Preface

The aim of Martindale is to provide healthcare professionals with unbiased evaluated information on drugs and medicines used throughout the world. It therefore has to develop as the body of knowledge on existing drugs grows, new drugs emerge, new preparations are launched, and old preparations are abandoned, reformulated, or redefined. It also has to reflect the changing needs of those practising pharmacy and medicine. We try to ensure that each new edition continues to meet all these needs.

In order to provide more up-to-date information the interval between the publication of the printed versions of Martindale has been reduced over successive editions and the book is now produced about every 2 years. For those who require even more up-to-date information from Martindale there are various electronic versions, sections of which are updated more frequently.

The year 2008 saw the publication of the third Spanish edition of Martindale, the translation having again been undertaken by our colleagues at Grupo Ars XXI, and also saw the appearance of the first edition of a Chinese language version of Martindale.

Martindale has been continuously expanded since it was first published in 1883, and to present all the extra information this edition of Martindale maintains the recent return to a two-volume publication. The first volume contains this preface and the drug monographs, and the second holds the proprietary preparations and the index, as well as manufacturers' contact information.

As always the contents have been extensively revised, with all the text scanned and revalidated where necessary by a team of experienced pharmacists. Over 260 monographs have been added, and 89 removed from the book (abbreviated information on the latter remains available in the electronic versions). In our continuing attempts to improve the clinical relevance of the book, the chapters on Prostaglandins and Hypothalamic and Pituitary Hormones have been split up and most of their contents added to new chapters on Obstetric Drugs and Growth Hormone and its Modulators. The chapter on Sex Hormones has been reorganised and renamed Sex Hormones and their Modulators.

The disease treatment reviews, 668 in all and generally located in the chapter introductions, have also been revised in order to reflect current trends and provide key references. Cross-references to these reviews appear in the monographs of the drugs cited; the reviews can also be accessed via the general index. It is hoped that these reviews will be of use to readers who want an overview of a particular disease and its drug treatment and will provide a useful starting point for those who want to pursue particular aspects further.

Martindale contains much nomenclature information intended to assist the reader in identifying a particular drug or compound, and for this edition we have again greatly expanded our coverage of synonyms, with the addition of names from Poland and Turkey, and increased coverage of Russian synonyms and 'street names' for substances of abuse. Coverage of ATC codes has been expanded to include codes assigned to veterinary medicines

This edition of Martindale also sees the number of graphical representations of the chemical structures increased.

The information on proprietary preparations, an important feature of Martindale, has been updated and more countries have been covered for this edition.

Martindale is based on published information and more than 47 700 selected references are included. The amount of drug information now published electronically has increased significantly since the last printed edition of Martindale and this edition now includes nearly 2700 citations to material available on the Internet as web pages. Because of the nature of the Internet, there is no way to guarantee that the material referred to by a URL will remain at that location, as many sites are subject to periodic reorganisation; additionally, the content of Internet documents may change without warning. All URLs in Martindale are rechecked shortly before publication to ensure that a document is present. The accession date given in the citation represents the last date on which the content of the document referred to was revalidated.

Our objective is to evaluate the literature, covering important studies, guidelines, and useful reviews and placing them in context. Multicentre studies, meta-analyses, and systematic reviews play an important role in the study of drug treatment, and their findings and conclusions are considered in many of our chapters. However, there is also a place for the anecdotal report and the small study, and information from such sources is included where appropriate. In compiling the text of a Martindale monograph extensive use is made of the drug's licensed product information as published in various countries and approved by the relevant regulatory health bodies. Acknowledgement is also given to information referenced from a number of authoritative sources including the *British National Formulary*, the *British National Formulary for Children*, the *British Pharmacopoeia*, the *European Pharmacopoeia*, the *United States National Formulary*, and the *United States Pharmacopeia*.

Martindale is not a book of standards. Inclusion of a substance or a preparation is not to be considered as a recommendation for use, nor does it confer any status on the substance or preparation. While considerable efforts have been made to check the material in Martindale, the publisher cannot accept any responsibility for errors and omissions. Also the reader is assumed to possess the necessary knowledge to interpret the information that Martindale provides.

Philosophy and methodology

Martindale's uses are as varied as its users. However, our primary aims are:

- to summarise clinically useful information on all drugs and medicines around the world
- to provide accurate, unbiased, reasonably comprehensive, and regularly re-evaluated information in a concise format
- to provide a lead-in to the published evidence base from which we derive our information

In order to achieve the aims specified above, our working practices have to optimise internal knowledge management.

MARTINDALE STAFF. Martindale is currently produced by a team of 21 people, 18 of whom are pharmacists or pharmacy technicians with relevant expertise. The team is divided into 5 revising groups each of 2 staff editors, as well as 5 assistant editors, 1 editor-in-chief, a co-ordinator for the processing of information on proprietary medicines, and 4 clerical and support staff. A number of pharmacists work as external evaluators to maintain coverage of non-UK preparations.

Staff editors receive formal training in literature evaluation and searching techniques, as well as specific, 'on-the-job' training in internal procedures. Each revision team has responsibility for the re-evaluation and update of a particular group of chapters. Senior editorial staff edit and approve the output of the teams. Staff are responsible for ongoing data collection as well as the revision process.

DATA COLLECTION. In order to reduce the amount of formal data collection required at revision, a prospective data-collection roster is in operation. This involves all staff members in hand-searching selected major medical journals, as well as regular searches of the internet sites of regulatory authorities (EMEA, FDA, and MHRA), and sources of high-quality systematic reviews and guidelines (such as Bandolier, Clinical Evidence, Cochrane, and NICE), for drug information. In addition, pharmacopoeial, governmental and WHO publications are hand-searched for information relating to drugs and drug therapy.

The list of sources used has been iteratively developed over many years by analysis of previous citations, and is reviewed and updated regularly.

PROPRIETARY PREPARATIONS. The Martindale proprietary preparations team evaluate licensed product information for 40 countries and regions, in order to maintain the widest possible coverage of drugs in use internationally. Preparation names, manufacturers, ingredients, and licensed uses are included in the internal Martindale database for review during the revision process, and any significant additional information is forwarded to the relevant revision team.

REVISION. In order to maintain the quality and currency of our content, it is constantly revised and updated. Our revision processes cover both scheduled, in-depth revision of the content of every chapter in the book on a chapter-by-chapter basis, and updates in reaction to new information as it arrives. The revision procedure involves the formalised re-evaluation of all standing information, the assessment of new collected references for quality and relevance, and the selective use of search techniques on bibliographic databases and the Internet to identify further candidate information.

CHECKING. Once the material for a given chapter has been re-evaluated and updated it undergoes a rigorous check, designed to ensure not only that all changes are valid and appropriate, but also that important points have not been missed.

EDITING. The chapter is then passed to a member of the senior editorial staff, who performs a second check and preliminary editing of the data. This process is designed to ensure consistency of approach and style, as well as offering an opportunity to pick up any errors missed at the first check. Changes and questions are fed back to the revision team in an iterative process that may involve more than one cycle. Once past its preliminary edit the chapter is sent to the Editor for a final check and approval, which again may require changes to be made and checked, before passing it to the next stage.

KEYING, PROOF-READING, AND DOSE-CHECKING. Once approved by the Editor, amendments can be incorporated into the database, which remains untouched until this stage as a security measure. These changes are then proofread for errors, corrected if necessary, and any corrections checked. Extensive electronic testing for spelling, style, and format is also carried out at all stages. The amended chapter then undergoes an independent check of the dose information against its recorded sources. This check is performed by a member of staff outside the original revising and editing team, and is an additional safeguard against the inadvertent introduction of potentially dangerous dose errors. Once past these stages the data are cleared for release, and can be published in the next update of the Martindale electronic products, and, at appropriate points in the publishing cycle, in the book.

ADDITIONAL CHECKS FOR PUBLICATION. Some additional checks are made before publishing a print edition of Martindale. An second independent dose check of all chapters is made by an external expert, all cross-references are revalidated, and tests of the typesetting and page structure are made. In addition our extensive index is generated and carefully checked for accuracy, order, and consistency.

FEEDBACK. We are always grateful to get feedback from our users and, whenever possible, we try to incorporate information or suggestions that help us to improve Martindale. Anyone wishing to comment on the editorial content of Martindale can contact us at the following e-mail address: martindale@rpsgb.org

Arrangement

VOLUME 1: • MONOGRAPHS ON DUGS AND ANCILLARY SUBSTANCES (pages 1–2418). This section contains 5827 monographs arranged in 54 chapters. These chapters generally bring together monographs on drugs and groups of drugs that have similar uses or actions. The introductions of those chapters that describe drugs used in the management of disease may contain disease treatment reviews—descriptions of those diseases together with reviews of the choice of treatments.The last chapter in this section consists of a series of monographs arranged in the alphabetical order of their main titles. It includes monographs on drugs not easily classified, on herbals, and on drugs no longer used clinically but still of interest. There are also monographs on toxic substances, the effects of which may require drug therapy.

VOLUME 2: • PREPARATIONS (pages 2191–2880). This section contains over 146 000 proprietary preparations from a range of countries and regions. For this edition we have covered Argentina, Australia, Austria, Belgium, Brazil, Canada, Chile, Czech Republic, Denmark, Finland, France, Germany, Greece, Hong Kong, Hungary, India, Indonesia, Ireland, Israel, Italy, Malaysia, Mexico, the Netherlands, New Zealand, Norway, Philippines, Poland, Portugal, Russia, Singapore, South Africa, Spain, Sweden, Switzerland, Thailand, Turkey, the United Arab Emirates, UK, USA, and Venezuela. We have also included some proprietary preparations from Japan. The information provided includes the proprietary name, the manufacturer or distributor, the active ingredients with cross-references to the drug monographs, and a summary of the indications as given by the manufacturer.

• DIRECTORY OF MANUFACTURERS (pages 3205–3274). In Martindale the names of manufacturers and distributors are abbreviated. Their full names are given in this directory together with the full address and website if it is available. This directory contains nearly 13 000 entries.

• GENERAL INDEX (pages 3275–3694). To make fullest use of the contents of Martindale the general index should always be consulted. The exhaustive index, prepared from 153 000 entries, includes entries for drugs (approved names, synonyms, and chemical names), preparations, pharmacological and therapeutic groups, and clinical uses (disease treatment reviews). As in previous editions, the index is arranged alphabetically 'word-by-word' rather than 'letter-by-letter'. The index indicates the column in which the relevant entry appears as well as the page. To improve clarity and the ease of location of index entries long chemical names have been omitted from the index.

This edition includes both nonproprietary and proprietary names in Russian, and these names may be found in Russian alphabetical order in the Cyrillic section of the index immediately following the entries in the Latin alphabet.

Nomenclature

TITLES AND SYNONYMS. The title of each monograph is in English, with preference usually being given to International Nonproprietary Names (INN), British Approved Names (BAN), and United States Adopted Names (USAN). These 3 authorities are shown where appropriate. A European Directive (92/27/EEC) requires the use of Recommended International Nonproprietary Names (rINNs) in the labelling of medicinal products throughout member states of the European Community and where the BAN and INN differed in the past the BAN has been changed to accord with the rINN. The major exception to this convention is the retention of the names adrenaline and noradrenaline, these being the terms used as the titles of the monographs in the European Pharmacopoeia and therefore the official names in the member states. In some approved names it is now general policy to use 'f' for 'ph' in sulpha, 't' for 'th', and 'i' for 'y'; for this reason entries in alphabetical lists and indexes should be sought in alternative spellings if the expected spellings are not found. Inevitably there may be some inconsistencies of style with older approved names but wherever possible the names used for drugs or radicals in Martindale have been altered in accordance with the guidelines on the use of INNs for pharmaceutical substances. A table of contracted names for ions and groups used in approved names and titles is given on page xi. INNs in the four other main official languages (French, Latin, Russian, and Spanish) have also been included in the list of synonyms where these differ from the English INN. BAN names for substance combinations and United States Pharmacy Equivalent Names (PEN) for dosage forms containing two or more active ingredients are given in the text of the relevant monographs; these names start with the prefix 'Co-'.

This section also includes names given as synonyms such as commonly used abbreviated names; Latin versions of the titles in the European Pharmacopoeia; English, American, and Latin synonyms; names used in other languages when these may not be readily identifiable; manufacturers' code numbers; and chemical names. Official titles and synonyms used in the British, European, and US Pharmacopoeias are given in the section on pharmacopoeias where the relevant pharmacopoeial substance is described.

STREET NAMES. This edition of Martindale once again includes greatly expanded coverage of 'street names' for substances of abuse. Street terms and other slang names for drugs of abuse are included for guidance only and should be used with caution. Because of the very nature of their origin they cannot be relied upon for definitive identification of a substance. The use of such terms changes rapidly, and can vary between different geographical locations, and any given name may potentially be applied to more than one substance or even to a mixture of substances. Furthermore, established or well recognised generic drug names or herbal names have sometimes been misused as street terms for completely unrelated substances. In order to enable the reader to distinguish them from better validated synonyms, in the index, such names are included in italics and in quotation marks.

CAS REGISTRY NUMBERS. Chemical Abstracts Service (CAS) registry numbers are provided, where available, for each monograph substance to help readers refer to other information systems. Numbers for various forms of the monograph substance are listed with the variation in form given in parentheses.

ATC CODES. Codes from the Anatomical Therapeutic Chemical (ATC) classification system (see http://www.whocc.no) have been provided, where available, for each monograph substance to help readers refer to other information systems. The codes assigned in the equivalent classification system for veterinary medicines (ATC Vet—see http://www.whocc.no/atcvet) have been included where possible.

Atomic and Molecular Weights

Atomic weights are based on the table of Atomic Weights as revised in 2007 by the Commission on Atomic Weights and Isotopic Abundance, International Union of Pure and Applied Chemistry (IUPAC) and based on the ^{12}C scale (see page xiii). Molecular weights are given corrected to one place of decimals or to four significant figures for relative weights of less than 100.

Pharmacopoeias

The selected pharmacopoeias in which each substance appears are listed. A description of the substance and a summary of the pharmaceutical information (see below) that appears in the British, European, or US Pharmacopoeias is also included. Current copies of the pharmacopoeias and their addenda should be consulted for confirmation and for details of standards.

The pharmacopoeias covered include: *British, British Veterinary, Chinese, European, French, German, International, Italian, Japanese, Polish, Spanish, Swiss, United States* (including the *National Formulary*), and *Vietnamese*. The abbreviations for these pharmacopoeias are included in the list of abbreviations used in Martindale, see page viii, which also includes details of the edition and/or supplement(s) consulted.

Several countries are parties to the Convention on the Elaboration of a European Pharmacopoeia. This means that they must adopt the standards of the European Pharmacopoeia. These countries are currently Austria, Belgium, Bosnia and Herzegovina, Bulgaria, Croatia, Cyprus, the Czech Republic, Denmark, Estonia, Finland, France, Germany, Greece, Hungary, Iceland, Ireland, Italy, Latvia, Lithuania, Luxembourg, Malta, Montenegro, the Netherlands, Norway, Poland, Portugal, Romania, Serbia, Slovak Republic, Slovenia, Spain, Sweden, Switzerland, Turkey, the United Kingdom, and the Former Yugoslav Republic of Macedonia. Hence the European Pharmacopoeia is cited in the drug monograph lists of pharmacopoeias rather than these individual national pharmacopoeias.

Official preparations, mainly from the current British, European, and US Pharmacopoeias, are listed at the end of drug monographs.

Pharmaceutical Information

Information on the chemical and physical properties of each substance is given when it is likely to be of use or interest, but only when it is certain that it applies to the form of substance being described in the monograph.

PERCENTAGE STRENGTHS. Unless otherwise stated, solutions of solids in liquids are expressed as percentage w/v, of liquids in liquids as percentage v/v, and of gases in liquids as percentage w/w.

SOLUBILITY. The figures given for solubility in each monograph have generally been obtained from the major pharmacopoeias in which the substance is described, but should not be considered absolute. Unless otherwise indicated in the text, the figures are for solubility at temperatures between 15° and 25°. The information usually relates to w/v solubilities but in some cases is v/v if the monograph substance itself is a liquid. Where solubilities are given in words, the following terms describe the indicated solubility ranges:

solubility	
very soluble	1 in less than 1
freely soluble	1 in 1 to 1 in 10
soluble	1 in 10 to 1 in 30
sparingly soluble	1 in 30 to 1 in 100
slightly soluble	1 in 100 to 1 in 1000
very slightly soluble	1 in 1000 to 1 in 10 000
practically insoluble	1 in more than 10 000

STORAGE. Substances and preparations should be stored under conditions which prevent contamination and diminish deterioration, and the conditions of storage given in the text indicate the precautions recommended in specific cases. The term ‘a cool place’ is generally used to describe a place in which the temperature is between 8° and 15°. In general, the storage conditions apply to the monograph substance and not its solutions or preparations.

TEMPERATURE. Temperatures are expressed in degrees Celsius (centigrade) unless otherwise indicated.

Drugs in Sport

Wherever possible we have attempted to indicate those drugs and substances that may be subject to restriction in some or all sports, either in their own right, or because they are a derivative of a restricted substance or a member of a prohibited group. Proprietary preparations containing such compounds are also marked in the preparation section in Volume 2. The definitive guide used for identifying restricted drugs for this edition is the 2008 Prohibited List issued by the World Anti-Doping Agency (WADA—see www.wada-ama.org). However, these regulations, which are issued annually, are subject to interpretation and therapeutic exemption, and may vary from sport to sport; particular sporting authorities may also issue additional restrictions, and competitors should always check with the appropriate body. The rules are constantly evolving and the absence of any indication of restriction in Martindale should not be taken as absolute confirmation that the substance may legitimately be taken by a competitor.

Pharmacological and Therapeutic Information

Information on adverse effects, treatment of adverse effects, precautions (including contra-indications), interactions, pharmacokinetics, and uses and administration of each substance is provided by concise statements and these may be elaborated and expanded by referenced reviews and abstracts from papers and other publications. This edition contains about 15 000 such abstracts or reviews based on information in an ever widening range of publications.

Much information has been found in sources such as World Health Organization publications, government reports and legislation, and other official and standard publications. Licensed product information and manufacturers' literature has been considered in the light of other available information.

The risks of giving drugs in pregnancy are well known and the general principle is to give a drug only when the benefit to the individual mother outweighs the risk to the fetus. Where there is a clear risk it is noted under the Precautions or Adverse Effects heading but safety should not be inferred from the absence of a statement for any drug.

Some drugs given to the mother are distributed into breast milk and therefore may pose a risk to a breast-fed infant. Whenever possible, information has been included to help determine the safety of continuing to breast feed while the mother is receiving a particular drug. Safety during breast feeding should not be inferred from the absence of a statement for any drug.

Doses

Doses are described under the Uses and Administration heading with as much detail as is necessary and available. Unless otherwise stated the doses represent the average range of quantities which are generally regarded as suitable for adults when given by mouth. More information on doses and drug administration may be given in the abstracts or reviews. Unless otherwise specified, glucose injection is 5% w/v and sodium chloride injection is 0.9% w/v.

When doses for children are expressed as a range of quantities within specified age limits, the lower dose applies at the lower age and the higher dose at the higher age.

Acknowledgements

The Editor gratefully acknowledges the advice and assistance of the many experts who have suggested amendments to the text of Martindale. Thanks are also due to K Baxter, M Jane, CR Lee, DK Mehta, F Post, and AB Prasad, for advice and comments on specific issues during revision. The Editor is grateful to the many organisations that have helped in providing information, including the World Health Organization, the British Pharmacopoeia Commission, and our Spanish colleagues at Grupo Ars XXI.

Martindale staff have been able to call on the expertise of other members of the Royal Pharmaceutical Society's staff. In particular the Editor is grateful to J Martin and the staff of the British National Formulary, and the staff of the library and information department. Thanks are due to I Baxter, M Davis, S Driver, EJ Laughton, R McLarney, and SJ Shankie for their editorial tasks. Thanks are also due to PJ Weller, C Fry and the staff of the Pharmaceutical Press for their support.

The contents of this 36th edition were planned, written, checked, indexed, keyed, proofed, and processed by the Martindale staff. The Editor is pleased to acknowledge the skills and commitment of all the Martindale staff and to record his gratitude: to Christine Iskandar for clerical assistance; to Michael Evans for Knowledge Systems support; to Chloë Hatwal, Elizabeth King, James O’Reilly, and Elen Shute for editorial assistance; to the Staff Editors Catherine Cadart, Kathleen Eager, Sue Handy, Fauziah Hashmi, Sue Ho, Joanna Humm, Jean Macpherson, Melissa Siew, Sandra Sutton, and Gerda Viedge; to the Assistant Editors Alison Brayfield, Julie McGlashan, Gail Neathercoat, and Anne Parsons; and to the Senior Assistant Editor Paul Blake.

FAO/WHO—Food and Agriculture Organization of the United Nations *and the* World Health Organization.
FDA—Food and Drug Administration of USA.
FdAC—Food Advisory Committee of the former Ministry of Agriculture, Fisheries and Food (UK).
FD & C—designation applied in USA to dyes permitted for use in foods, drugs, and cosmetics.
FEV_1—forced expiratory volume in 1 second.
Fin.—Finland.
FIP—Fédération Internationale Pharmaceutique.
f.p.—freezing point.
FPA—Family Planning Association (UK).
Fr.—France.
Fr. P.—French Pharmacopoeia 1982 (Pharmacopée Francaise, X^e Edition) and updates up to 2003.
g—gram(s).
Ger.—Germany.
Ger. P.— German Pharmacopoeia (Deutsches Arzneibuch, 2007).
GFR—glomerular filtration rate.
G6PD—glucose-6-phosphate dehydrogenase.
Gr.—Greece.
HAART—highly active antiretroviral therapy.
Hb— haemoglobin.
Hib—*Haemophilus influenzae* type b.
HIV—human immunodeficiency virus.
HLA—human lymphocyte antigens.
HLB—hydrophilic-lipophilic balance.

HRT—hormone replacement therapy.
HSE—Health and Safety Executive (UK).
Hung.—Hungary.
IARC—International Agency for Research on Cancer.
ibid.—*ibidem*, 'in the same place (journal or book)'.
idem—'the same': used for the same authors and titles.
i.e.—*id est*, 'that is'.
Ig—immunoglobulin.
Indon.—Indonesia.
INN—International Nonproprietary Name.
INNM—International Nonproprietary Name Modified.
Int. P.—International Pharmacopoeia 4th ed., 2006.
IPCS—International Programme on Chemical Safety.
IQ—intelligence quotient.
Irl.—Ireland.
ISH—International Society of Hypertension.
It. P.—Italian Pharmacopoeia 11th ed., 2002 (Farmacopea Ufficiale della Repubblica Italiana, XI Edizione, 2002).
Ital.—Italy.
IUD—intra-uterine device.
IUPAC—International Union of Pure and Applied Chemistry.
IVF—*in-vitro* fertilisation.
J—joule(s).
Jpn—Japan.
Jpn P.—The Pharmacopoeia of Japan, 15th ed., 2006.
K—kelvin.
kcal—kilocalorie(s).
kg—kilogram(s).
kJ—kilojoule(s).
lb—pound(s) avoirdupois.
LD50—a dose lethal to 50% of the specified animals or micro-organisms.
m—metre(s).
m^2—square metre(s).
m^3—cubic metre(s).
M—molar.
MAFF—the former Ministry of Agriculture, Fisheries and Food (UK), now Department of Environment, Food, and Rural Affairs (DEFRA).
MAOI—monoamine oxidase inhibitor.
max.—maximum.
MBC—minimum bactericidal concentration.
MCA—Medicines Control Agency, now MHRA (UK).
mEq—milliequivalent(s).
Mex.—Mexico.
mg—milligram(s).
MHRA—Medicines and Healthcare products Regulatory Agency (UK).
MIC—minimum inhibitory concentration.
min—minute.
min.—minimum.
MJ—megajoule(s).
mL—millilitre(s).
mm—millimetre(s).
mm^2—square millimetre(s).
mm^3—cubic millimetre(s).
mmHg—millimetre(s) of mercury.
mmol—millimole.
mol—mole.
mol. wt—molecular weight.
Mon.—Monaco.
mosmol—milliosmole.
m.p.—melting point.
MRC—Medical Research Council (UK).
MRSA—meticillin-resistant *Staphylococcus aureus*.
μg—microgram(s).
μm—micrometre(s).
Neth.—The Netherlands.
NICE—National Institute for Health and Clinical Excellence (formerly the National Institute for Clinical Excellence) (UK).
NIH—National Institutes of Health (USA).
nm—nanometre(s).
NMDA—*N*-methyl-D-aspartate.
NNRTI—non-nucleoside reverse transcriptase inhibitor.
Norw.—Norway.
NRTI—nucleoside reverse transcriptase inhibitor.
NSAID—nonsteroidal anti-inflammatory drug.
NYHA—New York Heart Association.
NZ—New Zealand.
OP—over proof.
o/w—oil-in-water.
P—probability.
Pa—pascal(s).
pCO_2—plasma partial pressure (concentration) of carbon dioxide.
p_aCO_2—arterial plasma partial pressure (concentration) of carbon dioxide.
PEN—Pharmacy Equivalent Name, see page vi.
pg—picogram(s).
pH—the negative logarithm of the hydrogen ion concentration.
Ph. Eur.—European Pharmacopoeia, 6th ed., 2008 and Supplements 6.1 and 6.2.
Pharm. Soc. Lab. Rep.—Royal Pharmaceutical Society's Laboratory Report.
Philipp.—Philippines.
PHLS—Public Health Laboratory Service (UK).
pINN—Proposed International Nonproprietary Name.
pINNM—Proposed International Nonproprietary Name Modified.
pK_a—the negative logarithm of the dissociation constant.
p.m.—*post meridiem*, 'afternoon'.
pO_2—plasma partial pressure (concentration) of oxygen.
p_aO_2—arterial plasma partial pressure (concentration) of oxygen.
Pol.—Poland.
Pol. P.—Polish Pharmacopoeia 6th ed., 2002 (Farmakopea Polska VI, 2002) and Supplement 2005.
Port.—Portugal.
ppm—parts per million.
PSGB—The Pharmaceutical Society of Great Britain. Now the Royal Pharmaceutical Society of Great Britain.
PUVA—psoralen with UVA light irradiation.
PVC—polyvinyl chloride.
RCGP—Royal College of General Practitioners (UK).
RIMA—reversible inhibitor of monoamine oxidase type A.
rINN—Recommended International Nonproprietary Name.
rINNM—Recommended International Nonproprietary Name Modified.
RNA—ribonucleic acid.
RPSGB—The Royal Pharmaceutical Society of Great Britain.
RSV—respiratory syncytial virus.
S. Afr.—South Africa.
SGOT—serum glutamic oxaloacetic transaminase (serum aspartate aminotransferase *now preferred*).

SGPT—serum glutamic pyruvic transaminase (serum alanine aminotransferase *now preferred*).
SI—Statutory Instrument *or* Système International d'Unités (International System of Units).
sic—written exactly as it appears in the original.
SLE—systemic lupus erythematosus.
sp.—species (plural spp.).
sp. gr.—specific gravity.
Span.—Spanish.
Span. P.—Spanish Pharmacopoeia 2nd ed., 2002 (Real Farmacopoea Española, Segunda Edición, 2002) and Supplement 2.1.
SSRI—selective serotonin reuptake inhibitor.
St—stokes.
subsp.—subspecies.
suppl—supplement(s).
Swed.—Sweden.
Swiss P.—Swiss Pharmacopoeia 2006 (Pharmacopoea Helvetica, 10 Ausgabe, Deutsche Ausgabe).
Switz.—Switzerland.
Thai.—Thailand.
TNF—tumour necrosis factor.
TPN—total parenteral nutrition.
Turk.—Turkey.
UAE—United Arab Emirates.
UK—United Kingdom.
UNICEF—United Nations Children's Fund.
UP—under proof.
Urug.—Uruguay.
US and ***USA***—United States of America.
USAN—United States Adopted Name.
USNF—The United States 'National Formulary 26', 2008, and Supplements 1 and 2.
USP—The United States Pharmacopeia 31, 2008, and Supplements 1 and 2.
UV—ultraviolet.
var.—variety.
Venez.—Venezuela.
Viet.—Vietnamese.
Viet. P.—Vietnamese Pharmacopoeia 2002 (Pharmacopoeia Vietnamica, Editio III).
vol.—volume(s).
v/v—volume in volume.
v/w—volume in weight.
WHO—World Health Organization.
w/o—water-in-oil.
wt—weight.
wt per mL—weight per millilitre.
w/v—weight in volume.
w/w—weight in weight.

Contracted Names for Ions and Groups

Contracted Name	Chemical Name
acefurate	acetate (ester) and furan-2-carboxylate (ester)
aceglumate	*rac*-hydrogen *N*-acetylglutmate
aceponate	acetate (ester) and propionate (ester)
acetonide	isopropylidenedioxy or propane-2,2-diylbis(oxy)
aceturate	*N*-acetylglycinate
acibutate	acetate (ester) and 2-methylpropanoate (ester)
acistrate	acetate (ester) and stearate (salt)
acoxil	acetoxymethyl or (acetyloxy)methyl
alfoscerate	(2*R*)-2,3-dihydroxypropyl hydrogen phosphate
alideximer	poly([oxy(2-hydroxyethane-1,1-diyl)]{oxy[1-(hydroxymethyl)ethane-1,2-diyl]}) partly *O*-etherified with carboxymethyl groups with some carboxy groups amide linked to the tetrapeptide residue (glyglyglycyl-L-phenylalanylglycyl)
amsonate	4,4′-diaminostilbene-2,2′-disulfonate or 2,2′-ethene-1,2-diylbis(5-aminobenzene-1-sulfonate)
anisatil	2-(4-methoxyphenyl)-2-oxoethyl or *p*-methoxyphenacyl
arbamel	2-(dimethylamino)-2-oxoethyl or ester with *N*,*N*-dimethylglycolamide
argine	30^{B}α–L-argine-30^{B}β-L-argine
aritox	ricin A chain-MAB immunotoxine
aspart	28^{B}-L-aspartic acid-
axetil	(*RS*)-1-acetoxyethyl or *rac*-1-(acetyloxy)ethyl
beloxil	benzyloxy
benetonide	*N*-benzoyl-2-methyl-β-alanine (ester) and acetonide
besilate (besylate)	benzenesulfonate
betadex	β-cyclodextrin
bezomil	(benzoyloxy)methyl
buciclate	*trans*-4-butylcyclohexanecarboxylate
bunapsilate	3,7-di-*tert*-butylnaphthalene-1,5-disulfonate
buteprate	butyrate (ester) and propionate (ester)
camsilate (camsylate)	camphor-10-sulfonate or (7,7-dimethyl-2-oxobicyclo[2.2.1]heptan-1-yl)methanesulfonate
caproate	hexanoate
carbesilate	4-sulfobenzoate
ciclotate (cyclotate)	4-methylbicyclo[2.2.2]oct-2-ene-1-carboxylate
cilexetil	(*RS*)-1-{[(cyclohexyloxy)carbonyl]oxy}ethyl or *rac*-1-{[(cyclohexyloxy)carbonyl]oxy}ethyl
cipionate (cypionate)	cyclopentanepropionate or 3-cyclopentylpropanoate
cituxetan	*rac*-*N*-(4-{2-[bis(carboxymethyl)amino]-3-({2-[bis(carboxymethyl)amino]ethyl}(carboxymethyl)amino)propyl}phenyl)thiocarbamoyl
clofibrol	2-(4-chlorophenoxy)-2-methylpropyl
closilate (closylate)	4-chlorobenzene-1-sulfonate
crobefate	*rac*-{3-[(3*E*)-4-methoxybenzylidene]-2-(4-methoxyphenyl)chroman-6-yl phosphate(2-)}
cromacate	2-[(6-hydroxy-4-methyl-2-oxo-2*H*-chromen-7-yl)oxy]acetate
cromesilate	6,7-dihydroxycoumarin-4-methanesulfonate or (6,7-dihydroxy-2-oxo-2*H*-chromen-4-yl)methanesulfonate
crosfumaril	(2*E*)-but-2-enedioyl
cyclamate	cyclohexylsulfamate
daloxate	L-alaninate (ester) and (5-methyl-2-oxo-1,3-dioxol-4-yl)methyl
daropate (dapropate)	*N*,*N*-dimethyl-β-alaninate or 3-(dimethylamino)propanoate
deanil	2-(dimethylamino)ethyl
decil	decyl
defalan	des-1^{B}-L-phenylalanine-insulin
detemir	tetradecanoyl
dibudinate	2,6-di-*tert*-butylnaphthalene-1,5-disulfonate
dibunate	2,6-di-*tert*-butylnaphthalene-1-sulfonate
dicibate	dicyclohexylmethyl carbonate
diftitox	*N*-L-methionyl-387-L-histidine-388-L-alanine-1-388-toxin (*Corynebacterium diphtheriae* strain C7) (388→2′)-protein
digolil	2-(2-hydroxyethoxy)ethyl
diolamine	2,2′-azanediyldiethanol or diethanolamine
docosil	docosyl
dofosfate	octadecyl hydrogen phosphate
ecamate	*N*-ethylcarbamate
edamine	ethane-1,2-diamine or ethylenediamine
edetate	ethylenediamine-*NNN′N′*-tetra-acetate
edisilate (edisylate)	ethane-1,2-disulfonate
embonate	4,4′-methylenebis(3-hydroxynaphthalene-2-carboxylate) or 4,4′-methylenebis(3-hydroxy-2-naphthoate) (=pamoate)
enantate (enanthate)	heptanoate
enbutate	acetate (ester) and butanoate (ester)
epolamine	1-pyrrolidineethanol or 2-(pyrrolidin-1-yl)ethanol
erbumine	*tert*-butylamine or 2-methylpropan-2-amine
esilate (esylate)	ethanesulfonate
estolate	propanoate (ester) and dodecyl sulfate (salt) or propionate dodecyl sulfate
etabonate	(ethoxycarbonyl)oxy (=ethyl carbonate)
etilsulfate	ethyl sulfate
farnesil	(2*E*,6*E*)-3,7,11-trimethyldodeca-2,6,10-trien-1-yl
fendizoate	2-(6-hydroxybiphenyl-3-carbonyl)benzoate
fostedate	tetradecyl hydrogen phosphate
furetonide	1-benzofurane-2-carboxylate (ester) and propane-2,2-diylbis(oxy)
gamolenate	(6*Z*,9*Z*,12*Z*)-octadeca-6,9,12-trienoate
glargine	21^{A}-glycine-30^{B}α-L-arginine-30^{B}β-L-arginine
gluceptate	D-*glycero*-D-*gulo*-heptanoate or D-*glycero*-D-*gulo*-heptonate
glulisine	[3^{B}-L-lysine,29^{B}-L-glutamic acid]
glutamer	glutaraldehyde polymer
guacil	2-methoxyphenyl
hemisuccinate	hydrogen butanedioate

Contracted Name	Chemical Name
hexacetonide	3,3-dimethylbutanoate (ester) and propan-2,2-diylbis(oxy) or 3,3-dimethylbutyrate (ester) and acetonide
hibenzate (hybenzate)	2-(4-hydroxybenzoyl)benzoate
hyclate	monohydrochloride hemi-ethanolate hemihydrate
hydroxynaphtoate	3-hydroxynapthalene-2-carboxylate
isetionate (isethionate)	2-hydroxyethane-1-sulfonate
laurate	dodecanoate
lauril	dodecyl
laurilsulfate (lauryl sulphate)	dodecyl sulfate
lisetil	L-lysinate (ester) and diethyl (ester)
lisicol	{*N*-[(5*S*)-5-carboxy-5-(3α,7α,12α-trihydroxy-5β-cholan-24-amido)pentyl]carbamothioyl}amino
lispro	28^{B}-L-lysine-29^{B}-L-proline
mafenatox	enterotoxin A (227-alanine) (*Staphylococcus aureus*)
medoxomil	(5-methyl-2-oxo-1,3-dioxol-4-yl)methyl
megallate	3,4,5-trimethoxybenzoate
meglumine	*N*-methylglucamine
merpentan	4,5-bis(2-mercaptoacetamido) valeric acid or {*N*,*N*′-[1-(3-oxopropyl)ethane-1,2-diyl]bis(2-sulfanylacetamidato)}(4-)
mertansine	tetrakis{(4*RS*)-4[(3-{[(1*S*)-2-{[(1*S*,2*R*,3*S*,5*S*,6*S*,16*E*,18*E*,20*R*,21*S*)-11-chloro-21-hydroxy-12,20-dimethoxy-2,5,9,16-tetramethyl-8,23-dioxo-4,24-dioxa-9,22-diazatetracyclo[19.3.1.$1^{10,14}$.$0^{3,5}$]hexacosa-10,12,14(26),16,18-pentaen-6-yl]oxy}-1-methyl-oxoethyl]methylamino}-3-oxopropyl)disulfanyl]pentanoyl}
mesilate (mesylate)	methanesulfonate
metembonate	4,4′-methylenebis(3-methoxynaphthalene-2-carboxylate)
methonitrate	*N*-methyl, nitrate (salt)
metilsulfate	methyl sulfate
metiodide	*N*-methyl, iodide (salt)
methylbromide	*N*-methyl, bromide (salt)
mofetil	2-(morpholino)ethyl or 2-(morpholin-4-yl)ethyl
napadisilate	naphthalene-1,5-disulfonate
napsilate (napsylate)	naphthalene-2-sulfonate
nicotinate	pyridine-3-carboxylate
octil	octyl
olamine	2-aminoethanol or ethanolamine
oleate	(9*Z*)-octadec-9-enoate
oxoglurate	hydrogen 2-oxopentanedioate
palmitate	hexadecanoate
pamoate	4,4′-methylenebis(3-hydroxy-2-naphthoate) (=embonate)
pegol	α-(2-carboxyethyl)-ω-methoxypoly(oxyethane-1,2-diyl)
pendetide	N^6-{*N*-[2-({2-[bis(carboxymethyl)amino]-ethyl}(carboxymethyl)amino)ethyl]-*N*-(carboxymethyl)glycyl}-N^2-(*N*-glycyl-L-tyrosyl)-L-lysine
pentexil	(*RS*)-1-[(2,2-dimethylpropanoyl)oxy]ethyl
phenpropionate	3-phenylpropionate
pivalate	2,2-dimethylpropanoate (ester) or trimethylacetate
pivoxetil	*rac*-1-[(2-methoxy-2-methylpropanoyl)oxy]ethyl or 1-(2-methoxy-2-methylpropionyloxy)ethyl
pivoxil	(2,2-dimethyl-1-oxopropoxy)methyl or [(2,2-dimethylpropanoyl)oxy]methyl or (pivaloyloxy)methyl
poliglumex	[poly(L-glutamic acid)$_z$—(L-glutamate-γ-ester)—poly(L-glutamic acid)$_y$]$_n$
probutate	17-(1-oxobutoxy) (ester) and 21-(1-oxopropoxy) (ester) or propionate (ester) and butyrate (ester)
proxetil	1-[(isopropoxycarbonyl)oxy]ethyl or *rac*-1-{[(propan-2-yloxy)carbonyl]oxy}ethyl
raffimer	(2*S*,4*R*,6*R*,8*S*,11*S*,13*S*)-2,4,8,13-tetrakis(hydroxymethyl)-4,6,11-tris(ylomethyl)-3,5,7,10,12-pentaoxatetradecane-1,14-diyl
salicylate	2-hydroxybenzoate
sesquioleate	(9*Z*)-octadec-9-enoate(1.5)
soproxil	{[(propan-2-yloxy)carbonyl]oxy}methyl
steaglate	2-(octadecanoyloxy)acetate (ester)
stearate	octadecanoate
stinoprate	*N*-acetylcysteinate (salt) and propanoate (ester)
succinil	3-carboxypropanoyl
sudotox	248-L-histidine-249-L-methionine-250-L-alanine-251-L-glutamic acid-248-613-endotoxin A (*Pseudomonas aeruginosa* reduced)
suleptanate	monosodium 8-[methyl(2-sulfoethyl)amino]-8-oxooctanoate or monosodium 7-[methyl(2-sulfonatomethyl)carbamoyl]heptanoyl
sulfoxylate	sulfinomethyl, monosodium salt
tafenatox	enterotoxin A (*Staphylococcus aureus*)
tartrate	(2*R*,3*R*)-2,3-dihydroxybutanedioate
tebutate	*tert*-butylacetate or 3,3-dimethylbutyrate
tenoate	thiophene-2-carboxylate
teoclate	8-chloro-1,3-dimethyl-2,6-dioxo-3,6-dihydro-1*H*-purin-7-(2*H*)-ide or 8-chlorotheophyllinate
teprosilate	3-(1,3-dimethyl-2,6-dioxo-1,2,3,6-tetrahydro-7*H*-purin-7-yl)propane-1-sulfonate
tidoxil	*rac*-2-(decyloxy)-3-(dodecylsulfanyl)propyl
tiuxetan	*N*-(4-{(2*S*)-2-[bis(carboxymethyl)amino]-3-[(2*RS*)-{2-[bis(carboxymethyl)amino]propyl}(carboxymethyl)amino]propyl}phenyl) thiocarbamoyl
tocoferil	*rac*-(2*R*)-2,5,7,8-tetramethyl-2-[(4*R*,8*R*)-4,8,12-trimethyltridecyl]chroman-6-yl
tofesilate	3-(1,3-dimethyl-2,6-dioxo-1,2,3,6-tetrahydro-7*H*-purin-7-yl)ethane-1-sulfonate
tosilate (tosylate)	4-methylbenzene-1-sulfonate or toluene-4-sulfonate
triclofenate	2,4,5-trichlorophenolate
triflutate	trifluoroacetate
trioleate	(9*Z*)-octadec-9-enoate(3) or tris[(9*Z*)-octadec-9-enoate]
tristearate	octadecanoate(3) or tris(octadecanoate)
trolamine	2,2′,2″-nitrilotriethanol or triethanolamine
troxundate	[2-(2-ethoxyethoxy)ethoxy]acetate or 3,6,9-trioxaundecanoate
undecylate	undecanoate
undecylenate	undec-10-enoate
valerate	pentanoate
xinafoate	1-hydroxynaphthalene-2-carboxylate or 1-hydroxy-2-naphthoate

Elements marked (*) have no stable nuclides and IUPAC states "there is no general agreement on which of the isotopes of the radioactive elements is, or is likely to be judged 'important' and various criteria such as 'longest half-life', 'production in quantity', 'used commercially', etc., have been applied in the Commission's choice." However, atomic weights are given for radioactive elements marked (†) as they do have a characteristic terrestrial isotopic composition. Commercially available lithium (‡) materials have atomic weights ranging from 6.939 to 6.996; if a more accurate value is required, it must be determined for the specific material.

The drugs described in this chapter are used mainly in the relief of pain, inflammation and, in some cases, fever. They can be grouped broadly into one of the categories briefly described below.

Aspirin and other salicylates

Aspirin and other salicylates have analgesic, anti-inflammatory, and antipyretic properties. Like other NSAIDs (see below) they are inhibitors of the enzyme cyclo-oxygenase; however, aspirin (though not the non-acetylated salicylates) irreversibly acetylates the enzyme whereas other NSAIDs compete with arachidonic acid for the active site. Salicylates are used for the relief of mild to moderate pain, minor febrile conditions, and for acute and chronic inflammatory disorders such as osteoarthritis, rheumatoid arthritis, juvenile idiopathic arthritis, and ankylosing spondylitis. Some salicylates are applied topically in rubefacient preparations for the relief of muscular and rheumatic pain. Aspirin also inhibits platelet aggregation and is used in cardiovascular disorders. Non-acetylated salicylates do not have antiplatelet activity.

Disease-modifying antirheumatic drugs

Disease-modifying antirheumatic drugs (DMARDs) have anti-inflammatory properties thought to be mediated, in some cases, by the inhibition of the release or activity of cytokines. They are used in the treatment of rheumatoid arthritis and juvenile idiopathic arthritis; some are also of benefit in ankylosing spondylitis and psoriatic arthritis. Many DMARDs also possess other therapeutic properties and are used in non-rheumatic conditions. The DMARD gold is referred to below; other DMARDs include sulfasalazine (p.1773), penicillamine (p.1456), the antimalarials chloroquine (p.599) and hydroxychloroquine (p.604), rituximab (p.767), and the immunosuppressants azathioprine (p.1818), ciclosporin (p.1822), cyclophosphamide (p.702), and methotrexate (p.745).

Gold compounds

Gold compounds are used mainly for their anti-inflammatory effect in active progressive rheumatoid arthritis and progressive juvenile idiopathic arthritis; they may also be beneficial in psoriatic arthritis. The mechanism of action of gold compounds in rheumatic disorders is as yet unknown.

Nonsteroidal anti-inflammatory drugs

Nonsteroidal anti-inflammatory drugs (NSAIDs) are a group of structurally unrelated organic acids that have analgesic, anti-inflammatory, and antipyretic properties (see p.96). NSAIDs are inhibitors of the enzyme cyclo-oxygenase, and so directly inhibit the biosynthesis of prostaglandins and thromboxanes from arachidonic acid (see p.2374). There are 2 forms of cyclo-oxygenase (COX), COX-1, which is the constitutive form of the enzyme, and COX-2, which is the form induced in the presence of inflammation. Inhibition of COX-2 is therefore thought to be responsible for at least some of the analgesic, anti-inflammatory, and antipyretic properties of NSAIDs whereas inhibition of COX-1 is thought to produce some of their toxic effects, particularly those on the gastrointestinal tract. Most of the NSAIDs currently available for clinical use inhibit both COX-1 and COX-2, although selective COX-2 inhibitors such as celecoxib are now available.

