosage of 100 000 to 200 000 units daily for 14 days or longer as pessaries or vaginal cream. For cutaneous lesions, ointment, gel, cream, or dusting powder containing 100 000 units/g may be applied 2 to 4 times daily.

A liposomal formulation of nystatin for *parenteral* use is under investigation.

Candidiasis. A systematic review[1] of 14 studies (12 of prophylaxis, 2 of treatment) considered that nystatin could not be recommended for prophylaxis or treatment of *Candida* infections in patients with immunosuppression. In practice, fluconazole is usually preferred in such patients (see p.518).

Omoconazole Nitrate *(USAN, rINNM)*

10-80-07; Nitrato de omoconazol; Omoconazole, Nitrate d'; Omoconazoli Nitras. (*Z*)-1-{2,4-Dichloro-β-[2-(*p*-chlorophenoxy)ethoxy]-α-methylstyryl}imidazole nitrate.

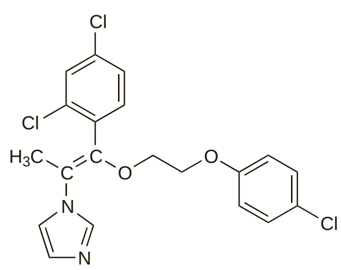
Омоконазола Нитрат

$C_{20}H_{17}Cl_3N_2O_2,HNO_3 = 486.7.$

CAS — 74512-12-2 (omoconazole); 83621-06-1 (omoconazole nitrate).

ATC — D01AC13; G01AF16.

ATC Vet — QD01AC13; QG01AF16.



(omoconazole)

Profile

Omoconazole is an imidazole antifungal used locally for fungal skin infections (p.521) and for vaginal candidiasis (p.518). It is applied topically as the nitrate as a 1% cream, powder, or solution in the treatment of cutaneous candidiasis, dermatophytosis, and pityriasis versicolor. For vaginal candidiasis, omoconazole nitrate is given as pessaries in doses of 150 mg daily for 6 days, 300 mg daily for 3 days, or 900 mg as a single dose.

Intravaginal preparations of azoles may damage latex contraceptives.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Oxiconazole Nitrate *(BANM, USAN, rINNM)*

Nitrato de oxiconazol; Oxiconazole, Nitrate d'; Oxiconazoli Nitras; Ro-13-8996; Ro-13-8996/001; Ro-13-8996/000 (oxiconazole); SGD-301-76; ST-813. 2′,4′-Dichloro-2-imidazol-1-ylacetophenone (*Z*)-*O*-(2,4-dichlorobenzyl)oxime mononitrate.

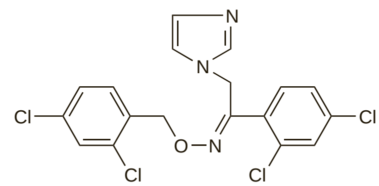
Оксиконазола Нитрат

$C_{18}H_{13}Cl_4N_3O,HNO_3 = 492.1.$

CAS — 64211-45-6 (oxiconazole); 64211-46-7 (oxiconazole nitrate).

ATC — D01AC11; G01AF17.

ATC Vet — QD01AC11; QG01AF17.



(oxiconazole)

Profile

Oxiconazole is an imidazole antifungal applied topically as the nitrate as a cream, solution, or powder equivalent to oxiconazole 1% in the treatment of fungal infections of the skin (p.521). It is also given as a pessary in a single dose equivalent to 600 mg of oxiconazole in the treatment of vaginal candidiasis (p.518).

Local reactions including burning and itching have been reported. Intravaginal preparations of azoles may damage latex contraceptives.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

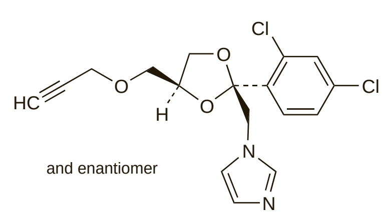
Parconazole Hydrochloride *(USAN, rINNM)*

Hidrocloruro de parconazol; Parconazole, Chlorhydrate de; Parconazoli Hydrochloridum; R-39500. *cis*-1-{[2-(2,4-Dichlorophenyl)-4-[(2-propynyloxy)methyl]-1,3-dioxolan-2-yl]methyl}-1*H*-imidazole hydrochloride.

Парконазола Гидрохлорид

$C_{17}H_{16}Cl_2N_2O_3. HCl = 403.7.$

CAS — 61400-59-7 (parconazole); 68685-54-1 (parconazole); 62973-77-7 (parconazole hydrochloride).



(parconazole)

Profile

Parconazole is an antifungal that has been used as the hydrochloride in the treatment of gastrointestinal candidiasis in veterinary medicine.

Pentamycin

Fungichromin; Lagosin; Pentamicina.

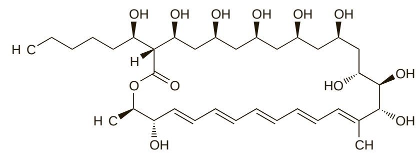
Пентамицин

$C_{35}H_{58}O_{12} = 670.8.$

CAS — 6834-98-6.

ATC — G01AA11.

ATC Vet — QG01AA11.



Profile

Pentamycin is a polyene antifungal antibiotic obtained from *Streptomyces pentaticus*. It has been used in the treatment of vaginal candidiasis and for the protozoal infection trichomoniasis.

Posaconazole *(BAN, USAN, rINN)*

Posaconazol; Posaconazolum; Sch-56592. 4-{*p*-[4-(*p*-{[(3*R*,5*R*)-5-(2,4-Difluorophenyl)tetrahydro-5-(1*H*-1,2,4-triazol-1-ylmethyl)-3-furyl]methoxy}phenyl)-1-piperazinyl]phenyl}-1-[(1*S*,2*S*)-1-ethyl-2-hydroxypropyl]-Δ^2-1,2,4-triazolin-5-one.

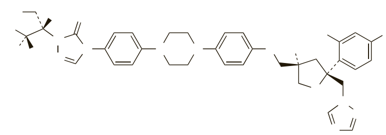
Позаконазол

$C_{37}H_{42}F_2N_8O_4 = 700.8.$

CAS — 171228-49-2.

ATC — J02AC04.

ATC Vet — QJ02AC04.



Adverse Effects

The most commonly reported adverse effects with posaconazole are headache and nausea. Other common adverse effects include abdominal pain, anorexia, asthenia, back pain, diarrhoea, dyspepsia, dizziness, dry mouth, dry skin, fatigue, fever, flatulence, hot flushes, insomnia, neutropenia, paraesthesia, pruritus, rash, somnolence, and vomiting. An increase in liver enzyme values has occurred in some patients, especially in those with serious underlying disease. Hypersensitivity and allergic reactions, including Stevens-Johnson syndrome, have occurred rarely.

Precautions

Some azoles have been associated with QT interval prolongation and licensed product information therefore advises that posaconazole should be used with caution in patients with potentially proarrhythmic conditions. Patients who develop abnormal liver function tests while being treated with posaconazole should be routinely monitored for the development of more serious liver injury.

Breast feeding. Breast feeding while taking posaconazole is not recommended by licensed product information.

Pregnancy. Posaconazole has been shown to be teratogenic and embryotoxic in *animal* studies and its use is generally not recommended during pregnancy. For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532. Licensed product information recommends that women of child-bearing potential should use effective contraception during treatment with posaconazole.

Interactions

Posaconazole is metabolised by the uridine diphosphate glucuronosyltransferase UGT1A4, and is a substrate for p-glycoprotein. The use of drugs that either inhibit (for example, clarithromycin, erythromycin, ciclosporin, and verapamil) or induce (see below) enzymes in this pathway may increase or decrease plasma-posaconazole concentrations, respectively. Rifabutin and phenytoin have been shown to decrease plasma-posaconazole concentrations and a similar effect may be expected with rifampicin, carbamazepine, primidone, and phenobarbital. Concentrations of posaconazole are reduced by cimetidine possibly due to reduced absorption of posaconazole as a result of decreased acid production and reduced posaconazole concentrations may also be expected with other H_2-antagonists and proton pump inhibitors.

Posaconazole is an inhibitor of the cytochrome P450 isoenzyme CYP3A4 and concentrations of other drugs that are metabolised by this enzyme pathway may be increased by posaconazole. Increased plasma concentrations of astemizole, cisapride, halofantrine, pimozide, quinidine, and terfenadine could be expected and concomitant use is contra-indicated because of the risk of cardiac arrhythmias including torsade de pointes. Use with ergot alkaloids such as ergotamine and dihydroergotamine is also contra-indicated because of the possible risk of ergotism. HMG-CoA reductase inhibitors such as atorvastatin, lovastatin, and simvastatin are contra-indicated as concomitant use as been associated with rhabdomyolysis. Increased plasma concentrations of sirolimus and tacrolimus have been noted; doses of sirolimus and tacrolimus may need to be reduced and concentrations monitored. Similarly, dose reduction with monitoring is recommended for ciclosporin. Close monitoring of blood glucose is necessary if posaconazole is used with oral hypoglycaemics such as the sulfonylureas. Dose reductions may be needed for calcium-channel blockers, digoxin, vinca alkaloids, and some benzodiazepines (such as alprazolam, midazolam, and triazolam). It is expected that posaconazole will increase the concentrations of HIV-protease inhibitors and NNRTIs.

Interactions may occur where both posaconazole and the other drug are affected. Examples are ciclosporin (where concentrations of both posaconazole and ciclosporin are increased) and rifabutin (where concentrations of posaconazole are reduced but those of rifabutin are increased).

For further information on interactions between drugs metabolised by the cytochrome P450 isoenzyme CYP3A and azoles, see under Itraconazole, p.537.

◊ For reviews of drug interactions with azole antifungals, see Itraconazole, p.537.

Antimicrobial Action

Posaconazole is a triazole antifungal drug that in sensitive fungi inhibits the enzyme lanosterol 14α-demethylase (CYP51) resulting in the impairment of ergosterol synthesis in fungal cell membranes. Posaconazole has activity against *Candida* spp., *Aspergillus* spp., *Coccidioides immitis*, *Fonsecaea pedrosoi*, and some species of *Fusarium* and zygomycetes.

Pharmacokinetics

Posaconazole exhibits linear pharmacokinetics after single and multiple doses with a high fat meal. No further increases in plasma concentration are seen with doses above 800 mg daily. It is slowly absorbed from the gastrointestinal tract and has a large volume of distribution. Peak plasma concentrations occur about 5 hours after an oral dose. Steady state plasma-posaconazole concentrations occur after 7 to 10 days of multiple dosage. Plasma protein binding is over 98%.

Metabolism plays only a minor role in the elimination of posaconazole; most circulating metabolites are glucuronide conjugates with only small amounts of oxidative metabolites. Posaconazole is slowly eliminated with a mean elimination half-life of 35 hours. The main elimination route of posaconazole is via the faeces (77%) where 66% of a dose is excreted unchanged. About 14% of a dose is excreted in the urine with only trace amounts excreted unchanged.

◊ Reviews.

1. Courtney R, *et al.* Pharmacokinetics, safety, and tolerability of oral posaconazole administered in single and multiple doses in healthy adults. *Antimicrob Agents Chemother* 2003; **47:** 2788–95.

Uses and Administration

Posaconazole is an oral triazole antifungal used in the treatment of severe oropharyngeal candidiasis. It is also indicated in the treatment of invasive aspergillosis, chromoblastomycosis, coccidioidomycosis, fusariosis, or mycetoma infections in patients who are resistant to, or intolerant of, other antifungals. Posaconazole is also given for the prophylaxis of fungal infections in patients who are at high risk for invasive fungal disease due to prolonged neutropenia.

Posaconazole is given orally as a suspension; doses should be given with a meal, or a nutritional supplement in those who cannot tolerate food, in order to enhance oral absorption and ensure adequate exposure.

For the treatment of **oropharyngeal candidiasis** posaconazole is given in a loading dose of 200 mg on the first day, followed by 100 mg daily for 13 days. In patients with oropharyngeal candidiasis refractory to itraconazole and/or fluconazole, posaconazole is given at a dose of 400 mg twice daily.

In patients with refractory **invasive systemic fungal infections**, it is given at a dose of 400 mg twice daily. Patients not tolerating food or nutritional supplements should take 200 mg four times daily.

In the **prophylaxis** of invasive fungal infections, the recommended dose is 200 mg three times daily. Treatment is continued until recovery from neutropenia or immunosuppression. In patients undergoing cytotoxic chemotherapy for haematological malignancies, or haematopoietic stem-cell transplantation, treatment should begin several days before the anticipated onset of neutropenia and continue for 7 days after the neutrophil count rises above 500 cells/mm^3.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Propionate). Slightly hygroscopic colourless crystals or white or almost white powder. Freely soluble in water; sparingly soluble in alcohol; practically insoluble in dichloromethane. A 2% solution in water has a pH of 7.8 to 9.2. Store in airtight containers.

USNF 26 (Sodium Propionate). Colourless transparent crystals or a granular crystalline powder; odourless or with a faint acetic-butyric odour. Deliquescent in moist air. Soluble 1 in 1 of water, 1 in 0.65 of boiling water, and 1 in 24 of alcohol; practically insoluble in chloroform and in ether. Store in airtight containers.

Profile

Propionic acid and its salts are antifungals. Calcium and sodium propionate have been used topically, usually with other antimicrobials for the treatment of dermatophyte infections. Eye drops containing sodium propionate have also been used.

Propionic acid and its calcium, sodium, and potassium salts are used in the baking industry as inhibitors of moulds.

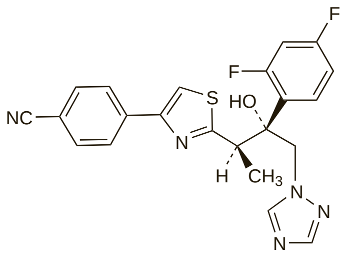
Ravuconazole *(pINN)*

BMS-207147; ER-30346; Ravuconazol; Ravuconazolum. 4-{2-[(1*R*,2*R*)-2-(2,4-Difluorophenyl)-2-hydroxy-1-methyl-3-(1*H*-1,2,4-triazol-1-yl)propyl]-4-thiazolyl}-benzonitrile.

Равуконазол

$C_{22}H_{17}F_2N_5OS$ = 437.5.

CAS — 182760-06-1.



Profile

Ravuconazole is a triazole antifungal said to possess a broader spectrum of activity than fluconazole or itraconazole. It is under investigation for the treatment of systemic fungal infections.

Sertaconazole Nitrate *(BANM, rINNM)*

Nitrato de sertaconazol; Sertaconazole, nitrate de; Sertaconazoli nitras; Sertakonatsolinitraatti; Sertakonazol Nitrat; Sertakonazol-nitrat; Sertakonazol-nitrát; Sertakonazolo nitratas; Szertakonazol-nitrát. (±)-1-{2,4-Dichloro-β-[(7-chlorobenzo[*b*]thien-3-yl)-methoxy]phenethyl}imidazole nitrate.

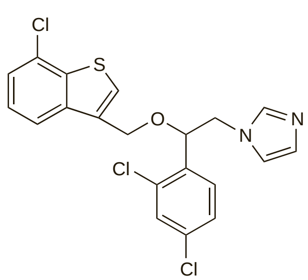
Сертаконазола Нитрат

$C_{20}H_{15}Cl_3N_2OS,HNO_3$ = 500.8.

CAS — 99592-32-2 (sertaconazole); 99592-39-9 (sertaconazole nitrate).

ATC — D01AC14.

ATC Vet — QD01AC14.



(sertaconazole)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Sertaconazole Nitrate). A white or almost white powder. Practically insoluble in water; sparingly soluble in alcohol and in dichloromethane; soluble in methyl alcohol. Protect from light.

Profile

Sertaconazole is an imidazole antifungal used topically as the nitrate as a 2% cream, gel, solution, or powder in the treatment of superficial candidiasis, dermatophytosis, seborrhoeic dermatitis, and pityriasis versicolor. In the treatment of vaginal candidiasis it is used as a 2% vaginal cream daily for 7 or 8 days or as a single dose of a 300-mg or 500-mg pessary.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Terbinafine Hydrochloride). A white or almost white powder. Very slightly or slightly soluble in water; freely soluble in dehydrated alcohol and in methyl alcohol; slightly soluble in acetone. Protect from light.

USP 31 (Terbinafine Hydrochloride). A white or off-white powder. Very slightly or slightly soluble in water; freely soluble in dehydrated alcohol and in methyl alcohol; slightly soluble in acetone; Protect from light.

Adverse Effects

The most frequent adverse effects after oral use of terbinafine hydrochloride are gastrointestinal disturbances such as nausea, diarrhoea, and mild abdominal pain. Loss or disturbance of taste may occur and occasionally may be severe enough to lead to anorexia and weight loss. Other frequent adverse effects include headache and skin reactions, including rash or urticaria, sometimes with arthralgia or myalgia. Severe skin reactions including angioedema, photosensitivity, Stevens-Johnson syndrome, and toxic epidermal necrolysis have occurred rarely. Liver dysfunction with isolated reports of cholestasis, hepatitis, and jaundice, has occurred and there have also been rare cases of hepatic failure, sometimes leading to death or needing liver transplantation, in patients both with and without pre-existing liver disease. Other rare adverse effects include paraesthesia, hypoaesthesia, dizziness, malaise, fatigue, and alopecia. Haematological disorders including neutropenia, thrombocytopenia, and agranulocytosis, psychiatric disturbances such as depression and anxiety, and precipitation or exacerbation of cutaneous and systemic lupus erythematosus have been reported very rarely.

There may be local reactions after topical use of terbinafine.

Incidence of adverse effects. Postmarketing surveillance of about 10 000 patients[1] suggested the following incidences of adverse effects to oral terbinafine: gastrointestinal symptoms, 4.7%; dermatological effects, 3.3%; CNS symptoms (commonly headache), 1.8%; taste disturbances, 0.6%; and transient disturbances in liver function, 0.1%. Serious adverse effects possibly or probably related to terbinafine included angioedema, bronchospasm, erythema multiforme, extended stroke, and unilateral leg oedema. Combined data from 25 884 patients from this and 3 further studies[2] generally confirmed these results. Overall, adverse effects were reported in 10.5% of patients and caused treatment to be stopped in 5.3%. Serious adverse effects probably or possibly related to terbinafine occurred in 12 patients (0.046%).

1. O'Sullivan DP, *et al.* Postmarketing surveillance of oral terbinafine in the UK: report of a large cohort study. *Br J Clin Pharmacol* 1996; **42:** 559–65.
2. O'Sullivan DP. Terbinafine: tolerability in general medical practice. *Br J Dermatol* 1999; **141** (suppl 56): 21–5.

Effects on the blood. Up to August 2006, the Australian Adverse Drug Reactions Advisory Committee had received 16 reports of blood dyscrasias attributed to oral terbinafine including agranulocytosis (7 reports), neutropenia (7), and pancytopenia (2).[1] The reactions generally occurred within 4 to 6 weeks of starting therapy. Eleven patients recovered, 4 within one week of stopping treatment. However, a 79-year-old patient who developed agranulocytosis about 2 months after starting terbinafine died from septic shock.

1. Adverse Drug Reactions Advisory Committee (ADRAC). Life threatening blood dyscrasias with oral terbinafine. *Aust Adverse Drug React Bull* 2006; **25:** 15. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0608.htm (accessed 02/05/08)

Effects on the eyes. The US manufacturer has noted that changes in the lens and retina of the eye have sometimes been associated with oral terbinafine, although the significance of these changes is not known.

Effects on the salivary glands. Bilateral parotid swelling was associated with terbinafine in a 38-year-old man.[1] Information from the manufacturer and the UK CSM indicated that this effect had occurred in other patients but was very rare. More recently, severe sialadenitis as a complication of drug reaction with eosinophilia and systemic complications (DRESS—a type of hypersensitivity reaction) was reported in an 80-year-old woman treated with terbinafine.[2] She also had severe xerostomia, lachrymal gland swelling, dry eyes, and keratitis.

2. Abecassis S, *et al.* Severe sialadenitis: a new complication of drug reaction with eosinophilia and systemic symptoms. *J Am Acad Dermatol* 2004; **51:** 827–30.

Effects on the skin. Serious skin reactions are occasionally reported in patients receiving terbinafine and have included erythema multiforme,[1,2] erythroderma,[1] severe urticaria,[1] pityriasis rosea,[1] worsening of pre-existing psoriasis,[1,3] acrodermatitis continua of Hallopeau,[4] bullous pemphigoid,[5] acute generalised exanthematous pustulosis,[6] and lupus erythematosus.[7-10] Several of these patients had a history of auto-immune disease[2,9] and it has been suggested that this could be a risk factor for developing severe reactions.[2]

10. Hill VA, *et al.* Subacute lupus erythematosus-like eruption due to terbinafine: report of three cases. *Br J Dermatol* 2003; **148:** 1056.

Effects on taste. Disturbance and loss of taste have been reported in about 0.6% of patients taking terbinafine. While this usually resolves gradually once the drug is withdrawn, persistent impairment of taste has been reported.[1,2]

1. Bong JL, *et al.* Persistent impairment of taste resulting from terbinafine. *Br J Dermatol* 1998; **139:** 747–8.
2. Duxbury AJ, *et al.* Persistent impairment of taste associated with terbinafine. *Br Dent J* 2000; **188:** 295–6.

Precautions

Terbinafine should not be used in patients with existing liver disease and liver function tests should be performed in all patients before starting oral therapy. Terbinafine should be stopped if clinical or biochemical evidence of hepatotoxicity develops. It should also be stopped if any progressive skin rash occurs and should be used with caution in patients with psoriasis.

Terbinafine should be given in reduced doses to patients with renal impairment (see Administration in Renal Impairment, under Uses and Administration, below).

Breast feeding. Terbinafine is excreted in breast milk and licensed product information states that it should be avoided during breast feeding.

Interactions

Plasma concentrations of terbinafine may be increased by drugs that inhibit its metabolism by cytochrome P450, such as cimetidine, and decreased by drugs that induce cytochrome P450 enzymes, such as rifampicin.

Menstrual disturbances including breakthrough bleeding have been reported in patients taking oral contraceptives and terbinafine.

Terbinafine has been shown *in vitro* to inhibit metabolism mediated by the cytochrome P450 isoenzyme CYP2D6. Hence it may affect the plasma concentrations of drugs predominantly metabolised by this enzyme such as tricyclic antidepressants, beta blockers, SSRIs, and type B MAOIs.

For the effects of terbinafine on some other drugs, see carbamazepine (p.475), ciclosporin (p.1826), nortriptyline (p.380), and warfarin (p.1429).

Antimicrobial Action

Terbinafine is an allylamine derivative reported to have a broad spectrum of antifungal activity. It is considered to act through inhibition of fungal sterol synthesis. Terbinafine is fungicidal against dermatophytes, moulds, and certain dimorphic fungi and some yeasts.

Microbiological interactions. Additive and synergistic activity was reported with terbinafine plus fluconazole or itraconazole against strains of *Candida albicans* that had reduced susceptibility to azoles *in vitro*.[1] Terbinafine was also reported to enhance the activity of azoles against *Scedosporium prolificans*[2] and against the protozoan *Leishmania braziliensis*.[3]

1. Barchiesi F, *et al.* In vitro activities of terbinafine in combination with fluconazole and itraconazole against isolates of Candida albicans with reduced susceptibility to azoles. *Antimicrob Agents Chemother* 1997; **41:** 1812–14.
2. Meletiadis J, *et al.* In vitro interaction of terbinafine with itraconazole against clinical isolates of Scedosporium prolificans. *Antimicrob Agents Chemother* 2000; **44:** 470–2.
3. Rangel H, *et al.* Naturally azole-resistant Leishmania braziliensis promastigotes are rendered susceptible in the presence of terbinafine: comparative study with azole-susceptible Leishmania mexicana promastigotes. *Antimicrob Agents Chemother* 1996; **40:** 2785–91. Correction. *ibid.* 1997; **41:** 496.

Pharmacokinetics

Terbinafine hydrochloride is well absorbed from the gastrointestinal tract. The bioavailability is about 40% because of first-pass hepatic metabolism. Mean peak plasma concentrations of about 1 microgram/mL occur within 2 hours of a single oral dose of 250 mg. Steady state concentrations are about 25% higher than those seen after a single dose and are reached in 10 to 14 days. Terbinafine is extensively bound to plasma proteins. Terbinafine is distributed into the stratum corneum of the skin, the nail plate, and hair where it reaches concentrations considerably higher than those found in plasma. It appears in breast milk.

Terbinafine is metabolised in the liver to inactive metabolites which are excreted mainly in the urine. A plasma elimination half-life varying from 17 to 36 hours has been reported and a terminal elimination half-life of up to 400 hours in patients given prolonged therapy, probably representing elimination from skin and adipose tissue. Fungicidal concentrations in nails are maintained for several weeks after therapy is stopped. The elimination rate may be altered in patients with liver or kidney disease. Less than 5% of a topical dose of terbinafine hydrochloride is absorbed.

Uses and Administration

Terbinafine is an allylamine antifungal given by mouth as the hydrochloride in the treatment of dermatophyte infections of the skin and nails (p.521). Oral doses are stated in terms of the base. Terbinafine hydrochloride 1.13 g is equivalent to about 1 g of terbinafine. It is also applied, as the hydrochloride, to the skin in dermatophytoses, in pityriasis versicolor (see Skin Infections, p.521), and in cutaneous candidiasis (p.518).

An oral dose of 250 mg is given once daily for 2 to 4 weeks for tinea cruris; treatment may be continued for up to 6 weeks for tinea pedis infections; a 4-week course is used in tinea corporis infections. A cream, gel, or solution containing 1% terbinafine hydrochloride is applied once or twice daily for 1 to 2 weeks to treat tinea corporis and tinea cruris; a 1-week course is recommended for tinea pedis. A 2-week course of treatment is used in cutaneous candidiasis and pityriasis versicolor.

Dermatophyte infections of the nails are treated with the equivalent of terbinafine 250 mg orally once daily for 6 to 12 weeks although longer treatment may be necessary in toe-nail infections.

Dosage should be reduced in patients with renal impairment (see below).

Administration in children. Although terbinafine is not currently licensed in the UK for use in children, the *BNFC* suggests the following oral doses for the treatment of tinea capitis in children over 1 year of age:

- in those weighing 10 to 20 kg: the equivalent of terbinafine 62.5 mg once daily
- in those weighing 20 to 40 kg: 125 mg once daily
- in those weighing over 40 kg: 250 mg once daily Treatment is usually given for 4 weeks for tinea capitis, 2 to 4 weeks for tinea cruris, 4 weeks for tinea corporis, and may be continued for up to 6 weeks in tinea pedis. Infections of the nails are treated for 6 weeks to 3 months, although longer treatment may occasionally be required for toe-nail infections.

Similar regimens have been reported in the literature.[1,2] A review on the use of terbinafine in children considered it both safe and effective in the management of tinea capitis and onychomycosis.[3]

3. Gupta AK, *et al.* The efficacy and safety of terbinafine in children. *J Eur Acad Dermatol Venereol* 2003; **17:** 627–40.

Administration in renal impairment. The UK licensed product information recommends that in patients with renal impairment (creatinine clearance less than 50 mL/minute or serum creatinine greater than 300 micromol/litre) usual oral doses should be halved to the equivalent of 125 mg of terbinafine daily.

Leishmaniasis. An inadvertent beneficial response has been reported[1] in an HIV-positive patient with cutaneous leishmaniasis (p.824) who was taking terbinafine 250 mg daily for tinea corporis and onychomycosis. Beneficial results were also reported in a pilot study[2] in which patients with cutaneous leishmaniasis took either terbinafine 125 mg twice daily (those aged 5 to 15 years), or terbinafine 250 mg twice daily (those over 15 years), for 4 weeks.

Seborrhoeic dermatitis. Terbinafine has been tried in the treatment of seborrhoeic dermatitis (p.1584). In one study, 60 patients were randomised to receive oral terbinafine 250 mg daily or a placebo cream applied twice daily for 4 weeks.[1] Clinical improvement, maintained 8 weeks after completing treatment, in the terbinafine group led the investigators to conclude that oral terbinafine is an effective treatment for seborrhoeic dermatitis, and to suggest that this might be due to its activity against *Malassezia ovalis* (*Pityrosporum ovale*) as well as to some anti-inflammatory action. However, the methodology of this study has been questioned[2] and further investigation is needed. A further, uncontrolled, study[3] of 661 patients who received oral terbinafine 250 mg daily for 12 days each month for 3 months concluded that intermittent oral terbinafine could be effective for seborrhoeic dermatitis, at least in severe or recalcitrant forms. It has also been tried topically as a 1% cream.[4]

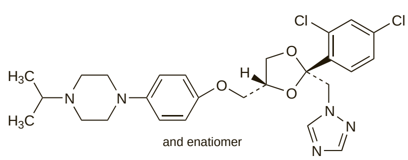
Терконазол

$C_{26}H_{31}Cl_2N_5O_3$ = 532.5.
CAS — 67915-31-5.
ATC — G01AG02.
ATC Vet — QG01AG02.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Terconazole). A white or almost white powder. It exhibits polymorphism. Practically insoluble in water; sparingly soluble in alcohol; soluble in acetone; freely soluble in dichloromethane. Protect from light.

Adverse Effects

Local reactions including burning and itching have been reported with vaginal use of terconazole. Other adverse effects have included dysmenorrhoea and genital, body, and abdominal pain. A flu-like syndrome with headache, fever, chills, and hypotension has been reported in some patients and may be more prevalent with vaginal pessaries providing doses larger than 80 mg.

Flu-like syndrome. References.

1. Moebius UM. Influenza-like syndrome after terconazole. *Lancet* 1988; **ii:** 966–7.

Precautions

Intravaginal preparations of terconazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Antimicrobial Action

Terconazole is a triazole derivative that is thought to disrupt normal fungal cell membrane permeability. Terconazole is active *in vitro* against *Candida* spp. and other fungi. It has some antibacterial activity *in vitro* but not against usual vaginal flora such as lactobacilli.

Pharmacokinetics

After intravaginal use, 5 to 16% of terconazole is absorbed. Systemically absorbed drug is metabolised by the liver and excreted in urine and faeces.

Uses and Administration

Terconazole is a triazole antifungal used in the local treatment of vulvovaginal candidiasis (p.518). Intravaginal dosage regimens are terconazole 40 mg (as 0.8% vaginal cream) or 80 mg (as a pessary) at bedtime for 3 nights or 20 mg (as 0.4% cream) at bedtime for 7 nights.

Preparations

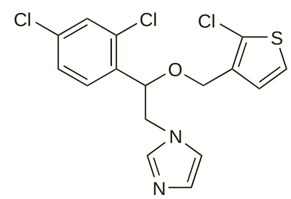
Tioconazole *(BAN, USAN, rINN)*

Tioconazol; Tioconazolum; Tiokonatsoli; Tiokonazol; Tiokonazolas; UK-20349. 1-[2,4-Dichloro-β-(2-chloro-3-thenyloxy)phenethyl]imidazole.

Тиоконазол

$C_{16}H_{13}Cl_3N_2OS$ = 387.7.
CAS — 65899-73-2.
ATC — D01AC07; G01AF08.
ATC Vet — QD01AC07; QG01AF08.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Tioconazole). A white or almost white crystalline powder. Very slightly soluble in water; freely soluble in alcohol; very soluble in dichloromethane. Protect from light.

USP 31 (Tioconazole). Store in airtight containers.

Adverse Effects and Precautions

Local reactions to tioconazole including burning, itching, and erythema have been reported.

Intravaginal preparations of tioconazole may damage latex contraceptives and additional contraceptive measures are therefore necessary during local application.

For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532.

Hypersensitivity. Tioconazole, an imidazole antifungal widely used in Finland, appeared to be an important cause of contact allergy in that country, since an incidence of more than 1% was reported in patients undergoing routine patch testing.[1] There may be cross-reactivity with other commonly used imidazole derivatives.

1. Heikkilä H, *et al*. A study of 72 patients with contact allergy to tioconazole. *Br J Dermatol* 1996; **134:** 678–80.

Antimicrobial Action

Tioconazole is an imidazole antifungal with a broad spectrum of activity including action against dermatophytes, *Malassezia furfur*, and *Candida albicans.* Tioconazole is active *in vitro* against some Gram-positive bacteria.

Uses and Administration

Tioconazole is an imidazole antifungal used in the treatment of superficial candidiasis (p.518), and dermatophytoses and pityriasis versicolor (see Skin Infections, p.521).

For vaginal candidiasis it is used as pessaries or vaginal ointment usually as a single 300-mg dose.

It has been used topically as a 1% cream, lotion, or powder in the treatment of superficial fungal infections. Tioconazole has also been used for nail infections as a 28% w/w topical solution, although systemic treatment is generally preferred.

Preparations

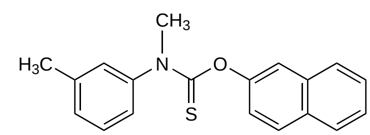
Sch-10144; Tolnaftaatti; Tolnaftát; Tolnaftat; Tolnaftatas; Tolnaftato; Tolnaftatum. *O*-2-Naphthyl *m*,*N*-dimethylthiocarbanilate.

Тольнафтат

$C_{19}H_{17}NOS$ = 307.4.
CAS — 2398-96-1.
ATC — D01AE18.
ATC Vet — QD01AE18.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Tolnaftate). A white or yellowish-white powder. Practically insoluble in water; very slightly soluble in alcohol; freely soluble in acetone and in dichloromethane. Protect from light.

USP 31 (Tolnaftate). A white to creamy-white, fine powder, with a slight odour. Practically insoluble in water; slightly soluble in alcohol; freely soluble in acetone and in chloroform; sparingly soluble in ether. Store in airtight containers.

Adverse Effects

Skin reactions occur rarely with tolnaftate and include irritation and contact dermatitis.

Antimicrobial Action

Tolnaftate inhibits the growth of the dermatophytes *Epidermophyton, Microsporum, Trichophyton* spp., and *Malassezia furfur*, but is not active against *Candida* spp. or bacteria.

Uses and Administration

Tolnaftate is an antifungal used topically as a 1% gel, solution, powder, ointment, or cream in the treatment or prophylaxis of superficial dermatophyte infections and of pityriasis versicolor (see Skin Infections, p.521). Tolnaftate is applied twice daily for 2 to 6 weeks. Repeat treatment may be required.

Preparations

USP 31: Tolnaftate Cream; Tolnaftate Gel; Tolnaftate Topical Aerosol; Tolnaftate Topical Powder; Tolnaftate Topical Solution.

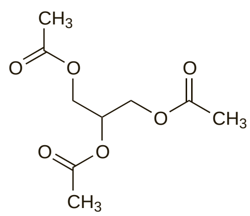
Triacetin *(rINN)*

E1518; Glicerin-triacetát; Glycerol Triacetate; Glycerolum Triacetas; Glyceryl Triacetate; Triacetina; Triacetinas; Triacétine; Triacetinum; Triacetyna; Triasetiini. 1,2,3-Propanetriol triacetate.

Триацетин

$C_9H_{14}O_6$ = 218.2.

CAS — 102-76-1.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Triacetin). A clear, colourless, slightly viscous, oily liquid. Soluble in water; miscible with dehydrated alcohol and with toluene. Store in well-filled containers.

USP 31 (Triacetin). A colourless, somewhat oily liquid with a slight, fatty odour. Soluble in water; slightly soluble in carbon disulfide; miscible with alcohol, with chloroform, and with ether. Store in airtight containers.

Profile

Triacetin is reported to possess fungistatic properties based on the liberation of acetic acid. It has been applied topically in the treatment of superficial dermatophyte infections. It has also been used as a plasticiser in oral preparations.

Triacetin may destroy rayon fabric. It should not come into contact with metals.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Braz.:*** Micosan†; ***Hong Kong:*** Alber T†; ***Thai.:*** Alber T; Ezon-T.

Trimetrexate Glucuronate *(BANM, USAN, rINNM)*

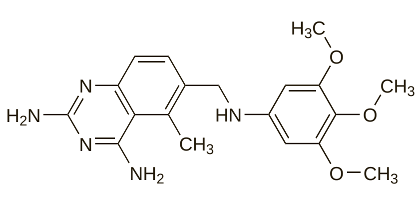
CI-898 (trimetrexate); Glucuronato de trimetrexato; JB-11 (trimetrexate); NSC-352122; NSC-249008 (trimetrexate); NSC-328564 (trimetrexate); Trimétrexate, Glucuronate de; Trimetrexati Glucuronatum. 5-Methyl-6-(3,4,5-trimethoxyanilinomethyl)quinazolin-2,4-diyldiamine mono-D-glucuronate.

Триметрексата Глюкуронат

$C_{19}H_{23}N_5O_3,C_6H_{10}O_7$ = 563.6.

CAS — 52128-35-5 (trimetrexate); 82952-64-5 (trimetrexate glucuronate).

ATC — P01AX07.



(trimetrexate)

Incompatibility. Trimetrexate is reported to be incompatible with foscarnet. Trimetrexate should not be mixed with folinic acid or chloride ions, since precipitation occurs instantly.

Adverse Effects, Treatment, and Precautions

Trimetrexate is a dihydrofolate reductase inhibitor and therefore adverse effects and precautions are similar to those of methotrexate, p.745. It must be given with folinic acid, which should be continued for 72 hours after the last dose of trimetrexate.

Interactions

Studies in *animals* suggest that cimetidine and imidazole antifungals such as clotrimazole and ketoconazole may inhibit trimetrexate metabolism, and there is a risk of possible interactions with all drugs that affect hepatic cytochrome P450 systems.

Antimicrobial Action

Trimetrexate is an inhibitor of dihydrofolate reductase and consequently prevents formation of the active coenzyme tetrahydrofolate and production of DNA and RNA precursors, leading to cell death. At therapeutic doses the selective transport of trimetrexate, but not folinic acid, into *Pneumocystis jirovecii* allows folinic acid to protect normal host cells from the cytotoxicity of trimetrexate without inhibiting its antifungal activity. *In-vitro* trimetrexate has shown dose-related inhibition of growth of the trophozoite stage of *P. jirovecii.*

Pharmacokinetics

The pharmacokinetics of intravenous trimetrexate have been described as both biphasic and triphasic, with a terminal elimination half-life of about 16 to 18 hours. After use with folinic acid a biphasic disposition with a terminal half-life of 11 hours has also been reported. It is extensively protein bound; reports suggest that it is 95 to 98% bound at low serum concentrations, but that binding is saturable, with free fraction increasing at plasma concentrations above 1 microgram/mL. Trimetrexate is excreted mainly in the urine, as unchanged drug and metabolites, some of which may be active. The major metabolic pathway appears to be oxidative O-demethylation followed by conjugation to the sulfate or glucuronide.

Uses and Administration

Trimetrexate is a dihydrofolate reductase inhibitor with general properties similar to those of methotrexate (p.749). It is used in the management of moderate to severe pneumocystis pneumonia in immunocompromised patients, notably patients with AIDS, where other therapy has proved ineffective (see also p.521). It has also been tried as an antineoplastic in the management of various solid tumours.

Trimetrexate is given as the glucuronate but doses are stated in terms of trimetrexate. Trimetrexate glucuronate 1.53 mg is equivalent to about 1 mg of trimetrexate. It is given by intravenous infusion, over 60 to 90 minutes. The schedule in pneumocystis pneumonia is 45 mg/m^2 daily for 21 days, in association with folinic acid rescue for 24 days. The dosage of trimetrexate and folinic acid should be adjusted according to the results of blood tests, which should be performed at least twice a week during therapy. Renal and hepatic function and haemoglobin values should also be monitored. Treatment with zidovudine and other myelosuppressive drugs should be interrupted to allow full doses of trimetrexate to be given.

Undecenoic Acid

Acide Undécylénique; Acidum undecylenicum; 10-Hendecenoic Acid; Kyselina undecylenová; Undecilénico, ácido; Undecileno rūgštis; Undecilénsav; Undecylenic Acid; Undecylensyra; Undesenoatlar; Undesilenatlar; Undesyleenihappo. Undec-10-enoic acid.

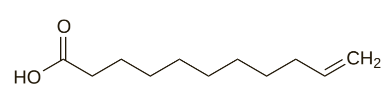
Ундеценовая Кислота

$C_{11}H_{20}O_2$ = 184.3.

CAS — 112-38-9.

ATC — D01AE04.

ATC Vet — QD01AE04.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Undecylenic Acid; Undecenoic Acid BP 2008). A colourless or pale yellow liquid or a white or very pale yellow crystalline mass. Practically insoluble in water; freely soluble in alcohol and in fatty and essential oils. Store in nonmetallic containers. Protect from light.

USP 31 (Undecylenic Acid). A clear, colourless to pale yellow liquid with a characteristic odour. Practically insoluble in water; miscible with alcohol, with chloroform, with ether, with benzene, and with fixed and volatile oils. Store in airtight containers. Protect from light.

Calcium Undecenoate

Calcium Undecylenate *(USAN)*; Undecilenato de calcio. Calcium di(undec-10-enoate).

Ундециленат Кальция

$(C_{11}H_{19}O_2)_2Ca$ = 406.6.

ATC — D01AE04.

ATC Vet — QD01AE04.

Pharmacopoeias. In *US.*

USP 31 (Calcium Undecylenate). A fine white powder with a characteristic odour and no grit. Practically insoluble in water, in cold alcohol, in acetone, in chloroform, and in ether; slightly soluble in hot alcohol.

Zinc Undecenoate

Cinko undecilenatas; Çinko Undesilenat; Cink-undecilenát; Sinkkiundesylenaatti; Undecilenato de zinc; Undecilinato de Zinco; Undecylenan zinečnatý; Zinc Undecylenate; Zinc, undécylénate de; Zinci undecylenas; Zinkundecylenat. Zinc di(undec-10-enoate).

Ундециленат Цинка

$(C_{11}H_{19}O_2)_2Zn$ = 431.9.

CAS — 557-08-4.

ATC — D01AE04.

ATC Vet — QD01AE04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Zinc Undecylenate; Zinc Undecenoate BP 2008). A fine white or almost white powder. Practically insoluble in water and in alcohol. Protect from light.

USP 31 (Zinc Undecylenate). A fine, white powder. Practically insoluble in water and in alcohol.

Adverse Effects

Irritation may rarely occur after the topical application of undecenoic acid or its salts.

Antimicrobial Action

Undecenoic acid and its derivatives are active against some pathogenic fungi, including the dermatophytes *Epidermophyton, Trichophyton,* and *Microsporum* spp.

Uses and Administration

Undecenoic acid and its zinc salt are applied topically in the prophylaxis and treatment of superficial dermatophytoses, particularly tinea pedis (p.521). Typical concentrations are undecenoic acid 2 to 5% and zinc undecenoate 20%. They are used in creams, ointments, solutions, or powders, often with each other. Calcium undecenoate is used as a 10 or 15% powder.

Several other salts and derivatives of undecenoic acid including methyl, phenyl, and propyl undecenoate, disodium sulfosuccinated undecenoic acid monoethanolamide, and undecenoic acid monoethanolamide and diethanolamide have been used similarly.

◊ A systematic review[1] of topical treatments for fungal skin or nail infections considered undecenoates to be effective, although comparative studies with other classes of topical antifungal were largely lacking.

Voriconazole *(BAN, USAN, rINN)*

UK-109496; Voriconazol; Voriconazolum; Vorikonazol. (2*R*,3*S*)-2-(2,4-Difluorophenyl)-3-(5-fluoropyrimidin-4-yl)-1-(1,2,4-triazol-1-yl)butan-2-ol.

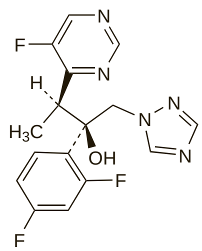
Вориконазол

$C_{16}H_{14}N_5F_3O = 349.3$.

CAS — 137234-62-9.

ATC — J02AC03.

ATC Vet — QJ02AC03.



Adverse Effects

The most commonly reported adverse effects with voriconazole are visual disturbances, fever, rashes, nausea, vomiting, diarrhoea, abdominal pain, headache, sepsis, respiratory disorders, and peripheral oedema. There have been some serious hepatic reactions including fatalities. Skin reactions have included rare cases of erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis. Photosensitivity reactions may occur and are more likely during long-term treatment.

Other adverse effects reported as being common during treatment with voriconazole include: chills, flu-like syndrome, asthenia, back pain, chest pain, injection site reactions, facial oedema, hypotension, sinusitis, altered liver function tests, jaundice, cheilitis, blood disorders, hypokalaemia, hypoglycaemia, dizziness, hallucinations, confusion, depression, anxiety, tremor, agitation, paraesthesia, pruritus, alopecia, exfoliative dermatitis, acute renal failure, and haematuria. Hypersensitivity reactions, including anaphylaxis, have occurred rarely.

Effects on the blood. Fever and leucocytosis with eosinophilia in one patient has been attributed to voriconazole treatment.[1]

1. Vishnubhotla P, *et al.* Fever and eosinophilia associated with voriconazole. *Ann Pharmacother* 2004; **38:** 900–901.

Effects on the heart. Bradycardia with a prolonged QT interval and asymptomatic episodes of torsade de pointes occurred in a 15-year-old patient, after 3 weeks of voriconazole therapy at usual doses.[1] All drug treatment was stopped but the effects recurred on rechallenge with a small dose of voriconazole.

1. Alkan Y, *et al.* Voriconazole-induced QT interval prolongation and ventricular tachycardia: a non-concentration-dependent adverse effect. *Clin Infect Dis* 2004; **39:** e49–e52.

Effects on mental function. There have been reports[1,2] of patients experiencing hallucinations (auditory or visual) during treatment with voriconazole. In one study 18 of 415 patients (4.3%) given voriconazole had visual hallucinations compared with 2 of 422 (0.5%) given amphotericin B.[1]

1. Walsh TJ, *et al.* Voriconazole compared with liposomal amphotericin B for empirical antifungal therapy in patients with neutropenia and persistent fever. *N Engl J Med* 2002; **346:** 225–34.
2. Agrawal AK, Sherman LK. Voriconazole-induced musical hallucinations. *Infection* 2004; **32:** 293–5.

Precautions

Acute renal failure may occur with voriconazole and renal function should be monitored during treatment. Liver function should also be monitored before and during treatment with voriconazole. It should be used with caution in patients with hepatic impairment and doses may need to be adjusted (see under Uses and Administration, below). Patients should avoid sunlight during treatment as photosensitivity reactions have been reported. Visual disturbances may occur and patients affected should not drive or operate hazardous machinery. In addition, all patients, whether affected by visual disturbances or not, should not drive at night, and should have their visual function monitored if they are receiving voriconazole for more than 28 days. Voriconazole has been associated with QT interval prolongation and should therefore be given with caution to patients with potentially pro-arrhythmic conditions.

Voriconazole has been shown to be teratogenic and embryotoxic in *animal* studies and its use is generally not recommended during pregnancy. For a discussion of the caution needed when using azole antifungals during pregnancy, see under Pregnancy in Precautions of Fluconazole, p.532. Licensed product information recommends that women of child-bearing potential should use effective contraception during treatment with voriconazole.

Interactions

Voriconazole is metabolised by cytochrome P450 isoenzymes CYP2C19, CYP2C9, and CYP3A4. Use of drugs that either inhibit or induce these isoenzymes may increase or decrease plasma concentrations of voriconazole, respectively. Rifampicin has been shown to decrease voriconazole plasma concentrations and a similar effect may be expected with carbamazepine or phenobarbital; use of voriconazole with these drugs is therefore not recommended.

Concentrations of other drugs that are metabolised by CYP2C19, CYP2C9, or CYP3A4 may be increased by voriconazole. Increased plasma concentrations of astemizole, cisapride, pimozide, quinidine, and terfenadine could be expected and concomitant use is contra-indicated because of the risk of cardiac arrhythmias including torsade de pointes. Use with ergot alkaloids such as ergotamine and dihydroergotamine is also contra-indicated because of the possible risk of ergotism. Increased plasma concentrations of sirolimus and tacrolimus have been noted; use with sirolimus is contra-indicated, although tacrolimus may be used providing its dose is reduced and concentrations monitored. Similarly, reduced dose with monitoring is recommended for ciclosporin. Likewise, monitoring and possible dose reductions of methadone are recommended during concomitant use. Concentrations of oral anticoagulants may be affected and increased prothrombin time has occurred with warfarin; monitoring should therefore be carried out. Close monitoring of blood glucose is necessary if voriconazole is used with oral hypoglycaemics such as the sulfonylureas. Dose reductions may be needed for some statins, calcium-channel blockers, vinca alkaloids, and some benzodiazepines (such as midazolam and triazolam) if their plasma concentrations are increased.

Interactions may occur where both voriconazole and the other drug are affected. Examples are phenytoin and rifabutin (where concentrations of voriconazole are reduced but those of phenytoin or rifabutin are increased). If it is essential to give either drug with voriconazole, then an increase in the dose of voriconazole is recommended. With omeprazole, the plasma concentration of both drugs may be increased and a reduced dose of omeprazole is recommended.

Voriconazole may inhibit metabolism of non-nucleoside reverse transcriptase inhibitors and they in turn may either inhibit the metabolism of voriconazole (e.g. delavirdine and efavirenz) or induce the metabolism of voriconazole (e.g. efavirenz and nevirapine). Co-administration of voriconazole and efavirenz is contra-indicated. Similarly, voriconazole may inhibit metabolism of HIV-protease inhibitors (e.g. saquinavir, amprenavir, and nelfinavir) while they may in turn inhibit the metabolism of voriconazole. High doses of ritonavir (400 mg twice daily) significantly decrease plasma concentrations of voriconazole and co-administration is contra-indicated. Similar effects have been seen with low doses of ritonavir (100 mg twice daily) and use with voriconazole should be avoided where possible. Indinavir, however, does not appear to interact with voriconazole.

For further information on interactions between drugs metabolised by the cytochrome P450 isoenzyme CYP3A and azoles, see under Itraconazole, p.537.

◊ For reviews of drug interactions with azole antifungals, see Itraconazole, p.537.

Antimicrobial Action

Voriconazole is a triazole antifungal that in sensitive fungi inhibits cytochrome P450-dependent enzymes resulting in the impairment of ergosterol synthesis in fungal cell membranes. Voriconazole has a broad spectrum of activity against all *Candida* species, including fluconazole-resistant strains, as well as *Aspergillus* spp., *Scedosporium* spp., and *Fusarium* spp.

◊ Reports of breakthrough zygomycosis and other fungal infections in immunocompromised patients treated empirically or prophylactically with voriconazole.[1-5]

3. Imhof A, *et al.* Breakthrough fungal infections in stem cell transplant recipients receiving voriconazole. *Clin Infect Dis* 2004; **39:** 743–6.
4. Oren I. Breakthrough zygomycosis during empirical voriconazole therapy in febrile patients with neutropenia. *Clin Infect Dis* 2005; **40:** 770–1.
5. Vigouroux S, *et al.* Zygomycosis after prolonged use of voriconazole in immunocompromised patients with hematologic disease: attention required. *Clin Infect Dis* 2005; **40:** e35-e37.

Pharmacokinetics

Voriconazole exhibits non-linear pharmacokinetics due to saturable metabolism. It is rapidly and almost completely absorbed from the gastrointestinal tract. Peak plasma concentrations occur about 1 to 2 hours after an oral dose. Plasma protein binding of voriconazole is about 58%. Voriconazole diffuses into CSF.

Voriconazole is metabolised by hepatic cytochrome P450 isoenzyme CYP2C19; the major metabolite is the inactive *N*-oxide. Metabolism via isoenzymes CYP2C9 and CYP3A4 has also been demonstrated *in vitro*. About 80% of voriconazole is excreted in the urine.

Uses and Administration

Voriconazole is a triazole antifungal used mainly in immunocompromised patients for the treatment of invasive aspergillosis (p.517), candidaemia (p.518) in non-neutropenic patients, fluconazole-resistant serious invasive candidiasis, oesophageal candidiasis, and serious fungal infections due to *Scedosporium* and *Fusarium* spp.

Voriconazole may be given orally or intravenously.

Oral doses as film-coated tablets should be taken at least 1 hour before, or 1 hour after, a meal; oral suspensions should be taken at least 1 hour before, or 1 to 2 hours after, a meal. The oral suspension may be preferred in children.

The following ***oral loading doses*** of voriconazole are given every 12 hours for the first 24 hours:

- adults and adolescents weighing more than 40 kg: 400 mg
- under 40 kg: 200 mg
- children aged 2 to 12 years: no loading dose

Subsequent ***oral maintenance doses*** are:

- adults and adolescents over 40 kg: 200 mg twice daily, increased to 300 mg twice daily if the response is inadequate
- under 40 kg: 100 mg twice daily, increased to 150 mg twice daily if the response is inadequate
- children aged 2 to 12 years: 200 mg twice daily

US licensed product information does not suggest a loading dose for oesophageal candidiasis; oral maintenance doses are as above and treatment should be given for a minimum of 14 days and continued for at least 7 days after resolution of symptoms.

Intravenous loading doses of voriconazole are:

- adults and adolescents: 6 mg/kg every 12 hours for the first 24 hours
- children aged 2 to 12 years: no loading dose

Intravenous maintenance doses are:

- adults and adolescents: 4 mg/kg twice daily; a lower dose of 3 mg/kg twice daily may be suitable for candidaemia in non-neutropenic patients or for deep tissue *Candida* infections, or for patients unable to tolerate the higher dose
- children aged 2 to 12 years: 7 mg/kg twice daily; 4 mg/kg twice daily may be used in those unable to tolerate the higher dose

Intravenous infusions should be given at a maximum rate of 3 mg/kg per hour over 1 to 2 hours. UK licensed product information recommends that intravenous therapy should not be given for longer than 6 months.

Doses of voriconazole should be modified in patients with hepatic or renal impairment (see below). For a suggested dose in patients taking the NNRTI efavirenz see Interactions, Antifungals, p.873.

◊ Reviews.

Administration in hepatic impairment. No dosage adjustment is necessary when voriconazole is given to patients with acute hepatic impairment but doses should be modified in patients with chronic disease. Patients with mild to moderate hepatic cirrhosis (Child-Pugh category A and B) should receive the standard loading doses of voriconazole (see above) but maintenance doses should be halved. Doses for patients with severe hepatic cirrhosis (Child-Pugh category C) have not been established.

Administration in renal impairment. No dose adjustment is needed for oral voriconazole in patients with renal impairment. Patients with a creatinine clearance less than 50 mL/minute should receive oral voriconazole instead of intravenous voriconazole, as accumulation of the intravenous vehicle, sulfobutyl ether beta-cyclodextrin sodium (SBECD), may occur. When intravenous voriconazole is considered justified in such patients, serum creatinine should be closely monitored and consideration given to changing to the oral route if increases occur.

Although voriconazole is haemodialysed, no dose adjustment is required for patients on haemodialysis.

Antigout Drugs

This chapter deals with the treatment of gout and hyperuricaemia and the drugs used mainly for these disorders.

Gout and hyperuricaemia

Uric acid is the final product of the metabolism of endogenous and exogenous purine in man. An excess of uric acid, measured in the plasma as sodium urate, constitutes **hyperuricaemia**. This excess may be caused by an overproduction or underexcretion of urate. It is influenced by genetic and environmental factors and may be classified as primary (mainly idiopathic) or secondary. An increase in urate production may be caused by excessive dietary purine intake, certain cancers or their treatment, or, more rarely, enzyme defects of purine metabolism. Reduced urate excretion may be caused by renal disease, hypertension, or the intake of certain drugs such as thiazide diuretics. Other factors contributing to hyperuricaemia include hyperlipidaemia, obesity, alcohol consumption, and lead exposure.

A patient is usually considered to be hyperuricaemic when plasma-urate concentrations exceed 0.42 mmol/litre (7 mg per 100 mL) in men and postmenopausal women or 0.36 mmol/litre (6 mg per 100 mL) in premenopausal women. At these high concentrations there is a risk of crystals of monosodium urate monohydrate being formed and deposited in synovial fluid and various tissues. However, some subjects may have supersaturated plasma-urate concentrations without any crystal deposits, while others may suffer from deposits in the absence of apparent hyperuricaemia.

The presence of urate crystals in the synovial fluid leads to an inflammatory response in the affected joint, commonly at the base of the big toe (podagra). The ensuing exquisite pain, tenderness, erythema, and swelling constitute the clinical manifestations of **acute inflammatory gouty arthritis**. Repeated acute attacks may be associated with a visible or palpable build up of crystal deposits (**tophi**) at various sites including in and around the affected joint. Tophi release urate crystals into the synovial fluid after various stimuli and so cause further acute attacks, leading to **chronic tophaceous gout**. Intra-articular and peri-articular tophi may cause gradual joint erosion, which, without treatment, results in disabling **chronic gouty arthritis**. Rarely, the kidney can be affected by urate deposits producing a gouty nephropathy or by uric acid calculi or stones (uric acid nephrolithiasis or urolithiasis).

Treatment aims to alleviate the acute attack, prevent future attacks, and lower plasma-urate concentration.

Plasma-urate concentrations may be reduced by control of obesity and modification of diet and alcohol intake. Drug treatment can relieve the pain of acute attacks but more prolonged therapy for hyperuricaemia is generally only considered if there are recurrent attacks of gout or there is renal involvement (see under Chronic Gout, below).

Acute gout. An attack of acute inflammatory gouty arthritis is best treated as soon as possible with an NSAID. Aspirin or other salicylates are not suitable since they may increase plasma-urate concentrations. Treatment is started with high doses of an NSAID, the doses being reduced as the patient responds. Usually treatment can be withdrawn within 1 to 2 weeks. Colchicine is an effective alternative; it may be used alone, or with an NSAID. Patients who do not respond to NSAIDs or colchicine, or for whom these drugs are contra-indicated, may be treated with a systemic corticosteroid. Intra-articular corticosteroids are effective in acute monoarticular gout, or when used adjunctively in patients with polyarticular gout; infection of joints should be excluded prior to injection. Intravenous, intramuscular, or subcutaneous corticotropin has been reported to alleviate pain and inflammation in acute gout. It may be used alone or adjunctively, and may be a useful alternative in patients with renal and gastrointestinal contra-indications to other therapies. Other therapies for acute gout include adjunctive analgesics and topical ice. Drugs used for chronic gout (allopurinol or the uricosurics) should not be started during an acute attack since they can exacerbate and prolong it (see below).

Chronic gout. If the patient suffers frequent acute attacks or develops tophaceous gout, or has renal complications as a result of urate overproduction, then long-term treatment of hyperuricaemia may be needed. Such **urate-lowering therapy** should not be started during an acute attack, or for 2 to 3 weeks thereafter, as fluctuations in urate concentration may prolong the existing attack or initiate a new one. Treatment involves inhibiting the production of uric acid or enhancing its urinary excretion, in order to maintain a serum urate concentration at or below 0.3 or 0.36 mmol/litre. Hyperuricaemia due to overproduction of urate is treated with allopurinol which inhibits the enzyme xanthine oxidase, involved in purine metabolism. Hyperuricaemia associated with underexcretion of uric acid can be treated with either allopurinol or a uricosuric such as benzbromarone, probenecid or sulfinpyrazone. Allopurinol is most commonly given as first-line therapy, but may be combined with or replaced by uricosurics if treatment fails. Allopurinol should also be used for patients with renal urate deposits or with uric acid renal calculi as it reduces urolithiasis. Febuxostat is an alternative xanthine oxidase inhibitor under investigation.

With either treatment there is mobilisation of urate crystals from established tophi, as the plasma-urate concentration falls, which can trigger further acute attacks of gout. Patients are thus also given **prophylaxis** with an NSAID or colchicine from the start of urate-lowering treatment until at least a month after the plasma-urate has been reduced to an acceptable concentration; up to 6 months of prophylactic cover has been recommended.

Once the hyperuricaemia is corrected, the patient continues to receive therapy with allopurinol or uricosurics indefinitely. If an acute attack occurs during such maintenance therapy, this therapy should be continued to avoid fluctuations in urate concentration, and the acute attack treated in its own right.

Surgery may have to be considered for patients severely affected by chronic tophaceous gout.

Allopurinol *(BAN, USAN, rINN)*

Allopürinol; Allopurinoli; Allopurinolum; Allopurynol; Alopurinol; Alopurinolis; BW-56-158; HPP; NSC-1390.

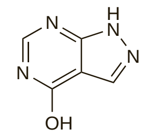
Аллопуринол

$C_5H_4N_4O$ = 136.1.

CAS — 315-30-0 (allopurinol); 17795-21-0 (allopurinol sodium).

ATC — M04AA01.

ATC Vet — QM04AA01.



Description. Allopurinol is a tautomeric mixture of 1*H*-pyrazolo[3,4-*d*]pyrimidin-4-ol and 1,5-dihydro-4*H*-pyrazolo[3,4-*d*]pyrimidin-4-one.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Allopurinol). A white or almost white powder. Very slightly soluble in water and in alcohol; dissolves in dilute solutions of alkali hydroxides.

USP 31 (Allopurinol). A fluffy white to off-white powder having only a slight odour. Very slightly soluble in water and in alcohol; practically insoluble in chloroform and in ether; soluble in solutions of potassium and sodium hydroxides.

Incompatibility. Allopurinol sodium as a 3 mg/mL solution in 0.9% sodium chloride was visually incompatible with amikacin sulfate, amphotericin B, carmustine, cefotaxime sodium, chlormethine hydrochloride, chlorpromazine hydrochloride, cimetidine hydrochloride, clindamycin phosphate, cytarabine, dacarbazine, daunorubicin hydrochloride, diphenhydramine hydrochloride, doxorubicin hydrochloride, doxycycline hyclate, droperidol, floxuridine, gentamicin sulfate, haloperidol lactate, hydroxyzine hydrochloride, idarubicin hydrochloride, imipenem with cilastatin sodium, methylprednisolone sodium succinate, metoclopramide hydrochloride, minocycline hydrochloride, nalbuphine hydrochloride, netilmicin sulfate, ondansetron hydrochloride, pethidine hydrochloride, prochlorperazine edisilate, promethazine hydrochloride, sodium bicarbonate, streptozocin, tobramycin sulfate, and vinorelbine tartrate.[1]

Adverse Effects

The most common adverse effect of allopurinol is skin rash. Rashes are generally maculopapular or pruritic, sometimes purpuric, but more serious hypersensitivity reactions may occur and include exfoliative rashes, the Stevens-Johnson syndrome, and toxic epidermal necrolysis. It is therefore recommended that allopurinol be withdrawn immediately if a rash occurs (see Precautions, below). Further symptoms of hypersensitivity include fever and chills, lymphadenopathy, leucopenia or leucocytosis, eosinophilia, arthralgia, and vasculitis leading to renal and hepatic damage and, very rarely, seizures. These hypersensitivity reactions may be severe, even fatal, and patients with hepatic or renal impairment are at special risk.

Hepatotoxicity and signs of altered liver function may also be found in patients who are not hypersensitive. Haematological effects include thrombocytopenia, aplastic anaemia, agranulocytosis, and haemolytic anaemia.

Many other adverse effects have been noted rarely and include paraesthesia, peripheral neuropathy, alopecia, gynaecomastia, hypertension, taste disturbances, nausea, vomiting, abdominal pain, diarrhoea, headache, malaise, drowsiness, vertigo, and visual disturbances.

Patients with gout may have an increase in acute attacks on beginning treatment with allopurinol, although attacks usually subside after several months.

Incidence of adverse effects. A Boston Collaborative Drug Surveillance Program involving 29 524 hospitalised patients found that, with the exception of skin reactions, 33 of 1835 patients treated with allopurinol (1.8%) had adverse effects. These effects were dose-related and the most frequent were haematological (11 patients, 0.6%), diarrhoea (5 patients, 0.3%), and drug fever (5 patients, 0.3%). Hepatotoxicity was reported in 3 patients (0.2%). Two patients developed possible hypersensitivity reactions to allopurinol.[1]

A further analysis involving 1748 outpatients indicated no instances of acute blood disorders, skin diseases, or hypersensitivity that warranted hospital treatment. Liver disease, although found, was not considered to be associated with allopurinol.

There were only 2 patients in whom renal disease could possibly have been caused by allopurinol.[2]

2. Jick H, Perera DR. Reactions to allopurinol. *JAMA* 1984; **252:** 1411.

Effects on the blood. In addition to the haematological abnormalities of leucopenia, thrombocytopenia, haemolytic anaemia, and clotting abnormalities noted in the Boston Collaborative Drug Surveillance Program,[1] aplastic anaemia has also been reported, sometimes in patients with renal impairment.[2] Pure red cell aplasia has also been reported.[3,4]

4. Chao S-C, *et al.* Hypersensitivity syndrome and pure red cell aplasia following allopurinol therapy in a patient with chronic kidney disease. *Ann Pharmacother* 2005; **39:** 1552–6.

Effects on the eyes. Some case reports have suggested an association between allopurinol use and the development of cataracts,[1] but a detailed ophthalmological survey involving 51 patients who had taken allopurinol failed to confirm this.[2] However, a large retrospective case-control study in elderly patients concluded that long-term, or high-dose, allopurinol therapy did increase the risk of cataract extraction.[3]

1. Fraunfelder FT, *et al.* Cataracts associated with allopurinol therapy. *Am J Ophthalmol* 1982; **94:** 137–40.
2. Clair WK, *et al.* Allopurinol use and the risk of cataract formation. *Br J Ophthalmol* 1989; **73:** 173–6.
3. Garbe E, *et al.* Exposure to allopurinol and the risk of cataract extraction in elderly patients. *Arch Ophthalmol* 1998; **116:** 1652–6.

Effects on the skin. Skin reactions are the most common adverse effects of allopurinol.

One report calculated that of 215 adverse effects noted over a 16-year period 188 (87.4%) were related to the skin or mucous membranes.[1] An analysis by the Boston Collaborative Drug Surveillance Program of data on 15 438 patients hospitalised between 1975 and 1982 detected 6 allergic skin reactions attributed to allopurinol among 784 recipients of the drug.[2] Desensitisation protocols[3] and alternative drugs[4] have been used after cutaneous reactions to allopurinol.

Serious skin reactions to allopurinol may occur as part of a generalised hypersensitivity reaction. A review of the literature between 1970 and the end of 1990 revealed 101 cases of allopurinol hypersensitivity syndrome, 94 of which involved the skin.[5] Skin reactions included erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, or a diffuse maculopapular or exfoliative dermatitis; 27 of the 101 patients died. The relative risk of toxic epidermal necrolysis or Stevens-Johnson syndrome occurring with allopurinol was high (calculated to be 5.5) in a case-control study including 13 patients with these cutaneous reactions who had received allopurinol.[6] This risk was not constant over time, being higher during the first 2 months of treatment. During these 2 months the estimated excess risk was 1.5 cases per million users per week. Another case-control study,[7] involving 379 patients with Stevens-Johnson syndrome or toxic epidermal necrolysis, found that allopurinol was the drug most frequently associated with these reactions. The risk again appeared to be restricted to short-term use (less than 8 weeks) and was greater in patients taking 200 mg or more daily.

Precautions

Allopurinol should not be used for the treatment of an acute attack of gout; additionally, allopurinol therapy should not be begun for any purpose during an acute attack. However, allopurinol is continued when acute attacks occur in patients already receiving the drug, and the acute attack is treated separately.

Treatment should be stopped immediately if any skin reactions or other signs of hypersensitivity develop. A cautious reintroduction at a low dose may be attempted when mild skin reactions have cleared (see Effects on the Skin, above); allopurinol should not be reintroduced in those patients who have experienced other forms of hypersensitivity reaction. Dosage should be reduced in renal or hepatic impairment. Care is advised in patients being treated for hypertension or cardiac insufficiency, who may also have renal impairment.

To reduce the risk of renal xanthine deposition an adequate fluid intake (2 to 3 litres daily) is required. In addition, a neutral or slightly alkaline urine may be desirable.

Breast feeding. Allopurinol and its metabolite, oxipurinol, are distributed into breast milk, and licensed product information recommends that allopurinol should be used with caution in breast-feeding women. Although oxipurinol was detected in the plasma of a breast-fed infant, no adverse effects were noted in the infant during 6 weeks of maternal treatment with allopurinol.[1] The American Academy of Pediatrics noted that there had been no documented problems with allopurinol and considered its use to be usually compatible with breast feeding.[2]

Interactions

Drugs that can increase uric acid concentrations may decrease the efficacy of allopurinol. Aspirin and the salicylates possess this activity and should generally be avoided in hyperuricaemia and gout. An increase in hypersensitivity reactions, and possibly also other adverse effects, has been reported in patients taking allopurinol with ACE inhibitors or thiazide diuretics, particularly in patients with renal impairment.

The metabolism of azathioprine and mercaptopurine is inhibited by allopurinol and their doses should be markedly reduced when either of them is given with allopurinol to avoid potentially life-threatening toxicity. There have also been reports of allopurinol enhancing the activity of, and possibly increasing the toxicity of, a number of other drugs including some antibacterials, some anticoagulants, some other antineoplastics, ciclosporin, some sulfonylurea antidiabetics, theophylline, and vidarabine.

ACE inhibitors. An apparent interaction between allopurinol and *captopril* has been reported in patients with chronic renal failure. In one patient it was suggested that the development of fatal Stevens-Johnson syndrome after the introduction of allopurinol was due to potentiation by captopril.[1] In the second patient hypersensitivity, characterised by fever, arthralgia, and myalgia, occurred and was believed to be due to captopril, or one of its metabolites, potentiated by the addition of allopurinol.[2] Care is advised if allopurinol is used with captopril, especially in patients with chronic renal failure.

1. Pennell DJ, *et al.* Fatal Stevens-Johnson syndrome in a patient on captopril and allopurinol. *Lancet* 1984; **i:** 463.
2. Samanta A, Burden AC. Fever, myalgia, and arthralgia in a patient on captopril and allopurinol. *Lancet* 1984; **i:** 679.

Antacids. Allopurinol failed to reduce blood-uric-acid concentrations when given at the same time as *aluminium hydroxide* in 3 patients on chronic haemodialysis. However, if allopurinol was given 3 hours before aluminium hydroxide the expected decrease in uric acid concentration did occur.[1]

1. Weissman I, Krivoy N. Interaction of aluminium hydroxide and allopurinol in patients on chronic hemodialysis. *Ann Intern Med* 1987; **107:** 787.

Antibacterials. Although an increased incidence of skin rashes has been noted when allopurinol has been used with *ampicillin* or *amoxicillin*, data currently available are insufficient to confirm whether this is due to allopurinol or not. For further details, see Ampicillin, p.204.

Anticoagulants. For the effect of allopurinol on *dicoumarol*, *phenprocoumon*, or *warfarin*, see Warfarin, p.1429.

Antiepileptics. For a report of allopurinol possibly inhibiting the metabolism of *phenytoin*, see under Antigout Drugs, p.499.

Antigout drugs. Uricosuric drugs are likely to increase the renal elimination of oxipurinol (the major active metabolite of allopurinol). For example, *benzbromarone* lowered plasma concentrations of oxipurinol by about 40% when used with allopurinol, although plasma concentrations of allopurinol itself were not affected.[1] The interaction was not of concern, since the combination was more effective than allopurinol alone in lowering serum concentrations of uric acid. Licensed product information recommends reassessing the dosage of allopurinol on an individual basis when a uricosuric drug is added.

Probenecid has been reported to decrease the clearance of oral allopurinol riboside.[2] In a pharmacokinetic study in healthy subjects,[3] giving allopurinol and probenecid together significantly reduced oxipurinol concentrations; however, this combination had a greater hypouricaemic effect than either drug given alone.

1. Müller FO, *et al.* The effect of benzbromarone on allopurinol/oxypurinol kinetics in patients with gout. *Eur J Clin Pharmacol* 1993; **44:** 69–72.
2. Were JBO, Shapiro TA. Effects of probenecid on the pharmacokinetics of allopurinol riboside. *Antimicrob Agents Chemother* 1993; **37:** 1193–6.
3. Stocker SL, *et al.* Pharmacokinetic and pharmacodynamic interaction between allopurinol and probenecid in healthy subjects. *Clin Pharmacokinet* 2008; **47:** 111–18.

Antineoplastics. Allopurinol inhibits the metabolism of *mercaptopurine* and marked dosage reduction of this drug to one-quarter to one-third of the usual dose is required if it is used with allopurinol. There are also reports of interactions between allopurinol and other antineoplastics. Mild chronic allopurinol-induced hepatotoxicity has been reported in a male patient to have been exacerbated by *tamoxifen*.[1] Hypersensitivity vasculitis resulting in the death of a patient receiving allopurinol and *pentostatin* has been described. Although it could not be ascertained whether this effect was due to one of the drugs alone or to an interaction it was believed that this combination should not be used.[2]

For a report of an increased incidence of bone-marrow toxicity in patients given allopurinol with *cyclophosphamide*, see p.703.

1. Shah KA, *et al.* Allopurinol hepatotoxicity potentiated by tamoxifen. *N Y State J Med* 1982; **82;** 1745–6.
2. Steinmetz JC, *et al.* Hypersensitivity vasculitis associated with 2-deoxycoformycin and allopurinol therapy. *Am J Med* 1989; **86:** 499.

Antivirals. For the effect of allopurinol on *didanosine*, see p.871.

Immunosuppressants. Allopurinol inhibits the metabolism of mercaptopurine, the metabolite of *azathioprine*, and marked dosage reduction of azathioprine to one-quarter to one-third of the usual dose is required if it is used with allopurinol. Similar caution is also required with mercaptopurine itself (see Antineoplastics, above). The effects of allopurinol on *ciclosporin* concentrations (a marked increase) are reported on p.1826.

Xanthines. For the effect of allopurinol on the pharmacokinetics of *caffeine* and *theophylline*, see p.1117 and p.1144 respectively.

Pharmacokinetics

Up to 90% of an oral dose of allopurinol is rapidly absorbed from the gastrointestinal tract; its plasma half-life is about 1 to 2 hours. Allopurinol's major metabolite is oxipurinol (alloxanthine), which is also an inhibitor of xanthine oxidase with a plasma half-life of about 15 or more hours in patients with normal renal function, although this is greatly prolonged by renal impairment. Both allopurinol and oxipurinol are conjugated to form their respective ribonucleosides. Allopurinol and oxipurinol are not bound to plasma proteins.

Excretion is mainly through the kidney, but it is slow since oxipurinol undergoes tubular reabsorption. About 70% of a daily dose may be excreted in the urine as oxipurinol and up to 10% as allopurinol; prolonged use may alter these proportions, as allopurinol inhibits its own metabolism. The remainder of the dose is excreted in the faeces. Allopurinol and oxipurinol have also been detected in breast milk.

Uses and Administration

Allopurinol is used to treat hyperuricaemia (p.552) associated with chronic gout, acute uric acid nephropathy, recurrent uric acid stone formation, certain enzyme disorders, or cancer and its treatment (see Tumour Lysis Syndrome, p.639). It is not used for asymptomatic hyperuricaemia. Allopurinol is also used in the management of renal calculi caused by the deposition of calcium oxalate (in the presence of hyperuricosuria) and of 2,8-dihydroxyadenine (see Renal Calculi, below). It may have the potential to reduce oxidative stress by blocking the production of free radicals and is an ingredient of kidney preservation solutions. In addition allopurinol has antiprotozoal activity and has been used in leishmaniasis and American trypanosomiasis.

Allopurinol is used in **gout and hyperuricaemia** to inhibit the enzyme xanthine oxidase, thus preventing the oxidation of hypoxanthine to xanthine and xanthine to uric acid. The urinary purine load, normally almost entirely uric acid, is thereby divided between hypoxanthine, xanthine, and uric acid, each with its independent solubility. This results in the reduction of urate and uric acid concentrations in plasma and urine, ideally to such an extent that deposits of monosodium urate monohydrate or uric acid are dissolved or prevented from forming. At low concentrations allopurinol acts as a competitive inhibitor of xanthine oxidase and at higher concentrations as a non-competitive inhibitor. However, most of its activity is due to the metabolite oxipurinol which is a non-competitive inhibitor of xanthine oxidase.

Allopurinol is used in chronic gout to correct hyperuricaemia, reduce the likelihood of acute attacks, and prevent the sequelae of chronic gout. Initially, it may increase plasma-concentrations of urate and uric acid by dissolving deposits. This can trigger or exacerbate acute attacks, hence allopurinol should not be started until an acute attack has completely subsided, and treatment should be started with a low dose increased gradually; an NSAID (but not aspirin or salicylates) or colchicine should also be given for at least 1 month after hyperuricaemia is corrected, usually 3 months. It may take several months to deplete the uric acid level sufficiently to control acute attacks.

A suggested oral starting dose of allopurinol is 100 mg daily, gradually increased by 100 mg for example at weekly intervals until the concentration of urate in plasma is reduced to 0.36 mmol/litre (6 mg per 100 mL) or less. A daily dose range of 100 to 300 mg may be adequate for those with mild gout and up to 600 mg for those with moderately severe tophaceous gout. The maximum recommended daily dose is 800 mg in the USA and 900 mg in the UK. Up to 300 mg may be taken as a single daily dose; larger amounts should be taken in divided doses to reduce the risk of gastric irritation. Taking allopurinol after food will also minimise gastric irritation. Patients should maintain an adequate fluid intake to prevent renal xanthine deposition.

Doses of allopurinol should be reduced in patients with renal impairment (see below)

When used for the prevention of uric acid nephropathy associated with cancer therapy 600 to 800 mg may be given daily, generally for 2 or 3 days before starting the cancer treatment. A high fluid intake is essential. In hyperuricaemia secondary to cancer or cancer chemotherapy, maintenance doses of allopurinol are similar to those used in gout and are given according to the response.

The main use of allopurinol in children is for hyperuricaemia associated with cancer or cancer chemotherapy or with enzyme disorders. The dosage used may vary: in the UK a dose of 10 to 20 mg/kg daily up to a maximum of 400 mg daily is recommended for children under 15 years of age, while in the USA the dose is 150 mg daily for children under 6 years of age and 300 mg daily for those aged 6 to 10 years, adjusted if necessary after 48 hours.

Allopurinol sodium has been given by intravenous infusion in sodium chloride 0.9% or glucose 5% to patients (usually cancer patients) unable to take allopurinol orally. The recommended dose in adults is the equivalent of allopurinol 200 to 400 mg/m^2 daily up to a maximum of 600 mg daily. Allopurinol sodium 116.2 mg is equivalent to 100 mg of allopurinol.

Administration in renal impairment. Excretion of allopurinol and its active metabolite oxipurinol is primarily via the kidneys and therefore the dosage should be reduced in renal impairment according to creatinine clearance (CC).

In the USA the following doses are suggested for oral and intravenous use:
- CC 10 to 20 mL/minute: 200 mg daily
- CC less than 10 mL/minute: no more than 100 mg daily
- CC less than 3 mL/minute: consider also a longer dosage interval

In the UK a maximum initial oral daily dosage of 100 mg is recommended for those with renal impairment, increased only if the response is inadequate. Doses less than 100 mg daily or 100 mg at intervals longer than 1 day are recommended for those with severe renal insufficiency. Because of the imprecision of low creatinine clearance values, it is suggested that, if facilities are available for monitoring, the allopurinol dose should be adjusted to maintain plasma-oxipurinol concentrations below 100 micromoles/litre (15.2 micrograms/mL). A suggested alternative dose for patients requiring dialysis two or three times weekly is 300 to 400 mg allopurinol immediately after dialysis only.

The difficulties of maintaining an appropriate dose in such patients were illustrated by a study[1] in New Zealand involving 227 allopurinol-treated patients. The guidelines used suggested maintenance doses based on CC as follows:
- less than 10 mL/minute: 100 mg every 3 days
- 10 mL/minute: 100 mg every 2 days
- 20 mL/minute: 100 mg daily
- 40 mL/minute: 150 mg daily
- 60 mL/minute: 200 mg daily

The recommended dose or less was used in the majority of cases (183 of 227). However, of 214 patients for whom serum-uric acid concentrations were available, only 48 achieved values of 0.36 mmol/litre or less. The proportion of patients achieving acceptable serum-uric acid concentrations was higher (38%) in patients given higher than recommended doses than in those on doses recommended by the guidelines (19%). Although guidelines might be useful for initial dosing, longer term use could lead to inadequate control of hyperuricaemia.

Diagnosis and testing. Deficiency of the enzyme ornithine carbamoyltransferase can result in severe CNS dysfunction or even in death, and identification of women at risk of being carriers of this genetic enzyme deficiency has been described.[1] The enzyme deficiency causes carbamoyl phosphate to accumulate, which stimulates the synthesis of orotidine. The test relies on giving a single dose of allopurinol, which will, in carriers, greatly increase the urinary excretion of orotidine. However, mutation analysis is now more usually used to establish the diagnosis.

Epilepsy. Reduction in the frequency of seizures has been described in some patients with severe or intractable epilepsy (p.465) when allopurinol was added to their existing antiepileptic therapy.[1-4] Although the mode of action was not known it was noted that the patients were not hyperuricaemic and that allopurinol did not affect plasma concentrations of existing antiepileptics.[1] However, others[5] have seen no benefit.

Organ and tissue transplantation. Allopurinol 25 mg on alternate days has been added to the immunosuppressive treatment for renal transplantation,[1] and is reported to reduce the frequency of acute rejection. One possible explanation for this effect is allopurinol's ability to suppress the production of free radicals (see Oxidative Stress, below). Organ and tissue transplantation, and the more usual drugs used in immunosuppressive regimens are discussed on p.1810. It should be noted that allopurinol interacts with azathioprine (see Immunosuppressants, under Interactions, above) and ciclosporin (p.1826).

1. Chocair P, *et al.* Low-dose allopurinol plus azathioprine/cyclosporin/prednisolone, a novel immunosuppressive regimen. *Lancet* 1993; **342:** 83–4.

Oxidative stress. Allopurinol, through its inhibition of xanthine oxidase, can block the development of superoxide free radicals during reperfusion after an ischaemic episode. Consequently, the ability of allopurinol to reduce oxidative stress has been investigated in a number of clinical situations.

In a small study[1] of patients with idiopathic dilated cardiomyopathy, short-term intracoronary allopurinol improved myocardial efficiency by decreasing the oxygen demand of left ventricular contraction.

In patients undergoing coronary artery bypass graft surgery, perioperative allopurinol reduced hospital mortality, the incidence of arrhythmias, the number of ischaemic events, and the need for inotropic support, although the findings were not consistent in all studies.[2]

Improved endothelial dysfunction has been found in patients with chronic heart failure given allopurinol.[3,4]

A large study[5] in neonates undergoing cardiac surgery found that allopurinol caused a reduction in seizures and cardiac events in those with hypoplastic left heart syndrome. No benefit was found in neonates with less severe forms of congenital heart disease, considered to be at lower risk of adverse surgical outcome or reperfusion injury. Allopurinol also failed to reduce the incidence of periventricular leucomalacia (thought to represent ischaemic infarction of the developing brain) in preterm infants compared with placebo in a large study.[6] Similarly, allopurinol did not reduce the incidence of infarct extension in patients with acute myocardial infarction.[7]

The possibility that allopurinol limits the production of free radicals has also led to allopurinol sodium being included as an ingredient of the University of Wisconsin solution [UW Solution; Belzer UW Solution (commercially available as *Viaspan*)], which is used for the preservation of organs for transplantation.[8]

A pilot study using allopurinol showed a beneficial effect on free radical formation, cerebral blood volume, and electrical brain activity in severely asphyxiated newborns.[9] However, a systematic review[10] of this and 2 other studies in such infants was unable to determine whether allopurinol produced clinically important benefits.

Prostatitis. Although allopurinol has been reported to be of benefit[1] in a small study in patients with chronic prostatitis (p.2181), a systematic review[2] found no other satisfactory evidence of benefit, and considered that the clinical relevance of the original study results was unclear.

Protozoal infections. Allopurinol has been widely used as an adjunct to pentavalent antimonials in the treatment[1,2] of Old World *visceral leishmaniasis* (p.824), particularly where resistance to antimony alone is likely, although the degree of benefit has been called into question.[3] It has also been used with other drugs such as pentamidine[4] or azole antifungals[5-8], including in transplant patients[7] or those with AIDS,[5] or in whom antimonials were otherwise poorly tolerated.[8] Allopurinol has also been tried alone[9,10] or with other drugs in both Old World[11] and New World[12-14] *cutaneous* or *mucocutaneous leishmaniasis*; results, particularly in the latter, have been variable.

Some beneficial results have been noted[15-17] in indeterminate and chronic Chagas' disease (*American trypanosomiasis*, p.827), although it may be less effective than itraconazole.

The selective antiparasitic action of allopurinol is believed to be due to its incorporation into the protozoal, but not the mammalian, purine salvage pathway. This leads to the formation of 4-aminopyrazolopyrimidine ribonucleotide triphosphate, a highly toxic analogue of adenosine triphosphate, that is incorporated into ribonucleic acid. This action of allopurinol is shared by allopurinol riboside, one of the minor metabolites in man, but not by oxipurinol, the major human metabolite. Thus, some studies have been conducted with allopurinol riboside, rather than allopurinol, in an attempt to enhance activity by avoiding host-mediated inactivation.[18]

Renal calculi. In conjunction with a reduced dietary purine intake, high fluid intake, and potassium citrate, allopurinol may be used to prevent the recurrence of calcium oxalate renal calculi (p.2181) in patients with hyperuricosuria.[1,2] The recommended oral dose of allopurinol is 200 to 300 mg daily adjusted on the basis of subsequent 24-hour urinary urate excretion. Allopurinol is also advocated for the management of 2,8-dihydroxyadenine (2,8-DHA) renal stones associated with deficient activity of the enzyme adenine phosphoribosyltransferase.

Schizophrenia. Involvement of purinergic neurotransmission has been hypothesised to play some role in schizophrenia (p.955), and allopurinol has been investigated as a possible adjunctive treatment, with some evidence of benefit, especially in patients with refractory positive symptoms.[1]

1. Buie LW, *et al.* Allopurinol as adjuvant therapy in poorly responsive or treatment refractory schizophrenia. *Ann Pharmacother* 2006; **40:** 2200–4.

Skin disorders. Reactive perforating collagenosis (RPC) is a condition in which altered collagen is eliminated through the epidermis; it may be inherited or acquired. In 3 of 4 patients with RPC refractory to antibacterials and oral and topical corticosteroids, significant improvement was seen with allopurinol, in terms of reduction of new lesions, improvement of existing lesions, and reduction of pruritus. The fourth patient died from unrelated causes before review.[1]

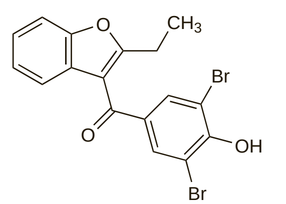
Benzbromarone *(BAN, USAN, rINN)*

Bensbromaron; Bentsbromaroni; Benzbromaron; Benzbromarona; Benzbromaronas; Benzbromaronum; L-2214; MJ-10061. 3,5-Dibromo-4-hydroxyphenyl 2-ethylbenzofuran-3-yl ketone.