NSAIDs are used for the relief of mild to moderate pain, minor febrile conditions, and for acute and chronic inflammatory disorders such as osteoarthritis, rheumatoid arthritis, juvenile idiopathic arthritis, and ankylosing spondylitis. Indometacin and some other NSAIDs are used to close patent ductus arteriosus in premature neonates. Some NSAIDs are applied topically for the relief of muscular and rheumatic pain, and some are used in ophthalmic preparations for ocular inflammatory disorders. Aspirin (see above) is considered to be an NSAID, although it also has other properties.

Opioid analgesics

Opioid analgesics include the opium alkaloids morphine and codeine and their derivatives as well as synthetic substances with agonist, partial agonist, or mixed agonist and antagonist activity at opioid receptors (see p.101). The term opiate analgesics refers only to those opioids derived from opium, or their semisynthetic congeners. The term narcotic analgesics has legal connotations and is no longer used pharmacologically or clinically.

Most opioids are used as analgesics, and morphine is the standard against which all other opioid analgesics are compared. Opioids such as codeine or dextropropoxyphene are used in the treatment of less severe pain, and are often combined with non-opioid analgesics such as aspirin, other NSAIDs, or paracetamol. More potent opioids such as morphine are used in severe acute and chronic pain, including cancer pain. Some opioids such as codeine, morphine, and diamorphine are also used as antitussives, although the latter two are usually reserved for use in terminal lung disease. Some opioid analgesics such as fentanyl and its congeners are used mainly as adjuncts to anaesthesia; some of these may also be used in higher doses as the sole anaesthetic drug.

Some opioids are rarely if ever used as analgesics and are described elsewhere; they include the antitussives dextromethorphan (p.1555) and pholcodine (p.1570), and the antidiarrhoeals diphenoxylate (p.1724) and loperamide (p.1741).

Opioids can produce physical dependence and withdrawal symptoms if suddenly stopped. They are also subject to abuse.

Paracetamol and other para-aminophenols

Paracetamol is the principal para-aminophenol derivative in use. Acetanilide and phenacetin have generally been replaced by safer analgesics. Propacetamol is hydrolysed to paracetamol in the plasma.

Paracetamol has analgesic and antipyretic properties and weak anti-inflammatory activity. The mechanism of analgesic action remains to be fully elucidated, but may be due to inhibition of prostaglandin synthesis both centrally and peripherally. Paracetamol is used for the relief of mild to moderate pain and minor febrile conditions.

Analgesia and Pain

Pain is defined by the International Association for the Study of Pain as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage.'

Under normal circumstances pain is the result of stimulation of peripheral receptors that transmit impulses through pain pathways to the brain. Pain receptors or nociceptors are of two basic types:

- *mechanoheat receptors* have a high stimulation threshold and respond to intense or potentially damaging noxious stimuli. These receptors are associated with rapidly conducting, thinly myelinated Aδ fibres, and their stimulation produces rapid sharp localised pain that serves to activate withdrawal reflexes
- *polymodal nociceptors* respond to mechanical, thermal, or chemical insults. These receptors are also activated by cellular components that are released after tissue damage. Their impulses are transmitted slowly along unmyelinated C type fibres and produce dull, aching, and poorly localised pain with a slower onset

Nerve fibres from nociceptors terminate in the dorsal root of the spinal cord before transmission by ascending pathways to the brain. There have been many theories on the processing of pain signals at the spinal level but the 'gate theory' proposed by Melzack and Wall is one of the best known. This theory postulates that the transmission of impulses to the brain is modulated by a gate mechanism in the substantia gelatinosa. Stimulation of small fibres opens the gate and facilitates transmission whereas stimulation of large fibres, which normally carry non-painful sensory input, can close the gate and inhibit transmission. Transmission also appears to be modulated by several other mechanisms which can influence the sensitivity of the gate.

Inflammatory mediators such as bradykinin, histamine, serotonin, and prostaglandins produced in response to tissue damage can produce peripheral sensitisation so that receptors respond to low intensity or innocuous stimuli; central sensitisation also occurs. Pain associated with tissue damage hence results in increased sensitivity of the sensory system so that the pain can occur in the absence of a clear stimulus. There may be a reduction in the pain threshold (*allodynia*) resulting in an exaggerated response (*hyperalgesia*) or a prolonged effect (*hyperpathia*).

Pain is often classified as being acute or chronic in nature.

- **Acute pain** is associated with trauma or disease and usually has a well-defined location, character, and timing. It is accompanied by symptoms of autonomic hyperactivity such as tachycardia, hypertension, sweating, and mydriasis.
- **Chronic pain** is usually regarded as pain lasting more than a few months. It may not be clearly associated with trauma or disease or may persist after the initial injury has healed; its localisation, character, and timing are more vague than with acute pain. Furthermore, as the autonomic nervous system adapts, the signs of autonomic hyperactivity associated with acute pain disappear. Some forms of pain regarded as being chronic may consist of intermittent attacks of pain followed by relatively long pain-free periods. Patients with chronic pain experience physical, psychological, social, and functional deterioration which contributes towards exacerbation of the pain.

Physiologically, pain may be divided into nociceptive pain and neuropathic pain.

- **Nociceptive pain** follows activation of nociceptors by noxious stimuli as described above but is not associated with injury to peripheral nerves or the CNS. It may be somatic or visceral, depending on which receptors or nerves are involved. *Somatic pain* is usually well localised and may be described as deeply located, sharp or dull, nagging, stabbing, throbbing, or pressure-like. *Visceral pain* is generally less localised and more diffuse than somatic pain and may be referred to remote areas of the body. Depending on the structure involved it is variously described as deeply located, aching, nagging, cramping, or pressing and may be accompanied by nausea and vomiting. Nociceptive pain usually responds to treatment with conventional analgesics.
- Pain resulting from damage or dysfunction of peripheral nerves/receptors or of the CNS is known as **neuropathic pain** (or neurogenic pain). The term covers *sympathetically maintained pain* including causalgia and reflex sympathetic dystrophy, and painful conditions such as postherpetic and trigeminal neuralgia, and diabetic neuropathy. Neuropathic pain associated with central nervous tissue, such as in central post-stroke pain (the thalamic syndrome) is referred to as *central pain*. The clinical signs of neuropathic pain can vary greatly. Some of the more common features include heightened pain sensitivity and sensations of superficial burning or stabbing (lancinating) pain. The pain may be associated with areas of sensory deficit or some form of autonomic instability. Neuropathic pain responds poorly to conventional analgesics and can be difficult to treat.

Early **treatment** of pain is important as unrelieved pain can have profound psychological effects on the patient, and acute pain that is poorly managed initially can degenerate into chronic pain, which may prove to be much more difficult to treat. It is important to assess and treat the mental and emotional aspects of the pain as well as its physical aspects. Although drug therapy is a mainstay of pain treatment (see below), physical methods such as physiotherapy (including massage and the application of heat and cold), surgery, and nervous system stimulation techniques such as acupuncture and transcutaneous electrical nerve stimulation (TENS) are also used.

Choice of analgesic

Paracetamol and **NSAIDs** are the first choice analgesics for treating mild to moderate pain and are also used in moderate to severe pain to potentiate the effects of opioids. They are suitable for use in acute or chronic pain. Effective relief of acute pain can be achieved with oral NSAIDs and with paracetamol (particularly in combination with an opioid—see below). Dependence and tolerance are not a problem with non-opioid analgesics but they have a rather flat dose-response curve: as the dose is increased, the increase in pain relief may be quite small. Aspirin and other non-selective NSAIDs inhibit blood platelet function, adversely affect the gastrointestinal tract, and can precipitate hypersensitivity reactions including asthma. The risk of severe upper gastrointestinal adverse effects may be less with selective inhibitors of cyclo-oxygenase-2 (COX-2) such as the coxibs, but their use has been greatly restricted by concerns about serious cardiovascular effects. Paracetamol does not have the haematological or gastrointestinal adverse effects of aspirin but large doses can produce severe or sometimes fatal hepatotoxicity. Giving paracetamol with an NSAID improves analgesia.

For the treatment of moderate or moderate to severe opioid-sensitive pain **codeine** is the traditional choice; alternatives include **dihydrocodeine** and **tramadol**. They are often given with non-opioid analgesics. Combinations of codeine with paracetamol at full doses produce a small but significant increase in analgesia compared with paracetamol alone and are one of the most effective options for acute pain, but the incidence of adverse effects increases with repeated use. Combinations of **dextropropoxyphene** with paracetamol or aspirin are no more effective in acute pain than the non-opioid alone; efficacy in chronic pain is unclear and adverse effects may become troublesome. The combination preparation co-proxamol (dextropropoxyphene with paracetamol) has been gradually withdrawn from the UK market because of poorly established efficacy and the risk of toxicity in overdose.

More potent opioids such as **morphine** are mainly used in the treatment of severe acute non-malignant pain and cancer pain (see below). Their use in chronic non-malignant pain is somewhat controversial because of fears of psychological dependence and respiratory depression. However, in practice such problems rarely occur and those fears should not prevent patients being given effective analgesic therapy. Opioids may also be of value in neuropathic pain in some patients.

Morphine is the opioid of choice in severe pain. It is absorbed when given orally and has a short half-life so that the use of immediate-release oral preparations offers a flexible means of dosage titration in, for example, palliative care. Once initial pain relief has been achieved, administration of a modified-release preparation every 12 or 24 hours is more convenient for maintenance of analgesia in severe chronic pain. It may also be given parenterally (e.g. for control of acute severe pain in emergency departments or in patient-controlled analgesia—see also below), or rectally or transdermally, where there would be problems with the oral route.

Occasionally **other opioids** may be useful. Switching to an alternative opioid may be effective in patients who have inadequate pain control or intolerable adverse effects with morphine. Methadone (which also acts as an NMDA antagonist) or oxycodone have a longer duration of action than morphine, but it should be noted that methadone, which has a long half-life, should not be given more than twice daily when used long term because of the risk of progressive CNS depression and overdosage. A rapid onset of action is provided by alfentanil and fentanyl but use of pethidine is no longer recommended. Diamorphine or hydromorphone may be preferred to morphine when the parenteral route has to be used because they are more soluble and can be given in a smaller volume. Tramadol, which may impair respiratory and gastrointestinal function less than other opioids at equianalgesic doses, is also of benefit in neuropathic pain.

Adverse effects of opioids include sedation, nausea, vomiting, constipation, and, most seriously, respiratory depression. Tolerance generally develops to all of these effects except constipation, which may be prevented by regular use of laxatives.

A number of other groups of drugs have significant roles in pain management either alone or as **analgesic adjuvants**.

Subantidepressant doses of tricyclic **antidepressants** (usually amitriptyline) are considered to be useful in refractory chronic pain, including neuropathic pain of the burning, dysaesthetic type such as postherpetic neuralgia and diabetic neuropathy; shooting pain has also been reported to respond. They may be used in addition to conventional analgesics, notably in the treatment of cancer pain of mixed aetiology. There is little evidence for benefit in acute pain although musculoskeletal pain has sometimes responded. Amitriptyline has also been found to be useful for tension-type headache and for the prophylaxis of migraine. The role of other antidepressants in the treatment of neuropathic pain is less clear although venlafaxine may be useful.

Antiepileptics (often carbamazepine and, more recently, gabapentin and pregabalin) have been found useful in the relief of neuropathic pain, especially when there is a stabbing (lancinating) element, as in trigeminal neuralgia; there have also been reports of efficacy in the treatment of diabetic neuropathy and for migraine prophylaxis.

Benzodiazepines and **other muscle relaxants** such as baclofen or dantrolene are useful for relieving painful muscle spasm in acute or chronic conditions.

Bone modulating drugs such as calcitonin and bisphosphonates may be useful in cancer pain arising from bone metastases (see below) but have a slow onset of action and are second choice to NSAIDs. Bisphosphonates may cause an initial transient increase in bone pain.

Caffeine has been used with the aim of enhancing the effects of non-opioid and opioid analgesics but is of debatable benefit. There are similar doubts about whether caffeine enhances the effect of ergotamine in the treatment of migraine (see Pharmacokinetics, p.621); it may also add to gastrointestinal adverse effects and in large doses can itself cause headache.

Corticosteroids have produced improvement, often substantial, in neuropathic pain. They can also relieve headache caused by raised intracranial pressure and refractory pain caused by bone metastases, and have the added benefits of increasing well-being and appetite.

Some **inhalational anaesthetics** are used in subanaesthetic doses as inhalation analgesics for acute pain. In particular, nitrous oxide is given with oxygen for pain relief in obstetrics and during dental and other procedures, and in emergency management. Isoflurane, enflurane, and in some countries methoxyflurane or trichloroethylene have been used similarly.

Miscellaneous drugs. Following the discovery that epidural or intrathecal injection of opioids can produce effective analgesia many other drugs have been tried by these routes, either alone or with opioids or local anaesthetics, but their role, if any, in the management of pain remains to be determined. Some of these drugs, such as clonidine and ketamine, also appear to have analgesic properties when given by other routes, and ketamine may be useful in reducing opioid requirements. Some antiarrhythmics (including systemic lidocaine) may be effective in chronic neuropathic pain, but must be used with extreme caution. The use of antipsychotics, such as the phenothiazines, as adjuvant analgesics is controversial; levomepromazine is sometimes used as an adjunct in palliative care.

See below for discussions of the use of patient-controlled analgesia, and rubefacients and topical analgesics. Nerve blocks are discussed under Pain, on p.1852.

Choice of analgesics in children

Pain has often been undertreated in infants and children because of fears of respiratory depression, cardiovascular collapse, depressed levels of consciousness, and addiction with potent opioid analgesics. Assessment of pain is also a problem in children of all ages[1-3] and it is not that long since it was widely believed that neonates were incapable of feeling pain.

Non-opioid analgesics are used in ***infants and children***, either alone for minor pain or as an adjunct to opioid analgesics in severe pain,[4,5] (they can reduce opioid requirements,[1,6] perhaps by up to 40%[5]). Paracetamol is frequently used but it lacks any anti-inflammatory effect. NSAIDs such as ibuprofen are useful for minor pain,[4,5,7] especially when associated with inflammation or trauma. The use of aspirin is greatly restricted by its association with Reye's syndrome.

The **opioids** are still the mainstay of analgesia for moderate to severe pain in paediatric patients, and morphine is the standard against which the others are compared. It is given intravenously for rapid relief of severe pain (for example after burns, fractures or other injuries), and is titrated to achieve a suitable analgesic dose.[4,5,7,8] Where intravenous access is not readily achievable, oral morphine may be given but its onset is slower and less predictable; some favour intranasal diamorphine as an alternative to intravenous morphine.[4] Continuous intravenous morphine infusion with or without initial loading doses has become popular for postoperative pain relief,[6,8] but titration of the infusion rate is necessary to achieve a balance between analgesia and respiratory depression (particular care is needed in neonates, see below). Subcutaneous infusions of morphine have also been used,[5] mostly for the relief of terminal cancer pain in children. Intramuscular injections are painful[7-10] and therefore probably only suitable for short-term use. Fentanyl has also been widely used for short-term analgesia in surgical procedures,[6-8,10,11] and other opioids such as buprenorphine, hydromorphone, oxycodone, and tramadol have been given.[5] Patient-controlled analgesia using morphine has been tried in children (see below).

Morphine has also been given to children by the epidural route;[8] experience with the intrathecal route is more limited. Other methods of opioid drug delivery of possible value in paediatric analgesia include transmucosal,[6,11] nasal,[4,7] and transdermal[6,9] dosage.

Cancer pain in children may be treated using the analgesic ladder scheme described under Cancer Pain (see below).

Inhaled **nitrous oxide** and oxygen mixtures may be useful for preliminary pain relief and short, painful procedures.[4,7,8,10]

Local anaesthetics are especially suitable for the management of acute pain in day-care situations. Single injections given by the epidural route are often used to provide analgesia during and after surgery. Continuous epidural infusions of local anaesthetics have also been used. However, simpler techniques such as wound infiltration or peripheral nerve blocks can also provide effective analgesia for some procedures and are free of the problems of lower limb weakness or urinary retention associated with caudal blocks.[5,7,8,10] Application of eutectic creams (see Surface Anaesthesia, p.1866) containing lidocaine with prilocaine to intact skin, to produce surface anaesthesia, may be sufficient for some minor painful procedures in children.[6-9,11]

Ketamine is used in outpatients for brief, painful procedures such as fracture reduction and to provide immobility for repair of facial lacerations in young children.[11,12] The emergence reactions that limit its use in adults are less common in children,[11] and can be ameliorated by benzodiazepines.[7,10]

Most ***neonates*** requiring analgesia and receiving respiratory support can be managed with an infusion of morphine but in neonates who are breathing spontaneously there is a substantial risk of respiratory depression. Morphine has been used in such neonates[8] but should be limited to those under intensive care, as for example after major surgery (see also Intensive Care, p.957). Fentanyl citrate[1] and codeine phosphate have also been used in neonates. **Sucrose** and other sweet tasting solutions have been shown to reduce physiologic and behavioural indicators of stress and pain in neonates undergoing painful procedures[9] although there had been some doubt expressed over whether this indicates effective analgesia.[13] The American Academy of Pediatrics has suggested that oral sucrose together with other non-pharmacological methods such as swaddling should be used for minor routine procedures; topical local anaesthetics may be used for more painful procedures such as venepuncture if time permits. Opioids should be the basis of postoperative analgesia after major surgery in the absence of regional anaesthesia; a rapidly acting opioid such as fentanyl is advocated, together with infiltration of the site with a local anaesthetic where time permits, for insertion of a chest drain.[14] Similar recommendations for painful procedures in neonates have been made by an international consensus group.[15]

The use of **analgesic adjuncts** (see Choice of Analgesic, above) has also been advocated in some children.[16]

Nerve blocks

For a discussion of the use of nerve blocks in the management of pain, see under Pain, p.1852.

Patient-controlled analgesia

Patient-controlled analgesia (PCA) involves the use of automated delivery systems that enable patients to receive doses of an analgesic on demand. The technique is now widely favoured in the management of acute pain,[1-3] and appears to produce slightly better analgesia, and greater patient acceptance, than conventional analgesic methods.[4,5] It has been used successfully in children as young as 4 years, and in elderly patients.[6] Most experience relates to systems using intravenous opioids.

Initial analgesia must be established by giving the patient bolus doses of the analgesic, to achieve effective blood concentrations.[2,3] In the simplest type of PCA the patient is then able to self-administer a small fixed dose on demand; further doses are not permitted until a pre-programmed lockout interval has expired. The demand dose should be large enough to produce an appreciable analgesic effect, but not large enough to lead readily to toxic concentrations; the lockout period should also be long enough for the maximum analgesic effect to be felt before another dose is permitted, and should therefore relate to the speed of onset of action of the drug.[2] Some devices allow the dose to be given as a short infusion[2] to reduce adverse effects associated with high peak concentrations of opioids. In another commonly used method, sometimes described as patient-augmented analgesia, the patient is given a continuous background infusion which is supplemented by self-administered bolus doses.[2,3,6] However, with this method patients may receive more opioids without any improvement in analgesia;[6,7] There is also a greater risk of adverse effects, including respiratory depression.[2,3,7] It remains to be seen if there is any advantage with the more sophisticated devices that can be programmed to adjust the background infusion according to the frequency of the bolus demands.[6,7]

Most of the common opioids have been used successfully for PCA.[2] Morphine remains the gold standard, and fentanyl, hydromorphone, or tramadol are widely used alternatives.[2,3] Use of pethidine is no longer advised because of the risk of accumulation of its toxic metabolite, norpethidine.[2] Drugs with very short (remifentanil) or very long (methadone) half-lives may be less suitable for use.

Although generally perceived as safer than conventional opioid analgesia, occasional serious adverse effects and fatalities have resulted from errors in programming, or incorrect or inappropriate use (including operation by persons other than the patient). These risks can be minimised by safety features built into the PCA device itself, and by the development of standard protocols for the use of the technique.[2,3]

Most experience relates to the use of the intravenous route. However, epidural PCA is also used. It appears to be as effective, or more effective, than intravenous PCA,[2,3] although it may not be suitable in all cases, and carries additional risks to do with the placement of the epidural catheter.[3] Epidural PCA generally produces analgesia with a combination of a lipid-soluble opioid such as fentanyl or sufentanil plus a long-acting local anaesthetic such as bupivacaine or ropivacaine; the optimum combination has yet to be defined.[2,3] In addition, unlike intravenous PCA, the use of a background infusion is recommended.

Other routes have been investigated, including intranasal[7] and, in particular, transdermal[2,8] PCA. An iontophoretic patient-controlled delivery system for transdermal fentanyl has been developed,[8,9] and allows PCA to be given in a non-invasive manner.

Although it is not always considered in terms of PCA, inhaled nitrous oxide in oxygen also has a long history of effective use as a patient-controlled analgesic during childbirth; opioid PCA may not be suitable for such pain although local anaesthetics have been used with satisfactory results.[10]

Postoperative analgesia

Pain relief after surgery has often been inadequate and it is now recognised that pain control should be adjusted for each patient and each situation.[1-3] Multimodal regimens, using several classes of analgesic, and ideally more than one route, are now generally favoured.[3-5] Pre-operative evaluation of the patient,[2,4] and frequent assessment of pain intensity after surgery (both to allow appropriate analgesia, and to detect possible complications)[3] are fundamental. Evidence-based procedure-specific guidelines are under development.[6] Giving pain control on a preventative basis (pre-emptive analgesia) has been recommended, and may be more effective than conventional management, at least for some regimens, although results have varied.[7,8]

Patients undergoing minor surgery can be adequately managed with oral analgesics, such as paracetamol, NSAIDs, tramadol, and oxycodone. Those undergoing more extensive surgery usually require parenteral opioids or local analgesic techniques such as regional block, sometimes in combination.[3]

- **Opioid analgesics**, in particular morphine, are the mainstay of treatment for moderate to severe postoperative pain.[3] Opioid dose should be individually titrated; they may be given by numerous routes, but intravenous doses give more predictable results than intramuscular or subcutaneous doses and are widely favoured.[2,3,9] Intravenous *patient-controlled analgesia* (see above) is now a standard method of management for postoperative pain.[3,4] Where it is unavailable, intramuscular or subcutaneous dosage every 2 hours as needed for 24 to 72 hours, followed by conversion to an oral analgesic regimen, may be an alternative.[3] Careful monitoring for potential adverse effects, in particular respiratory depression, is needed.[3]

  Opioids injected centrally via the epidural and intrathecal routes provide effective regional analgesia[2,4,9] (and may be more effective than intravenous opioids,[10] although whether this improves the ultimate outcome is unclear[3]). Morphine is the opioid most commonly given centrally, but others such as fentanyl, which is more lipid soluble, may be preferable in the case of epidural injection. The epidural and intrathecal routes have also been used for patient-controlled analgesia.

  Oral opioids may not be suitable in the immediate postoperative period, but oral regimens are generally preferred if the patient can swallow and gastrointestinal function has recovered.[1,3] Tramadol is useful in patients undergoing minor or intermediate surgery.[3]

  Management of postoperative pain in patients who have been receiving long-term opioids before surgery may be particularly difficult.[3,11] Baseline requirements should be calculated for each patient, but may go up or down after surgery; typically, at least 50% of the baseline dose will be needed postoperatively, with additional opioids titrated according to pain requirements. Such patients may thus require larger than normal doses of opioids to be given, and a balanced multimodal approach to analgesia is particularly important.[11]
- **NSAIDs** and **paracetamol** are useful analgesic adjuncts that can improve pain relief,[3] but are not suitable alone after major surgery.[2] After minor or intermediate surgery an oral regimen of paracetamol plus an NSAID such as naproxen may be adequate, with oxycodone or tramadol being given for breakthrough pain.[3] NSAIDs can be used effectively with other drugs, and use of an NSAID with an opioid after major surgery enables the dose of the opioid to be reduced without loss of analgesic effect.[1-5,9] However, the risk of gastric ulceration, impaired coagulation, and reduced renal function may limit the use of NSAIDs in some patients,[3,9] and the potential cardiovascular effects of the selective inhibitors of cyclo-oxygenase-2 (COX-2) have also been a cause of great concern.[3]

  Diclofenac, flurbiprofen, ketoprofen, ketorolac, lornoxicam, and naproxen are among the NSAIDs used for postoperative pain; the COX-2 inhibitors including parecoxib have also been used. Diclofenac, ketoprofen, ketorolac, and parecoxib may be given by injection, and a parenteral formulation of paracetamol is available in some countries.
- Infiltration of **local anaesthetics** at the site of operation is a simple method of preventing postoperative wound pain.[1,4] Central nerve blocks obtained with epidural or intrathecal local anaesthetics produce excellent analgesia,[1,2,4] although again, whether this improves outcome is unclear.[2,3] Insertion of a catheter during the operation allows subsequent infusion or bolus injection.[9] However, there may be complications related to both the procedure and the drugs used (see also Adverse Effects of Central Block, p.1850). Local anaesthetics are rarely used alone, as a mixture of an opioid and a local anaesthetic produces effective analgesia using relatively smaller doses of each drug.[9] Such combinations are also used in patient-controlled epidural analgesia (see above).
- There is growing interest in the use of **analgesic adjuvants**, including antiepileptics such as gabapentin or pregabalin,[12] or the NMDA antagonist ketamine,[13,14] to modulate opioid dosage and efficacy for postoperative pain. (For further discussion of analgesic adjuvants see Choice of Analgesic, above.)

Rubefacients and topical analgesia

Substances applied topically can relieve local pain through a number of different mechanisms.[1] Rubefacients or counter-irritants can relieve superficial or deep-seated local pain probably by producing counter stimulation, which according to the 'gate theory' of pain (see Analgesia and Pain, above) helps to inhibit the transmission of pain signals. Their topical application produces hyperaemia or irritation of the skin and they are used alone or as an adjunct to massage in the management of a variety of painful musculoskeletal conditions.[2] Some are also traditionally used in preparations for the symptomatic relief of minor peripheral vascular disorders such as chilblains. Substances commonly used in **rubefacient** preparations include nicotinate and salicylate compounds, essential oils, capsicum, solutions of ammonia, camphor, and nonivamide. They may be of benefit in acute pain, but seem to be less effective in chronic arthritic and rheumatic pain.[3]

Capsaicin, which is one of the active ingredients of capsicum, is used alone as a topical analgesic in a range of painful conditions, including neuropathic pain and rheumatic disorders; its benefits are modest though it may be useful in some patients.[4] It does not rely on vasodilatation in the skin and it is therefore not considered to be a traditional counter-irritant.

Some **NSAIDs** have been used topically in the treatment of soft-tissue injuries and inflammatory musculoskeletal conditions, although this route does not necessarily avoid the adverse effects of systemic treatment. There is some evidence[5] to suggest that topical NSAIDs might be more effective than placebo.

Other agents used as topical analgesics include compounds such as ethyl chloride and the halogenated hydrocarbon propellants; their evaporation produces an intense cold that numbs the tissues. Transdermal clonidine has been used in the treatment of chronic pain. Ketamine also appears to have some local analgesic effect when applied topically.[1]

Local anaesthetics are sometimes included in topical preparations used for the relief of painful skin and musculoskeletal disorders.

Application of heat to the skin can also help to relieve pain and melted hard paraffin has been used in wax baths as an adjunct to physiotherapy for painful joints and sprains. Warm kaolin poultices have also been used as a means of applying heat for pain relief.

Specific pain states

Biliary and renal colic. Gallstones (see Ursodeoxycholic Acid, p.2409) or other biliary disorders that result in obstruction of the bile ducts may produce **biliary colic**. Morphine may relieve the accompanying pain, but as it can also produce spasm of the sphincter of Oddi it can raise intrabiliary pressure and exacerbate the pain. It is therefore usually recommended that morphine and its derivatives should either be avoided in patients with biliary disorders or that they should be given with an antispasmodic. Historically, pethidine has been regarded as a more suitable choice because it was thought to have less smooth muscle activity than morphine; however, this has been questioned. Prostaglandins have also been implicated in the aetiology of biliary colic and NSAIDs such as diclofenac or ketorolac have been successfully used to relieve the pain.[1-3] Antimuscarinic antispasmodics have been tried for their action on biliary smooth muscle and the sphincter of Oddi.

Ureteral obstruction, such as in the formation and passage of renal calculi (see p.2181), produces painful **renal** or **ureteral colic**.[4-6] The acute pain of renal or ureteral colic has been traditionally relieved using opioid analgesics such as pethidine that have a minimal effect on smooth muscle, although morphine has also been used.[4,6] However, opioids, and especially pethidine, are particularly associated with nausea and vomiting,[5,7] and NSAIDs are increasingly used in their place; they appear to be at least comparable with the opioids in terms of efficacy.[4-7] They can be given intramuscularly, intravenously, orally, and rectally, although the best route is unclear.[5,8] Diclofenac sodium given intramuscularly is recommended as first-line treatment by some authors.[6] Parenteral ketorolac also seems to be effective.[5] The use of intranasal desmopressin is also being studied.[4,5]

Cancer pain. The pain cancer patients experience may be acute, chronic, or intermittent. It may result from tumour involvement of the viscera and extension into soft tissues, tumour-induced nerve compression and injury, raised intracranial pressure, or bone metastases. Pain may also arise as a result of adverse effects of treatment, or from a concurrent disease, and may be exacerbated by emotional or mental changes. Many patients will have more than one type of pain. There may also be exacerbations due to movement (incident pain) or worsening of cancer: pain occurs in about a quarter of patients with newly diagnosed malignancies, but in up to three-quarters of those with advanced disease.

Pain relief involves the treatment of the cause of the pain as well as treatment of the pain itself, together with explanation, reassurance, and supportive care to improve any mental and social complicating factors. The mainstay of cancer pain management is drug treatment with non-opioid or opioid analgesics, or both together, plus adjuvant analgesics if necessary. A small proportion of patients (about 10 to 20%) may experience pain that responds poorly or not at all to opioid analgesics given at tolerable doses, e.g. neuropathic pain resulting from nerve destruction or compression, incident bone pain, pancreatic pain, and muscle spasm.

In the management of cancer pain the aim is to achieve adequate continuous pain relief with the minimum of adverse effects and this calls for appropriate assessment of the intensity and quality of pain, and regular monitoring of the treatment. Guidelines for the relief of cancer pain, published by WHO in 1986[1] and revised in 1996,[2] are widely endorsed by specialists in pain relief and the care of the terminally ill[3-7] despite some questions about the robustness of supporting studies.[7] Subsequent guidelines[8] issued by the Scottish Intercollegiate Guidelines Network in 2000 and the annually updated guidelines of the US National Comprehensive Cancer Network (NCCN)[9] are also widely referred to. Specific guidelines for the relief of cancer pain in children have also been published.[10,11]

Treatment should be given regularly, by mouth if possible, and should follow the accepted three-step **'analgesic ladder'**.[1,2] This approach is often described as treatment 'by mouth, by the clock, and by the ladder'. Regular dosage rather than treatment as required aims to prevent pain re-emerging and to minimise the expectation of pain. The analgesic ladder consists of 3 stages, treatment beginning at step 1 and progressing to step 3 if pain is uncontrolled or increases. The stages are as follows:

1. a non-opioid analgesic such as aspirin, other NSAIDs, or paracetamol; an adjuvant (see below) may also be given if necessary to tackle specific pain or associated symptoms
2. an opioid analgesic such as codeine, dihydrocodeine, or tramadol plus a non-opioid analgesic; an adjuvant may also be given
3. a potent opioid analgesic such as oral morphine; a non-opioid analgesic may also be given, as may an adjuvant.

Combining analgesics with different pharmacological actions can produce additive or synergistic increases in analgesia but only one analgesic from each of the 3 groups (non-opioid, less potent opioid, potent opioid) should be used at the same time.

Evidence to support the **choice of analgesic** is often scanty. A systematic review[12] found some evidence of benefit from the use of NSAIDs to treat cancer pain, and supported their use in mild pain (WHO step 1), but there was little to support the choice of one NSAID over another, and little evidence for the addition of an opioid to an NSAID in moderate pain (WHO step 2).

In moderate to severe pain (WHO step 3), morphine is generally held to be the opioid of choice;[5] alternatives include fentanyl, hydrocodone, and oxycodone.[5,9] Partial agonists or opioids with long half-lives (such as methadone or levorphanol) are less suitable for treatment than pure opioid agonists with less prolonged actions.[9] In patients who do not achieve effective analgesia at an acceptable level of adverse effects with one opioid, **opioid rotation**, switching to an alternative opioid at an equivalent dose, may enable pain control.[9,13]

The optimal **route** for use is by mouth. For best effect, both conventional (for dose titration) and modified-release (for maintenance) dosage forms are required. The European Association for Palliative Care (EAPC) suggests[5] that the simplest method of dose titration is with conventional morphine dosage every 4 hours, and the same dose for breakthrough pain. This 'rescue' dose may be given as often as required, up to hourly. The total daily dose of morphine should be reviewed each day and the regular dose adjusted to take account of the amount needed for breakthrough pain. If pain returns consistently before the next dose is due the regular dose should be increased. Conventional formulations do not generally need to be given more often than every 4 hours, and modified-release products should be given according to the intended duration of the preparation (usually every 12 or 24 hours). Patients stabilised on regular oral morphine require continued access to a rescue dose for breakthrough pain. For patients taking conventional morphine preparations every 4 hours, a double dose at bedtime is effective to prevent pain disturbing sleep.

Similar recommendations are given by the NCCN.[9] They advise that the oral rescue dose for breakthrough pain should be calculated as 10 to 20% of the total 24-hour requirement; this may then be increased by 50 to 100% in patients who still have increased pain, with hourly reassessment of efficacy and adverse effects. If inadequate response is still seen after 2 or 3 cycles, a change of route (e.g. intravenous titration) may be considered.

If patients are unable to take morphine orally the EAPC considers the preferred alternative route to be subcutaneous,[5] and the NCCN suggests either continuous parenteral infusion, intravenous, or subcutaneous dosage.[9] There is no indication for intramuscular morphine for cancer pain since subcutaneous dosage is simpler and less painful.[5] In the UK diamorphine hydrochloride is often preferred to morphine sulfate for parenteral use because it is more soluble and allows a smaller dose volume; hydromorphone hydrochloride is an alternative to diamorphine.

Epidural or intrathecal opioids, either by injection or infusion, have been used when conventional routes have failed.[9,14] Some advocate the use of these routes because smaller doses may produce analgesia equivalent to that of larger doses given orally or parenterally, although there has been little conclusive evidence for a lower incidence of adverse effects or a better quality of analgesia.

The buccal, sublingual, and nebulised routes have been investigated, but these are not recommended for morphine because there is no current evidence of clinical advantage over conventional routes.[5] However, buprenorphine is given sublingually and although may be a useful alternative in patients with dysphagia, although experience of long-term use in cancer pain is limited. Buprenorphine or fentanyl can be given via a transdermal system that provides continuous and controlled delivery for up to 72 hours. Calculating an appropriate conversion regimen for transfer of patients from oral or parenteral therapy to transdermal can be difficult,[15] but the NCCN suggests that the total daily requirement of oral morphine is equivalent to about 2000 times the hourly dose of transdermal fentanyl.[9] An oral transmucosal dosage form of fentanyl is also available for the management of breakthrough cancer pain.[9]

Automated delivery systems for self-administration of parenteral analgesics (patient-controlled analgesia) have been used to administer opioid analgesics (see above).

Adjuvant drugs that may be necessary at any stage include antidepressants, antiepileptics, and class I antiarrhythmics for neuropathic pain, corticosteroids for nerve compression and headache resulting from raised intracranial pressure, and muscle relaxants for muscle spasm. Radiotherapy and radioisotopes such as strontium-89 may be of use when the bone pain of metastases is unresponsive to NSAIDs alone. Bone modulating drugs such as calcitonin and bisphosphonates may be of additional benefit but have a slow onset of action and bisphosphonates may cause an initial transient increase in pain. Corticosteroids have been used as an alternative to NSAIDs in refractory bone pain but long-term use should be avoided. Nerve blocks with local anaesthetics or neurolytic solutions may benefit a few patients, in particular those with sympathetically maintained pain or specific localised pain (see under Pain, p.1852). Topical local anaesthetics or capsaicin may also be of use in some patients.[9] Physiotherapy and relaxation techniques may be useful for painful muscle spasm. The addition of an NMDA antagonist such as dextromethorphan or ketamine to conventional analgesic regimens has been tried with some success in patients with refractory pain.[13] Adjuvant therapy should be fully explored before moving on to the next 'rung' of the treatment ladder or increasing the dosage of an opioid analgesic.[16] For further details of analgesic adjuvants, see Choice of Analgesic, above.

Management of cancer pain also requires monitoring to prevent and reduce **adverse effects** of therapy, particularly of opioids. Appropriate bowel regimes to manage constipation should be started at the same time as opioid therapy, as should antiemetic therapy; sedation and nausea usually become less marked as treatment progresses,[5] and warrant reassessment if they persist for longer than a week.[9] Concerns about respiratory depression and dependence should not be allowed to interfere with appropriate treatment: patients whose pain ameliorates can generally reduce and stop opioid treatment without difficulty.[5]

Central post-stroke pain. Central pain is a neuropathic pain arising from lesions of the CNS.[1-4] Pain following a cerebrovascular accident has been referred to as thalamic syndrome but is now commonly known as central post-stroke pain and may arise not only from classical stroke but also from surgery or trauma to the head. The pain, which has been described as burning, stabbing, and aching, may be mild to intolerable and occurs spontaneously or in response to a mild stimulus.

As in other types of neuropathic pain, whether opioid analgesics can be of benefit is controversial: it has been suggested that the value of conventional opioids such as high-dose morphine is modest, but that NMDA receptor antagonists such as methadone may be of more benefit.[2] Ketamine, another NMDA antagonist, may also be of value. Conventional management of central post-stroke pain involves the use of antidepressants such as amitriptyline and antiepileptics including lamotrigine or gabapentin. Early peripheral sympathetic blockade may produce temporary relief in some cases. Mexiletine may be of use in patients with refractory pain; it has often been given with amitriptyline. Oral or intrathecal baclofen may be tried. Transcutaneous electrical nerve stimulation (TENS) may occasionally be of help but some advocate brain or spinal cord stimulation. Surgical treatment generally gives disappointing results.

Complex regional pain syndrome. Complex regional pain syndrome (CRPS) is a regional, post-traumatic neuropathic pain that generally affects the limbs. CRPS has also been referred to as reflex sympathetic dystrophy, post-traumatic dystrophy, causalgia, Sudeck's atrophy, and shoulder-hand syndrome. Causalgia has also been used to describe the burning pain that follows a penetrating injury. Historically, it was considered that the pain was maintained by the sympathetic nervous system and the term 'reflex sympathetic dystrophy' was commonly used to describe the syndrome (although recent studies have shown that the sympathetic nervous system is not always involved). However, the terms given above are now considered to be inappropriate and CRPS is now broadly classified as:

- Type I: (previously reflex sympathetic dystrophy) which develops after tissue trauma, such as that accompanying myocardial infarction, stroke, burns, frostbite, fractures, and shoulder or limb injury, but where there is no identifiable nerve lesion
- Type II: (previously causalgia) which develops after trauma to a major peripheral nerve

Clinically the two subsets are identical and typical symptoms include pain, allodynia, and hyperalgesia; as the syndrome becomes chronic, trophic changes to the bone, muscles, and skin may occur. Sympathetic dysfunction may also be present. If the pain is relieved by a sympathetic block (see below), this pain is regarded as 'sympathetically-maintained', if not it is known as 'sympathetically-independent' pain.

The treatment of CRPS is difficult especially in chronic disorders and is usually aimed at pain control and restoring limb function. The cornerstone of treatment is physiotherapy, with pain relief provided in order to allow physical exercise. Patients with mild disease may not require pain management; those with moderate pain should be tried with a tricyclic antidepressant, an antiepileptic such as gabapentin, or a less potent opioid. Oral or intravenous bisphosphonates have also produced some promising results. A sympathetic nerve block with bretylium or perhaps a local anaesthetic may be useful in carefully selected patients with sympathetically-maintained pain; those who do not respond to a sympathetic nerve block may be given an epidural block. Other methods that have been tried in refractory pain include spinal cord stimulation and intrathecal baclofen or opioids. There are small studies or anecdotal reports of the use of a variety of other drugs and interventions.

Diabetic neuropathy. Sensory polyneuropathy, a complication of diabetes mellitus, is the commonest of the neuropathies producing neuropathic pain. The pain is mainly experienced as a burning sensation, sometimes accompanied by shooting, or aching pain. Painful neuropathy may benefit from optimal diabetic control (see under Diabetic Complications, p.433). Non-opioid analgesics such as aspirin or other NSAIDs, or paracetamol may be tried, although neuropathic pain is often resistant to conventional analgesics, and the treatment of painful diabetic neuropathy is generally as for postherpetic neuralgia (see below). Relief may be obtained using tricyclic antidepressants and the *BNF* considers them to be the drugs of choice. SSRIs have been tried but studies suggest that they are ineffective or less effective than tricyclic antidepressants. Duloxetine, a serotonin and noradrenaline reuptake inhibitor, is licensed for use in diabetic neuropathy. Antiepileptics such as carbamazepine, gabapentin, phenytoin, and pregabalin can be used to control any shooting or stabbing components of the pain; lamotrigine and topiramate are also under investigation. Antiarrhythmics such as lidocaine given intravenously or mexiletine given orally have been shown to be effective against some components of the pain. Topical application of capsaicin or lidocaine may have some effect. Neuropathic pain may respond partially to some opioid analgesics and they may be of use when other treatments are ineffective.

Dysmenorrhoea. Dysmenorrhoea is painful menstruation. The primary form arises from uterine contractions produced by release of prostaglandins from the endometrium in the luteal phase of the menstrual cycle. For this reason, drugs that inhibit ovulation or prostaglandin production are often effective treatments.[1] NSAIDs inhibit cyclo-oxygenase (prostaglandin synthetase) and are usually the drugs of first choice.[1-3] They are taken at the onset of discomfort and continued for a few days while symptoms persist. Those most commonly used have included aspirin, diflunisal, flurbiprofen, ibuprofen, indometacin, ketoprofen, mefenamic acid, naproxen, and piroxicam. Theoretically, mefenamic acid has the advantage of inhibiting both the synthesis and the peripheral action of prostaglandins, but clinical studies have not consistently shown fenamates to be more effective than other cyclo-oxygenase inhibitors. Paracetamol has also been given for pain relief. A systematic review[2] comparing several of these drugs concluded that ibuprofen appeared to have the best risk-benefit ratio in dysmenorrhoea and was the preferred analgesic; naproxen, mefenamic acid, and aspirin were also effective, but the limited data on paracetamol did not show such clear benefits. Another such review considered that there was insufficient evidence to determine which NSAID should be preferred.[3]

Patients who fail to respond to analgesics may benefit from the use of progestogens either alone for part of the cycle or more usually together with oestrogens in the form of oral contraceptive preparations.

Antispasmodic drugs such as hyoscine butylbromide are included in some preparations promoted for the relief of spasm associated with dysmenorrhoea but the *BNF* considers that they do not generally provide significant relief. There is limited evidence[4] that vitamin B_1 may be effective and some consider[1] that it may be worth trying; evidence of benefit from other therapies such as magnesium or vitamin E is considered to be weaker.[1,4,5]

Secondary dysmenorrhoea is associated with various other disorders such as endometriosis, and treatment is primarily aimed at the underlying cause.

Headache. Aspirin and other NSAIDs, or paracetamol are often tried first for the symptomatic treatment of various types of headache including migraine (p.616) and tension-type headache (p.617). NSAIDs may also be effective for the prophylaxis of migraine, although they are not considered first-line options.

Opioid analgesics such as codeine are sometimes included in oral compound analgesic preparations used in the initial treatment of migraine or tension-type headache, but are best avoided, especially in patients who have frequent attacks.

Labour pain. It is important to assess the adverse effects, on both the mother and the fetus, when selecting any method for the management of labour pain. Non-pharmacological methods of pain relief may include relaxation techniques, transcutaneous electrical nerve stimulation (which is popular with patients, although there is no robust evidence of benefit[1]), and various other complementary therapies: of the latter, there is some evidence of benefit with the use of acupuncture and hypnosis.[2] Water immersion (use of a birthing pool) during the first stage of labour has been shown to reduce reported maternal pain.[3] Subcutaneous or intradermal injection of sterile water into the back has also been used for the relief of low back pain during labour.[4,5]

However, at some point during labour many women will request some sort of pharmacological analgesia.

The inhalational anaesthetic **nitrous oxide**, given with oxygen, is suitable for self-administration and is commonly used to relieve labour pain. It is relatively safe and can produce substantial analgesia in most patients.[6] Other inhalational analgesics such as isoflurane or sevoflurane are also sometimes used[7] (see Choice of Analgesic, above).

Opioid analgesics have been given systemically in the management of labour pain for many years, although they do not appear to provide adequate analgesia in most patients at a tolerable dosage.[8,9] There is no clear evidence to favour one opioid over another.[10] Morphine is considered unsuitable,[7] and the widest experience has been with pethidine.[7,10] However, its effectiveness has been queried,[7,10] and its use has declined in many countries.[7] Fentanyl and its derivatives sufentanil and alfentanil have been used, particularly when given as intravenous patient-controlled analgesia,[7] but it is not clear that they have any great advantages, and as with other opioids they may cross the placenta and produce respiratory depression and other adverse effects in the newborn. The use of the very short-acting opioid remifentanil for patient-controlled analgesia during labour has been investigated, with some benefit,[11] but although it is less likely to produce effects on neonatal respiration it is not clear that the degree of supervision required to guard against unacceptable respiratory depression in the mother can be widely achieved on busy labour wards.[7] Nalbuphine has been used in some countries because of its mixed agonist/antagonist action,[7] although there does not seem to be clear evidence that it conveys any substantial benefit.

Epidural analgesia with a *local anaesthetic* is now considered the gold standard for treatment and provides the most effective pain relief during labour.[9,12-14] Medical indications may include a history of malignant hyperthermia, certain cardiovascular or respiratory disorders, or pre-eclampsia, but the primary indication is the patient's desire for pain relief.[9,13] Bupivacaine is one of the local anaesthetics most often used in epidural analgesia; others include ropivacaine and lidocaine.[14]

Epidural block has few contra-indications and serious adverse events are rare. Nonetheless, it has been associated with an increased risk of prolonged second-stage labour, forceps delivery, and caesarean section[9,13,14] (although meta-analysis[8] and a systematic review[14] refute the latter), and it may not improve maternal experience of childbirth. Many centres stop epidural analgesia for the second stage of labour to reduce the incidence of forceps delivery but substantive evidence for this is lacking.[15] Central blocks may also produce adverse effects including shivering, post-puncture headache, and hypotension (for further details of the adverse effects of and precautions for epidural block see p.1850 and p.1851, respectively). Occasionally epidural local anaesthetic does not produce adequate analgesia due to patchy or incomplete block.

Some of the adverse effects associated with epidural analgesia are associated with the motor block and profound analgesia resulting from traditional techniques using relatively high concentrations of local anaesthetic. There has therefore been an increasing trend to the use of lower-dose techniques. Although *opioid analgesics* are not particularly effective for labour analgesia when given systemically (see above), addition of a small amount of an opioid to epidural solutions enables effective analgesia to be achieved with lower concentrations of local anaesthetic, and with less motor block;[9,12,16,17] however, the incidence of pruritus (a known effect of opioids) is greater than with a local anaesthetic alone.[18] There is no standard combination of local anaesthetic and opioid, although one large study used bupivacaine 0.1% with fentanyl 2 micrograms/mL.[16] Sufentanil is also widely used with either bupivacaine[18] or ropivacaine. The epidural use of other adjuvants such as clonidine and neostigmine is also being studied.[19] Low-dose techniques are the basis of so-called 'ambulatory' or 'walking' epidural management, although it is unclear to what extent this mobility improves outcomes or patient satisfaction.[20]

Once an initial block is established, additional analgesia can be provided through a catheter by intermittent 'top-up' doses or by a continuous epidural infusion; a combination of the two methods forms the basis of some types of patient-controlled epidural analgesia.

Another method of reducing the adverse effects of traditional epidural techniques is to combine a spinal block, which is quick acting but not long lasting enough to be used alone for analgesia in labour, with epidural delivery. Although studies have reported superior pain relief[17] with such **combined spinal-epidural analgesia**, a systematic review[18] considered that there was no overall benefit with the technique when compared with low-dose epidural techniques, although onset of analgesia was faster.

The use of **spinal blocks** in obstetrics has been more commonly associated with anaesthesia and management of postoperative pain in caesarean section.[12] Spinal blocks with local anaesthetics have a greater tendency to produce hypotension and headache than epidural blocks (for further details of the adverse effects of and precautions for spinal block see p.1850 and p.1851, respectively).

Pudendal nerve blocks with lidocaine followed by a local anaesthetic given into the perineum provide pain relief during labour.[12] However, the technique of paracervical local anaesthetic block is now largely of historic interest in labour analgesia[21] because of reports of fetal arrhythmias, acidosis, and asphyxia and isolated reports of fetal death.

Local anaesthetics have been applied topically for **perineal pain** caused by tearing or episiotomy in women who have given birth. However, a systematic review[22] considered that the evidence of effectiveness was not compelling.

Low back pain. Low back pain (sometimes referred to as lumbago), is a common complaint but only a small percentage of patients suffer from a recognised organic disease, most frequently disc disease. In patients with a lumbar disc prolapse or herniation, the rupture of one of the fibrocartilagenous intervertebral discs can exert pressure on spinal nerve roots and produce a condition characterised by severe and often acute pain radiating from the back along the distribution of the nerves affected (radiculopathy). The sciatic nerve may be involved and patients experience pain (sciatica), usually in one leg along the typical distribution of the nerve. Non-specific back pain (back pain of unknown origin) is usually self-limiting with a good prognosis, although recurrence is common.[1-3] Back pain is considered to be acute if it lasts for less than 6 weeks, sub-acute if it lasts for 6 to 12 weeks, or chronic if it persists for more than 12 weeks.[4]

Treatment for **acute back pain** should be given early to prevent the condition becoming chronic. For simple back pain (in the absence of nerve root symptoms or signs of serious spinal pathology) paracetamol should be tried first. NSAIDs are probably more effective,[1,5] but are associated with a higher frequency of adverse effects and should be reserved for those in whom paracetamol is ineffective.[1,4-7] If these treatments fail, muscle relaxants, including baclofen or tizanidine, may be added to therapy, although adverse effects may limit their usefulness;[1-6,8,9] benzodiazepines such as diazepam (which should only be given for a short period because of the risk of dependence)[1] are among the most effective muscle relaxants, but there is little comparative evidence, and some suggest that they act primarily as sedatives.[6] Opioids have moderate benefits in severe or disabling pain not relieved by paracetamol or NSAIDs,[1,5,6] but again should only be used in the short term.[3] There is strong evidence that remaining active speeds recovery and reduces the risk of chronicity, even if pain or discomfort is caused; bed rest delays recovery and is not recommended.[2-4,8,10,11] Other non-pharmacological approaches that have evidence of a benefit include topical heat wraps and spinal manipulation.[1,2,4,12,13] There is little or no clinical evidence that acupuncture, transcutaneous electrical nerve stimulation (TENS), massage, traction, specific back exercises, or lumbar support are beneficial.[1,2,4,10,12] However, patient expectations of benefit from different therapies may influence outcomes, and this should be taken into consideration.[1]

Sciatica usually resolves with conservative management including analgesics and continued activity; however, if sciatic pain persists for longer than 6 to 8 weeks, surgery may be indicated.[14] Dissolution of the disc by injection of enzymes (chemonucleolysis) such as chymopapain or collagenase has been used as an effective alternative to surgery, but concerns about its safety have led to a decline in use, and discectomy is often preferred.[15]

Epidural injections of corticosteroids, using either the caudal or lumbar route, have been given to patients with sciatica; any relief is temporary only, the evidence of a benefit is conflicting, and their use is no longer recommended.[14,16] There is no evidence of benefit in patients with non-specific acute or chronic back pain.[2,4,17]

About 2 to 7% of patients with acute lower back pain go on to develop **chronic** pain,[4] and in the majority of cases, the source of the pain cannot be identified. Chronic pain is not necessarily the same as prolonged acute back pain and treatment is difficult. Conservative treatment is as for acute pain (see above);[1,2,5,17,18] tricyclic antidepressants may also be tried[1-3,5,17,18] although a systematic review found the evidence of benefit to be lacking.[19] Topical application of capsaicin may be considered for short-term relief.[17] Surgery may be indicated for disc disease (see above) or spondylosis,[20] although it is not recommended for non-specific chronic back pain until conservative treatments have been tried for at least 2 years.[17] Epidural corticosteroids, intra-articular corticosteroid injections, local facet nerve blocks, trigger point injections, and spinal cord stimulation also lack evidence of efficacy.[17] Other methods that may be tried for intractable chronic back pain include multidisciplinary physical and psychological approaches;[1-3,12,17] evidence for TENS, massage, acupuncture, laser therapy, and traction is scant, however.[2,17,18,21]

Myocardial infarction pain. The severe pain of acute myocardial infarction is located in the retrosternal area with radiation to the arms, neck, jaw, and epigastrium. Pain relief is of benefit not only in its own right but also because pain may cause adverse haemodynamic effects such as increases in blood pressure, heart rate, and stroke volume. Although early treatment of the myocardial infarction (p.1175) may relieve pain dramatically, opioid analgesics are the first-line treatment for pain and should be given intravenously as soon as possible, that is before hospital admission, to patients with suspected infarction.[1-4] Opioids can also help to reduce anxiety. An inhaled mixture of nitrous oxide and oxygen has sometimes been used to provide pain relief before arrival in hospital; sublingual glyceryl trinitrate or an alternative fast-acting nitrate may also be given.

Diamorphine or morphine given by slow intravenous injection have generally been the opioids of choice, partly because of a better haemodynamic profile, but pethidine has also been used. An intravenous antiemetic such as metoclopramide or, if left ventricular function is not compromised, cyclizine, should also be given. The intramuscular route should only be used if venous access is unobtainable since it is relatively ineffective in shocked patients, complicates the enzymatic assessment of the infarction, and may result in large haematomas when patients are given thrombolytics. Alternative analgesics include nalbuphine or buprenorphine, although the latter may not produce pain relief as quickly as diamorphine. The cardiovascular effects of pentazocine make it unsuitable for use during or after myocardial infarction. Selective cyclo-oxygenase-2 (COX-2) inhibitors and non-selective NSAIDs (other than aspirin) should not be used in patients with acute myocardial infarction because of their known cardiovascular risks[5] (see Thrombotic Events under Adverse Effects of NSAIDs, p.97).

Neuropathic pain syndromes. The definition and characteristics of neuropathic pain are described under Analgesia and Pain, above. Treatment can be difficult and is best undertaken in specialist pain clinics, since neuropathic pain often responds poorly to conventional analgesics.[1-5] The painful disorders characterised by neuropathic pain (either as the predominant form of pain or as one component of the overall pain) discussed in this section are:

- Central Post-stroke Pain
- Complex Regional Pain Syndromes
- Diabetic Neuropathy
- Phantom Limb Pain
- Postherpetic Neuralgia
- Trigeminal Neuralgia

Orofacial pain. Orofacial pain may arise from a wide range of disorders so its effective management depends very much on the correct identification and treatment of any underlying cause, which may include:

- dental disease
- cluster headache (p.616)
- migraine (p.616)
- trigeminal neuralgia (see below)
- sinusitis (p.193)
- ear disease such as otitis media (p.182)
- giant cell arteritis (p.1503)
- aneurysms
- neoplasms

In the treatment of dental pain, analgesics are used judiciously as a temporary measure until the underlying cause has been effectively managed. Paracetamol or aspirin or other NSAIDs are adequate for most purposes. Opioid analgesics are relatively ineffective and are rarely needed.

Burning mouth syndrome (stomatodynia; glossodynia) is characterised by a burning sensation or other dysaesthesias of the oral mucosa in the absence of specific oral lesions. It is often accompanied by xerostomia and altered taste. Those treatments for which there is the best evidence of efficacy include topical therapy with clonazepam, systemic treatment with thioctic acid, SSRIs, or amisulpride, and cognitive therapy. Other treatments that may produce some benefit include capsaicin used topically or systemically, topical lidocaine, or systemic therapy with other antidepressants.

In addition, a large number of patients have a type of facial pain of unknown cause which is typically exacerbated by stress and can develop into a chronic debilitating disorder. Many patients with such idiopathic facial pain respond to non-opioid analgesics, explanation, and reassurance. Antidepressants such as the tricyclics are often of value. Antiepileptics, including carbamazepine and sodium valproate, and the oral lidocaine analogue mexiletine have been used as adjuncts to the tricyclics. Topical treatment with capsaicin has also been tried. Treatment needs to be continued for several months to avoid pain recurrence on withdrawal. Psychological treatments can also be helpful.

Botulinum A toxin has been tried for the relief of facial pain associated with some disorders of the orofacial muscles.

Pancreatic pain. Pain in pancreatitis (p.2361) can be severe and may require opioid analgesics. Concerns over the long-term use of opioids in non-malignant pain should not prevent the patient being given effective analgesia which may be achieved by following the general principles recommended by the WHO for treatment of cancer pain (see above); this involves giving non-opioid analgesics such as NSAIDs for mild attacks, with or without antispasmodics such as antimuscarinics, and progressing to 'weak' opioids such as codeine, and 'strong' opioids including morphine according to the severity of pain.

There has been some controversy about the appropriate choice of opioid: traditionally, morphine and its derivatives have been avoided in favour of pethidine, in the belief that they are more likely to cause spasm of the sphincter of Oddi. However, the evidence supporting this has been questioned. Some suggest that κ-receptor agonists such as oxycodone may be of value. In addition, there is some evidence that pancreatic pain may have a neuropathic element, and the use of an antiepileptic such as gabapentin, or an SSRI such as paroxetine, may be considered for pain syndromes associated with chronic pancreatitis.

Analgesics are given before meals to help to alleviate the postprandial exacerbation of pain. They should be given on a regular basis and doses titrated for each patient. Pancreatic extracts may ease the pain but are otherwise reserved for those with symptomatic malabsorption. Coeliac plexus block has been used for the relief of severe intractable pain in some patients with chronic pancreatitis; it has also been used similarly in patients with cancer of the pancreas. However, the benefits of such a block are unclear.

Phantom limb pain. Phantom limb pain is associated with an amputated limb and is more common when there has been severe pre-amputation pain. It is frequently a mixture of neuropathic and other types of pain. Management may be difficult[1-7] but in a survey of war veteran amputees, for those who took any form of treatment for phantom limb pain, conventional analgesics such as NSAIDs or paracetamol with or without opioid analgesics were reported as being satisfactory.[1] The use of the WHO analgesic ladder, as in cancer pain (see p.5) may guide the choice of analgesic;[7] although the use of opioids has been questioned in what is essentially a neuropathic pain syndrome, many consider them of potential value in phantom limb pain.[6,7] Transcutaneous electrical nerve stimulation (TENS) was another method used by some and considered to be at least as effective as other therapies.[1] Tricyclic antidepressants and antiepileptics may be of help for the neuropathic components of the pain[2,3,5] and some relief may be obtained with sympathetic blocks. Intravenous ketamine may also be of use.[2,4,5] From a review[8] of studies investigating the effect of regional anaesthesia in preventing phantom limb pain in patients undergoing lower-limb amputation it appeared that epidural blockade started before and continuing for the duration of surgery or for several days after amputation conferred more protection from long-term pain than blockade begun late intra-operatively or postoperatively. However, a randomised, double-blind, controlled study[9] failed to show any benefit of pre-emptive analgesia using epidural blockade in such patients. A subsequent review[4] that included this study concluded that the pre-emptive use of epidural block was of limited success.

Postherpetic neuralgia. About 10% of patients who have had acute herpes zoster still experience neuropathic pain resulting from peripheral nerve injury one month or more after the rash has healed. The elderly are the most susceptible. The affected area (commonly head, neck, and limbs) is extremely sensitive to any stimuli; even the pressure of clothing can produce unbearable pain. Spontaneous remission occurs in many patients within a few months. However, in a small percentage of patients the pain can last for several years.

Attempts have been made to **prevent** the development of postherpetic neuralgia. A meta-analysis[1] concluded that, if started within 72 hours of the onset of rash, aciclovir might reduce the incidence of residual pain at 6 months in some patients. A subsequent analysis[2] considered that there was only marginal evidence of a decreased incidence of postherpetic neuralgia with aciclovir treatment and that there was no reduction in incidence with either famciclovir or valaciclovir treatments. It is, however, generally agreed that antiviral treatment does reduce the duration of postherpetic neuralgia.[2-4] Epidural injection of methylprednisolone with bupivacaine has been shown to reduce short-term pain from herpes zoster, but was ineffective in preventing postherpetic neuralgia in the longer term,[5] and evidence of the preventive value of corticosteroids is generally lacking.[6]

Various **treatments** have been tried once neuralgia develops.[2-4,7-12] The value of conventional analgesics is limited because of the neuropathic character of the pain although opioid analgesics have been used in refractory cases (see below). Low-dose tricyclics such as amitriptyline, or in particular nortriptyline, have been widely used for treatment, and appear to be of benefit in about half of all cases;[4] however, the antiepileptics gabapentin and pregabalin may now be preferred, and gabapentin is licensed for this indication in a number of countries. A comparative study has suggested that gabapentin is as effective as nortriptyline and better tolerated.[13] Topical lidocaine has also been licensed for treatment of postherpetic neuralgia, but the evidence for such use has been questioned.[14] However, it is likely to be better tolerated than the other main topical alternative, capsaicin.[4] Opioids, including methadone, morphine, and oxycodone, are usually reserved for patients who fail to respond to tricyclics or gabapentin.[9] Nerve blocks and surgical techniques may provide temporary pain relief, but results have generally been disappointing. Transcutaneous electrical nerve stimulation (TENS) has also been tried. Topical preparations of aspirin or indometacin, have shown some promise.

Sickle-cell crisis. The management of pain of sickle-cell crisis (p.1044) is similar to that of other forms of acute pain. The pain of mild crises may be controlled using oral analgesics such as paracetamol, an NSAID, codeine, or dihydrocodeine. Partial agonist and antagonist opioids such as buprenorphine are not recommended to treat acute pain before transfer to hospital.[1] Crises severe enough to need hospital admission usually require the use of more potent parenteral opioid analgesics but NSAIDs may be useful as an adjunct for bone pain. In most centres, morphine is the opioid of choice for moderate to severe pain. Some patients appear to prefer pethidine but many clinicians[2-7] avoid its use if possible as control of pain may be inadequate and doses of pethidine needed to manage crises can lead to accumulation of its neuroexcitatory metabolite norpethidine and precipitate seizures (see also Effects on the Nervous System, p.114). UK guidelines[8] recommend that pethidine should only be used in exceptional circumstances such as in patients hypersensitive to other opioids. Diamorphine, fentanyl, hydromorphone, and methadone have been used as alternatives to morphine. Nalbuphine may also be suitable.[9] As the dose of opioid required to control the pain can vary considerably, not only during each episode but also from one episode to another and between individual patients, patient-controlled analgesia (see above) may be of help to manage the pain once initial pain relief has been obtained with loading doses of parenteral opioids;[4,10,11] opioids used have included morphine and fentanyl. The use of continuous epidural analgesia with local anaesthetics alone or with opioids has been tried. However, a randomised study[12] of morphine for the management of severe painful sickle-cell crises in children showed that oral modified-release morphine was a safe and effective alternative to continuous intravenous morphine. Inhalation of a mixture of nitrous oxide and oxygen may be a useful analgesic during transfer to hospital.[1,8]

Trigeminal neuralgia. Trigeminal neuralgia (tic douloureux) is a neuropathic pain characterised by sudden, brief, sharp, agonising, episodic pain in the distribution of one or more branches of the fifth cranial nerve. There may be several episodes (lasting several seconds or minutes) a day over a number of weeks, followed by a pain-free interval which may last for weeks or years. Trigeminal neuralgia generally has a 'trigger zone' in which even a very light stimulus such as a draught of air produces pain. In some cases firm pressure applied around but not to the zone itself may help to relieve pain. Trigeminal neuralgia may be idiopathic or may be secondary to nerve compression (such as that caused by a tumour), facial injury, or multiple sclerosis.

Carbamazepine is the drug of choice for the management of trigeminal neuralgia and initially may produce satisfactory pain relief in 70% or more of patients, although increasingly large doses may be required.[1-7] If pain relief is inadequate phenytoin or baclofen may be added to carbamazepine therapy; these drugs may also be used alone in patients intolerant of carbamazepine.[4] Other antiepileptics such as gabapentin, lamotrigine, oxcarbazepine, valproate, and clonazepam have also been used in patients intolerant of, or resistant to, carbamazepine.[1-6] Evidence for the value of non-antiepileptic drugs in trigeminal neuralgia is mostly poor.[8]

In some patients drug therapy eventually fails to control the pain or produces unacceptable adverse effects and invasive procedures become necessary. These may include the selective destruction of pain bearing nerve fibres with radiofrequency thermocoagulation, instillation of glycerol (although the efficacy and safety of the procedure is debatable), gamma knife radiation, and microvascular decompression of the trigeminal nerve root.[2,3,6,7]

Increased Body Temperature

The hypothalamus is the centre of the thermoregulatory system and is responsible for maintaining the body temperature at a set point (known as the set-point temperature) which is normally 37°. Mechanisms that produce or conserve body heat include passive heat absorption from the environment, peripheral vasoconstriction, and thermogenic processes such as metabolic reactions and shivering. Heat loss is achieved mainly through sweating and peripheral vasodilatation. Various states may lead to an abnormal increase in body temperature.

Fever and hyperthermia

As mentioned above, body temperature is normally regulated by the hypothalamus. *Fever* (pyrexia) is a controlled increase in body temperature due to an elevated hypothalamic set-point temperature. Common reasons for this include infections, inflammatory disorders, neoplastic disease, and some drug treatment. *Hyperthermia* (hyperpyrexia) implies a disturbance of thermoregulatory control. It is caused by external factors such as injury to the hypothalamus, heat stroke following defective heat loss (as occurs in dehydration or excessive heat production following strenuous activities), excessive dosage of some drugs, or a reaction to certain drugs such as anaesthetics (malignant hyperthermia, p.1896) or antipsychotics (neuroleptic malignant syndrome, p.972). Underlying thermoregulatory defects may be a particular problem in sedentary elderly subjects.

Whenever possible the underlying cause of **fever** should be identified and treated.[1] Body temperatures up to 41° are relatively harmless[2] and it is not clear if there is any value in treating fever at lower temperatures,[1] but some groups may be more vulnerable, such as young children, pregnant women, or patients who are already dehydrated or malnourished or those with cardiac, respiratory, or neurological diseases.

Both physical means and antipyretics may be used to reduce body temperature in fever. Maintaining an adequate fluid intake is important. Fanning, removal of clothing, and tepid sponging are often used,[1-3] but they do not reduce the set-point of the hypothalamus, and lead to shivering (rigor) or other adverse effects as the body tries to meet the raised set-point, and their value is therefore questionable;[1] similarly, cold baths should not be used as they may actually increase body temperature by inducing vasoconstriction, and the risks of a cold-induced pressor response should be borne in mind. Antipyretics appear mostly to help return the set-point temperature to normal by inhibiting central synthesis and release of prostaglandin E_2, which mediates the effect of endogenous pyrogens in the hypothalamus.[4] This mechanism cannot lower the body temperature below normal, and antipyretics are ineffective against raised body temperature not associated with fever.

Choice of antipyretic in children has been widely debated. The drugs most commonly used are paracetamol and ibuprofen; salicylates (including aspirin) are generally contra-indicated because of the possible link between their use and the development of Reye's syndrome. A systematic review[5] found inconsistent evidence to support the use of paracetamol to reduce fever in children, since the number of reliable studies was too low to be sure that it was effective. Although studies have found that ibuprofen was superior to paracetamol in terms of both efficacy and duration of action, some of the doses of paracetamol were below those recommended in the UK and NICE did not consider that either drug had a significant advantage over the other.[1] Alternation of the two may be more effective than either alone[6] but again this is controversial.[1,7,8]

Antipyretics should not be given to all children with fever, but only to those in obvious discomfort or distress.[1,9] It has been suggested that the use of antipyretics might prolong infection,[2] and that in severe infection the use of antipyretics might increase mortality:[10] WHO has[10] recommended that in developing countries antipyretics should not be given routinely to children with fever but should be reserved for those with severe discomfort or high fever. In the UK, the Joint Committee on Vaccination and Immunisation recommends antipyretic therapy to treat post-immunisation fever developing after some vaccines. However, if the fever persists after the second dose of antipyretic medical advice should be sought.

Antipyretics have also been given as *prophylaxis* against febrile convulsions, especially in those with a history of such seizures or in those with epilepsy. However, antipyretic therapy does not appear to prevent recurrence of febrile convulsions (p.470).[1,11,12] There is also little to support the use of antipyretics for prophylaxis of post-immunisation fever although some suggest offering it to infants at higher risk of seizures receiving diphtheria-tetanus-pertussis or polio immunisation.[13]

Recommendations for management of fever in adults are similar to those for children,[2,4] although aspirin may also be used.

Hyperthermia may produce body temperatures greater than 41°. These high temperatures are life-threatening and need to be lowered immediately. Antipyretics are ineffective since the high temperatures are a result of thermoregulatory failure. One of the most rapid and effective means of cooling is to immerse the patient in very cold water but core temperature should be monitored to avoid inducing hypothermia.[14] Evaporative cooling methods may be more efficient.[15] Intravenous or intraperitoneal administration of cool fluids, gastric lavage or enemas with ice water have also been used.[14,16]

When hyperthermia is associated with muscle rigidity and fulminant hypermetabolism of skeletal muscle, as in the neuroleptic malignant syndrome and malignant hyperthermia, temperature reductions may be obtained using the muscle relaxant dantrolene. There is also anecdotal evidence that dantrolene may produce beneficial effects for the treatment of similar symptoms resulting from poisoning with various agents. However, dantrolene is not an effective treatment for all types of hyperthermia and rigidity accompanying poisoning. Although dantrolene has been tried in patients with heat stroke, there is no evidence that it affects outcome.[17] In severe cases of hyperthermia when neuromuscular hyperactivity may also impair ventilation, a neuromuscular blocker has been used, although suxamethonium is best avoided as it can itself precipitate malignant hyperthermia.

Musculoskeletal and Joint Disorders

The **rheumatic disorders** are painful disorders affecting primarily the joints and related structures of the musculoskeletal system, but there may also be widespread involvement of other systems. The term arthritis is used when the disease is largely confined to the joints. Some of the most common forms of arthritis are discussed in this section and these include rheumatoid arthritis, osteoarthritis, juvenile idiopathic arthritis, and the spondyloarthropathies such as ankylosing spondylitis. Other conditions that are associated with arthritis and which are discussed elsewhere include gout (p.552) and SLE (p.1513).

The names **soft-tissue rheumatism** (see below) and **non-articular rheumatism** have been used to describe a number of painful conditions associated with disease of the structures that surround a joint. For a discussion of the management of **low back pain**, see above.

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (juvenile chronic arthritis) is a term used to describe a clinically heterogeneous group of idiopathic arthritides occurring in children under 16 years of age; subtypes include systemic arthritis, oligoarthritis (particularly of leg joints), and polyarthritis, either positive or negative for rheumatoid factor.[1,2]

Treatment involves many of the same drugs used for rheumatoid arthritis in adults (see below), although there may be limited evidence for their use in children.[1-8] Appropriate management will depend on the subtype of disease, but there is no definitive consensus on the drugs of choice.

- The **NSAIDs** have been a mainstay of treatment for many years, and continue to be important.[1,2] Most children begin therapy with an NSAID,[1] and they may be particularly useful in oligoarthritis.[2] Naproxen, ibuprofen, or indometacin are among the most often used.[1] Aspirin is now rarely prescribed,[8] although in many countries juvenile idiopathic arthritis remains one of its few licensed indications in children.
- Intra-articular injections of a **corticosteroid** (often triamcinolone hexacetonide) are rapidly effective, and well tolerated, and are often used in oligoarthritis with, or instead of, NSAIDs;[1,2,5] they may reduce the development of deformity secondary to contracture.[1] They also have a role in the management of disease flare in

patients already taking second-line drugs, although it is unclear whether multiple intra-articular injections would be preferable to systemic corticosteroids in patients with polyarthritis.[5]

Moderate or high-dose systemic corticosteroids are more generally reserved for patients with systemic arthritis whose disease is not controlled by NSAIDs. In other subtypes, the adverse effects of systemic therapy are likely to outweigh the benefits. A course of low-dose prednisone might be considered for reduction of pain and stiffness in patients with severe polyarthritis who are unresponsive to other drugs, or awaiting response to slow-acting second-line treatments.[1]

- The second-line treatment of choice in children with persistent active arthritis is **methotrexate**.[1,2,6,8] Like several other second-line drugs it is of less benefit in systemic arthritis than in polyarthritis or refractory oligoarthritis.[8] Improvement may take up to 12 weeks to be seen.[1]
- The so-called **biological therapies** have become increasingly important in managing more severe or refractory forms of juvenile idiopathic arthritis.[1,2,4,8] The tumour necrosis factor inhibitor etanercept, which is licensed for paediatric use in many countries, produces excellent responses in many patients with polyarthritis, particularly those who are rheumatoid-factor positive.[8] Like methotrexate, it may be less effective in those with systemic juvenile idiopathic arthritis.[2] Infliximab, although unlicensed, also seems to be of benefit,[1,2,8] and may be more effective than etanercept in the treatment of associated uveitis.[2] Other drugs that have been tried with some evidence of benefit include abatacept, adalimumab, tocilizumab, and anakinra;[1,2,8] there is some evidence that the latter, an interleukin-1 receptor antagonist, may be more effective than the tumour necrosis factor inhibitors in treating patients with systemic arthritis.[2]
- Many **other drugs** have been tried in juvenile idiopathic arthritis, often on the basis of effectiveness in adults. Sulfasalazine may be of benefit in late-onset oligoarthritis[1] but adverse effects are often troublesome.[8] Concern about adverse effects may also have limited the use of cytotoxic and immunosuppressant drugs other than methotrexate, and there are few controlled studies,[8] although benefit has been reported with leflunomide in polyarticular disease.[1,8] Thalidomide has been suggested for treatment-resistant systemic arthritis.[1] In very severe unremitting disease, autologous bone marrow transplantation has been tried.[1,7,8]

Drug treatment aimed at the complications of disease, rather than the disease process itself, may be needed. There is some evidence that bisphosphonates may be useful in controlling low bone mineral density and fragility fractures associated with juvenile idiopathic arthritis.[1,9] Growth hormone has also been widely used to moderate the severe growth retardation that is often seen.[1] Topical treatment with glucocorticoids and mydriatics may be needed for eye disease.[1]

Physiotherapy and occupational therapy are also important components of disease management, and surgery may be needed in selected cases.[1]

Osteoarthritis

Osteoarthritis is the clinical and pathological outcome of a range of disorders that cause structural and functional failure of synovial joints. It is characterised by involvement of the entire joint, with loss and erosion of articular cartilage, subchondral bone changes, meniscal degeneration, mild to moderate synovial inflammation, and outgrowth of bone and cartilage at the joint margins (osteophytes).[1-4] These changes result in pain, stiffness (especially after inactivity) and reduced mobility,[1-6] although patients with changes characteristic of osteoarthritis are often asymptomatic.[4,6] Increased loading of the joint, and mechanical factors such as misalignment and muscle weakness, contribute to joint damage and loss of function.[1,2,4] The joints most often affected are hands, hips, and knees.[4,6]

Current treatment for osteoarthritis is not curative, and management is largely concerned with relief of pain and maintenance of joint function.[1-6]

Physical methods of treatment may be preferred initially, and include physiotherapy, heat and cold therapy, exercises, splinting, correction of misalignment, and weight reduction in the obese.[1-8] Acupuncture may also be tried, and appears to be of benefit in improving pain and functionality in knee osteoarthritis.[9] Transcutaneous electrical nerve stimulation (TENS) may also be of benefit.[8,10]

For the management of pain, paracetamol is recommended as the drug of first choice.[1-6,8] Despite its benefits it has been shown to be less effective than an NSAID in patients with osteoarthritis,[11] and the latter may therefore be considered as an alternative first-line treatment.[2,4] However, because of the risk of potentially serious toxicity in a predominantly elderly group of patients, it is generally considered that a low-dose NSAID should only be added or substituted in patients with an inadequate response to paracetamol alone,[2,4,5] and the long-term use needed for osteoarthritis management may be problematic.[12] Like other treatments NSAIDs do not slow the disease process, and there has even been a concern that some NSAIDs such as indometacin might accelerate it.[6]

In order to reduce the risk of gastrointestinal toxicity with NSAIDs, use of a gastroprotective drug such as a proton pump inhibitor or misoprostol has been recommended.[1-5,8] The use of topical NSAIDs has also been advocated,[4,6,8] although a meta-analysis[13] in 2004 found little evidence of long-term benefit. In the light of concerns about cardiovascular safety, treatment with NSAIDs such as celecoxib that are selective inhibitors of cyclo-oxygenase-2 (COX-2) is limited[14] to those patients considered to be at high risk of developing serious gastrointestinal problems if given a non-selective NSAID and who do not have pre-existing cardiovascular risk factors (see p.97).

In patients in whom paracetamol and/or NSAIDs are ineffective or not tolerated, addition of an opioid analgesic may be appropriate;[2,3,5,8,15] codeine or dihydrocodeine are often used as combinations with paracetamol, and there is evidence of benefit with tramadol, but more potent opioids such as hydrocodone, oxycodone, transdermal fentanyl, or morphine, may have a role in a selected subgroup of patients.[15]

The anthraquinone derivative diacerein has been widely used in some countries, and appears to produce a small but consistent benefit in the treatment of osteoarthritis.[16] Topical capsaicin also produces some relief of pain.[1,4,5,8] There are some interesting data[17] to suggest that doxycycline may have a favourable effect on the progression of osteoarthritis, which might open the way for the development of disease-modifying drugs. Experimental therapies include anakinra[18] and the combined cyclo-oxygenase/lipoxygenase inhibitor licofelone.[19]

Systemic corticosteroids have no place in the management of osteoarthritis. Intra-articular injection of a corticosteroid produces short-term relief of pain and inflammation,[2-4,8,20,21] and may be useful for acute exacerbations. Triamcinolone hexacetonide appears to be more effective than betamethasone.[21] There may also be some benefit from intra-articular injection of hyaluronic acid, to improve the viscosity and elasticity of the synovial fluid;[22,23] improvement may be longer lasting than with intra-articular corticosteroids.[21]

Alternative and complementary therapies have been widely used in osteoarthritis.[2] Powdered rose hip has been reported to be of benefit,[24] as has a mixture of unsaponifiable fractions from avocado and soya oils (avocado-soybean unsaponifiables; ASU).[25] Particular attention has focused on the use of oral glucosamine and chondroitin. Results, however, have been ambiguous:[26-29] overall it is not clear to what extent these therapies have a benefit over placebo, but there is some evidence that combined treatment may be useful in the subset of patients with moderate to severe knee pain.[26] Evidence for chondroitin seems particularly weak.[29]

Surgery, including joint replacement, is of great benefit to patients with severe osteoarthritis that cannot be effectively managed by physical or medical therapy.[2-6,8]

Rheumatoid arthritis

Rheumatoid arthritis is a common chronic systemic inflammatory disease that results in progressive disability and increased mortality. Early disease is characterised primarily by inflammation of the synovium (the inner membrane of the capsule of synovial joints); as the disease progresses the patient suffers destruction of cartilage and bone. Extra-articular features commonly include general malaise, fatigue, weight loss, fever, and anaemia. More severe disease may be associated with vasculitis, pericarditis, pleurisy, pleural effusion, pulmonary interstitial fibrosis, peripheral neuropathies, subcutaneous and pulmonary nodules, scleritis, and Sjögren's syndrome. Palindromic rheumatism is characterised by repeated episodes of arthritis and periarthritis without fever; the joints appear normal between attacks.

The severity and course of rheumatoid arthritis varies greatly between patients. Some have brief attacks with little or no disease progression, but the majority will have slowly progressive joint destruction and deformity despite intermittent relapses and remissions; a few patients may have very severe and rapidly progressive disease. Because irreversible joint damage occurs early in the course of disease, rapid diagnosis and institution of treatment aimed at preventing progression is crucial.[1-3] Although there is no cure, remission or substantial slowing of the disease process is increasingly seen as an achievable goal in the majority of patients.[4,5]

The choice of **drugs for relief of pain** depends upon the severity of symptoms. In mild cases an analgesic such as paracetamol (with codeine if needed) may be all that is required but most patients prefer an NSAID; although these are thought to have an advantage because of their anti-inflammatory effects, the clinical evidence for this has been questioned.[6] There is little apparent difference between the various NSAIDs in terms of anti-inflammatory activity, but patient responses vary widely. When starting an NSAID the dose is gradually increased to the recommended maximum over 1 to 2 weeks; if the response is inadequate after a total of about 4 weeks, or if adverse effects are intolerable, other NSAIDs are tried. In the light of concerns about cardiovascular safety, treatment with NSAIDs such as celecoxib that are selective inhibitors of cyclo-oxygenase-2 (COX-2) is limited to those patients considered to be at high risk of developing serious gastrointestinal problems if given a non-selective NSAID and who do not have pre-existing cardiovascular risk factors[7] (see p.97). Topical analgesics such as NSAIDs or capsaicin, or rubefacients may provide slight relief of pain but their role, if any, is unclear.

Once the diagnosis is confirmed and severity and progression of the disease have been assessed, introduction of a **disease-modifying antirheumatic drug** (DMARD) should take place as early as possible.[1-4,8] Although opinions vary, there is an increasing trend to aggressive management in early disease, with tight control of the disease process.[4,5,9]

Available DMARDs include antimalarials (hydroxychloroquine), sulfasalazine, gold compounds (auranofin, sodium aurothiomalate), penicillamine, conventional immunosuppressants (methotrexate, azathioprine, ciclosporin, cyclophosphamide, and leflunomide), and so-called biological therapies, including the tumour necrosis factor-α (TNF-α) inhibitors (adalimumab, etanercept, and infliximab), co-stimulation blockers (abatacept), interleukin-1 receptor antagonists (anakinra), and B-cell-targeted antibodies (rituximab). It is thought that most DMARDs inhibit the release or activity of cytokines involved in maintaining the inflammatory process, although other actions may also contribute. Since any therapeutic effect may not be apparent for 4 to 6 months, treatment should continue for at least 6 months before considered ineffective.

There is evidence of disease modifying effect for methotrexate, sulfasalazine, leflunomide, and intramuscular gold, with less compelling data for hydroxychloroquine, penicillamine, oral gold, ciclosporin, and azathioprine.[9-15] Concerns about toxicity or effectiveness mean that gold compounds and penicillamine seem now to be less widely used. There is good evidence of the effectiveness of the TNF-α inhibitors,[4,5,9,15-17] and some in favour of anakinra,[16] but good evidence of an effect of other biological therapies on disease progression is currently scanty, although clinical benefit has been found with, for example, abatacept and rituximab.[5,16,18]

The choice of DMARD to begin treatment is based on the risk/benefit ratio, with the antimalarial hydroxychloroquine an option in mild disease, and sulfasalazine or methotrexate preferred in those with moderate to severe disease, or judged likely to progress.[9] Methotrexate has become the DMARD of first choice in the majority of patients.[1,2,8,9] Subcutaneous or intramuscular methotrexate may be an option in patients who cannot be satisfactorily managed with weekly oral dosage.[1,9] Addition of sulfasalazine, hydroxychloroquine, or both may be a suitable option in patients refractory to optimal methotrexate therapy,[1,9] and addition of corticosteroids or leflunomide are also options, although evidence for combining methotrexate with ciclosporin is not entirely convincing.[9] At what stage biological therapies are to be recommended remains a matter of debate. In the UK, official recommendations are still that TNF-α inhibitors should be reserved for patients who have failed treatment with two conventional DMARDs,[17,19] but others permit earlier introduction, for example after failure of the first conventional DMARD.[8,16,20] Other classes of biological therapy are likely to be reserved for patients in whom TNF-α inhibitors are ineffective or contra-indicated, as is currently the case with rituximab.[18,21]

There is also some evidence in favour of beginning therapy with a combination of DMARDs, and subsequently 'stepping down' once control is achieved.[1,4,5,8,9,22,23] The large, multicentre BeSt study found that although initial combination therapy (methotrexate and infliximab, or methotrexate, sulfasalazine, and tapered high-dose prednisone) produced earlier clinical improvement and less progression of joint damage, the ultimate clinical improvement was similar in patients assigned to sequential monotherapy or 'step-up' therapy.[24] There is a concern that combination therapy may expose patients to an increased risk of toxicity,[22] although the BeSt study did not find this to be the case.[24] Combinations of TNF-α inhibitors with other biological response modifiers such as anakinra or abatacept are not advisable, because of an increased risk of serious infection.[5,16]

Since rheumatoid arthritis is a chronic disease, treatment may need to be very prolonged, but evidence of the long-term tolerability and efficacy of DMARDs is patchy. Studies have suggested that many DMARDs are stopped after a few years, usually because of a decline in efficacy rather than adverse events.[25]

Addition of **corticosteroids** to DMARD therapy may be useful in early disease to control synovitis, or as bridging therapy when starting or increasing DMARDs, since they produce rapid symptomatic control.[9] Although they produce bone loss, this may be outweighed (at least short-term) by their beneficial effects on the disease process: there is good evidence that adding a corticosteroid to treatment reduces the progression of joint erosion.[26] Short-term and moderate-term intermittent use of relatively low doses has therefore been suggested (not exceeding the equivalent of 15 mg of prednisolone daily).[27,28] However, prolonged therapy is associated with significant adverse effects, and long-term use is not considered justified.[9] Intra-articular injection is recommended for acute flares, and may be particularly effective when combined with aggressive DMARD therapy.[9]

There is little good evidence to support most **other drugs** tried in rheumatoid arthritis.[8] Meta-analysis[29] has confirmed that tetracyclines, and in particular minocycline, can produce some reduction in disease activity; effects on serological markers appear to be more marked than clinical improvements in tender and swollen joints. The effects may be greater in patients with early disease. Much research has been conducted into immunomodulators and immunotherapy. Although alternative immunosuppressants such as mycophenolate mofetil and tacrolimus have been tried, most interest in recent years has surrounded new biological therapies. Matrix metalloproteinase inhibitors have proved disappointing, but new TNF-α inhibitors such as certolizumab pegol and golimumab, the interleukin-6 receptor antagonist tocilizumab, and modulators of B-cell function such as atacicept, belimumab, and epratuzumab are under investigation. In addition, denosumab is of interest for its potential to control joint destruction.[5] Other methods of treatment that are being or have been investigated include gene therapy and autologous bone marrow transplantation. A rheumatoid arthritis vaccine is also in clinical trials. Induction of tolerance with collagen and other antigens given orally has also been tried, but results are reported to be variable.[30]

Some studies suggest that addition of fish oils[31] and/or evening primrose oil to standard antirheumatic therapy might help to reduce pain and joint swelling. Many alternative and herbal therapies have been tried, although good evidence of benefit is scanty.

There has been considerable interest in the possibility that statins such as atorvastatin may produce clinical improvements, albeit modest, in symptoms of rheumatoid arthritis,[32] as well as in any accompanying cardiovascular risk factors.

The importance of managing co-morbidity in patients with rheumatoid arthritis has been emphasised;[1] in particular infection (especially pulmonary infection), cardiovascular disease, and osteoporosis require appropriate management and action to reduce risk factors.

The treatment of rheumatoid arthritis during **pregnancy** presents its own problems; some of the most effective DMARDs such as methotrexate and leflunomide have teratogenic properties, and for others, including the biological therapies, there is little evidence.[33,34] Hydroxychloroquine, and perhaps azathioprine and sulfasalazine, may be relatively safe to use, but it is important to weigh benefit against risk for each individual case.[33]

Soft-tissue rheumatism

Soft-tissue rheumatism includes conditions such as:

- bursitis (e.g. housemaid's knee)
- fasciitis
- fibromyalgia (fibrositis, muscular rheumatism, myofascial pain)
- frozen shoulder
- humeral epicondylitis (e.g. tennis or golfer's elbow)
- sprains and strains
- tendinitis
- tenosynovitis
- Tietze's syndrome

Inflamed or displaced tissue may also impinge on nearby nerves and produce compression neuropathies such as carpal tunnel syndrome.

Some forms of soft-tissue rheumatism respond to selective rest of the affected region, massage, splinting, or application of heat, cold, or rubefacients.[1-3] Exercise is of value in neck pain,[3,4] fibromyalgia,[5,6] and frozen shoulder,[7] but its benefit in epicondylitis is unclear.[4]

For patients with epicondylitis oral or topical NSAIDs may offer short-term pain relief, but it is unclear if they are effective in producing longer term benefit.[4] They are of unknown benefit in frozen shoulder,[7] and are not thought to be helpful in fibromyalgia,[5] although some benefit has been reported with paracetamol and tramadol.[8]

Corticosteroid injections produce dose-dependent benefit for up to 9 months in shoulder pain such as that associated with rotator cuff tendinitis or frozen shoulder,[9] and oral corticosteroids may be of benefit for up to 6 weeks although it is not clear that benefit is subsequently maintained[10] (a study[11] in patients with epicondylitis suggested that benefits of corticosteroid injection in this group were paradoxically reversed after 6 weeks). Corticosteroid injections are often combined with a local anaesthetic; injection of a local anaesthetic alone has been shown to be of benefit in chronic neck pain.[4]

Botulinum toxin has been tried in epicondylitis[12] and myofascial pain.[13] There is evidence that nitric oxide plays a role in healing in patients with tendinitis, and topical application of a patch containing glyceryl trinitrate has proved of benefit in patients with epicondylitis or tendinitis.[14]

Fibromyalgia appears to be associated with abnormal pain responses, and some consider it a central pain syndrome rather than a rheumatic syndrome. There is strong evidence that low-dose tricyclic antidepressants are of benefit in many patients, as is the tricyclic compound cyclobenzaprine. Combination of amitriptyline with the SSRI fluoxetine also appears beneficial, although SSRIs alone have produced equivocal results; serotonin and noradrenaline reuptake inhibitors (SNRIs) such as duloxetine, milnacipran, or venlafaxine have also been reported to be of value. Pregabalin and gabapentin have been shown to be of benefit in controlled studies.[5,6,8]

Surgery may be of benefit in some conditions such as epicondylitis and possibly shoulder pain.[4] Surgical decompression is also the definitive treatment for carpal tunnel syndrome,[15] although there is also evidence of benefit from splinting[16] and local corticosteroid injection[17] (although benefit may not be long term, and the procedure carries some risks[18]). Oral corticosteroids and ultrasound have also demonstrated benefit in patients with carpal tunnel syndrome.[16]

Spondyloarthropathies

The spondyloarthropathies are a group of seronegative arthritides which include ankylosing spondylitis, psoriatic arthritis, arthritis associated with inflammatory bowel disorders (enteropathic arthritis), and arthritis associated with infection as in reactive arthritis (aseptic arthritis).