Бензбромарон

$C_{17}H_{12}Br_2O_3$ = 424.1.
CAS — 3562-84-3.
ATC — M04AB03.
ATC Vet — QM04AB03.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Benzbromarone). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; freely soluble in acetone and in dichloromethane. Protect from light.

Adverse Effects

Benzbromarone may cause gastrointestinal adverse effects, especially diarrhoea. It may precipitate an acute attack of gout and cause uric acid renal calculi and renal colic. Hepatotoxicity has occurred and monitoring of liver function has been recommended.

Effects on the liver. Benzbromarone-induced liver damage has been reported.[1-4]

1. Van Der Klauw MM, *et al.* Hepatic injury caused by benzbromarone. *J Hepatol* 1994; **20:** 376–9.
2. Anonymous. Benzbromarone and hepatitis. *WHO Drug Inf* 2000; **14:** 29.
3. Wagayama H, *et al.* Fatal fulminant hepatic failure associated with benzbromarone. *J Hepatol* 2000; **32:** 874.
4. Arai M, *et al.* Fulminant hepatic failure associated with benzbromarone treatment: a case report. *J Gastroenterol Hepatol* 2002; **17:** 625–6.

Precautions

Benzbromarone should be avoided in patients with moderate or severe renal impairment, in those with uric acid renal calculi, and in those with urinary uric acid excretion rates of greater than 700 mg per 24 hours. Like other uricosurics, treatment with benzbromarone should not be started during an acute attack of gout. Similarly, an adequate fluid intake should be maintained to reduce the risk of uric acid renal calculi; additionally, alkalinisation of the urine may be considered.

Porphyria. Benzbromarone is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Aspirin and other salicylates antagonise the effect of benzbromarone. Benzbromarone may increase the anticoagulant activity of coumarin oral anticoagulants (see under Interactions of Warfarin, p.1429).

Antigout drugs. For mention of the effects of benzbromarone on the clearance of oxipurinol, the major active metabolite of *allopurinol*, and the view that this was not clinically significant, see under Interactions of Allopurinol, p.553.

Pharmacokinetics

Benzbromarone is only partially absorbed from the gastrointestinal tract, reaching peak plasma concentrations about 2 to 4 hours after an oral dose. Benzbromarone is extensively bound to plasma proteins. It is metabolised in the liver, and is excreted mainly in the faeces; a small amount appears in the urine.

2. Walter-Sack I, *et al.* Variation of benzbromarone elimination in man—a population study. *Eur J Clin Pharmacol* 1990; **39:** 173–6.

Uses and Administration

Benzbromarone is a uricosuric drug that reduces plasma concentrations of uric acid by blocking renal tubular reabsorption. It has been suggested that benzbromarone may also increase the intestinal elimination of uric acid. It has been used to treat hyperuricaemia including that associated with chronic gout (p.552) although it has been withdrawn in many countries due to reports of hepatotoxicity.

Benzbromarone is not used to treat acute attacks of gout and may exacerbate and prolong them if given during an attack; treatment should not start therefore until an acute attack has subsided.

The usual oral dose has been 50 to 200 mg daily. An NSAID or colchicine should be given initially to reduce the risk of precipitating acute gout. An adequate fluid intake should be maintained. Lower doses of benzbromarone (20 mg) have also been used in the form of a combination product with allopurinol.

Colchicine

Colchicina; Colchicinum; Kolchicin; Kolchicinas; Kolkicin; Kolkisiini; Kolşisin. (*S*)-*N*-(5,6,7,9-Tetrahydro-1,2,3,10-tetramethoxy-9-oxobenzo[α]heptalen-7-yl)acetamide.

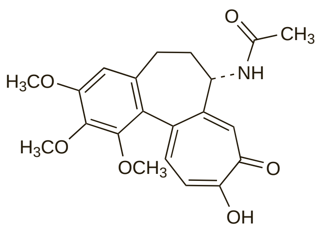
Колхицин

$C_{22}H_{25}NO_6$ = 399.4.

CAS — 64-86-8.

ATC — M04AC01.

ATC Vet — QM04AC01.



Description. Colchicine is an alkaloid obtained from various *Colchicum* spp.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*
Chin. also has a monograph for colchicine amide.

Ph. Eur. 6.2 (Colchicine). A yellowish-white amorphous or crystalline powder. Very soluble in water, rapidly recrystallising from concentrated solutions as the sesquihydrate; freely soluble in alcohol and in chloroform. Protect from light.

USP 31 (Colchicine). An alkaloid obtained from various *Colchicum* spp. and other genera. Pale yellow to pale greenish-yellow amorphous scales, or powder or crystalline powder. Is odourless or nearly so, and darkens on exposure to light. Soluble 1 in 25 of water and 1 in 220 of ether; freely soluble in alcohol and in chloroform. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

The most frequent adverse effects of oral colchicine are those involving the gastrointestinal tract and may be associated with its antimitotic action. Diarrhoea, nausea, vomiting, and abdominal pain are often the first signs of toxicity and are usually an indication that colchicine therapy should be stopped or the dose reduced. Larger doses may cause profuse diarrhoea, gastrointestinal haemorrhage, skin rashes, and renal and hepatic damage.

Rarely, bone marrow depression with agranulocytosis, thrombocytopenia, and aplastic anaemia have occurred on prolonged treatment as have peripheral neuropathy, myopathy, rashes, and alopecia.

Adverse effects after intravenous use include cardiac arrhythmias and local reactions such as thrombophlebitis and neuritis. Extravasation may cause tissue necrosis.

Symptoms of acute **overdosage** with oral colchicine often do not appear for 2 to 12 hours. The first signs of toxicity are nausea, vomiting, and diarrhoea; a burning sensation of the throat, stomach, and skin may also occur. The diarrhoea may be severe and haemorrhagic and, coupled with vascular damage or paralytic ileus can lead to dehydration, hypotension, and shock. Multiple organ failure may occur, manifest as CNS toxicity (confusion, delirium, sometimes coma), bone marrow depression, hepatocellular damage, muscle damage, neuropathy, respiratory distress, myocardial depression, and renal damage. A toxic epidermal necrolysis-like reaction has also been reported. Death may be due to respiratory depression, cardiovascular collapse, or sepsis after pancytopenia. In surviving patients, alopecia, rebound leucocytosis, and stomatitis may occur about 10 days after the acute overdose. The lethal dose varies: 7 mg of colchicine has caused death, yet recovery has occurred after much larger doses.

When treating colchicine overdosage or acute poisoning patients should be carefully monitored for some time to take account of the delayed onset of symptoms. The stomach may be emptied by lavage in adults within 1 hour of acute poisoning; multiple dose activated charcoal should be given to adults and children who have ingested more than 300 micrograms/kg of colchicine provided vomiting has not started. Treatment is primarily symptomatic and supportive with attention being given to the control of respiration, maintenance of blood pressure and the circulation, and correction of fluid and electrolyte imbalance.

Effects on the neuromuscular system. Colchicine-induced myoneuropathy may be a common but unrecognised condition in patients with *reduced* renal function who receive usual doses of colchicine.[1] Although both skeletal muscles and peripheral nerves are affected, myopathy is most prominent and associated axonal neuropathy is mild. The condition usually presents with proximal muscle weakness and is always accompanied by elevations in serum creatine kinase concentrations. Withdrawal of colchicine leads to spontaneous remission of these symptoms within a few weeks but resolution of the polyneuropathy is slow. Examination of proximal muscles shows marked abnormal spontaneous activity and, because of the features of the condition, it is often initially misdiagnosed as probable polymyositis or uraemic myopathy. A literature review[2] identified renal impairment as the primary risk factor for the development of colchicine-induced myopathy; dosage adjustment is advised in these patients.

There have been reports suggesting colchicine-induced myopathy may develop in patients who have *normal* renal function.

A patient with normal renal function but chronic alcohol-induced liver disease developed an unusual form of myoneuropathy after receiving only a short course of colchicine. This patient was also taking tolbutamide, the microsomal enzyme-inhibiting activity of which may have exacerbated the toxicity of colchicine.[3] A teenager with familial Mediterranean fever who had normal renal and hepatic function developed toxic myopathy due to colchicine use. Myopathy improved after colchicine was stopped and recurred when it was restarted at a lower dose.[4]

Rhabdomyolysis has also been reported.[5,6]

Effects on the reproductive system. UK licensing information states that colchicine may adversely affect spermatogenesis under certain conditions of therapy. *Animal* data has shown that colchicine in high doses may arrest spermatogenesis and lead to azoospermia. However, in clinical practice male infertility does not seem to be common in patients given colchicine, and may be related in some cases to the underlying disease rather than the drug.[1] Similarly, although colchicine is not recommended in the first trimester of pregnancy, it may improve fertility in women with familial Mediterranean fever, and results in women who have been taking colchicine at conception and during pregnancy have been relatively reassuring[1] (see also under Pregnancy, below).

1. Mijatovic V, *et al.* Familial Mediterranean fever and its implications for fertility and pregnancy. *Eur J Obstet Gynecol Reprod Biol* 2003; **108:** 171–6.

Inappropriate administration. Intravenous use of colchicine is associated with a risk of severe or fatal adverse effects (see Administration, below). Although unlicensed either orally or parenterally for use in back pain, intravenous colchicine has apparently been used in alternative medicine for this indication. As of February 2008, the FDA had received reports of 50 adverse events, including 23 deaths, associated with the unapproved use of intravenous colchicine. Three of the reported deaths were associated with compounded colchicine that, due to preparation errors, was 8 times more potent than the amount stated on the label. Potentially fatal effects include neutropenia, thrombocytopenia, pancytopenia, acute renal failure, and congestive heart failure.[1,2]

Precautions

Colchicine should be given with great care to elderly or debilitated patients who may be particularly susceptible to cumulative toxicity. It should also be used with caution in patients with cardiac, hepatic, renal, or gastrointestinal disease. Colchicine should be avoided in patients with blood disorders. It should also generally be avoided in pregnancy since it is known to be teratogenic in *animals* and there have also been some suggestions of a risk of fetal chromosome damage in humans.

Colchicine should not be given by subcutaneous or intramuscular injection as it causes severe local irritation.

Breast feeding. Colchicine is distributed into breast milk,[1-3] and some have recommended waiting for 8 hours[2] or 12 hours[3] after a dose before breast feeding to minimise exposure of the infant. However, since no adverse effects on the infant have been noted in these reports, the American Academy of Pediatrics considered its use to be usually compatible with breast feeding.[4]

Pregnancy. Colchicine is contra-indicated in pregnancy because of *animal* teratogenicity. However, it has been used during pregnancy in women with familial Mediterranean fever (see under Uses, below). There was no increase in abnormality rate of the newborns and no problems were detected in 130 offspring.[1]

1. Rabinovitch O, *et al.* Colchicine treatment in conception and pregnancy: two hundred thirty-one pregnancies in patients with familial Mediterranean fever. *Am J Reprod Immunol* 1992; **28:** 245–6.

Interactions

Use of colchicine with clarithromycin, erythromycin, or tolbutamide may cause colchicine toxicity. Thiazide diuretics may increase serum uric acid and interfere with the activity of colchicine. Muscle disorders have been reported when colchicine is used with ciclosporin. Colchicine may impair the absorption of vitamin B_{12}.

Cardiovascular drugs. Acute myopathy has been reported in patients with chronic renal impairment given colchicine with *simvastatin*.[1,2] Similar effects have been seen in patients with renal impairment given colchicine with *fluvastatin*[3], or *pravastatin*.[4] Since many statins are metabolised by the cytochrome P450 isoenzyme CYP3A4, as is colchicine, this has been proposed as one possible mechanism.[3,4] However, fluvastatin and pravastatin are cleared through different isoenzymes. Alternative proposed mechanisms are synergistic myopathy[2,3] or interference with transport mediated by P-glycoprotein.[4] Tetraparesis developed in a patient who took colchicine with *verapamil*; this was considered to be due to a pharmacokinetic interaction which increased serum and CSF concentrations of colchicine.[5]

Ciclosporin. There is a need for caution if colchicine is used with ciclosporin. Myopathies or rhabdomyolysis[1] may be a problem, especially in transplant patients[2] or those with renal impairment.[3] In addition, increased blood-ciclosporin concentrations and nephrotoxicity developed in a renal transplant patient after the introduction of colchicine therapy.[4]

4. Menta R, *et al.* Reversible acute cyclosporin nephrotoxicity induced by colchicine administration. *Nephrol Dial Transplant* 1987; **2:** 380–1.

Macrolides. Life-threatening colchicine toxicity has been described after use for 2 weeks with *erythromycin* in a patient with hepatic and renal impairment.[1] In a patient with end-stage renal disease, but no hepatic impairment, fatal colchicine toxicity developed after 4 days of *clarithromycin* therapy.[2] A patient with moderate chronic renal impairment developed acute but non-fatal colchicine intoxication on day 4 of a 7-day *Helicobacter pylori* treatment course containing clarithromycin.[3] A retrospective study in 116 patients given both drugs concluded that clarithromycin increased the risk of colchicine toxicity, especially in those patients with renal impairment, and that the two drugs should not be used together.[4]

4. Hung IFN, *et al.* Fatal interaction between clarithromycin and colchicine in patients with renal insufficiency: a retrospective study. *Clin Infect Dis* 2005; **41:** 291–300.

Tolbutamide. For a suggestion that tolbutamide may have exacerbated the toxicity of colchicine in a patient with liver disease, see under Effects on the Neuromuscular System, above.

Pharmacokinetics

Peak plasma concentrations of colchicine are reached within 2 hours of oral use. Colchicine is partially deacetylated in the liver and the unchanged drug and its metabolites are excreted in the bile and undergo intestinal reabsorption. Colchicine is found in high concentrations in leucocytes, kidneys, the liver, and spleen. Most of the drug is excreted in the faeces but 10 to 20% is excreted in the urine and this proportion rises in patients with liver disorders. Colchicine is distributed into breast milk.

Uses and Administration

Colchicine is used for the relief of acute gout (p.552) and for the prophylaxis of acute attacks, particularly during the first few months of treatment with allopurinol or uricosurics. Colchicine produces a dramatic response in acute gout, probably by reducing the inflammatory reaction to urate crystals; this effect might be due to several actions including decreased leucocyte mobility. It is not an analgesic and has no effect on blood concentrations of uric acid, or on the excretion of uric acid. Colchicine also has an antimitotic action.

Colchicine has also been used in several other conditions including amyloidosis, Behçet's syndrome, familial Mediterranean fever, idiopathic thrombocytopenic purpura, pericarditis, primary biliary cirrhosis, and pyoderma gangrenosum.

If colchicine is used for acute attacks of **gout**, then treatment should be started as soon as possible and an effect may be expected within 12 hours. The recommended oral dose in the UK is 1 mg initially, then 500 micrograms every 2 to 3 hours until pain relief is obtained or gastrointestinal adverse effects occur (but see also Administration, below). Although some licensed products allow doses up to a maximum of 10 mg, the *BNF* considers that the total dose should not exceed 6 mg. At least 3 days should elapse before another course is given. In the USA the oral dose is 1 to 1.2 mg initially; this may be repeated every 2 hours, or 500 or 600 micrograms may be taken every hour (or even every 2 or 3 hours if sufficient), until pain is relieved or gastrointestinal adverse effects occur. The maximum total dose for an acute attack should not exceed 8 mg.

Colchicine has sometimes been given intravenously in a dose of 1 or 2 mg over 2 to 5 minutes with additional doses of 0.5 or 1 mg every 6 hours as required to a total dose of not more than 4 mg in 24 hours; once this amount of colchicine has been given further doses should not then be given by any route for at least 7 days. For the view that the intravenous route should be avoided, see Administration, below.

When used for the prophylaxis of gout oral doses are 500 or 600 micrograms once daily; some patients may require doses up to 1.8 mg daily.

Consideration should be given to using reduced dosages in patients with renal impairment, see below.

Administration. Although colchicine 1 mg orally, followed by 500 micrograms every 2 to 3 hours, is recommended in the UK for the treatment of acute gout, many rheumatologists consider this excessive; a low-dose regimen of 500 micrograms no more than 3 times daily has been advocated in preference.[1] It has also been suggested that intravenous colchicine, although undoubtedly effective, should not be used because of the risk of severe or fatal adverse effects.[2] For reports of fatalities with intravenous colchicine during unlicensed use, see Inappropriate Administration, above.

2. Morris I, *et al.* Colchicine in acute gout. *BMJ* 2004; **328:** 289.

Administration in renal impairment. Some licensed product information in the UK recommends that the dose of colchicine given *orally* should be reduced by up to 50% in patients with mild to moderate renal impairment, and that it should not be used in those with severe impairment. Similar recommendations have been made by various sources in the USA; for example, the *American Hospital Formulary Service* notes that some recommend the prophylactic oral dose should not exceed 600 micrograms daily in patients with a serum creatinine of 1.6 mg per 100 mL or greater, or with a creatinine clearance (CC) of 50 mL/minute or less. Some patients may only need 600 micrograms every alternate day. The *intravenous* dose should be reduced by 50% in patients with a CC of between 10 and 50 mL/minute, and it is contra-indicated in those patients with a CC less than 10 mL/minute.

Amyloidosis. Colchicine is well known to have a useful role in amyloidosis (p.743) secondary to familial Mediterranean fever, where results have suggested the possibility of reversing nephropathic changes due to renal amyloid deposition (see below). However, combination therapy with melphalan and prednisone was found to be more effective than colchicine alone in primary amyloidosis,[1] and a later study[2] found no benefit in adding colchicine to the standard therapy. The mechanism of the anti-amyloid effect of colchicine is not clear.

1. Skinner M, *et al.* Treatment of 100 patients with primary amyloidosis: a randomised trial of melphalan, prednisone, and colchicine versus colchicine only. *Am J Med* 1996; **100:** 290–8.

Behçet's syndrome. Behçet's syndrome (p.1499) has been treated with numerous drugs. Where possible, topical treatment of local lesions should be tried before starting systemic therapy. Corticosteroids are favoured for systemic treatment in many countries, but colchicine has also been widely used. Beneficial responses have been described for most of the symptoms including the arthritic, ocular, and cutaneous manifestations, although a systematic review has questioned colchicine's efficacy.[1] The mechanism of action in this condition is believed to be based on the effect on polymorphonuclear leucocytes and other cellular effects.[2] Colchicine has also been used with corticosteroids for acute exacerbations, followed by colchicine maintenance;[3] colchicine with aspirin has also been recommended in acute disease,[4] and colchicine with benzathine benzylpenicillin has been tried.[5]

Diffuse parenchymal lung disease. Colchicine is a potential alternative to corticosteroid therapy in patients with cryptogenic fibrosing alveolitis (see Diffuse Parenchymal Lung Disease, p.1502). However the degree of benefit, if any, is unclear although colchicine does appear to be safer and better tolerated than corticosteroid therapy.[1]

1. Davies HR, *et al.* Immunomodulatory agents for idiopathic pulmonary fibrosis. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2003 (accessed 27/04/05).

Familial Mediterranean fever. Familial Mediterranean fever (recurrent or paroxysmal polyserositis; periodic disease) is an inherited disorder that primarily affects Sephardic Jews or persons of Arab, Armenian, or Turkish ancestry.[1,2] It is characterised by attacks of acute abdominal pain, fever, and signs of peritonitis, which resolve spontaneously, usually in 24 to 48 hours. Pleuritic chest pain, arthritis, skin rash, pericarditis, and headache may occur. The most dangerous complication, however, is type AA amyloidosis (see also p.743), which can lead to nephrotic syndrome, renal failure, and death.

Familial Mediterranean fever is managed with colchicine.[1-3] Colchicine cannot stop an established attack, but, given prophylactically in oral adult doses of 1 to 3 mg daily, it reduces the frequency of attacks, prevents amyloidosis and reverses proteinuria. An initial daily dose of 500 micrograms or less has been suggested for children younger than 5 years of age, 1 mg for those aged 5 to 10 years, and 1.5 mg for children aged over 10 years; doses may be increased in a stepwise fashion to a maximum of 2 mg daily if needed.[3] Attacks are usually treated with NSAIDs[2,3] or, in severe cases, opioids.[3] Anecdotal evidence has suggested that prazosin may also be of benefit,[4] but initial reports of improvement with interferon alfa have not been borne out.[2] Anakinra has also been investigated.[5]

Idiopathic thrombocytopenic purpura. In idiopathic thrombocytopenic purpura (p.1505), refractory to standard therapy, a few patients have had partial or complete response to colchicine[1,2] and further studies have been suggested.[2,3]

3. McMillian R. Therapy for adults with refractory chronic immune thrombocytopenic purpura. *Ann Intern Med* 1997; **126:** 307–14.

Pericarditis. Mild cases of recurrent pericarditis may be treated with colchicine, as an adjunct to NSAID therapy.[1-3] It may also provide effective prophylaxis, allowing the tapering of corticosteroids, which are usually reserved for the treatment of severe acute attacks.[2,3] The drug has also been used successfully in children.[4] In an open-label study, colchicine added to conventional therapy with aspirin or prednisone significantly decreased the recurrence rate in patients with a first episode of recurrent pericarditis, compared with conventional therapy alone.[5] Another open-label study had similar results using adjunctive colchicine for the first episode of acute pericarditis.[6] In patients with two or more relapses of acute pericarditis, colchicine was found to be highly effective in preventing recurrence.[7] The proportion of patients with relapses during or after colchicine therapy was significantly higher, and the duration of colchicine therapy significantly longer, in those who had pre-treatment with corticosteroids.

7. Artom G, *et al.* Pretreatment with corticosteroids attenuates the efficacy of colchicine in preventing recurrent pericarditis: a multi-centre all-case analysis. *Eur Heart J* 2005; **26:** 723–7.

Peyronie's disease. Beneficial effects have been reported with colchicine in men with Peyronie's disease. Small studies show colchicine to be most effective in reducing pain during penile erection.[1] A combination of vitamin E and colchicine has also been suggested as an alternative in early disease.[2]

1. Kadioğlu A, *et al.* Treatment of Peyronie's disease with oral colchicine: long-term results and predictive parameters of successful outcome. *Int J Impot Res* 2000; **12:** 169–75.
2. Prieto Castro RM, *et al.* Combined treatment with vitamin E and colchicine in the early stages of Peyronie's disease. *BJU Int* 2003; **91:** 522–4.

Primary biliary cirrhosis. Primary biliary cirrhosis (p.2408) is a chronic progressive liver disease with no specific treatment, and in general drug therapy has been poor or largely ineffective. Reviewers have noted[1-3] that several studies have been conducted with colchicine, and, although biochemical parameters were improved, a beneficial effect on clinical symptoms or liver histology was not found. A comparative study of colchicine and methotrexate showed that while both drugs improved biochemical test results and symptoms, the response to methotrexate was greater.[4] Some consider that combination therapy with colchicine, methotrexate, and ursodeoxycholic acid may be more promising than monotherapy.[2]

Pyoderma gangrenosum. Pyoderma gangrenosum (p.1583) associated with inflammatory bowel disease has been successfully treated with colchicine in 2 patients.[1,2] Colchicine was also of benefit in 3 patients with pyoderma associated with familial Mediterranean fever.[3] Other isolated reports include the use of low-dose colchicine in idiopathic pyoderma gangrenosum.[4]

Colchicum

Colchico; Colchique.

Безвременник

Profile

Colchicum, the dried ripe seeds or dried corm of the meadow saffron, *Colchicum autumnale*, contains colchicine (p.556) and has been used similarly for the prophylaxis and relief of acute gout.

It is also included in several herbal preparations.

Homoeopathy. Colchicum has been used in homoeopathic medicines under the following names: Colchicinum; Colchicum autumnale; Colchicum, tuber; Colch. at.

Poisoning. *Colchicum autumnale* is quite similar to a species of garlic *Allium ursinum*, especially in leaf appearance, and both plants grow in the same areas at the same time of year. There are reports of colchicine poisoning, some of them fatal, after accidental ingestion of *C. autumnale*.[1-6] Colchicine poisoning should be considered in patients with gastroenterocolitis after a wild plant meal.

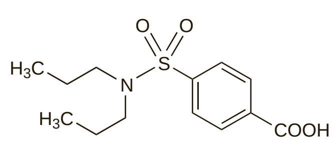
Probenecid *(BAN, rINN)* ⊗

Probenecidas; Probénécide; Probenecidum; Probenesid; Probenesidi. 4-(Dipropylsulphamoyl)benzoic acid.

Пробенецид

$C_{13}H_{19}NO_4S$ = 285.4.
CAS — 57-66-9.
ATC — M04AB01.
ATC Vet — QM04AB01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Probenecid). A white or almost white crystalline powder or small crystals. Practically insoluble in water; sparingly soluble in dehydrated alcohol; soluble in acetone.

USP 31 (Probenecid). A white or practically white, fine, practically odourless, crystalline powder. Practically insoluble in water and in dilute acids; soluble in alcohol, in acetone, in chloroform, and in dilute alkali.

Adverse Effects and Treatment

Probenecid may cause nausea, vomiting, anorexia, headache, sore gums, flushing, alopecia, dizziness, anaemia, and urinary frequency. Hypersensitivity reactions, with fever, dermatitis, pruritus, urticaria, and, rarely, anaphylaxis, and Stevens-Johnson syndrome have occurred. There have been reports of leucopenia, hepatic necrosis, nephrotic syndrome, and aplastic anaemia. Haemolytic anaemia has also occurred, and may be associated with G6PD deficiency.

When used in chronic gout, and particularly during the first few months of therapy, probenecid may precipitate acute attacks. Uric acid renal calculi, with or without haematuria, costovertebral pain and renal colic may occur.

In massive overdosage probenecid causes stimulation of the CNS, with convulsions and death from respiratory failure. Severe overdosage should be managed by lavage and symptomatic treatment.

Precautions

Probenecid therapy should not be started during an acute attack of gout; however treatment is usually continued when acute attacks occur in patients already receiving the drug, and the acute attack is treated separately. Probenecid is also unsuitable for the control of hyperuricaemia secondary to cancer or cancer chemotherapy. Probenecid should not be given to patients with a history of uric acid renal calculi or blood disorders. It should be used with caution in patients with a history of peptic ulceration. Probenecid should not be used as an antibacterial adjunct in patients with known renal impairment, and it is ineffective in gout in patients with severe renal impairment.

To reduce the risk of uric acid renal calculi in patients with gout an adequate fluid intake (2 to 3 litres daily) is required, and, if necessary, especially during the first few months of treatment, sodium bicarbonate or potassium citrate may be given to render the urine alkaline.

A reducing substance has been found in the urine of some patients taking probenecid, and may give false positive results with some tests for glucose in the urine. Probenecid reduces the excretion of some iodinated contrast media and may interfere with laboratory tests by decreasing the excretion of aminohippuric acid, phenolsulfonphthalein, and sulfobromophthalein.

Abuse. It has been alleged that some athletes using banned anabolic steroids have taken probenecid in an attempt to inhibit the urinary excretion of steroid metabolites in order to avoid detection by urine screening tests.[1]

1. Anonymous. Does probenecid mask steroid use? *Pharm J* 1987; **239:** 299.

Porphyria. Probenecid is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Interactions

The dose of probenecid may need to be increased if patients are also given drugs, such as diuretics or pyrazinamide, that increase the blood concentration of uric acid. Salicylates, including aspirin, and probenecid are mutually antagonistic and should not be given together.

Probenecid may also affect many other drugs. By inhibiting renal tubular secretion, it has the potential to increase the toxicity and/or to enhance the therapeutic efficacy of drugs excreted by that route. In some instances a reduction in dose is essential to counteract an increase in toxicity, as is the case with methotrexate. Some combinations, such as that with ketorolac, should be avoided. Conversely, probenecid may be given with some antibacterials such as the penicillins and cephalosporins to increase their effects.

Altered excretion may also increase serum concentrations of other antibacterials (aminosalicylic acid, conjugated sulfonamides, dapsone, meropenem, some quinolones, rifampicin), some antivirals (aciclovir, ganciclovir, zalcitabine, zidovudine, and possibly famciclovir), some benzodiazepines (adinazolam, lorazepam, and nitrazepam), some ACE inhibitors (captopril and enalapril), some NSAIDs (diflunisal, indometacin, ketoprofen, meclofenamate, naproxen), paracetamol, and sulfonylurea hypoglycaemic drugs. The clinical significance of such interactions is not entirely clear although the possibility of the need for a reduction in dosage of these drugs should be borne in mind.

It has been reported that patients receiving probenecid require lower doses of thiopental for induction of anaesthesia. Probenecid may increase the speed of induction of anaesthesia with midazolam.

Reducing the urinary concentration of some drugs could diminish their activity in certain diseases as might happen with nitrofurantoin or some quinolones in urinary-tract infections and penicillamine in cystinuria.

Allopurinol. Probenecid may increase the clearance of allopurinol despite an increased hypouricaemic effect when these 2 drugs are given together (see Antigout Drugs, under Allopurinol, p.553).

Pharmacokinetics

Probenecid is completely absorbed from the gastrointestinal tract with peak plasma concentrations achieved 2 to 4 hours after a dose. It is extensively bound to plasma proteins (85 to 95%). The plasma half-life is dose-dependent and ranges from less than 5 to more than 8 hours. Probenecid crosses the placenta. It is metabolised by the liver, and excreted in the urine mainly as metabolites. Excretion of unchanged probenecid is increased in alkaline urine.

Uses and Administration

Probenecid is a uricosuric drug used to treat hyperuricaemia (p.552) associated with chronic gout; it has also been used to treat hyperuricaemia caused by diuretic therapy. It is also used as an adjunct to some antibacterials to reduce their renal tubular excretion and is given with the antiviral cidofovir to reduce nephrotoxicity.

Probenecid is used in **chronic gout and hyperuricaemia** to inhibit the renal tubular reabsorption of uric acid so increasing the urinary excretion of uric acid, lowering plasma-urate concentrations, and eventually reducing urate deposits in the tissues. Probenecid is therefore of value in hyperuricaemia caused by decreased uric acid excretion rather than increased urate production, and is not used for hyperuricaemia associated with cancer or cancer therapy.

Probenecid has no analgesic or anti-inflammatory action and is of no value in acute gout. Initially it may increase plasma concentrations of urate and uric acid by dissolving deposits. This can trigger or exacerbate acute attacks, hence probenecid should not be started until an acute attack has completely subsided, and an NSAID or colchicine may be given during the first few months.

It is usual to start treatment for gout with oral doses of 250 mg twice daily increased after a week to 500 mg twice daily and later, if the therapeutic effects are inadequate, by increments of 500 mg every 4 weeks, up to 2 g daily. Probenecid may not be effective in chronic renal impairment particularly when the glomerular filtration rate is less than 30 mL/minute. An adequate fluid intake is required to reduce the risk of uric acid renal calculi.

When the patient has been free from acute attacks for at least 6 months, and provided that the plasma-urate concentration is within acceptable limits, the daily dose may be gradually reduced, by 500 mg every 6 months, to the lowest effective maintenance dose which is then given indefinitely.

Probenecid may also be used as an **adjunct to antibacterial therapy** particularly when treating severe or resistant infections. It reduces the tubular excretion of penicillins and most cephalosporins and may increase their plasma concentrations up to fourfold. The usual dosage for reducing tubular excretion of penicillins and cephalosporins is 500 mg four times daily, or less in elderly patients with suspected renal impairment. When renal impairment is sufficient to retard the excretion of antibacterials, probenecid should not be given.

The dosage for children over 2 years of age and weighing less than 50 kg is 25 mg/kg (700 mg/m^2) initially, followed by 10 mg/kg (300 mg/m^2) every 6 hours.

Single oral doses of probenecid 1 g are given with a suitable oral antibacterial, or at least 30 minutes before an injected antibacterial, in the single-dose treatment of gonorrhoea (p.191).

Doses of probenecid to be used with cidofovir are given on p.868.

Sulfinpyrazone *(BAN, rINN)*

G-28315; Sulfinpirazona; Sulfinpirazonas; Sulfinpyratsoni; Sulfinpyrazon; Sulfinpyrazonum; Sulphinpyrazone; Sulphoxyphenylpyrazolidine; Szulfinpirazon. 1,2-Diphenyl-4-(2-phenylsulphinylethyl)pyrazolidine-3,5-dione.

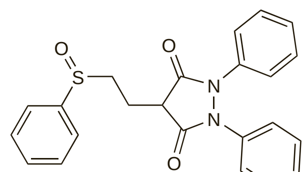
Сульфинпиразон

$C_{23}H_{20}N_2O_3S$ = 404.5.

CAS — 57-96-5.

ATC — M04AB02.

ATC Vet — QM04AB02.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US*.

Ph. Eur. 6.2 (Sulfinpyrazone). A white or almost white powder. Very slightly soluble in water; sparingly soluble in alcohol; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Sulfinpyrazone). A white to off-white powder. Practically insoluble in water and in petroleum spirit; soluble in alcohol and in acetone; sparingly soluble in dilute alkali.

Adverse Effects and Treatment

The most frequent adverse effects of sulfinpyrazone involve the gastrointestinal tract, and include nausea, vomiting, diarrhoea and abdominal pain. It may cause gastric bleeding or aggravate existing peptic ulcers. Skin rashes have been reported, and may be associated with a hypersensitivity reaction. Aplastic anaemia, agranulocytosis, leucopenia, and thrombocytopenia have been reported rarely as have raised liver enzyme values, jaundice, and hepatitis, renal impairment, salt and water retention, and acute renal failure.

When used in chronic gout, particularly during the first few months of treatment, sulfinpyrazone may precipitate acute attacks and there is a risk of uric acid renal calculi developing.

Symptoms of overdosage include hypotension, acute renal failure, arrhythmias, respiratory disorders, convulsions, and coma, as well as gastrointestinal effects. Treatment of overdose may involve activated charcoal if a substantial amount has been ingested within 1 hour of presentation, followed by symptomatic and supportive therapy.

Effects on the kidneys. Although renal failure has been reported occasionally in patients receiving sulfinpyrazone for gout[1] many of the cases have occurred in those given the drug for myocardial infarction.[2,3] Acute renal failure may also occur after overdose or in patients with intravascular volume depletion.[4,5]

2. Boelaert J, *et al.* Sulphinpyrazone-induced decrease in renal function: a review of reports with discussion of pathogenesis. *Acta Clin Belg* 1982; **37:** 368–75.
3. Lijnen P, *et al.* Decrease in renal function due to sulphinpyrazone treatment early after myocardial infarction. *Clin Nephrol* 1983; **19:** 143–6.
4. Florkowski CM, *et al.* Acute non-oliguric renal failure secondary to sulphinpyrazone overdose. *J Clin Pharm Ther* 1992; **17:** 71.
5. Walls M, *et al.* Acute renal failure due to sulfinpyrazone. *Am J Med Sci* 1998; **315:** 319–21.

Precautions

Sulfinpyrazone should not be started during an acute attack of gout; however, treatment is usually continued when acute attacks occur in patients already receiving the drug, and the acute attack is treated separately. Sulfinpyrazone is not suitable for the control of hyperuricaemia associated with cancer or cancer chemotherapy.

Sulfinpyrazone should be given with care to patients with renal impairment or heart failure and is contra-indicated in those with severe renal or hepatic impairment. It is also contra-indicated in patients with blood dyscrasias or blood coagulation disorders, and in patients with uric acid renal calculi or peptic ulcer disease or a history of such disorders.

Sulfinpyrazone should not be given to patients hypersensitive to it or to other pyrazole derivatives such as phenylbutazone; nor should it be given to patients in whom hypersensitivity reactions (including bronchospastic reactions in asthmatics) have been provoked by aspirin or by other drugs with prostaglandin-synthetase inhibiting activity.

To reduce the risk of uric acid renal calculi an adequate fluid intake (2 to 3 litres daily) is required; alkalinising the urine with sodium bicarbonate or potassium citrate may also be considered. It is recommended that patients have periodic full blood counts to detect any haematological abnormalities.

Renal-function tests involving aminohippuric acid or phenolsulfonphthalein may be invalidated.

Porphyria. Sulfinpyrazone is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

Doses of sulfinpyrazone may need to be increased if it is given with other drugs, such as diuretics or pyrazinamide, that increase uric acid concentrations. Sulfinpyrazone and salicylates including aspirin are mutually antagonistic and should not be used together. There may also be an increased risk of bleeding when sulfinpyrazone is used with other drugs such as aspirin that inhibit platelet function.

Sulfinpyrazone's renal tubular secretion is inhibited by probenecid although with little clinical effect. Since sulfinpyrazone, like probenecid, inhibits the tubular secretion of weak organic acids, interactions can be expected with penicillins although the effect is not considered to be clinically useful.

Sulfinpyrazone can potentiate the action of some drugs. The most significant interaction of this type involves warfarin, acenocoumarol, and possibly other coumarin anticoagulants (p.1429). Patients receiving sulfinpyrazone and such an anticoagulant should have their prothrombin times monitored and the anticoagulant dosage reduced as appropriate. Similarly, sulfinpyrazone may potentiate the effects of phenytoin (see Antigout Drugs, p.499), and possibly some sulfonamides and sulfonylureas.

In contrast, sulfinpyrazone may increase the metabolism of theophylline (p.1144) and diminish its activity.

Pharmacokinetics

Sulfinpyrazone is readily absorbed from the gastrointestinal tract. It is about 98% bound to plasma proteins and has a plasma half-life of about 2 to 4 hours. Sulfinpyrazone is partly metabolised in the liver and some of the metabolites are active. On long-term therapy, sulfinpyrazone induces its own metabolism. Unchanged drug and metabolites are mainly excreted in the urine.

2. Schlicht F, *et al.* Pharmacokinetics of sulphinpyrazone and its major metabolites after a single dose and during chronic treatment. *Eur J Clin Pharmacol* 1985; **28:** 97–103.

Uses and Administration

Sulfinpyrazone is a uricosuric drug used to treat hyperuricaemia associated with chronic gout (p.552). It also has some antiplatelet activity.

Sulfinpyrazone is used in chronic gout to inhibit the renal tubular reabsorption of uric acid so increasing the urinary excretion of uric acid, lowering plasma-urate concentrations, and eventually reducing urate deposits in the tissues. It is therefore of value in hyperuricaemia caused by decreased uric acid excretion rather than increased urate production and is not used for hyperuricaemia associated with cancer or cancer therapy.

Sulfinpyrazone has little analgesic or anti-inflammatory action and is of no value in acute gout. Initially, it may increase plasma concentrations of urate and uric acid by dissolving deposits. This can trigger or exacerbate acute attacks, hence sulfinpyrazone should not be given until an acute attack has completely subsided, and an NSAID or colchicine may be given during the first few months.

The initial oral dose of sulfinpyrazone in the UK is 100 to 200 mg daily (the USA allows up to 200 mg twice daily), taken with meals or milk. This may be gradually increased over 1 to 3 weeks until a daily dosage of 600 mg is reached; up to 800 mg daily may be given if necessary. After the plasma-urate concentration has been controlled, the daily maintenance dose may be reduced to as low as 200 mg. An adequate fluid intake is required to prevent formation of uric acid renal calculi.

Antiplatelet therapy. Sulfinpyrazone inhibits platelet function, thereby inhibiting thrombosis. A meta-analysis of studies, conducted by the Antiplatelet Trialists' Collaboration, has shown that it reduces the risk of myocardial infarction, stroke, or vascular death in patients at high risk of occlusive vascular disease[1] and also reduces the risk of occlusion in patients undergoing arterial reperfusion and revascularisation procedures.[2] However, aspirin is the most widely used antiplatelet therapy, as discussed under Cardiovascular Risk Reduction, on p.1164.

Rasburicase *(BAN, USAN, rINN)*

Rasburicasa; Rasburicasum; Rasburikaasi; Rasburikas; Rasburikaz; SR-29142.

Разбуриказа

CAS — 134774-45-1.
ATC — V03AF07.
ATC Vet — QV03AF07.

Description. Rasburicase is a recombinant form of the enzyme urate oxidase.

Adverse Effects

The most serious adverse effects of rasburicase involve hypersensitivity reactions, including anaphylaxis, rashes, bronchospasm, rhinitis, urticaria, hypotension, dyspnoea, and chest pain and tightness. Haemolysis and methaemoglobinaemia have also been reported. Other adverse effects are nausea, vomiting, abdominal pain, constipation, diarrhoea, headache, fever, respiratory distress, sepsis, neutropenia, and mucositis.

Precautions

Treatment with rasburicase should be immediately and permanently stopped if hypersensitivity reactions, methaemoglobinaemia, or haemolysis develop. Rasburicase is contra-indicated in patients with G6PD deficiency or other cellular metabolic disorders known to cause haemolytic anaemia; hydrogen peroxide, which is produced during oxidation of uric acid to allantoin, can induce haemolytic anaemia in these patients. Patients at higher risk of having G6PD deficiency should be screened before receiving rasburicase.

Uses and Administration

Rasburicase is a recombinant form of the enzyme urate oxidase, which oxidises uric acid to allantoin. It is used in the treatment and prophylaxis of severe hyperuricaemia (p.552) associated with the treatment of malignancy. It is given by intravenous infusion before and during the start of chemotherapy, in a dose of 150 or 200 micrograms/kg daily over 30 minutes. Duration of treatment may vary from 5 to 7 days.

The native form of urate oxidase has also been used.

Gout. Rasburicase has been used successfully to treat gout in patients allergic to allopurinol.[1,2]

1. Vogt B. Urate oxidase (rasburicase) for treatment of severe tophaceous gout. *Nephrol Dial Transplant* 2005; **20:** 431–3.
2. Richette P, Bardin T. Successful treatment with rasburicase of a tophaceous gout in a patient allergic to allopurinol. *Nat Clin Pract Rheumatol* 2006; **2:** 338–42.

Tumour lysis syndrome. The tumour lysis syndrome (p.639) represents a biochemical disturbance after massive release of cellular breakdown products from tumour cells sensitive to therapy; hyperuricaemia is a cardinal feature. Rasburicase was effective in the prophylaxis or treatment of hyperuricaemia in children and young adults with leukaemia or lymphoma who either presented with abnormally high plasma concentrations of uric acid or had large tumour cell burdens.[1] Treatment was mostly well tolerated; one patient developed nausea and vomiting and one experienced bronchospasm and hypoxaemia 3 hours after infusion. Antibodies to rasburicase were seen in 17 of 121 assessable patients. Safety and efficacy were confirmed in further studies of children[2] and adults[2,3] considered to be at particularly high risk of tumour lysis syndrome. In children[4] with haematologic malignancies at high risk for tumour lysis, rasburicase given intravenously achieved more rapid control and lower levels of plasma uric acid than oral allopurinol. No antibodies to rasburicase were detected at day 14. In 3 children with acute lymphoblastic leukaemia, hyperuricaemia was reportedly controlled with oral allopurinol and a single dose of rasburicase, although subclinical tumour lysis was apparent.[5] Rasburicase has also been used for tumour lysis syndrome in neonates. One infant was given a single dose of rasburicase after 2 days of induction chemotherapy for neuroblastoma, started on day 21 of life; serum urate normalised and chemotherapy was completed without further incident. A second infant, with acute lymphoblastic leukaemia and renal dysfunction, presented with tumour lysis syndrome, and had 6 doses of intravenous rasburicase plus aggressive supportive therapy, but died of complications on day 7 of life.[6] Reviews[7,8] have concluded that rasburicase is highly effective at decreasing uric acid concentrations rapidly and thoroughly; there is some suggestion that shorter durations of treatment (between 1 and 3 days as opposed to 5 days) may be sufficient even in high-risk patients.