Ankylosing spondylitis is characterised by arthritis of the spine and sacroiliac joints and sometimes there is also asymmetrical peripheral involvement. Males under 40 years of age are mainly affected. The aim of management of the disease is to reduce pain and stiffness and to prevent spine and joint deformity, which is accomplished using a combination of active physical therapy and drug therapy. Exercises are used to strengthen muscles and to maintain a good posture and range of movement in joints. NSAIDs are used to relieve pain and inflammation, thus allowing the exercises to be performed; they do not influence the progression of the disease. Some patients may need to add other non-opioid analgesics such as paracetamol for additional pain control. Systemic corticosteroids are rarely indicated but intra-articular injections of corticosteroids may be beneficial when one or two peripheral joints are severely affected. The disease-modifying antirheumatic drug (DMARD) sulfasalazine is of benefit for peripheral arthritis, but not for spinal symptoms. The efficacy of most other DMARDs used in rheumatoid arthritis (see above) remains to be demonstrated. However, the tumour necrosis factor-α (TNF-α) inhibitors adalimumab, etanercept, and infliximab improve spinal pain, function, and peripheral joint disease. They produce rapid benefit (usually within 12 weeks) although most patients relapse once they are withdrawn. Treatment with a TNF-α inhibitor should be considered in patients with active disease despite conventional treatments. There is some evidence that early intervention may produce better remission rates, but it is yet unknown if this results in longer-lasting remission on withdrawal. Evidence is mostly lacking for other biological therapies, but no marked benefit has been seen in conflicting studies with the interleukin-1 receptor antagonist anakinra.

Psoriatic arthritis (or psoriatic arthropathy) is an inflammatory seronegative arthritis occurring in patients with psoriasis. In some patients the spine may be involved when the condition may be indistinguishable from ankylosing spondylitis. Less frequently some patients have a form of symmetrical arthritis resembling rheumatoid arthritis. The psoriasis (p.1583) and the arthritis usually require separate treatment. Treatment of the arthritis is initially as for ankylosing spondylitis with NSAIDs and physical therapy. If these methods fail treatment with a DMARD may be instituted, although chloroquine and hydroxychloroquine should be avoided since they may precipitate skin reactions (see Psoriatic Arthritis, p.601). There is most evidence to support the use of sulfasalazine or methotrexate. Leflunomide may be effective but is likely to be restricted by its toxicity and prolonged half-life. Ciclosporin is also restricted by its toxicity. As in ankylosing spondylitis, however, significant benefit has now been found with the TNF-α inhibitors, and treatment with these is recommended in patients with active disease despite treatment with NSAIDs and/or DMARDs. In the UK, etanercept or adalimumab are preferred to infliximab, but treatment should be individualised; a monoclonal antibody such as adalimumab or infliximab is advocated by others in patients who also have inflammatory bowel disease. There is some suggestion that alefacept may also be of benefit in psoriatic arthritis. Systemic corticosteroids have little or no place in the management of psoriatic arthritis.

Reactive arthritis is characterised by sterile synovitis following 1 to 4 weeks after an infection, most commonly of the gastrointestinal or genito-urinary tract. Extra-articular features involving the skin, eyes, or genito-urinary tract may or may not be present. Reactive arthritis is also a feature of Reiter's syndrome. Reactive arthritis is treated with physical therapy and NSAIDs and, if indicated, intra-articular injections of corticosteroids; the role of antibacterials is less certain (see Bone and Joint Infections, p.164).

Still's disease

Adult-onset Still's disease is a syndrome characterised by high fever, with body temperature classically spiking daily or twice daily, an evanescent pink maculopapular rash, and arthritis (usually oligoarthritis initially). It is most common in patients aged 16 to 35 years.

Treatment has traditionally relied on NSAIDs, corticosteroids, and immunosuppressants or other DMARDs similar to those used in rheumatoid arthritis (above).[1-3] A trial of NSAIDs is worthwhile in patients with mild disease, but most patients cannot be managed with NSAIDs alone.[2,3] Corticosteroids may be needed for initial therapy if manifestations are severe, but will eventually be needed in about 80% of cases.[2] DMARDs (generally methotrexate) are introduced when corticosteroid therapy fails to control the disease or when their adverse effects become problematic. Most patients will respond to methotrexate although liver function must be closely monitored. The value of other DMARDs is uncertain. Intravenous immunoglobulin is also frequently tried, although supporting evidence is lacking.[2,3]

The TNF-α inhibitors have also been tried,[2,3] but results have been variable.[2] There is, however, some evidence that interleukin-1 and interleukin-6 play a role in pathogenesis of the condition, and there have been a few reports of dramatic improvement with anakinra (an interleukin-1 receptor antagonist) in resistant disease, while tocilizumab (an interleukin-6 receptor antagonist) has also been suggested as an investigational therapy.[2,3]

The name Still's disease has also been used rather inconsistently to describe some types of juvenile idiopathic arthritis (above).

Abatacept *(BAN, USAN, rINN)*

Abataceptum; BMS-188667; CTLA4-Ig. 1-25-oncostatin M (human precursor) fusion protein with CTLA-4 (antigen) (human) fusion protein with immunoglobulin G1 (human heavy chain fragment), bimolecular (146→146′)-disulfide.

Абатацепт

CAS — 332348-12-6.
ATC — L04AA24.
ATC Vet — QL04AA24.

Adverse Effects and Precautions

Acute infusion reactions occurring within 1 hour of starting an infusion are common with abatacept use. The most frequently reported infusion events are dizziness, headache, and hypertension; hypotension and dyspnoea occur less commonly. Other acute events include nausea, flushing, pruritus, rash, and wheezing. Most events are usually mild to moderate although stopping treatment may be necessary in a few patients.

Other common adverse effects include headache, nasopharyngitis, nausea, dyspepsia, diarrhoea, dizziness, back pain, fatigue, cough, and abnormal liver function values. Antibodies to abatacept may develop and anaphylaxis or anaphylactic reactions have been reported rarely. Uncommon adverse reactions include paraesthesia, thrombocytopenia, and leucopenia.

Infections are frequent in patients treated with abatacept and most often affect the respiratory and urinary tracts. More serious infections such as pneumonia, sepsis, cellulitis, bronchitis, diverticulitis, and acute pyelonephritis have also been rarely associated with abatacept treatment. Treatment should be stopped in patients who develop a serious infection. Abatacept should not be given to patients with severe and uncontrolled infections such as sepsis and opportunistic infections. It should be used with caution in patients with a history of recurrent infections, with underlying conditions that may predispose to infections, or with chronic, latent, or localised infections. Patients should be screened for latent tuberculosis before starting treatment; those testing positive should be treated with standard chemoprophylaxis before beginning abatacept.

Some disease-modifying antirheumatic drugs have been associated with hepatitis B reactivation; licensed product information for abatacept recommends screening for viral hepatitis before starting treatment.

Adverse effects of abatacept are more frequent in patients with chronic obstructive pulmonary disease and may include a worsening of their respiratory symptoms.

Carcinogenicity. The role of abatacept in the onset of malignancies such as lymphoma in humans is not known.

In placebo-controlled studies the overall frequency of malignancies in patients treated with abatacept compared to those that received placebo was similar (1.4% and 1.1%, respectively). However, there were more cases of lung cancer and lymphomas in those given abatacept. In *animal* studies in mice, increases in lymphomas and mammary tumours have been noted, although these increases have not been seen in some studies with other mammals.

Interactions

Live vaccines should not be given with abatacept, or within 3 months of stopping it, as its effect on vaccine efficacy or the risk of infection transmission is unknown. The use of TNF inhibitors with abatacept may increase the risk of serious infections (see p.71); such combinations are not recommended. Use with anakinra or rituximab is also not recommended because of insufficient evidence to assess safety.

Pharmacokinetics

Abatacept is reported to have linear pharmacokinetics at usual dosages. After repeated intravenous doses, its mean terminal half-life is about 13 days.

Studies in *animals* suggest that abatacept is distributed into breast milk.

Uses and Administration

Abatacept, a fusion protein, is a co-stimulation blocker. It prevents the activation of T-cells; activated T-cells have been found in the synovium of patients with rheumatoid arthritis. It is used in the treatment of moderate to severe active rheumatoid arthritis to delay structural damage and improve physical function. In the UK, it is licensed for use in patients who have had an inadequate response to standard disease-modifying antirheumatic drugs (DMARDs), including at least one TNF inhibitor; in the USA, it may be used to reduce the signs and symptoms of early disease.

Abatacept is given by intravenous infusion over a period of 30 minutes in the following doses, based on body-weight:

- 500 mg for patients weighing less than 60 kg
- 750 mg for those weighing 60 to 100 kg
- 1 g for those over 100 kg.

The dose is repeated at 2 and 4 weeks, then every 4 weeks thereafter. If a response to treatment is not seen within 6 months, the benefits of continuing abatacept may need to be considered. In the UK, abatacept is licensed for use with methotrexate; however, in the USA it may be given alone or with other DMARDs (but see Interactions, above).

For the use of abatacept in children, and recommended doses, see below.

Abatacept is also being studied for other auto-immune diseases such as inflammatory bowel disease, psoriatic arthritis, and SLE.

Administration in children. In the USA, abatacept is licensed in the treatment of moderate to severe, active juvenile idiopathic arthritis in children aged 6 years and above; it may be used alone or with methotrexate. The dose is calculated according to body-weight and is given as an intravenous infusion over 30 minutes; those weighing less than 75 kg should be given 10 mg/kg initially, while heavier children may receive the appropriate adult dose (see above). Doses should be repeated at 2 and 4 weeks, and then every 4 weeks thereafter.

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Hypersensitivity. Leukocytoclastic vasculitis, a type III hypersensitivity reaction, has been reported after therapy with aceclofenac.[1,2] Anaphylaxis has also occurred.[3]

Precautions

As for NSAIDs in general, p.98.

Aceclofenac should be avoided in patients with moderate to severe renal impairment.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Aceclofenac is well absorbed from the gastrointestinal tract; peak plasma concentrations are reached 1 to 3 hours after an oral dose. Aceclofenac is more than 99% bound to plasma proteins. The plasma-elimination half-life is about 4 hours. About two-thirds of a dose is excreted in the urine, mainly as hydroxymetabolites. A small amount is converted to diclofenac.

◊ It has been suggested[1] that low concentrations of diclofenac, a minor metabolite, may account for some of the actions of aceclofenac.

Uses and Administration

Aceclofenac, a phenylacetic acid derivative, is an NSAID (see p.99) related to diclofenac (p.44). It is used in the management of osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis, in usual oral doses of 100 mg twice daily. Reduced doses should be used in patients with hepatic impairment, see below.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Acemetacin). A yellow or greenish-yellow, crystalline powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in anhydrous alcohol; soluble in acetone. Protect from light.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Acemetacin is well absorbed after oral dosage. Its major metabolite is indometacin (p.66) which, after repeated doses, is present at higher concentrations than those of acemetacin. Acemetacin is bound to plasma proteins to a slightly lesser extent than indometacin. It is eliminated via both the liver and the kidneys.

Uses and Administration

Acemetacin, a glycolic acid ester of indometacin, is an NSAID (p.99). Its pharmacological activity is due to both acemetacin and its major metabolite, indometacin (p.66). Acemetacin is used in rheumatoid arthritis, osteoarthritis, and low back pain, and for postoperative pain and inflammation. Usual oral doses are 120 to 180 mg daily in divided doses. Acemetacin is eliminated by both hepatic and renal routes, although pharmacokinetics are not affected by moderate renal or hepatic impairment and appear to be unchanged in the elderly.

CAS — 331731-18-1.

ATC — L04AB04.

ATC Vet — QL04AB04.

Adverse Effects and Precautions

As for Infliximab, p.69.

Injection site reactions including erythema, itching, pain, and swelling are the most common adverse reactions with adalimumab; however, most reactions are mild and do not result in drug withdrawal. Other common reactions include headache, rashes, back pain, hypertension, paraesthesias, increased alkaline phosphate levels, and cough.

Autoantibodies to adalimumab have been detected.

Interactions

As for Infliximab, p.71.

Methotrexate is reported to reduce the clearance of adalimumab by up to 44% but licensed product information for the latter states that dosage adjustment for either drug does not appear to be necessary.

Pharmacokinetics

Adalimumab is reported to have linear pharmacokinetics at usual dosages. After subcutaneous injection peak concentrations are reached in about 3 to 8 days and bioavailability is estimated to be 64%. The mean terminal half-life is about 2 weeks.

Uses and Administration

Adalimumab is a recombinant human monoclonal tumour necrosis factor (TNF) antibody that binds specifically to TNF-α and blocks its interaction with endogenous cell-surface TNF receptors. It also modulates biological responses that are induced or regulated by TNF. Elevated levels of TNF have been found in the affected tissues and fluids of patients with rheumatoid arthritis, ankylosing spondylitis, psoriatic arthritis, plaque psoriasis, and Crohn's disease.

Adalimumab is used in the treatment of moderate to severe, active **rheumatoid arthritis** and active and progressive **psoriatic arthritis** to delay structural damage and improve physical function. In the UK, it is licensed for use in patients who have had an inadequate response to standard disease-modifying antirheumatic drugs (DMARDs), although in severe progressive rheumatoid arthritis it may be used in patients not previously treated with methotrexate; in the USA, it may be used to reduce the signs and symptoms of early disease. Adalimumab is also used in the treatment of active **ankylosing spondylitis**: UK licensed product information recommends that it should only be used in patients with severe disease who have had an inadequate response to conventional treatment; however, in the USA it may be used to reduce signs and symptoms in early disease. For all the above indications, it is given by subcutaneous injection in a dose of 40 mg every other week. In the treatment of rheumatoid arthritis, UK licensed product information recommends that adalimumab should be given with methotrexate, although monotherapy may be used where treatment with methotrexate would be inappropriate. When used as monotherapy in rheumatoid arthritis, some patients may benefit from increasing the dose to 40 mg every week. Clinical response is usually achieved within 12 weeks of treatment.

Adalimumab is also used in the treatment of moderate to severe, active **Crohn's disease** unresponsive to conventional treatment; it may also be used in patients who have relapsed while taking infliximab. Patients may be given an initial dose of 160 mg on day 1 (given as four 40-mg injections in one day or two 40-mg injections daily for 2 consecutive days), followed by 80 mg two weeks later (day 15). After a further two weeks (day 29), a maintenance dose of 40 mg every other week may be started. Alternatively, UK licensed product information advises that patients at risk of adverse effects may be given 80 mg initially, followed by 40 mg 2 weeks later; thereafter, usual maintenance doses may be given. A clinical response is usually seen within 12 weeks of starting treatment; those patients who relapse while on adalimumab may benefit from increasing the maintenance dose to 40 mg every week.

In the treatment of moderate to severe chronic **plaque psoriasis** in patients unresponsive to, or intolerant of, conventional systemic therapy including phototherapy, the recommended initial dose of adalimumab is 80 mg subcutaneously; this may be followed by a maintenance dose of 40 mg subcutaneously on alternate weeks, starting 1 week after the initial dose. A clinical response is usually seen within 16 weeks of starting treatment.

For the uses of adalimumab in children, and recommended doses, see below.

Administration in children. In the USA, adalimumab is licensed in the treatment of moderate to severe, active juvenile idiopathic arthritis in children aged 4 years and above: it may be used alone or with methotrexate. The dose is calculated according to weight and is given subcutaneously: those weighing 15 kg to less than 30 kg should be given 20 mg every other week, while heavier children may receive 40 mg every other week.

Inflammatory bowel disease. Adalimumab is used in the management of Crohn's disease[1-4] (p.1697), including in patients who are intolerant of, or relapse on, infliximab treatment.[5-8] It has also been tried in the treatment of ulcerative colitis (p.1697).[9]

Uveitis. Adalimumab has been tried with some success in the treatment of idiopathic uveitis (p.1515). Uveitis can also develop as a complication of other inflammatory disorders such as rheumatoid arthritis; treatment with adalimumab may improve ocular symptoms in addition to its effect on the primary disorder.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102, and for Fentanyl, p.56.

Effects on the cardiovascular system. Sinus arrest had occurred[1] during intubation in 2 patients given alfentanil 30 micrograms/kg.

1. Maryniak JK, Bishop VA. Sinus arrest after alfentanil. *Br J Anaesth* 1987; **59:** 390–1.

Effects on mental function. Like fentanyl, alfentanil 7.5 or 15 micrograms/kg intravenously had no effect on memory in healthy subjects.[1] In another study impairment of memory for new facts did occur 2 hours after operation in patients anaesthetised with alfentanil 7.5 micrograms/kg, but not in those given fentanyl;[2] methohexital might have contributed to the impairment.

Effects on the respiratory system. Alfentanil, like other opioid agonists, causes dose-related respiratory depression; it is significant with doses of more than 1 mg. Recovery has been reported to be faster after alfentanil than after fentanyl (see p.56),[1,2] possibly reflecting the shorter elimination half-life of alfentanil. Even so, accumulation of alfentanil is possible with large doses over a prolonged period. Profound analgesia is accompanied by marked respiratory depression which may persist or recur postoperatively.

Sudden respiratory arrest usually within an hour after the end of alfentanil infusion has been reported in patients who initially appeared to have made a rapid recovery from anaesthesia;[3-5] all responded to treatment with naloxone. Close monitoring of respiration in the initial postoperative period was recommended and this was reinforced by the manufacturers;[6] factors such as hyperventilation and the use of opioid premedication might enhance or prolong the respiratory depressant effects of alfentanil.

Precautions

As for Opioid Analgesics in general, p.103.

Children. Alfentanil given to preterm infants undergoing paralysis and mechanical ventilation for respiratory distress syndrome resulted in a rapid and significant fall in heart rate and blood pressure, emphasising that proper evaluation of the pharmacological and clinical effects was necessary.[1]

The *BNFC* states that the half-life of alfentanil is prolonged in neonates and accumulation is likely with prolonged use; muscle rigidity may occur and the use of muscle relaxants may be required.

1. Marlow N, *et al.* Hazards of analgesia for newborn infants. *Arch Dis Child* 1988; **63:** 1293.

The elderly. EEG changes suggested that elderly patients had increased brain sensitivity to alfentanil,[1] and that lower doses might be indicated in older patients for pharmacodynamic rather than pharmacokinetic reasons. See also under Pharmacokinetics, below.

1. Scott JC, Stanski DR. Decreased fentanyl and alfentanil dose requirements with age: a simultaneous pharmacokinetic and pharmacodynamic evaluation. *J Pharmacol Exp Ther* 1987; **240:** 159–66.

Handling. Avoid contact with the skin and the inhalation of particles of alfentanil hydrochloride.

Inflammatory bowel disease. Patients with Crohn's disease required higher doses of alfentanil than control patients[1] although there were no differences in alfentanil pharmacokinetics between the 2 groups of patients.

1. Gesink-van der Veer BJ, *et al.* Influence of Crohn's disease on the pharmacokinetics and pharmacodynamics of alfentanil. *Br J Anaesth* 1993; **71:** 827–34.

Pregnancy. UK licensed product information contra-indicates the use of alfentanil in labour, or before clamping of the cord during caesarean section, because placental transfer means there is a risk of neonatal respiratory depression.

Interactions

For interactions associated with opioid analgesics, see p.103.

Drugs that depress the heart or increase vagal tone, such as beta blockers and anaesthetic drugs, may predispose patients given alfentanil to develop bradycardia and hypotension. Use of alfentanil with non-vagolytic neuromuscular blockers may produce bradycardia and possibly asystole.

The metabolism of alfentanil via the cytochrome P450 isoenzyme CYP3A4 may be reduced by potent inhibitors of this isoenzyme, resulting in a risk of prolonged or delayed respiratory depression. Reduced doses of alfentanil may be required if given with a CYP3A4 inhibitor such as cimetidine, diltiazem, erythromycin, fluconazole, itraconazole, ketoconazole, or ritonavir.

Antibacterials. The elimination half-life of alfentanil was increased and clearance decreased when given after a 7-day course of oral *erythromycin* in healthy subjects.[1] Prolonged respiratory depression has also occurred in a 32-year-old man given alfentanil during anaesthesia after three 1-g doses of erythromycin in the 24 hours before surgery.[2] In another study of healthy subjects, the clearance (three-compartment model) of alfentanil was reduced by 70% in those given oral *troleandomycin*.[3]

Other hepatic enzyme inhibitors and drugs interfering with hepatic blood flow might also affect the clearance of alfentanil.

Antifungals. Azole antifungals such as *fluconazole*, *ketoconazole*, or *voriconazole* can inhibit the metabolism of alfentanil. In a study,[1] giving alfentanil 1 hour after intravenous or oral fluconazole decreased the clearance of alfentanil by 60 and 55%, respectively and increased the mean half-life of alfentanil from 1.5 hours to 2.7 and 2.5 hours, respectively. Similarly, another study[2] found that giving alfentanil 1 hour after oral voriconazole decreased the clearance of alfentanil by 85% and increased the mean half-life of alfentanil to 6.6 hours.

Pharmacokinetics

After parenteral doses alfentanil hydrochloride has a rapid onset and short duration of action. Alfentanil is about 90% protein bound and has a small volume of distribution. Its terminal elimination half-life is about 1 to 2 hours. It is metabolised in the liver; oxidative *N*- and *O*-dealkylation by the cytochrome P450 isoenzyme CYP3A4 leads to inactive metabolites, which are excreted in the urine. Alfentanil crosses the blood-brain barrier and the placenta and has been detected in colostrum.

◊ Alfentanil is less lipid-soluble than fentanyl, but more so than morphine. It is highly bound to plasma proteins, mainly to α_1-acid glycoprotein. Decreased lipid solubility can be expected to limit penetration of the blood-brain barrier when compared with fentanyl, but the majority of unbound alfentanil is unionised and can rapidly gain access to the CNS. Alfentanil has a smaller volume of distribution than fentanyl and its elimination half-life is shorter. The manufacturers have given values for a three-compartment pharmacokinetic model with a distribution half-life of 0.4 to 3.1 minutes, a redistribution half-life of 4.6 to 21.6 minutes, and a terminal elimination half-life of 64.1 to 129.3 minutes after single bolus injections of 50 or 125 micrograms/kg. Accumulation is less likely than with fentanyl, but can occur after repeated or continuous dosage especially in patients with reduced clearance. The mean elimination half-life reported is usually about 90 minutes, but this is reduced in children and increased in the elderly and neonates, in hepatic impairment, in the obese, and during cardiopulmonary bypass (see below).

Administration. *CONTINUOUS INTRAVENOUS INFUSION.* Small studies of alfentanil by continuous intravenous infusion[1-3] have found pharmacokinetic parameters to be similar to those after a single bolus injection, but with some conflicting results. In 29 patients undergoing orthopaedic surgery an initial bolus intravenous injection of alfentanil 50 micrograms/kg was followed by intravenous infusion of 1 microgram/kg per minute, continued for 44 to 445 minutes; a second bolus injection of 50 micrograms/kg was given immediately before incision and an additional bolus injection of 1 mg given if necessary.[4] The time course of the plasma-alfentanil concentration fitted a two-compartmental model in 26 patients. Terminal half-lives varied widely from 56 to 226 minutes (mean 106 minutes), the highest values being mainly in patients over 60 years. There was no significant correlation between pharmacokinetic parameters and the duration of the infusion or the total dose. Plasma clearance and volumes of distribution did not correlate significantly with body-weight although steady-state volume of distribution was enlarged with increasing age. The mean estimated steady-state concentration was 293 nanograms/mL (range 147 to 636 nanograms/mL).

INTRAMUSCULAR. See The Elderly, below.

Burns. The volume of distribution and total clearance of alfentanil were reduced and its elimination half-life prolonged in patients with burns.[1] This was due, in part, to raised concentrations of α_1-acid glycoprotein leading to increased protein binding.

1. Macfie AG, *et al.* Disposition of alfentanil in burns patients. *Br J Anaesth* 1992; **69:** 447–50.

Cardiopulmonary bypass. The elimination half-life of alfentanil increased from 72 minutes before cardiopulmonary bypass to 195 minutes afterwards in 5 patients.[1] This was attributed to an increase in volume of distribution, based in part on a dilution-induced decrease in plasma protein binding. Others[2,3] found that on starting cardiopulmonary bypass total serum concentrations of alfentanil were halved, mainly because of dilution of α_1-acid glycoprotein and an increase in unbound alfentanil.

Children. Alfentanil has been shown to have a shorter elimination half-life (about 40 minutes) and a smaller volume of distribution in children than in adults.[1] However, the half-life of alfentanil is prolonged in neonates. See also Hepatic Impairment, below.

The elderly. Plasma clearance of alfentanil after a single intravenous dose of 50 micrograms/kg was reduced in patients more than 65 years old when compared with that in healthy young adults.[1] Mean elimination half-life was 137 minutes in the elderly and 83 minutes in the young adults. Volumes of distribution were similar and it was considered that reduced clearance might be due to decreased hepatic metabolism in the elderly. In a study in male patients the terminal elimination half-life of alfentanil increased with age, although clearance was not significantly affected.[2] In patients given alfentanil 1 microgram/kg per minute by continuous intravenous infusion during orthopaedic surgery,[3] terminal half-life increased linearly with age in those older than 40 years and steady-state volume of distribution was enlarged with increasing age; clearance did not correlate significantly with age and was thought to be more variable during a continuous infusion in long-term surgery than after a single bolus injection. Others have reported[4] that the effects of age on alfentanil pharmacokinetics are dependent on gender. In this study total plasma clearance decreased and terminal half-life increased with increasing age in women, but not in men. It has been suggested that this effect in women may be more dependent on menopausal status than on age.[5]

In a study[6] in elderly patients plasma concentrations of alfentanil were greater and the maximum concentration occurred earlier when alfentanil was injected into the deltoid muscle compared with injection into the gluteal muscle.

Hepatic impairment. Total plasma clearance and protein binding of alfentanil were decreased in patients with alcoholic cirrhosis when compared with control subjects. Elimination half-life was prolonged from 90 to 219 minutes in the cirrhotic patients following a single intravenous dose of 50 micrograms/kg and was attributed in part to alterations in binding sites of α_1-acid glycoprotein.[1] There might be different effects on alfentanil disposition in patients with non-alcoholic cirrhosis or other liver disorders.[2] The pharmacokinetics of alfentanil were apparently not affected in children with cholestatic hepatic disease whereas clearance was reduced postoperatively in 3 patients who had undergone liver transplantation.[3]

Obesity. The pharmacokinetics of alfentanil are reportedly altered in obesity.[1] Elimination half-life was 172 minutes in 6 obese patients compared with 92 minutes in 7 who were not obese. Plasma clearance of alfentanil was also decreased, although others[2] found that obesity had no effect on clearance, but it did have a direct relationship with the volume of the central compartment.

Renal impairment. The pharmacokinetics of alfentanil were not affected significantly in adults[1] or children[2] with chronic renal failure. In another study[3] increased volume of distribution of alfentanil at steady state was associated with decreased plasma protein binding in patients with chronic renal failure.

Uses and Administration

Alfentanil is a short-acting opioid analgesic (p.104) related to fentanyl (p.58).

Alfentanil is used in surgical procedures as an analgesic and adjunct to general anaesthetics or as a primary anaesthetic. It is also used as an analgesic and respiratory depressant in the management of mechanically ventilated patients under intensive care.

Alfentanil is given intravenously as the hydrochloride although doses are expressed in terms of the base. Alfentanil hydrochloride 108.8 micrograms is equivalent to about 100 micrograms of alfentanil. A peak effect may be seen within 1.5 to 2 minutes of an injection and analgesia can be expected to last for up to 10 minutes; dose supplements are therefore required if it is to be used for more prolonged surgical procedures. It may be given by continuous intravenous infusion in ventilated patients.

The dosage of alfentanil used depends on whether the patient has spontaneous respiration or assisted ventilation and on the expected duration of anaesthesia. Doses are adjusted according to the needs of the patient. Children may require higher or more frequent doses than adults, whereas the elderly or debilitated patients may require lower or less frequent doses. Obese patients may require doses based on their ideal (lean) body-weight.

When used as an adjunct in the **maintenance of general anaesthesia** the initial licensed dose in the UK is as follows:

- in patients with *spontaneous respiration*, up to 500 micrograms may be given slowly over about 30 seconds with supplementary doses of 250 micrograms
- *ventilated* patients may be given 30 to 50 micrograms/kg with supplements of 15 micrograms/kg. When given by infusion to ventilated patients there is an initial loading dose of 50 to 100 micrograms/kg given as a bolus or by infusion over 10 minutes, followed by infusion at a rate of 0.5 to 1 microgram/kg per minute

Typical doses that have been used in the USA are as follows:

- for *short surgical procedures of less than 1 hour* in patients with spontaneous respiration or assisted ventilation, the dose is 8 to 20 micrograms/kg; this may be followed by supplementary doses of 3 to 5 micrograms/kg every 5 to 20 minutes or an infusion of 0.5 to 1 microgram/kg per minute. Alternatively patients with assisted or controlled ventilation may be given an initial dose of 20 to 50 micrograms/kg, followed by supplementary doses of 5 to 15 micrograms/kg every 5 to 20 minutes
- in *general surgical procedures* in patients with assisted or controlled ventilation, an initial dose of 50 to 75 micrograms/kg may be followed by an infusion of 0.5 to 3 micrograms/kg per minute. If alfentanil has been given in anaesthetic doses (see below) for the induction of anaesthesia, infusion rates may need to be reduced by 30 to 50% during the first hour of maintenance

Maintenance infusions of alfentanil should be stopped 10 to 30 minutes before the anticipated end of surgery.

For details of doses in children, see below.

The dose for the **induction of anaesthesia** in patients with assisted ventilation undergoing procedures of at least 45 minutes is 130 to 245 micrograms/kg, followed by an inhalation anaesthetic or maintenance doses of alfentanil of 0.5 to 1.5 micrograms/kg per minute.

In the UK, *ventilated* patients in **intensive care** may be given alfentanil initially at an infusion rate of 2 mg/hour or a loading dose of 5 mg may be given in divided doses over 10 minutes or more slowly if hypotension or bradycardia occur. Thereafter a suitable rate of infusion should be determined for each patient (rates of 0.5 to 10 mg/hour have been used); patients should be carefully monitored and the duration of treatment should not generally exceed 4 days. During continuous infusion additional bolus injections of 0.5 to 1 mg may be given if required to provide analgesia for short painful procedures that may be carried out in intensive care.

Alfentanil is also used as an analgesic in patients with *spontaneous respiration* receiving monitored anaesthesia care; in the USA, an initial dose of 3 to 8 micrograms/kg may be followed by supplementary doses of 3 to 5 micrograms/kg every 5 to 20 minutes or an infusion of 0.25 to 1 microgram/kg per minute.

Administration. Alfentanil is usually given by intravenous injection or infusion, but has also been given intramuscularly,[1,2] intrathecally,[3] or epidurally (see Pain, below).

Administration in children. Alfentanil is licensed in the UK for use in ventilated children during surgical procedures as an analgesic and adjunct to general anaesthetics or as a primary anaesthetic. When used as an adjunct in the **maintenance of general anaesthesia** licensed product information states that ventilated children may be given the usual intravenous *injection* doses as for ventilated adults (see above). However, the *BNFC* suggests that neonates may be given 5 to 20 micrograms/kg initially and children aged from 1 month to 18 years, 10 to 20 micrograms/kg initially; supplementary doses of up to 10 micrograms/kg may be given. When given by *infusion* the *BNF* states that ventilated children may be given the usual doses as for ventilated adults (see above); the *BNFC* suggests that usual adult doses may be given to those aged as young as 1 month. The *BNFC* also suggests that neonates may be given an initial loading dose of 10 to 50 micrograms/kg over 10 minutes followed by infusion at a rate of 0.5 to 1 microgram/kg per minute.

Anaesthesia. Alfentanil, like fentanyl (p.59), appears to produce fewer circulatory changes than morphine and may be preferred for anaesthetic use, especially in cardiovascular surgery. It is generally considered to have a shorter duration of action than fentanyl. It has been used with propofol to facilitate intubation, and for total intravenous anaesthesia.

For a discussion of the drugs used to facilitate intubation and of opioids such as alfentanil used to control the pressor response and the rise of intra-ocular pressure associated with intubation, see Anaesthesia, p.1900. For reference to a study indicating that pretreatment with alfentanil can reduce the pain associated with injection of propofol, see p.1791.

CAESAREAN SECTION. UK licensed product information contra-indicates the use of alfentanil before clamping the cord during caesarean section because of the risk of respiratory depression in the neonate. A study of alfentanil 30 micrograms/kg in women undergoing caesarean section was abandoned after massive respiratory depression had occurred in 4 of 5 neonates.[1] Another study[2] in patients undergoing elective caesarean section found that although maternal haemodynamic responses to intubation were minimised when alfentanil 10 micrograms/kg was given intravenously immediately before induction, neonates in the alfentanil group had lower Apgar scores compared with those in the placebo group.

However, alfentanil has been used successfully to minimise haemodynamic responses to intubation and surgery in patients with severe cardiovascular disorders undergoing caesarean section.[3,4] A baby delivered after the successful use of alfentanil 35 micrograms/kg in a mother with severe aortic stenosis[3] was apnoeic and unresponsive with poor muscle tone; the baby responded rapidly to naloxone. Alfentanil 10 micrograms/kg immediately before induction attenuated the cardiovascular response to intubation in patients with severe pregnancy-induced hypertension[4] and was considered a suitable alternative to fentanyl 2.5 micrograms/kg; no effect on neonatal mortality could be attributed to anaesthetic technique. However, it has been suggested that the use of smaller doses of alfentanil of 7.5 micrograms/kg with magnesium sulfate 30 mg/kg may provide better cardiovascular control.[5]

PHAEOCHROMOCYTOMA. Alfentanil does not release histamine and was of value in the anaesthetic management of patients with phaeochromocytoma.[1] It has a very rapid onset of action, good vasodilating properties, and a relatively short elimination half-life. These patients are often very somnolent for the first 48 hours after surgery and postoperative opioid dosage requirements may be less than expected. Alfentanil infusion continued into the postoperative period allows careful titration of dosage.

Pain. ***POSTOPERATIVE ANALGESIA.*** Continuous on-demand epidural infusions of alfentanil 200 micrograms/hour or fentanyl 20 micrograms/hour provided comparable analgesia to morphine 200 micrograms/hour in the early postoperative period;[1] alfentanil (16 minutes) and fentanyl (13 minutes) had the advantage of more rapid onset of analgesia than morphine (44 minutes). However, some considered that there was no overall advantage of epidural over intravenous alfentanil either as patient-controlled analgesia[2] or by continuous infusion.[3]

Profile

Aminophenazone, a pyrazolone derivative, is an NSAID (p.96), but the risk of agranulocytosis is sufficiently great to render it unsuitable for systemic use. Onset of agranulocytosis may be sudden and unpredictable. Aminophenazone has been used as salts or complexes, including topically as the salicylate.

Precautions. CARCINOGENICITY. Some[1] consider that aminophenazone should be regarded as a potential carcinogen because it reacted readily with nitrous acid to form dimethylnitrosamine. The reaction was catalysed by thiocyanate present in the saliva particularly in smokers.

Adverse Effects and Precautions

Mild to moderate injection site reactions with symptoms of erythema, bruising, swelling, and pain are common with anakinra particularly in the first month of treatment. Other common reactions include headache, nausea, diarrhoea, and abdominal pain. Antibodies to anakinra may develop. Allergic reactions such as rashes have been reported rarely; if a severe allergic reaction occurs, anakinra should be stopped and appropriate treatment given.

Serious infections have been reported with anakinra, particularly in patients with asthma. These infections are mainly bacterial, such as cellulitis, pneumonia, and bone and joint infections. More rarely, opportunistic infections involving fungal, mycobacterial, and viral pathogens have also been seen. Anakinra should be stopped in those who develop a serious infection. In addition, therapy should not be started in patients with active infections, including chronic or localised infections; caution is recommended in those with a history of recurrent infections or with underlying conditions that may predispose to infections.

A small decrease in absolute neutrophil count (ANC) is commonly seen with anakinra treatment; however, true neutropenia

(ANC <1500 cells/mm^3) is rare. Licensed product information recommends that neutrophil counts should be taken before starting anakinra and periodically throughout treatment. UK licensed information recommends monthly monitoring during the first 6 months and then quarterly thereafter; US licensed information requires monthly monitoring for the first 3 months and then quarterly monitoring for a period of up to 1 year. Anakinra should not be started in patients with neutropenia. Small reductions in the total white blood cell and platelets counts and a small increase in eosinophils have also been noted. Anakinra is also associated with an increased incidence of lymphoma in patients with rheumatoid arthritis.

For caution in patients with renal impairment see under Uses and Administration, below.

Effects on the cardiovascular system. A 29-year-old woman with refractory adult-onset Still's disease developed shortness of breath, which progressed to cardiorespiratory failure, 3 months after being started on anakinra;[1] although resuscitation was tried, the patient died. The authors considered that the role of anakinra in this event was unclear, particularly as the patient had shown some evidence of myocardial or pulmonary dysfunction before starting the drug.

1. Ruiz PJ, *et al.* Cardiac death in a patient with adult-onset Still's disease treated with the interleukin 1 receptor inhibitor anakinra. *Ann Rheum Dis* 2007; **66:** 422–3.

Effects on the skin. Inflammatory lesions at injection sites were reported in 5 patients after anakinra use.[1] The lesions were erythematous, oedematous, painful, and itchy plaques, and were seen within 16 days of starting treatment. Treatment with anakinra was completely stopped in 1 patient and interrupted in 2 other patients; when reintroduced, one patient developed abdominal pain, dyspnoea, and facial and abdominal erythema with pruritus.

1. Vila AT, *et al.* Adverse cutaneous reactions to anakinra in patients with rheumatoid arthritis: clinicopathological study of five patients. *Br J Dermatol* 2005; **153:** 417–23.

Interactions

Live vaccines should not be given with anakinra as its effect on vaccine efficacy or the risk of infection transmission is unknown.

The risk of serious infection and neutropenia is increased when anakinra and etanercept are used together (see under Infliximab, p.71); a similar effect may occur with other TNF antagonists. The use of anakinra with etanercept or other TNF inhibitors is not recommended.

Pharmacokinetics

After subcutaneous doses, peak plasma concentrations of anakinra are reached in 3 to 7 hours. Its terminal half-life is about 4 to 6 hours. Anakinra is excreted mainly in the urine.

Uses and Administration

Anakinra is a recombinant receptor antagonist of interleukin-1 (p.2325), an inflammatory mediator found in the plasma and synovial fluid of patients with rheumatoid arthritis.

Anakinra is used for the treatment of the signs and symptoms of moderate to severely active rheumatoid arthritis in patients who have had an inadequate response to methotrexate or another disease-modifying antirheumatic drug (DMARD) alone (but see below). In the UK, it is only licensed for use with methotrexate; however, in the USA, it may be given either alone or with another DMARD, although not one that inhibits TNF (see Interactions, above). The usual dose in adults is 100 mg once daily by subcutaneous injection. The dose should be given at about the same time each day.

Anakinra has been tried in septic shock and graft-versus-host disease in transplant recipients, but results were disappointing.

Administration in renal impairment. Caution may be advisable if anakinra is used in patients with renal impairment. A study[1] in patients with varying degrees of renal function indicated that no dosage adjustment was needed for anakinra in patients with mild or moderate renal impairment but dosage on alternate days appeared advisable in those with severe renal impairment. US licensed product information also recommends alternate-day dosing in patients with severe impairment or end-stage disease (creatinine clearance less than 30 mL/minute). However, in the UK, licensed product information contra-indicates use in those with this degree of impairment.

Dialysis does not affect anakinra concentrations to any significant degree.

Familial Mediterranean fever. For mention of anakinra having been tried in familial Mediterranean fever, see p.557.

Rheumatoid arthritis. In the UK, anakinra is licensed for the treatment of rheumatoid arthritis (p.11) in patients with an inadequate response to methotrexate alone; however, NICE does not recommend its use except in the context of a controlled, long-term clinical study.

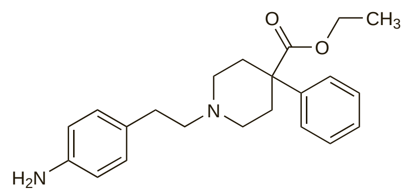
Anileridine *(BAN, rINN)*

Anileridiini; Anileridin; Anileridina; Aniléridine; Anileridinum. Ethyl 1-(4-aminophenethyl)-4-phenylpiperidine-4-carboxylate.

Анилеридин

$C_{22}H_{28}N_2O_2$ = 352.5.
CAS — 144-14-9.
ATC — N01AH05.
ATC Vet — QN01AH05.



Pharmacopoeias. In *US.*

USP 31 (Anileridine). A white to yellowish-white, odourless or practically odourless, crystalline powder. When exposed to light and air it oxidises and darkens in colour. It exhibits polymorphism, and of two crystalline forms observed, one melts at about 80° and the other at about 89°. Very slightly soluble in water; soluble 1 in 2 of alcohol and 1 in 1 of chloroform; soluble in ether but solutions may be turbid. Store in airtight containers. Protect from light.

Anileridine Hydrochloride *(BANM, rINNM)*

Aniléridine, Chlorhydrate d'; Anileridini Hydrochloridum; Hidrocloruro de anileridina.

Анилеридина Гидрохлорид

$C_{22}H_{28}N_2O_2,2HCl$ = 425.4.
CAS — 126-12-5.

Pharmacopoeias. In *US.*

USP 31 (Anileridine Hydrochloride). A white or nearly white odourless crystalline powder. Soluble 1 in 5 of water and 1 in 80 of alcohol; practically insoluble in chloroform and in ether. pH of a 5% solution in water is 2.5 to 3.0. Store in airtight containers. Protect from light.

Anileridine Phosphate *(BANM, rINNM)*

Aniléridine, Phosphate d'; Anileridini Phosphas; Fosfato de anileridina.

Анилеридина Фосфат

$C_{22}H_{28}N_2O_2,H_3PO_4$ = 450.5.
CAS — 4268-37-5.

Profile

Anileridine, a phenylpiperidine derivative, is an opioid analgesic (p.101) chemically related to pethidine (p.113) and with similar actions. It has been used as the hydrochloride in the management of moderate to severe pain. Anileridine has also been given by injection as the phosphate.

Preparations

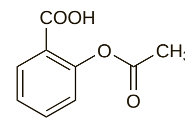
USP 31: Anileridine Hydrochloride Tablets; Anileridine Injection.

Aspirin *(BAN)*

Acetilsalicílico, ácido; Acetilsalicilo rūgštis; Acetilszalicilsav; Acetylsal. Acid; Acetylsalicylic Acid; Acetylsalicylsyra; Acide acétylsalicylique; Acidum acetylsalicylicum; Asetilsalisilik Asit; Asetyylisalisyylihappo; Kwas acetylosalicylowy; Kyselina acetylsalicylová; Polopiryna; Salicylic Acid Acetate. *O*-Acetylsalicylic acid; 2-Acetoxybenzoic acid.

Аспирин

$C_9H_8O_4$ = 180.2.
CAS — 50-78-2.
ATC — A01AD05; B01AC06; N02BA01.
ATC Vet — QA01AD05; QB01AC06; QN02BA01.



NOTE. The use of the name Aspirin is limited; in some countries it is a trade-mark.

Compounded preparations of aspirin may be represented by the following names:

- Co-codaprin (*BAN*)—aspirin 50 parts and codeine phosphate 1 part (w/w)
- Co-codaprin (*PEN*)—aspirin and codeine phosphate.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Acetylsalicylic Acid; Aspirin BP 2008). White or almost white, crystalline powder or colourless crystals. Slightly soluble in water; freely soluble in alcohol. Store in airtight containers.

USP 31 (Aspirin). White crystals, commonly tubular or needle-like, or white crystalline powder; odourless or has a faint odour. Is stable in dry air; in moist air it gradually hydrolyses to salicylic and acetic acids. Soluble 1 in 300 of water, 1 in 5 of alcohol, 1 in 17 of chloroform, and 1 in 10 to 15 of ether; sparingly soluble in absolute ether. Store in airtight containers.

Adverse Effects and Treatment

Aspirin has many properties in common with the non-aspirin NSAIDs, the adverse effects of which are described on p.96.

The most common adverse effects of therapeutic doses of aspirin are gastrointestinal disturbances such as nausea, dyspepsia, and vomiting. Gastrointestinal symptoms may be minimised by giving aspirin with food. Irritation of the gastric mucosa with erosion, ulceration, haematemesis, and melaena may occur. Histamine H_2-antagonists, proton pump inhibitors, and prostaglandin analogues such as misoprostol may be used in the management of NSAID-induced ulceration (see Peptic Ulcer Disease, p.1702), including that caused by aspirin. Slight blood loss, which is often asymptomatic, may occur in about 70% of patients; it is not usually of clinical significance but may, in a few patients, cause iron-deficiency anaemia during long-term therapy. Such occult blood loss is not affected by giving aspirin with food but may be reduced by use of enteric-coated or other modified-release tablets, H_2-antagonists, or high doses of antacids. Major upper gastrointestinal bleeding occurs rarely.

Some persons, especially those with asthma, chronic urticaria, or chronic rhinitis, exhibit notable hypersensitivity to aspirin (see also below), which may provoke reactions including urticaria and other skin eruptions, angioedema, rhinitis, and severe, even fatal, paroxysmal bronchospasm and dyspnoea. Persons sensitive to aspirin often exhibit cross-sensitivity to other NSAIDs.

Aspirin increases bleeding time, decreases platelet adhesiveness, and, in large doses, can cause hypoprothrombinaemia. It may cause other blood disorders, including thrombocytopenia.

Aspirin and other salicylates may cause hepatotoxicity, particularly in patients with juvenile idiopathic arthritis or other connective tissue disorders. In children the use of aspirin has been implicated in some cases of Reye's syndrome, leading to severe restrictions on the indications for aspirin therapy in children. For further details see under Reye's Syndrome, below.

Aspirin given rectally may cause local irritation; anorectal stenosis has been reported.

Mild chronic salicylate intoxication, or salicylism, usually occurs only after repeated use of large doses. Salicylism can also occur following excessive topical application of salicylates. Symptoms include dizziness, tinnitus, deafness, sweating, nausea and vomiting, headache, and confusion, and may be controlled by reducing the dosage. Tinnitus can occur at the plasma concentrations of 150 to 300 micrograms/mL required for optimal anti-inflammatory activity; more serious adverse effects occur at concentrations above 300 micrograms/mL. Symptoms of more severe intoxication or of acute poisoning following overdosage include hyperventilation, fever, restlessness, ketosis, and respiratory alkalosis and metabolic acidosis. Depression of the CNS may lead to coma; cardiovascular collapse and respiratory failure may also occur. In children drowsiness and metabolic acidosis commonly occur; hypoglycaemia may be severe.

In acute oral salicylate overdosage the UK National Poisons Information Service recommends that repeated oral doses of activated charcoal be given if the patient is suspected of ingesting more than 125 mg/kg of salicylate within 1 hour of presentation. Activated charcoal not only prevents the absorption of any salicylate remaining in the stomach but also aids the elimination of any that has been absorbed.

Measurement of plasma-salicylate concentration should be carried out in patients who have ingested more than 125 mg/kg of salicylate, although the severity of poisoning cannot be estimated from plasma concentrations alone. Absorption of aspirin can be delayed by reduced gastric emptying, formation of concretions in the stomach, or as a result of ingestion of enteric-coated preparations. In consequence, plasma concentrations should be measured at least 2 hours (symptomatic patients) or 4 hours (asymptomatic patients) after ingestion and repeated 2 hours later. Patients who overdose with enteric preparations require continual monitoring of plasma concentrations.

Fluid and electrolyte management is essential to correct acidosis, hyperpyrexia, hypokalaemia, and dehydration. Intravenous sodium bicarbonate is given to enhance urinary salicylate excretion if plasma salicylate concentrations exceed 500 micrograms/mL (350 micrograms/mL in children under 5 years). Haemodialysis or haemoperfusion are also effective methods of removing salicylate from the plasma. The *BNF* considers haemodialysis the method of choice in severe poisoning; it should be seriously considered when the plasma salicylate concentration is more than 700 micrograms/mL or if there is severe metabolic acidosis. Vulnerable patients such as children or the elderly may require dialysis at an earlier stage.

Effects on the blood. Although it has beneficial effects on platelets, aspirin can cause adverse blood effects. An indication of this toxicity is given by an early reference[1] to reports submitted to the UK CSM. There were 787 reports of adverse reactions to aspirin reported to the CSM between June 1964 and January 1973. These included 95 reports of blood disorders (17 fatal) including thrombocytopenia (26; 2 fatal), aplastic anaemia (13; 7 fatal), and agranulocytosis or pancytopenia (10; 2 fatal). Aspirin has also been associated with haemolytic anaemia in patients with G6PD deficiency.[2]

Effects on the cardiovascular system. Salicylate poisoning may result in cardiovascular collapse but details of such cases have not been widely reported. In 2 patients with salicylate intoxication asystole developed after intravenous diazepam.[1] It was suggested that diazepam-induced respiratory depression affected the acid–base balance so that the concentration of non-ionised membrane-penetrating fraction of salicylate was increased. Fatal aspirin intoxication in a 5-year-old child was marked by hypotension and rapidly progressive cardiac symptoms including ventricular tachycardia and AV block.[2] Extensive myocardial necrosis was found at autopsy.

Effects on the gastrointestinal tract. Clinical and epidemiological evidence suggests that aspirin produces dose-related gastrointestinal toxicity[1,2] that is sometimes, but rarely, fatal.[2] Meta-analysis[3] suggests that the risk of gastrointestinal bleeding is not significantly lowered with the use of oral low-dose aspirin (less than 300 mg daily). A systematic review[4] of observational epidemiologic studies also concurred with this finding. More recently, a systematic review[5] of randomised, controlled studies found that although low-dose aspirin (up to 325 mg daily) increased the risk of major bleeding including gastrointestinal bleeding by twofold when compared to placebo, the actual risk of bleeding was modest; for every 833 patients taking low-dose aspirin for cardiovascular prophylaxis only 1 additional major bleeding episode will occur annually. In another, population-based study,[6] the annual excess risk of upper gastrointestinal complications was about an extra 5 cases per 1000 patients; however, the excess risk varied with underlying gastrointestinal risk factors such as old age and might exceed an extra 10 cases per 1000 patients in a higher risk group comprising over 10% of aspirin users. It has been suggested that very small doses of aspirin can produce prophylactic benefits in cardiovascular disease without the risk of gastrointestinal toxicity,[7] although others have reported gastric injury even with doses of 10 mg daily.[8]

There appears to be no convincing evidence that the risk of major gastrointestinal bleeding associated with a 75-mg dose is reduced by using enteric-coated or modified-release formulations rather than soluble aspirin,[3,4,9] although individual studies have reported a reduction in acute mucosal injury with enteric coating.[10] All known NSAIDs have the potential for causing acute damage to the gastric mucosa (see p.97), and comparative studies of acute gastric mucosal damage caused by such drugs consistently associate aspirin with the most severe lesions.[1] Gastric mucosal injury can occur even with cutaneous application.[11]

Effects on hearing. Studies have shown that tinnitus develops at serum-salicylate concentrations above 200 micrograms/mL.[1] However, there appears to be considerable intersubject variation in the response of the ear to salicylate;[2] tinnitus may occur at lower concentrations, whereas patients with pre-existing hearing loss may not experience tinnitus despite serum-salicylate concentrations of 311 to 677 micrograms/mL.[1] A graded increase in intensity of ototoxicity with increasing salicylate dose and plasma concentration has been demonstrated.[2] For example, at an average total plasma-salicylate concentration of 110 micrograms/mL, the hearing loss at any given frequency was about 12 decibels; such a deficit might be relevant to patients with pre-existing hearing impairment.[2]

Effects on the kidneys. Although abuse of combined analgesic preparations containing aspirin has been implicated in the development of analgesic nephropathy, kidney damage associated with the therapeutic use of aspirin alone appears to be comparatively rare. Many studies have failed to find an increased risk of renal damage in patients taking aspirin.[1-9]

Effects on the liver. Aspirin-induced hepatic injury is generally mild and manifests as a mild to moderate elevation in aminotransferase values; however, there is a risk of severe liver injury.[1] One review[2] reported an increase in aminotransferase values in 59 of 439 patients given aspirin; the increase was considered to be probably related to aspirin in 23. Hepatotoxicity appears to be correlated with serum-salicylate concentrations greater than 150 micrograms/mL and with active rheumatoid disease. Aspirin-induced liver injury is usually reversible on stopping the drug.[2]

Hypersensitivity. The main clinical features of patients who have aspirin hypersensitivity include middle-age, female sex, diagnoses of asthma or rhinitis, a personal or family history of atopy, and a history of nasal polyps.[1,2] Aspirin sensitivity occurring with asthma and nasal polyps has been referred to in some reports as the 'aspirin triad'. Other sensitivities often found concomitantly include allergy to food dyes such as tartrazine and to drugs such as other NSAIDs.

The prevalence of aspirin-induced asthma can vary according to the method used to measure it. A systematic review[3] calculated the prevalence of aspirin-induced asthma to be 21% in the general adult asthma population and 5% in children when determined by oral provocation testing. However, when based on medical history alone it was only 2.7% in adults and 2% in children. In another study[4] using data from patient questionnaires the prevalence of aspirin-induced asthma was 10 to 11% in patients with asthma and 2.5% in non-asthmatics.

There is considerable cross-reactivity between aspirin and other NSAIDs and it is generally recommended that patients who have had a hypersensitivity reaction to aspirin or any other NSAID should avoid all NSAIDs. In a systematic review[3] cross-sensitivity to other NSAIDs (ibuprofen, diclofenac, and naproxen) occurred in over 90% of those patients with aspirin-induced asthma. Paracetamol is usually safe in patients sensitive to aspirin and cross-sensitivity to paracetamol has been calculated as about 7%.[3] Based on these figures, it is considered that less than 2% of asthmatic patients would be likely to react to both paracetamol and aspirin.

The response to individual NSAIDs is believed to be closely linked to the extent to which they inhibit prostaglandin synthesis.[5,6] There may be a dose threshold below which no detectable symptoms occur and patients who may be tolerant of regular low-dose aspirin can develop symptoms when they take larger doses.[6] Some[6] use a formal challenge with a 300-mg oral dose of aspirin to confirm a diagnosis of NSAID sensitivity but others[7] consider this to be a dangerous technique and use inhalation of lysine aspirin which they consider to be a safer and more predictable alternative. Intranasal challenge with lysine aspirin has also been used.[8,9]

DESENSITISATION. Successful desensitisation has been achieved using oral aspirin challenge protocols.[1-5] Incremental doses of aspirin (traditionally starting at 30 mg) are given until an allergic response occurs; aspirin is readministered at the dose that caused the response and again incremental doses are given until finally a 650-mg dose is tolerated.[1,2] After desensitisation, an interruption of continuous aspirin dosage results in the reappearance of sensitivity.

Hypoglycaemia. A review of the literature[1] on drug-induced hypoglycaemia highlighted the fact that overdosage with salicylates could produce hypoglycaemia in children. Although therapeutic doses of salicylates in adults can lower blood-glucose concentrations in diabetic and non-diabetic subjects alike, opinion on the clinical significance of this effect varies. Salicylates have been implicated in a few cases of hypoglycaemia in adults[1] and some[2] suggest that patients with renal impairment or those receiving large doses, such as in the treatment of rheumatoid arthritis, may be at risk. Hypoglycaemia has been reported in a patient with renal failure after excessive application of a topical preparation containing salicylic acid.[3]

Reye's syndrome. Reye's syndrome is a disorder characterised by acute encephalopathy and fatty degeneration of the liver. It occurs almost exclusively in young children although cases have been seen[1] in patients over the age of 12. Many factors may be involved in its aetiology but it typically occurs after a viral infection such as chickenpox or influenza and may be precipitated by a chemical trigger. Several large studies, as well as individual case reports, have found a link between Reye's syndrome and the prior ingestion of aspirin.[2-6] The evidence for other salicylates could not be adequately evaluated.[4] Although the role of aspirin and possibly other salicylates in the pathogenesis of Reye's syndrome remains to be determined, the use of aspirin and other acetylated salicylates as analgesics or antipyretics is generally considered contra-indicated in children under the age of 12 years and, in some countries, in teenagers. For example, the UK CSM has recommended that all children under 16 should not take aspirin.[7] (This advice superseded their earlier recommendations to avoid aspirin during fever or viral infection in children under 16 years; the Committee felt that this advice was too complex for products on general sale and, given the wide availability of other analgesic preparations, there was no need to expose this age group to any risk.) Some countries also extend these recommendations to non-acetylated salicylates. One group of workers[8] who re-examined some of the original studies suggested that there might also be a link between Reye's syndrome and the use of antiemetics, phenothiazines, and some other antihistamines, but their conclusions have been criticised.[9] More recently, others[10] have suggested that Reye's syndrome was caused by a viral mutation or the result of misdiagnoses of metabolic disorders but again these conclusions have been questioned.[6,11]

Precautions

Aspirin has many properties in common with the non-aspirin NSAIDs, the precautions of which are described on p.98.

Aspirin should be used cautiously, if at all, in patients prone to dyspepsia or known to have a lesion of the gastric mucosa. It should not be given to patients with haemophilia or other haemorrhagic disorders, nor to treat patients with gout (since low doses increase urate concentrations).

Aspirin should be used with caution in patients with asthma or allergic disorders. It should not be given to patients with a history of sensitivity reactions to aspirin or other NSAIDs, including those in whom attacks of asthma, angioedema, urticaria, or rhinitis have been precipitated by such drugs (for further details of risk factors see Hypersensitivity under Adverse Effects, above).

Caution is necessary when renal or hepatic function is impaired; aspirin should be avoided in severe renal or hepatic impairment. Aspirin should be used cautiously in dehydrated patients and in the presence of uncontrolled hypertension.

High doses may precipitate acute haemolytic anaemia in patients with G6PD deficiency. Aspirin may interfere with insulin and glucagon control in diabetics (see Hypoglycaemia under Adverse Effects, above).

The use of aspirin in children is extremely limited because of the risk of Reye's syndrome (see under Adverse Effects, above, and under Uses and Administration, below).

Although low-dose aspirin might be used in some pregnant patients, analgesic doses of aspirin should not be used at term as they may be associated with delayed onset and prolongation of labour and with maternal and neonatal bleeding. High doses may cause closure of fetal ductus arteriosus *in utero* and possibly persistent pulmonary hypertension in the newborn (but see Pregnancy, below); kernicterus may occur in jaundiced neonates.

Continuous prolonged use of aspirin should be avoided in the elderly because of the risk of gastrointestinal bleeding.

Aspirin should be stopped several days before scheduled surgical procedures (see below).

Aspirin and other salicylates can interfere with thyroid function tests.

Breast feeding. The American Academy of Pediatrics[1] considers that salicylates should be given with caution to breast-feeding mothers, since aspirin has been associated with metabolic acidosis in the infant.[2] The *BNF* also recommends that aspirin should be avoided in breast-feeding mothers because of the possible risk of Reye's syndrome in nursing infants; they also advise that infants with neonatal vitamin K deficiency may be at risk of hypoprothrombinaemia after the regular use of high doses of aspirin in breast-feeding mothers. However, a prospective study[3] found no adverse effects in 15 breast-fed infants whose mothers were receiving aspirin.

Pregnancy. The potential adverse effects of aspirin when used during pregnancy have been reviewed.[1] Salicylates readily cross the placenta and have been shown to be teratogenic in *animals*. Although some studies and anecdotal reports have implicated aspirin in the formation of congenital abnormalities, most large studies[2-4] have failed to find any significant risk or evidence of teratogenicity. Analysis of data collected by the Slone Epidemiology Unit Birth Defects Study suggests that use of aspirin during the early months of pregnancy, when the fetal heart is developing, is not associated with an increased risk of cardiac defects.[5] The ability of aspirin, however, to alter platelet function may be a potential risk. There have been a few reports of haemorrhagic disorders in infants whose mothers had consumed aspirin during pregnancy[6] and of salicylate-associated haemorrhagic complications in mothers.[7] However, no clinically significant adverse effects on maternal or neonatal bleeding or on fetal ductus flow were reported in a meta-analysis[8] of 6 controlled studies which evaluated low-dose aspirin (less than 325 mg daily) in pregnancy-induced hypertension. Two more recent placebo-controlled studies[9,10] have also observed no clinically significant adverse effects on neonatal bleeding with low-dose aspirin. It appeared that the degree of cyclo-oxygenase inhibition produced by aspirin was unlikely to be great enough to cause premature closure of the ductus arteriosus or to affect the pulmonary blood vessels.[1] See also under Surgical Procedures, below. However, in some studies in patients considered to have high-risk pregnancies the risk of abruptio placentae[11] or consequent perinatal death[12] was increased by maternal dosage with aspirin. For reference to a possible association between aspirin and other NSAIDs and persistent pulmonary hypertension of the newborn, see under NSAIDs, p.99.

Although aspirin has the potential to inhibit uterine contractions of labour it was considered that intermittent or low-dose aspirin was unlikely to inhibit cyclo-oxygenase for long enough to prolong pregnancy or labour.[1]

Resistance. Some patients given aspirin for the management of cardiovascular disease do not respond to treatment, a phenomenon that has been described as aspirin resistance. At present, aspirin resistance is poorly understood and further studies are needed to define it.

Surgical procedures. Aspirin prolongs bleeding time, mainly by inhibiting platelet aggregation. This effect is irreversible and new platelets must be released into the circulation before bleeding time can return to normal. Therefore aspirin therapy should be stopped several days before surgical procedures. In some clinical situations, aspirin may have been given shortly before a surgical procedure. When emergency coronary bypass surgery is required for myocardial infarction, most patients would have received aspirin as part of the initial treatment for infarction. Perioperative bleeding, transfusion requirements, and surgical re-exploration rates may be increased when aspirin is given.[1] However, some studies[2,3] have shown that the increase in bleeding is not significant; in addition, there have been reports that pre-operative aspirin may reduce the rate of perioperative myocardial infarction (with aprotinin),[4] improve oxygenation,[5] and even decrease mortality.[3,6] Desmopressin may reduce the risk of perioperative bleeding (see under Haemorrhagic Disorders, p.2187).

Aspirin is sometimes given during the second and third trimester for the prevention of pregnancy-induced hypertensive disease (see under Hypertension, p.1171). Studies indicate that when given in a dose of 325 mg daily or less, clinically significant effects on maternal or neonatal bleeding do not occur.[7] Some have suggested that aspirin therapy may increase the risk of formation of extradural haematoma thus making epidural anaesthesia inadvisable[8] but a subsequent study[9] found that low-dose aspirin during pregnancy did not increase the risk of bleeding complications during epidural anaesthesia.

Patients on low-dose aspirin, in whom tourniquets are used for nerve blocks or other procedures, may be at increased risk of developing purpuric rash.[10]

It has been suggested that in patients undergoing dermatological,[11] or minor dental[12] surgery, aspirin need only be stopped before surgery in those patients with a prolonged bleeding time, whereas patients with a normal bleeding time could continue therapy.

Interactions

Aspirin has many properties in common with the non-aspirin NSAIDs, the interactions of which are described on p.99.

Some of the effects of aspirin on the gastrointestinal tract are enhanced by alcohol. Use of gold compounds with aspirin may exacerbate aspirin-induced liver damage.

Use of aspirin with dipyridamole may result in an increase in plasma-salicylate concentrations. Drugs such as metoclopramide in patients with migraine headache result in earlier absorption of aspirin and higher peak plasma-salicylate concentrations. Metoprolol may also increase peak plasma-salicylate concentrations. Salicylate intoxication has occurred in patients on high-dose salicylate regimens and carbonic anhydrase inhibitors.

Plasma-salicylate concentrations may be reduced by corticosteroids. This interaction is likely to be important in patients receiving high-dose long-term salicylate treatment. Conversely, salicylate toxicity may occur if corticosteroids are withdrawn. Also the risk of gastrointestinal bleeding and ulceration associated with aspirin is increased when used with corticosteroids. Antacids may increase the excretion of aspirin in alkaline urine.

Aspirin may increase the activity of coumarin anticoagulants, sulfonylurea hypoglycaemic drugs, zafirlukast, methotrexate, phenytoin, and valproate. Aspirin diminishes the effects of uricosurics such as probenecid and sulfinpyrazone. The manufacturer of mifepristone advises of a theoretical risk that prostaglandin synthetase inhibition by aspirin or NSAIDs may alter the efficacy of mifepristone.

Use of aspirin with other NSAIDs should be avoided because of the increased risk of adverse effects; the cardioprotective effects of aspirin may be abolished by ibuprofen and possibly other NSAIDS. Aspirin may decrease the plasma concentration of some other NSAIDs, for example, fenbufen, indometacin, and piroxicam.

General anaesthetics. For the effect of aspirin on *thiopental* anaesthesia, see p.1796.

NSAIDs. It has been suggested that *ibuprofen* and possibly other *NSAIDs* may reduce the cardioprotective effect of aspirin. A study[1] involving 7107 patients found that cardiovascular mortality was increased in patients taking low-dose aspirin for cardiovascular disease when also taking ibuprofen (adjusted hazard ratio 1.73 times that of patients not taking ibuprofen). Another study[2] found that although taking low-dose aspirin or NSAIDs alone decreased the incidence of myocardial infarction, there was a non-significant increase in the risk of myocardial infarction when both were taken. Another large study also found the risk to be increased in those taking regular rather than intermittent NSAID treatment with aspirin.[3] However, a study[4] involving 14 098 patients concluded that the risk of myocardial infarction was reduced in patients taking ibuprofen with aspirin when compared to those taking aspirin alone. Furthermore, a study[5] in 70 316 patients found that the risk of death in patients prescribed aspirin and ibuprofen was comparable to that of patients prescribed aspirin alone or with another NSAID.

The timing of doses may be important; a study[6] has shown that irreversible platelet aggregation occurred when a single daily dose of ibuprofen was given 2 hours after aspirin; however, when ibuprofen was given before aspirin as a single daily dose or given three times daily, platelet aggregation was reversible which may limit the cardioprotective effects of aspirin.

There are limitations to all these studies and further studies are needed before any recommendations can be made.[7-11]

Pharmacokinetics

Aspirin and other salicylates are absorbed rapidly from the gastrointestinal tract when taken orally but absorption after rectal doses is less reliable. Aspirin and other salicylates can also be absorbed through the skin.

After oral doses, absorption of non-ionised aspirin occurs in the stomach and intestine. Some aspirin is hydrolysed to salicylate in the gut wall. Once absorbed, aspirin is rapidly converted to salicylate, but during the first 20 minutes after an oral dose aspirin is the main form of the drug in the plasma. Aspirin is 80 to 90% bound to plasma proteins and is widely distributed; its volume of distribution is reported to be 170 mL/kg in adults. As plasma-drug concentrations increase, the binding sites on the proteins become saturated and the volume of distribution increases. Both aspirin and salicylate have pharmacological activity although only aspirin has an anti-platelet effect. Salicylate is extensively bound to plasma proteins and is rapidly distributed to all body parts. Salicylate appears in breast milk and crosses the placenta.

Salicylate is mainly eliminated by hepatic metabolism; the metabolites include salicyluric acid, salicyl phenolic glucuronide, salicylic acyl glucuronide, gentisic acid, and gentisuric acid. The formation of the major metabolites, salicyluric acid and salicyl phenolic glucuronide, is easily saturated and follows Michaelis-Menten kinetics; the other metabolic routes are first-order processes. As a result, steady-state plasma-salicylate concentrations increase disproportionately with dose. After a 325-mg aspirin dose, elimination is a first-order process and the plasma-salicylate half-life is about 2 to 3 hours; at high aspirin doses, the half-life increases to 15 to 30 hours. Salicylate is also excreted unchanged in the urine; the amount excreted by this route increases with increasing dose and also depends on urinary pH, about 30% of a dose being excreted in alkaline urine compared with 2% of a dose in acidic urine. Renal excretion involves glomerular filtration, active renal tubular secretion, and passive tubular reabsorption.

Salicylate is removed by haemodialysis.

Uses and Administration

Aspirin is a salicylate NSAID and has many properties in common with non-aspirin NSAIDs (p.99). Aspirin and other salicylates have analgesic, anti-inflammatory, and antipyretic properties; they act as inhibitors of the enzyme cyclo-oxygenase, which results in the direct inhibition of the biosynthesis of prostaglandins and thromboxanes from arachidonic acid (see p.2374). Aspirin also inhibits platelet aggregation; non-acetylated salicylates do not.

Aspirin is used for the relief of mild to moderate pain such as headache, dysmenorrhoea, myalgias, and dental pain. It has also been used in the management of pain and inflammation in acute and chronic rheumatic disorders such as rheumatoid arthritis, juvenile idiopathic arthritis, osteoarthritis, and ankylosing spondylitis. In the treatment of minor febrile conditions, such as colds or influenza, aspirin can reduce temperature and relieve headache and joint and muscle pains.

Aspirin is also used for its antiplatelet activity in the initial treatment of cardiovascular disorders such as angina pectoris and myocardial infarction and for the prevention of cardiovascular events in patients at risk. Other such uses include the treatment and prevention of cerebrovascular disorders such as stroke. For further details see under Antiplatelet Therapy, below.

Aspirin is usually taken by mouth. Gastric irritation may be reduced by taking doses after food. Various dosage forms are available including plain uncoated tablets, buffered tablets, dispersible tablets, enteric-coated tablets, and modified-release tablets. In some instances aspirin may be given rectally by suppository.

The usual oral dose of aspirin as an analgesic and antipyretic is 300 to 900 mg, repeated every 4 to 6 hours according to clinical needs, to a maximum of 4 g daily. The dose as suppositories is 450 to 900 mg every 4 hours to a maximum of 3.6 g daily.

Plasma-salicylate concentrations of 150 to 300 micrograms/mL are required for optimal anti-inflammatory activity (but see also Adverse Effects, above). Doses need to be adjusted individually to achieve optimum concentrations. Generally doses of about 4 to 8 g daily in divided doses are used for acute rheumatic disorders such as rheumatoid arthritis or osteoarthritis. Doses of up to 5.4 g daily in divided doses may be sufficient in chronic conditions.

Indications for aspirin therapy in children are extremely limited because of the risk of Reye's syndrome (see under Adverse Effects, above), but include Kawasaki disease (see below), and juvenile idiopathic arthritis and Still's disease (see Rheumatic Disorders, below).

Sodium aspirin has also been used for the treatment of pain and fever.

Administration in children. Indications for aspirin therapy in children are extremely limited because of the risk of Reye's syndrome (see under Adverse Effects, above). For further information, including some doses, see Antiplatelet Therapy, Kawasaki Disease, and Rheumatic Disorders, below.

Antiplatelet therapy. Aspirin is an inhibitor of the enzyme cyclo-oxygenase, the **action** being considered to be due to an irreversible acetylation process.

- In blood platelets such enzyme inhibition prevents the synthesis of thromboxane A_2, a compound which is a vasoconstrictor, causes platelet aggregation, and is thus potentially thrombotic.
- In blood vessel walls the enzyme inhibition prevents the synthesis of prostacyclin, which is a vasodilator, has anti-aggregating properties, and is thus potentially anti-thrombotic.

Aspirin therefore appears to have paradoxical biological effects. The duration of these effects, however, may differ, with the *effects on the vascular tissue generally being shorter than the effects on the platelets* (although the *animal* species studied, the type of blood vessel used, and the prevailing experimental conditions may alter the results). The difference may be explained by the fact that vascular cells regain the ability to regenerate prostacyclin in a few hours but platelets are unable to re-synthesise cyclo-oxygenase, which results in no new thromboxane A_2 being produced for about 24 hours until more platelets are released by the bone marrow; as platelet activity in bone marrow may also be affected by aspirin it is generally considered that aspirin only needs to be given once daily for inhibition of platelet aggregation to occur. The inhibitory effect on thromboxane is rapid and unrelated to serum concentrations of aspirin, probably because of the inactivation of cyclo-oxygenase in platelets in the presystemic circulation. Since the effect is unrelated to systemic bioavailability, modified-release and dermal delivery preparations which do not achieve high systemic concentrations of aspirin are being developed to limit extraplatelet effects of aspirin. Inhibition is cumulative on repeated dosage, and it has been estimated that a daily dose of 20 to 50 mg will result in virtually complete suppression of platelet thromboxane synthesis within a few days. Large doses of 150 to 300 mg can produce maximum suppression almost instantaneously.

Uses. Aspirin's antiplatelet activity has led to its use for the treatment or prevention of a variety of disorders.[1-6]

- It is used as part of the initial **treatment** of unstable *angina* (p.1157) and is given in the early treatment of *myocardial infarction* (p.1175); it is also of benefit in the initial treatment of acute *ischaemic stroke* (p.1185).
- Aspirin is used for its combination of anti-inflammatory, antipyretic, and antiplatelet activity in the treatment of *Kawasaki disease* (see below). It is also used to treat thrombotic symptoms associated with *antiphospholipid syndrome*, such as occurs in patients with SLE (p.1513), and has been recommended for prophylactic use in pregnant patients with antiphospholipid antibodies who are at risk of fetal loss. The thrombolytic action of aspirin has also led to its use in thrombotic thrombocytopenic purpura (see Thrombotic Microangiopathies, p.1076). Aspirin has been tried in *pregnancy-induced hypertension* (see under Hypertension, p.1171) for the prevention of pre-eclampsia and intra-uterine growth retardation and may provide a small to moderate benefit in some women.
- It is of value for the **prevention** of cardiovascular events in patients at high risk, including those with stable or unstable angina, current or previous myocardial infarction, ischaemic stroke, or transient ischaemic attack (see Cardiovascular Risk Reduction, p.1164). It has also been used in the long-term management of atrial fibrillation (see under Cardiac Arrhythmias, p.1160) for the prevention of stroke in patients with contra-indications to warfarin or if there are no other risk factors for stroke.
- The value of aspirin for **primary prevention** of cardiovascular events, particularly *myocardial infarction* and *stroke* depends upon the accurate estimation of overall cardiovascular risk but is probably not justified in healthy individuals.[7-9]

  Although aspirin may prevent *venous thromboembolism* (p.1189) after surgery, other treatments have been preferred. However, it is recommended for use in preventing thrombotic complications associated with procedures such as angioplasty and coronary bypass grafting (see under Reperfusion and Revascularisation Procedures, p.1181). Aspirin is often given as an adjunct to patients with *peripheral arterial thromboembolism* (p.1178) to prevent propagation of the clot and also to prevent postoperative complications. It may have some effect in delaying disease progression and reducing vascular events in patients with *peripheral arterial disease* (p.1178) but an analysis[10] concluded that there was insufficient evidence to support its prophylactic use in patients with intermittent claudication but no additional cardiovascular risk factors.

  The benefit of aspirin for the primary prevention of cardiovascular events in patients with *diabetes mellitus* (see under Diabetic Complications, p.433) and who have no other cardiovascular risk factors remains to be determined.[8] Use is recommended in all those at increased risk, which includes (in the USA) all diabetics over 40 years of age,[11] or those aged 50 and over or with existing atherosclerosis or hypertension or a history of diabetes for over 10 years (in the UK).[12]

  The value of adding aspirin to anticoagulants for the prophylaxis of thromboembolism in patients with *prosthetic heart valves* (see p.1187) is also still to be firmly established. It is usually recommended as an adjunct in patients with other risk factors. Aspirin alone may be considered in patients with bioprosthetic valves who do not require anticoagulation.

Several pharmacological studies have attempted to find a **dose** of aspirin that would inhibit synthesis of platelet thromboxane A_2 while sparing the effect on prostacyclin production[13-15] but it has been pointed out[3] that in patients with vascular disease accompanying or caused by endothelial dysfunction, such as in atherosclerosis, a selective sparing of vascular prostacyclin production may not be obtained at any effective antiplatelet dose. However, the clinical relevance of inhibiting the synthesis of prostacyclin may have been exaggerated.[16] Experimental evidence indicates that aspirin is thrombogenic only at extremely high doses (200 mg/kg), far exceeding the minimum dose required to inhibit prostacyclin production. Also aspirin is clinically effective as an antithrombotic drug at doses that inhibit the synthesis of prostacyclin. Further support for the lack of importance of inhibition of prostacyclin synthesis comes from epidemiological studies in patients with arthritis given large doses of aspirin and patients with congenital cyclo-oxygenase deficiency; neither of these groups of patients have experienced an excess of thrombotic episodes.

In a meta-analysis conducted by the Antithrombotic Trialists' Collaboration[8] daily doses of 75 to 325 mg appeared to be equally effective for their antiplatelet effect; doses greater than 500 mg did not appear to be superior and caused more gastrointestinal adverse effects. Whether doses less than 75 mg offer the same efficacy with reduced gastrointestinal toxicity remains to be determined (see Effects on the Gastrointestinal Tract, above). The meta-analysis concluded that for the long-term prevention of serious vascular events in high-risk patients, a daily dose of aspirin in the range of 75 to 150 mg should be effective; if an immediate effect is required as in the initial treatment of acute myocardial infarction, acute ischaemic stroke, or unstable angina, a loading dose of 150 to 300 mg may be given. Other analyses[10,17] have made similar dose recommendations. However, another review[18] has suggested that doses as low as 75 or 80 mg daily may be inadequate for the primary prevention of stroke and myocardial infarction; it was considered that the most appropriate dose of aspirin for primary prevention was 160 mg daily. Aspirin should be chewed or dispersed in water; chewing a tablet of aspirin ensures that some buccal absorption occurs.

The use of aspirin in **children** is limited because of the risk of Reye's syndrome (see under Adverse Effects, above); however, it may be specifically indicated in those at risk of clot formation after cardiac surgery or for the prophylaxis of stroke in high-risk children. The *BNFC* has suggested oral doses of 1 to 5 mg/kg (up to a usual maximum of 75 mg) once daily in neonates and children up to 12 years of age; older children may be given 75 mg daily.

Behçet's syndrome. For reference to the use of aspirin in the management of vasculitic symptoms of Behçet's syndrome, see p.1499.

Cataract. Evidence to support or disprove the hypothesis that aspirin has a protective effect against cataract formation is considered inconclusive. A study in the US in over 22 000 males concluded that low-dose aspirin (325 mg on alternate days) for 5 years was unlikely to have a major effect on cataract formation but that a slightly decreased risk for cataract extraction could not be excluded.[1] In a later study[2] in the UK ophthalmic examination of over 1800 patients who were receiving 300 mg to 1.2 g of aspirin daily for transient ischaemic attacks failed to confirm any protective effect. Re-analysis[3] of the results of the original US study identified additional cases of cataract formation or extraction although these cases did not affect the overall conclusions of the original study. However, when the study patients were followed up over 15 years, observational data[4] suggested that the use of low-dose aspirin may, in fact, increase the risk of cataract development. It was considered that further trials were needed to establish the role of long-term aspirin in cataract prevention.

Dysmenorrhoea. Drugs such as aspirin and other NSAIDs that inhibit prostaglandin production through inhibition of cyclo-oxygenase are effective drugs in the treatment of dysmenorrhoea (p.6).

Fever. Methods for controlling fever (see p.10) include the use of antipyretics and/or physical cooling methods (although the value of the latter is questionable). Paracetamol, salicylates such as aspirin, and some other NSAIDs are the main antipyretics used. However, salicylates are generally contra-indicated for the management of fever in children because of the possible link between their use and the development of Reye's syndrome (see under Adverse Effects, above).

Headache. Aspirin is often used for the symptomatic treatment of various types of headache including migraine (see p.616) and tension-type headache (see p.617). Aspirin given at the onset of symptoms can successfully treat an acute attack of migraine. However, absorption may be poor due to gastric stasis which is commonly present in migraine. For this reason dispersible and effervescent preparations and compound preparations containing drugs such as metoclopramide which relieve gastric stasis have been advocated.

Kawasaki disease. Aspirin has been given in regimens with normal immunoglobulins to children with Kawasaki disease (p.2228) because of its anti-inflammatory, antipyretic, and antiplatelet activity.[1-4]

The usual practice is to use an anti-inflammatory regimen until the fever has settled and then convert to an antithrombotic regimen. The *BNFC* recommends an oral dose of 30 to 50 mg/kg daily in 4 divided doses in children aged 1 month and over (neonates may be given 32 mg/kg daily in 4 divided doses); this should be continued until the patient is afebrile or for the first 14 days after the onset of symptoms. Once fever and signs of inflammatory disease resolve, the aspirin dose is reduced to 2 to 5 mg/kg daily (neonates may be given 5 mg/kg daily) as a single dose for its antiplatelet effect. Aspirin may be stopped 6 to 8 weeks after the onset of illness but is usually continued for at least one year if coronary abnormalities are present and is continued indefinitely if coronary aneurysms persist. Similar regimens[3,4] are used in the USA although the initial dose of aspirin is more usually 80 to 100 mg/kg daily.

Despite this widespread use the optimum dose and duration of treatment have not been clearly established, and the value of aspirin in the initial management of Kawasaki disease has been questioned. In a meta-analysis[5] fever duration was significantly shorter in those on high-dose aspirin; however, other studies[6] have not shown such a benefit. Meta-analyses[5,7] have also shown that the incidence of coronary artery abnormalities is not significantly different for regimens using high (over 80 mg/kg daily) or low doses of aspirin. Furthermore, a retrospective study[8] suggested that aspirin use (irrespective of dose) in the acute phase of the disease may be unnecessary as its addition to immunoglobulin treatment had no effect on the rate of coronary artery abnormalities. A more recent review[9] found that evidence from comparative studies failed to show that aspirin reduced the rate of coronary artery abnormalities; a lack of good quality randomised controlled trials prevented any recommendations on the use of aspirin in the treatment of Kawasaki disease.

Leg ulcers. A 4-month placebo-controlled study[1] in 20 patients suggested that aspirin 300 mg daily aided healing of chronic venous leg ulcers; the mechanism of action was unclear.[2] However, the validity of the findings has been challenged.[3] The management of leg ulcers is discussed on p.1585.

Malignant neoplasms. For references to studies suggesting that regular use of aspirin and other NSAIDs may reduce the risk of developing malignant neoplasms of the gastrointestinal tract, see under NSAIDs, p.100.

Myeloproliferative disorders. Aspirin in low doses may be used to provide symptomatic relief for erythromelalgia (burning pain and erythema of the hands and feet) in patients with polycythaemia vera (p.654) and primary thrombocythaemia (p.654).

Pain. Aspirin, along with other NSAIDs and paracetamol, may be used for treating mild or moderate pain (see Choice of Analgesic, p.2) and is also used in moderate or severe pain to potentiate the effects of opioids. It is suitable for use in acute or chronic pain. Aspirin should not be used for pain relief in children because of its association with Reye's syndrome (see under Adverse Effects, above).

Dependence and tolerance are not a problem with non-opioid analgesics such as aspirin, but there is a ceiling of efficacy, above which increasing the dose has no further therapeutic effect.

Rheumatic disorders. Aspirin was once widely used in the treatment of rheumatoid arthritis (p.11) but has been superseded by better tolerated NSAIDs; however, juvenile idiopathic arthritis including Still's disease (p.10) are among the limited number of indications for aspirin use in children. The *American Hospital Service Formulary* suggests that children weighing 25 kg or less may be given an initial oral dose of 60 to 130 mg/kg daily in divided doses; heavier children should be started on 2.4 to 3.6 g daily. The usual maintenance dose is 80 to 100 mg/kg daily although up to 130 mg/kg daily may be required in some children; however, because of the risk of toxicity, it is recommended that children weighing over 25 kg should not receive doses of 100 mg/kg daily or above.

Adverse Effects and Treatment

The most common adverse effects of auranofin involve the gastrointestinal tract and include nausea, abdominal pain, and sometimes vomiting, but most often diarrhoea, which can affect up to 50% of patients and may be severe enough to cause patients to withdraw from treatment. Other adverse effects are similar to those experienced with sodium aurothiomalate (p.122), although they appear to be less troublesome since fewer patients stop treatment with auranofin than with injectable gold. As with other gold salts, treatment of adverse effects is generally symptomatic (see p.123). Modifying the diet to increase bulk, use of a bulking agent such as bran, or a temporary reduction in auranofin dosage, may help the diarrhoea (but see Effects on the Gastrointestinal Tract, below).

Effects on the gastrointestinal tract. Diarrhoea and abdominal pain are common with auranofin. The mechanism of gastrointestinal toxicity has not been established but may be associated with a reversible defect in intestinal permeability.[1] Although some have suggested that diarrhoea may occur in up to 50% of patients taking auranofin, a study in 269 patients given the drug for rheumatoid arthritis found that only about 15% experienced loose and watery stools over a six-month period.[2] Although bulking agents have been recommended in the management of auranofin-induced diarrhoea, no overall difference in incidence was seen between patients given prophylactic psyllium and those given placebo; however, patients given psyllium had slightly fewer days with loose and watery stools.

Gold-induced colitis has also been reported in patients taking auranofin.[3,4]

Effects on the kidneys. In a retrospective review[1] of 1283 patients who had received auranofin for treatment of rheumatoid arthritis 41 (3.2%) were found to have developed proteinuria. In most cases proteinuria was treated by stopping auranofin therapy. Long-term follow-up of 36 patients indicated that proteinuria had resolved in 31 within 2 years and in 29 within 1 year. Seven of 8 patients later rechallenged with auranofin had no relapses. In a further review of 2 comparative double-blind studies using gold compounds in the treatment of rheumatoid arthritis, proteinuria was found to have developed in 27% (23 of 85) of patients treated with sodium aurothiomalate, in 17% (42 of 247) of those treated with auranofin, and in 17% (36 of 210) of those receiving placebo. All patients were receiving NSAIDs.

Precautions

As for Sodium Aurothiomalate, p.123. Urine and blood tests should be carried out before starting auranofin and monthly thereafter; licensed product information advises that auranofin should be withdrawn if the platelet count falls below 100 000 cells/mm^3 or if signs and symptoms suggestive of thrombocytopenia, leucopenia or aplastic anaemia occur. US licensed product information states that baseline renal and liver function levels should also be established before starting auranofin therapy. Auranofin should be used with caution in patients with inflammatory bowel disease.

Porphyria. Auranofin has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Sodium Aurothiomalate, p.123.

Pharmacokinetics

Auranofin is incompletely absorbed from the gastrointestinal tract, only about 25% of the gold being absorbed. Gold from auranofin is bound to plasma proteins as well as to red blood cells. After 2 to 3 months of treatment the steady-state concentration of gold in the blood is reported to be about 0.7 micrograms/mL. The average terminal plasma half-life of gold at steady state is about 26 days while the biological half-life is 80 days. Tissue retention and total gold accumulation in the body are less than with intramuscular gold. Gold from auranofin penetrates into synovial fluid.

Most of a dose of auranofin appears in the faeces due to its poor absorption. About 60% of the absorbed gold from auranofin is excreted in the urine and the remainder in the faeces.

Uses and Administration

Auranofin is a gold compound with a gold content of about 29%; it has similar actions and uses to those of sodium aurothiomalate (p.123). It is given orally in active progressive rheumatoid arthritis (below); such oral treatment is less toxic than intramuscular gold but is also much less effective. The usual initial dose of auranofin is 6 mg daily given in two divided doses at first, then, if tolerated, as a single dose. Treatment should be continued for at least 6 months to assess the response; the dose may be increased after 6 months, if the response is inadequate, to 3 mg three times daily. If the response is still inadequate after 3 months at this dosage, then treatment should be stopped.

Asthma. A systematic review[1] found that oral or parenteral gold compounds reduced corticosteroid requirements in the management of asthma (p.1108); however, it was considered that the effect was probably of limited clinical significance and, given the adverse effects and monitoring requirements of gold compounds, their use in asthma could not be recommended.

Lupus. Since the introduction of less toxic drugs gold compounds are now rarely used in the treatment of SLE, however, there have been anecdotal reports suggesting that auranofin may still be of use in patients with discoid lupus erythematosus[1] or cutaneous lupus erythematosus[2] refractory to conventional treatment.

Psoriasis. Although topical auranofin has been shown in a placebo-controlled study[1] to be effective in the treatment of plaque-type psoriasis (p.1583) the high incidence of adverse skin reactions, such as contact dermatitis, was thought to outweigh any benefit.

1. Helm KF, *et al.* Topical auranofin ointment for the treatment of plaque psoriasis. *J Am Acad Dermatol* 1995; **33:** 517–19.

Rheumatic disorders. Gold compounds are among the disease-modifying antirheumatic drugs (DMARDs) that may be used in the treatment of rheumatoid arthritis (p.11). Oral gold is less toxic than intramuscular gold but is also much less effective. Gold compounds may also be of benefit in psoriatic arthritis (see under Spondyloarthropathies, p.13) and have been used in juvenile idiopathic arthritis (p.10).

Pharmacokinetics

As for Sodium Aurothiomalate, p.123; absorption is slower and more irregular.

Uses and Administration

Aurothioglucose is a gold compound with a gold content of about 50%; it has similar actions and uses to those of sodium aurothiomalate (p.123). It is used in the treatment of active rheumatoid arthritis (p.11) and juvenile idiopathic arthritis (p.10). Aurothioglucose is given intramuscularly as a suspension in oil in an initial weekly dose of 10 mg increasing gradually to up to 50 mg weekly. Therapy is continued at weekly intervals until a total dose of 0.8 to 1 g has been given; if improvement has occurred with no signs of toxicity 50 mg may then be given at intervals of 3 to 4 weeks. Children aged 6 to 12 years have been given one-quarter the adult dose, to a maximum of 25 mg per dose.

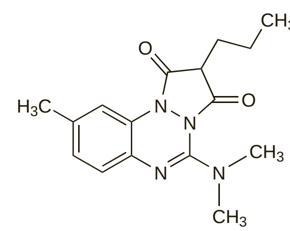
Азапропазон

$C_{16}H_{20}N_4O_2$ = 300.4.

CAS — 13539-59-8.

ATC — M01AX04.

ATC Vet — QM01AX04.



Pharmacopoeias. *Br.* includes the dihydrate.