  Vertigo, p.565

The peripheral effects of histamine are chiefly mediated by 2 sets of receptors termed H_1 and H_2. Effects mediated by the H_1 receptors include the contraction of smooth muscle and the dilatation and increased permeability of the capillaries. The effects of histamine on vascular smooth muscle are mediated by H_2 as well as H_1 receptors. Other effects that are mediated by H_2 receptors include cardiac accelerating effects and, in particular, the stimulating action of histamine on the secretion of gastric acid. An H_3 receptor has also been identified in a number of systems including the CNS and peripheral nerves. It is thought that H_3 receptors are involved in the autoregulation of the release of histamine and other neurotransmitters from neurones.

The term 'antihistamines' is normally reserved for histamine H_1-antagonists and this is the convention used in *Martindale*. H_2-antagonists, typified by cimetidine (p.1716), are described in the chapter on Gastrointestinal Drugs. H_3-antagonists are under investigation.

The older antihistamines are associated with troublesome sedative and antimuscarinic effects, and are often termed 'sedating antihistamines'. The newer antihistamines, which are essentially devoid of these effects, are correspondingly termed 'non-sedating antihistamines' and include acrivastine, astemizole, cetirizine, loratadine, and terfenadine.

On the basis of their chemical structure most antihistamines can be classified into one of 6 groups:

- *Alkylamines:* drugs within this group typically possess significant sedative actions, although paradoxical stimulation can occur, especially in children. They are highly potent H_1-antagonists. Brompheniramine and chlorphenamine are typical alkylamines; acrivastine is a non-sedating alkylamine antihistamine.
- *Monoethanolamines:* monoethanolamine derivatives have pronounced sedative and antimuscarinic actions but a low incidence of gastrointestinal effects. Examples include clemastine and diphenhydramine.
- *Ethylenediamines:* these antihistamines are selective H_1-antagonists. They cause moderate sedation (despite having weak CNS effects), gastric disturbances, and skin sensitisation. Antazoline and mepyramine are examples.
- *Phenothiazines:* phenothiazine antihistamines have significant sedative, and pronounced antiemetic and antimuscarinic effects. Photosensitivity reactions have occurred. Promethazine is a typical phenothiazine.
- *Piperazines:* this group of antihistamines possesses moderate sedative and significant antiemetic actions. Piperazine derivatives include cetirizine, cyclizine, and hydroxyzine. Cetirizine causes less sedation than other members of this group.
- *Piperidines:* piperidines cause moderate or low sedation and are highly selective for H_1 receptors. Examples include azatadine, cyproheptadine, and the non-sedating antihistamines astemizole, loratadine, and terfenadine.

Although characteristic pharmacological properties have been described for members of each group it should be noted that many of the effects of antihistamines vary as much with each patient as with each drug and that, in particular, some of the newer non-sedating antihistamines may share the chemical structure of a group in which the other members have sedative effects.

Hypersensitivity. Hypersensitivity may be defined as an exaggerated or inappropriate immune response causing tissue damage. Hypersensitivity reactions are generally classified into 4 types (types I to IV) although this may be considered an over simplification and more than one type can often be postulated for a patient's hypersensitivity. In each of the 4 types, prior sensitisation of the patient to the specific antigen is required. The term *'allergy'* by definition originally covered all types of hypersensitivity reactions as well as the induction of immunity in an individual. Nowadays, the term is more commonly applied to type I hypersensitivity reactions.

Type I, immediate hypersensitivity reactions occur after exposure to an antigen (the allergen) in a sensitised subject; that is, one in whom the initial exposure to the antigen has caused the production of specific antibodies, mainly IgE (immunoglobulin E), which are bound to the surface of mast cells and basophils. At subsequent exposure, antigen binds to antibody resulting in degranulation of mast cells and basophils with release of mediators. These include preformed mediators such as histamine and chemotactic factors, and newly synthesised mediators such as leukotrienes, platelet-activating factor, and prostaglandins. Although type I reactions are usually described as being acute and short-lived, clinically there may often also be a late-phase and more prolonged reaction affecting the skin and bronchi. Examples of type I hypersensitivity reactions discussed below include allergic conjunctivitis, allergic rhinitis, urticaria and angioedema, and anaphylactic shock.

Type II, cell-surface hypersensitivity reactions are caused by the interaction of circulating antibodies, mainly IgG (immunoglobulin G) and IgM (immunoglobulin M), with antigens that are on the surface of specific cells or tissues. This interaction results in activation of complement and of phagocytic and killer cells leading to cell damage or lysis. Type II reactions are responsible for blood transfusion reactions, some drug-induced blood disorders, and many auto-immune disorders.

Type III, immune complex hypersensitivity reactions, are caused by the interaction of fixed or circulating antigens with circulating antibodies, mainly IgG and IgM (either soluble or particulate), resulting in formation of immune complexes. The immune complexes trigger a variety of inflammatory processes including complement activation, mediator release from mast cells and basophils, and platelet aggregation. Examples of type III reactions include serum sickness, some auto-immune and neoplastic disorders, type 2 lepra reactions (see Leprosy, p.176), and reactions, particularly in the lung, to some particulate antigens such as micro-organisms.

Type IV, cell-mediated or delayed hypersensitivity reactions, are caused by interaction of an antigen with sensitised T-lymphocytes; lymphokines are released by T-lymphocytes and inflammation ensues. Type IV reactions usually occur at least 24 hours after contact with the antigen. A type IV reaction is responsible for tuberculin reactions used for sensitivity testing, contact dermatitis, and some reactions to chronic infectious disease for example type 1 lepra reactions (p.176).

An **anaphylactoid** (pseudoallergic) reaction produces similar symptoms to those of anaphylaxis (see below), but is caused by direct release of histamine provoked by an unclear, non-immune mechanism. There is thus no requirement for prior exposure to the triggering factor, commonly a drug.

Adverse Effects of Antihistamines

The most common adverse effect of the *sedating antihistamines* is CNS depression, with effects varying from slight drowsiness to deep sleep, and including lassitude, dizziness, and incoordination (although paradoxical stimulation may occasionally occur, especially at high doses and in children or the elderly). These sedative effects, when they occur, may diminish after a few days of treatment. A major advantage of the *non-sedating antihistamines* is that they generally cause little or no drowsiness (but see Sedation, below).

Other adverse effects that are more common with the *sedating antihistamines* include headache, psychomotor impairment, and antimuscarinic effects, such as dry mouth, thickened respiratory-tract secretions, blurred vision, urinary difficulty or retention, constipation, and increased gastric reflux. Another major advantage of the *non-sedating antihistamines* is that most have little or no antimuscarinic effect.

Occasional gastrointestinal adverse effects of antihistamines include nausea, vomiting, diarrhoea, or epigastric pain. Those with antiserotonin actions, such as cyproheptadine, may cause an increase in appetite with resultant weight gain, whereas anorexia has been reported with some other antihistamines.

Palpitations and arrhythmias have been reported occasionally with most antihistamines, but a major disadvantage of the *non-sedating antihistamines* astemizole and terfenadine is the rare occurrence of hazardous ventricular arrhythmias which has led to important restrictions on their use (see Precautions, below).

Antihistamines sometimes cause rashes and hypersensitivity reactions (including bronchospasm, angioedema, and anaphylaxis) and cross-sensitivity to related drugs may occur. Photosensitivity can be a problem, particularly with the phenothiazine antihistamines.

Blood disorders, including agranulocytosis, leucopenia, haemolytic anaemia, and thrombocytopenia, although rare, have been reported. Jaundice has also been observed, particularly with the phenothiazine antihistamines.

Other adverse effects that have been reported with the antihistamines include convulsions, sweating, myalgia, paraesthesias, extrapyramidal effects, tremor, sleep disturbances, depression, confusion, tinnitus, hypotension, and hair loss.

Despite reports suggesting a possibility of human fetal abnormalities resulting from the use of some antihistamines, especially the piperazine derivatives, a causal relationship has largely been rejected; for details see Pregnancy, under Precautions, below.

Some antihistamines have been abused for their CNS effects.

Antihistamines available as preparations for application to the skin may occasionally cause skin sensitisation; systemic adverse effects have been reported after topical application to large areas of the skin.

Overdosage with *sedating antihistamines* is associated with antimuscarinic, extrapyramidal, and CNS effects. When CNS stimulation predominates over CNS depression, which is more likely in children or the elderly, it causes ataxia, excitement, tremors, psychoses, hallucinations, and convulsions; hyperpyrexia may also occur. Deepening coma and cardiorespiratory collapse may follow. In adults, CNS depression is more common with drowsiness, coma, and convulsions, progressing to respiratory failure and cardiovascular collapse. In the case of the *non-sedating antihistamines*, antimuscarinic effects are less marked, but hazardous ventricular arrhythmias (below) may be a special problem with astemizole and terfenadine, even in modest overdoses, and have led to restrictions on their use.

Arrhythmias. Ventricular arrhythmias have been reported rarely with astemizole and terfenadine particularly in association with increased blood concentrations. For full details and specific warnings see under Astemizole, p.567, and Terfenadine, p.590.

The suspicion that such life-threatening arrhythmias may be a class effect of the non-sedating antihistamines has so far proven unfounded. Data[1] from the WHO adverse drug reaction database showed that cardiac events had been reported with the 5 most widely prescribed non-sedating antihistamines at that time (acrivastine, astemizole, cetirizine, loratadine, and terfenadine), and an attempt to quantify the risk[2] suggested that use of these drugs was associated overall with a fourfold increase in likelihood of developing ventricular arrhythmias, although the absolute risk remained low. However, other centres[3] have argued that definitive causality has only been proven for astemizole and terfenadine. In addition, a possible mechanism for drug-induced cardiac toxicity has only been found with astemizole and terfenadine;[4] both drugs have been shown to block cardiac potassium channels *in vitro*, a phenomenon that results in prolongation of the QT interval, which is a risk factor for developing ventricular arrhythmias. Studies[5] with loratadine and cetirizine have found that neither drug blocked potassium channels *in vitro*, and a similar lack of activity might be expected with desloratadine and levocetirizine; however, there is some evidence that mizolastine can block potassium channels at high concentrations *in vitro*[6] (although a small study in healthy subjects noted no adverse effects on cardiac conduction at doses up to 4 times those normally given).[7] A case report[8] of arrhythmias in a patient with pre-existing QT-prolongation given fexofenadine, did not appear to be associated with blocking of potassium channels.[9]

Reye's syndrome. For criticism of a suggested link in children between antihistamines and Reye's syndrome, see p.22.

Sedation. CNS depression is a common adverse effect of the sedating antihistamines and sedative effects can range from slight drowsiness to deep sleep. Daytime sedation can be a problem especially for those who have to drive or operate machinery. When sedative effects do occur they are most apparent at the start of treatment and often diminish after a few days despite continued use. Sedation caused by alcohol or other CNS depressants is enhanced. Many studies have attempted to quantify and compare the sedative effects of the older antihistamines, but results vary widely and classifications are difficult to make. Theoretically, the onset, degree, and persistence of sedation depend on factors such as penetration of the blood-brain barrier and on the relative affinity for central and peripheral histamine H_1 receptors. In general, antihistamines of the monoethanolamine and phenothiazine classes cause the most sedation.

In view of these problems, non-sedating antihistamines have been developed. These compounds have poor penetration into the CNS and/or higher affinity for peripheral rather than central histamine H_1 receptors. Studies with acrivastine,[1] astemizole,[2] fexofenadine,[3] loratadine,[4] and terfenadine[5] have generally indicated a lower incidence of sedation and related CNS effects than that observed with older antihistamines and comparable with that of placebo; prescription-event monitoring suggested that sedation was lower with fexofenadine and loratadine than with acrivastine or cetirizine, although the risk was low with all 4 drugs.[6] In a study[7] to compare the effects of acrivastine, terfenadine, and diphenhydramine on driving performance, terfenadine had no significant effect on driving performance. Acrivastine's effects were dose-related, but with little effect at the normal therapeutic dose, whereas diphenhydramine profoundly impaired all the measures of driving performance. In another study,[8] the effects of fexofenadine on driving performance were comparable with placebo. Studies with terfenadine[5] suggest that the incidence of sedation does not increase significantly with increased dose or duration of administration. Cetirizine appears to be more sedating than loratadine or terfenadine but less sedating than older antihistamines; the effect appears to be dose dependent.[9] Limited data with azelastine[10] indicate a similar incidence of drowsiness to that with terfenadine. An incidence of sedation comparable with that caused by terfenadine has also been seen for mequitazine when given in the recommended dosage of 5 mg twice daily.[5] Sedation has, however, occurred after doses of 10 mg twice daily.[11] Other newer antihistamines claimed to produce no troublesome sedation include ebastine, epinastine, mizolastine, and setastine. A review[12] of studies in drivers divided antihistamines into:

- first-generation (such as clemastine, diphenhydramine, and triprolidine), which produced significant impairment of driving ability
- second-generation (acrivastine, cetirizine, ebastine, emedastine, loratadine, mizolastine, and terfenadine), which produced more modest degrees of impairment; higher doses than normal produced significant impairment
- third-generation (levocetirizine, fexofenadine), which seemed to produce little or no impairment

A number of studies have indicated that the non-sedating antihistamines do not seem to enhance the effects of alcohol and other CNS depressants.

A few patients treated with non-sedating antihistamines have experienced drowsiness. Therefore it is prudent to exercise caution before driving or operating machinery; the effect of a drug on a particular patient can be ascertained after the first few doses.

Precautions for Antihistamines

Drowsiness is a major problem with the *sedating antihistamines* and those affected should not drive or operate machinery; alcohol should be avoided. In the case of *non-sedating antihistamines*, although drowsiness is rare, it can occur and may affect the performance of skilled tasks.

Because of their antimuscarinic actions the *sedating antihistamines* should be used with care in conditions such as angle-closure glaucoma, urinary retention, prostatic hyperplasia, or pyloroduodenal obstruction; antimuscarinic adverse effects are not a significant problem with the *non-sedating antihistamines.*

Occasional reports of convulsions in patients taking antihistamines suggest a need for caution in patients with epilepsy.

Many antihistamines are excreted in the urine in the form of active metabolites so that dosage reduction may be necessary in renal impairment (see individual monographs for specific advice). Caution is also needed in hepatic impairment, notably with phenothiazine antihistamines (for further details, see Effects on the Liver, under Chlorpromazine, p.971) and, above all, with the *non-sedating antihistamines*, astemizole and terfenadine (hazardous ventricular arrhythmias may occur in the presence of excessive blood concentrations). Other important cautions for astemizole and terfenadine include avoidance of use with drugs liable to interfere with their hepatic metabolism or otherwise increase the risk of arrhythmias, and contra-indication in patients with cardiac disease, known or suspected prolongation of the QT interval, or hypokalaemia or other electrolyte imbalances. For full details see under Astemizole, p.567, and Terfenadine, p.590.

Antihistamines should not be given to neonates because the latter are more susceptible to antimuscarinic effects. It has also been recommended that antihistamines should be avoided in young children (see Children, below, and under Promethazine, p.589, and Alimemazine, p.566). Elderly patients are also more susceptible to many of the adverse effects of antihistamines and, in particular, their inappropriate use for postural giddiness should be avoided (see Vertigo, below).

Topical preparations containing antihistamines should not be used on broken or eczematous skin.

A number of large studies have failed to find any strong associations between fetal abnormalities and antihistamines taken during pregnancy (see under Pregnancy, below).

Asthma. Antihistamines are not considered effective in the management of asthma[1] and their use has often been contra-indicated in patients with asthma because of fears that they may cause airway obstruction. However, antihistamine-induced airway obstruction has rarely been noted clinically and many patients with asthma tolerate concurrent treatment with antihistamines without obvious adverse effects. Therefore the American Academy of Allergy and Immunology has recommended that antihistamines are not contra-indicated in patients with asthma, unless an adverse reaction has previously been demonstrated, and the FDA no longer warns against the use of over-the-counter antihistamines by people with asthma.[2]

Children. In 2004, the FDA[1] reviewed all reports that it had received, between 1969 and 2003, of serious adverse events in children (aged from birth to 16 years) given promethazine. Of 125 reports there were 38 cases of respiratory depression, apnoea, or cardiac arrest; 29 cases of extrapyramidal dystonic reactions; 24 cases of other CNS reactions; 15 cases of seizures or seizure-like activity; 12 cases of dermatological reactions; and 5 cases of neuroleptic malignant syndrome. These reports included 22 cases of respiratory depression in patients aged 1.5 months to 2 years, 7 of which were fatal. Doses received in these 22 cases ranged from 0.45 to 6.4 mg/kg. Serious outcomes occurred with all routes of administration (oral, rectal, and parenteral). US licensed product information for promethazine hydrochloride now contra-indicates its use in children under 2 years of age because of the potential for fatal respiratory depression; a strengthened warning regarding use in children aged 2 years and older advises use of the lowest effective dose and to avoid concomitant use of other drugs with respiratory depressant effects. UK licensed product information for phenothiazine antihistamines, such as promethazine and alimemazine, also warns that these should not be given to children under 2 years of age, and the *BNFC* advises that sedating antihistamines such as these should not be given to children under 2 years of age, except on specialist advice, because safety has not been established.

Concern has also been expressed about the safety in children of cough and cold preparations that contain antihistamines, cough suppressants, expectorants, and sympathomimetic decongestants, either alone or in combination. A systematic review[2] has also found no good evidence for or against the effectiveness of over-the-counter preparations in acute cough. In early 2008, the FDA[3] and MHRA[4] both advised that over-the-counter cough and cold preparations should not be given to children under 2 years of age. They warn of the potential for serious and potentially life-threatening adverse effects and that such preparations provide only symptomatic relief, at best. If these products are used in children older than 2 years of age, the recommended dose should be followed carefully and measured accurately, and only one preparation should be used to avoid overdosage of the same drug or similar drugs. A review by the FDA of the use of such preparations in older children (2 to 11 years of age) is ongoing. For the MHRA's suggested management of the symptoms of coughs and colds, see Cough, p.1547.

An association between phenothiazine antihistamines and sudden infant death syndrome has also been investigated—see p.588.

Pregnancy. Antihistamines have been used for antiemetic therapy during pregnancy, but considerable anxiety has surrounded such use and its potential for risk to the fetus. The most widely studied preparation was *Debendox* which contained doxylamine, dicycloverine, and pyridoxine, and was known as *Bendectin* in some countries. Dicycloverine was removed from the preparation in 1976 in the USA and subsequently in other countries, and the product was withdrawn from the market in 1983 because of threatened litigation.[1] By that time *Debendox* had been used for over 27 years and in over 33 million pregnancies worldwide.[1]

Initial concern came from anecdotal reports of malformations in infants whose mothers had taken *Debendox* during pregnancy.[2,3] Evidence was found[4] of an association between prenatal exposure to the 3-component formulation of *Bendectin* and an increased risk of pyloric stenosis and possibly also defective heart valves in a study of 1369 malformed infants and 2968 healthy control cases. Other studies have suggested an increased incidence of oral clefts,[5] gastrointestinal atresia,[6] and genital tract disorders,[7] but generally such increases have been small. No overall pattern of malformations appears to have emerged, and many large studies have failed to confirm an association between doxylamine use and congenital malformations.[8-13]

A prospective study of 11 481 pregnancies found no increased incidence of either severe congenital abnormalities or perinatal mortality rates in women who had been prescribed prochlorperazine, meclozine, cyclizine, or *Bendectin* during pregnancy, although there was some evidence of an excess number of congenital abnormalities in patients taking trimethobenzamide.[14]

The Collaborative Perinatal Project[15] monitored the mothers of 50 282 children between 1958 and 1965. Of these, 5401 were exposed to antihistamines and 1309 to phenothiazines during the first 4 months of pregnancy. There was no evidence to suggest that exposure to these drugs was related to malformations, although there were slight suggestions of associations between respiratory malformations and pheniramine, inguinal hernia and meclozine, inguinal hernia or genito-urinary malformations and diphenhydramine, and cardiovascular deformities and phenothiazines. A report[16] on the same study found no effects of phenothiazines on perinatal mortality, birth-weight, or IQ scores at the age of 4 years. The Collaborative Perinatal Project also noted a relationship between cardiovascular defects and inguinal hernia and dimenhydrinate exposure.[15]

Both the UK CSM[17] and the FDA in the USA[18] reviewed the literature in 1981 and concluded that while the scientific evidence did not show an increase in birth defects with *Debendox*, the risk of teratogenicity could not be completely excluded. A subsequent review[19] by the FDA in 1999 into the reasons for withdrawal stated that the evidence supported the conclusion that the combination had not been withdrawn from the market for reasons of safety or efficacy. In some countries a combination preparation of doxylamine and pyridoxine remains available for the treatment of nausea and vomiting in pregnancy. There has been a study indicating that vomiting itself is not teratogenic.[20]

A number of other studies have been carried out on meclozine prompted by reports of fetal abnormalities in 10 patients associated with a preparation of meclozine and pyridoxine;[21] these studies have not supported the original reports.[22-24]

Interactions of Antihistamines

Sedating antihistamines may enhance the sedative effects of CNS depressants including alcohol, barbiturates, hypnotics, opioid analgesics, anxiolytic sedatives, and antipsychotics. Sedative interactions apply to a lesser extent with the *non-sedating antihistamines*; they do not appear to potentiate the effects of alcohol, but it should be avoided in excess.

Sedating antihistamines have an additive antimuscarinic action with other antimuscarinic drugs, such as atropine and some antidepressants (both tricyclics and MAOIs).

Potentially hazardous ventricular arrhythmias have occurred when the *non-sedating antihistamines* astemizole and terfenadine have been given with drugs liable to interfere with their hepatic metabolism, with other potentially arrhythmogenic drugs including those that prolong the QT interval, or with those likely to cause electrolyte imbalance. For full details see under Astemizole, p.567, and Terfenadine, p.591.

It has been suggested that some *sedating antihistamines* could mask the warning signs of damage caused by ototoxic drugs such as aminoglycoside antibiotics.

Antihistamines may suppress the cutaneous histamine response to allergen extracts and should be stopped several days before skin testing.

Uses of Antihistamines

Histamine H_1-antagonists (termed 'antihistamines' in *Martindale*) diminish or abolish the major actions of histamine in the body by competitive, reversible blockade of histamine H_1-receptor sites on tissues; they do not inactivate histamine or prevent its synthesis, nor, in most cases, its release (although some are claimed to have mast-cell stabilising properties). Histamine H_1 receptors are responsible for vasodilatation, increased capillary permeability, flare and itch reactions in the skin, and to some extent for contraction of smooth muscle in the bronchi and gastrointestinal tract.

Many of the *sedating antihistamines* also possess antimuscarinic, adrenaline-antagonising, serotonin-antagonising, and local anaesthetic effects. Some have calcium-channel blocking activity.

Antihistamines are used primarily for the alleviation of conditions such as urticarial **rashes** and **nasal allergy** that are characterised by type I hypersensitivity (see above), but by virtue of their associated pharmacological actions they are also used to alleviate the symptoms of a wide range of other conditions (such as pruritus and nausea and vomiting).

The antihistamines can improve or relieve the symptoms of **seasonal allergic rhinitis** ('hay fever') in many patients. They alleviate rhinorrhoea and sneezing (and ocular symptoms such as conjunctivitis) but may be less effective for nasal congestion. The relief obtained is dependent on the severity and nature of the symptoms, being greater in the milder stages. The *non-sedating antihistamines* are preferred for daytime control, but a *sedating antihistamine* may be preferred at night. Antihistamines may also be of value in **vasomotor rhinitis**, despite the fact that this is not primarily an allergic condition. *Sedating antihistamines* are widely marketed, often with a decongestant, in compound preparations for the symptomatic treatment of coughs and **colds** although there is little evidence of value.

Antihistamines are of value in preventing **urticaria** and are used to treat urticarial rashes and mild **angioedema**. They are also used as adjuncts to adrenaline in the emergency treatment of **anaphylaxis** and severe angioedema. However, the use of an antihistamine is not appropriate for the control of blood transfusion reactions caused by ABO incompatibility.

The *sedating antihistamines* are of value in the alleviation of **pruritus** both of allergic and of non-allergic origin; they have a major role in pruritus associated with atopic eczema. The *non-sedating antihistamines* do not alleviate pruritus of non-allergic origin owing to their poor penetration of the blood-brain barrier.

Sedating antihistamines have marked antiemetic activity and are used to control **nausea and vomiting** caused by a variety of vestibular disorders. In the case of motion sickness a sedating antihistamine, such as dimenhydrinate or promethazine, is used if severe drowsiness (or even sleep) is not considered undesirable, but generally a less sedative antihistamine, such as cyclizine, cinnarizine, or meclozine may be preferred. Sedating antihistamines are similarly used to control the vertigo and nausea associated with **Ménière's disease** and related conditions, with cinnarizine promoted as a specific treatment. Sedating antihistamines also have an important role in the alleviation of the nausea and vomiting of **migraine**, and buclizine or cyclizine are marketed in some countries in a combination preparation for this purpose; cyproheptadine, which has serotonin antagonist and calcium-channel blocking activity, may be of value in the prophylaxis of migraine. Sedating antihistamines have a very limited role in the short-term management of vomiting of pregnancy but are no longer considered appropriate for nausea alone. *Sedating antihistamines* have also been widely used for **premedication** in anaesthetic practice and still have a major role in the prevention of postoperative nausea and vomiting.

Some of the antihistamines with very pronounced sedative effects, such as diphenhydramine and promethazine, have been marketed for treatment of occasional **insomnia** but their long duration of action can cause hangover effects. Some antihistamines are also available as preparations for topical application for the alleviation of **insect bites**, but there is little evidence of any real value and such use may be associated with sensitisation.

Anaesthesia

Phenothiazine antihistamines have been used for anaesthetic premedication (p.1780) and to relieve anxiety during surgical and obstetric procedures, but benzodiazepines are now used more routinely. However, sedating antihistamines such as promethazine and cyclizine do have a role in the control of postoperative vomiting (below). Alimemazine is licensed for premedication in children, although when given alone it may cause postoperative restlessness if pain is present.

Anaphylaxis

Anaphylaxis is commonly a type I (immediate) hypersensitivity reaction (see above) to various allergens such as drugs, foods, and insect venoms. A clinically identical reaction can, however, be provoked by some other immune mechanisms, or by non-immune mechanisms (an anaphylactoid reaction). Symptoms of anaphylaxis and anaphylactoid reactions include erythema, pruritus, urticaria, and angioedema; respiratory obstruction may result from oedema of the larynx or epiglottis. Gastrointestinal disturbances, bronchospasm, hypotension, and coma can occur in severe reactions.

Patients with severe anaphylactic or anaphylactoid reactions should be given immediate treatment with adrenaline (see Anaphylaxis and Anaphylactic Shock, p.1205). Addition of a parenteral antihistamine such as chlorphenamine maleate or diphenhydramine hydrochloride and a corticosteroid such as hydrocortisone after the acute episode may decrease the duration and severity of symptoms and prevent relapse. The use of antihistamines in treating the symptoms of milder forms of anaphylaxis is discussed under individual symptoms such as Pruritus (below) and Urticaria and Angioedema (below).

Angioedema

See under Urticaria and Angioedema, below.

Asthma

Antihistamines appear to have no place in the treatment of asthma (p.1108). A meta-analysis[1] of double-blind randomised placebo-controlled studies published since 1980 did not support the use of antihistamines in the treatment of asthma, although the quality of the studies was generally considered to be poor.

1. Van Ganse E, *et al.* Effects of antihistamines in adult asthma: a meta-analysis of clinical trials. *Eur Respir J* 1997; **10:** 2216–24.

Conjunctivitis

Allergic conjunctivitis is a type I hypersensitivity reaction (above). It is usually seasonal but perennial attacks due to allergens such as house dust mites can occur. Itching, tears, and burning are common symptoms and frequently rhinitis (below) will co-exist. Conjunctivitis can also be caused by pathogenic micro-organisms (see Eye Infections, p.171).

Avoidance of unnecessary exposure to aeroallergens is of prime importance in the management of allergic conjunctivitis. Since a large number of inflammatory mediators are involved in its pathogenesis no single drug will be completely effective. Systemic sedating and non-sedating antihistamines are effective in reducing allergic symptoms and preventing attacks; the choice of drug depends on the degree of sedation required. Ophthalmic antihistamine preparations such as antazoline, azelastine, emedastine, levocabastine, and olopatadine may also be used for acute attacks. Ophthalmic corticosteroids may reduce inflammation, but should be restricted to severe cases only and limited to 5 to 7 days of use because of the risk of local adverse effects such as cataract or raised intra-ocular pressure. Mast-cell stabilisers including ketotifen, lodoxamide, nedocromil, and sodium cromoglicate have been widely used for prophylaxis; some antihistamines also have mast-cell stabilising properties. Diclofenac and ketorolac eye drops are available for the treatment of allergic conjunctivitis. Combined preparations of astringents such as zinc sulfate and sympathomimetics or other conjunctival decongestants such as naphazoline may also be used for symptomatic relief.

Coughs and colds

Sedating antihistamines are frequently used in combination preparations for the treatment of coughs and colds (p.1547 and p.850 respectively). The mechanism of their antitussive action may involve reduction in cholinergic nerve transmission or may simply result from their sedative effects; reduction of nasal secretions may be of value in treating cough caused by postnasal drip. Antihistamines should not be used to treat productive coughs because reduction in bronchial secretions may cause formation of viscid mucus plugs. The sedative effects of antihistamines may prove troublesome for daytime use but may be a short-term advantage for night coughs.

Antihistamines may be useful in the management of children with an acute allergic cough in the pollen season. They may also be used, with allergen avoidance and intranasal corticosteroids, in children with a chronic throat clearing type of cough and signs of allergic rhinitis.[1]

Food allergy

The term food allergy (food hypersensitivity) should be reserved for instances in which an immune mechanism for the reaction is proven, as may occur, for example, with nuts; food intolerance is used to describe a non-immune reaction. Food allergy may be the result of a type I (immediate), or possibly a type III (immune complex), hypersensitivity reaction (see above). Management revolves around the identification of the provoking food allergen and its subsequent avoidance. Individualised diets are designed and patients are educated about possible hidden sources of the allergen. Drug therapy has a very limited role in the prevention of food allergy; oral sodium cromoglicate has been used but efficacy has not been unequivocally established.

Inadvertent exposure to an allergen resulting in anaphylactic shock (p.1205) requires immediate treatment with adrenaline. Milder symptoms may be controlled by antihistamines and corticosteroids. Allergen immunotherapy (p.2251) plays no role in the routine management of food allergy.

Hay fever

Hay fever is a seasonal form of allergic rhinitis in which symptoms of conjunctivitis are also present. Management is symptomatic and therapies used are discussed under Conjunctivitis, above and Rhinitis, below.

Insomnia

Some of the older sedating antihistamines including diphenhydramine and promethazine, have been promoted to the public for occasional insomnia (p.957), although their long duration of action may cause hangover effects. Promethazine was formerly popular for children but the use of hypnotics in this age group is not usually justified. Moreover a possible association between phenothiazines and sudden infant death syndrome (see under the Adverse Effects of Promethazine, p.588) contributed to the recommendation that such antihistamines should not be used in young children.

Ménière's disease

Ménière's disease is a disorder of the labyrinth (the inner ear) characterised by recurrent attacks of vertigo, progressive hearing loss, and worsening tinnitus (p.1866). It usually presents in middle age and may equally affect men and women. The main pathological feature is an excess of endolymph fluid producing an increase in pressure in the membranous labyrinth (endolymphatic hydrops). Attacks occur in clusters over a few weeks with periods of remission lasting weeks or months.

The aims of treatment are to alleviate symptoms and preserve hearing if possible. It is therefore important to assess how far the disease has progressed, particularly in terms of hearing loss. In addition to conventional hearing tests, cochlear dysfunction may be assessed pharmacologically. Hypertonic glycerol has been given orally to reduce the endolymphatic fluid volume by osmotic diuresis, any temporary improvement in hearing indicating reversible impairment. However, this test is associated with adverse effects that some consider unacceptable. Urea has been used as an alternative to glycerol. Intravenous acetazolamide has been used diagnostically to increase endolymphatic pressure temporarily in order to produce transient hearing loss in patients in the reversible stages of the disease.

Acute attacks of vertigo in the early stages may be treated with the same drugs used for vertigo of any cause (see below).

Vasodilators have been advocated for maintenance treatment because ischaemia of the labyrinth has been postulated as a factor in the aetiology. Betahistine, a histamine analogue, is used. Restriction of dietary sodium and administration of diuretics, such as chlortalidone, furosemide, and hydrochlorothiazide, has also been used traditionally to reduce the amount of fluid in the endolymphatic spaces.

As the disease progresses, vestibular ablation with aminoglycosides may be indicated. Systemic streptomycin has been used but the risk of further hearing loss and other serious adverse effects has limited its use. Intratympanic use of gentamicin is now preferred, and can improve vertigo in up to 90% of patients, although exacerbation of hearing loss is still a risk, albeit at a lower incidence than that with systemic streptomycin.

Surgical treatment remains an option for patients with Ménière's disease refractory to medical interventions.

Migraine

Antihistamines have a number of uses in the management of migraine (p.616). Those with antiemetic activity such as buclizine and cyclizine are used to alleviate the nausea and vomiting associated with migraine; they are common ingredients of compound analgesic preparations given for the initial treatment of migraine.

Those antihistamines with antiserotonin actions, including cyproheptadine and flunarizine, have been used for the prophylaxis of migraine.

Nausea and vomiting

The management of various types of nausea and vomiting is discussed in detail on p.1700.

The older antihistamines such as cinnarizine, cyclizine, dimenhydrinate, meclozine, and promethazine are among the principal drugs used for **motion sickness**. They are all of similar efficacy but may differ in onset and duration of action and in the extent of adverse effects such as drowsiness. If a sedative effect is desired dimenhydrinate and promethazine are useful, otherwise a slightly less sedating antihistamine such as cinnarizine, cyclizine, or meclozine may be preferred. The aim is prevention of motion sickness since antiemetics are more effective for prophylaxis than for treatment; intramuscular promethazine may be effective as a treatment if injection is feasible. Antihistamines may be slightly less effective against motion sickness than the antimuscarinic hyoscine (p.1733), but are often better tolerated. Non-sedating antihistamines such as terfenadine, which penetrate poorly into the CNS, do not appear to be effective against motion sickness.

Diphenhydramine has been included in antiemetic regimens for the control of nausea and vomiting associated with **cancer chemotherapy** to reduce the extrapyramidal reactions associated with metoclopramide; it may also improve overall antiemetic control. Cyclizine is used as an antiemetic in **palliative care**.

Cyclizine is given as a supplement to opioids for premedication and has been effective prophylactically as well as in established **postoperative nausea and vomiting**. Promethazine has also been used for the prevention and treatment of postoperative nausea and vomiting, but has marked sedative effects. Dimenhydrinate is also effective for prophylaxis.

Nausea in the first trimester of **pregnancy** does not require drug therapy, but on rare occasions if vomiting is severe an antihistamine such as promethazine may be required pending specialist advice. See under Precautions for Antihistamines, above, for a discussion of the risks of antiemetic therapy during pregnancy.

Otitis media

Acute otitis media (p.182) and otitis media with effusion may resolve without treatment although antibacterials are often given. Antihistamines and decongestants, alone or in combination, have been widely given to children for symptomatic management of acute otitis media and associated respiratory symptoms, but studies have failed to show benefit and their use is not recommended.[1] Indeed in one study,[2] adjunctive treatment with chlorphenamine was found to prolong the duration of middle ear effusion.

1. Griffin GH, *et al.* Antihistamines and/or decongestants for otitis media with effusion (OME) in children. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2006 (accessed 07/03/07).
2. Chonmaitree T, *et al.* A randomized, placebo-controlled trial of the effect of antihistamine or corticosteroid treatment in acute otitis media. *J Pediatr* 2003; **143:** 377–85.

Pruritus

The sedating antihistamines are commonly used to relieve pruritus (itching) (p.1582) from a variety of causes. They are effective in relieving pruritus associated with urticaria (below) but are also used for itching associated with dermatoses such as atopic eczema (p.1579), where the degree of benefit is less certain. They are given in the latter to control nocturnal itching and for severe pruritus associated with relapse.

The exact pathophysiology of itching remains unclear.[1-3] Although histamine release is associated with itching in atopic eczema different inflammatory mediators are involved in other dermatoses. The CNS is also thought to play a part in the perception of itch. Hence, the relative roles of CNS sedation and peripheral histamine-receptor blockade in the mode of action of antihistamines in these conditions is a matter of debate. Although sedation has generally been considered the more important, the benefits of sedating antihistamines appear to be less in eczema than in urticaria. In addition, clemastine has been reported to provide no antipruritic benefit, yet it induces significant sedation. Studies with non-sedating antihistamines have been inconclusive; most found no benefit in pruritus associated with atopic eczema, although one early study has shown a slight benefit from the addition of acrivastine or terfenadine to treatment with a topical corticosteroid and an emollient.[4] Some have questioned whether any antihistamine offers much benefit in pruritus.[5]

Rhinitis

Rhinitis may be allergic or non-allergic in origin. Allergic rhinitis is a type I hypersensitivity reaction (see above); both early (sneezing, rhinorrhoea, and nasal congestion) and late (nasal congestion) reactions may be provoked. It may be seasonal (as in hay fever) or perennial and, in some patients, will frequently co-exist with conjunctivitis (above). Non-allergic rhinitis may be divided into eosinophilic non-allergic rhinitis or non-eosinophilic non-allergic rhinitis. The term vasomotor rhinitis has been used to describe the latter although its use is best avoided since no vasomotor dysfunction has been clearly identified.

In the management of **allergic rhinitis**, avoidance of unnecessary exposure to aeroallergens is of prime importance. However, in most sufferers this is not possible and some form of drug therapy will be necessary. A large number of inflammatory mediators are involved in the pathogenesis of rhinitis and no single drug is completely effective in the alleviation of symptoms.

- Some antihistamines may nonetheless be useful in reducing secretions, nasal itching, sneezing, and ocular symptoms such as conjunctivitis, but are less effective for relief of nasal congestion. Non-sedating antihistamines such as acrivastine, cetirizine, ebastine, fexofenadine, loratadine, and mizolastine are now considered the first-choice treatment for mild and/or intermittent allergic rhinitis. They are also used for the management of breakthrough symptoms in those sufferers using prophylactic intranasal corticosteroids or sodium cromoglicate (see below). Since the maximum effect of antihistamines occurs several hours after peak serum concentrations have been obtained, they should be given in anticipation of a reaction to achieve the maximum response. Most antihistamines are unsuitable for topical use in the nose or eye since they are generally ineffective at the concentrations suitable for local therapy; also there is the potential for sensitisation. However, the antazoline salts, azelastine and levocabastine have been used topically in the nose for control of symptoms. Such preparations are considered less effective than intra-nasal corticosteroids but probably more effective than cromoglicate.
- The actions of topical corticosteroids in allergic rhinitis include relief of inflammation, a decrease in capillary permeability and in mucus production, and vasoconstriction; they inhibit both the early and late response to allergen exposure. Corticosteroids are first-line treatment for the prophylaxis of moderate and/or persistent allergic rhinitis. In seasonal allergic rhinitis, they should be started at least 2 weeks before the pollen season and taken regularly throughout the season. Those applied intranasally include beclometasone, budesonide, flunisolide, fluticasone, mometasone, and triamcinolone. At recommended dosage, local adverse effects are mild and transient, and systemic effects are not a risk; aqueous sprays may cause less local effects than pressurised aerosols. Treatment of allergic rhinitis with oral or parenteral corticosteroids has been reserved for short-term treatment in special circumstances only, although some have contested even this practice.
- Mast-cell stabilisers such as ketotifen, nedocromil, and sodium cromoglicate are thought to act primarily by preventing release of inflammatory mediators from sensitised mast cells through stabilisation of mast-cell membranes. They are an alternative to corticosteroids in the prophylactic treatment of allergic rhinitis and may be preferred for therapy in children. They may also be useful in controlling mild to moderate symptoms.
- The leukotriene receptor antagonist montelukast has produced benefits comparable to those seen with antihistamines, and is licensed in some countries for management of seasonal allergic rhinitis.
- Intranasal sympathomimetics such as phenylephrine, naphazoline, oxymetazoline, and xylometazoline may be useful for short-term treatment of allergic rhinitis to relieve severe nasal congestion which can be painful and may impede delivery of sodium cromoglicate or a corticosteroid to the mucosal surfaces. Oral sympathomimetic decongestants such as pseudoephedrine and phenylpropanolamine are less effective than topical sympathomimetics and adverse effects may be troublesome.
- Ipratropium bromide given intranasally may be useful as adjunctive therapy in patients with rhinorrhoea as it has a localised parasympathetic blocking action which reduces watery hypersecretion from nasal mucosa.

Allergen immunotherapy (p.2251) is generally only indicated in severe allergic rhinitis when sensitivity testing demonstrates sensitivity to one allergen and when exposure to the allergen is unavoidable or symptomatic treatment has failed.

The management of **non-allergic rhinitis** is similar to that of allergic rhinitis despite different mechanisms being involved in its aetiology. Topical corticosteroids are often first-line therapy especially if nasal congestion is a dominant feature. The role of antihistamines is more limited; sedating antihistamines are useful in reducing nasal secretions because of their antimuscarinic actions; however, non-sedating antihistamines are relatively ineffective. In patients in whom rhinorrhoea is a particular problem, intranasal ipratropium is of value. Although intranasal sympathomimetics have also been used they should generally be avoided because of the risk of rebound congestion. Oral sympathomimetics are largely ineffective.

Other therapies tried include topical capsaicin, to induce local desensitisation, and nasal douching with a saline and sodium bicarbonate solution.

Urticaria and angioedema

Most patients with urticaria or angioedema (p.1584) derive some benefit from oral antihistamines, especially in relief of pruritus. However, patients who are severely affected, particularly those with laryngeal oedema, are allergic emergencies and require immediate treatment with adrenaline (see Anaphylaxis and Anaphylactic Shock, p.1205). Also, large doses of antihistamines are sometimes required and urticarias with a type I immunological origin and iatrogenic urticarias respond better than physical urticarias. If attacks of urticaria are frequent, antihistamines may be given prophylactically. Sedating antihistamines such as chlorphenamine and diphenhydramine have been widely used in the treatment of urticaria but non-sedating antihistamines are now generally preferred. Hydroxyzine has been used particularly in dermographism and cholinergic urticaria. Cyproheptadine has generally been considered the drug of choice for cold urticaria, although appetite stimulation may be a problem.

Some drugs with both H_1-antagonist and mast-cell stabilising actions, such as ketotifen, oxatomide, and azatadine have shown efficacy in the treatment of urticaria; the role of mast-cell stabilisation is unknown.

Topical treatment is rarely effective except for cases of mild urticaria; topical antihistamines carry a risk of sensitisation.

Vertigo

Vertigo is a symptom of vestibular disorders. It is characterised by a sensation of rotation of the surroundings or of movement of static objects. Dizziness is considered to be a wider term, although some use it as a synonym for vertigo.

A variety of disorders may affect the vestibular system and produce vertigo, including cerebrovascular disorders, epilepsy, head injury, malignant neoplasms, Ménière's disease, migraine, multiple sclerosis, and infections. Motion sickness can induce vertigo. Ototoxic drugs may also cause vestibular damage and precipitate vertigo.