BP 2008 (Azapropazone). The dihydrate is a white to pale yellow crystalline powder. Very slightly soluble in water and in chloroform; soluble in alcohol; dissolves in solutions of alkali hydroxides.

Profile

Azapropazone is an NSAID (see p.96), structurally related to phenylbutazone (p.117). It also has uricosuric properties. Because azapropazone appears to be associated with a higher incidence of adverse effects than with some other NSAIDs, its use has been restricted to the treatment of rheumatoid arthritis, ankylosing spondylitis, and acute gout in patients for whom other NSAIDs have been ineffective.

Azapropazone is used as the dihydrate and doses are expressed in terms of this hydrated form. For the treatment of rheumatoid arthritis or ankylosing spondylitis the usual oral dose was up to 1.2 g daily in 2 divided doses. Patients *over 60 years of age* have been given 300 mg twice daily. Reduced doses were also recommended in patients with renal impairment, see below.

Administration in renal impairment. In the treatment of *rheumatoid arthritis* or *ankylosing spondylitis* in patients with reduced renal function the usual dose was reduced according to creatinine clearance (CC) as follows:

- CC 50 to 75 mL/minute: reduce usual dose (see above) by one-third to one-half
- CC less than 50 mL/minute: reduce usual dose by one-half to two-thirds

Breast feeding. Small quantities of azapropazone are excreted into breast milk.[1] However, the American Academy of Pediatrics[2] states that there have been no reports of any clinical effect on the infant associated with the use of azapropazone by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding.

Effects on the blood. Auto-immune haemolytic anaemia, occasionally fatal, often with pulmonary infiltration, allergic alveolitis, pulmonary fibrosis, or fibrosing alveolitis, has been reported in patients receiving azapropazone.[1-3]

Effects on the gastrointestinal tract. In a review[1] of the relative safety of 7 oral NSAIDs, the UK CSM commented that azapropazone was associated with the highest risk of gastrointestinal reactions in both epidemiological studies and an analysis of spontaneous reporting of adverse reactions. Although it appeared that some patients over 60 years of age had received doses exceeding those recommended for this age group, it was considered that even when this was taken into account a marked difference remained between gastrointestinal reactions for azapropazone compared with other NSAIDs.

The CSM recommended that azapropazone should be restricted to use in rheumatoid arthritis, ankylosing spondylitis, and acute gout and only when other NSAIDs have been ineffective. Its use in patients with a history of peptic ulceration was contra-indicated. It was also recommended that when used in patients over 60 years of age for rheumatoid arthritis or ankylosing spondylitis the dose should be restricted to a maximum of 600 mg daily.

Azapropazone has been withdrawn in many countries including the UK.

Effects on the skin. Of 917 reports of adverse reactions associated with azapropazone forwarded to the WHO Collaborating Centre for International Drug Monitoring[1] before September 1984, 190 (21%) were of photosensitivity. Of 154 reports of photosensitivity evaluated a causal relationship to use of azapropazone was considered certain in 6, probable in 138, and possible in 10. In May 1994 the UK CSM stated[2] that since 1976 they had received 464 reports of photosensitivity reactions associated with azapropazone and commented that, when corrected for prescription volume, reporting of this reaction was 50 times greater than with other commonly prescribed NSAIDs. They recommended that patients should be advised to avoid direct exposure to sunlight or to use sunblock preparations.

BP 2008 (Benorilate). A white or almost white, odourless or almost odourless, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol and in methyl alcohol; soluble in acetone and in chloroform.

Profile

Benorilate is an aspirin-paracetamol ester with analgesic, anti-inflammatory, and antipyretic properties. After absorption, it is rapidly metabolised to salicylate and paracetamol. It has been used orally in the treatment of mild to moderate pain (see Choice of Analgesic, p.2) and fever (p.10). It has also been used in osteoarthritis, rheumatoid arthritis, and soft-tissue rheumatism.

When an overdose of benorilate is suspected, it has been suggested that plasma concentrations of both salicylate and paracetamol should be measured since a normal plasma-paracetamol concentration cannot necessarily be assumed from a normal plasma-salicylate measurement.

Profile

Benoxaprofen is an NSAID (p.96) structurally related to ibuprofen (p.64). It was formerly given orally in rheumatoid arthritis and osteoarthritis but because of reports of adverse reactions and fatalities the manufacturers halted worldwide marketing of the preparation known as *Opren* in the early 1980s. Adverse effects that have occurred with benoxaprofen include skin disorders, notably photosensitivity reactions but also erythema multiforme and the Stevens-Johnson syndrome, onycholysis and other nail disorders, gastrointestinal disturbances including peptic ulceration and bleeding, blood disorders such as thrombocytopenia, cholestatic jaundice and other liver or biliary disorders, and renal failure.

Pharmacopoeias. In *Br.* and *Pol.*

BP 2008 (Benzydamine Hydrochloride). A white crystalline powder. Very soluble in water; freely soluble in alcohol and in chloroform; practically insoluble in ether. A 10% solution in water has a pH of 4.0 to 5.5.

Adverse Effects

After topical application to the skin local reactions such as erythema or rash may occur and photosensitivity has been reported. After use as mouth and throat preparations, numbness or stinging sensations of the oral mucosa have been reported; hypersensitivity reactions including urticaria, photosensitivity, and bronchospasm may also occur rarely.

Effects on the kidneys. A 57-year-old woman who had used 400 g of a topical cream containing benzydamine hydrochloride 3% over a period of 4 months was found to have raised plasma concentrations of creatinine and urea consistent with a substantial reduction in glomerular filtration rate.[1]

Uses and Administration

Benzydamine hydrochloride is an NSAID (p.99). It is used topically on the skin in concentrations of 3 to 5% in painful musculoskeletal and soft-tissue disorders. Benzydamine hydrochloride is also used as a mouthwash or spray in concentrations of 0.15% for the relief of inflammatory conditions of the mouth and throat. It has been given orally or rectally for the relief of painful and inflammatory conditions, and as a topical solution for vaginal irrigation.

Benzydamine salicylate (benzasal) has been used topically on the skin as a 6% cream or spray.

Mouth disorders. Results of a randomised placebo-controlled study in patients undergoing radiotherapy for oropharyngeal cancer indicated that benzydamine as an oral rinse was effective in reducing the area and severity of mucositis.[1] Benzydamine is also used locally for the management of mouth ulcers (p.1700) although an early study[2] found it no more useful than placebo.

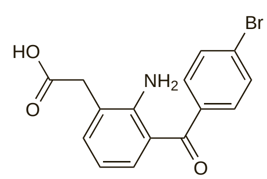
CAS — 91714-94-2 (bromfenac); 91714-93-1 (bromfenac sodium); 120638-55-3 (bromfenac sodium).



(bromfenac)

Profile

Bromfenac sodium, a phenylacetic acid derivative related to diclofenac (p.44), is an NSAID (p.96). It is instilled twice daily as 0.1% eye drops for ocular pain and inflammation including postoperative inflammation in patients who have undergone cataract extraction. When used postoperatively, it may be started 24 hours after surgery and continued for the next 14 days.

It was formerly given orally in the management of acute pain but was withdrawn from the market after reports of severe and sometimes fatal hepatic failure.

Effects on the eyes. Severe corneal melting (ulceration) was seen in 3 patients after topical use of bromfenac sodium.[1] All patients recovered after bromfenac was withdrawn. Similar effects have been reported with other ophthalmic NSAID preparations; for further details see under Adverse Effects of Diclofenac, p.45.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Buprenorphine may have a lower potential for producing dependence than pure agonists such as morphine. However, it has been subject to abuse (see under Precautions, below). Abrupt withdrawal of buprenorphine is said to produce only a mild abstinence syndrome, which may be delayed in onset.

Buprenorphine is used for substitution therapy in the management of opioid dependence (see under Uses and Administration, below).

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

Acute hepatotoxicity, including elevated liver enzyme values, hepatitis with jaundice, hepatic failure, necrosis, and encephalopathy, and hepatorenal syndrome, has been reported in opioid-dependent addicts; these reactions have also occurred after the misuse of buprenorphine, particularly after high doses or intravenous use.

Local reactions such as rash, erythema, and itching have been reported with the transdermal patches. In isolated cases delayed local allergic reactions with marked signs of inflammation have occurred; the patches should be withdrawn in such cases.

Treatment of adverse effects is similar to that for other opioid analgesics (p.102). The effects of buprenorphine are only partially reversed by naloxone (see Effects on the Respiratory System, below) but use of the latter is still recommended.

Incidence of adverse effects. Adverse effects reported[1] after *parenteral* buprenorphine in 8187 patients were nausea (8.8%), vomiting (7.4%), drowsiness (4.3%), sleeping (1.9%), dizziness (1.2%), sweating (0.98%), headache (0.55%), confusion (0.53%), lightheadedness (0.38%), blurred vision (0.28%), euphoria (0.27%), dry mouth (0.11%), depression (0.09%), and hallucinations (0.09%). Some studies[2,3] have reported nausea, vomiting, and dizziness to be more troublesome with buprenorphine than with morphine.

In a study[4] of *sublingual* buprenorphine, 50 of 141 cancer patients withdrew because of adverse effects, especially dizziness, nausea, vomiting, and drowsiness; constipation was not reported. A woman developed[5] a painless ulcer on the upper surface of her tongue after she had put sublingual buprenorphine tablets on rather than under her tongue.

Shock occurred[6] in 2 patients 2 hours after receiving *epidural* buprenorphine 300 micrograms; treatment with naloxone was unsuccessful but symptoms disappeared spontaneously after 2 to 3 hours.

In a multicentre study[7] of *transdermal* buprenorphine, 252 of 1223 patients with moderate to severe cancer pain or non-cancer pain withdrew due to adverse effects. The most commonly reported were nausea (11%), vomiting (9.2%), constipation (7.8%), dizziness (7.5%), drowsiness (4.0%), retching (3.7%), generalised pruritus (2.0%), and headache (1.6%); local adverse effects included pruritus (1.4%), dermatitis (1.3%), and erythema (1.3%). Another study[8] reported oedema, headache, nausea, palpitation, and difficulty concentrating as causes for therapy withdrawal in 4 out of 90 patients.

Effects on the heart. For a report of myocardial infarction associated with abuse of buprenorphine, see Abuse under Precautions, below.

Effects on mental function. Psychotomimetic effects have been relatively uncommon with buprenorphine. Hallucinations were reported[1] in only 7 of 8147 patients (0.09%) given buprenorphine by injection. There have been reports of hallucinations after sublingual[2] or epidural[3] use.

Effects on the respiratory system. There have been varying reports on the occurrence of respiratory depression with buprenorphine. It may be subject to a 'ceiling effect' in which respiratory depression does not increase further above doses of about 3 micrograms/kg.[1] However, high doses of 30 or 40 micrograms/kg given as sole intravenous analgesic in balanced anaesthesia have been associated with severe respiratory depression.[2]

Respiratory depression may be delayed in onset and more prolonged than with morphine and is only partially reversed by naloxone, possibly because buprenorphine is very firmly bound to opioid receptors. A study of sublingual buprenorphine for postoperative pain relief was abandoned when 3 of the first 16 patients showed signs of late-onset respiratory depression after the second dose of buprenorphine; the respiratory depression did not respond to naloxone.[3] Successful reversal has been shown in healthy subjects with buprenorphine-induced respiratory depression given large doses of naloxone 5 or 10 mg, but not with 1 mg; reversal was gradual in onset and decreased the duration of the normally prolonged respiratory depression.[4] Other studies found that lower doses of naloxone 2 to 4 mg given over 30 minutes,[5,6] or bolus doses of 2 to 3 mg followed by a continuous infusion of 4 mg/hour,[6] were effective in reversing buprenorphine-induced respiratory depression. The authors of both these studies suggested that a longer duration of naloxone infusion may be needed for reversal of respiratory depression caused by high doses of buprenorphine. The respiratory depressant and analgesic effects of buprenorphine were decreased by the *concomitant* use of naloxone.[7] It should be noted that a combined sublingual preparation of buprenorphine hydrochloride and naloxone hydrochloride is available in some countries for the treatment of opioid dependence.

Overdosage. A small case series reported[1] acute buprenorphine intoxication in 5 children, aged from 15 to 22 months, after accidental ingestion of sublingual tablets; of these, 4 had ingested a combined preparation containing naloxone (*Suboxone; Reckitt Benckiser, USA*). Symptoms included drowsiness and miosis; decreased respiratory rates were reported in 4. All 5 children required hospital admission; 4 were treated with naloxone and 1 needed mechanical ventilation. Accidental poisoning has also been reported[2] in a 9-month-old infant who ingested *Suboxone*; his symptoms were reversed by naloxone. A retrospective review[3] of buprenorphine overdoses in children under 6 years of age reported by US poison centres to a national surveillance system from November 2002 to December 2005 concluded that overdosage is generally well tolerated. Out of 86 reports, 54 children developed symptoms of toxicity. Such symptoms included: drowsiness or lethargy (55%), vomiting (21%), miosis (21%), respiratory depression (7%), agitation or irritability (5%), pallor (3%), and coma (2%). There were no fatalities, and significant CNS and respiratory depression occurred in 7%. *Suboxone* preparations were the most commonly ingested products. The authors considered that any child who has ingested more than 2 mg and any aged under 2 years who has had more than a lick or taste should be referred to the emergency department.

During the years 1980 to 2002, buprenorphine was mentioned in 43 cases of adult fatalities in the UK.[4] Of these, 27 deaths were confirmed to have involved buprenorphine including 7 cases where it was taken alone. In those deaths where multiple drugs were involved sedatives or benzodiazepines were detected in 23 cases and other opioids were found in 17 cases; alcohol had also been taken in 10 cases. The authors also found an increase in buprenorphine-related fatalities since 1999 when the high-dose formulation became available.

Precautions

As for Opioid Analgesics in general, p.103.

Buprenorphine has opioid antagonist actions and may precipitate withdrawal symptoms if given to patients physically dependent on opioids.

Respiratory depression, if it occurs, is relatively slow in onset and of prolonged duration; it may be only partially reversed by naloxone.

Licensed product information states that baseline liver function levels should be established before starting buprenorphine therapy, and periodic monitoring of liver function should be performed throughout therapy in patients being treated for opioid dependence. It should be used with caution in all patients with pre-existing hepatic impairment.

Absorption of buprenorphine from transdermal patches may be increased as the temperature rises and patients should therefore avoid exposing the patch to external heat; similarly, patients with fever may require monitoring because of increased absorption. It may take up to 30 hours for plasma concentrations of buprenorphine to decrease by 50% after removal of a patch; patients who have had adverse effects should be monitored during this period.

Abuse. A 22-year-old man had chest pains on each of two occasions after he had inhaled crushed buprenorphine tablets.[1] An ECG taken after the second episode suggested that the patient had suffered a myocardial infarction. Intravenous injection of crushed sublingual tablets was associated with rhabdomyolysis and sciatic neuropathy in 2 patients.[2] A case series[3] of 4 patients reported severe limb and digit complications, such as ischaemia and gangrene, from parenteral abuse of sublingual buprenorphine tablets; intra-arterial injection in 2 cases resulted in amputation of the affected digits or limb. The use of adulterants in illicit preparations may also cause adverse effects: 4 patients on substitution treatment developed candida endophthalmitis after intravenously injecting sublingual buprenorphine diluted with lemon juice.[4]

Hepatotoxicity has been seen in opioid-dependent addicts after buprenorphine abuse (see Adverse Effects and Treatment, above).

Breast feeding. From a study[1] of a breast-feeding mother who was receiving buprenorphine 4 mg daily, it was estimated that at the age of 4 weeks the total amount ingested by the infant during a 24-hour period was 3.28 micrograms for buprenorphine and 0.33 micrograms for norbuprenorphine. Another study[2] found that buprenorphine was present in the breast milk of a breast-feeding mother with a maternal milk-to-plasma ratio of about one. The authors of both studies considered the amount absorbed through breast feeding to be low.

The *BNF* and some licensed product information states that buprenorphine should not be given to mothers who are breast feeding.

Studies in *rats* have shown that it may inhibit lactation.

Pregnancy. An infant born to a mother who was being treated with buprenorphine 4 mg daily for diamorphine addiction suffered a minor withdrawal syndrome 2 days after birth.[1] The infant rapidly recovered without any treatment. No further signs of withdrawal occurred when breast feeding was abruptly stopped at the age of 8 weeks. In another report[2] of 15 opioid-dependent mothers who had received buprenorphine maintenance during their pregnancies, withdrawal symptoms were either absent or mild in 12 of the neonates. The remaining 3 neonates required treatment with morphine. There appeared to be no correlation between the buprenorphine dose and the degree of withdrawal symptoms. A literature review[3] found that of about 309 infants born to opioid-dependent mothers maintained on buprenorphine (sublingual dose range: 0.4 to 24 mg daily), 193 developed neonatal abstinence syndrome; of these, 149 required treatment. More than 40% of treated cases were confounded by misuse of other drugs. Onset of symptoms occurred within the first 12 to 48 hours and peaked within about 72 to 96 hours; duration of symptoms was about 120 to 168 hours although in some infants, it was reported to last for 6 to 10 weeks.

The 67 pregnancies of 66 women using buprenorphine have been followed in a prospective study.[4] The incidences of premature birth, caesarean section, and low Apgar scores in buprenorphine-exposed neonates were no greater than those seen in the general population although the mean birth-weight of the exposed neonates was significantly lower. In the exposed group, 91% of neonates needed intensive care treatment: 76% had neonatal abstinence syndrome and 57% needed opioid replacement therapy. There were also 2 cases of sudden infant deaths in the exposed group, which was considered to be higher than that generally expected.

Interactions

For interactions associated with opioid analgesics, see p.103.

Buprenorphine is metabolised by the cytochrome P450 isoenzyme CYP3A4; consequently, use with other drugs that induce or inhibit this isoenzyme may result in changes in plasma concentrations of buprenorphine and, possibly adverse effects. Some manufacturers state that dosage adjustment of buprenorphine may be necessary when used with such drugs. The UK licensed product information for one sublingual formulation (*Subutex; Schering-Plough*) recommends that the dose of buprenorphine should be halved when starting treatment with the potent CYP3A4 inhibitor, ketoconazole.

There have been reports of respiratory and cardiovascular collapse in patients given therapeutic doses of intravenous buprenorphine and diazepam.

Use with other potentially hepatotoxic drugs may increase the risk of liver damage.

Analgesics. There is a risk that, with opioid agonist-antagonists such as buprenorphine, their antagonistic effects might impair more effective analgesic therapy. This appeared to happen in 2 cancer patients both of whom were given sublingual buprenorphine that was later substituted by *morphine*.[1] Conventional doses of morphine were inadequate and in one patient raising the dose of morphine proved fatal.

1. Overweg-van Kints J, Stricker BHC. Falende pijnbestrijding tijdens sublinguaal gebruik van buprenorfine. *Ned Tijdschr Geneeskd* 1987; **131:** 1973–4.

Antivirals. Various HIV-protease inhibitors and NNRTIs can inhibit or induce cytochrome P450 isoenzymes, and most are also substrates for CYP3A4; thus, they have the potential to interact with buprenorphine. A pharmacokinetic study[1] found that usual doses of *nelfinavir*, *ritonavir*, and *lopinavir-ritonavir* given to HIV-negative patients taking buprenorphine with naloxone for opiate dependence did not produce any clinically significant interactions: ritonavir increased the area under the concentration-time curve (AUC) of buprenorphine by about 57%, although no adverse effects were seen. Another pharmacokinetic study[2] in a similar group of patients also found no clinically significant interactions between buprenorphine with naloxone and *delavirdine* or *efavirenz*: delavirdine increased the AUC of buprenorphine fourfold, and efavirenz decreased it by about 50%, but no adverse effects were seen. However, a small case series[3] of 3 opioid-dependent patients reported symptoms of buprenorphine toxicity, such as dizziness, daytime somnolence, and decreased mental functioning, with concomitant *atazanavir* and ritonavir therapy.

Buprenorphine does not appear to significantly affect the pharmacokinetics of antiretrovirals.[1,2]

Pharmacokinetics

After intramuscular injection, buprenorphine rapidly reaches peak plasma concentrations. Absorption also takes place through the buccal mucosa after sublingual doses and peak plasma concentrations are achieved after 90 minutes. Transdermal application results in absorption through the skin; the minimum effective concentration is reached in 12 to 24 hours and peak plasma concentrations are achieved after about 60 hours. However, there is a lack of correlation between plasma concentrations and analgesic activity. Buprenorphine is about 96% bound to plasma proteins.

Elimination of buprenorphine is bi- or triphasic; metabolism takes place in the liver by oxidation via the cytochrome P450 isoenzyme CYP3A4 to the pharmacologically active metabolite *N*-dealkylbuprenorphine (norbuprenorphine), and by conjugation to glucuronide metabolites. Buprenorphine is subject to considerable first-pass metabolism after oral doses. However, when given by the usual routes buprenorphine is excreted mainly unchanged in the faeces; there is some evidence for enterohepatic recirculation. Plasma elimination half-lives have ranged from 1.2 to 7.2 hours after intravenous injection; elimination half-lives after sublingual or transdermal use are longer and may range from 20 to 36 hours or more. Metabolites are excreted in the urine, but very little unchanged drug is excreted in this way. Buprenorphine crosses the placenta and small amounts are distributed into breast milk.

Administration. *BUCCAL ROUTE.* Absorption of sublingual buprenorphine is relatively slow. In a 10-hour study[1] plasma concentrations after 400 or 800 micrograms given sublingually peaked at about 200 minutes (range 90 to 360 minutes) and buprenorphine was still detected in plasma at the end of the study. Systemic availability was about 55% (range 16 to 94%) and absorption was more or less complete 5 hours after a dose. However, the authors of a subsequent study[2] considered that this was an overestimation, possibly due to methodological flaws. The later study results indicated that the bioavailability of sublingual buprenorphine is about 30% and that sublingual holding times between 3 and 5 minutes are bioequivalent. Another single-dose study[3] found that the bioavailability of sublingual buprenorphine was 50% less from a tablet than from a liquid formulation. Later studies[4,5] noted that the bioavailability of buprenorphine from a sublingual tablet relative to a sublingual liquid formulation was about 70% after daily dosing for 7 days. One of these studies[4] also found that the bioavailability of sublingual buprenorphine from a tablet formulation containing naloxone was higher than from a single-ingredient tablet formulation and similar to that seen with liquid formulations.

Children. The terminal elimination half-life of buprenorphine was only about 1 hour in small children aged 4 to 7 years given 3 micrograms/kg intravenously as premedication, but could not be estimated reliably because of the rapid decline in plasma-buprenorphine concentrations.[1] Clearance values did, however, appear higher than in adults; steady-state volume of distribution was similar. Premature neonates (gestational age 27 to 32 weeks) given a similar dose followed by an infusion of 0.72 micrograms/kg per hour had a considerably lower clearance rate and had a mean elimination half-life of 20 hours.[2] Although this dosing regimen appeared to be safe, sedation was judged to be inadequate in 4 of the 12 neonates studied. It was suggested that as buprenorphine given by infusion might not produce consistent sedation and analgesia in premature neonates, it could not be recommended for use in neonatal care.

Renal impairment. Buprenorphine clearance appears to occur mainly by hepatic extraction and metabolism and would not be expected to be related to renal function, whereas metabolites are excreted in urine. In a study, buprenorphine kinetics were similar in anaesthetised healthy patients to those in patients with renal impairment, with a mean elimination half-life of 398 and 239 minutes, respectively.[1] Plasma concentrations of the metabolites norbuprenorphine and buprenorphine-3-glucuronide were increased about 4 times and 15 times, respectively in patients with renal impairment,[1] but significant pharmacological activity was unlikely since norbuprenorphine has little analgesic activity compared with the parent compound and buprenorphine-3-glucuronide has none.

Uses and Administration

Buprenorphine is an opioid analgesic (p.104) classified as an opioid agonist and antagonist. It is used for the relief of moderate to severe pain and as an adjunct to anaesthesia. Buprenorphine is also used in the treatment of opioid dependence.

Buprenorphine has a relatively slow onset but prolonged duration of action. On intramuscular injection analgesia is apparent within 15 minutes and lasts up to 6 hours. A slower, more prolonged response is achieved after sublingual doses. The analgesic effects of buprenorphine after transdermal application may not be seen for at least 12 to 24 hours or up to 72 hours in the case of the once-weekly patch.

Buprenorphine is usually given by intramuscular or intravenous injection or sublingually as the hydrochloride or as transdermal patches as the base. For all routes doses are expressed in terms of the base. Buprenorphine hydrochloride 107.8 micrograms is equivalent to about 100 micrograms of buprenorphine.

Buprenorphine is given by all the above routes for opioid analgesia in moderate to severe **pain**.

- The dose by intramuscular or slow intravenous injection is 300 to 600 micrograms repeated every 6 to 8 hours as required
- By the sublingual route, doses of 200 to 400 micrograms may be repeated every 6 to 8 hours as required
- For opioid treatment of chronic pain in patients aged 18 years and over transdermal patches delivering varying amounts of buprenorphine are available. Doses should be individually titrated for each patient according to previous opioid usage. During transfer to treatment with buprenorphine patches previous opioid analgesic therapy should be phased out gradually in order to allow for the gradual increase in plasma-buprenorphine concentrations. Depending on dose required up to 2 patches may be applied, however, this should be done at the same time to avoid confusion. Buprenorphine patches are not appropriate for acute pain. In the UK, transdermal buprenorphine patches are available as follows:

  Transtec (*Napp, UK*) delivering buprenorphine in a range of 35 to 70 micrograms/hour. Initial dosages should not exceed 35 micrograms/hour in *opioid-naive* patients. For *patients who have been receiving a strong opioid analgesic* the initial dose should be based on the previous 24-hour opioid requirement. Use of a patch providing 35 micrograms/hour of buprenorphine is roughly equivalent to 30 to 60 mg daily of oral morphine sulfate. Patches should be replaced every 96 hours at the latest with the new patch being applied to a different site; use of the same area of the skin should be avoided for at least the next 2 applications.

  BuTrans (*Napp, UK*) delivering buprenorphine in a range of 5 to 20 micrograms/hour. Initial dosages should not exceed 5 micrograms/hour in *all* patients. Patches should be replaced every 7 days with the new patch being applied to a different site; use of the same area of the skin should be avoided for the next 3 to 4 weeks.

When used in balanced **anaesthesia** 300 micrograms may be given intramuscularly or 400 micrograms sublingually for premedication; 300 to 450 micrograms may be given intravenously as a perioperative analgesic supplement.

For the treatment of **opioid dependence** in patients aged 16 years and over, the initial dose is 0.8 to 4 mg sublingually once daily. The dose may be increased as necessary but maintenance doses should not exceed 32 mg daily. Once the patient has been stabilised, the dosage should be reduced gradually to a lower maintenance dose; treatment may eventually be stopped if appropriate. For addicts who have not undergone opioid withdrawal before starting buprenorphine, the first dose of buprenorphine should not be given until the first signs of craving appear or until at least 4 (USA) or 6 (UK) hours after the last opioid use. In those already receiving methadone replacement, the dose of methadone should be reduced to a maximum of 30 mg daily before starting buprenorphine therapy. As a deterrent to abuse, a combined sublingual preparation of buprenorphine hydrochloride and naloxone hydrochloride is available in some countries for the treatment of opioid dependence.

For details of doses in **children**, see below.

Action. Buprenorphine is generally described as a mixed agonist-antagonist acting mainly as a partial agonist at μ opioid receptors, with some antagonist activity at κ receptors. It has also been shown to bind at μ, δ, and κ opioid binding sites and to have high affinity for the μ and δ receptors and lesser affinity for the κ receptor.[1] Buprenorphine, like fentanyl, has high lipid solubility, but has a lower intrinsic activity than fentanyl. Differences between buprenorphine and pure μ opioid agonists such as fentanyl, including relatively slow onset of action, prolonged duration of action, resistance to antagonism by naloxone, and lack of correlation between plasma concentrations and analgesic effects, have been explained by differences in the way buprenorphine binds to opioid receptors. In a study *in vitro* buprenorphine had slow rates of association and dissociation from the opioid receptor when compared with fentanyl.[2]

Administration in children. Buprenorphine is used for the relief of moderate to severe **pain** in children. In the UK, those aged from 6 months to 12 years may be given 3 to 6 micrograms/kg by *intramuscular* or slow *intravenous* injection every 6 to 8 hours; up to 9 micrograms/kg may be given if required in refractory cases. In the USA, parenteral buprenorphine is licensed in children aged 2 years and over; usual doses of 2 to 6 micrograms/kg may be given intramuscularly or intravenously every 4 to 6 hours to those up to 12 years old. The *sublingual* route is licensed in the UK in children aged from 6 to 12 years and the following doses are given every 6 to 8 hours according to body-weight: 16 to 25 kg, 100 micrograms; 25 to 37.5 kg, 100 to 200 micrograms; 37.5 to 50 kg, 200 to 300 micrograms. Older children requiring pain relief may be given the usual adult dose (see above) for all the above routes.

Buprenorphine is also used in the treatment of **opioid dependence**; adolescents aged 16 years and over may be given the usual adult dose (see above).

Opioid dependence. Buprenorphine is used in the treatment of opioid dependence (p.101). Its agonist-antagonist properties may mean that it has a lower potential for dependence and a lower risk of respiratory depression in overdose than pure agonists such as methadone. Buprenorphine can be used as substitution therapy in patients with moderate opioid dependence for acute management of withdrawal and in maintenance treatment as an alternative to or together with methadone. However, in patients dependent on high doses of opioids buprenorphine may precipitate withdrawal due to its partial antagonist properties; the daily opioid dose should be reduced gradually in such patients before beginning buprenorphine. Abuse of the preparation, as with other substitution therapies, may be a problem. A combined sublingual preparation of buprenorphine hydrochloride and naloxone hydrochloride is available in some countries as a deterrent to abuse.

Pain. ***ACUTE PAIN.*** The *BNF* considers that buprenorphine may antagonise the analgesic effect of other opioids and is generally not recommended for the management of *postoperative* pain. Nonetheless, it can be given intramuscularly, intravenously, or sublingually for this purpose, although the intravenous route may be preferred for acute pain relief. The epidural route[1] and continuous subcutaneous infusion[2] have also been used; an intranasal formulation of buprenorphine is under investigation for the management of postoperative pain.[1] Patient-controlled analgesia with intravenous[3] and intramuscular[4] buprenorphine has been effective although its long half-life may limit such use.

Buprenorphine had no adverse cardiovascular effects when given intravenously after open-heart surgery,[5] suggesting that it was a suitable analgesic for patients with unstable circulation. Epidural analgesia with buprenorphine has also been used after cardiac surgery.[6] Buprenorphine was also considered suitable for the relief of pain in *myocardial infarction*.[7]

CHRONIC PAIN. Transdermal buprenorphine is used for chronic intractable cancer pain.[1-4] It has also been used successfully in chronic non-cancer pain including neuropathic pain;[1,2,4-6] however, licensed product information states that this route is not suitable for the treatment of acute pain.

USP 31 (Butorphanol Tartrate). A white powder. Its solutions are slightly acidic. Sparingly soluble in water; insoluble in alcohol, in chloroform, in ether, in ethyl acetate, and in hexane; slightly soluble in methyl alcohol; soluble in dilute acids. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Butorphanol may have a lower potential for producing dependence than pure agonists such as morphine. However, it has been subject to abuse (see under Precautions, below). Abruptly stopping chronic butorphanol has produced a less severe withdrawal syndrome than with morphine.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102, and for Pentazocine, p.112.

Headache, and feelings of floating may also occur. Hallucinations and other psychotomimetic effects are rare and have been reported less frequently than with pentazocine. In addition insomnia and nasal congestion may occur frequently when butorphanol is given intranasally.

Because butorphanol has opioid agonist and antagonist activity, naloxone is the recommended antagonist for the treatment of overdosage.

Effects on the respiratory system. Butorphanol 2 mg produces a similar degree of respiratory depression to morphine 10 mg, but a ceiling effect is apparent with higher doses of butorphanol.[1] It has been reported to be a less potent respiratory depressant than fentanyl,[2] but more potent than nalbuphine.[3]

Precautions

As for Opioid Analgesics in general, p.103.

Although cardiovascular effects may be less than with pentazocine, butorphanol should generally be avoided after myocardial infarction.

Butorphanol may precipitate withdrawal symptoms if given to patients physically dependent on opioids. The dosage regimen of butorphanol may need to be adjusted in the elderly and in patients with hepatic or renal impairment.

Abuse. A WHO expert committee considered in 2006 that the likelihood of butorphanol abuse was low and was not great enough to warrant international control.[1] Abuse had been reported infrequently and only in a few countries. The committee also commented that, pharmacologically, intranasal preparations of butorphanol do not appear to differ in their abuse potential from parenteral preparations; however, other factors such as availability and usage patterns may affect the likelihood of abuse. Indeed, US licensed product information states that there have been more reports of abuse with intranasal preparations than with injectable ones.

Cases of butorphanol abuse have been published[2,3] including a report of fibrous myopathy associated with chronic intramuscular abuse.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were given butorphanol, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

In a study[2] of 12 women, butorphanol was detected in breast milk after both intramuscular and oral doses. However, the milk-to-plasma ratio after a 2-mg intramuscular dose (0.7) was significantly less than that after an 8-mg oral dose (1.9). Although the mothers were not breast feeding at the time of the study, the authors concluded that the potential for any adverse effects on nursing infants after maternal butorphanol use would be minimal.

Pregnancy. Two instances of sinusoidal fetal heart rate pattern were noted out of 188 consecutive cases of butorphanol use in active-phase labour.[1] Visual hallucinations and paranoid delusions developed in a woman on receiving a 1-mg intravenous injection of butorphanol early in labour; the psychosis had resolved 40 hours after the injection and was not noted on follow-up 2 weeks later.[2]

Interactions

For interactions associated with opioid analgesics, see p.103.

Antimigraine drugs. No pharmacokinetic interactions were reported when butorphanol nasal spray and subcutaneous *sumatriptan* were used together within a minute of each other in healthy subjects.[1] However, another study[2] in healthy subjects found that the AUC and maximum plasma concentration of intranasal butorphanol were reduced by about 29% and 38%, respectively when given 1 minute after intranasal sumatriptan. No such effect was noted when administration was separated by 30 minutes. It was suggested that sumatriptan may reduce butorphanol absorption by inducing transient nasal vasoconstriction.

Pharmacokinetics

Butorphanol is absorbed from the gastrointestinal tract but it undergoes extensive first-pass metabolism. Peak plasma concentrations occur 0.5 to 1 hour after intramuscular and intranasal doses and 1 to 1.5 hours after oral doses. Butorphanol has a plasma elimination half-life of about 4.5 hours. About 80% is bound to plasma proteins.

Butorphanol is extensively metabolised in the liver through hydroxylation, *N*-dealkylation, and conjugation, only 5% being excreted unchanged. Excretion is mainly in the urine; about 15% of a parenteral dose is excreted in the bile. It crosses the placenta and is distributed into breast milk.

Uses and Administration

Butorphanol tartrate, a phenanthrene derivative, is an opioid analgesic (p.104) with opioid agonist and antagonist properties; it is pharmacologically similar to pentazocine (p.113). Butorphanol is used for the relief of moderate to severe pain, including the pain of labour, and as an adjunct to anaesthesia. Onset of analgesia occurs within 15 minutes of intramuscular injection or an intranasal dose and may last for 3 to 4 hours after parenteral doses or for 4 to 5 hours after intranasal doses.

For the relief of moderate to severe **pain**, butorphanol tartrate is given in doses of 1 to 4 mg (usually 2 mg) by intramuscular injection or in doses of 0.5 to 2 mg (usually 1 mg) by intravenous injection every 3 to 4 hours. It may also be given as a nasal spray, in usual doses of 1 mg (1 spray in 1 nostril), repeated after 60 to 90 minutes, if necessary. This sequence may be repeated after 3 to 4 hours as needed. An initial dose of 2 mg (1 spray in each nostril) may be given for severe pain, but should not be repeated until 3 to 4 hours later.

In *obstetric analgesia* 1 to 2 mg may be given by intramuscular or intravenous injection during early labour in women at term. This dose may be repeated after 4 hours if necessary but an alternative analgesic should be used if delivery is expected within 4 hours.

In **anaesthesia**, 2 mg may be given intramuscularly for premedication 60 to 90 minutes before surgery. For use in balanced anaesthesia, a usual dose is 2 mg given intravenously shortly before induction and/or 0.5 to 1 mg given intravenously in increments during anaesthesia. The total dose needed varies but most patients require 4 to 12.5 mg.

Dosage adjustment may be needed in the elderly. When given by injection the initial dose of butorphanol for pain should be half the usual initial adult dose. Subsequent doses should be determined by the patient's response; a dosage interval of at least 6 hours has been recommended. For nasal use the initial dose should be limited to 1 mg followed by 1 mg after 90 to 120 minutes if necessary; subsequent doses if required should generally be given at intervals of not less than 6 hours. Similar recommendations have also been made for patients with hepatic or renal impairment, see below.

Administration in hepatic or renal impairment. The dosage of butorphanol may need to be adjusted in patients with hepatic or renal impairment. When given by injection the initial dose for pain should be half the usual initial adult dose (see above). Subsequent doses should be determined by the patient's response; a dosage interval of at least 6 hours has been recommended. For nasal use the initial dose should be limited to 1 mg followed by 1 mg after 90 to 120 minutes if necessary; subsequent doses if required should generally be given at intervals of not less than 6 hours.

Headache. Butorphanol has been advocated for use as a nasal spray in the treatment of migraine, but there have been problems with abuse and dependence (see above) and its place in therapy, if any, still remains to be established. See also Antimigraine Drugs, under Interactions, above.

Pruritus. Results from a small study[1] of 6 patients with severe opioid-induced pruritus unresponsive to diphenhydramine, and from a case series of 5 patients with intractable pruritus from other causes,[2] suggest that intranasal butorphanol may be an effective treatment. Doses have ranged from 1 mg every other day to 2 mg every 4 to 6 hours.

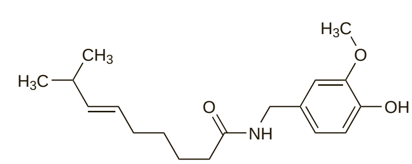
$C_{18}H_{27}NO_3$ = 305.4.
CAS — 404-86-4.
ATC — N01BX04.
ATC Vet — QN01BX04.



NOTE. Do not confuse capsaicin with capsicin, which is capsicum oleoresin (see Capsicum, p.2276).

Pharmacopoeias. In *US.*

USP 31 (Capsaicin). An off-white powder. M.p. 57° to 66°. Practically insoluble in cold water; soluble in alcohol, in chloroform, and in benzene; slightly soluble in carbon disulfide. Store in a cool place in airtight containers. Protect from light.

Adverse Effects

A warm, stinging, or burning sensation may occur at the site of application; this usually disappears after a few days of use but may persist longer if applications are less frequent than recommended (see Uses and Administration, below). Coughing, sneezing, or other signs of respiratory irritation may occur if dried residue from topical preparations is inhaled.

Precautions

Capsaicin should be handled with care. Particles should not be inhaled nor come into contact with any part of the body.

For topical application, contact with eyes and broken or irritated skin should be avoided. The hands should be washed after application of the cream, unless the hands are the treated areas, in which case, they should be washed 30 minutes after application. If bandages are used to cover treated areas they should not be wound too tightly. Heating pads should not be used with capsaicin, and patients should avoid taking a hot bath or shower immediately before or after application, as the burning sensation may be exacerbated. Thick applications of the cream should be avoided.

Uses and Administration

Capsaicin is the active principle of the dried ripe fruits of *Capsicum* spp. It is used as a topical analgesic (p.5) in painful conditions such as postherpetic neuralgia after the lesions have healed, diabetic neuropathy, osteoarthritis, and rheumatoid arthritis. Capsaicin is usually applied sparingly 3 or 4 times daily (and not more often than every 4 hours) as a 0.025% or 0.075% cream; in the UK these creams are not licensed for use in children, but in the USA they may be used in children over 2 years of age. A more concentrated cream containing 0.25% capsaicin is available in some countries.

Capsaicin cream should be rubbed well into the skin until little or no residue is left on the surface. Therapeutic response may not be evident for 1 to 2 weeks for arthritic disorders, or 2 to 4 weeks for neuralgias (or even longer if the head or neck are involved). For the management of painful diabetic neuropathy, licensed UK product information recommends that capsaicin should only be used under specialist supervision and that treatment should be reviewed after the first 8 weeks and regularly re-evaluated thereafter.

Although not a counter-irritant itself, capsaicin has been included in rubefacient preparations for the relief of muscular and rheumatic pain.

Action. The action of capsaicin and related compounds (vanilloids) are complex and still being investigated. Capsaicin has been found to produce burning pain[1,2] by activating specific vanilloid receptors such as TRPV1 (transient receptor potential channel, vanilloid subfamily member 1) which are also stimulated by heat and acids. TRPV1 is expressed by nerves and other tissues such as the keratinocytes of the epidermis, bladder urothelium and smooth muscle, and liver.

The analgesic effect of capsaicin has been suggested to be due to both depletion of substance P from local sensory C-type nerve fibres[3-7] and to the desensitisation of vanilloid receptors.[1,2,8] Since the effect of capsaicin does not rely on vasodilatation in the skin it is therefore not considered to be a traditional counter-irritant.

Headache. Prevention of attacks of *cluster headache* (p.616) by repeated application of capsaicin to the nasal mucosa has been reported.[1] The *Z*-isomer (zucapsaicin; civamide) has also been found to be modestly effective.[2]

Repeated nasal application of capsaicin has also been found to be effective in *chronic migraine*.[3]

Micturition disorders. Intravesical capsaicin has been tried for painful bladder disorders and to treat bladder detrusor hyperreflexia.[1-9] Results have been variable, and the characteristic sensory effects of capsaicin make blinding of studies difficult, but some patients have reported benefit particularly those with neurological bladder disorders. Instillation into the ureter has also been tried in the management of the loin pain/haematuria syndrome.[10]

Neuropathic pain. Capsaicin has been tried topically in various types of pain including neuropathic pain, which does not generally respond to conventional systemic analgesics. Topical capsaicin is used in the management of diabetic neuropathy (p.6) and postherpetic neuralgia (p.9), but while a meta-analysis[1] of randomised, double-blind, placebo-controlled studies and later studies[2] suggested that it is effective in painful diabetic neuropathy the evidence for efficacy in postherpetic neuralgia was considered[1] to be less convincing. Another meta-analysis[3] and a systematic review[4] have suggested that capsaicin was of benefit in neuropathic pain, although this effect may be modest.[4] The difficulty of blinding in placebo-controlled trials of capsaicin has also been noted, because of the burning sensation it produces. Other types of pain syndrome for which capsaicin has been tried include reflex sympathetic dystrophy (see Complex Regional Pain Syndrome, p.6), postmastectomy neuroma, amputation stump pain, chronic neck pain, and the pain of oral mucositis.[5]

Pruritus. Substance P is a possible mediator of itch sensations and since capsaicin acts as a depletor of substance P it has been tried in the relief of pruritus (p.1582) associated with various diseases and haemodialysis.[1-7] It has also been used to provide relief from pruritus induced by hetastarch[8] and for the itch and pain associated with PUVA therapy.[9,10]

Psoriasis. Since substance P has been implicated in the pathophysiology of several inflammatory dermatological processes, capsaicin, a substance P depletor, has been tried with some benefit in a number of skin disorders including psoriasis.[1-3]

The usual management of psoriasis is discussed on p.1583.

Rheumatic disorders. Topical capsaicin is used for the temporary relief of the pain of arthritis. From the results of a meta-analysis[1] of randomised, double-blind, placebo-controlled studies and later studies[2,3] it appears that capsaicin is effective in easing the pain of osteoarthritis (p.11) but its role, if any, is unclear; published evidence[4] for efficacy in rheumatoid arthritis (p.11) appears to be limited. A review of use in both neuropathic and musculoskeletal chronic pain concluded that its benefits were at best moderate, but noted that in a minority of patients unresponsive to, or intolerant of, other treatments it might be useful.[5] Capsaicin may be a useful therapy for pain associated with primary fibromyalgia[6] (see under Soft Tissue Rheumatism, p.13), which responds poorly to conventional treatment.

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Carbasalate Calcium). A white or almost white, crystalline powder. It contains not less than 99.0% and not more than the equivalent of 101.0% of an equimolecular compound of calcium di[2-(acetyloxy)benzoate] and urea, calculated with reference to the anhydrous substance. Freely soluble in water and in dimethylformamide; practically insoluble in acetone and in anhydrous methyl alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20.

Carbasalate calcium, like aspirin, should not generally be given to children because of the risk of Reye's syndrome.

Effects on hearing. As of June 2006 the Netherlands Pharmacovigilance Centre[1] database contained 8 reports of tinnitus and 1 of ototoxicity associated with use of low oral doses of carbasalate calcium (38 or 100 mg usually once daily). The association between low-dose carbasalate calcium and tinnitus was considered to be disproportional.

Interactions

For interactions associated with aspirin, see p.23.

Uses and Administration

Carbasalate calcium is a 1:1 complex of calcium acetylsalicylate and urea. It is metabolised to aspirin after absorption and thus has the actions of aspirin (p.23). Carbasalate calcium is given in oral doses equivalent to about 400 to 800 mg of aspirin every 4 to 8 hours up to a maximum of about 3 g daily for pain or fever. Carbasalate calcium has also been used in the management of thromboembolic disorders.

As for NSAIDs in general, p.96.

Serious skin reactions such as exfoliative dermatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis have been reported with celecoxib. Other hypersensitivity reactions, including anaphylaxis and angioedema, have also occurred. Celecoxib should be stopped at the first signs of hypersensitivity. Some of these reactions have been seen in patients with a history of allergic reactions to sulfonamides and the use of celecoxib is contra-indicated in such patients.

Celecoxib should not be used after coronary artery bypass surgery as there may be an increased risk of adverse effects such as myocardial infarction and stroke. It should be used with caution, if at all, in patients with a history of ischaemic heart disease, peripheral arterial disease, or cerebrovascular disease; it should also be used with caution in patients with significant risk factors for cardiovascular disease such as hypertension, hyperlipidaemia, and diabetes mellitus. For further details see Effects on the Cardiovascular System, below.

Therapy is contra-indicated in patients with moderate to severe heart failure (NYHA class II to IV), inflammatory bowel disease, and renal impairment associated with a creatinine clearance of less than 30 mL/minute. Celecoxib should also not be used in patients with severe hepatic impairment (Child-Pugh category C). Caution is recommended when using celecoxib in dehydrated patients; rehydration may be advisable before giving celecoxib.

Celecoxib treatment may need to be stopped if signs or symptoms of organ toxicity develop.

Incidence of adverse effects. A prescription-event monitoring study[1] conducted after the introduction of celecoxib in England in May 2000 found that the most common adverse events reported were gastrointestinal effects including dyspepsia (4.7% of all events), abdominal pain (1.8%), nausea or vomiting (1.6%), and diarrhoea (1.4%). Rash (1.2%) was also common. Uncommon events included anaemia, cough, anxiety, hypertension, visual disturbances, and insomnia. Blood dyscrasias, gastrointestinal bleeds, myocardial infarction, heart failure, abnormal liver function tests, nephritis, confusion, hallucinations, serious skin disorders, anaphylaxis, and bronchospasm were rare.

Breast feeding. Licensed product information recommends that celecoxib should not be used in breast-feeding women because of the potential for serious adverse effects in nursing infants.

No adverse effects were noted in 2 older infants (aged 17 and 22 months) whose mothers took celecoxib while breast feeding.[1] The authors of this report also measured celecoxib plasma concentrations in 2 other women; from these values, the average milk-to-plasma ratio was calculated to be 0.23 and infant exposure was estimated at about 0.3% of the weight-adjusted maternal dose. Similar values have also been estimated from a study of blood and milk concentrations of celecoxib in 6 women.[2]

Effects on the blood. Severe methaemoglobinaemia has been reported in an elderly patient after taking celecoxib for 1 month.[1]

Effects on the cardiovascular system. Prelicensing studies did not report any increased risk of serious cardiovascular effects in patients given celecoxib.[1,2] Nonetheless, by February 2001 the UK CSM had received a small number of reports[3] of *myocardial infarction* or *ischaemia* associated with the selective cyclo-oxygenase-2 (COX-2) inhibitors. There have also been 3 cases of *torsade de pointes* associated with celecoxib use.[4] Subsequently, in September 2004, the COX-2 inhibitor rofecoxib was generally withdrawn worldwide by the manufacturer after further reports of cardiovascular adverse effects (see p.121) and this has prompted re-evaluation of the safety of other selective COX-2 inhibitors.

In December 2004 a large study of celecoxib for prevention of colon polyps (the APC study) was halted because of an increased risk of cardiovascular events (including death from cardiovascular causes, myocardial infarction, stroke, and heart failure) in patients receiving the drug compared with those receiving placebo.[5] The results of this long-term study suggested that there was a 2.8-fold increase in the risk of such events in patients taking either celecoxib 400 or 800 mg daily and that the increase was dose-related. The possibility of a dose-adverse effect relationship was supported by some at-the-time unpublished studies, the PreSAP and ADAPT studies, that showed no increase in the risk of cardiovascular effects with celecoxib 400 mg daily when compared with placebo.[6] These studies[7,8] have since been published and their finished reports were less reassuring than initially thought. The risk of serious cardiovascular events was found to be increased in the celecoxib group when compared with the placebo group although the difference was not significant. In addition, an update[9] of the original APC study confirmed that the risk of adverse cardiovascular events was significantly increased for both high-dose (800 mg daily) and low-dose (400 mg daily) celecoxib when compared with placebo treatment; however, high-dose treatment was associated with the greatest risk. Increases in blood pressure were also more likely with both celecoxib groups than with placebo. An analysis[10] using pooled data from the APC and PreSAP studies provides further evidence of an increased cardiovascular risk with celecoxib.

Based on the findings of the above studies, EU regulatory authorities[11-13] recommend that:

- selective COX-2 inhibitors should not be used in patients with established ischaemic heart disease or cerebrovascular disease; they are also contra-indicated in those with peripheral arterial disease
- patients with risk factors for heart disease such as hypertension, hyperlipidaemia, diabetes, and smoking should be carefully monitored if given selective COX-2 inhibitors
- all patients should be assessed individually on the risks and benefits of selective COX-2 inhibitor treatment, particularly cardiovascular and gastrointestinal risk factors, and alternative treatments considered

Similar advice has also been issued by the FDA;[14] however, the only absolute contra-indication is in the immediate postoperative period after coronary artery bypass surgery. (In the USA celecoxib is currently the only available selective COX-2 inhibitor.)

COX-2 inhibitors such as celecoxib do not possess the intrinsic antiplatelet activity associated with aspirin and possibly other non-selective NSAIDs and consequently do not provide protection against ischaemic cardiac events.[3,15]

Effects on the gastrointestinal tract. It is generally accepted that the inhibition of cyclo-oxygenase-1 (COX-1) plays a role in the adverse gastrointestinal effects of the NSAIDs, and that the selective inhibition of the other isoform, COX-2, by NSAIDs such as celecoxib may cause less gastrotoxicity than the non-selective inhibition of the traditional NSAIDs.

Results from controlled studies suggested that NSAIDs selective for COX-2 were associated with a lower incidence of serious gastrointestinal effects. In a placebo-controlled study[1] the incidence of endoscopically determined gastroduodenal ulcers in patients taking celecoxib for rheumatoid arthritis (dose range 200 to 800 mg daily) was not significantly different to that seen with the placebo group. Another study[2] in patients taking celecoxib at supratherapeutic doses (800 mg daily) concluded that there was a lower combined incidence of symptomatic gastrointestinal ulcers and ulcer complications (bleeding, perforation, and obstruction) after 6 months of treatment when compared with non-selective NSAIDS (ibuprofen 2.4 g daily or diclofenac 150 mg daily). However, the incidence of ulcer complications alone was not significantly different to that seen with other NSAIDs. A re-analysis of the study by the FDA, including both the 6-month and full-term data, also found that there was no significant reduction in the rate of ulcer complications with celecoxib compared with the non-selective NSAIDs although, in subjects not taking aspirin, there was a strong trend in favour of celecoxib compared to ibuprofen.[3] The risk of ulcer complications was also significantly increased in celecoxib users taking concomitant low-dose aspirin.[2] A later systematic review[4] of studies of patients receiving celecoxib or NSAIDs for at least 12 weeks claimed to show improved gastrointestinal safety and tolerability in those receiving celecoxib (including in patients also taking low-dose aspirin) but this has been criticised on grounds of data selection.[5,6]

It has been noted that the use of aspirin appears to nullify any potential protective effect of COX-2 selectivity by celecoxib.[7,8]

There have been individual case reports of gastrotoxicity with celecoxib.[9-11]

Effects on the kidneys. Increasing evidence suggests that selective cyclo-oxygenase-2 (COX-2) inhibitors such as celecoxib appear to have adverse effects on renal function similar to those of the non-selective NSAIDs (see p.98).

Effects on the liver. Cholestatic hepatitis developed in a 54-year-old woman taking celecoxib;[1] her liver function tests improved and her symptoms resolved after drug withdrawal. Despite the temporal relationship between celecoxib use and the onset of hepatotoxicity, the manufacturers have stated that current evidence does not support such a relationship.[2] Other cases[3,4] have since been reported.

Hypersensitivity. A 52-year-old man suffered an allergic vasculitis after 8 days of treatment with celecoxib.[1] Despite intensive treatment the patient died from multiple organ failure and diffuse cutaneous necrolysis. The authors noted that potentially fatal skin reactions have occurred with other sulfa-containing drugs, although there is some evidence suggesting that the potential for cross-reactivity in patients sensitive to sulfonamides is relatively low;[2] nonetheless, licensed product information contra-indicates the use of celecoxib in such patients.

Interactions

The metabolism of celecoxib is mediated mainly by the cytochrome P450 isoenzyme CYP2C9. Use with other drugs that inhibit or induce or are metabolised by this isoenzyme may result in changes in plasma concentration of celecoxib; fluconazole has increased plasma concentrations of celecoxib and licensed product information recommends that the dose of celecoxib should be halved when given with fluconazole.

Celecoxib is an inhibitor of the isoenzyme CYP2D6 and the potential therefore exists for an effect on drugs metabolised by this enzyme.

For interactions associated with NSAIDs in general, see p.99.

Pharmacokinetics

Celecoxib is absorbed from the gastrointestinal tract, peak plasma concentrations being achieved after about 3 hours. Protein binding is about 97%. Celecoxib is metabolised in the liver mainly by the cytochrome P450 isoenzyme CYP2C9; the three identified metabolites are inactive as inhibitors of COX-1 or COX-2 enzymes. It is eliminated mainly as metabolites in the faeces and urine; less than 3% is recovered as unchanged drug. The effective terminal half-life is about 11 hours. Celecoxib is distributed into breast milk. The pharmacokinetics of celecoxib may vary in different ethnic groups; it has been stated that the area under the curve is elevated in patients of Afro-Caribbean origin, although any clinical significance is unclear.

Uses and Administration

Celecoxib is an NSAID (p.99) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It is used in the treatment of rheumatoid arthritis including juvenile idiopathic arthritis, osteoarthritis, and ankylosing spondylitis, and in the adjunctive treatment of adenomatous colorectal polyps. Celecoxib is also used in the management of acute pain and dysmenorrhoea.

For **osteoarthritis** the recommended oral dose is 200 mg daily given as a single dose or in 2 divided doses. If necessary a dose of 200 mg twice daily may be used. For **rheumatoid arthritis** the dose is 100 to 200 mg given twice daily. Celecoxib is also used for **ankylosing spondylitis** in an initial dose of 200 mg daily, as a single dose or in 2 divided doses. In the USA, the dose may be increased to 400 mg daily after 6 weeks, although if no response is seen at this dose after a further 6 weeks, alternative treatments should be considered. A similar increase is also permitted in UK licensed product information; however, it is recommended that if ineffective, the higher dose should only be continued for 2 weeks before considering alternative treatments. In elderly patients treatment should be begun at the lowest recommended dose.

For doses in children with **juvenile idiopathic arthritis**, see below.

In the treatment of **pain** and **dysmenorrhoea**, an initial dose of 400 mg followed by an additional dose of 200 mg, if necessary, is recommended on the first day; thereafter the dose is 200 mg twice daily.

Celecoxib is also used as an adjunct to standard therapy to reduce the number of adenomatous **colorectal polyps** in patients with familial adenomatous polyposis. For this purpose it may be given in doses of 400 mg twice daily with food.

Reduced doses are recommended in patients with hepatic impairment (see below).

Administration in children. In the USA, celecoxib is licensed for the treatment of juvenile idiopathic arthritis in children aged 2 years and over. The recommended oral doses, based on body-weight, are:

- 10 kg to 25 kg: 50 mg twice daily
- over 25 kg: 100 mg twice daily

Licensed product information recommends that the contents of a celecoxib capsule may be sprinkled onto apple sauce if a patient has difficulty swallowing the capsules. The sprinkled capsule should be taken immediately; however, it remains stable at a temperature between 2° to 8° for up to 6 hours.

Administration in hepatic impairment. Licensed product information recommends that doses of celecoxib should be reduced by 50% in patients with moderate hepatic impairment (Child-Pugh category B); its use is contra-indicated in those with severe impairment (Child-Pugh category C or a score of 10 or more).

Familial adenomatous polyposis. Celecoxib is used in the treatment of familial adenomatous polyposis, an inherited syndrome known to predispose sufferers to the development of colonic cancer (see p.666). A randomised study[1,2] found that treatment with celecoxib reduced the number of colonic polyps; the authors considered celecoxib to be a useful adjunct to the standard therapy of colectomy.

Malignant neoplasms. Celecoxib is under investigation as adjuvant therapy in the treatment of cancer;[1-9] preliminary results have been variable. It has also been investigated for chemoprevention of malignancy[10-13] (see also Familial Adenomatous Polyposis, above), but a large study for the prevention of colon cancer was terminated early because of increased cardiovascular risk.[11,12]

Musculoskeletal and joint disorders. Celecoxib is used in the treatment of osteoarthritis (p.11) and rheumatoid arthritis (p.11) including juvenile idiopathic arthritis (p.10). However, in the UK it is recommended that the use of celecoxib and other selective cyclo-oxygenase-2 (COX-2) inhibitors be limited to those patients considered to be at high risk of developing serious gastrointestinal problems if given a non-selective NSAID and who do not have pre-existing cardiovascular risk factors (see Adverse Effects, above).

Celecoxib is also used in the treatment of ankylosing spondylitis (see Spondyloarthropathies, p.13).

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20.

The use of aspirin and other acetylated salicylates is generally not recommended for children unless specifically indicated, because of the risk of Reye's syndrome. US licensing information extends this precaution to choline magnesium trisalicylate.

Interactions

For interactions associated with salicylates, see Aspirin, p.23.

Uses and Administration

Choline magnesium trisalicylate is a combination of the salicylic acid derivatives choline salicylate (p.36) and magnesium salicylate (p.79). It has analgesic, anti-inflammatory, and antipyretic actions similar to those of aspirin (p.23). After oral administration, choline magnesium trisalicylate dissociates and the salicylate moiety is rapidly absorbed. Each unit dose of 500 mg of salicylate is provided by about 293 mg of choline salicylate with 362 mg of magnesium salicylate (anhydrous). Choline magnesium trisalicylate has been used in osteoarthritis, rheumatoid arthritis, and other arthritides in oral doses equivalent to 1 or 1.5 g of salicylate twice daily; doses may also be given as a single daily dose if required. A dose of 750 mg given three times daily may be more suitable for elderly patients. Choline magnesium trisalicylate is also used in similar doses in the general management of other forms of pain and for fever.

Pharmacopoeias. *Br.* includes a solution.

BP 2008 (Choline Salicylate Solution). An aqueous solution containing 47.5 to 52.5% of choline salicylate. It is a clear colourless liquid. It may contain a suitable antimicrobial preservative.

Profile

Choline salicylate is a salicylic acid derivative (see Aspirin, p.20) used in the treatment of pain and fever, and in the management of rheumatic disorders. In terms of salicylate content, choline salicylate 435 mg is equivalent to about 325 mg of aspirin. Choline salicylate is given orally in doses of 435 to 870 mg every four hours as necessary for pain and fever, and in doses of 4.8 to 7.2 g daily in divided doses for rheumatic disorders.

Choline salicylate is also used as a local analgesic. Solutions containing up to about 20% choline salicylate are used in ear disorders such as the relief of pain in otitis media and externa but are considered to be of doubtful value; they are also used to soften ear wax as an aid to removal (see p.1725). An 8.7% gel is used for lesions of the mouth (p.1700). Choline salicylate has also been applied topically in a rubefacient preparation for the relief of muscular and rheumatic pain.

Choline salicylate is also given in the form of choline magnesium trisalicylate (see above).

Adverse effects. A 21-month-old boy developed salicylate poisoning after his mother had rubbed the contents of 3 tubes of *Bonjela* teething ointment (containing a total of 2.61 g of choline salicylate) on his gums over 48 hours.[1]

In another case, an 8-year-old boy with G6PD deficiency developed an oral mucosal burn a few hours after application of about half a tube of *Teejel* oral gel.[2] He developed mouth ulcers and displayed signs of apathy, lethargy, and nasal congestion 3 days after exposure. His condition improved after a week. The authors felt that G6PD deficiency may have been a contributing factor in the occurrence of adverse effects.

2. Sapir S, Bimstein E. Cholinsalicylate gel induced oral lesion: report of case. *J Clin Pediatr Dent* 2000; **24:** 103–6.

REYE'S SYNDROME. The link between aspirin use in children and the development of Reye's syndrome is established although the evidence for other salicylates could not be adequately evaluated (see p.22). However, a 20-month-old boy who had received a teething gel containing choline salicylate (applied in doses of 1.31 g daily, equivalent to acetylsalicylate 100 mg/kg daily, which exceeds the recommended dose) developed Reye's syndrome following a viral illness.[1] The authors noted that the MHRA in the UK were aware of two earlier reports suggesting an association between choline salicylate and Reye's syndrome.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Codeine is subject to abuse (see under Precautions, below), but produces less euphoria and sedation than morphine.

Neonatal abstinence syndrome. Some of the symptoms characteristic of the neonatal abstinence syndrome were seen in a neonate whose mother had taken about 90 mg of codeine daily during the last 2 months of pregnancy.[1]

1. Khan K, Chang J. Neonatal abstinence syndrome due to codeine. *Arch Dis Child* 1997; **76:** F59–F60.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

In therapeutic doses codeine is much less liable than morphine to produce adverse effects, although constipation may be troublesome with long-term use. After large doses of codeine, excitement and convulsions may occur.

Codeine, like morphine, has a dose-related histamine-releasing effect. Anaphylactic reactions after intravenous use have been reported rarely.

Effects on mental function. Central effects of codeine phosphate appeared to be limited, but dose-related, in subjects given 30, 60, or 90 mg; visuo-motor coordination was altered with doses of 60 and 90 mg and dynamic visual acuity with 90 mg.[1] Drowsiness reported by subjects given 90 mg of codeine phosphate could not be linked with impaired performance whereas nausea could.

1. Bradley CM, Nicholson AN. Effects of a μ-opioid receptor agonist (codeine phosphate) on visuo-motor coordination and dynamic visual acuity in man. *Br J Clin Pharmacol* 1986; **22:** 507–12.

Effects on the pancreas. A 26-year-old woman developed acute pancreatitis on 2 separate occasions a few hours after taking a single, 40-mg dose of codeine.[1] There was no history of alcohol consumption and her recovery was uneventful. Other cases have been reported.[2-5]

Effects on the skin. Pruritus and burning erythemato-vesicular plaques that developed in a patient in response to oral codeine were attributed to a fixed drug eruption.[1] A similar reaction occurred in another patient after taking various analgesics including a combined preparation of paracetamol and codeine;[2] patch testing showed a positive response for codeine only. Maculopapular rash has been seen as part of a hypersensitivity syndrome associated with oral codeine phosphate;[3] fever, splenomegaly, and lymphadenopathy also occurred.

Hypersensitivity. See Effects on the Skin, above.

Overdosage. Acute codeine intoxication in 430 children, due to accidental ingestion of antitussive preparations, was reviewed.[1] The children were nearly all between 1 and 6 years old. Symptoms in decreasing order of frequency included somnolence, rash, miosis, vomiting, itching, ataxia, and swelling of the skin. Respiratory failure occurred in 8 children and 2 died; all 8 had taken 5 mg/kg or more. Infants are at special risk and there have been fatalities[2,3] and severe adverse effects[4,5] after inappropriate treatment in infants given mixtures containing codeine.

Opioid toxicity, in addition to severe salicylate toxicity, has occurred in adults after overdoses of aspirin and codeine tablets.[6]

Precautions

As for Opioid Analgesics in general, p.103.

Abuse. Although the risk of dependence on codeine is low with normal use,[1] it is the subject of deliberate abuse. In France[2] and in the UK linctuses containing codeine have been particularly liable to abuse. Reports in the literature include the use in New Zealand of codeine-containing preparations to produce demethylated products known as "Homebake" containing variable amounts of morphine[3] and abuse of co-codaprin tablets for their codeine content.[4-6]

Breast feeding. Breast-fed infants of mothers taking codeine may be at an increased risk of toxicity from its metabolite, morphine, if the mother is an ultrarapid metaboliser of codeine. In a recent report,[1] a 13-day-old infant died from opioid toxicity after being exposed to morphine in his mother's breast milk; the mother had been taking oral codeine 30 mg twice daily as part of a combination preparation with paracetamol for about 2 weeks. Assayed morphine concentrations in the breast milk were found to be 87 nanograms/mL; the usual range is 1.9 to 20.5 nanograms/mL after repeated doses of codeine 60 mg four times daily. Subsequent investigations found that the mother's genotype for the cytochrome P450 isoenzyme CYP2D6 (the enzyme involved in the conversion of codeine to morphine) classified her as an ultrarapid metaboliser of codeine.

Based on this case, the FDA has advised[2] that nursing mothers taking codeine should be informed of the potential risk of morphine overdose and the need to monitor breast-fed infants for signs of toxicity such as increased sleepiness, difficulty feeding or breathing, or limpness. Nursing mothers, themselves, may also experience overdose symptoms including extreme sleepiness, confusion, shallow breathing, and severe constipation. Similar advice has also been issued by the MHRA in the UK.[3] Nonetheless, codeine appears to have been used safely for many years in breast-feeding mothers and several authorities including the American Academy of Pediatrics[4] and the *BNF* consider that it is usually compatible with breast feeding.

Genetic polymorphism. Life-threatening toxicity in a patient given moderate doses of codeine was thought to be due to a genotype predisposing him to ultrarapid metabolism of the drug into morphine by the cytochrome P450 isoenzyme CYP2D6, coupled with drug-induced inhibition of the usual major metabolic pathway mediated by CYP3A4, and transient reduction in renal function.[1] For a report of the effect of this genotype in a breast-feeding mother, see Breast Feeding, above.

Pregnancy. See Neonatal Abstinence Syndrome under Dependence and Withdrawal, above.

Renal impairment. The renal clearance of codeine and its metabolites is significantly reduced in patients with end-stage renal disease on regular haemodialysis therapy. One such elderly patient developed tonic-clonic seizures 7 days after starting oral codeine phosphate 30 mg 4 times daily; no further seizures occurred after codeine was stopped and naloxone started.[1] The dosage of codeine should be reduced according to renal function in patients with renal impairment but no specific recommendations appear to be given in the literature.

Interactions

For interactions associated with opioid analgesics, see p.103.

Quinidine. For reference to a suggestion that quinidine can inhibit the analgesic effect of codeine, see Metabolism under Pharmacokinetics, below.

Pharmacokinetics

Codeine and its salts are absorbed from the gastrointestinal tract. Rectal absorption of codeine phosphate has been reported. Ingestion of codeine phosphate produces peak plasma-codeine concentrations in about one hour. Codeine is metabolised by *O*- and *N*-demethylation in the liver to morphine, norcodeine, and other metabolites including normorphine and hydrocodone. Metabolism to morphine is mediated by the cytochrome P450 isoenzyme CYP2D6, which shows genetic polymorphism. Codeine and its metabolites are excreted almost entirely by the kidney, mainly as conjugates with glucuronic acid.

The plasma half-life has been reported to be between 3 and 4 hours after an oral or intramuscular dose.

Codeine crosses the placenta and is distributed into breast milk.

Administration. In a comparative study[1] codeine had an oral/intramuscular analgesic relative potency ratio of 6:10. This was high compared with that of morphine and was attributed to protection from rapid first-pass metabolism rather than more efficient absorption after oral doses. In a comparative study in children[2] the absorption rate of codeine from a suppository was found to be similar to that from an intramuscular injection; however, peak plasma concentrations were not as high when given rectally.

Metabolism. The analgesic effect of codeine may be partly due to its metabolite morphine and it has been suggested that its efficacy may be impaired in patients who are poor metabolisers of codeine[1-4] or in those who are also receiving drugs, such as quinidine, that impair its metabolism.[1] However, patients unable to demethylate codeine to produce detectable plasma concentrations of morphine obtained a similar analgesic effect to patients with detectable plasma morphine concentrations.[5] A study[6] involving infants aged 6 to 10 months has indicated that children were capable of demethylating codeine to morphine at the age of 6 months although glucuronidation of the morphine appeared to be impaired when compared with older children.

Uses and Administration

Codeine, a phenanthrene derivative, is an opioid analgesic (p.104) obtained from opium or made by methylating morphine. It is much less potent as an analgesic than morphine and has relatively mild sedative effects.

Codeine or its salts, especially the phosphate, are given orally in the form of linctuses for the relief of cough, and as tablets for the relief of mild to moderate pain, often with a non-opioid analgesic such as aspirin, ibuprofen, or paracetamol. The phosphate is also given by intramuscular or subcutaneous injection, in doses similar to those used orally, for the relief of pain; the intravenous and rectal routes have also been used.

For the relief of **pain** codeine phosphate may be given in doses of 30 to 60 mg every 4 hours to a usual maximum of 240 mg daily.

To allay non-productive **cough** codeine phosphate may be given in doses of 15 to 30 mg three or four times daily.

Codeine phosphate is also used as tablets or in mixtures for the symptomatic relief of **acute diarrhoea** in doses of 15 to 60 mg given 3 or 4 times daily.

For details of doses in children, see below.

Other codeine salts used include the hydrochloride, sulfate, camsilate, and hydrobromide. Codeine polistirex (a codeine and sulfonated diethenylbenzene-ethenylbenzene copolymer complex) is used in modified-release preparations.

Administration in children. Licensed product information for codeine in the treatment of *pain* often restricts its use to those over 1 year of age, but some authorities consider codeine to be an effective analgesic in neonates and children.[1] In the UK, the *BNFC* suggests that neonates and children aged up to 12 years may be given codeine phosphate 0.5 to 1 mg/kg every 4 to 6 hours for mild to moderate pain up to the usual adult maximum dose of 240 mg daily; these doses can be given orally, rectally, or by the subcutaneous or intramuscular routes. Guidelines[2] for analgesia in children in Accident and Emergency departments in the UK recommend the use of oral codeine as an alternative, or in addition, to diclofenac, for moderate pain such as that associated with small burns or scalds, finger tip injuries, or appendicitis. With a single dose of codeine phosphate 1 mg/kg given orally or by intramuscular injection there was a relatively small risk of respiratory depression in neonates, but significant respiratory depression has occurred with multiple doses and patients should be observed closely.[1] Case reports of adverse reactions such as vasodilatation, severe hypotension, and apnoea in infants and children after intravenous doses of codeine have precluded its use by this route in children of all ages.[3]

Antimotility drugs such as codeine should not be used in infants and young children with acute *diarrhoea*.[4,5]

The *BNFC* advises that *cough* suppressants containing pholcodine or similar opioids (such as codeine) are generally not recommended for children and should be avoided in those under 2 years of age. However, codeine phosphate is licensed to allay non-productive cough and children aged 1 to 5 years may be given 3 mg three or four times daily; and those aged 5 to 12 years, 7.5 to 15 mg three or four times daily.

Children and adolescents aged 12 years and over may be given the usual adult doses of codeine phosphate for all these indications (see above).

Cough. A systematic review[1] of over-the-counter preparations for acute cough concluded that codeine appeared no more effective than placebo in reducing cough symptoms in adults or children, although the number of patients in the studies considered was small.

Systematic reviews[1,2] comparing paracetamol-codeine combinations versus paracetamol alone concluded that in single-dose studies addition of codeine to paracetamol produced a comparatively small but statistically significant increase in analgesic effect; however, there was an increased incidence of adverse effects with the combination.

Pharmacopoeias. *Chin.* includes fruits of *Croton tiglium.*

Profile

Croton oil is an oil expressed from the seeds of *Croton tiglium* (Euphorbiaceae). Externally, it is a powerful counter-irritant and vesicant. Croton oil is also used with phenol in cosmetic chemical peeling of the skin.

Croton oil has such a violent purgative action that it should not be used as a laxative. Croton oil contains phorbol esters, which are carcinogenic.

Homoeopathy. Croton has been used in homoeopathic medicines under the following names: Croton tiglium; Crot. tig.

Contains not less than 1.2% harpagoside ($C_{24}H_{30}O_{11}$ = 494.5), calculated with reference to the dried drug. Protect from light.

Profile

Devil's claw root is used in herbal remedies for musculoskeletal and joint disorders. Its activity is attributed in part to the plant's content of iridoid glycosides, notably harpagoside.

Pain. Preparations containing devil's claw root have been tried with some success in the treatment of musculoskeletal disorders such as low back pain and osteoarthritis. There is some evidence of efficacy for daily doses standardised to 50 to 100 mg harpagoside but the quality of reporting in trials is generally poor and further studies are needed to establish its place in therapy.[1,2]

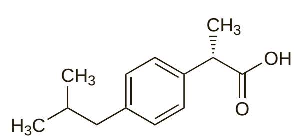
Dexibuprofen *(BAN, USAN, rINN)*

Deksibuprofeeni; Dexibuprofène; Dexibuprofeno; Dexibuprofenum; *S*-(+)-Ibuprofen.
Дексибупрофен
CAS — 51146-56-6.
ATC — M01AE14.
ATC Vet — QM01AE14.



Profile

Dexibuprofen is the *S*(+)-enantiomer of ibuprofen (p.64) and is used similarly in the management of mild to moderate pain and inflammation in conditions such as dysmenorrhoea, headache, postoperative pain, dental pain, sprains, and soft-tissue rheumatism. It is also used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis. It may be used as an antipyretic to reduce fever.

The usual adult dose is 600 to 900 mg daily by mouth in up to 3 divided doses, adjusted according to response, to a usual maximum of 1.2 g daily. Elderly patients should be started at the lower end of the dose range; dosage may then be increased according to tolerance. Dose reductions are also recommended in patients with hepatic or renal impairment, see below.

For doses in children, see below.

Administration in children. Although dexibuprofen is not licensed for use in children under 18 years of age in the UK, some countries permit such use. For example, in Switzerland, dexibuprofen has been given to children aged 6 years and over; usual oral doses are 10 to 15 mg/kg daily in 2 to 4 divided doses. Licensed product information for one preparation recommends a maximum dose of 300 mg daily for those weighing less than 30 kg.

Administration in hepatic and renal impairment. UK licensed product information specifies that the initial dose of dexibuprofen should be reduced in patients with mild to moderate hepatic or renal impairment; it should not be used in those with severe impairment.

Pharmacokinetics. For mention of the metabolism of dexibuprofen, see p.65.

Adverse Effects

As for Opioid Analgesics in general, p.102.

In the recommended dosage the adverse effects of dextropropoxyphene are less marked than those of morphine. Gastrointestinal effects, dizziness, and drowsiness are the most common. Liver impairment, manifest as abnormal liver function tests and, more rarely, as reversible jaundice, has been reported.

There have been a large number of fatalities from either accidental or intentional overdosage with dextropropoxyphene. Many reports emphasise the rapidity with which death ensues; death within an hour of overdosage is not uncommon, and it can occur within 15 minutes. Overdosage is often complicated by patients also taking other CNS depressants such as alcohol and using mixed preparations such as dextropropoxyphene with paracetamol or aspirin.

Symptoms of overdosage are similar to those of opioid poisoning in general, but in addition patients may experience psychotic reactions. There may be cardiac conduction abnormalities and arrhythmias.

Dextropropoxyphene injections are painful and have a very destructive effect on soft tissues and veins when abused in this way.

Anorectal reactions have followed the prolonged use of suppositories containing dextropropoxyphene; the reactions appear to be dose dependent.

Effects on the blood. A 12-year history of haemolysis and subsequent significant haemolytic anaemia in an elderly woman[1] was associated with chronic, periodic, and occasionally excessive intake of co-proxamol.

1. Fulton JD, McGonigal G. Steroid responsive haemolytic anaemia due to dextropropoxyphene paracetamol combination. *J R Soc Med* 1989; **82:** 228.

Effects on the ears. A report of complete nerve deafness associated with chronic abuse of co-proxamol was made to the UK CSM.[1] The CSM had received 2 other reports of permanent hearing loss attributed to co-proxamol abuse; transient hearing loss had also been reported in 2 patients taking usual doses; 7 further reports described tinnitus.

Effects on the liver. There have been occasional reports of jaundice in patients taking dextropropoxyphene alone but many of the 49 suspected hepatic reactions with dextropropoxyphene reported to the UK CSM by 1985[1] had involved use with paracetamol; clinical features including malaise, jaundice, raised serum transaminases, and sometimes fever, were however generally characteristic of dextropropoxyphene alone. Relapsing jaundice mimicking biliary disease was attributable to the dextropropoxyphene component of co-proxamol in 3 patients,[2] whereas there was no abnormality of liver function in 11 patients on long-term co-proxamol analgesia.[3] Another report of 9 cases found that the hepatotoxicity of dextropropoxyphene mimicked symptoms of large bile duct obstruction, and suggested that such toxicity might be misdiagnosed.[4] A more recent review[5] also concluded that hepatotoxicity with dextropropoxyphene might mimic a biliary tract disease, sometimes with few or no symptoms.

Overdosage. There have been several reviews or retrospective studies of acute self-poisoning with dextropropoxyphene.[1-4] At a symposium on the safety and efficacy of dextropropoxyphene[5] many of the participants dealt with the problems of dextropropoxyphene overdosage, often in conjunction with paracetamol and sometimes with alcohol. Profound and even fatal CNS depression can develop rapidly as a result of the dextropropoxyphene content and in many cases death has occurred within an hour;[6] it was suggested that as few as 15 to 20 tablets of co-proxamol may be fatal.[7,8] Analysis of suicides involving drugs in England and Wales between 1997 and 1999 revealed that the odds of dying after overdose with co-proxamol were 2.3 times that for tricyclic antidepressant overdose, and 28.1 times greater than for paracetamol.[9] Another analysis of suicides due to poisoning in 3 areas of the UK between 2000 and 2001 identified 123 cases of fatal overdose with co-proxamol;[10] those who also consumed alcohol had generally taken fewer co-proxamol tablets than those who had not, emphasising the increased toxicity of the combination.

An analysis of overdosage involving combination analgesic preparations prescribed in Scotland between 2000 and 2002 also found that overdoses with co-proxamol were 10 times more likely to be fatal when compared with co-dydramol or co-codamol.[11] In the USA[12] the incidence of dextropropoxyphene-associated deaths reached a peak in 1977 and then fell at a rate that was not matched by a decline in prescribing.

It is not clear whether the metabolite, nordextropropoxyphene, plays an important role in fatalities.[12] However, nordextropropoxyphene, like dextropropoxyphene, is considered to have local anaesthetic activity and the membrane stabilising activity of dextropropoxyphene has been implicated as a major factor responsible for its severe cardiac depressant effect.[13]

In January 2005, the UK CSM found the risk of toxicity of co-proxamol in overdose to be unacceptable;[14] consequently, co-proxamol has been gradually withdrawn from the UK market. Fixed-dose combinations of dextropropoxyphene and paracetamol have also been withdrawn in several other countries including Sweden and Switzerland.

Treatment of Adverse Effects

As for Opioid Analgesics in general, p.102.

Rapid treatment of overdosage with naloxone and assisted respiration is essential. Cardiac effects may not be reversed by naloxone. Gastric lavage and activated charcoal may be of value within 1 hour of ingestion, but dialysis is of little use.

Convulsions may require control with an anticonvulsant, bearing in mind that the CNS depressant effects of dextropropoxyphene can be exacerbated (see also Interactions, below). Stimulants should not be used because of the risk of inducing convulsions.

Patients taking overdoses of dextropropoxyphene with paracetamol will also require treatment for paracetamol poisoning (p.108). Mixtures of dextropropoxyphene and aspirin may be involved; the treatment of aspirin poisoning is described on p.20.

Precautions

As for Opioid Analgesics in general, p.103.

Abuse. There have been reports[1] of the abuse of dextropropoxyphene, and some[2] considered that the ready availability of dextropropoxyphene made it liable to abuse although it was a relatively weak opioid analgesic. However, others[3] thought there was no evidence that dextropropoxyphene was frequently associated with abuse, or concluded that, although there was abuse potential, it was of relatively low importance in terms of the community as a whole.[4]

A severe withdrawal syndrome has been reported[5] in an elderly patient who covertly consumed a daily dose of dextropropoxyphene of 1 to 3 g for at least 12 months. The patient was treated by a gradually decreasing dosage schedule of dextropropoxyphene over 9 weeks.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving dextropropoxyphene, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. The *BNF* also considers that the amount of dextropropoxyphene in breast milk is too small to be harmful.

Porphyria. Dextropropoxyphene has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with opioid analgesics, see p.103.

Plasma concentrations of dextropropoxyphene are increased by ritonavir, with a resultant risk of toxicity; they should not be given together.

CNS depressants, including alcohol, may contribute to the hazards of dextropropoxyphene, see also Overdosage, above. The convulsant action of high doses of dextropropoxyphene may be enhanced by CNS stimulants.

Dextropropoxyphene interacts with several other drugs through inhibition of liver metabolism. Drugs reported to be affected include antidepressants (see p.379), benzodiazepines (see p.989), beta blockers (see p.1229), carbamazepine (see p.474), phenobarbital (see p.493), phenytoin (see p.497), and warfarin (see p.1427).

Antimuscarinics. A suggested interaction between *orphenadrine* and dextropropoxyphene has been questioned (see p.812).

Pharmacokinetics

Dextropropoxyphene is readily absorbed from the gastrointestinal tract, the napsilate tending to be more slowly absorbed than the hydrochloride, but both are subject to considerable first-pass metabolism. Peak plasma concentrations occur about 2 to 2.5 hours after ingestion. It is rapidly distributed and concentrated in the liver, lungs, and brain. About 80% of dextropropoxyphene and its metabolites are reported to be bound to plasma proteins. Dextropropoxyphene crosses the placenta. It has been detected in breast milk.

Dextropropoxyphene is *N*-demethylated to nordextropropoxyphene (norpropoxyphene) in the liver. It is excreted in the urine mainly as metabolites. It is now recognised that dextropropoxyphene and nordextropropoxyphene have prolonged elimination half-lives; values of 6 to 12 hours and 30 to 36 hours, respectively, have been reported. Accumulation of dextropropoxyphene and its metabolites may occur with repeated doses and nordextropropoxyphene may contribute to the toxicity seen with overdosage.

The elderly. The elimination half-lives of dextropropoxyphene and its metabolite nordextropropoxyphene were prolonged in healthy elderly subjects when compared with young controls.[1] After multiple dosing median half-lives of dextropropoxyphene and nordextropropoxyphene were 36.8 and 41.8 hours, respectively in the elderly compared with 22.0 and 22.1 hours in the young subjects. In this study[1] there was a strong correlation between half-life of nordextropropoxyphene and estimated creatinine clearance.

Hepatic impairment. Plasma concentrations of dextropropoxyphene were higher in patients with cirrhosis given the drug than in healthy subjects whereas concentrations of nordextropropoxyphene were lower.[1]

Renal impairment. Higher and more persistent plasma concentrations of dextropropoxyphene and nordextropropoxyphene in anephric patients when compared with healthy subjects[1] were attributed to decreased first-pass metabolism of dextropropoxyphene and decreased renal excretion of nordextropropoxyphene in the anephric patients.

Uses and Administration

Dextropropoxyphene is an opioid analgesic (p.104) structurally related to methadone (p.82). It has mild analgesic activity and is given orally as the hydrochloride or napsilate to alleviate mild to moderate pain. Unlike the laevo-isomer (levopropoxyphene), dextropropoxyphene has little antitussive activity.

Dextropropoxyphene is mainly used with other analgesics that have anti-inflammatory and antipyretic effects, such as aspirin or paracetamol. In the USA the usual dose is 65 mg of the hydrochloride or 100 mg of the napsilate given every 4 hours up to a maximum total daily dose of 390 mg or 600 mg, respectively. In the UK similar doses have been given three or four times daily.

The combination preparation co-proxamol (dextropropoxyphene with paracetamol) has been gradually withdrawn from the UK market (see also Pain, below) although such combinations may remain available in a number of countries.

Pain. A detailed review[1] of the analgesic effectiveness of dextropropoxyphene suggested that with respect to single oral doses, recommended doses of dextropropoxyphene were no more (and probably less) effective than usual doses of paracetamol, aspirin, or other NSAIDs. However, the comparative effectiveness may vary substantially depending on the cause of the pain.

When it comes to comparative studies involving combinations of dextropropoxyphene with other analgesics, findings are even less clear-cut.[2] The effectiveness of co-proxamol has long been a matter of controversy yet despite this a survey[3] conducted in 30 UK teaching hospitals found that co-proxamol was the most widely used paracetamol-containing analgesic. It was suggested that the popularity of co-proxamol was purely down to prescribing habits passed on to new medical staff, rather than hard evidence regarding efficacy. This view has been refuted by others[4] who say that a large number of studies have shown clear analgesic effects for dextropropoxyphene. However, any assumption that the combination was widely used because it was more effective than paracetamol alone was not supported by a systematic overview of single-dose studies.[5] This concluded that while co-proxamol was indeed an effective analgesic it was no better than paracetamol alone. Although the evidence from this and other systematic reviews indicate that co-proxamol should be replaced by paracetamol alone for acute pain, the position for chronic use is considered to be not so clear (but see below).[6]

In January 2005, the UK CSM found the efficacy of co-proxamol to be poorly established and its risk of toxicity in overdose to be unacceptable;[7] they considered that there was no robust evidence of the superior efficacy of co-proxamol to full-strength paracetamol alone in either acute or chronic pain. Consequently, co-proxamol has been gradually withdrawn from the UK market. Fixed-dose combinations of dextropropoxyphene and paracetamol have also been withdrawn in several other countries including Sweden and Switzerland.

Profile

Diacerein is an anthraquinone derivative that is used in osteoarthritis (p.11) in oral doses of 50 mg twice daily. Doses should be halved in patients with creatinine clearance less than 30 mL/minute. Diarrhoea is a common adverse effect with diacerein. Its active metabolite, rhein, a constituent of rhubarb (p.1768), is reported to act as an interleukin-1 inhibitor.

Administration in renal impairment. See above and Pharmacokinetics, below.

Musculoskeletal and joint disorders. Diacerein is thought to act via inhibition of interleukin-1β,[1] which plays a role in inflammatory processes. Systematic reviews[2,3] on the use of diacerein in the treatment of osteoarthritis have indicated that diacerein produces a small, but consistent, improvement in pain. Further research is necessary to confirm its short- and long-term effectiveness and safety but there is some evidence of residual benefit on stopping treatment,[3] which has been postulated to represent an improvement in the disease process.

Pharmacopoeias. In *Br.* and *Swiss. Swiss* also includes the anhydrous form.

BP 2008 (Diamorphine Hydrochloride). A white or almost white crystalline powder, odourless when freshly prepared but develops an odour characteristic of acetic acid on storage. Freely soluble in water and in chloroform; soluble in alcohol; practically insoluble in ether. Protect from light.

Incompatibility. Diamorphine hydrochloride is incompatible with mineral acids and alkalis and with chlorocresol.[1]

The *BNF* notes that cyclizine may precipitate from mixtures with diamorphine hydrochloride at concentrations of cyclizine greater than 10 mg/mL, or in the presence of sodium chloride 0.9%, or as the concentration of diamorphine relative to cyclizine increases; mixtures of diamorphine and cyclizine are also liable to precipitate after 24 hours.

It also considers that mixtures of diamorphine and haloperidol are liable to precipitate after 24 hours if the haloperidol concentration is above 2 mg/mL. Under some conditions mixtures of metoclopramide and diamorphine may become discoloured and should be discarded.

Stability. Diamorphine is relatively unstable in aqueous solution and is hydrolysed to 6-*O*-monoacetylmorphine and then morphine to a significant extent at room temperature; 3-*O*-monoacetylmorphine is only occasionally detected. The rate of decomposition is at a minimum at about pH 4.[1,2]

In a study of the stability of aqueous solutions of diamorphine in chloroform water it was concluded that such solutions should be used within 3 weeks of preparation when stored at room temperature.[3] Another study[4] noted that the degradation products of diamorphine were not devoid of analgesic activity. Using a more sensitive analytical method it was reported that although the pH range of maximum stability of diamorphine in aqueous solution was 3.8 to 4.4, the addition of buffers reduced stability.[5] Simple unbuffered chloroform water gave maximum stability, the shelf-life of such a solution being 4 weeks at room temperature.

The BP 2008 recommends that solutions for injection be prepared immediately before use by dissolving Diamorphine Hydrochloride for Injection in Water for Injections. This may pose a problem with solutions for subcutaneous infusion when concentrated solutions may remain in infusion pump reservoirs for some time.[6] Investigation of 9 concentrations of diamorphine stored at 4 different temperatures for 8 weeks[7] revealed instability under conditions of concentration, time, and temperature prevalent during subcutaneous infusion. Degradation of diamorphine occurred at all concentrations (0.98 to 250 mg/mL) at temperatures of 4° and above; the effect of temperature was significant at 21° and 37°. The percentage fall in diamorphine concentration was directly related to initial concentration and was accompanied by a corresponding increase in 6-*O*-monoacetylmorphine and, to a lesser extent, morphine; other possible breakdown products such as 3-*O*-monoacetylmorphine were not present in detectable quantities. Diamorphine degradation was associated with a fall in pH and the development of a strong acetic acid-like odour. Precipitation and a white turbidity was seen in solutions of 15.6 mg/mL and above after incubation for 2 weeks at 21° and 37°. It has been noted that solutions for infusion are generally freshly prepared and used within 24 hours, but that signs of precipitation should be watched for, especially when using longer-term infusions and high concentrations of diamorphine.[7]

In another stability study[8] diamorphine hydrochloride in concentrations of both 1 and 20 mg/mL in sodium chloride 0.9% was stable for a minimum of 15 days at room temperature (23° to 25°) and 4° when stored in a PVC container. In one type of disposable infusion device (Infusor) similar solutions were stable for 15 days even at 31°. In another infusion device (Intermate 200) diamorphine was stable for a minimum of 15 days at both concentrations and all temperatures except for the 1 mg/mL solution kept at 31° when stability was only maintained for a minimum of 2 days. When stored in glass syringes both strengths of diamorphine hydrochloride were stable for 15 days at 4° and at room temperature the 1 mg/mL solution was stable for a minimum of 7 days and the 20 mg/mL solution was stable for a minimum of 12 days. There were no substantial changes in physical appearance or pH.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Diamorphine is subject to abuse (see under Adverse Effects, Treatment, and Precautions, below).