Patients suffering from vertigo should undergo thorough investigations to identify any underlying cause. Simple measures to improve the integration of sensory input from visual, proprioceptive, and vestibular receptors may prove effective, especially in the elderly, in whom the inappropriate prescribing of drugs for postural instability needs to be avoided. Such measures include improving visual acuity, balance exercises, and the use of walking aids.

The most widely used drugs for acute vertigo are the antihistamines. They may have a direct action on the inner ear besides acting centrally. Antimuscarinic actions may contribute to their activity; antimuscarinics, especially hyoscine, have a long history of use in vertigo. Antihistamines used in the treatment of vertigo include buclizine, cyclizine, dimenhydrinate, diphenhydramine, meclozine, and promethazine. Cinnarizine and flunarizine are also used for vertigo although they are devoid of any significant antimuscarinic actions; their activity may be due to calcium-channel blockade. Phenothiazines such as prochlorperazine are also used to control any associated vomiting. Benzodiazepines including diazepam have been given in acute severe attacks. However their prolonged use in those with chronic symptoms is of questionable value.

Vasodilators may be of benefit in the treatment of vertigo of vascular aetiology. Parenteral or sublingual histamine was formerly widely used, and betahistine is still advocated especially for vertigo associated with Ménière's disease. Nicotinyl alcohol has also been used.

Acrivastine *(BAN, USAN, rINN)*

Acrivastin; Acrivastina; Acrivastinum; Akrivastiini; Akrivastin; BW-825C. (*E*)-3-{6-[(*E*)-3-Pyrrolidin-1-yl-1-*p*-tolylprop-1-enyl]-2-pyridyl}acrylic acid.

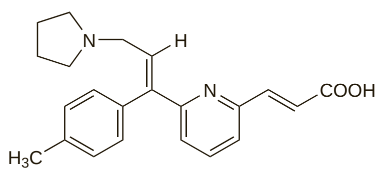
Акривастин

$C_{22}H_{24}N_2O_2$ = 348.4.

CAS — 87848-99-5.

ATC — R06AX18.

ATC Vet — QR06AX18.



Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561. Acrivastine should be given with care in renal impairment; UK licensed product information recommends that it should not be given to patients with significant renal impairment, while product information in other countries, such as Switzerland for example, contra-indicates its use in those with a creatinine clearance of less than 50 mL/minute. Acrivastine should not be used in patients hypersensitive to triprolidine.

Sedation. For a discussion of the sedative effects of antihistamines see p.562.

Interactions

As for the non-sedating antihistamines in general, p.563.

Pharmacokinetics

Acrivastine is well absorbed from the gastrointestinal tract; peak plasma concentrations are achieved in about 1.5 hours. The plasma half-life of acrivastine is about 1.5 hours and the drug does not appear to cross the blood-brain barrier to a significant extent. Acrivastine along with an active metabolite is excreted principally in the urine.

Uses and Administration

Acrivastine is a non-sedating antihistamine structurally related to triprolidine. It does not have any significant sedative or antimuscarinic actions. It is used for the symptomatic relief of allergic conditions such as rhinitis (p.565) and various types of urticaria (p.565) when it is given in oral doses of 8 mg three times daily. It is also used with a decongestant such as pseudoephedrine hydrochloride.

Administration in renal impairment. See Precautions, above

Alimemazine Tartrate *(BANM, rINNM)*

Alimémazine, Tartrate d'; Alimemazini Tartras; Tartrato de alimemazina; Trimeprazine Tartrate. *NN*-Dimethyl-2-methyl-3-(phenothiazin-10-yl)propylamine tartrate.

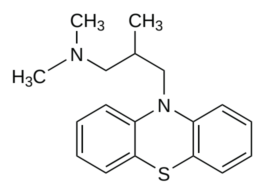
Алимемазина Тартрат

$(C_{18}H_{22}N_2S)_2,C_4H_6O_6$ = 747.0.

CAS — 84-96-8 (alimemazine); 4330-99-8 (alimemazine tartrate).

ATC — R06AD01.

ATC Vet — QR06AD01.



(alimemazine)

Pharmacopoeias. In *Br.*, *Fr.*, *Jpn*, and *US.*

BP 2008 (Alimemazine Tartrate). A white or slightly cream powder. It darkens on exposure to light. Freely soluble in water; sparingly soluble in alcohol; very slightly soluble in ether. A 2% solution in water has a pH of 5.0 to 6.5. Protect from light.

USP 31 (Trimeprazine Tartrate). A white to off-white, odourless, crystalline powder. Soluble 1 in 2 of water, 1 in 20 of alcohol, 1 in 5 of chloroform, and 1 in 1800 of ether; very slightly soluble in benzene. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Children. There have been reports of adverse effects in children given alimemazine tartrate orally. Fatal malignant hyperthermia[1] and severe cardiovascular depression[2] have occurred after its use for premedication, and severe respiratory and CNS depression[3] after use as a postoperative sedative. Doses in these 3 reports ranged from 2.4 to 4.4 mg/kg. Although unconfirmed, a possible association between phenothiazine sedatives and sudden infant death syndrome has also been suggested (see Promethazine Hydrochloride, p.588). Alimemazine tartrate is no longer licensed in the UK for short-term sedation in children and it is recommended that it should not be used in infants less than 2 years of age (but see below). The maximum recommended oral dose for premedication of children aged 2 to 7 years is 2 mg/kg. There has been a warning[4] that the use of alimemazine for deep sedation in diagnostic and therapeutic procedures in children is associated with prolonged drowsiness and that standards of monitoring, starvation, and postprocedural care should be similar to those with general anaesthesia.

Pregnancy. For a discussion of the use of antihistamines in pregnancy, including studies involving phenothiazines, see p.563.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Alimemazine, a phenothiazine derivative, is a sedating antihistamine with antiemetic activity and pronounced sedative effects. It also has some antimuscarinic actions. It is used mainly for the relief of urticaria (p.565) and pruritus (p.565), and, in the UK, for pre-operative medication in children. Alimemazine may also be used in compound preparations for the symptomatic treatment of coughs (p.564).

Alimemazine tartrate is given orally; doses in the UK are given as the amount of alimemazine tartrate, while those in some other countries are expressed in terms of the equivalent amount of alimemazine. Alimemazine tartrate 25 mg is equivalent to about 20 mg of alimemazine.

- The adult dose of alimemazine tartrate used for the relief of **urticaria** and **pruritus** in the *UK* is 10 mg two or three times daily; up to 100 mg daily has been given in refractory cases. Elderly patients are given 10 mg once or twice daily and children over 2 years of age 2.5 to 5 mg three or four times daily. Despite the view that alimemazine should not be given to younger children (see above), and although not licensed in the UK, the *BNFC* suggests that 250 micrograms/kg (maximum of 2.5 mg) three or four times daily may be given to those aged 6 months to 2 years for the relief of urticaria and pruritus, but only under specialist care.
- Doses used in the *USA* have been lower, even allowing for them being expressed in terms of alimemazine. The adult dose was the equivalent of alimemazine 2.5 mg four times daily. Children in the USA 3 years of age and over have been given 2.5 mg at night or three times daily. However, it appears that proprietary preparations are no longer available in the USA.
- The usual recommended dose in the UK for **premedication** in children aged 2 to 7 years is up to 2 mg/kg given about one to two hours before the operation.

Anaesthesia. Alimemazine tartrate may be used for anaesthetic premedication (see p.563) in children if the oral route is preferred to the more usual parenteral route of other phenothiazine antihistamines. Adverse effects have, however, been reported in children (see under Adverse Effects and Precautions, above), and in the UK alimemazine tartrate is not licensed for use in infants less than 2 years of age.

Insomnia. Antihistamines such as alimemazine tartrate have been used as alternatives to benzodiazepines for the short-term treatment of insomnia (p.564), particularly for children. However, their antimuscarinic side-effects may prove troublesome.

Regimens involving a short course of alimemazine tartrate in high dosage were tried in order to alter the sleep pattern of children with sleeping difficulties.[1,2] Adverse effects have, however, been reported in children (see under Adverse Effects and Precautions, above). The UK product is no longer indicated for short-term sedation in children and should not be used in infants less than 2 years of age.

CAS — 24359-81-7 (anhydrous antazoline sulfate).
ATC — R01AC04; R06AX05.
ATC Vet — QR01AC04; QR06AX05.

NOTE. The above molecular formula is that provided in the *It. P.* Other sources give a molecular formula of $C_{17}H_{19}N_3$,H_2SO_4.

Pharmacopoeias. In *It.*

Adverse Effects and Precautions

As for the antihistamines in general, p.561.

Hypersensitivity. Reports of acute interstitial pneumonitis (with fever, rash, and dyspnoea)[1] and of immune thrombocytopenic purpura[2] were attributed to hypersensitivity reactions after the oral use of antazoline.

1. Pahissa A, *et al.* Antazoline-induced allergic pneumonitis. *BMJ* 1979; **2:** 1328.
2. Nielsen JL, *et al.* Immune thrombocytopenia due to antazoline (Antistina). *Allergy* 1981; **36:** 517–19.

Uses and Administration

Antazoline, an ethylenediamine derivative, is an antihistamine used topically for the treatment of allergic conjunctivitis (p.564). It is used as the hydrochloride, phosphate, or sulfate in eye drops, most commonly in a concentration of 0.5%; the mesilate has also been used. Antazoline salts are often used with a vasoconstrictor such as naphazoline hydrochloride or nitrate or xylometazoline hydrochloride.

The hydrochloride and sulfate salts of antazoline have been used topically for the treatment of minor skin irritations, but as with other antihistamines there is a risk of sensitisation. The hydrochloride has also been given by mouth.

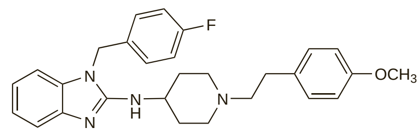
Astemizole *(BAN, USAN, rINN)*

Astemitsoli; Astemizol; Astemizolas; Astémizole; Astemizolum; Asztemizol; MJD-30. 1-(4-Fluorobenzyl)-2-{[1-(4-methoxyphenethyl)-4-piperidyl]amino}benzimidazole.

Астемизол

$C_{28}H_{31}FN_4O$ = 458.6.
CAS — 68844-77-9.
ATC — R06AX11.
ATC Vet — QR06AX11.



NOTE. The code R-43512 has been used to describe both astemizole and its metabolite tecastemizole (norastemizole).

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Astemizole). A white or almost white powder. Practically insoluble in water; soluble in alcohol; freely soluble in dichloromethane and in methyl alcohol. Protect from light.
USP 31 (Astemizole). Store in airtight containers.

Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561. Increased appetite and weight gain have been reported with astemizole.

Ventricular arrhythmias, including torsade de pointes, have occurred rarely with astemizole, particularly in association with raised blood concentrations (see Arrhythmias below) and as a result the drug has been withdrawn from the market in most countries. To reduce the risk of developing such arrhythmias recommendations were that licensed doses should **not** be exceeded, and that it should be **avoided** in patients with cardiac or significant hepatic disease, with hypokalaemia or other electrolyte imbalance, or with known or suspected prolonged QT interval. Use with drugs liable to interfere with the hepatic metabolism of astemizole, other potentially arrhythmogenic drugs including those that prolong the QT interval, and drugs likely to cause electrolyte imbalance, is **contra-indicated** (see Interactions below).

Arrhythmias. Although severe life-threatening cardiovascular effects including torsade de pointes and other ventricular arrhythmias were initially reported mainly after substantial overdoses of astemizole, such reactions have also occurred rarely with doses as low as 20 to 30 mg daily and even as low as 10 mg daily in those with possible predisposing factors. There has been a report[1] of astemizole-induced torsade de pointes in a 15-year-old girl who claimed to have taken 10 mg daily for 10 weeks but pharmacokinetic data were more consistent with acute ingestion of higher doses. There have also been several reports of cardiotoxicity after accidental overdosage with astemizole in children.[2-4]

Although the drug is now withdrawn in the UK, recommendations were made by the UK CSM to reduce the risk of developing serious arrhythmias[5-7] (see Adverse Effects above for details). It was considered that astemizole should be stopped immediately in patients who experience syncope, and appropriate clinical evaluation including ECG monitoring instituted, because syncope has preceded or accompanied severe arrhythmias in some cases. Convulsions in patients taking astemizole may also be related to cardiovascular effects.[8]

Studies have suggested that astemizole induces ventricular arrhythmias by inhibiting cardiac potassium channels which results in prolongation of the QT interval, a risk factor for developing arrhythmias.[9] For further discussion, see p.562.

5. CSM. Ventricular arrhythmias due to terfenadine and astemizole. *Current Problems* **35** 1992. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024453&RevisionSelectionMethod=LatestReleased (accessed 14/07/08)
6. CSM/MCA. Drug-induced prolongation of the QT interval. *Current Problems* 1996; **22:** 2. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2024458&RevisionSelectionMethod=LatestReleased (accessed 14/07/08)
7. CSM/MCA. Astemizole (Hismanal): only available on prescription. *Current Problems* 1999; **25:** 2. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023233&RevisionSelectionMethod=LatestReleased (accessed 19/05/06)
8. Clark A, Love H. Astemizole-induced ventricular arrhythmias: an unexpected cause of convulsions. *Int J Cardiol* 1991; **33:** 165–7.
9. Rankin AC. Non-sedating antihistamines and cardiac arrhythmia. *Lancet* 1997; **350:** 1115–16.

Overdosage. Severe cardiac events have been associated with astemizole overdosage (see Arrhythmias, above); management is mainly supportive. The absorption of astemizole from the gastrointestinal tract can be prevented by giving activated charcoal[1] but because astemizole is rapidly absorbed it would need to be given as soon as possible after poisoning. Haemodialysis does not appear to increase the clearance of astemizole.

1. Laine K, *et al.* The effect of activated charcoal on the absorption and elimination of astemizole. *Hum Exp Toxicol* 1994; **13:** 502–5.

Porphyria. Astemizole is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Sedation. For discussion of the sedative effects of antihistamines see p.562.

Interactions

As for the non-sedating antihistamines in general, p.563.

Astemizole should not be given with drugs that inhibit its hepatic metabolism because of the increased risk of serious ventricular arrhythmias. These drugs include the imidazole and triazole antifungals such as ketoconazole and itraconazole, and the macrolide antibacterials clarithromycin, erythromycin, troleandomycin, and possibly other macrolides. Others, similarly to terfenadine (p.591), may include serotonin reuptake inhibitors, HIV-protease inhibitors, NNRTIs, and zileuton. The metabolism of astemizole may also be inhibited by grapefruit juice and use together should be avoided.

Use with other potentially arrhythmogenic drugs (including those that prolong the QT interval) such as antiarrhythmics, tricyclic antidepressants, the antimalarials halofantrine and quinine, antipsychotics, cisapride, and the beta blocker sotalol should be avoided, as should diuretics that cause electrolyte imbalances such as hypokalaemia. The use of terfenadine and astemizole together is not recommended.

Pharmacokinetics

Absorption of astemizole from the gastrointestinal tract is rapid and is reduced by food. First-pass metabolism is extensive, therefore plasma concentrations of unchanged drug are very low. The plasma concentration of astemizole plus metabolites takes about 4 to 8 weeks to reach steady state. The metabolism of astemizole is mediated through the cytochrome P450 enzyme system by the isoenzymes CYP3A4, CYP2D6, and CYP2A6. The elimination half-life of astemizole and its metabolites at steady state is about 19 days. Unchanged astemizole is highly bound to plasma proteins and does not appear to cross the blood-brain barrier to a significant extent. Desmethylastemizole, the major metabolite of astemizole, has histamine H_1-receptor-blocking activity; tecastemizole (norastemizole) is another active metabolite. The metabolites of astemizole are excreted slowly in the urine and faeces, and undergo enterohepatic recycling. Virtually none of an oral dose is excreted as unchanged drug.

Uses and Administration

Astemizole, a piperidine derivative, is a non-sedating antihistamine with a very long duration of action. It does not have significant sedative or antimuscarinic actions. Astemizole has been used for the symptomatic relief of allergic conditions including rhinitis (p.565) and conjunctivitis (p.564), and skin disorders such as urticaria (p.565). Preparations of astemizole have now been withdrawn from the market in most countries because of the risk of adverse effects.

Astemizole has been given in an oral dose of 10 mg once daily, or 5 mg daily in children aged 6 to 12 years. These doses must not be exceeded because of the risk of cardiac arrhythmias with higher doses.

The active metabolite of astemizole, tecastemizole (norastemizole) has been investigated for the treatment of allergic rhinitis.

Preparations

USP 31: Astemizole Tablets.

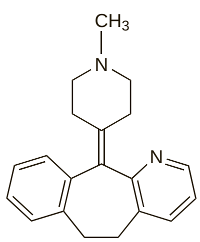
ATC — R06AX09.

ATC Vet — QR06AX09.



(azatadine)

Pharmacopoeias. In *US.*

USP 31 (Azatadine Maleate). A white to light cream-coloured, odourless powder. Freely soluble in water, in alcohol, in chloroform, and in methyl alcohol; practically insoluble in ether and in benzene.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Extrapyramidal effects. An acute dystonic reaction was reported in a patient who had taken azatadine maleate 20 to 30 mg orally over a 24-hour period.[1] The condition was reversed by intravenous injection of benzatropine 2 mg.

1. Joske DJL. Dystonic reaction to azatadine. *Med J Aust* 1984; **141:** 449.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Azatadine maleate is readily absorbed from the gastrointestinal tract and is partly metabolised. Peak plasma concentrations are achieved in about 4 hours. The elimination half-life has been reported to be 9 to 12 hours. Excretion of unchanged drug and metabolites is via the urine.

Uses and Administration

Azatadine maleate is a piperidine derivative closely related to cyproheptadine. It is a sedating antihistamine with a long duration of action; it also has antimuscarinic and antiserotonin properties.

Azatadine maleate is used for the symptomatic relief of allergic conditions including rhinitis (p.565) and urticaria (p.565); it is also used for other pruritic skin disorders as well as reactions to insect bites and stings. It is given in usual oral doses of 1 mg twice daily; if necessary 2 mg twice daily may be given. Children aged 6 to 12 years may be given 0.5 to 1 mg twice daily.

It is also used with a decongestant such as pseudoephedrine sulfate.

Preparations

USP 31: Azatadine Maleate Tablets.

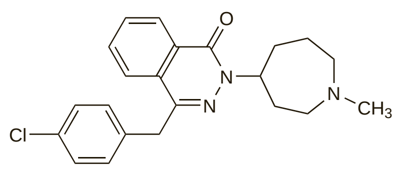
Азеластина Гидрохлорид

$C_{22}H_{24}ClN_3O,HCl = 418.4.$

CAS — 58581-89-8 (azelastine); 79307-93-0 (azelastine hydrochloride).

ATC — R01AC03; R06AX19; S01GX07.

ATC Vet — QR01AC03; QR06AX19; QS01GX07.



(azelastine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Azelastine Hydrochloride). A white or almost white, crystalline powder. Sparingly soluble in water; soluble in dehydrated alcohol and in dichloromethane.

Adverse Effects and Precautions

As for the antihistamines in general, p.561.

When given intranasally, irritation of the nasal mucosa and taste disturbances have been reported; somnolence, headache, and dry mouth have also been noted in some patients. Taste disturbance can occur after use in the eye.

Pharmacokinetics

About 40% of an intranasal dose of azelastine reaches the systemic circulation. Elimination is via hepatic metabolism with excretion mainly in the faeces.

◊ Azelastine is rapidly and almost completely absorbed when given *orally*, peak plasma concentrations being achieved in 4 to 5 hours. Azelastine undergoes hepatic metabolism; the major metabolite, demethylazelastine, has antihistamine activity. The elimination half-life of azelastine is about 25 hours, increasing to 35.5 hours after multiple oral doses, possibly as a result of accumulation of the demethyl metabolite. Azelastine and its metabolites are excreted predominantly in the faeces and also in urine.

Uses and Administration

Azelastine hydrochloride is an antihistamine that, in addition to its histamine H_1-receptor-blocking activity, appears to inhibit the release of inflammatory mediators from mast cells. It is used topically in the symptomatic relief of allergic conditions including rhinitis (p.565) and conjunctivitis (p.564). It is also used in the treatment of non-allergic rhinitis.

In the treatment of allergic **rhinitis** in adults and children aged 5 years and over, the usual dose in the UK is 140 micrograms by nasal spray into each nostril twice daily. In the USA, however, 2 sprays of a similar preparation (supplying 137 micrograms per spray) may be given into each nostril twice daily; children aged 5 years and over may be given 1 spray into each nostril twice daily. In the USA, azelastine is also used in the treatment of non-allergic rhinitis in adults and children aged 12 years and over. The dose is 2 sprays into each nostril twice daily. In the treatment of **conjunctivitis**, azelastine is licensed in the UK for the treatment of seasonal allergic conjunctivitis in adults and children aged 4 years and over and for the treatment of perennial allergic conjunctivitis in adults and children aged 12 years and over. In the USA, it is licensed for the treatment of allergic conjunctivitis in adults and children aged 3 years and over. Regardless of the age and indication, a 0.05% solution is instilled into each eye twice daily; this may be increased to four times daily in severe conditions.

Azelastine hydrochloride has also been given by mouth.

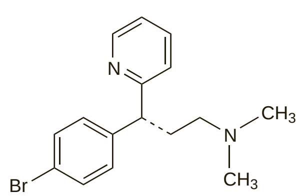
ATC Vet — QR06AB06.



(dexbrompheniramine)

Pharmacopoeias. In *US.*

USP 31 (Dexbrompheniramine Maleate). A white, odourless, crystalline powder. It exists in two polymorphic forms, one melting between 106° and 107°, and the other between 112° and 113°; a mixture of the two forms may melt between 105° and 113°. Soluble 1 in 1.2 of water, 1 in 2.5 of alcohol, 1 in 2 of chloroform, and 1 in 3000 of ether. pH of a 1% solution in water is about 5. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Breast feeding. The American Academy of Pediatrics[1] states that, although usually compatible with breast feeding, preparations used by breast-feeding mothers which contain dexbrompheniramine maleate with pseudoephedrine have resulted in crying, irritability, and poor sleep patterns in the infant.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/04/04)

Effects on the blood. A report[1] that agranulocytosis in a 34-year-old alcoholic man was possibly associated with brompheniramine therapy.

1. Hardin AS, Padilla F. Agranulocytosis during therapy with a brompheniramine-medication. *J Arkansas Med Soc* 1978; **75:** 206–8.

Extrapyramidal disorders. Facial dyskinesias have been reported[1,2] after use of antihistamines including brompheniramine or dexbrompheniramine maleate.

1. Thach BT, *et al.* Oral facial dyskinesia associated with prolonged use of antihistaminic decongestants. *N Engl J Med* 1975; **293:** 486–7 (brompheniramine maleate, chlorpheniramine maleate, and phenindamine tartrate).
2. Barone DA, Raniolo J. Facial dyskinesia from overdose of an antihistamine. *N Engl J Med* 1980; **303:** 107 (dexbrompheniramine maleate).

Withdrawal. Withdrawal symptoms have been reported[1] after stopping long-term therapy with brompheniramine maleate. A patient had been taking 48 mg almost every day for 20 years and developed tremor, nausea, depression, and apyrexial sweating within 48 hours of stopping treatment; symptoms resolved over the following weeks.

1. Kavanagh GM, *et al.* Withdrawal symptoms after discontinuation of long-acting brompheniramine maleate. *Br J Dermatol* 1994; **131:** 913–14.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Brompheniramine maleate appears to be well absorbed from the gastrointestinal tract after oral doses. Peak plasma concentrations are achieved within about 5 hours. An elimination half-life of about 25 hours has been reported. Unchanged drug and metabolites are excreted primarily in the urine.

◊ References.

2. Paton DM, Webster DR. Clinical pharmacokinetics of H -receptor antagonists (the antihistamines). *Clin Pharmacokinet* 1985; **10:** 477–97.

Uses and Administration

Brompheniramine maleate, an alkylamine derivative, is a sedating antihistamine with antimuscarinic and moderate sedative actions.

Brompheniramine is a racemic mixture; dexbrompheniramine, the dextrorotatory isomer, has about twice the activity of brompheniramine by weight. Brompheniramine maleate and dexbrompheniramine maleate are used for the symptomatic relief of allergic conditions, mainly rhinitis (p.565) and conjunctivitis (p.564). They are common ingredients of compound preparations for the symptomatic treatment of coughs and the common cold (p.564). However, such preparations should be used with caution in children, and generally avoided in those under 2 years of age (see p.562). Brompheniramine tannate has been used similarly.

Brompheniramine maleate is given in usual oral doses of 4 to 8 mg three or four times daily. Children up to 3 years of age are given 0.4 to 1 mg/kg over 24 hours in four divided doses. Children aged 3 to 6 years are given 1 to 2 mg three or four times daily and those aged 6 to 12 years 2 to 4 mg three or four times daily.

Brompheniramine maleate has also been given by subcutaneous, intramuscular, or slow intravenous injection; the dose is usually 10 mg every 8 to 12 hours as necessary and the total parenteral dose should not exceed 40 mg in 24 hours.

The symbol † denotes a preparation no longer actively marketed

Dexbrompheniramine maleate is normally given as an ingredient of decongestant preparations containing pseudoephedrine. The dose of dexbrompheniramine maleate by mouth in these combinations is 2 mg up to four times daily. Children over 6 years can be given 1 mg up to four times daily.

Modified-release oral preparations of brompheniramine maleate or dexbrompheniramine maleate are available in some countries; dosage is specific to a particular formulation.

(buclizine)

Pharmacopoeias. In *Br.*

BP 2008 (Buclizine Hydrochloride). A white or slightly yellowish, crystalline powder. Practically insoluble in water; very slightly soluble in alcohol; sparingly soluble in chloroform and in propylene glycol.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Buclizine hydrochloride, a piperazine derivative, is a sedating antihistamine with antimuscarinic and moderate sedative actions. It is used mainly for its antiemetic action, particularly in the prevention of motion sickness (p.564) and with analgesics in the treatment of migraine (p.616). In some countries it is given in the management of allergic conditions and in pruritic skin disorders (p.565). Buclizine has also been used in the treatment of vertigo (p.565) associated with disorders of the vestibular system, although its value in these conditions remains to be established.

To prevent motion sickness, buclizine hydrochloride is given at least 30 minutes before travelling in an oral dose of 25 or 50 mg, which may be repeated, if necessary, after 4 to 6 hours. The usual dose to alleviate nausea is 25 or 50 mg daily up to 100 mg daily in divided doses; in severe cases up to 150 mg daily has been given.

In the treatment of migraine, buclizine hydrochloride is given in usual doses of 12.5 mg at the start of an attack or when one is known to be imminent; children aged 10 to 14 years may be given 6.25 mg and older children the usual adult dose.

In pruritic skin disorders the usual dose of buclizine hydrochloride is 25 to 50 mg daily.

Preparations

Carbinoxamine Maleate *(BANM, rINNM)*

Carbinoxamine, Maléate de; Carbinoxamini Maleas; Karbinoksamin Maleat; Maleato de carbinoxamina. 2-[4-Chloro-α-(2-pyridyl)benzyloxy]-*NN*-dimethylethylamine hydrogen maleate.

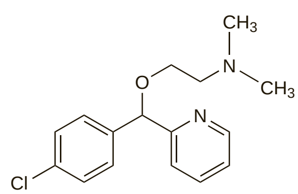
Карбиноксамина Малеат

$C_{16}H_{19}ClN_2O,C_4H_4O_4 = 406.9.$

CAS — 486-16-8 (carbinoxamine); 3505-38-2 (carbinoxamine maleate).

ATC — R06AA08.

ATC Vet — QR06AA08.



(carbinoxamine)

Pharmacopoeias. In *US.*

USP 31 (Carbinoxamine Maleate). A white, odourless, crystalline powder. Soluble 1 in less than 1 of water, 1 in 1.5 of alcohol and of chloroform, and 1 in 8300 of ether. pH of a 1% solution in water is between 4.6 and 5.1. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Carbinoxamine maleate, a monoethanolamine derivative, is a sedating antihistamine with antimuscarinic, significant sedative, and serotonin antagonist effects. Carbinoxamine maleate is used for the relief of allergic conditions such as rhinitis (p.565), and is a common ingredient of compound preparations for symptomatic treatment of coughs and the common cold (p.564).

Dose recommendations for carbinoxamine maleate may vary between preparations. Licensed US product information suggests a usual oral dose of carbinoxamine maleate in adults of 4 to 8 mg given 3 or 4 times daily. Children of 2 to 3 years of age may be given a dose of 2 mg three or four times daily, children aged 3 to 6 years given 2 to 4 mg three or four times daily, and those above 6 years given 4 to 6 mg three or four times daily. Lower doses, sometimes less than half these licensed in the US, may be used in other countries. Carbinoxamine polistirex has also been given by mouth.

Preparations

USP 31: Carbinoxamine Maleate Tablets; Pseudoephedrine Hydrochloride, Carbinoxamine Maleate, and Dextromethorphan Hydrobromide Oral Solution.

Cetirizine Hydrochloride

(BANM, USAN, rINNM)

Cetirizin-dihidroklorid; Cetirizin-dihydrochlorid; Cetirizindihydroklorid; Cétirizine, Chlorhydrate de; Cétirizine, dichlorhydrate de; Cetirizini dihydrochloridum; Cetirizini Hydrochloridum; Cetirizino dihidrochloridas; Cetyryzyny dichlorowodorek; Hidrocloruro de cetirizina; P-071; Setiritsiinidihydrokloridi; Setirizin Hidroklorür; UCB-P071. The dihydrochloride of 2-[4-(4-chlorobenzhydryl)piperazin-1-yl]ethoxyacetic acid.

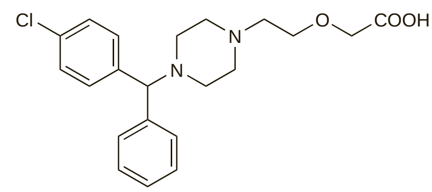
Цетиризина Гидрохлорид

$C_{21}H_{25}ClN_2O_3,2HCl = 461.8.$

CAS — 83881-51-0 (cetirizine); 83881-52-1 (cetirizine hydrochloride).

ATC — R06AE07.

ATC Vet — QR06AE07.



(cetirizine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Cetirizine Dihydrochloride; Cetirizine Hydrochloride BP 2008). A white or almost white powder. Freely soluble in water; practically insoluble in acetone and in dichloromethane. A 5% solution in water has a pH of 1.2 to 1.8. Protect from light.

Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561. Reduced dosage is recommended for patients with hepatic or renal impairment (see under Uses and Administration, below).

Arrhythmias. The ECG effects of cetirizine were studied[1] in normal subjects; doses of up to six times the usual recommended dose did not prolong the QT interval. Additionally, the FDA[2] in the USA and representatives of the manufacturers[3] in Belgium did not find any association between cetirizine and the development of ventricular arrhythmias. However, there has been a subsequent report[4] of torsade de pointes after overdosage with cetirizine in a hypokalaemic patient undergoing haemodialysis for chronic renal failure. See also p.562.

2. Himmel MH, *et al.* Dangers of non-sedating antihistamines. *Lancet* 1997; **350:** 69.
3. Coulie P, *et al.* Non-sedating antihistamines and cardiac arrhythmias. *Lancet* 1998; **351:** 451.
4. Renard S, *et al.* Torsades de pointes induites par surdosage en cétirizine. *Arch Mal Coeur Vaiss* 2005; **98:** 157–61.

Effects on the liver. Life-threatening hepatitis developed in a 23-year-old man who had been taking cetirizine long-term for atopic dermatitis.[1] He recovered after treatment with prednisolone.

There has been a report of recurrent acute hepatitis associated with the short-term use of cetirizine for seasonal allergic rhinitis in a 26-year-old man.[2]

1. Watanabe M, *et al.* Severe hepatitis in a patient taking cetirizine. *Ann Intern Med* 2001; **135:** 142–3.
2. Pompili M, *et al.* Recurrent acute hepatitis associated with use of cetirizine. *Ann Pharmacother* 2004; **38:** 1844–7.

Hypersensitivity. Hypersensitivity reactions manifesting as urticaria[1,2] and fixed drug eruptions[3] have been reported with cetirizine.

1. Karamfilov T, *et al.* Cetirizine-induced urticarial reaction. *Br J Dermatol* 1999; **140:** 979–80.
2. Calista D, *et al.* Urticaria induced by cetirizine. *Br J Dermatol* 2001; **144:** 196.
3. Inamadar AC, *et al.* Multiple fixed drug eruptions due to cetirizine. *Br J Dermatol* 2002; **147:** 1025–6.

Sedation. For discussion of the sedative effects of antihistamines see p.562.

Interactions

As for the non-sedating antihistamines in general, p.563. However, some interactions are less likely with cetirizine than with non-sedating antihistamines such as astemizole and terfenadine, since cetirizine appears to have low hepatic metabolism and little arrhythmogenic potential (see Arrhythmias, above).

Anticoagulants. For a report of an interaction between cetirizine and *acenocoumarol*, see under Interactions in Warfarin, p.1429.

Pharmacokinetics

Cetirizine is rapidly absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations being attained within about an hour. Food delays the time to peak plasma concentrations but does not decrease the amount of drug absorbed. Cetirizine is highly bound to plasma proteins and has an elimination half-life of about 10 hours. It has been detected in breast milk. Cetirizine is excreted primarily in the urine mainly as unchanged drug. It does not appear to cross the blood-brain barrier to a significant extent.

Uses and Administration

Cetirizine hydrochloride, a piperazine derivative and metabolite of hydroxyzine (p.581), is described as a long-acting non-sedating antihistamine with some mast-cell stabilising activity. It appears to have a low potential for drowsiness in usual doses and to be virtually free of antimuscarinic activity. It is used for the symptomatic relief of allergic conditions including rhinitis (p.565) and chronic urticaria (p.565).

In adults and children aged 6 years and over, cetirizine hydrochloride is given in an oral dose of 10 mg once daily or 5 mg twice daily. Children aged 2 to 5 years may be given cetirizine 5 mg once daily or 2.5 mg twice daily. In the USA, children aged 6 months to 2 years may be given a dose of 2.5 mg once daily, increased to a maximum of 2.5 mg twice daily in those aged 12 months and over, for the treatment of perennial allergic rhinitis and chronic urticaria.

It is also used with a decongestant such as pseudoephedrine hydrochloride.

Dosage of cetirizine should be reduced in patients with hepatic or renal impairment, see below.

◊ References.

1. Curran MP, *et al.* Cetirizine: a review of its use in allergic disorders. *Drugs* 2004; **64:** 523–61.

Administration in hepatic or renal impairment. In patients with hepatic impairment, US licensed product information recommends that the dosage of cetirizine may need to be reduced to half the usual oral daily dose (see above). Similarly in patients with renal impairment, both the UK and US product information recommends a dosage reduction to half the usual daily dose.

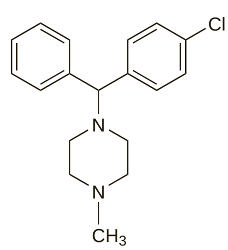
ATC — R06AE04.

ATC Vet — QR06AE04.



(chlorcyclizine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Chlorcyclizine Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in dichloromethane; soluble in alcohol. A 1% solution in water has a pH of 5.0 to 6.0. Protect from light.

Profile

Chlorcyclizine hydrochloride, a piperazine derivative, is a sedating antihistamine (p.561). It has been given orally for the symptomatic relief of hypersensitivity reactions; it has also been used as an antiemetic. It has been used in topical preparations, although as with other antihistamines, there is a risk of sensitisation.

Chlorcyclizine dibunate (naftoclizine) has been used as a cough suppressant similarly to sodium dibunate (p.1573).

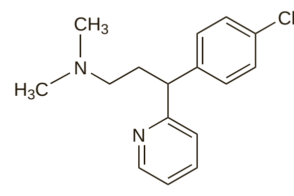
CAS — 132-22-9 (chlorphenamine); 113-92-8 (chlorphenamine maleate).

ATC — R06AB04.

ATC Vet — QR06AB04.



(chlorphenamine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Chlorphenamine Maleate). A white or almost white, crystalline powder. Freely soluble in water; soluble in alcohol. Protect from light.

USP 31 (Chlorpheniramine Maleate). A white, odourless, crystalline powder. Soluble 1 in 4 of water and 1 in 10 of alcohol and of chloroform; slightly soluble in ether and in benzene. Its solutions in water have a pH between 4 and 5. Store in airtight containers. Protect from light.

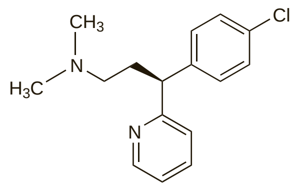
Incompatibility. Chlorphenamine maleate has been reported to be incompatible with calcium chloride, kanamycin sulfate, noradrenaline acid tartrate, pentobarbital sodium, and meglumine adipiodone.

Dexchlorpheniramine Maleate *(BANM, rINNM)*

Dekschlorfeniramino maleatas; Dekskloorifeniramiinimaleaatti; Dexchlorfeniramin-maleinát; Dexchlorphenamine Maleate; Dexchlorphéniramine, Maléate de; Dexchlorpheniramini maleas; Dexklorfeniraminmaleat; Dexklórfeniramin-maleát; Maleato de dexclorfeniramina.

Дексхлорфенирамина Малеат

CAS — 25523-97-1 (dexchlorpheniramine); 2438-32-6 (dexchlorpheniramine maleate).
ATC — R06AB02.
ATC Vet — QR06AB02.



(dexchlorpheniramine)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Dexchlorpheniramine Maleate). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol, in dichloromethane, and in methyl alcohol. A 1% solution in water has a pH of 4.5 to 5.5. Protect from light.

USP 31 (Dexchlorpheniramine Maleate). A white, odourless, crystalline powder. Soluble 1 in 1.1 of water, 1 in 2 of alcohol, 1 in 1.7 of chloroform, and 1 in 2500 of ether; slightly soluble in benzene. pH of a 1% solution in water is between 4.0 and 5.0. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Exfoliative dermatitis may develop. Injections may be irritant and cause transient hypotension or stimulation of the CNS.

Effects on the blood. There are several old and isolated reports of blood dyscrasias after use of chlorphenamine maleate; these include agranulocytosis,[1,2] thrombocytopenia,[3] pancytopenia,[4] and aplastic anaemia.[5] Haemolytic anaemia has occurred after use of dexchlorpheniramine maleate.[6] The association with antihistamine use has been questioned in some of these cases.[7]

7. Spry CJF. Chlorpheniramine-induced bone-marrow suppression. *Lancet* 1976; **i:** 545.

Effects on the senses. Chlorphenamine has been reported to affect the senses of smell and taste.[1]

1. Schiffman SS. Taste and smell in disease. *N Engl J Med* 1983; **308:** 1275–9.

Extrapyramidal disorders. Facial dyskinesias have been reported[1,2] after oral doses of chlorphenamine maleate.

1. Thach BT, *et al.* Oral facial dyskinesia associated with prolonged use of antihistaminic decongestants. *N Engl J Med* 1975; **293:** 486–7.
2. Davis WA. Dyskinesia associated with chronic antihistamine use. *N Engl J Med* 1976; **294:** 113.

Interactions

As for the sedating antihistamines in general, p.563.

Antiepileptics. For a report of the effect of chlorphenamine on *phenytoin*, see p.499.

Pharmacokinetics

Chlorphenamine maleate is absorbed relatively slowly from the gastrointestinal tract, peak plasma concentrations occurring about 2.5 to 6 hours after oral doses. Bioavailability is low, values of 25 to 50% having been reported. Chlorphenamine appears to undergo considerable first-pass metabolism. About 70% of chlorphenamine in the circulation is bound to plasma proteins. There is wide interindividual variation in the pharmacokinetics of chlorphenamine; values ranging from 2 to 43 hours have been reported for the half-life. Chlorphenamine is widely distributed in the body, and enters the CNS.

Chlorphenamine maleate is extensively metabolised. Metabolites include desmethyl- and didesmethylchlorphenamine. Unchanged drug and metabolites are excreted primarily in the urine; excretion is dependent on urinary pH and flow rate. Only trace amounts have been found in the faeces.

A duration of action of 4 to 6 hours has been reported; this is shorter than may be predicted from pharmacokinetic parameters.

More rapid and extensive absorption, faster clearance, and a shorter half-life have been reported in children.

Uses and Administration

Chlorphenamine maleate, an alkylamine derivative, is a sedating antihistamine that causes a moderate degree of sedation; it also has antimuscarinic activity.

Chlorphenamine is a racemic mixture; the dextrorotatory isomer, dexchlorpheniramine, has about twice the activity of chlorphenamine by weight.

Chlorphenamine maleate and dexchlorpheniramine maleate are used for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565), and conjunctivitis (p.564), and in pruritic skin disorders (p.565). They are common ingredients of compound preparations for symptomatic treatment of coughs and the common cold (p.564). However, such preparations should be used with caution in children, and generally avoided in those under 2 years of age (see p.562). Chlorphenamine may be given intravenously as an adjunct in the emergency treatment of anaphylactic shock (p.563).

Chlorphenamine maleate is given in oral doses of 4 mg every 4 to 6 hours up to a maximum of 24 mg daily. Doses for children, according to age, are: 1 to 2 years, 1 mg twice daily; 2 to 5 years, 1 mg every 4 to 6 hours (maximum 6 mg daily); 6 to 12 years, 2 mg every 4 to 6 hours (maximum 12 mg daily). Although not licensed in the UK, the *BNFC* suggests that children aged 1 month and over may be given 1 mg twice daily.

Chlorphenamine maleate may be given by intramuscular, by subcutaneous, or by slow intravenous injection over a period of 1 minute. The usual dose is 10 to 20 mg and the total dose given by these routes in 24 hours should not normally exceed 40 mg. For children, doses of 87.5 micrograms/kg subcutaneously four times daily have been suggested. The following parenteral doses may also be used in children: the usual dose in those aged 1 month to 1 year is 250 micrograms/kg; those aged 1 to 5 years may be given a dose of 2.5 to 5 mg and those aged 6 to 12 years, 5 to 10 mg. Alternatively, children and adolescents aged 1 to 18 years may be given a dose of 200 micrograms/kg. The *BNFC* suggests that doses for children may be repeated if necessary up to 4 times in 24 hours.

Dexchlorpheniramine maleate is given in oral doses of 2 mg every 4 to 6 hours up to a maximum of 12 mg daily. Children aged 2 to 5 years may be given 0.5 mg every 4 to 6 hours (maximum 3 mg daily), and those aged 6 to 12 years, 1 mg every 4 to 6 hours (maximum 6 mg daily).

Modified-release oral preparations of chlorphenamine maleate or dexchlorpheniramine maleate are available in some countries; dosage is specific to a particular formulation.

Dexchlorpheniramine maleate has been applied topically in some countries, although as with other antihistamines there is a risk of sensitisation. Chlorphenamine polistirex (a sulfonated diethenylbenzene-ethenylbenzene copolymer complex), chlorphenamine tannate, and dexchlorpheniramine tannate are given orally and are used similarly to the maleate.

Malaria. Chlorphenamine may be tried in patients with malaria who have chloroquine-induced pruritus (see Effects on the Skin, p.600), but additionally it has been shown to have some promise as an adjunct in the treatment of chloroquine-resistant malaria itself. Early studies indicated that chlorphenamine was only one of a number of drugs that reversed chloroquine resistance *in vitro* in isolates of *Plasmodium falciparum*. Later clinical studies in children in Nigeria showed enhanced efficacy when chlorphenamine was given with chloroquine.[1-5] The overall management of malaria is discussed on p.594.

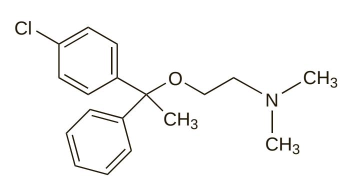
$C_{18}H_{22}ClNO,HCl = 340.3.$

CAS — 77-38-3 (chlorphenoxamine); 562-09-4 (chlorphenoxamine hydrochloride).
ATC — D04AA34; R06AA06.
ATC Vet — QD04AA34; QR06AA06.



(chlorphenoxamine)

Profile

Chlorphenoxamine, a congener of diphenhydramine (p.577), has antimuscarinic and antihistaminic properties. It has been used in nausea, vomiting, and vertigo, and was formerly used in the symptomatic treatment of parkinsonism. Chlorphenoxamine has also been used in hypersensitivity reactions.

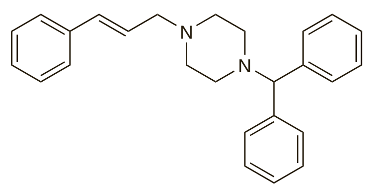
Циннаризин

$C_{26}H_{28}N_2$ = 368.5.

CAS — 298-57-7.

ATC — N07CA02.

ATC Vet — QN07CA02.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Cinnarizine). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol and in methyl alcohol; soluble in acetone; freely soluble in dichloromethane. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

There have been rare reports of extrapyramidal symptoms after taking cinnarizine, sometimes associated with depressive feelings.

High doses of cinnarizine should be used with caution in patients with hypotension because of the possibility of decreasing blood pressure further.

Extrapyramidal disorders. For reference to extrapyramidal disorders associated with the use of cinnarizine, see Flunarizine, p.580.

Hypersensitivity. Immunologically-defined lichen planus pemphigoides has been reported[1] in a 72-year-old woman taking cinnarizine. Lesions began to clear when treatment was stopped but challenge with cinnarizine provoked severe itching and reactivation of pigmented lesions. Another case[2] has also been described.

1. Miyagawa S, *et al.* Lichen planus pemphigoides-like lesions induced by cinnarizine. *Br J Dermatol* 1985; **112:** 607–13.
2. Ramallal M, *et al.* Lichenoid eruption associated with cinnarizine use. *Pharm World Sci* 2002; **24:** 215–16.

Porphyria. Cinnarizine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Tinnitus. The Spanish System of Pharmacovigilance had received reports[1] of tinnitus associated with calcium-channel blockers; some of the reports, including the one relating to cinnarizine, were in patients also receiving other ototoxic drugs. WHO was said to have additional reports of tinnitus associated with calcium-channel blockers including cinnarizine.

1. Narváez M, *et al.* Tinnitus with calcium-channel blockers. *Lancet* 1994; **343:** 1229–30.

Weight gain. There has been a report[1] of weight gain in 4 patients who had taken cinnarizine for 1 to 2 years; in all cases the weight gain was associated with increased appetite.

1. Navarro-Badenes J, *et al.* Weight-gain associated with cinnarizine. *Ann Pharmacother* 1992; **26:** 928–30.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Cinnarizine is absorbed from the gastrointestinal tract, peak plasma concentrations occurring 2 to 4 hours after oral doses. It undergoes metabolism and has a half-life of 3 to 6 hours. Cinnarizine is excreted in the faeces mainly as unchanged drug, and in the urine predominantly as metabolites.

Uses and Administration

Cinnarizine is a piperazine derivative with antihistamine, sedative, and calcium-channel blocking activity. It is used for the symptomatic treatment of nausea and vertigo caused by Ménière's disease and other vestibular disorders (see Vertigo, p.565) and for the prevention and treatment of motion sickness (p.564). It is also used in the management of various peripheral and cerebral vascular disorders.

In the UK, the usual oral dose for vertigo and vestibular disorders is 30 mg three times daily. For motion sickness a dose of 30 mg is taken 2 hours before the start of the journey and 15 mg every 8 hours during the journey if necessary. Children aged 5 to 12 years are given half the adult dose for both indications. In other European countries, a dose of 75 mg once or twice daily has been given for vertigo and vestibular disorders. Doses of 75 mg have also been given 1 to 3 times daily for cerebrovascular disorders and 2 or 3 times daily for peripheral vascular disorders.

(+)-(2*R*)-2-{2-[(*R*)-4-Chloro-α-methylbenzhydryloxy]ethyl}-1-methylpyrrolidine hydrogen fumarate.

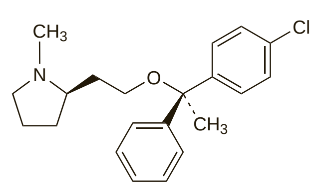
Клемастина Фумарат

$C_{21}H_{26}ClNO,C_4H_4O_4$ = 460.0.

CAS — 15686-51-8 (clemastine); 14976-57-9 (clemastine fumarate).

ATC — D04AA14; R06AA04.

ATC Vet — QD04AA14; QR06AA04.



(clemastine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Clemastine Fumarate). A white or almost white, crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol (70%); slightly soluble in alcohol (50%) and in methyl alcohol. A 10% suspension in water has a pH of 3.2 to 4.2.

USP 31 (Clemastine Fumarate). A colourless to faintly yellow, odourless, crystalline powder. Very slightly soluble in water; very slightly soluble in chloroform; slightly soluble in methyl alcohol. pH of a 10% suspension in water is between 3.2 to 4.2. Store in airtight containers at a temperature not exceeding 25°. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Breast feeding. The American Academy of Pediatrics[1] considers that clemastine should be given with caution to breast-feeding mothers, since it has been associated with adverse effects in the infant. Drowsiness, irritability, a high-pitched cry, neck stiffness, and refusal to feed in a 10-week-old breast-fed baby occurred 12 hours after her mother started treatment with clemastine.[2] Clemastine was detected in the mother's breast milk. The baby recovered and was feeding normally on the day after the drug was stopped.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/04/04)
2. Kok THHG, *et al.* Drowsiness due to clemastine transmitted in breast milk. *Lancet* 1982; **i:** 914–15.

Porphyria. Clemastine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Clemastine fumarate is rapidly and almost completely absorbed from the gastrointestinal tract; peak plasma concentrations are achieved in 2 to 4 hours. Unchanged drug and metabolites are excreted principally in the urine. An elimination half-life of about 21 hours has been reported. Clemastine is distributed into breast milk.

◊ References.

1. Schran HF, *et al.* The pharmacokinetics and bioavailability of clemastine and phenylpropanolamine in single-component and combination formulations. *J Clin Pharmacol* 1996; **36:** 911–22.

Uses and Administration

Clemastine fumarate, a monoethanolamine derivative, is a sedating antihistamine with antimuscarinic and moderate sedative properties. It has been reported to have a duration of action of about 10 to 12 hours. It is used for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565) and conjunctivitis (p.564), and in pruritic skin disorders (p.565).

Clemastine is given as the fumarate although doses are expressed in terms of the base. Clemastine fumarate 1.34 mg is equivalent to about 1 mg of clemastine base. The usual oral dose is 1 mg twice daily. Up to 6 mg daily has been given, particularly for urticaria and angioedema. Children aged 1 to 3 years may be given 250 to 500 micrograms twice daily; those aged 3 to 6 years, 500 micrograms twice daily; and those aged 6 to 12 years, 0.5 to 1 mg twice daily.

Clemastine fumarate may be given by intramuscular or slow intravenous injection in a total daily dose equivalent to 4 mg of clemastine for acute allergic reactions; for prophylaxis 2 mg is given by intravenous injection. The dose for children is 25 micrograms/kg daily in two divided doses by intramuscular injection.

Clemastine fumarate has also been used topically, although as with other antihistamines, there is a risk of sensitisation.

Pharmacopoeias. In *Br.*
BP 2008 (Cyclizine). A white or creamy white, crystalline powder. Practically insoluble in water. It dissolves in most organic solvents and in dilute acids. M.p. about 107°. A saturated solution in water has a pH of 7.6 to 8.6.

Cyclizine Hydrochloride *(BANM, rINNM)*

Ciklizin-hidroklorid; Ciklizino hidrochloridas; Cyclizine, chlorhydrate de; Cyclizini hydrochloridum; Cyklizin hydrochlorid; Cyklizinhydroklorid; Hidrocloruro de ciclizina; Syklitsiinihydrokloridi.

Циклизина Гидрохлорид

$C_{18}H_{22}N_2,HCl = 302.8.$
CAS — 303-25-3.
ATC — R06AE03.
ATC Vet — QR06AE03.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Cyclizine Hydrochloride). A white or almost white, crystalline powder. Slightly soluble in water and in alcohol. A 2% solution in alcohol 2 vol. and water 3 vol. has a pH of 4.5 to 5.5. Protect from light.
USP 31 (Cyclizine Hydrochloride). A white, odourless, crystalline powder or small colourless crystals. Soluble 1 in 115 of water and of alcohol and 1 in 75 of chloroform; insoluble in ether. pH of a 2% solution in alcohol 2 vol. and water 3 vol. is between 4.5 and 5.5. Store in airtight containers. Protect from light.

Cyclizine Lactate *(BANM, rINNM)*

Cyclizine, Lactate de; Cyclizini Lactas; Lactato de ciclizina.

Циклизина Лактат

$C_{18}H_{22}N_2,C_3H_6O_3 = 356.5.$
CAS — 5897-19-8.
ATC — R06AE03.
ATC Vet — QR06AE03.

Pharmacopoeias. *Br.* includes an injection of cyclizine lactate.

Incompatibility. Cyclizine lactate is reported to be incompatible with oxytetracycline hydrochloride, chlortetracycline hydrochloride, benzylpenicillin, and solutions with a pH of 6.8 or more.

Cyclizine Tartrate *(BANM, rINNM)*

Cyclizine, Tartrate de; Cyclizini Tartras; Tartrato de ciclizina.

Циклизина Тартрат

$C_{18}H_{22}N_2,C_4H_6O_6 = 416.5.$
ATC — R06AE03.
ATC Vet — QR06AE03.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Cyclizine may aggravate severe heart failure. Hypotension may occur on injection.

Abuse. Cyclizine tablets have been abused either alone or with opioids for their euphoric effects.[1-7] They have been taken by mouth or used to make injections. It has been suggested that cyclizine dependence may occur when it is used with opioids in the treatment of chronic pain.[8]

1. Gott PH. Cyclizine toxicity—intentional drug abuse of a proprietary antihistamine. *N Engl J Med* 1968; **279:** 596.
2. Kahn A, Harvey GJ. Increasing misuse of cyclizine. *Pharm J* 1985; **235:** 706.
3. Atkinson MK. Misuse of cyclizine. *Pharm J* 1985; **235:** 773.
4. Halpin D. Misuse of cyclizine. *Pharm J* 1985; **235:** 773.
5. Council of the Pharmaceutical Society of Great Britain. Sales of preparations containing cyclizine. *Pharm J* 1985; **235:** 797.
6. Ruben SM, *et al.* Cyclizine abuse among a group of opiate dependents receiving methadone. *Br J Addict* 1989; **84:** 929–34.
7. Bassett KE, *et al.* Cyclizine abuse by teenagers in Utah. *Am J Emerg Med* 1996; **14:** 472–4.
8. Hughes AM, Coote J. Cyclizine dependence. *Pharm J* 1986; **236:** 130.

Effects on the blood. Agranulocytosis occurred in a patient after 6 weeks of treatment with cyclizine 50 mg three times daily.[1] The blood count returned to normal once cyclizine was withdrawn.

1. Collier PM. Agranulocytosis associated with oral cyclizine. *BMJ* 1986; **292:** 174.

Effects on the heart. In a study[1] of 11 patients with severe heart failure, cyclizine produced detrimental haemodynamic effects including increased systemic and pulmonary artery pressures and ventricular filling pressures, and negated the vasodilator effects of diamorphine. It was suggested that the use of cyclizine should be avoided in patients with acute myocardial infarction or severe heart failure.

1. Tan LB, *et al.* Detrimental haemodynamic effects of cyclizine in heart failure. *Lancet* 1988; **i:** 560–1.

Effects on the liver. An 8-year-old girl developed jaundice on 2 occasions after taking cyclizine hydrochloride 25 mg daily by mouth. 'Hypersensitivity hepatitis' was considered responsible.[1]

1. Kew MC, *et al.* "Hypersensitivity hepatitis" associated with administration of cyclizine. *BMJ* 1973; **2:** 307.

Pregnancy. For discussion of the use of antihistamines in pregnancy, including studies involving cyclizine, see p.563.

Interactions

As for the sedating antihistamines in general, p.563. Cyclizine may counteract the haemodynamic benefits of opioids (see Effects on the Heart, above) and this should be considered before using preparations that contain a combination of cyclizine and an opioid analgesic.

General anaesthetics. For a possible interaction between cyclizine premedication and *barbiturate anaesthetics* see under Thiopental, p.1795.

Pharmacokinetics

Cyclizine is absorbed from the gastrointestinal tract and has an onset of action within 2 hours. The duration of action is reported to be about 4 hours. Cyclizine is metabolised in the liver to the relatively inactive metabolite, norcyclizine. Both cyclizine and norcyclizine have plasma elimination half-lives of 20 hours. Less than 1% of the total oral dose is eliminated in the urine in 24 hours.

Uses and Administration

Cyclizine, a piperazine derivative, is a sedating antihistamine with antimuscarinic activity, although the sedative effects are not marked.

It is used as an antiemetic in the management of nausea and vomiting (p.564) including motion sickness, postoperative nausea and vomiting, after radiotherapy, and in drug-induced nausea and vomiting. It is included as an antiemetic with some opioids, and in combination preparations for the treatment of migraine attacks (p.616). Cyclizine is also used for the symptomatic treatment of vertigo (p.565) caused by Ménière's disease and other vestibular disturbances.

In the management of nausea and vomiting, cyclizine hydrochloride is given in a usual oral dose of 50 mg up to three times daily, although up to 200 mg may be given in 24 hours if necessary. For the prevention of motion sickness, the first dose should be given about 30 minutes before travelling. Children aged 6 to 12 years may be given 25 mg up to three times daily. Although not licensed in the UK, the *BNFC* suggests that those aged 1 month to 6 years may be given 0.5 to 1 mg/kg (maximum of 25 mg) up to 3 times daily.

Cyclizine is given intramuscularly or intravenously as the lactate. Doses of cyclizine lactate are similar to those of cyclizine hydrochloride given orally. For the prevention of postoperative nausea and vomiting the first dose of cyclizine lactate should be given about 20 minutes before the anticipated end of surgery.

Although not licensed in the UK, cyclizine is also available as suppositories on a named-patient basis. The *BNFC* suggests that children aged 2 to 6 years may be given rectal doses of 12.5 mg; those aged 6 to 12 years, 25 mg; and those aged 12 to 18 years, 50 mg. Doses may be given up to 3 times daily.

Cyclizine salts are used as antiemetics in combination with morphine or dipipanone; the use of such fixed-combination opioid preparations is considered to be unsuitable for the prolonged treatment that may be required in palliative care. See also under Interactions, above.

Preparations

BP 2008: Cyclizine Injection; Cyclizine Tablets; Dipipanone and Cyclizine Tablets;
USP 31: Cyclizine Hydrochloride Tablets.

Cyproheptadine Hydrochloride

(BANM, rINNM)

Ciproheptadin-hidroklorid; Ciproheptadino hidrocloridas; Cyproheptadine, chlorhydrate de; Cyproheptadin-hydrochlorid seskvihydrát; Cyproheptadinhydroklorid; Cyproheptadini hydrochloridum; Cyproheptadini Hydrochloridum Sesquihydricum; Hidrocloruro de ciproheptadina; Siproheptadin Hidroklorür; Syproheptadiinihydrokloridi. 4-(5*H*-Dibenzo[*a,d*]cyclohepten-5-ylidene)-1-methylpiperidine hydrochloride sesquihydrate.

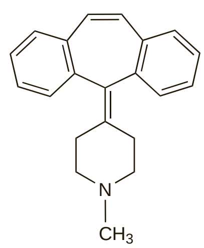
Ципрогептадина Гидрохлорид

$C_{21}H_{21}N,HCl,1\frac{1}{2}H_2O = 350.9.$

CAS — 129-03-3 (cyproheptadine); 969-33-5 (anhydrous cyproheptadine hydrochloride); 41354-29-4 (cyproheptadine hydrochloride sesquihydrate).

ATC — R06AX02.

ATC Vet — QR06AX02.



(cyproheptadine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Cyproheptadine Hydrochloride). A white or slightly yellow, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol; freely soluble in methyl alcohol. Protect from light.

USP 31 (Cyproheptadine Hydrochloride). A white to slightly yellow, odourless or practically odourless, crystalline powder. Soluble 1 in 275 of water, 1 in 35 of alcohol, 1 in 26 of chloroform, and 1 in 1.5 of methyl alcohol; practically insoluble in ether.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Increased appetite and weight gain may occur with cyproheptadine.

Abuse. Dependence developed in a patient who took about 180 mg of cyproheptadine daily by mouth for 5 years.[1]

1. Craven JL, Rodin GM. Cyproheptadine dependence associated with an atypical somatoform disorder. *Can J Psychiatry* 1987; **32:** 143–5.

Effects on the nervous system. Antimuscarinic toxicity manifest by hallucinations and agitation developed in a 9-year-old child taking cyproheptadine 4 mg twice daily for migraine prophylaxis.[1]

1. Watemberg NM, *et al.* Central anticholinergic syndrome on therapeutic doses of cyproheptadine. *Pediatrics* 1999; **103:** 158–60.

Interference with diagnostic tests. Cyproheptadine reduced hypoglycaemia-induced growth hormone secretion by between 5 and 97% in 8 healthy subjects.[1] It was suggested that if patients receiving cyproheptadine were given a pituitary function test that used growth hormone response to insulin-induced hypoglycaemia, then cyproheptadine therapy should be stopped before the test.

UK licensed product information states that cyproheptadine may cause a false positive test result for tricyclic antidepressants in urine.

1. Bivens CH, *et al.* Inhibition of hypoglycaemia-induced growth hormone secretion by the serotonin antagonists cyproheptadine and methysergide. *N Engl J Med* 1973; **289:** 236–9.

Interactions

As for the sedating antihistamines in general, p.563.

Antidepressants. For reports suggesting that cyproheptadine can reduce the effectiveness of *SSRIs*, see under Fluoxetine, p.396.

Pharmacokinetics

After absorption from the gastrointestinal tract, cyproheptadine hydrochloride undergoes almost complete metabolism. Metabolites are excreted principally in the urine as conjugates, and also in the faeces.

Uses and Administration

Cyproheptadine, a piperidine derivative, is a sedating antihistamine with antimuscarinic, serotonin-antagonist, and calcium-channel blocking actions. It is used as the hydrochloride for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565) and conjunctivitis (p.564), and in pruritic skin disorders (p.565). Other uses include the management of migraine (p.564). Cyproheptadine hydrochloride is given as the sesquihydrate although doses are expressed in terms of the anhydrous substance. Anhydrous cyproheptadine hydrochloride 10 mg is equivalent to about 11 mg of cyproheptadine hydrochloride sesquihydrate.

For allergic conditions and pruritus the oral dose in adults is initially 4 mg three times daily, adjusted as necessary. The average dose requirement is 12 to 16 mg daily in three or four divided doses, but up to 32 mg daily may occasionally be necessary. The dose for children aged 2 to 6 years is 2 mg two or three times daily increasing to a maximum of 12 mg daily and for children aged 7 to 14 years, 4 mg two or three times daily up to a maximum of 16 mg daily. Cyproheptadine is not recommended in debilitated elderly patients.

A dose of 4 mg is used for both prophylaxis and treatment of migraine and other vascular headaches and may be repeated after 30 minutes; patients who respond usually obtain relief with 8 mg, and this dose should not be exceeded within a 4- to 6-hour period. A maintenance dose of 4 mg may be given every 4 to 6 hours.

Other cyproheptadine salts that have been given orally include the acetylaspartate, aspartate, cyclamate, orotate, acefyllinate (7-theophyllineacetate), and the pyridoxal phosphate salt (dihexazine).

Abdominal migraine. Cyproheptadine has been tried in the prophylactic treatment of children with abdominal migraine (see Pizotifen, p.624).

Angina pectoris. Cyproheptadine was used successfully to treat 2 patients with Prinzmetal's angina (p.1157) refractory to standard treatment with calcium-channel blockers and nitrates.[1] Serotonin is an important endocrine mediator of coronary vasospasm and the beneficial effects of cyproheptadine were attributed to its activity as a serotonin antagonist.

1. Schecter AD, *et al.* Refractory Prinzmetal angina treated with cyproheptadine. *Ann Intern Med* 1994; **121:** 113–14.

Appetite disorders. Cyproheptadine has been widely used as an appetite stimulant, including for anorexia nervosa and cachexia (see under Megestrol, p.2115), but in the long-term appears to have little value in producing weight gain and such use is no longer generally recommended. There has been concern that cyproheptadine was being promoted and used inappropriately as an appetite stimulant in some developing countries.[1]

1. Anonymous. Cyproheptadine: no longer promoted as an appetite stimulant. *WHO Drug Inf* 1994; **8:** 66.

Carcinoid syndrome. The management of carcinoid tumours (p.643) is largely symptomatic. Cyproheptadine hydrochloride, a serotonin antagonist, has had limited success in relieving symptoms such as diarrhoea but somatostatin analogues may now be preferred.[1] It has been used successfully with fenclonine, aprotinin, methylprednisolone, and antibacterials to prevent complications arising from release of tumour metabolites during hepatic embolisation, a procedure sometimes used to relieve the symptoms of carcinoid syndrome.[2] There have been a few reports of tumour regression, in addition to symptomatic control, after treatment of carcinoid tumours with cyproheptadine.[3,4]

1. Caplin ME, *et al.* Carcinoid tumour. *Lancet* 1998; **352:** 799–805.
2. Maton PN, *et al.* Role of hepatic arterial embolisation in the carcinoid syndrome. *BMJ* 1983; **287:** 932–5. Correction to dosage. ibid.; 1664.
3. Harris AL, Smith IE. Regression of carcinoid tumour with cyproheptadine. *BMJ* 1982; **285:** 475.
4. Leitner SP, *et al.* Partial remission of carcinoid tumor in response to cyproheptadine. *Ann Intern Med* 1989; **111:** 760–1.

Serotonin syndrome. Cyproheptadine has been successfully used to treat the serotonin syndrome (p.416) in patients who have developed the syndrome after overdoses involving serotonergic drugs or who have had their antidepressant therapy changed without an adequate wash-out period.[1,2]

1. Lappin RI, Auchincloss EL. Treatment of the serotonin syndrome with cyproheptadine. *N Engl J Med* 1994; **331:** 1021–2.
2. McDaniel WW. Serotonin syndrome: early management with cyproheptadine. *Ann Pharmacother* 2001; **35:** 870–3.

Sexual dysfunction. Cyproheptadine has been tried in the management of sexual dysfunction induced by SSRIs (see Effects on Sexual Function under Fluoxetine, p.393) but may possibly reduce the effectiveness of the SSRI.

Deptropine Citrate *(BANM, rINNM)*

Citrato de deptropina; Deptropiinisitraatti; Deptropincitrat; Deptropin-citrát; Deptropine, citrate de; Deptropini citras; Deptropino citratas; Dibenzheptropine Citrate. (1*R*,3*r*,5*S*)-3-(10,11-Dihydro-5*H*-dibenzo[*a,d*]cyclohepten-5-yloxy)tropane dihydrogen citrate.

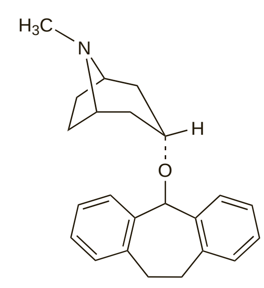
Дептропина Цитрат

$C_{23}H_{27}NO,C_6H_8O_7 = 525.6.$

CAS — 604-51-3 (deptropine); 2169-75-7 (deptropine citrate).

ATC — R06AX16.

ATC Vet — QR06AX16.



(deptropine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Deptropine Citrate). A white or almost white, microcrystalline powder. Very slightly soluble in water and in dehydrated alcohol; practically insoluble in dichloromethane. A saturated solution in water has a pH of 3.7 to 4.5. Protect from light.

Profile

Deptropine citrate is a sedating antihistamine (p.561) with a marked antimuscarinic action. It was given by mouth mainly in the treatment of respiratory-tract disorders.

Desloratadine *(BAN, USAN, rINN)*

Descarboethoxyloratadine; Desloratadin; Desloratadina; Desloratadinum; Sch-34117. 8-Chloro-6,11-dihydro-11-(4-piperidylidene)-5*H*-benzo[5,6]cyclohepta[1,2-*b*]pyridine.

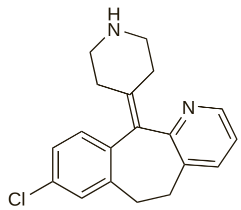
Дезлоратадин

$C_{19}H_{19}ClN_2$ = 310.8.

CAS — 100643-71-8.

ATC — R06AX27.

ATC Vet — QR06AX27.



Profile

Desloratadine, the major, active metabolite of loratadine (p.583), is a non-sedating antihistamine. Desloratadine is used in the symptomatic relief of allergic conditions including rhinitis (p.565) and urticaria (p.565).

Desloratadine is given in an oral dose of 5 mg once daily.

It is also used with a decongestant such as pseudoephedrine sulfate.

For dosage in children, and in hepatic or renal impairment, see below.

6. Canonica GW, *et al.* Efficacy of desloratadine in the treatment of allergic rhinitis: a meta-analysis of randomized, double-blind, controlled trials. *Allergy* 2007; **62:** 359–66.

Administration in children. In the UK, desloratadine is licensed for use in children aged 1 year and over in the treatment of allergic rhinitis and urticaria; in the USA, it may be given to those aged 6 months and over for perennial allergic rhinitis and urticaria and to those aged 2 years and over for seasonal allergic rhinitis.

Regardless of indication, oral doses of desloratadine are as follows:

- children aged 6 to 11 months: 1 mg once daily
- those aged 1 to 5 years: 1.25 mg once daily
- those aged 6 to 11 years: 2.5 mg once daily.

Administration in hepatic or renal impairment. US licensed product information recommends that patients with hepatic or renal impairment should be given desloratadine 5 mg orally on alternate days initially.

Breast feeding. Desloratadine is distributed into breast milk and consequently UK and US licensed product information does not recommend its use during breast feeding. For a discussion of the use of *loratadine* in breast feeding, see under Adverse Effects and Precautions, p.583.

Pregnancy. Desloratadine was not teratogenic in *animal* studies; however, product information recommends it should be used with caution, if at all, in pregnant women.

For a discussion of the use of loratadine in pregnancy, see under Adverse Effects and Precautions, p.583.

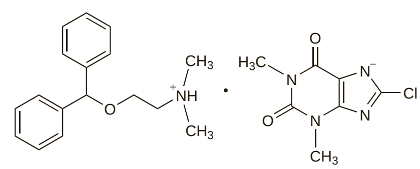
Дименгидринат

$C_{17}H_{21}NO,C_7H_7ClN_4O_2$ = 470.0.

CAS — 523-87-5.

ATC — R06AA02.

ATC Vet — QR06AA02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Dimenhydrinate). A white or almost white, crystalline powder or colourless crystals. M.p. 102° to 106°. Slightly soluble in water; freely soluble in alcohol. A saturated solution in water has a pH of 7.1 to 7.6.

USP 31 (Dimenhydrinate). A white, odourless, crystalline powder. Slightly soluble in water; freely soluble in alcohol and in chloroform; sparingly soluble in ether.

Incompatibility. Dimenhydrinate has been reported to be incompatible in solution with a wide range of compounds; those most likely to be encountered include: aminophylline, glycopyrronium bromide, hydrocortisone sodium succinate, hydroxyzine hydrochloride, meglumine adipiodone, some phenothiazines, and some soluble barbiturates.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Effects on the eyes. Dimenhydrinate 100 mg, given at 4-hourly intervals for 3 doses, was found to affect colour discrimination, night vision, reaction time, and stereopsis.[1]

1. Luria SM, *et al.* Effects of aspirin and dimenhydrinate (Dramamine) on visual processes. *Br J Clin Pharmacol* 1979; **7:** 585–93.

Porphyria. Dimenhydrinate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. For discussion of the use of antihistamines in pregnancy, including a suggestion of a relationship between cardiovascular defects or inguinal hernia and dimenhydrinate exposure, see p.563.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Dimenhydrinate, a monoethanolamine derivative, is a sedating antihistamine with antimuscarinic and significant sedative effects. It is used mainly as an antiemetic in the prevention and treatment of motion sickness (p.564). It is also used for the symptomatic treatment of nausea and vertigo caused by Ménière's disease and other vestibular disturbances (see Vertigo, p.565).

The usual oral dose of dimenhydrinate is 50 to 100 mg, given 3 or 4 times daily. For the prevention of motion sickness, the first dose should be given at least 30 minutes before travelling. Typical doses for children, according to age, are: 2 to up to 6 years, 12.5 to 25 mg every 6 to 8 hours to a maximum of 75 mg daily (in some countries lower doses of 6.25 to 12.5 mg are given two or three times daily); 6 to 12 years, 25 to 50 mg every 6 to 8 hours to a maximum of 150 mg daily (again lower doses are used in some countries).

Dimenhydrinate may be given parenterally in usual doses of 50 mg, a concentration of 5% being used for intramuscular injection and 0.5% for slow intravenous injection (usually over 2 minutes). Children have been given dimenhydrinate by intramuscular or slow intravenous injection in a dose of 1.25 mg/kg four times daily to a maximum of 300 mg daily.

Dimenhydrinate has also been given by the rectal route.

Preparations

BP 2008: Dimenhydrinate Tablets;
USP 31: Dimenhydrinate Injection; Dimenhydrinate Syrup; Dimenhydrinate Tablets.

Proprietary Preparations (details are given in Part 3)

Dimetindene Maleate *(BANM, rINNM)*

Dimethindene Maleate *(USAN)*; Dimethpyrindene Maleate; Dimethylpyrindene Maleate; Dimetindeenimaleaatti; Dimetinden Maleat; Dimétindène, maléate de; Dimetindeni maleas; Dimetindenmaleat; Dimetindén-maleát; Dimetinden-maleinát; Dimetindeno maleatas; Maleato de dimetindeno; NSC-107677; Su-6518. *NN*-Dimethyl-2-{3-[1-(2-pyridyl)ethyl]-1*H*-inden-2-yl}ethylamine hydrogen maleate.

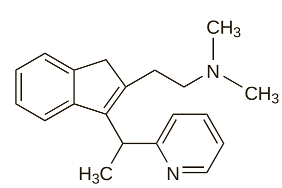
Диметиндена Малеат

$C_{20}H_{24}N_2,C_4H_4O_4$ = 408.5.

CAS — 5636-83-9 (dimetindene); 3614-69-5 (dimetindene maleate).

ATC — D04AA13; R06AB03.

ATC Vet — QD04AA13; QR06AB03.



(dimetindene)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Dimetindene Maleate). A white to almost white, crystalline powder. Slightly soluble in water; soluble in methyl alcohol. Protect from light.

Profile

Dimetindene maleate, an alkylamine derivative, is a sedating antihistamine (p.561); it is mildly sedative and is reported to have mast-cell stabilising properties. It is used for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565) and rhinitis (p.565), and in pruritic skin disorders (p.565). It is also used in compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

Dimetindene maleate is given in an oral dose of 1 to 2 mg three times daily; modified-release preparations are also available. It may also be given by the intravenous route. Dimetindene maleate is applied topically as a 0.1% gel or lotion although, as with other antihistamines, there is a risk of sensitisation. It is used in a strength of 0.025% in compound nasal preparations.

Preparations

Proprietary Preparations (details are given in Part 3)

Diphenhydramine Di(acefyllinate) *(rINNM)*

Benzhydramine Di(acefyllinate); Bietanautine; Di(acefilinato) de difenhidramina; Diphénhydramine Diacéfylline; Diphenhydramine Di(acephyllinate); Diphenhydramini Diacefyllinas. Diphenhydramine bis(theophyllin-7-ylacetate).

Дифенгидрамина Диацефиллинат

$C_{17}H_{21}NO,2C_9H_{10}N_4O_4 = 731.8.$

CAS — 6888-11-5.

ATC — D04AA32; R06AA02.

ATC Vet — QD04AA32; QR06AA02.

NOTE. The name Etanautine has been applied both to diphenhydramine monoacefyllinate and to ethylbenzhydramine, an antimuscarinic formerly used in the symptomatic treatment of parkinsonism.

Diphenhydramine Hydrochloride *(BANM, rINNM)*

Benzhydramine Hydrochloride; Difenhidramin Hidroklorür; Difenhidramin-hidroklorid; Difenhidramino hidrochloridas; Difenhydramiinihydrokloridi; Difenhydramin-hydrochlorid; Difenhydraminhydroklorid; Difenhydraminy chlorowodorek; Dimedrolum; Diphénhydramine, chlorhydrate de; Diphenhydramini hydrochloridum; Diphenhydraminium Chloride; Hidrocloruro de difenhidramina.

Дифенгидрамина Гидрохлорид

$C_{17}H_{21}NO,HCl = 291.8.$

CAS — 147-24-0.

ATC — D04AA32; R06AA02.

ATC Vet — QD04AA32; QR06AA02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Jpn also includes Diphenhydramine Tannate.

Ph. Eur. 6.2 (Diphenhydramine Hydrochloride). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. A 5% solution in water has a pH of 4.0 to 6.0. Protect from light.

USP 31 (Diphenhydramine Hydrochloride). A white, odourless, crystalline powder. It slowly darkens on exposure to light. Soluble 1 in 1 of water, 1 in 2 of alcohol and of chloroform, and 1 in 50 of acetone; very slightly soluble in ether and in benzene. Its solutions are neutral to litmus. Store in airtight containers. Protect from light.

Incompatibility. Diphenhydramine hydrochloride has been reported to be incompatible with amphotericin B, cefmetazole sodium, cefalotin sodium, hydrocortisone sodium succinate, some soluble barbiturates, some contrast media, and solutions of alkalis or strong acids.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Abuse. Reports of the abuse of diphenhydramine hydrochloride.

2. Santora J, Rozek S. Diphenhydramine-induced dystonia. *Clin Pharm* 1989; **8:** 471.
3. Roila F, *et al.* Diphenhydramine and acute dystonia. *Ann Intern Med* 1989; **111:** 92–3.

Overdosage. In an evaluation of 136 cases, one fatal, of intoxication with diphenhydramine, the plasma concentration was correlated with frequency or extent of symptoms.[1] The most common symptom was impaired consciousness; psychosis, seizures, antimuscarinic symptoms such as mydriasis, tachycardia, and tachyarrhythmias, and respiratory failure were also observed. The positive association between dose and frequency and severity of symptoms was confirmed in a more recent study;[2] it was also found that severe symptoms were more likely to occur when 1 g or more of diphenhydramine had been taken.

There have been reports[3,4] of rhabdomyolysis as an effect of oral diphenhydramine overdosage. The liberal application of a lotion containing diphenhydramine produced acute delirium with visual and auditory hallucinations in a 9-year-old boy[5] and similar effects were seen in 3 children with varicella-zoster infection following the topical application of diphenhydramine (2 of these children also received oral diphenhydramine).[6]

1. Köppel C, Tenczer J. Clinical symptomatology of diphenhydramine overdose: an evaluation of 136 cases in 1982 to 1985. *Clin Toxicol* 1987; **25:** 53–70.

6. Chan CYJ, Wallander KA. Diphenhydramine toxicity in three children with varicella-zoster infection. *DICP Ann Pharmacother* 1991; **25:** 130–2.

Porphyria. Diphenhydramine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. A pregnant woman who was receiving diphenhydramine hydrochloride 150 mg daily for a pruritic rash gave birth to an infant who developed diarrhoea and generalised tremulousness 5 days later.[1] The delay in appearance of withdrawal symptoms was considered to be due to reduced activity of glucuronyl conjugating enzymes in the first few days of life.

For discussion of the use of antihistamines in pregnancy, including a suggestion of a relationship between inguinal hernia or genito-urinary malformations and diphenhydramine exposure, see p.563. See also under Interactions, below, for a report of perinatal death possibly associated with temazepam and diphenhydramine.

1. Parkin DE. Probable Benadryl withdrawal manifestations in a new-born infant. *J Pediatr* 1974; **85:** 580.

Interactions

As for the sedating antihistamines in general, p.563. Diphenhydramine inhibits the cytochrome P450 isoenzyme CYP2D6 that is partly responsible for the metabolism of some beta blockers including metoprolol and the antidepressant venlafaxine.

Benzodiazepines. There has been a report[1] suggesting that a reduction in *temazepam* metabolism caused by diphenhydramine may have contributed to perinatal death after ingestion of these drugs by the mother.

1. Kargas GA, *et al.* Perinatal mortality due to interaction of diphenhydramine and temazepam. *N Engl J Med* 1985; **313:** 1417–18.

Pharmacokinetics

Diphenhydramine hydrochloride is well absorbed from the gastrointestinal tract, although high first-pass metabolism appears to affect systemic availability. Peak plasma concentrations are achieved about 1 to 4 hours after oral doses. Diphenhydramine is widely distributed throughout the body including the CNS. It crosses the placenta and has been detected in breast milk. Diphenhydramine is highly bound to plasma proteins. Metabolism is extensive. Diphenhydramine is excreted mainly in the urine as metabolites; little is excreted as unchanged drug. The elimination half-life has been reported to range from 2.4 to 9.3 hours.

Uses and Administration

Diphenhydramine, a monoethanolamine derivative, is a sedating antihistamine with antimuscarinic and pronounced sedative properties. It is used for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565) and conjunctivitis (p.564), and in pruritic skin disorders (p.565). It is also used for its antiemetic properties in the treatment of nausea and vomiting (p.564), particularly in the prevention and treatment of motion sickness (when it should be given at least 30 minutes before travelling), and in the treatment of vertigo of various causes (p.565). Diphenhydramine is used for its antimuscarinic properties in the control of parkinsonism (p.791) and drug-induced extrapyramidal disorders (p.971) (although the possibility that diphenhydramine itself may cause extrapyramidal symptoms should be remembered). Diphenhydramine has pronounced central sedative properties and may be used as a hypnotic in the short-term management of insomnia (p.564). It is a common ingredient of compound preparations for symptomatic treatment of coughs and the common cold (p.564). However, such preparations should be used with caution in children, and generally avoided in those under 2 years of age (see p.562). It may also be given in combination preparations containing analgesics, particularly paracetamol. Diphenhydramine may be used parenterally as an adjunct in the emergency treatment of anaphylactic shock (p.563) or when oral therapy is not feasible.

For most indications, diphenhydramine hydrochloride is given in usual oral doses of 25 to 50 mg three or four times daily. The dose for children is 6.25 to 25 mg three or four times daily, or a total daily dose of 5 mg/kg may be given in divided doses. The maximum dose in adults and children is about 300 mg daily. A dose of 20 to 50 mg may be used as a hypnotic in adults and children over 12 years old.

When oral therapy is not feasible, diphenhydramine hydrochloride may be given by deep intramuscular injection or by intravenous injection using concentrations of 1% or 5%. Usual doses are 10 to 50 mg, although doses of 100 mg have been given. No more than 400 mg should be given in 24 hours. Children may be given 5 mg/kg daily in divided doses to a maximum of 300 mg in 24 hours. Diphenhydramine hydrochloride is applied topically, usually in preparations containing 1 to 2% although, as with other antihistamines, there is a risk of sensitisation.

Diphenhydramine citrate is given orally in a dose of 76 mg at night in combination preparations for its hypnotic action. Diphenhydramine di(acefyllinate) is given as an antiemetic for the prevention and treatment of motion sickness. The usual oral dose is 90 to 135 mg, which may be repeated if necessary at intervals of at least 6 hours, to a maximum of 540 mg daily. Other diphenhydramine salts that have been used include the polistirex, the salicylate, and the tannate by mouth, the methylbromide rectally, and the metilsulfate applied topically.

Dimenhydrinate (p.576) is diphenhydramine teoclate and mefenidramium metilsulfate is diphenhydramine methylsulfomethylate.

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

◊ References.

1. Graham G, Bolt AG. Half-life of diphenylpyraline in man. *J Pharmacokinet Biopharm* 1974; **2:** 191–5 (ranged from 24 to 40 hours).

Uses and Administration

Diphenylpyraline hydrochloride, a piperidine derivative, is a sedating antihistamine with antimuscarinic and significant sedative properties.

It has been given for the symptomatic relief of allergic conditions including rhinitis (p.565), and in pruritic skin disorders (p.565). It has also been used in compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

Diphenylpyraline hydrochloride has been given in an oral dose of up to 6 mg daily in 3 or 4 divided doses. Diphenylpyraline and diphenylpyraline hydrochloride have been applied topically although, as with other antihistamines, there is a risk of sensitisation.

Diphenylpyraline teoclate is piprinhydrinate (p.588).

(doxylamine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Doxylamine Hydrogen Succinate; Doxylamine Succinate BP 2008). A white or almost white powder. Very soluble in water; freely soluble in alcohol.

USP 31 (Doxylamine Succinate). A white or creamy-white powder having a characteristic odour. Soluble 1 in 1 of water, 1 in 2 of alcohol and of chloroform, and 1 in 370 of ether; very slightly soluble in benzene. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. The controversy surrounding the use in pregnancy of combination products of doxylamine is discussed on p.563.

Overdosage. In an evaluation of 109 cases of intoxication with doxylamine,[1] no correlation was found between the amount ingested or plasma concentration and the frequency or extent of symptoms. The most common symptom was impaired consciousness. Psychotic behaviour, seizures, and antimuscarinic symptoms such as tachycardia and mydriasis were also observed. Rhabdomyolysis occurred in one patient and was accompanied by transient impairment of renal function. The same group commented[2] that rhabdomyolysis had been noted in 7 of 442 cases of doxylamine overdosage, with an associated rise in plasma creatine kinase and myoglobinuria, and suggested that doxylamine has a direct toxic effect on striated muscle.

2. Köppel C, *et al.* Rhabdomyolysis in doxylamine overdose. *Lancet* 1987; **i:** 442–3.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

After oral doses of doxylamine succinate peak plasma concentrations occur after 2 to 3 hours. An elimination half-life of about 10 hours has been reported.

◊ References.

Uses and Administration

Doxylamine succinate, a monoethanolamine derivative, is a sedating antihistamine with antimuscarinic and pronounced sedative effects.

Doxylamine succinate is given for the symptomatic relief of hypersensitivity reactions, in pruritic skin disorders (p.565), as a hypnotic in the short-term treatment of insomnia (p.564), and as an ingredient of compound preparations for symptomatic treatment of coughs and the common cold (p.564).

In general it is no longer used in the management of nausea and vomiting of early pregnancy (see p.563 for the controversy that has surrounded the use in pregnancy of combination products of doxylamine).

Oral doses of up to 25 mg of doxylamine succinate have been given every 4 to 6 hours to a maximum of 150 mg daily. The usual hypnotic dose is 25 mg orally at night.

Preparations

USP 31: Acetaminophen, Dextromethorphan Hydrobromide, Doxylamine Succinate, and Pseudoephedrine Hydrochloride Oral Solution; Doxylamine Succinate Syrup; Doxylamine Succinate Tablets.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Ebastine). A white or almost white crystalline powder. M.p. about 86°. Practically insoluble in water; very soluble in dichloromethane; sparingly soluble in methyl alcohol. Protect from light.

Profile

Ebastine, a piperidine derivative, is a non-sedating antihistamine (p.561) with a long duration of action. It does not have significant sedative or antimuscarinic actions.

Ebastine is given for the symptomatic relief of allergic conditions including rhinitis (p.565) and in pruritic skin disorders (p.565). The usual oral dose is 10 to 20 mg daily. It is also used with a decongestant such as pseudoephedrine hydrochloride.

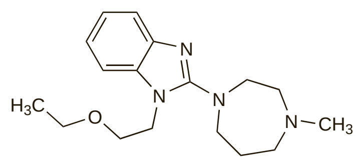
ATC — S01GX06.
ATC Vet — QS01GX06.



(emedastine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Emedastine Difumarate). A white or yellowish powder. It exhibits polymorphism. Soluble in water; sparingly soluble in dehydrated alcohol; very slightly soluble in acetone. A 0.2% solution in water has a pH of 3.0 to 4.5. Protect from light.

USP 31 (Emedastine Difumarate). A white to faintly yellow crystalline powder. Soluble in water. pH of a 0.2% solution in water is between 3.0 and 4.5. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the antihistamines in general, p.561.

Ocular corneal infiltrates, local irritation, photophobia, rhinitis, and headaches have been reported after use of emedastine eye drops. Treatment should be stopped if corneal infiltrates develop.

Pharmacokinetics

Emedastine is absorbed from the gastrointestinal tract, peak plasma concentrations being attained about 3 hours after an oral dose. It is mainly metabolised in the liver to two primary metabolites 5- and 6-hydroxyemedastine which are excreted in the urine along with a small amount of unchanged drug. Small amounts of emedastine are absorbed after application to the eye. The elimination half-life is reported to be 7 hours after an oral dose and 10 hours following topical use.

Uses and Administration

Emedastine is an antihistamine. It is instilled twice daily as the fumarate as eye drops containing the equivalent of 0.05% of emedastine for the symptomatic relief of allergic conjunctivitis (p.564). It is also given orally in usual doses of 2 to 4 mg of the fumarate daily in two divided doses for allergic rhinitis (p.565), urticaria (p.565), and pruritic skin disorders (p.565).

Preparations

USP 31: Emedastine Ophthalmic Solution.

(fexofenadine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Fexofenadine Hydrochloride). A white or almost white powder. Slightly soluble in water; freely soluble in methyl alcohol; very slightly soluble in acetone. It exhibits polymorphism.

USP 31 (Fexofenadine Hydrochloride). Store at a temperature of 20° to 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561.

Arrhythmias. A 67-year-old man suffered syncope after taking fexofenadine 180 mg daily for 2 months.[1] His ECG showed an abnormally prolonged QT interval which shortened once fexofenadine was stopped, although the interval tended to be long even without drug therapy. Nonetheless rechallenge was positive. The manufacturers of fexofenadine have commented[2] that the patient was at risk of developing arrhythmias before taking the drug.

The symbol † denotes a preparation no longer actively marketed

The ECG effects of fexofenadine have been studied[3] in normal subjects and doses of up to 480 mg daily [4 times the recommended dose for seasonal allergic rhinitis] did not prolong the QT interval. See also p.562.

1. Pinto YM, *et al.* QT lengthening and life-threatening arrhythmias associated with fexofenadine. *Lancet* 1999; **353:** 980.
2. Giraud T. QT lengthening and arrhythmias associated with fexofenadine. *Lancet* 1999; **353:** 2072.
3. Pratt CM, *et al.* Cardiovascular safety of fexofenadine HCl. *Am J Cardiol* 1999; **83:** 1451–4.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving fexofenadine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding.

See also under Adverse Effects and Precautions, in Terfenadine, p.590.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/04/04)

Psoriasis. Exacerbation of psoriasis has been reported[1] in association with the use of fexofenadine.

1. Saraswat A, Saraswat M. Pustular exacerbation of psoriasis due to fexofenadine. *Clin Exp Dermatol* 2006; **31:** 477–8.

Interactions

As for the non-sedating antihistamines in general, p.563.

Plasma concentrations of fexofenadine have been increased when given with erythromycin or ketoconazole, but, unlike terfenadine, licensed product information states that this was not associated with adverse effects on the QT interval.

Antacids containing aluminium and magnesium hydroxide have reduced the absorption of fexofenadine. Fruit juices including grapefruit may reduce the bioavailability of fexofenadine and use together should be avoided.

◊ References.

1. Dresser GK, *et al.* Effect of grapefruit juice volume on the reduction of fexofenadine bioavailability: possible role of organic anion transporting polypeptides. *Clin Pharmacol Ther* 2005; **77:** 170–7.

Pharmacokinetics

Fexofenadine is rapidly absorbed after oral doses with peak plasma concentrations being reached in 2 to 3 hours. It is about 60 to 70% bound to plasma proteins. About 5% of the total dose is metabolised, mostly by the intestinal mucosa, with only 0.5 to 1.5% of the dose undergoing hepatic biotransformation by the cytochrome P450 system. Elimination half-life of about 14 hours has been reported although this may be prolonged in patients with renal impairment. Excretion is mainly in the faeces with only 10% being present in the urine. Fexofenadine does not appear to cross the blood-brain barrier.

Fexofenadine is a metabolite of terfenadine and as such has been detected in breast milk after the administration of terfenadine.

◊ References.

1. Russell T, *et al.* Pharmacokinetics, pharmacodynamics, and tolerance of single- and multiple-dose fexofenadine hydrochloride in healthy male volunteers. *Clin Pharmacol Ther* 1998; **64:** 612–21.

Uses and Administration

Fexofenadine, an active metabolite of terfenadine (p.590), is a non-sedating antihistamine. It does not possess significant sedative or antimuscarinic actions. Fexofenadine is used as the hydrochloride in the symptomatic relief of allergic conditions including seasonal allergic rhinitis (p.565) and chronic urticaria (p.565).

In the UK a dose of fexofenadine hydrochloride 120 mg once daily is given orally in the treatment of seasonal allergic rhinitis; the recommended dose in chronic idiopathic urticaria is 180 mg once daily. US licensed product information suggests a dose of 60 mg twice daily or 180 mg once daily for both indications.

Fexofenadine is also used with a decongestant such as pseudoephedrine hydrochloride.

For doses in children or in patients with renal impairment, see below.

◊ References.

1. Markham A, Wagstaff AJ. Fexofenadine. *Drugs* 1998; **55:** 269–74.

5. Mansfield LE. Once-daily immediate-release fexofenadine and sustained-release pseudoephedrine combination: a new treatment option for allergic rhinitis. *Expert Opin Pharmacother* 2006; **7:** 941–51.

Administration in children. Fexofenadine hydrochloride is used in children for the treatment of seasonal allergic rhinitis in an oral dose of 30 mg twice daily; in the UK it is licensed for use in children aged 6 to 11 years whereas in the USA it may be used in children as young as 2 years.

In the USA, fexofenadine is also licensed for use in paediatric chronic idiopathic urticaria. The dose in children aged 6 months to less than 2 years is 15 mg twice daily; older children may be given 30 mg twice daily.

For suggested doses in children with renal impairment see below.

Administration in renal impairment. US licensed product information recommends that initial oral doses of fexofenadine hydrochloride in adults with renal impairment should be reduced to 60 mg once daily. In children with renal impairment, the initial dose should be reduced to 30 mg once daily in patients aged 2 to 11 years, and to 15 mg once daily in children aged 6 months to less than 2 years.

UK product information advises that fexofenadine should be given with caution to patients with renal impairment; however, it also states that dose adjustment is not considered to be necessary in such patients.

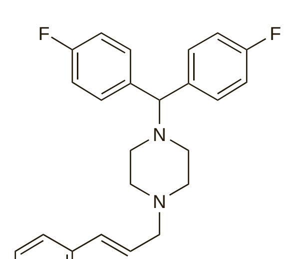
CAS — 52468-60-7 (flunarizine); 30484-77-6 (flunarizine hydrochloride).

ATC — N07CA03.

ATC Vet — QN07CA03.



(flunarizine)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Flunarizine Dihydrochloride). A white or almost white hygroscopic powder. Slightly soluble in water, in alcohol, and in dichloromethane; sparingly soluble in methyl alcohol. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Adverse effects also seen with flunarizine include weight gain, extrapyramidal symptoms (sometimes associated with depression), and, rarely, galactorrhoea.

Extrapyramidal disorders. Extrapyramidal motor signs (including parkinsonism, orofacial tardive dyskinesia, and akathisia) have been reported in 12 patients given flunarizine 10 to 40 mg daily for between 3 weeks and 15 months; 11 also had mental depression.[1] Partial or complete improvement of symptoms occurred after withdrawal of flunarizine. There have been other reports of similar effects,[2-5] but the association with flunarizine has not always been certain. Some workers have commented that flunarizine is often used in patients at increased risk of depression (migraine and geriatric patients) or extrapyramidal symptoms (geriatric patients)[2,6] or that flunarizine may unmask subclinical idiopathic Parkinson's disease.[6,7]

Extrapyramidal signs, including parkinsonism, have also been associated with the related drug, cinnarizine.[3-5] It has been suggested that such effects may be less likely to occur with cinnarizine than with flunarizine because of its shorter half-life and lower lipophilicity.[3]

1. Chouza C, *et al.* Parkinsonism, tardive dyskinesia, akathisia, and depression induced by flunarizine. *Lancet* 1986; **i:** 1303–4.
2. Meyboom RHB, *et al.* Parkinsonism, tardive dyskinesia, akathisia, and depression induced by flunarizine. *Lancet* 1986; **ii:** 292.

6. Amery W. Side-effects of flunarizine. *Lancet* 1986; **i:** 1497.
7. Benvenuti F, *et al.* Side-effects of flunarizine. *Lancet* 1986; **ii:** 464.

Porphyria. Flunarizine hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

As for the sedating antihistamines in general, p.563.

Hepatic enzyme inducers such as carbamazepine, phenytoin, and valproate may interact with flunarizine by increasing its metabolism; an increase in dosage of flunarizine may be required.

Pharmacokinetics

Flunarizine hydrochloride is well absorbed from the gastrointestinal tract, peak plasma concentrations occurring 2 to 4 hours after oral doses. Flunarizine hydrochloride is very lipophilic and is more than 90% bound to plasma proteins. It appears to undergo extensive metabolism; metabolites are excreted principally in the bile. Flunarizine hydrochloride has an elimination half-life of about 18 days.

Uses and Administration

Flunarizine is the difluorinated derivative of cinnarizine. It has antihistamine, sedative, and calcium-channel blocking activity. Flunarizine hydrochloride is used for migraine prophylaxis, for vertigo and vestibular disorders, and for peripheral and cerebral vascular disorders. It has also been used as adjunctive antiepileptic therapy in patients refractory to standard regimens.

Flunarizine is given orally as the hydrochloride although doses are expressed in terms of the base. Flunarizine hydrochloride 11.8 mg is equivalent to about 10 mg of flunarizine. The usual dose is 5 to 10 mg daily, usually given at night to minimise the effects of drowsiness.

Epilepsy. A number of drugs with calcium-channel blocking activity have been investigated as adjuncts in epilepsy (p.465), including flunarizine. Some individual studies have reported benefit, but a systematic review[1] concluded that although flunarizine might have a weak effect on seizure frequency the evidence was not convincing, and the withdrawal rate was significant, probably because of poor tolerability; it should therefore not be recommended as adjunctive antiepileptic therapy. The pharmacokinetic profile of flunarizine may in any case be too complex for clinical use as an antiepileptic.[2]

1. Chaisewikul R, *et al.* Calcium antagonists as an add-on therapy for drug-resistant epilepsy. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2001 (accessed 13/06/05).
2. Hoppu K, *et al.* Flunarizine of limited value in children with intractable epilepsy. *Pediatr Neurol* 1995; **13:** 143–7.

Migraine. Flunarizine reduces the frequency of migraine attacks in both adult and paediatric patients and is used for the prophylaxis of migraine (p.616) in some countries. Its effects are comparable with several other prophylactic antimigraine drugs, including the generally preferred propranolol,[1-4] but it is more likely to be reserved for use when first-line drugs have proved to be ineffective or unsuitable. Its mode of action in migraine is unclear; possible mechanisms are inhibition of vasospasm induced by mediators such as serotonin and prostaglandins, inhibition of cellular hypoxia, and improved blood viscosity and erythrocyte deformability. Calcium-channel blocking activity might have a role, but evidence for the efficacy of other calcium-channel blockers in migraine prophylaxis (see Nifedipine, p.1355) is less convincing than for flunarizine.

Case reports have indicated benefit with flunarizine in the prophylaxis of the rare disorder of alternating hemiplegia in childhood[5,6] but a subsequent study[7] in 12 children did not produce conclusive findings. A later long-term study[8] reported that 7 of 9 children given flunarizine for up to 5 years for hemiplegia showed a reduction in the duration of attacks, and 3 had a reduction in frequency, but only 1 of these obtained a complete cessation of episodes.

The role of antihistamines in general in the management of migraine is discussed briefly on p.564.

8. Silver K, Andermann F. Alternating hemiplegia of childhood: a study of 10 patients and results of flunarizine treatment. *Neurology* 1993; **43:** 36–41.

Tourette's syndrome. A small unblinded study[1] involving 7 patients has suggested that flunarizine is more effective than placebo in the treatment of Tourette's syndrome (see Tics, p.954).

1. Micheli F, *et al.* Treatment of Tourette's syndrome with calcium antagonists. *Clin Neuropharmacol* 1990; **13:** 77–83.

Vertigo. Antihistamines are the mainstay of the treatment of vertigo (p.565). However, their antimuscarinic adverse effects may prove troublesome, particularly in the elderly, and they produce central sedation. Flunarizine is devoid of antimuscarinic properties, although it may produce central sedation.

(homochlorcyclizine)

Pharmacopoeias. In *Jpn.*

Profile

Homochlorcyclizine hydrochloride, a piperazine derivative, is a sedating antihistamine (p.561) with antimuscarinic and moderate sedative properties. It is used for the symptomatic relief of allergic conditions including urticaria (p.565) and rhinitis (p.565), and in pruritic skin disorders (p.565). It is given in oral doses of 10 to 20 mg three times daily.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Hydroxyzine Hydrochloride). A white or almost white, crystalline, hygroscopic powder. Freely soluble in water and in alcohol; very slightly soluble in acetone. Store in airtight containers. Protect from light.

USP 31 (Hydroxyzine Hydrochloride). A white, odourless, powder. Soluble 1 in 1 of water, 1 in 4.5 of alcohol, and 1 in 13 of chloroform; slightly soluble in acetone; practically insoluble in ether. Store in airtight containers.

Incompatibility. Hydroxyzine hydrochloride has been reported to be incompatible with aminophylline, benzylpenicillin salts, chloramphenicol sodium succinate, dimenhydrinate, doxorubicin hydrochloride (in a liposomal formulation), thioridazine, and some soluble barbiturates.

Stability. A mixture of hydroxyzine hydrochloride, chlorpromazine hydrochloride, and pethidine hydrochloride stored in glass or plastic syringes was found[1] to be stable for 366 days at 4° and 25°.

1. Conklin CA, *et al.* Stability of an analgesic-sedative combination in glass and plastic single-dose syringes. *Am J Hosp Pharm* 1985; **42:** 339–42.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Intramuscular injection of hydroxyzine has been reported to cause marked local discomfort. Intravenous use has been associated with haemolysis.

Amputation. Accidental intra-arterial injection of hydroxyzine has led to necrosis of the extremity requiring amputation of the digits of the affected limb.[1]

1. Hardesty WH. Inadvertent intra-arterial injection. *JAMA* 1970; **213:** 872.

Arrhythmias. ECG abnormalities, particularly alterations in T-waves, were associated with anxiolytic doses of hydroxyzine hydrochloride and were similar to those produced by thioridazine and tricyclic antidepressants.[1]

1. Hollister LE. Hydroxyzine hydrochloride: possible adverse cardiac interactions. *Psychopharmacol Comm* 1975; **1:** 61–5.

Effects on sexual function. A 32-year-old man had prolonged penile erections (priapism) after taking two separate doses of hydroxyzine for a skin rash.[1] It was suggested that the effect might be due to a hydroxyzine metabolite that was found to be structurally similar to a metabolite of trazodone, a drug known to induce penile erections.

1. Thavundayil JX. *et al.* Prolonged penile erections induced by hydroxyzine: possible mechanism of action. *Neuropsychobiology* 1994; **30:** 4–6.

Effects on the skin. Four children given hydroxyzine hydrochloride for restlessness developed a fixed drug eruption of the penis.[1] All recovered on drug withdrawal and subsequently had positive rechallenges.

1. Cohen HA, *et al.* Fixed drug eruption of the penis due to hydroxyzine hydrochloride. *Ann Pharmacother* 1997; **31:** 327–9.

Liver disorders. A study[1] has suggested that hydroxyzine should only be given once daily for the relief of pruritus in patients with primary biliary cirrhosis. The mean serum elimination half-lives of hydroxyzine and its metabolite cetirizine in 8 patients with primary biliary cirrhosis were 36.6 and 25.0 hours respectively.

1. Simons FER, *et al.* The pharmacokinetics and pharmacodynamics of hydroxyzine in patients with primary biliary cirrhosis. *J Clin Pharmacol* 1989; **29:** 809–15.

Porphyria. Hydroxyzine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Hydroxyzine is rapidly absorbed from the gastrointestinal tract and is metabolised. Metabolites include cetirizine (p.570), which has antihistaminic activity. An elimination half-life of about 20 hours has been reported.

◊ References.

1. Paton DM, Webster DR. Clinical pharmacokinetics of H -receptor antagonists (the antihistamines). *Clin Pharmacokinet* 1985; **10:** 477–97.

Liver disorders. For reference to a prolonged half-life of hydroxyzine in patients with primary biliary cirrhosis, see under Adverse Effects and Precautions, above.

Uses and Administration

Hydroxyzine, a piperazine derivative, is a sedating antihistamine with antimuscarinic and significant sedative properties; it is also an antiemetic. Its main use is as an anxiolytic (p.952) but see Anxiety Disorders below. It is also used as an adjunct to pre- and postoperative medication (see Anaesthesia, p.563) and in the management of pruritus (p.565) and urticaria (p.565) and has been used as an adjunct to opioid analgesia in the management of cancer pain (p.5).

Hydroxyzine may be given orally as the hydrochloride or the embonate; doses are expressed in terms of the hydrochloride. Hydroxyzine embonate 170 mg is equivalent to about 100 mg of hydroxyzine hydrochloride.

The usual oral doses in adults are: 50 to 100 mg four times daily for the short-term management of anxiety; for pruritus an initial dose of 25 mg given at night, increased if necessary to 25 mg three or four times daily; and 50 to 100 mg for pre- or postoperative sedation. For pruritus in children over 6 years of age the initial dose is 15 to 25 mg daily increased if necessary to 50 to 100 mg daily in divided doses; for children 6 months to 6 years old the initial dose is 5 to 15 mg daily increased if necessary to 50 mg daily in divided doses.

Alternatively, 1 mg/kg daily may be given in divided doses, to a maximum of 2.5 mg/kg daily in children aged 1 to 6 years, and to a maximum of 2 mg/kg daily in those aged 6 years and over. The pre- or postoperative sedative dose in children is 600 micrograms/kg. Dosage should be reduced in patients with hepatic or renal impairment, see below.

Hydroxyzine hydrochloride may also be given by deep intramuscular injection. For prompt control of anxiety or agitation in adults 50 to 100 mg is injected intramuscularly initially, and the dose may be repeated every four to six hours as required. For other indications when oral dosage is not practical, the intramuscular dose is 25 to 100 mg for adults and 1.1 mg/kg for children. Hydroxyzine should not be given by intravenous injection since haemolysis may result.

Administration in hepatic or renal impairment. In patients with hepatic impairment, UK licensed product information recommends a 33% reduction in the total oral daily dose of hydroxyzine. In patients with moderate or severe renal impairment, a dose reduction of 50% is recommended.

Anxiety disorders. Although hydroxyzine is used in the management of anxiety, there is little evidence to support its efficacy in anxious patients,[1] and the *BNF* considers that use of antihistamines solely for their sedative effect in anxiety is not appropriate.

1. Ballenger JC, *et al.* Consensus statement on generalized anxiety disorder from the International Consensus Group on Depression and Anxiety. *J Clin Psychiatry* 2001; **62** (suppl 11): 53–8. Available at: http://www.psychiatrist.com/private/supplenet/v62s11/v62s1108.pdf (accessed 15/08/08)

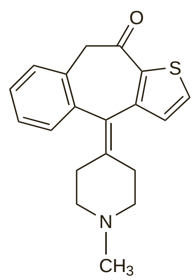
ATC — R06AX17; S01GX08.

ATC Vet — QR06AX17; QS01GX08.



(ketotifen)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Ketotifen Hydrogen Fumarate; Ketotifen Fumarate BP 2008). A white to brownish-yellow, fine crystalline powder. Sparingly soluble in water; very slightly soluble in acetonitrile; slightly soluble in methyl alcohol.

Adverse Effects and Precautions

As for the antihistamines in general, p.561; drowsiness may be a problem, and dry mouth and dizziness may occur at the beginning of treatment but usually resolve with continued use. Weight gain and CNS stimulation have been reported. Isolated cases of severe skin reactions, cystitis, and hepatitis have been reported. Irritation, pain, and punctate keratitis are commonly reported after topical application to the eye.

For precautions to be observed in asthmatic patients, see Sodium Cromoglicate, p.1136. Ketotifen may take several weeks to exert its full effect; existing anti-asthma treatment should not be abruptly withdrawn after starting ketotifen therapy. It should not be used for the treatment of acute asthma attacks.

Overdosage. Overdoses of ketotifen ranging from 10 to 120 mg were reported in 8 patients.[1] Symptoms included drowsiness, confusion, dyspnoea, bradycardia or tachycardia, disorientation, and convulsions. Gastric lavage was performed in 6 patients, and all 8 recovered within 12 hours after supportive treatment.

In an overview of 21 cases of overdosage (including those reported above) the manufacturers stated that no serious signs or symptoms had been reported with doses below 20 mg, and there had been no fatalities.[2] The most serious effects reported had included unconsciousness, convulsions, bradycardia and tachycardia, and a severe hypotensive reaction. Management is essentially supportive and symptomatic.

1. Jefferys DB, Volans GN. Ketotifen overdose: surveillance of the toxicity of a new drug. *BMJ* 1981; **282:** 1755–6.
2. Le Blaye I, *et al.* Acute ketotifen overdosage: a review of present clinical experience. *Drug Safety* 1992; **7:** 387–92.

Interactions

As for the sedating antihistamines in general, p.563.

A reversible fall in the platelet count has been seen in a few patients receiving ketotifen with oral antidiabetics and it has been suggested that this combination should therefore be avoided.

Pharmacokinetics

Ketotifen fumarate is almost completely absorbed from the gastrointestinal tract after oral doses, but bioavailability is reported to be only about 50% due to hepatic first-pass metabolism. Peak plasma concentrations occur 2 to 4 hours after an oral dose. It is mainly excreted in the urine as inactive metabolites with a small amount of unchanged drug; the terminal elimination half-life is about 21 hours.

Uses and Administration

Ketotifen is a sedating antihistamine (p.563) that also has a stabilising action on mast cells analogous to that of sodium cromoglicate (p.1137). It is used in the treatment of allergic conditions such as rhinitis (p.565) and conjunctivitis (p.564). Ketotifen has also been used in the prophylactic management of asthma, when it may take several weeks to exert its full effect; it should not be used to treat acute asthma attacks.

Ketotifen is given as the fumarate, but doses are expressed in terms of the base; ketotifen fumarate 1.38 mg is equivalent to about 1 mg of ketotifen.

Ketotifen fumarate is taken in oral doses equivalent to 1 mg of ketotifen twice daily with food, increased if necessary to 2 mg twice daily; 0.5 to 1 mg at night may be preferable for the first few days of treatment if drowsiness is likely to be a problem.

Ketotifen fumarate has also been applied topically, as eye drops equivalent to 0.025% ketotifen, used twice daily.

For children's doses, see below.

Action. It has been suggested that the anti-allergic action of ketotifen was independent of its antihistaminic properties.[1] This might be due to its effect on responses to platelet-activating factor (PAF).[2] However, the significance of PAF in the pathogenesis of asthma has been questioned.

1. Greenwood C. The pharmacology of ketotifen. *Chest* 1982; **82** (suppl): 45S–8S.
2. Morley J, *et al.* Effects of ketotifen upon responses to platelet activating factor: a basis for asthma prophylaxis. *Ann Allergy* 1986; **56:** 335–40.

Administration in children. Ketotifen fumarate can be given to children for the treatment of allergic conditions such as rhinitis (p.565) or conjunctivitis (p.564), and has been used in the prophylactic management of asthma. Oral doses equivalent to 1 mg of ketotifen twice daily with food may be used from 3 years of age. A dose equivalent to 500 micrograms ketotifen twice daily has been suggested in children between 6 months and 3 years of age.

Ketotifen fumarate has also been applied topically twice daily, as eye drops equivalent to 0.025% ketotifen, in children from 3 years of age.

Asthma. Results of studies on the effectiveness of ketotifen in the treatment of asthma (p.1108) have been conflicting; although some have found it effective in reducing symptoms[1-4] and in enabling a reduction in use of other anti-asthmatic drugs,[2,4] others have reported no significant benefits,[5,6] and UK guidelines on the management of asthma consider ketotifen to be ineffective.[7] A systematic review[8] found that it was of benefit in improving control of asthma and wheezing in children with mild to moderate disease, but noted that the high prevalence of atopy in several of the studies reviewed meant that the results might not be generalisable to children with asthma in general. A study in children described as 'preasthmatic' (that is, being at high risk of developing asthma) suggested that long-term therapy with ketotifen decreased the risk of asthma onset.[9]

Levocabastine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de levocabastina; Lévocabastine, chlorhydrate de; Levocabastini hydrochloridum; Levokabastiinihydrokloridi; Levokabastin-hydrochlorid; Levokabastinhydroklorid; Levokabastino hidrochloridas; Levokabasztin-hidroklorid; R-50547. (−)-*trans*-1-[*cis*-4-Cyano-4-(*p*-fluorophenyl)cyclohexyl]-3-methyl-4-phenylisonipecotic acid hydrochloride.

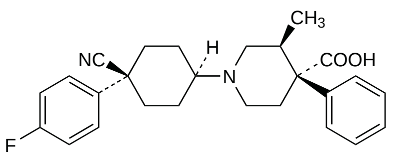
Левокабастина Гидрохлорид

$C_{26}H_{29}FN_2O_2,HCl$ = 457.0.

CAS — 79516-68-0 (levocabastine); 79547-78-7 (levocabastine hydrochloride); 79449-98-2 (cabastine).

ATC — R01AC02; S01GX02.

ATC Vet — QR01AC02; QS01GX02.



(levocabastine)

NOTE. Cabastine *(rINN)* is the racemate of levocabastine.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Levocabastine Hydrochloride). A white or almost white powder. Practically insoluble in water; slightly soluble in alcohol and in a 0.2% solution of sodium hydroxide; sparingly soluble in methyl alcohol. Protect from light.

USP 31 (Levocabastine Hydrochloride). Protect from light.

Adverse Effects and Precautions

As for the antihistamines in general, p.561. The most common adverse effects reported with levocabastine eye drops are transient stinging and burning of the eyes, urticaria, dyspnoea, drowsiness, and headache. With nasal use headache, nasal irritation, somnolence, and fatigue have been noted. The use of levocabastine nasal spray is not recommended in those with significant renal impairment.

Pharmacokinetics

Levocabastine is absorbed after both nasal and ocular use. Systemic availability has been estimated at 60 to 80% after nasal doses and 30 to 60% after ocular use. However absolute peak plasma concentrations are low. Plasma protein binding is about 55%. An elimination half-life of 35 to 40 hours has been reported for all routes of delivery. Elimination of levocabastine is primarily renal with 70% excreted as unchanged drug and 10% as an inactive acetylglucuronide metabolite; the remaining 20% is excreted unchanged in the faeces.

Trace amounts of levocabastine have been found in breast milk after ocular and nasal use.

Uses and Administration

Levocabastine, a piperidine derivative, is a long-acting and potent antihistamine with a rapid onset of action. Levocabastine hydrochloride equivalent to 0.05% levocabastine is used topically twice daily as eye drops or as a nasal spray in the treatment of allergic conjunctivitis (p.564) and rhinitis (p.565), respectively, in adults and children aged 9 years and over. The frequency of the dose in both conditions may be increased to 3 or 4 times daily if necessary. In conjunctivitis it is recommended that treatment should be stopped if there is no improvement within 3 days.

Levocetirizine *(BAN, USAN, rINN)*

Levocetirizina; Lévocétirizine; Levocetirizinum. (2-{4-[(*R*)-*p*-Chloro-α-phenylbenzyl]-1-piperazinyl}ethoxy)acetic acid.

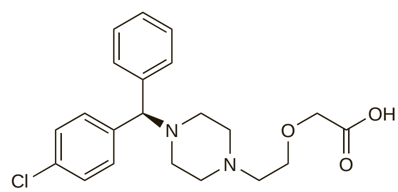
Левоцетиризин

$C_{21}H_{25}ClN_2O_3$ = 388.9.

CAS — 130018-77-8.

ATC — R06AE09.

ATC Vet — QR06AE09.



Levocetirizine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de levocetirizina; Lévocétirizine, Chlorhydrate de; Levocetirizine Dihydrochloride *(USAN)*; Levocetirizini Hydrochloridum; UCB-28556.

Левоцетиризина Гидрохлорид

$C_{21}H_{25}ClN_2O_3,2HCl$ = 461.8.

CAS — 130018-87-0.

ATC — R06AE09.

ATC Vet — QR06AE09.

Profile

Levocetirizine is the *R*-enantiomer of cetirizine (p.570) and is used similarly, as the hydrochloride, for the symptomatic relief of allergic conditions including rhinitis (p.565) and chronic urticaria (p.565). The usual oral dose of levocetirizine hydrochloride is 5 mg once daily. US licensed product information suggests that the dose should be given in the evening, and that a dose of 2.5 mg may be adequate in some patients.

For doses in children or in patients with renal impairment, see below.

Administration in children. Levocetirizine hydrochloride may be given orally to children for the symptomatic relief of allergic rhinitis and chronic idiopathic urticaria, although licensed doses may vary between countries. In the UK, children aged 2 to 6 years may be given a dose of 2.5 mg daily in 2 divided doses, and those older than 6 years may be given the adult dose of 5 mg daily. In the USA, however, levocetirizine hydrochloride is not recommended for children under 6 years of age. In those aged 6 to 11 years, a dose of 2.5 mg once daily in the evening may be given, and the adult dose of 5 mg daily only given to children aged 12 years and older.

For doses in children with renal impairment, see below.

Administration in renal impairment. The dose of levocetirizine hydrochloride should be reduced in patients with renal impairment according to creatinine clearance (CC), although recommendations can vary between countries. The following oral doses have been suggested for adults in the UK and for adults and adolescents aged 12 years and over in the USA:

- CC 50 to 79 mL/minute: 5 mg once daily in the UK; 2.5 mg once daily in the USA
- CC 30 to 49 mL/minute: 5 mg every other day in the UK; 2.5 mg every other day in the USA
- CC 10 to 29 mL/minute: 5 mg once every 3 days in the UK; 2.5 mg once every 3 or 4 days in the USA
- CC less than 10 mL/minute and patients undergoing dialysis: contra-indicated in both the UK and USA

Data are lacking for the use of levocetirizine in children with renal impairment. UK licensed product information suggests that the dose should be adjusted on an individual basis, taking into account the patient's renal clearance and body-weight.

Preparations

Proprietary Preparations (details are given in Part 3)

Arg.: Levomine; Supraler; ***Austria:*** Xyzall; ***Belg.:*** Xyzall; ***Braz.:*** Zyxem; ***Chile:*** Degraler; Neo Alertop; ***Cz.:*** Xyzal; ***Denm.:*** Xyzal; ***Fin.:*** Xyzal; ***Fr.:*** Xyzall; ***Ger.:*** Xusal; ***Gr.:*** Xozal; ***Hong Kong:*** Xyzal; ***Hung.:*** Xyzal; ***India:*** L-Cetridoc†; Leset; Levorid; Teczine; ***Indon.:*** Xyzal; ***Irl.:*** Xyzal; ***Ital.:*** Xyzal; ***Malaysia:*** Xyzal; ***Mex.:*** Xuzal; Zyxem; ***Neth.:*** Sopras; Virdos; Xyzal; ***Norw.:*** Xyzal; ***Philipp.:*** Xyzal; ***Pol.:*** Xyzal; ***Port.:*** Levrix; Xyzal; ***Rus.:*** Xyzal (Ксизал); ***S.Afr.:*** Xyzal; ***Singapore:*** Muntel; Sopras; Xazal; ***Switz.:*** Xyzal; ***Thai.:*** Xyzal; ***UK:*** Xyzal; ***USA:*** Xyzal.

Loratadine *(BAN, USAN, rINN)*

Loratadiini; Loratadin; Loratadina; Loratadinum; Loratadyna; Sch-29851. Ethyl 4-(8-chloro-5,6-dihydro-11*H*-benzo[5,6]cyclohepta[1,2-*b*]pyridin-11-ylidene)piperidine-1-carboxylate.

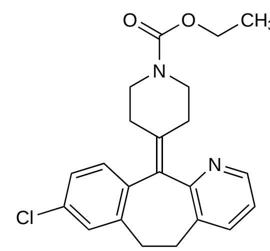
Лоратадин

$C_{22}H_{23}ClN_2O_2$ = 382.9.

CAS — 79794-75-5.

ATC — R06AX13.

ATC Vet — QR06AX13.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Loratadine). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; freely soluble in acetone and in methyl alcohol.

USP 31 (Loratadine). A white to off-white powder. Insoluble in water; freely soluble in acetone, in chloroform, in methyl alcohol, and in toluene.

Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving loratadine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding. However, UK licensed product information recommends that loratadine should not be used in breast-feeding mothers.

A study[2] in 6 women reported that about 0.03% of a single 40-mg oral dose of loratadine was distributed into breast milk over 48 hours as loratadine and its active metabolite, desloratadine.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/04/04)
2. Hilbert J, *et al.* Excretion of loratadine in human breast milk. *J Clin Pharmacol* 1988; **28:** 234–9.

Effects on the liver. Two patients[1] developed severe necroinflammatory liver injury after receiving loratadine 10 mg daily for allergic rhinitis. Although both recovered after drug withdrawal, one patient required a liver transplantation and recovery was prolonged.

The product information notes that abnormal hepatic function including jaundice, hepatitis, and hepatic necrosis has been reported rarely.

1. Schiano TD, *et al.* Subfulminant liver failure and severe hepatotoxicity caused by loratadine use. *Ann Intern Med* 1996; **125:** 738–40.

Pregnancy. UK product information does not recommend the use of loratadine in pregnancy.

Analysis of data collected by the Swedish Medical Birth Registry between 1994 and 2001 revealed 15 cases of hypospadias among a cohort of 2780 newborns exposed to loratadine during the first trimester of pregnancy.[1] The authors noted that the individual risk for having an infant with hypospadias after loratadine use is small (less than 1%) and the attributive risk of extra cases in the population is low. The US CDC has also analysed data from the National Birth Defects Prevention study;[2] they found no increase in the risk of second- or third-degree hypospadias in the infants of women who used loratadine in early pregnancy. In addition, an earlier prospective multicentre study[3] in 161 women taking a median dose of loratadine 10 mg daily in the first trimester of pregnancy suggested that its use was not associated with a significant risk of major congenital malformations.

1. Källén B, Olausson PO. Monitoring of maternal drug use and infant congenital malformations: does loratadine cause hypospadias? *Int J Risk Safety Med* 2001; **14:** 115–19.
2. CDC. Evaluation of an association between loratadine and hypospadias — United States, 1997-2001. *MMWR* 2004; **53:** 219–21. Also available at: http://www.cdc.gov/mmwr/PDF/wk/mm5310.pdf (accessed 11/05/04)
3. Moretti ME, *et al.* Fetal safety of loratadine use in the first trimester of pregnancy: a multicenter study. *J Allergy Clin Immunol* 2003; **111:** 479–83.

Sedation. For discussion of the sedative effects of antihistamines see p.562.

Interactions

As for the non-sedating antihistamines in general, p.563.

Loratadine is metabolised by cytochrome P450 isoenzymes CYP3A4 and CYP2D6. Therefore use with other drugs that inhibit or are metabolised by these hepatic enzymes may result in changes in plasma concentrations of either drug and, possibly, adverse effects. Drugs known to inhibit one or other of these enzymes include cimetidine, erythromycin, ketoconazole, quinidine, fluconazole, and fluoxetine.

Antibacterials. Data held on file by the manufacturer show that *erythromycin* can inhibit the metabolism of loratadine. However, even when given in large doses loratadine does not appear to cause the cardiac conduction disorders associated with the non-sedating antihistamines astemizole (see p.567) and terfenadine (see p.590).[1] Similarly, *clarithromycin* seemed to inhibit the metabolism of loratadine and its active metabolite desloratadine.[2]

1. Affrime MB, *et al.* Three month evaluation of electrocardiographic effects of loratadine in humans. *J Allergy Clin Immunol* 1993; **91:** 259.
2. Carr RA, *et al.* Steady-state pharmacokinetics and electrocardiographic pharmacodynamics of clarithromycin and loratadine after individual or concomitant administration. *Antimicrob Agents Chemother* 1998; **42:** 1176–80.

Antifungals. *Ketoconazole* also appears to be able to inhibit the metabolism of loratadine and at therapeutic doses, is about 3 times more inhibitory than erythromycin.[1] However, the concentrations of ketoconazole required are reported to be much higher than those required to inhibit the metabolism of astemizole or terfenadine. Clearance of the active metabolite desloratadine is also reduced.

1. Brannan MD, *et al.* Effects of various cytochrome P450 inhibitors on the metabolism of loratadine. *Clin Pharmacol Ther* 1995; **57:** 193.

Gastrointestinal drugs. *Cimetidine* appears to have an inhibitory effect on the metabolism of loratadine and also attenuates the clearance of its active metabolite desloratadine although no clinically significant consequences have been seen.[1]

1. Brannan MD, *et al.* Effects of various cytochrome P450 inhibitors on the metabolism of loratadine. *Clin Pharmacol Ther* 1995; **57:** 193.

Pharmacokinetics

Loratadine is rapidly absorbed from the gastrointestinal tract after oral doses, peak plasma concentrations being attained in about 1 hour. Bioavailability is increased and time to peak plasma concentrations is delayed when taken with food. Loratadine undergoes extensive metabolism. The major metabolite, desloratadine (p.576), has potent antihistaminic activity. Reported mean elimination half-lives for loratadine and desloratadine are 8.4 and 28 hours, respectively. Loratadine is about 98% bound to plasma proteins; desloratadine is less extensively bound. Loratadine and its metabolites have been detected in breast milk, but do not appear to cross the blood-brain barrier to a significant extent. Most of a dose is excreted equally in the urine and faeces, mainly in the form of metabolites.

Renal impairment. The disposition of loratadine does not appear to be significantly altered in patients with severe renal impairment and haemodialysis does not appear to be an effective means of removing loratadine or its metabolite desloratadine from the body.[1]

1. Matzke GR, *et al.* Pharmacokinetics of loratadine in patients with renal insufficiency. *J Clin Pharmacol* 1990; **30:** 364–71.

Uses and Administration

Loratadine, a piperidine derivative related to azatadine, is a long-acting, non-sedating antihistamine with no significant antimuscarinic activity. It is used for the symptomatic relief of allergic conditions including rhinitis (p.565) and chronic urticaria (p.565).

Loratadine is given in an oral dose of 10 mg once daily. Children aged 2 to 5 years may be given 5 mg once daily and those aged 6 to 12 years may be given 10 mg once daily for seasonal allergic rhinitis and chronic idiopathic urticaria.

It is also used with a decongestant such as pseudoephedrine sulfate.

For dosage in hepatic or renal impairment, see below.

◊ References.

1. Haria M, *et al.* Loratadine: a reappraisal of its pharmacological properties and therapeutic use in allergic disorders. *Drugs* 1994; **48:** 617–37.

Administration in hepatic or renal impairment. US product information recommends that patients with hepatic failure or renal impairment (glomerular filtration rate less than 30 mL/minute) should be given an initial oral dose of loratadine 10 mg on alternate days.

Preparations

USP 31: Loratadine Oral Solution; Loratadine Tablets.

Proprietary Preparations (details are given in Part 3)

Mebhydrolin *(BAN, rINN)*

Mebhidrolina; Mebhydroline; Mebhydrolinum. 5-Benzyl-1,2,3,4-tetrahydro-2-methyl-γ-carboline.

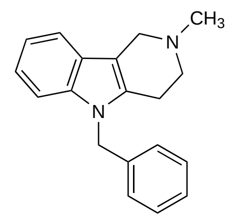
Мебгидролин

$C_{19}H_{20}N_2$ = 276.4.

CAS — 524-81-2.

ATC — R06AX15.

ATC Vet — QR06AX15.



Mebhydrolin Napadisilate *(BANM, rINNM)*

Diazolinum; Mebhydrolin Napadisylate; Mebhydrolin Naphthalenedisulphonate; Mebhydroline, Napadisilate de; Mebhydrolini Napadisilas; Napadisilato de mebhidrolina. Mebhydrolin naphthalene-1,5-disulphonate.

Мебгидролина Нападизилат

$(C_{19}H_{20}N_2)_2,C_{10}H_8O_6S_2$ = 841.0.

CAS — 6153-33-9.

ATC — R06AX15.

ATC Vet — QR06AX15.

Profile

Mebhydrolin, an ethylenediamine derivative, is a sedating antihistamine (p.561) with antimuscarinic and sedative properties. It has been given orally as the base or as the napadisilate salt for the symptomatic relief of allergic conditions including urticaria and rhinitis, and in pruritic skin disorders. Granulocytopenia and agranulocytosis have been reported.

Preparations

Proprietary Preparations (details are given in Part 3)

Indon.: Biolergy; Gabiten; Histapan; Incitin; Interhistin; Tralgi; Zoline; ***Israel:*** Cidalin; ***Rus.:*** Diazolin (Диазолин); ***S.Afr.:*** Fabahistin; ***Thai.:*** Dalhis; Dayhist; Manocidal; Manoeidai; Posidol.

Meclozine Hydrochloride

(BANM, pINNM)

Hidrocloruro de meclozina; Meclizine Hydrochloride; Meclizinium Chloride; Méclozine, chlorhydrate de; Meclozini Dihydrochloridum; Meclozini hydrochloridum; Meklotsiinihydrokloridi; Meklozin Hidroklorür; Meklozin-dihydrochlorid; Meklozin-hidroklorid; Meklozinhydroklorid; Meklozino hidrochloridas; Meklozyny chlorowodorek; Parachloramine Hydrochloride. 1-(4-Chlorobenzhydryl)-4-(3-methylbenzyl)piperazine dihydrochloride.

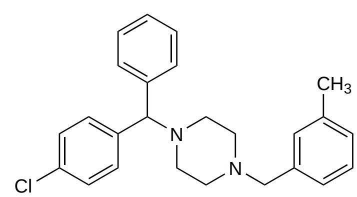
Меклозина Гидрохлорид

$C_{25}H_{27}ClN_2,2HCl$ = 463.9.

CAS — 569-65-3 (meclozine); 1104-22-9 (anhydrous meclozine hydrochloride); 31884-77-2 (meclozine hydrochloride monohydrate).

ATC — R06AE05.

ATC Vet — QR06AE05.



(meclozine)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).
US specifies the monohydrate.

Ph. Eur. 6.2 (Meclozine Hydrochloride). A yellow or yellowish-white, crystalline powder. Slightly soluble in water; soluble in alcohol and in dichloromethane. Store in airtight containers.

USP 31 (Meclizine Hydrochloride). The monohydrate is white or slightly yellowish crystalline powder that has a slight odour. Practically insoluble in water and in ether; freely soluble in chloroform, in pyridine, and in acid-alcohol-water mixtures; slightly soluble in dilute acids and in alcohol. Store in airtight containers.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. For reports of the use of antihistamines, including meclozine, in pregnancy, see p.563.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Meclozine hydrochloride, a piperazine derivative, is a sedating antihistamine with antimuscarinic and moderate sedative properties. It is mainly used for its antiemetic action, which may last for up to 24 hours. Meclozine hydrochloride is used in the prevention and treatment of nausea and vomiting associated with a variety of conditions including motion sickness (p.564) and for the symptomatic treatment of vertigo (p.565) caused by Ménière's disease and other vestibular disorders. Meclozine hydrochloride has also been used for the symptomatic relief of hypersensitivity reactions and pruritic skin disorders (p.565).

The usual oral dose of meclozine hydrochloride for motion sickness is 25 to 50 mg taken about one hour before travelling and repeated every 24 hours if necessary; up to 100 mg daily in divided doses has been given for the treatment of vertigo and vestibular disorders. In the prevention and treatment of motion sickness in children aged 6 to 12 years, 12.5 mg is given once daily; for children aged 2 to 6 years the dose is 6.25 mg once daily.

Both meclozine hydrochloride and meclozine base have been given by the rectal route; doses are similar to those given orally.

Preparations

USP 31: Meclizine Hydrochloride Tablets.

Proprietary Preparations (details are given in Part 3)

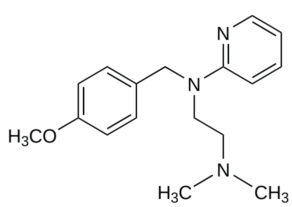
Mepyramine *(BAN, rINN)*

Mepiramina; Mepyramiini; Mepyramin; Mépyramine; Mepyraminum; Pyranisamine; Pyrilamine. 2-(*N*-*p*-Anisyl-*N*-2-pyridylamino)ethyldimethylamine.

Мепирамин

$C_{17}H_{23}N_3O$ = 285.4.
CAS — 91-84-9.
ATC — D04AA02; R06AC01.
ATC Vet — QD04AA02; QR06AC01.



Mepyramine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de mepiramina; Mépyramine, Chlorhydrate de; Mepyramini Hydrochloridum; Pyranisamine Hydrochloride; Pyrilamine Hydrochloride.

Мепирамина Гидрохлорид

$C_{17}H_{23}N_3O,HCl$ = 321.8.
CAS — 6036-95-9.
ATC — D04AA02; R06AC01.
ATC Vet — QD04AA02; QR06AC01.

Mepyramine Maleate *(BANM, rINNM)*

Maleato de mepiramina; Mepiramin Maleat; Mepiramin-maleát; Mepiramino maleatas; Mepyramiinimaleaatti; Mepyramin maleinát; Mépyramine, maléate de; Mepyramini maleas; Mepyraminmaleat; Pyranisamine Maleate; Pyrilamine Maleate. Mepyramine hydrogen maleate.

Мепирамина Малеат

$C_{17}H_{23}N_3O,C_4H_4O_4$ = 401.5.
CAS — 59-33-6.
ATC — D04AA02; R06AC01.
ATC Vet — QD04AA02; QR06AC01.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Mepyramine Maleate). A white or slightly yellowish, crystalline powder. Very soluble in water; freely soluble in alcohol. M.p. 99° to 103°. A 2% solution in water has a pH of 4.9 to 5.2. Protect from light.

USP 31 (Pyrilamine Maleate). A white crystalline powder usually having a faint odour. Soluble 1 in 0.5 of water, 1 in 3 of alcohol, 1 in 15 of dehydrated alcohol, and 1 in 2 of chloroform; slightly soluble in ether and in benzene. Its solutions are acid to litmus. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Mepyramine, an ethylenediamine derivative, is a sedating antihistamine with antimuscarinic and sedative properties. Mepyramine maleate is used for the symptomatic relief of hypersensitivity reactions and in pruritic skin disorders (p.565). Mepyramine maleate is also a common ingredient of compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

Mepyramine maleate has been given in an oral dose of 50 mg at night as a hypnotic in the short-term management of insomnia (p.564).

A cream containing 2% mepyramine maleate is used locally for insect bites or stings, and for hypersensitivity and pruritic skin conditions but, as with any antihistamine, there is a risk of sensitisation. It has also been used in eye drops.

In some countries mepyramine maleate is available for parenteral use. Mepyramine hydrochloride has also been given parenterally or by the rectal route. Mepyramine tannate and mepyramine acefyllinate have been used orally.

Preparations

BP 2008: Mepyramine Tablets;
USP 31: Pyrilamine Maleate Tablets.

Proprietary Preparations (details are given in Part 3)

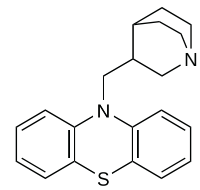
Mequitazine *(BAN, rINN)*

LM-209; Mekitatsiini; Mekitazin; Mequitazina; Méquitazine; Mequitazinum. 10-(Quinuclidin-3-ylmethyl)phenothiazine.

Мехитазин

$C_{20}H_{22}N_2S$ = 322.5.
CAS — 29216-28-2.
ATC — R06AD07.
ATC Vet — QR06AD07.



Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Sedation. For discussion of the sedative effects of antihistamines, see p.562. When mequitazine is given in the recommended dosage of 5 mg twice daily the incidence of sedation appears comparable with that of terfenadine. Sedation has, however, occurred after doses of 10 mg twice daily.

Interactions

As for the sedating antihistamines in general, p.563.

Antibacterials. For a report of torsade de pointes in a patient taking *spiramycin* and mequitazine, see Cytochrome P450 Isoenzymes under Interactions of Spiramycin, p.333.

Pharmacokinetics

After absorption from the gastrointestinal tract, mequitazine is metabolised. Unchanged drug and metabolites are excreted principally in the bile.

Uses and Administration

Mequitazine, a phenothiazine derivative, is a sedating antihistamine with antimuscarinic and mild sedative properties.

Mequitazine is used for the symptomatic relief of allergic conditions including urticaria (p.565), rhinitis (p.565) and conjunctivitis (p.564), and in pruritic skin disorders (p.565). It has been given in usual oral doses of 5 mg twice daily.

Preparations

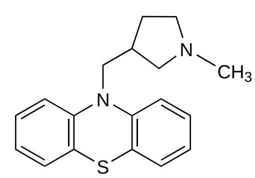
Proprietary Preparations (details are given in Part 3)
Arg.: Primalan; ***Chile:*** Mircol; ***Fr.:*** Primalan; Quitadrill; ***Ger.:*** Metaplexan; ***Ital.:*** Primalan†; ***Mex.:*** Primalan; ***Philipp.:*** Primalan; ***Port.:*** Primalan; ***Rus.:*** Primalan (Прималан); ***Spain:*** Mircol.

Methdilazine *(BAN, rINN)*

Metdilatsiini; Metdilazin; Metdilazina; Methdilazinum; Metodilazina. 10-(1-Methylpyrrolidin-3-ylmethyl)phenothiazine.

Метдилазин

$C_{18}H_{20}N_2S$ = 296.4.
CAS — 1982-37-2.
ATC — R06AD04.
ATC Vet — QR06AD04.



Methdilazine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de metodilazina; Methdilazine, Chlorhydrate de; Methdilazini Hydrochloridum.

Метдилазина Гидрохлорид

$C_{18}H_{20}N_2S,HCl$ = 332.9.
CAS — 1229-35-2.
ATC — R06AD04.
ATC Vet — QR06AD04.

The symbol † denotes a preparation no longer actively marketed

Pharmacopoeias. In *US.*

USP 31 (Methdilazine Hydrochloride). A light tan crystalline powder having a slight characteristic odour. Soluble 1 in 2 of water and of alcohol, 1 in 6 of chloroform, and 1 in 1 of 0.1N hydrochloric acid and of 0.1N sodium hydroxide solution; practically insoluble in ether. pH of a 1% solution in water is between 4.8 and 6.0. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Methdilazine, a phenothiazine derivative, is a sedating antihistamine with antimuscarinic and sedative activity. Methdilazine is also reported to have serotonin-antagonist properties.

Methdilazine hydrochloride is used for the symptomatic relief of hypersensitivity reactions and particularly for the control of pruritic skin disorders (p.565). An oral dose of 8 mg has been given 2 to 4 times daily. Methdilazine base has been used in similar doses. For children's doses, see below.

Administration in children. Methdilazine hydrochloride has been used in children for symptomatic relief of hypersensitivity reactions and particularly for the control of pruritic skin disorders. Oral doses of 4 mg given 2 to 4 times daily have been used in children aged 3 to 12 years. However, lower daily doses have also been used: children aged 3 to 6 years may be given 300 micrograms/kg daily (maximum 8 mg daily) and those aged 6 to 12 years, 4 mg twice daily.

Preparations

USP 31: Methdilazine Hydrochloride Syrup; Methdilazine Hydrochloride Tablets.

Proprietary Preparations (details are given in Part 3)

Austral.: Dilosyn†; ***Denm.:*** Tacryl†; ***India:*** Dilosyn.

Multi-ingredient: ***India:*** Dilosyn Expectorant.

Mizolastine *(BAN, rINN)*

Mitsolastiini; Mizolastin; Mizolastina; Mizolastinum; SL-85.0324-00. 2-{1-[1-(4-Fluorobenzyl)-1*H*-benzimidazol-2-yl]-4-piperidyl(methyl)amino}pyrimidin-4(1*H*)-one.

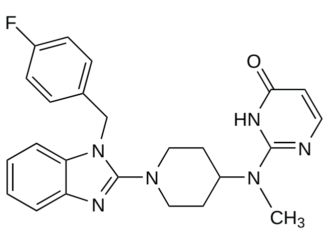
Мизоластин

$C_{24}H_{25}FN_6O$ = 432.5.

CAS — 108612-45-9.

ATC — R06AX25.

ATC Vet — QR06AX25.



Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561. Mizolastine has only a weak potential to prolong the QT interval (see also Arrhythmias, p.562) and has not been associated with arrhythmias. However, the manufacturers have warned against the use of mizolastine in patients with significant cardiac or hepatic disease, with hypokalaemia or other electrolyte imbalance, or with known or suspected QT prolongation. Use with drugs liable to interfere with the hepatic metabolism of mizolastine or with other potentially arrhythmogenic drugs should also be avoided (see under Interactions, below).

Interactions

As for the non-sedating antihistamines in general, p.563. Moderate increases in plasma concentrations of mizolastine have been reported with erythromycin and ketoconazole; use with macrolide antibacterials or systemic imidazole antifungals is contra-indicated by the manufacturer. They also advise against use of mizolastine with drugs known to prolong the QT interval, such as class I and III antiarrhythmics.

Other potent inhibitors of or substrates for the hepatic metabolism of mizolastine include cimetidine, ciclosporin, and nifedipine; caution is advised if given together.

Pharmacokinetics

Mizolastine is rapidly absorbed from the gastrointestinal tract with peak plasma concentrations being reached after about 1.5 hours. Plasma protein binding is about 98%. The mean elimination half-life is about 13 hours. Mizolastine is mainly metabolised by glucuronidation although other metabolic pathways are involved, including metabolism by the cytochrome P450 isoenzyme CYP3A4, with the formation of inactive hydroxylated metabolites.

2. Lebrun-Vignes B, *et al.* Clinical pharmacokinetics of mizolastine. *Clin Pharmacokinet* 2001; **40:** 501–7.

Uses and Administration

Mizolastine is a non-sedating antihistamine with a long duration of action. It does not have significant antimuscarinic actions; it is reported to have mast-cell stabilising properties. Mizolastine is used for the symptomatic relief of allergic conditions including rhinitis (p.565), conjunctivitis (p.564), and skin disorders such as urticaria (p.565). The oral dose is 10 mg daily.

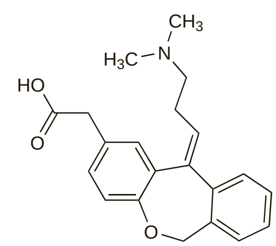
ATC — R01AC08; S01GX09.

ATC Vet — QS01GX09.



(olopatadine)

Adverse Effects and Precautions

As for the antihistamines in general, p.561. Headache and stinging or burning of the eye have occurred after ocular use.

Uses and Administration

Olopatadine hydrochloride is an antihistamine with mast-cell stabilising properties. It is used twice daily as eye drops containing the equivalent of 0.1% of olopatadine base in the treatment of allergic conjunctivitis (p.564) in adults and children aged three years and over.

◊ References.

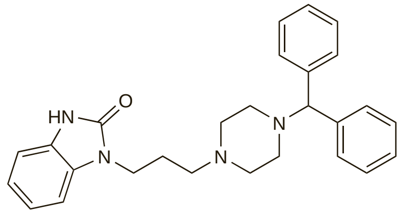
Oxatomide *(BAN, USAN, rINN)*

Oksatomidi; Oxatomid; Oxatomida; Oxatomidum; R-35443. 1-[3-(4-Benzhydrylpiperazin-1-yl)propyl]benzimidazolin-2-one.

Оксатомид

$C_{27}H_{30}N_4O$ = 426.6.
CAS — 60607-34-3.
ATC — R06AE06.
ATC Vet — QR06AE06.



Profile

Oxatomide, a piperazine derivative, is a sedating antihistamine (p.561) that has also been reported to have mast-cell stabilising properties. It is used for the symptomatic relief of allergic conditions including urticaria (p.565), rhinitis (p.565), and conjunctivitis (p.564). Oxatomide is given as the anhydrous substance or as the monohydrate; doses are expressed as the anhydrous substance. Oxatomide monohydrate 1.04 mg is equivalent to about 1 mg of anhydrous oxatomide. The usual oral dose is 30 mg twice daily. The hydrate has also been applied topically but, as with other antihistamines, there is a risk of sensitisation.

Effects on the nervous system. Acute dystonic reactions and long-lasting impaired consciousness were associated with oxatomide therapy in 6 children.[1] Impaired consciousness varied from lethargy and somnolence to a clinical picture resembling encephalitis and persisted for 2 days or more in 3 patients. Plasma-oxatomide concentrations were measured in 3 patients and found to be high, although 2 of these had been given the recommended dose.

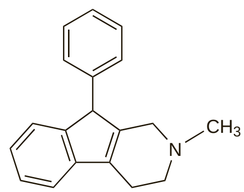
Phenindamine Acid Tartrate; Phénindamine, Tartrate de; Phenindamini Tartras; Phenindaminium Tartrate; Tartrato de fenindamina. 1,2,3,4-Tetrahydro-2-methyl-9-phenyl-2-azafluorene hydrogen tartrate; 2,3,4,9-Tetrahydro-2-methyl-9-phenyl-1*H*-indeno[2,1-c]pyridine hydrogen tartrate.

Фениндамина Тартрат

$C_{19}H_{19}N,C_4H_6O_6$ = 411.4.
CAS — 82-88-2 (phenindamine); 569-59-5 (phenindamine tartrate).
ATC — R06AX04.
ATC Vet — QR06AX04.



(phenindamine)

Pharmacopoeias. In *Br.*

BP 2008 (Phenindamine Tartrate). A white or almost white, odourless or almost odourless, voluminous powder. Sparingly soluble in water; slightly soluble in alcohol; practically insoluble in chloroform and in ether. A 1% solution in water has a pH of 3.4 to 3.9. Protect from light.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Phenindamine tartrate may have a stimulant effect in certain individuals; to avoid the possibility of insomnia patients may be advised to take the last dose of the day several hours before retiring.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Phenindamine, a piperidine derivative, is a sedating antihistamine; however it may be mildly stimulating in certain individuals. It is used as the tartrate for the symptomatic relief of allergic conditions including urticaria (p.565) and rhinitis (p.565), and as an ingredient of compound preparations for coughs and the common cold (p.564).

Phenindamine tartrate is given in oral doses of 25 mg every 4 to 6 hours, up to a maximum of 150 mg daily. Children over 6 years of age have been given half these doses.

Pregnancy. For discussion of the use of antihistamines, including pheniramine, in pregnancy, see p.563.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

◊ The pharmacokinetics of pheniramine and its metabolites, *N*-desmethylpheniramine and *N*-didesmethylpheniramine, were investigated in 6 healthy subjects.[1] After oral doses of pheniramine aminosalicylate, peak-plasma pheniramine concentrations were reached in 1 to 2.5 hours. The terminal half-life ranged between 8 and 17 hours after intravenous doses (pheniramine maleate) and 16 and 19 hours after oral doses. The total recovery of pheniramine as unchanged drug and metabolites from the urine was 68 to 94% of the intravenous dose and 70 to 83% of the oral dose.

1. Witte PU, *et al.* Pharmacokinetics of pheniramine (Avil) and metabolites in healthy subjects after oral and intravenous administration. *Int J Clin Pharmacol Ther Toxicol* 1985; **23:** 59–62.

Uses and Administration

Pheniramine, an alkylamine derivative, is a sedating antihistamine with antimuscarinic and moderate sedative properties.

It is used as the maleate for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565), and conjunctivitis (p.564), and in pruritic skin disorders (p.565). It has also been used for its antiemetic properties in the prevention and control of motion sickness (p.564). Pheniramine maleate is used as an ingredient of compound preparations for the symptomatic treatment of coughs and the common cold (p.564). It is also used in combination with a decongestant in eye and nasal preparations.

Pheniramine maleate is given as a syrup in usual oral doses of 15 to 30 mg two or three times daily. It may also be given as a tablet in doses up to about 45 mg three times daily. In some countries pheniramine maleate has been given parenterally.

The aminosalicylate, the hydrochloride, and the tannate have also been used.

Preparations

USP 31: Naphazoline Hydrochloride and Pheniramine Maleate Ophthalmic Solution.

ATC Vet — QD04AA10; QR06AD02.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Promethazine Hydrochloride). A white or faintly yellowish, crystalline powder. Very soluble in water; freely soluble in alcohol and in dichloromethane. A 10% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 31 (Promethazine Hydrochloride). A white to faint yellow, practically odourless, crystalline powder. Slowly oxidises and acquires a blue colour on prolonged exposure to air. Freely soluble in water, in hot dehydrated alcohol, and in chloroform; practically insoluble in acetone, in ether, and in ethyl acetate. pH of a 5% solution in water is between 4.0 to 5.0. Store in airtight containers. Protect from light.

Adsorption. The adsorption of promethazine hydrochloride onto various glass and plastic containers and infusion systems has been studied.[1-4] Factors affecting the degree of adsorption included the particular material tested and the pH of the solution.

1. Kowaluk EA, *et al.* Interactions between drugs and polyvinyl chloride infusion bags. *Am J Hosp Pharm* 1981; **38:** 1308–14.
2. Kowaluk EA, *et al.* Interactions between drugs and intravenous delivery systems. *Am J Hosp Pharm* 1982; **39:** 460–7.
3. Rhodes RS, *et al.* Stability of meperidine hydrochloride, promethazine hydrochloride, and atropine sulfate in plastic syringes. *Am J Hosp Pharm* 1985; **42:** 112–5.
4. Martens HJ, *et al.* Sorption of various drugs in polyvinyl chloride, glass, and polyethylene-lined infusion containers. *Am J Hosp Pharm* 1990; **47:** 369–73.

Incompatibility. Solutions of promethazine hydrochloride are incompatible with alkaline substances, which precipitate the insoluble promethazine base. Compounds reported to be incompatible with promethazine hydrochloride include aminophylline, barbiturates, benzylpenicillin salts, carbenicillin sodium, chloramphenicol sodium succinate, chlorothiazide sodium, cefmetazole sodium, cefoperazone sodium, cefotetan disodium, dimenhydrinate, doxorubicin hydrochloride (in a liposomal formulation), furosemide, heparin sodium, hydrocortisone sodium succinate, meticillin sodium, morphine sulfate, nalbuphine hydrochloride, and some contrast media and parenteral nutrient solutions.

Promethazine Teoclate *(BAN, rINN)*

Prométhazine, Téoclate de; Promethazine Theoclate; Promethazini Teoclas; Teoclato de prometazina. The promethazine salt of 8-chlorotheophylline .

Прометазина Теоклат

$C_{17}H_{20}N_2S,C_7H_7ClN_4O_2$ = 499.0.

CAS — 17693-51-5.

ATC — D04AA10; R06AD02.

ATC Vet — QD04AA10; QR06AD02.

Pharmacopoeias. In *Br.*

BP 2008 (Promethazine Teoclate). A white or almost white, odourless or almost odourless powder. Very slightly soluble in water; sparingly soluble in alcohol; freely soluble in chloroform; practically insoluble in ether. Protect from light.

Adverse Effects

As for the sedating antihistamines in general, p.561.

Cardiovascular adverse effects are more commonly seen after injection, and bradycardia, tachycardia, transient minor increases in blood pressure, and occasional hypotension have all been reported with promethazine hydrochloride. Jaundice and blood dyscrasias have been reported, and extrapyramidal effects may occur at high doses.

Venous thrombosis has been reported at the site of intravenous injections, and arteriospasm and gangrene may follow inadvertent intra-arterial injection.

Overdosage. A toxic neurological syndrome, which included CNS depression, acute excitomotor manifestations, ataxia and visual hallucinations, plus peripheral antimuscarinic effects developed in 2 children aged 44 months and 16 months after topical application of a 2% promethazine cream providing between 12.9 and 26 mg/kg.[1] The older child had also received hydroxyzine 10 mg orally 1 hour earlier.

1. Shawn DH, McGuigan MA. Poisoning from dermal absorption of promethazine. *Can Med Assoc J* 1984; **130:** 1460–1.

Sudden infant death syndrome. Although some early reports raised the possibility of an association between the use of phenothiazine antihistamines and the sudden infant death syndrome (SIDS) this has not been confirmed. Following an initial report that 4 of 7 infants with SIDS had been given alimemazine before death and that a series of severe apnoeic crises had been observed in the twin of a SIDS victim given promethazine,[1] the same workers studied 52 SIDS victims, 36 near-miss infants (those who had experienced severe unexplained episodes of cyanosis or pallor during sleep), and 175 control subjects to investigate the role of nasopharyngitis and phenothiazines in this syndrome.[2] They found that there was no difference in the incidence of nasopharyngitis between the 3 groups, but the proportion of infants given phenothiazines was higher in both the SIDS group (23%) and the near-miss group (22%) than in the control group (2%). In a subsequent study,[3] they found that the incidence of central and obstructive sleep apnoeas was increased in 4 healthy infants given promethazine for 3 days, although the duration of the attacks was unaltered and generally short, with a range of 3 to 10 seconds. A report on behalf of the European Commission,[4] stated that no link between sudden deaths in infants and drug use had been confirmed by national drug monitoring centres. It was likely that the risk of apnoea was associated with all sedative drugs, especially in overdose.[4] Previously, phenothiazine-induced hyperthermia had been proposed as a contributory factor in SIDS.[5]

For general precautions regarding the use of antihistamines in children, see p.562.

5. Stanton AN. Sudden infant death syndrome and phenothiazines. *Pediatrics* 1983; **71:** 986–7.

Precautions

As for the sedating antihistamines in general, p.562.

Intravenous injections of promethazine hydrochloride must be given slowly and extreme care must be taken to avoid extravasation or inadvertent intra-arterial injection, because of the risk of severe irritation. Intramuscular injection may be painful, and it should not be given by subcutaneous injection.

False negative and positive results have been reported with some pregnancy tests.

Anaesthesia. In 8 healthy subjects promethazine 25 mg intravenously decreased lower oesophageal sphincter pressure and increased the incidence of gastro-oesophageal reflux.[1] It might, therefore, increase the risk of regurgitation and aspiration of gastric contents during induction of and recovery from anaesthesia. The effect was attributed to the antimuscarinic properties of promethazine.

1. Brock-Utne JG, *et al.* The action of commonly used antiemetics on the lower oesophageal sphincter. *Br J Anaesth* 1978; **50:** 295–8.

Children. A possible association between phenothiazine sedatives and sudden infant death syndrome has been suggested, but has not been confirmed (see under Adverse Effects, above). The current view in the UK and USA is that promethazine should not be given to children under 2 years of age.

Porphyria. Promethazine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Pregnancy. For discussion of the use of antihistamines in pregnancy, including studies involving phenothiazines, see p.563.

Renal impairment. Phenothiazine-induced toxic psychosis occurred in a patient with chronic renal failure who had been given promethazine.[1]

1. McAllister CJ, *et al.* Toxic psychosis induced by phenothiazine administration in patients with chronic renal failure. *Clin Nephrol* 1978; **10:** 191–5.

Interactions

As for the sedating antihistamines in general, p.563.

Pharmacokinetics

Promethazine is well absorbed after oral or intramuscular doses. Peak plasma concentrations have been seen 2 to 3 hours after a dose by these routes, although there is low systemic bioavailability after oral doses, due to high first-pass metabolism in the liver. Promethazine crosses the blood-brain barrier and the placenta, and is distributed into breast milk. Values ranging from 76 to 93% have been reported for plasma-protein binding. Promethazine undergoes extensive metabolism, predominantly to promethazine sulfoxide, and also to *N*-desmethylpromethazine. It is excreted slowly via the urine and bile, chiefly as metabolites. Elimination half-lives of 5 to 14 hours have been reported.

Uses and Administration

Promethazine, a phenothiazine derivative, is a sedating antihistamine with antimuscarinic, significant sedative, and some serotonin-antagonist properties. It is usually given as the hydrochloride or teoclate. Promethazine embonate and promethazine maleate have also been given orally. Promethazine dioxide (dioxopromethazine) has been used as the hydrochloride in eye and nasal drops. The antihistamine action has been reported to last for between 4 and 12 hours.

Promethazine hydrochloride is used for the symptomatic relief of allergic conditions including urticaria and angioedema (p.565), rhinitis (p.565) and conjunctivitis (p.564), and in pruritic skin disorders (p.565). It may be given intravenously as an adjunct in the emergency treatment of anaphylactic shock (p.563).

Promethazine hydrochloride and promethazine teoclate are used for their antiemetic action in the prevention and treatment of nausea and vomiting in conditions such as motion sickness, drug-induced vomiting, and postoperative vomiting (p.564). They are also used for the symptomatic treatment of nausea and vertigo caused by Ménière's disease and other vestibular disorders (see Vertigo, p.565). Promethazine hydrochloride is also employed pre- and postoperatively in surgery and obstetrics for its sedative effects and for the relief of apprehension (see Anaesthesia, p.563); it is often given with pethidine hydrochloride. Promethazine hydrochloride may be used for night-time sedation (see Insomnia, p.564).

Promethazine hydrochloride is a common ingredient of compound preparations for the symptomatic treatment of coughs and the common cold (p.564).

The following doses have been given **orally**.

- For the treatment of *allergic conditions* promethazine hydrochloride is usually given in a dose of 25 mg at night increased to 25 mg twice daily if necessary; owing to its pronounced sedative effect it is preferably given at night but an alternative dose is 10 to 20 mg two or three times daily.
- Promethazine hydrochloride is given in doses of 20 to 50 mg at night for the short-term management of *insomnia* although its prolonged duration of action can lead to considerable drowsiness the following day.
- For the prevention of *motion sickness* promethazine hydrochloride can be given in a dose of 20 or 25 mg the night before travelling followed by a similar dose the following morning if necessary. The teoclate is used similarly. For the prevention of motion sickness the dose of promethazine teoclate is 25 mg at night or 25 mg one to two hours before travelling.
- For nausea and vomiting arising from causes such as *labyrinthitis* a dose of promethazine teoclate 25 mg at night is usually adequate; this may be increased to 50 or 75 mg at night or to 25 mg two or three times daily if necessary to a maximum of 100 mg daily.
- For *severe vomiting in pregnancy* the *BNF* recommends a dose of promethazine teoclate 25 mg at night, increased if necessary to a maximum of 100 mg.

In *children* the following oral doses of promethazine hydrochloride have been recommended.

- For allergic conditions: 2 to 5 years, 5 to 15 mg daily in one or two divided doses; 5 to 10 years, 10 to 25 mg daily in one or two divided doses.
- For night sedation or premedication: 2 to 5 years, 15 to 20 mg; 5 to 10 years, 20 to 25 mg.
- For the prevention of motion sickness the following doses of promethazine hydrochloride may be given the night before the journey and repeated on the following morning if necessary: 2 to 5 years, 5 mg; 5 to 10 years, 10 mg. Promethazine teoclate may also be given to children aged 5 to 10 years for the prevention of motion sickness in a dose of 12.5 mg daily, starting either on the night before travelling for long journeys or one to two hours before short journeys.
- Children aged 5 to 10 years may also receive promethazine teoclate for nausea and vomiting from causes such as labyrinthitis in a dose of 12.5 to 37.5 mg daily.

Promethazine hydrochloride is also given by the **rectal** route as suppositories. Doses are similar to those given orally.

Promethazine hydrochloride is given **parenterally** by deep intramuscular injection as a solution of 25 or 50 mg/mL. It may also be given by slow intravenous injection or injected into the tubing of a freely running infusion in a concentration of not more than 25 mg/mL, although it is usually diluted to 2.5 mg/mL. The rate of infusion should not exceed 25 mg/minute. The usual parenteral dose for all indications apart from nausea and vomiting is 25 to 50 mg; a dose of 100 mg should not be exceeded. Doses of 12.5 to 25 mg, repeated at intervals of not less than 4 hours, may be given for the treatment of nausea and vomiting, although not more than 100 mg is usually given in 24 hours.

Children aged 5 to 10 years may be given 6.25 to 12.5 mg of promethazine hydrochloride by deep intramuscular injection.

Promethazine has been used **topically** to provide relief in hypersensitivity disorders of the skin and for burns but, as with other antihistamines, it may produce skin sensitisation.

Sedation. For reference to the use of lytic cocktails of chlorpromazine, promethazine, and pethidine, and the view that alternatives should be considered in children, see under Pethidine, p.115.

Preparations

BP 2008: Promethazine Hydrochloride Tablets; Promethazine Injection; Promethazine Oral Solution; Promethazine Teoclate Tablets;

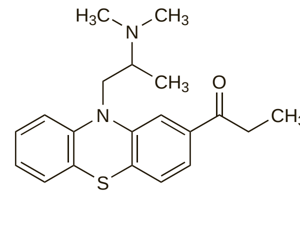
Propiomazine *(BAN, USAN, rINN)*

CB-1678 (propiomazine or propiomazine maleate); Propiomatsiini; Propiomazin; Propiomazina; Propiomazinum; Wy-1359 (propiomazine or propiomazine maleate). 1-[10-(2-Dimethylaminopropyl)phenothiazin-2-yl]propan-1-one.

Пропиомазин

$C_{20}H_{24}N_2OS = 340.5.$
CAS — 362-29-8.
ATC — N05CM06.
ATC Vet — QN05CM06.



Propiomazine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de propiomazina; Propiomazine, Chlorhydrate de; Propiomazini Hydrochloridum.

Пропиомазина Гидрохлорид

$C_{20}H_{24}N_2OS,HCl = 376.9.$
CAS — 1240-15-9.
ATC — N05CM06.
ATC Vet — QN05CM06.

Propiomazine Maleate *(BANM, rINNM)*

CB-1678 (propiomazine or propiomazine maleate); Maleato de propiomazina; Propiomazine Hydrogen Maleate; Propiomazine, Maléate de; Propiomazini Maleas; Wy-1359 (propiomazine or propiomazine maleate).

Пропиомазина Малеат

$C_{20}H_{24}N_2OS,C_4H_4O_4 = 456.6.$
CAS — 3568-23-8.
ATC — N05CM06.
ATC Vet — QN05CM06.

Adverse Effects and Precautions

As for the sedating antihistamines in general, p.561. Local irritation may occur at the site of intravenous injection of propiomazine hydrochloride and there may be thrombophlebitis.

Interactions

As for the sedating antihistamines in general, p.563.

Uses and Administration

Propiomazine, a phenothiazine derivative, is a sedating antihistamine that has been used for its sedative and antiemetic properties in insomnia (p.564) and nausea and vomiting (p.564).

Propiomazine is given as the maleate but doses are expressed in terms of the base; propiomazine maleate 1.3 mg is equivalent to about 1 mg of propiomazine. Doses equivalent to 25 to 50 mg orally at night have been given as a hypnotic.

Propiomazine hydrochloride has been given parenterally.

Preparations

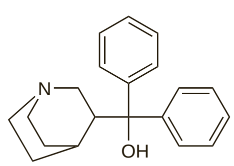
Proprietary Preparations (details are given in Part 3)
Swed.: Propavan.

Quifenadine Hydrochloride *(rINNM)*

Hidrocloruro de quifenadina; Quifénadine, Chlorhydrate de; Quifenadini Hydrochloridum. α,α-Diphenyl-3-quinuclidinemethanol hydrochloride.

Хифенадина Гидрохлорид

$C_{20}H_{23}NO,HCl = 329.9.$
CAS — 10447-39-9 (quifenadine); 10447-38-8 (quifenadine hydrochloride).



(quifenadine)

Profile

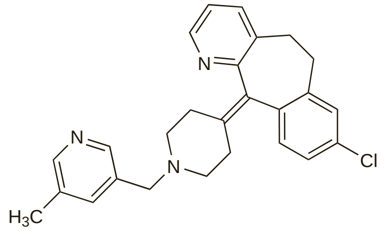
Quifenadine is an antihistamine given orally as the hydrochloride.

Rupatadine *(rINN)*

Rupatadina; Rupatadinum; UR-12592 (rupatadine fumarate). 8-Chloro-6,11-dihydro-11-{1-[(5-methyl-3-pyridyl)methyl]-4-piperidylidene}-5*H*-benzo[5,6]cyclohepta[1,2-*b*]pyridine.

Рупатадин

$C_{26}H_{26}ClN_3 = 416.0.$
CAS — 158876-82-5 (rupatadine); 182349-12-8 (rupatadine fumarate).
ATC — R06AX28.
ATC Vet — QR06AX28.



Profile

Rupatadine is an antihistamine with platelet-activating factor (PAF) antagonist activity that is used for the treatment of allergic rhinitis (p.565) and chronic idiopathic urticaria (p.565). It is given as the fumarate although doses are expressed in terms of the base; rupatadine fumarate 12.8 mg is equivalent to about 10 mg of rupatadine. The usual oral dose is the equivalent of 10 mg once daily of rupatadine.

Preparations

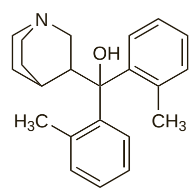
Proprietary Preparations (details are given in Part 3)
Braz.: Rupafin; ***Cz.:*** Tamalis; ***Gr.:*** Rupafin; ***Port.:*** Rinialer; ***Spain:*** Alergoliber; Rinialer; Rupafin.

Sequifenadine *(rINN)*

Bicarphene (sequifenadine or sequifenadine hydrochloride); Bikarfen (sequifenadine or sequifenadine hydrochloride); Sequifenadina; Séquifénadine; Sequifenadinum. α,α-Di-*o*-tolyl-3-quinuclidinemethanol.

Сехифенадин

$C_{22}H_{27}NO = 321.5.$
CAS — 57734-69-7.



Profile

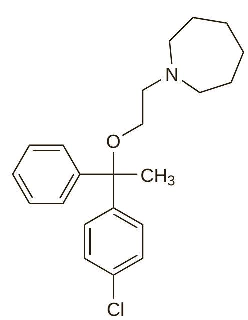
Sequifenadine is an antihistamine used in a wide range of allergic conditions. A usual dose is 50 to 100 mg given orally 2 or 3 times daily. Sequifenadine is reported also to have antiserotonin properties.

Setastine Hydrochloride *(rINNM)*

EGIS-2062; EGYT-2062; Hidrocloruro de setastina; Sétastine, Chlorhydrate de; Setastini Hydrochloridum. 1-{2-[(*p*-Chloro-α-methyl-α-phenylbenzyl)oxy]ethyl}hexahydro-1*H*-azepine hydrochloride.

Сетастина Гидрохлорид

$C_{22}H_{28}ClNO,HCl = 394.4.$
CAS — 64294-95-7 (setastine).



(setastine)

Profile

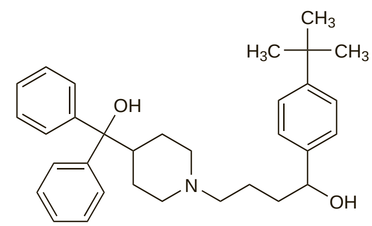
Setastine hydrochloride, a derivative of clemastine, is an antihistamine (p.561) claimed to have no sedative activity. It has been given orally for the symptomatic relief of hypersensitivity disorders.

Terfenadine *(BAN, USAN, rINN)*

MDL-9918; RMI-9918; Terfenadiini; Terfenadin; Terfenadina; Terfenadinas; Terfénadine; Terfenadinum. 1-(4-*tert*-Butylphenyl)-4-[4-(α-hydroxybenzhydryl)piperidino]butan-1-ol.

Терфенадин

$C_{32}H_{41}NO_2 = 471.7.$
CAS — 50679-08-8.
ATC — R06AX12.
ATC Vet — QR06AX12.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Terfenadine). A white or almost white, crystalline powder. It shows polymorphism. Very slightly soluble in water and in dilute hydrochloric acid; freely soluble in dichloromethane; soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

As for the non-sedating antihistamines in general, p.561. Erythema multiforme and galactorrhoea have also been reported.

Ventricular arrhythmias, including torsade de pointes, have occurred rarely with terfenadine, particularly in association with raised blood concentrations (see Arrhythmias, below). To *reduce the risk* of developing such arrhythmias the recommended dose should **not** be exceeded and terfenadine should be **avoided** in patients with cardiac or significant hepatic disease, with hypokalaemia or other electrolyte imbalance, or with known or suspected prolonged QT interval. Use with drugs liable to interfere with the hepatic metabolism of terfenadine, other potentially arrhythmogenic drugs including those that prolong the QT interval, and drugs likely to cause electrolyte imbalance is **contra-indicated** (see under Interactions, below). If palpitations, dizziness, syncope, or convulsions occur terfenadine should be withdrawn and the patient investigated for potential arrhythmias.

Alopecia. Hair loss was associated with use of terfenadine in a 24-year-old patient.[1] Regrowth occurred when treatment was stopped.

1. Jones SK, Morley WN. Terfenadine causing hair loss. *BMJ* 1985; **291:** 940.

Arrhythmias. Ventricular arrhythmias including torsade de pointes have occurred with terfenadine at doses greater than those recommended[1] and also at normal doses in patients whose metabolism of terfenadine is impaired by drugs or by liver disease. Generalised convulsions and a quinine-like effect on the ECG have also been reported after a presumed overdose of terfenadine.[2] Consequently a number of recommendations have been made to *reduce the risk* of developing serious arrhythmias (see Adverse Effects and Precautions, above, for details), including those from the UK CSM.[3,4] Terfenadine should be stopped immediately, and the patient evaluated for potential arrhythmias, in those who experience syncope, palpitations, dizziness, or convulsions after taking terfenadine.

Studies[5] have suggested that the ventricular arrhythmias are due to terfenadine itself rather than its active metabolite fexofenadine (p.579). Terfenadine has been shown to inhibit cardiac potassium channels, which results in prolongation of the QT interval, a risk factor for developing arrhythmias, while the non-sedating antihistamines cetirizine, fexofenadine, and loratadine have had no demonstrable effect[5,6] (see also p.562).

Breast feeding. No adverse effects have been observed in breast-fed infants whose mothers were receiving terfenadine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding.

In a study[2] of 4 healthy lactating women given 60 mg of terfenadine every 12 hours for 48 hours, terfenadine was undetected in breast milk; its active metabolite, fexofenadine, was excreted in limited amounts.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 08/04/04)
2. Lucas BD, *et al.* Terfenadine pharmacokinetics in breast milk in lactating women. *Clin Pharmacol Ther* 1995; **57:** 398–402.

Effects on the liver. Three episodes of acute hepatitis with jaundice occurred in a patient taking terfenadine intermittently over a period of 17 months.[1] Liver function tests returned to normal after the drug was stopped. Two further cases[2] of cholestatic hepatitis associated with terfenadine have been reported. Again, liver function tests returned to normal after drug withdrawal. A study[3] by the Boston Collaborative Drug Surveillance Program of 210 683 patients who had received prescriptions for terfenadine concluded that the use of terfenadine was rarely associated with important idiopathic liver disease. The investigators found only 3 cases of acute liver disease where a causal connection to terfenadine could not be ruled out; all these patients had also received a hepatotoxic drug and had made a full recovery.

3. Myers MW, Jick H. Terfenadine and risk of acute liver disease. *Br J Clin Pharmacol* 1998; **46:** 251–3.

Effects on the nervous system. Non-sedating effects on the CNS have been reported after a single dose of terfenadine;[1] these have included anxiety, palpitations, and insomnia. The UK manufacturers commented that clinical studies suggest that the incidence of such effects is similar to that seen after placebo.[2]

Workers who had described a generalised tonic-clonic seizure in a patient taking terfenadine[3] later reported that the patient had subsequently had a second unprovoked seizure[4] and now considered that terfenadine may not have been the cause of his original seizure. Convulsions have been reported after overdosage with terfenadine (see under Arrhythmias, above).

The sedative effects of the older antihistamines and the lack of such effects with the non-sedating antihistamines including terfenadine are discussed under Sedation on p.562.

Hypersensitivity. Terfenadine use was associated with 108 reports of skin reactions, including rashes, urticaria, angioedema, photosensitivity reactions and peeling of the skin of the hands or feet.[1]

Porphyria. Terfenadine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for the non-sedating antihistamines in general, p.563.

Terfenadine should not be given with drugs that inhibit its hepatic metabolism because of the increased risk of serious ventricular arrhythmias. These drugs include the triazole and imidazole antifungals such as itraconazole and ketoconazole, the macrolide antibacterials including clarithromycin, erythromycin, josamycin, and troleandomycin, the streptogramin antibacterial quinupristin/dalfopristin, the serotonin reuptake inhibitors citalopram, fluoxetine, fluvoxamine, nefazodone, and paroxetine, the HIV-protease inhibitors, the NNRTIs delavirdine and efavirenz, and zileuton. The metabolism of terfenadine may also be inhibited by grapefruit juice and use together should be avoided.

Use with other potentially arrhythmogenic drugs (including those that prolong the QT interval) such as antiarrhythmics, tricyclic antidepressants, the antimalarials halofantrine and quinine, antipsychotics, cisapride, probucol, pentamidine isetionate, and the beta blocker sotalol should be avoided as should diuretics that cause electrolyte imbalances especially hypokalaemia. The use of terfenadine and astemizole together is not recommended.

Antibacterials. Pharmacokinetic studies have shown that the macrolide antibiotics *erythromycin*[1] and *clarithromycin*[2] interfere with the metabolism of terfenadine leading to its accumulation. A high plasma-terfenadine concentration is associated with prolongation of the QT interval, and arrhythmias such as torsade de pointes have been reported in patients given terfenadine with erythromycin[3] or *troleandomycin*.[4]