Diamorphine is used for substitution therapy in the management of opioid dependence (see under Uses and Administration, below).

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

Pulmonary oedema after overdosage is a common cause of fatalities among diamorphine addicts. Nausea and hypotension are claimed to be less common than with morphine.

There are many reports of adverse effects associated with the abuse of diamorphine, usually obtained illicitly in an adulterated form.

Abuse. Most of the reports of adverse effects with diamorphine involve its abuse. In addition to the central effects, there are effects caused by the administration methods and by the adulterants.[1,2] Thus in many instances it is difficult to identify the factor causing the toxicity. Most body systems are involved including the immune system,[3] kidneys,[4,5] liver,[6] respiratory system,[7-10] and the nervous system.[11-16]

Other aspects of the illicit use of diamorphine include fatal overdose[17] and smuggling by swallowing packages of drug[18,19] or other methods of internal bodily concealment.

Administration. Although generally free from complications, sterile abscess formation was reported in 2 patients with advanced cancer receiving diamorphine by continuous *subcutaneous* infusions.[1] Acute dysphoric reactions have been reported after the use of *epidural* diamorphine.[2]

Breast feeding. The American Academy of Pediatrics has stated[1] that, when used as a drug of abuse by breast-feeding mothers, diamorphine has caused adverse effects in the infant, notably tremors, restlessness, vomiting, and poor feeding. However, the *BNF* considers that diamorphine when given in therapeutic doses to a breast-feeding mother is unlikely to affect the breast-fed infant.

Hypersensitivity. Anaphylaxis occurred in a patient given *intrathecal* diamorphine and bupivacaine for surgical anaesthesia;[1] the authors noted that the patient received patient-controlled analgesia with morphine shortly after the reaction without problem. Subsequent skin prick tests identified diamorphine as the likely causative agent.

Interactions

For interactions associated with opioid analgesics, see p.103.

Pharmacokinetics

Diamorphine hydrochloride is well absorbed from the gastrointestinal tract, although this may be erratic, and after subcutaneous or intramuscular injection. On injection it is rapidly hydrolysed to the active metabolite 6-*O*-monoacetylmorphine (6-acetylmorphine) in the blood and then to morphine (p.88). Oral doses are subject to extensive first-pass metabolism to morphine; neither diamorphine nor 6-acetylmorphine have been detected in the blood after giving diamorphine by this route. Both diamorphine and 6-acetylmorphine readily cross the blood-brain barrier. Morphine glucuronides are the main excretion products in the urine. A small amount is excreted in the faeces.

Administration. *INHALATIONAL ROUTE.* A literature review[1] found that intranasal diamorphine had a similar pharmacokinetic profile to that of intramuscular diamorphine. It is rapidly absorbed, as a dry powder, via the nasal mucosa although this is not as complete as by intramuscular injection; intranasal absorption appeared to be dose dependent.

The pharmacokinetics of inhaled diamorphine fumes ("chasing the dragon") has been studied[2] in diamorphine addicts receiving substitution therapy with diamorphine and methadone. Absorption through the lungs occurred very rapidly and was virtually complete immediately after inhalation; bioavailability was estimated to be about 53%.

INTRASPINAL ROUTE. Diamorphine is much more lipid-soluble and has a more rapid onset and shorter duration of action than morphine. Although deacetylation to morphine occurs rapidly in the blood it occurs only slowly in the CSF after intraspinal injection of diamorphine.[1] After intrathecal injection diamorphine was removed from the CSF much more rapidly than morphine.[2] Peak plasma concentrations of morphine after epidural diamorphine injection were significantly higher and were achieved significantly faster than after epidural injection of morphine.[3]

Children. Loading doses of either 50 micrograms/kg or 200 micrograms/kg of diamorphine were given as an infusion over 30 minutes to 19 ventilated neonates followed by a continuous infusion of 15 micrograms/kg per hour, and the pharmacokinetics of the products of diamorphine metabolism (morphine, morphine-6-glucuronide, and morphine-3-glucuronide) studied.[1] Although the overall elimination of morphine was reduced compared with adults, the relative contributions of the various metabolic routes of morphine remained similar between neonates and adults. Data from this study did not indicate any advantage for the higher loading dose (see also under Uses and Administration, below).

Uses and Administration

Diamorphine hydrochloride is an acetylated morphine derivative and is a more potent opioid analgesic (p.104) than morphine (p.89). Diamorphine is used for the relief of severe pain especially in palliative care. It is also used similarly to morphine for the relief of dyspnoea due to pulmonary oedema resulting from left ventricular failure. Diamorphine has a powerful cough suppressant effect and has been given as Diamorphine Linctus (BPC 1973) to control cough associated with terminal lung cancer although morphine is now preferred.

In the treatment of **acute pain** usual doses of diamorphine hydrochloride by subcutaneous or intramuscular injection are 5 to 10 mg every 4 hours. Doses equivalent to one-quarter to one-half of the corresponding intramuscular dose may be given by slow intravenous injection.

For the pain of myocardial infarction doses of 5 mg are given by slow intravenous injection at a rate of 1 mg/minute with a further dose of 2.5 to 5 mg if required; doses may be reduced by one-half for elderly or frail patients. Doses of 2.5 to 5 mg may be given intravenously at the same rate for acute **pulmonary oedema**.

For **chronic pain** 5 to 10 mg may be given by subcutaneous or intramuscular injection every 4 hours; the dose may be increased according to needs. Similar doses may be given orally, although it is converted to morphine by first-pass metabolism (see Pharmacokinetics, above). Diamorphine hydrochloride may also be given by continuous subcutaneous or intravenous infusion or intraspinally.

For details of doses in children, see below.

Action. Because of its abuse potential, supply of diamorphine is carefully controlled and in many countries it is not available for clinical use; morphine can provide equivalent analgesia by dose adjustment. There has been much debate regarding the relative merits of analgesia with diamorphine or morphine. Many now regard oral morphine to be the opioid analgesic of choice although diamorphine hydrochloride may be preferred for injection because it is more soluble in water thus allowing the use of smaller dose volumes. Diamorphine hydrochloride may also be preferred to morphine salts for intraspinal use because it is more lipid-soluble.

As a guide to relative potency diamorphine hydrochloride 5 mg given intramuscularly is equivalent to about 10 mg given orally, which in turn is equivalent to about 15 mg of oral morphine sulfate. When given by subcutaneous infusion, diamorphine hydrochloride 10 mg every 24 hours is equivalent to about 15 mg every 24 hours of morphine sulfate.

Administration in children. In the treatment of acute or chronic pain in children, the *BNFC* suggests the following doses according to age:

by continuous intravenous infusion

- neonates with spontaneous respiration may be given 2.5 to 7 micrograms/kg per hour
- ventilated neonates may be given 50 micrograms/kg initially by intravenous injection over 30 minutes followed by 15 micrograms/kg per hour by continuous intravenous infusion
- 1 month to 12 years, 12.5 to 25 micrograms/kg per hour

by intravenous injection

- 1 to 3 months, 20 micrograms/kg every 6 hours if necessary
- 3 to 6 months, 25 to 50 micrograms/kg every 6 hours if necessary
- 6 to 12 months, 75 micrograms/kg every 4 hours if necessary
- 1 to 12 years, 75 to 100 micrograms/kg every 4 hours if necessary

by mouth

- 1 month to 12 years, 100 to 200 micrograms/kg (maximum of 10 mg) every 4 hours if necessary

In a study[1] of the effects of diamorphine in 34 premature infants (gestational age 26 to 40 weeks), a loading dose of 50 micrograms/kg given as an *intravenous* infusion over 30 minutes followed by a continuous infusion at a rate of 15 micrograms/kg per hour was considered to be safe and resulted in plasma concentrations of morphine comparable with those that usually produce adequate analgesia in children and adults; the duration of the infusion ranged from 14 to 149 hours. Small but significant reductions in heart rate and mean blood pressure were noted but these were not associated with any clinical deterioration. The fall in respiration rate reflected the desired intention to encourage synchronisation of the infants' breathing with the ventilator. The authors concluded that intravenous diamorphine could be given safely to neonates and would provide adequate analgesia. A later study[2] indicated that the use of a 200 micrograms/kg loading dose conferred no benefit over a 50 micrograms/kg dose and might produce undesirable physiological effects. In a comparative study[3] with morphine (200 micrograms/kg loading dose over 2 hours, followed by maintenance infusion of 25 micrograms/kg per hour) in ventilated preterm neonates requiring sedation, diamorphine (120 micrograms/kg over 2 hours and then 15 micrograms/kg per hour) was as effective as morphine in producing sedation and also had a faster onset of action. The small but significant drop in blood pressure noted during morphine infusions was not seen with diamorphine infusions.

The *subcutaneous* route appeared to be as effective and safe as the intravenous route for infusions in children for postoperative pain relief after elective abdominal surgery.[4] The dose of diamorphine used in both groups of children was 1 mg/kg given at a rate of 20 micrograms/kg per hour.

Intranasal diamorphine has been investigated in adults and children, and appears to be effective and well tolerated; because it does not require a needle it may offer particular advantages in children.[5] Guidelines[6] for analgesia in children in Accident and Emergency departments in the UK recommend the use of intranasal diamorphine for severe pain such as that associated with large burns, long bone dislocation, appendicitis, or sickle-cell crisis. A suggested dose to be instilled into one nostril is 100 micrograms/kg given in 0.2 mL of sterile water.

Opioid dependence. The treatment of opioid dependence is discussed on p.101. Many opiate misusers have expressed a preference for withdrawal using diamorphine rather than methadone. In a comparative study stabilisation was achieved using either diamorphine or methadone 1 mg/mL oral solutions;[1] patients could not identify which they had been given. Whenever signs of physical withdrawal were seen 10 mL of either solution was given and the total amount over the first 24 hours taken as the patient's daily requirement. The mean dose of diamorphine required for stabilisation was 55 mg compared with 36 mg for methadone. Some centres have given diamorphine in the form of reefers. Diamorphine has also been prescribed with methadone in the management of addicts.[2] A systematic review[3] that included this study failed to produce conclusive results about the effectiveness of diamorphine (alone or with methadone) in maintenance treatment; however, since the studies were not directly comparable, continued evaluation in clinical studies is required. Oral tablets[4] and intravenous injection[5] of diamorphine have also been tried in severely dependent, treatment-resistant patients.

Breast feeding has been used to treat diamorphine dependence in the offspring of dependent mothers but this is no longer considered to be the best method and some authorities recommend that breast feeding should be stopped.

Pain. *ACUTE PAIN.* Rapid pain relief may be obtained with the intravenous injection of diamorphine. Other routes include the intraspinal route for which diamorphine is well suited because of its lipid solubility and pharmacokinetics. Epidural doses of diamorphine have ranged from 0.5 to 10 mg.[1] Analgesia was significantly more prolonged and more intense after epidural rather than intramuscular injection of diamorphine 5 mg in women who had had caesarean section;[2] itching was reported by 50% of patients undergoing epidural analgesia. Epidural diamorphine alone[3] or with bupivacaine[4] has been used for analgesia during labour; addition of adrenaline appeared to improve the quality and duration of analgesia with diamorphine.[3] In another study addition of diamorphine to bupivacaine produced a high incidence of pruritus and drowsiness.[5] A study[6] of patient-controlled analgesia for postoperative pain found that although epidural diamorphine, used alone or with bupivacaine, reduced the analgesic dose requirement, there was little clinical advantage over the subcutaneous route.

Continuous epidural infusion of diamorphine 500 micrograms/hour in 0.125% bupivacaine provided postoperative analgesia superior to that with either drug alone in patients undergoing major abdominal gynaecological surgery.[7] A similar infusion produced analgesia superior to that with either epidural bolus injection or patient-controlled intravenous diamorphine in patients undergoing total abdominal hysterectomy.[8] However, more patients receiving the continuous epidural infusion were hypoxaemic than in the other 2 groups.

Diamorphine has also been given intrathecally for postoperative analgesia and should be effective at lower doses than with the epidural route because of greater CSF concentrations. Diamorphine 250 or 500 micrograms given intrathecally with bupivacaine spinal anaesthesia both provided greater postoperative analgesia than bupivacaine alone,[9] but the incidence of adverse effects, especially nausea, vomiting, and urinary retention, was still high with either dose and routine use of this technique was not recommended. Intrathecal diamorphine with bupivacaine has also been used for analgesia during labour[10,11] and caesarean section.[12-16] In a study[12] in patients undergoing caesarean section, intrathecal diamorphine 250 micrograms showed comparable postoperative analgesia with a 5-mg epidural dose and was associated with less postoperative nausea and vomiting. Other studies[13,14] found that intrathecal diamorphine reduced supplemental analgesic requirements during and after caesarean section when compared with intrathecal fentanyl. Intrathecal diamorphine 400 micrograms was considered by some[15] to be the lowest dose required to reduce intraoperative analgesic supplementation to below 5%; however, lower doses of 300 micrograms have been used in practice.[16]

Diamorphine has been extensively used by cardiologists in the UK for the management of pain in acute left ventricular failure, unstable angina, and myocardial infarction. It has been theorised that diamorphine may offer benefits over morphine because its stimulatory effects at opioid δ receptors on the myocardium may reduce the extent of myocardial damage.[17] Evidence to support this theory is, however, lacking.

CHRONIC PAIN. Patients with chronic opioid-sensitive pain are often treated with diamorphine given by continuous subcutaneous infusion using a small battery-operated syringe driver. The following technique has been described.[1] Diamorphine hydrochloride 1 g could be dissolved in 1.6 mL of water to give a solution with a volume of 2.4 mL (415 mg/mL), but the maximum suggested concentration was 250 mg/mL. If the analgesic requirement was not known the following protocol was recommended:

- Start injections every 4 hours of 2.5 or 5 mg diamorphine, or, if the patient has already been taking opioids, a dose that is equivalent to the last dose
- If this is unsatisfactory increase this dose in 50% increments until the patient reports even a little pain relief
- Calculate the 24-hour requirement by multiplying by six, and start the infusion at this level
- Increase the 24-hour dosage in the pump by 50% increments until the pain is controlled. Note that requirements may vary from less than 20 mg to more than 5 g per 24 hours

When starting an infusion it is important not to allow any breakthrough pain. This may be achieved either by starting the infusion more than 2 hours before the previous oral dose wears off or by giving a loading dose injection of the 4-hourly requirement.

Although generally free from complications, sterile abscess formation was reported in 2 patients with advanced cancer receiving diamorphine by continuous subcutaneous infusions.[2]

The intraspinal[3] and intraventricular[4] routes have also been used successfully in patients with intractable pain. Topical application of diamorphine has also been tried[5,6] for the control of pressure ulcer pain in a small number of palliative care patients.

Preparations

BP 2008: Diamorphine Injection;
BPC 1973: Diamorphine Linctus.

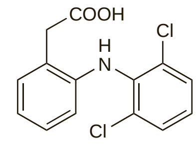
Proprietary Preparations (details are given in Part 3)
Switz.: Diaphin.

Diclofenac *(BAN, rINN)*

Diclofénac; Diclofenaco; Diclofenacum; Diklofenaakki; Diklofenak. [2-(2,6-Dichloroanilino)phenyl]acetic acid.

Диклофенак

$C_{14}H_{11}Cl_2NO_2$ = 296.1.
CAS — 15307-86-5.
ATC — D11AX18; M01AB05; M02AA15; S01BC03.
ATC Vet — QD11AX18; QM01AB05; QM02AA15; QS01BC03.



Diclofenac Diethylamine *(BANM)*

Diclofenac Diethylammonium; Diclofenaco dietilamina; Diklofenak Dietilamonyum.

Диклофенак Диэтиламин

$C_{18}H_{22}Cl_2N_2O_2$ = 369.3.
CAS — 78213-16-8.
ATC — D11AX18.
ATC Vet — QD11AX18.

Pharmacopoeias. In *Br.*

BP 2008 (Diclofenac Diethylamine). A white to light beige, crystalline powder. Sparingly soluble in water and in acetone; freely soluble in alcohol and in methyl alcohol; practically insoluble in 1M sodium hydroxide. The pH of a 1% solution in alcohol (10%) is between 6.4 and 8.4. Store in airtight containers. Protect from light.

Diclofenac Epolamine

DHEP; Diclofenac Hydroxyethylpyrrolidine.

Диклофенак Эполамин

$C_{14}H_{11}Cl_2NO_2,C_6H_{13}NO$ = 411.3.
CAS — 119623-66-4.
ATC — D11AX18.
ATC Vet — QD11AX18.

Diclofenac Potassium *(BANM, USAN, rINNM)*

CGP-45840B; Diclofénac potassique; Diclofenaco potásico; Diclofenacum kalicum; Diklofenaakkikalium; Diklofenak draselná sůl; Diklofenak Potasyum; Diklofenakkalium; Diklofenák-kálium; Diklofenako kalio druska; Kalii Diclofenacum. Potassium [o-(2,6-dichloroanilino)phenyl]acetate.

Калия Диклофенак

$C_{14}H_{10}Cl_2KNO_2$ = 334.2.
CAS — 15307-81-0.
ATC — D11AX18.
ATC Vet — QD11AX18.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Diclofenac Potassium). A white or slightly yellowish, slightly hygroscopic, crystalline powder. Sparingly soluble in water; soluble in alcohol; slightly soluble in acetone; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Diclofenac Potassium). pH of a 1% solution in water is between 7.0 and 8.5. Store at a temperature of 20° to 25°. Protect from light.

Diclofenac Sodium *(BANM, USAN, rINNM)*

Diclofénac sodique; Diclofenaco sódico; Diclofenacum natricum; Diclophenac Sodium; Diklofenaakkinatrium; Diklofenak sodná sůl; Diklofenak Sodyum; Diklofenaknatrium; Diklofenák-nátrium; Diklofenako natrio druska; GP-45840; Natrii Diclofenacum. Sodium [2-(2,6-dichloroanilino)phenyl]acetate.

Натрий Диклофенак

$C_{14}H_{10}Cl_2NNaO_2$ = 318.1.
CAS — 15307-79-6.
ATC — D11AX18.
ATC Vet — QD11AX18.

NOTE. DICL is a code approved by the BP 2008 for use on single unit doses of eye drops containing diclofenac sodium where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Diclofenac Sodium). A white to slightly yellowish, slightly hygroscopic, crystalline powder. Sparingly soluble in water; soluble in alcohol; slightly soluble in acetone; freely soluble in methyl alcohol. Store in airtight containers. Protect from light.

USP 31 (Diclofenac Sodium). A white to off-white, hygroscopic, crystalline powder. Sparingly soluble in water; soluble in alcohol; practically insoluble in chloroform and in ether; freely soluble in methyl alcohol. pH of a 1% solution in water is between 7.0 and 8.5. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

There may be pain and, occasionally, tissue damage at the site of injection when diclofenac is given intramuscularly. Diclofenac suppositories can cause local irritation. Transient burning and stinging may occur with diclofenac ophthalmic solution; more serious corneal adverse effects have also occurred (see Effects on the Eyes, below). Topical preparations of diclofenac, such as plasters and gel, may cause application site reactions.

Incidence of adverse effects. A review of worldwide clinical studies with diclofenac[1] has reported the incidence of drug-associated adverse effects to be about 12%; about 16% of patients who had adverse effects stopped treatment (a figure corresponding to about 2% of the entire patient sample). The most frequently reported adverse effects were gastrointestinal and were reported in 7.6% of patients. CNS-related adverse effects were reported in 0.7% of patients and allergy or local reactions in 0.4%. This and other reviews[2] have shown that adverse effects associated with diclofenac are usually mild and transient and appear to be unrelated to the dose given.

Effects on the blood. Results of a large survey undertaken to assess the relation between agranulocytosis, aplastic anaemia, and drug exposure indicated that diclofenac was significantly associated with aplastic anaemia, providing an estimated tenfold increase in risk.[1] There are reports of other haematological abnormalities including haemolytic anaemia,[2,3] thrombocytopenia,[4,5] neutropenia,[5] and agranulocytosis[6] occurring in patients given diclofenac.

Localised spontaneous bleeding,[7] bruising,[8] inhibition of platelet aggregation,[7] and prolonged bleeding time[8] have been reported.

Effects on the cardiovascular system. For a discussion of the cardiovascular effects of NSAIDs, including diclofenac, see p.96.

Effects on electrolytes. A syndrome resembling the syndrome of inappropriate antidiuretic hormone secretion has been reported in elderly women given diclofenac.[1,2] Also the UK CSM had received a report of fatal hyponatraemia in another elderly woman.[2]

Effects on the eyes. A patient who had been taking oral diclofenac for several years and had increasingly complained of dry, gritty eyes noticed that eye irritation disappeared within 3 days when diclofenac had to be stopped because of gastrointestinal effects.[1]

Ocular diclofenac and related drugs have been implicated in reports of corneal toxicity. Ulceration of the conjunctiva or cornea, corneal or scleral melts, and perforations have been reported in patients using diclofenac eye drops, particularly after cataract surgery.[2-5] Keratitis and perforations were also reported with ketorolac eye drops,[4] although less frequently. Effects on the gastrointestinal tract. The most frequent adverse effects reported in patients given diclofenac systemically are gastrointestinal in nature. Typical reactions include epigastric pain, nausea, vomiting, and diarrhoea. Rarely peptic ulcer and gastrointestinal bleeding have occurred. Diclofenac has also been implicated as the causative agent in colonic ulceration,[1] small bowel perforation,[2] and pseudomembranous colitis.[3] Diclofenac suppositories may cause local reactions such as itching, burning, or exacerbation of haemorrhoids.

Effects on the liver. Elevations of serum aminotransferase activity and clinical hepatitis,[1-8] including fatal fulminant hepatitis[2,5] have occurred in patients taking diclofenac. There has also been a case report of hepato-renal damage attributed to diclofenac.[9] Analysis[10] of 180 of the cases of diclofenac-associated hepatic injury received by the FDA between November 1988 and June 1991 suggested an increased risk of hepatotoxicity in female patients and those taking diclofenac for osteoarthritis. Hepatotoxicity had been detected within 6 months of starting diclofenac in 85% of the patients. The biochemical pattern of injury was hepatocellular or mixed hepatocellular in 66% of patients and cholestatic injury was found in 8% of patients. Signs of hypersensitivity were uncommon and it was considered that the mechanism of hepatic injury was likely to be a metabolic idiosyncratic reaction rather than due to intrinsic toxicity of diclofenac.

Effects on the skin. Self-limiting skin reactions such as rash or pruritus may occur in patients given diclofenac. More serious skin reactions attributed to diclofenac include bullous dermatitis[1] and erythema multiforme.[2,3] Local irritation and necrosis has occurred on intramuscular injection of diclofenac.[4-7]

Hypersensitivity. Aspirin-sensitive asthmatic patients have developed reactions (rhinorrhoea, tightness of chest, wheezing, dyspnoea) when challenged with diclofenac in doses of 10 to 25 mg[1] and the UK CSM has received a report of an aspirin-sensitive patient who died from acute asthma 4 hours after a single 25-mg dose of diclofenac.[2]

Precautions

As for NSAIDs in general, p.98. Systemic diclofenac is contra-indicated in patients with severe hepatic or renal impairment.

In addition, use of intravenous diclofenac is contra-indicated in patients with moderate or severe renal impairment, hypovolaemia, or dehydration; it should also not be given intravenously in patients with a history of haemorrhagic diathesis, cerebrovascular bleeding (including suspected), or asthma nor in patients undergoing surgery with a high risk of haemorrhage.

Ophthalmic preparations containing diclofenac should not be used by patients who wear soft contact lenses.

Breast feeding. Diclofenac is distributed into breast milk although the *BNF* and some licensed product information consider the amount to be too small to be harmful to breast-fed infants.

Porphyria. Diclofenac sodium has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Veterinary use. Veterinary use of diclofenac in cattle in South Asia has been associated with severe decline in the numbers of vultures, to whom the residues are highly toxic if they consume the carcasses.[1,2] Meloxicam (p.80) has been suggested as an alternative.

Interactions

For interactions associated with NSAIDs, see p.99.

Diclofenac should not be given intravenously to patients already receiving other NSAIDs or anticoagulants including low-dose heparin.

Ciclosporin. Deterioration in renal function has been attributed to the use of diclofenac with ciclosporin.[1] Increased concentrations of diclofenac were also noted with ciclosporin;[2] licensed product information for ciclosporin recommends that the dosage of diclofenac should be reduced by about one-half when the two are given together.

Misoprostol. The plasma concentration of diclofenac was reduced when it was given as a 100-mg dose daily in the form of a modified-release preparation to subjects receiving misoprostol 800 micrograms daily.[1] Use together was also associated with an increase in the incidence and severity of gastrointestinal effects. Studies by the manufacturer[2] had failed to find any significant pharmacokinetic interactions between diclofenac and misoprostol when given in a formulation containing diclofenac 50 mg and misoprostol 200 micrograms.

Pharmacokinetics

Diclofenac is rapidly absorbed when given as an oral solution, sugar-coated tablets, rectal suppository, or by intramuscular injection. It is absorbed more slowly when given as enteric-coated tablets, especially when this dosage form is given with food. Although diclofenac given orally is almost completely absorbed, it is subject to first-pass metabolism so that about 50% of the drug reaches the systemic circulation in the unchanged form. Diclofenac is also absorbed percutaneously. At therapeutic concentrations it is more than 99% bound to plasma proteins. Diclofenac penetrates synovial fluid where concentrations may persist even when plasma concentrations fall; small amounts are distributed into breast milk. The terminal plasma half-life is about 1 to 2 hours. Diclofenac is metabolised to 4′-hydroxydiclofenac, 5-hydroxydiclofenac, 3′-hydroxydiclofenac and 4′,5-dihydroxydiclofenac. It is then excreted in the form of glucuronide and sulfate conjugates, mainly in the urine (about 60%) but also in the bile (about 35%); less than 1% is excreted as unchanged diclofenac.

Uses and Administration

Diclofenac, a phenylacetic acid derivative, is an NSAID (p.99). It is used mainly as the sodium salt for the relief of pain and inflammation in various conditions: musculoskeletal and joint disorders such as rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis; peri-articular disorders such as bursitis and tendinitis; soft-tissue disorders such as sprains and strains; and other painful conditions such as renal colic, acute gout, dysmenorrhoea, migraine, and after some surgical procedures. It has also been used in some countries for the management of actinic keratoses and fever. Eye drops of diclofenac sodium are used for the prevention of intra-operative miosis during cataract extraction, for the treatment of inflammation after surgery or laser treatment of the eye, for pain in corneal epithelial defects after surgery or accidental trauma, and for the relief of ocular signs and symptoms of seasonal allergic conjunctivitis.

The usual **oral** or **rectal** dose of diclofenac sodium is 75 to 150 mg daily in divided doses. In the UK the maximum dose regardless of route or indication is 150 mg daily; however, in the USA a maximum oral dose of 200 mg daily is allowed in the treatment of rheumatoid arthritis. Modified-release preparations of diclofenac sodium are available for oral use. Diclofenac has also been given in equivalent oral doses as the free acid in dispersible preparations for short-term treatment up to 3 months long. Diclofenac is also given orally as the potassium salt. Doses of the potassium salt are similar to those for diclofenac sodium. Diclofenac potassium is also used in the treatment of migraine in an initial dose of 50 mg taken at the first signs of an attack; an additional dose of 50 mg may be taken after 2 hours if symptoms persist. If necessary further doses of 50 mg may be taken every 4 to 6 hours to a maximum daily dose of 200 mg.

Diclofenac sodium may also be given by deep intramuscular **injection** into the gluteal muscle in a dose of 75 mg once daily or, if required in severe conditions, 75 mg twice daily. Diclofenac sodium may also be given as a continuous or intermittent intravenous infusion in glucose 5% or sodium chloride 0.9% (both previously buffered with sodium bicarbonate) or as a bolus intravenous injection.. For the treatment of postoperative pain a dose of 75 mg may be given over 30 to 120 minutes or as a bolus injection. The dose may be repeated once after 4 to 6 hours if necessary. To prevent postoperative pain, an initial dose of 25 to 50 mg diclofenac sodium may be given after surgery over 15 to 60 minutes followed by 5 mg/hour to a maximum of 150 mg daily. Alternatively, the initial dose may be given as a bolus injection over 5 to 60 seconds followed by additional injections up to the maximum daily dosage; this may be repeated after 4 to 6 hours if necessary although the *total* dose should not exceed the maximum daily dose of 150 mg. The maximum period recommended for parenteral use is 2 days. Diclofenac sodium is also used intramuscularly in renal colic in a dose of 75 mg repeated once after 30 minutes if necessary.

For dosage details in children see below.

Diclofenac sodium is used as a 0.1% **ophthalmic solution** in a number of situations:

- for the prevention of intra-operative miosis during cataract surgery, it is instilled in the appropriate eye 4 times during the 2 hours before surgery
- for the treatment of postoperative inflammation after cataract surgery, it is instilled 4 times daily for up to 28 days starting 24 hours after surgery
- for the control of post-photorefractive keratectomy pain, it is instilled twice in the hour before surgery, then one drop twice at 5-minute intervals immediately after the procedure, and then every 2 to 5 hours while awake for up to 24 hours
- for pain control after accidental trauma one drop is instilled 4 times daily for up to 2 days
- in the treatment of inflammation and discomfort after strabismus surgery one drop is instilled 4 times daily for the first week; this is reduced to 3 times daily in the second week, twice daily in the third week, and as required for the fourth week
- for the control of inflammation after argon laser trabeculoplasty one drop is instilled 4 times during the 2 hours before the procedure followed by one drop 4 times daily for up to 7 days after the procedure
- for the treatment of pain and discomfort after radial keratotomy one drop is instilled before surgery followed by one drop immediately after surgery and then one drop 4 times daily for up to 2 days
- to relieve symptoms of seasonal allergic conjunctivitis one drop is instilled 4 times daily as necessary

Diclofenac diethylamine is used **topically** as a gel containing the equivalent of 1% of diclofenac sodium for the local symptomatic relief of pain and inflammation; it is applied to the affected site 3 or 4 times daily; treatment should be reviewed after 14 days or after 28 days if used for osteoarthritis. A topical solution of diclofenac sodium 1.6% is also available for the treatment of osteoarthritis in superficial joints such as the wrist or knee; it is applied in small aliquots to achieve a total of 20 or 40 drops, depending on the size of the joint, and repeated four times daily. Diclofenac is also used in the management of actinic keratoses; it is applied twice daily as diclofenac sodium gel 3% for 60 to 90 days but the optimum therapeutic effect may not be seen until 30 days after the end of treatment. Diclofenac epolamine is also used topically as a plaster containing the equivalent of 1% of diclofenac sodium for local symptomatic pain relief in ankle sprain and epicondylitis. In the treatment of ankle sprain, 1 plaster is applied once daily for a maximum of 3 days and for epicondylitis, 1 plaster is applied twice daily for a maximum of 14 days.

Diclofenac is available in combination with misoprostol (see p.2013) for patients at risk of NSAID-induced peptic ulceration.

Administration. ***IN CHILDREN.*** In children 1 to 12 years old the licensed UK *oral* or *rectal* dose of diclofenac sodium for juvenile idiopathic arthritis is 1 to 3 mg/kg daily in divided doses. In children 6 to 12 years old diclofenac sodium may also be given rectally for the treatment of acute postoperative pain, either alone or as an adjunct to opiate therapy; a usual dose is 1 to 2 mg/kg daily in divided doses for a maximum of 4 days. The *parenteral route* is not licensed for use in children although it has been used (see below).

The *BNFC* suggests slightly different doses of diclofenac sodium: in the management of rheumatic disease, including juvenile idiopathic arthritis, in children from 6 months of age, it recommends an oral dose of 3 to 5 mg/kg daily, in 2 or 3 divided doses, up to a maximum of 150 mg daily. For relief of pain and inflammation in, for example, soft-tissue disorders, the recommended oral or rectal dose in children from 6 months of age is 0.3 to 1 mg/kg given three times daily; children 2 years of age and older may be given a similar dose once or twice daily *by intravenous infusion* or *deep intramuscular (gluteal) injection* instead, for up to 2 days. Again, a maximum daily dose of 150 mg should not be exceeded.

Diclofenac potassium has also been used in children aged over 14 years for the treatment of rheumatic disease, musculoskeletal disorders, and postoperative pain; it is given in an *oral* dose of 75 to 100 mg daily in 2 to 3 divided doses.

Actinic keratoses. Diclofenac sodium 3% in hyaluronic acid gel is used[1-3] in the treatment of actinic keratoses (see Basal Cell and Squamous Cell Carcinoma, p.673), and a meta-analysis[4] found it to be of benefit, despite previous concerns that the preparation may not be significantly more effective than hyaluronic acid gel alone.[5] An open-label comparison involving 30 patients with multiple actinic keratoses suggested that 90 days of treatment with diclofenac sodium 3% gel (to lesions on one side of the face and scalp) was better tolerated, but slightly less effective, than 28 days of treatment with fluorouracil 5% cream (to lesions on the other side).[6]

Ph. Eur. 6.2 (Diflunisal). A white or almost white, crystalline powder. Practically insoluble in water; soluble in alcohol; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Diflunisal). A white to off-white, practically odourless, powder. Insoluble in water and in hexane; freely soluble in alcohol and in methyl alcohol; soluble in acetone and in ethyl acetate; slightly soluble in carbon tetrachloride, in chloroform, and in dichloromethane.

Adverse Effects and Treatment

As for NSAIDs in general, p.96. The commonest adverse effects occurring with diflunisal are gastrointestinal disturbances, headache, and rash. Peptic ulceration and gastrointestinal bleeding have been reported. Dizziness, drowsiness, insomnia, and tinnitus may also occur.

Effects on the blood. Haematological adverse effects associated with diflunisal appear to be infrequent. Thrombocytopenia associated with diflunisal-induced peripheral platelet destruction has been reported in a patient with rheumatoid arthritis.[1] Heinz-body haemolytic anaemia has also been reported, see Hypersensitivity, below.

Effects on the kidneys. Acute interstitial nephritis, presenting as acute oliguric renal failure, erythroderma, and eosinophilia has followed the use of diflunisal.[1]

1. Chan LK, *et al.* Acute interstitial nephritis and erythroderma associated with diflunisal. *BMJ* 1980; **280:** 84–5.

Effects on the lungs. For reference to pneumonitis associated with diflunisal therapy, see Hypersensitivity, below.

Effects on the skin. Reports of Stevens-Johnson syndrome associated with diflunisal.[1,2] See also Hypersensitivity, below.

2. Grom JA, *et al.* Diflunisal-induced erythema multiforme major. *Hosp Formul* 1986; **21:** 353–4.

Hypersensitivity. Three cases of hypersensitivity to diflunisal in which the main clinical features were fever, elevated liver enzyme values, erythroderma, and eosinophilia, have been reported.[1] Heinz-body haemolytic anaemia occurred in one of the patients. Other hypersensitivity reactions associated with diflunisal therapy have included pneumonitis[2] and fulminant necrotising fasciitis.[3]

3. Krige JEJ, *et al.* Necrotising fasciitis after diflunisal for minor injury. *Lancet* 1985; **ii:** 1432–3.

Overdosage. Diflunisal poisoning has sometimes been fatal.[1,2] A dose of 15 g has been reported to have caused death when no other drugs were involved but a dose of 7.5 g has also been fatal when taken with other drugs.

1. Court H, Volans GN. Poisoning after overdose with non-steroidal anti-inflammatory drugs. *Adverse Drug React Acute Poisoning Rev* 1984; **3:** 1–21.
2. Levine B, *et al.* Diflunisal related fatality: a case report. *Forensic Sci Int* 1987; **35:** 45–50.

Precautions

As for NSAIDs in general, p.98. Diflunisal may need to be given in reduced dosage in patients with significant renal impairment and should not be given when renal impairment is severe. Aspirin and other acetylated salicylates are not recommended for use in children unless specifically indicated, because of the risk of Reye's syndrome. Although this precaution has not been specifically extended to diflunisal it is not generally licensed for use in children.

Interactions

For interactions associated with NSAIDs, see p.99.

Aspirin may produce a small decrease in the plasma concentration of diflunisal. Diflunisal has been reported to increase the plasma concentrations of indometacin and paracetamol; diflunisal with indometacin has been associated with fatal gastrointestinal haemorrhage and therefore the combination should not be used. Regular use of antacids may reduce the absorption of diflunisal.

Benzodiazepines. For the effect of diflunisal on plasma concentrations of *oxazepam*, see p.989.

Probenecid. Average steady-state plasma concentrations of diflunisal were increased by 65% when it was given with probenecid.[1] This was due mainly to reduced formation of the phenolic and acyl glucuronides. However, plasma concentrations of these glucuronides and the sulfate conjugate were also increased even more because probenecid also reduced their renal clearance.

1. Macdonald JI, *et al.* Effect of probenecid on the formation and elimination kinetics of the sulphate and glucuronide conjugates of diflunisal. *Eur J Clin Pharmacol* 1995; **47:** 519–23.

Pharmacokinetics

Diflunisal is well absorbed from the gastrointestinal tract and peak plasma concentrations occur about 2 to 3 hours after ingestion of a single dose. It is more than 99% bound to plasma protein and has a plasma half-life of about 8 to 12 hours. Diflunisal exhibits non-linear pharmacokinetics so that doubling the dose more than doubles drug accumulation. Due to the long half-life and non-linear kinetics, several days are required to reach steady-state plasma concentrations after multiple dosing. The time to steady-state concentrations can be reduced by giving an initial loading dose. Concentrations of diflunisal in synovial fluid reach about 70% of those in plasma. Diflunisal is excreted in the urine mainly as glucuronide conjugates. Some biliary recycling may also occur. Diflunisal is distributed into breast milk with concentrations reported to be about 2 to 7% of those in plasma.

Uses and Administration

Diflunisal is a salicylic acid derivative (see Aspirin, p.23) but it is not hydrolysed to salicylate and its clinical effects resemble more closely those of propionic acid derivative NSAIDs such as ibuprofen (p.65). Diflunisal is given in the acute or long-term management of mild to moderate pain, and pain and inflammation associated with osteoarthritis and rheumatoid arthritis. The usual initial oral dose for pain relief is 1 g followed by a maintenance dose of 500 mg every 12 hours. In some patients 250 mg every 8 to 12 hours may be sufficient but others may require 500 mg every 8 hours. Maintenance doses greater than 1.5 g daily are not recommended. The usual oral dose for arthritis is 500 mg to 1 g daily in 2 divided doses. Doses may need to be reduced in patients with renal impairment, see below.

Diflunisal arginine has been used similarly given by mouth or by intramuscular or intravenous injection.

Administration in renal impairment. Diflunisal may need to be given in reduced dosage in patients with significant renal impairment and should not be given when renal impairment is severe.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Dihydrocodeine has been subject to abuse (see under Precautions, below).

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102; adverse effects of dihydrocodeine are less pronounced than those of morphine.

Overdosage. A 29-year-old man who had taken 2.1 g of dihydrocodeine had biochemical evidence of acute renal and hepatic impairment when admitted 13 hours after the overdose.[1] Severe life-threatening respiratory depression subsequently developed 36 hours after the overdose and only responded to treatment with naloxone after large doses (a total of 46.6 mg of naloxone) over a long period (106 hours). Commenting on this report some questioned the evidence for hepatic impairment and considered that the raised liver enzyme values were of muscular origin as a result of rhabdomyolysis.[2-4] Rhabdomyolysis may also have contributed to renal failure.

An anaphylactoid reaction after an overdose with an unspecified number of dihydrocodeine tablets[5] appeared to respond to intravenous naloxone.

Pain. For reference to increased postoperative pain associated with the use of dihydrocodeine, see under Uses and Administration, below.

Precautions

As for Opioid Analgesics in general, p.103.

Abuse. Dihydrocodeine has been reported to be widely abused by opiate addicts.[1-4]

4. Seymour A, *et al.* The role of dihydrocodeine in causing death among drug users in the west of Scotland. *Scott Med J* 2001; **46:** 143–6.

The elderly. Despite some renal impairment an elderly group of patients[1] appeared to handle dihydrocodeine similarly to healthy young subjects. There was marked variability in all measurements and on the basis of this study no clear conclusions on guidelines for dosage in elderly patients could be drawn. However, the recommendation that small doses be given initially with subsequent doses according to response was endorsed.

1. Davies KN, *et al.* The effect of ageing on the pharmacokinetics of dihydrocodeine. *Eur J Clin Pharmacol* 1989; **37:** 375–9.

Renal impairment. Caution is necessary when giving dihydrocodeine to patients with severe renal impairment. Severe narcosis occurred in a patient with anuria and on maintenance haemodialysis after she had received dihydrocodeine orally for 4 days.[1] She responded to treatment with naloxone.

See also under Pharmacokinetics, below.

1. Barnes JN, Goodwin FJ. Dihydrocodeine narcosis in renal failure. *BMJ* 1983; **286:** 438–9.

Interactions

For interactions associated with opioid analgesics, see p.103.

Quinidine. Dihydrocodeine is metabolised via the cytochrome P450 isoenzyme CYP2D6 to active metabolites, which may perhaps play a role in its analgesic activity in extensive metabolisers; quinidine impairs this metabolism, but a study in 11 healthy subjects did not find any reduced analgesic activity when dihydrocodeine was given with quinidine, despite a three- to fourfold reduction in plasma concentrations of the metabolite dihydromorphine.[1]

1. Wilder-Smith CH, *et al.* The visceral and somatic antinociceptive effects of dihydrocodeine and its metabolite, dihydromorphine: a cross-over study with extensive and quinidine-induced poor metabolizers. *Br J Clin Pharmacol* 1998; **45:** 575–81.

Pharmacokinetics

After oral doses peak concentrations of dihydrocodeine occur after about 1.2 to 1.8 hours; oral bioavailability is only about 20%, probably because of substantial first-pass metabolism in the gut wall or liver. Dihydrocodeine is metabolised in the liver via the cytochrome P450 isoenzyme CYP2D6, to dihydromorphine, which has potent analgesic activity, although the analgesic effect of dihydrocodeine appears to be primarily due to the parent compound; some is also converted via CYP3A4 to nordihydrocodeine. Dihydrocodeine is excreted in urine as unchanged drug and metabolites, including glucuronide conjugates. Elimination half-life is reported to range from about 3.5 to 5 hours.

Renal impairment. The pharmacokinetics of dihydrocodeine tartrate, given as a single oral 60-mg dose, were affected in 9 patients with chronic renal failure treated with haemodialysis when compared with 9 healthy subjects.[1] Time to peak plasma concentration in those with renal failure was 3 hours compared with 1 hour in healthy subjects; the area under the plasma concentration-time curve was greater in those with renal failure; and after 24 hours dihydrocodeine was still detectable in the plasma of all renal failure patients, but in only 3 of the healthy subjects.

1. Barnes JN, *et al.* Dihydrocodeine in renal failure: further evidence for an important role of the kidney in the handling of opioid drugs. *BMJ* 1985; **290:** 740–2.

Uses and Administration

Dihydrocodeine is an opioid analgesic (p.104). It is related to codeine (p.38) and has similar analgesic activity. Dihydrocodeine is used for the relief of moderate to severe pain, often in combination preparations with paracetamol. It has also been used as a cough suppressant.

For **analgesia** the usual oral dose of dihydrocodeine tartrate is 30 mg after food every 4 to 6 hours; up to 240 mg daily may be given for severe pain. Modified-release preparations are available for twice daily dosage in patients with chronic severe pain.

Dihydrocodeine tartrate may also be given by deep subcutaneous or intramuscular injection in doses of up to 50 mg every 4 to 6 hours.

For details of doses in children, see below.

As a **cough suppressant** dihydrocodeine tartrate may be given in oral doses of 10 to 30 mg up to three times daily.

Dihydrocodeine phosphate has also been used. Other salts of dihydrocodeine used, mainly for their antitussive effects, include the hydrochloride, the polistirex, and the thiocyanate. Dihydrocodeine polistirex has also been used in modified-release preparations.

Administration in children. In the UK, dihydrocodeine tartrate may be given orally, or by deep subcutaneous or intramuscular injection, for analgesia in children aged from 4 to 12 years in usual doses of 0.5 to 1 mg/kg (to a maximum of 30 mg) every 4 to 6 hours; older children may be given the usual adult dose (see above). Although unlicensed in children under 4 years, the *BNFC* suggests giving those aged 1 to 4 years 500 micrograms/kg every 4 to 6 hours.

Dyspnoea. Dihydrocodeine has been reported[1] to have produced benefit in normocapnic patients severely disabled by breathlessness due to chronic airflow obstruction. A dose of

15 mg was taken 30 minutes before exercise up to three times a day.

1. Johnson MA, *et al.* Dihydrocodeine for breathlessness in 'pink puffers'. *BMJ* 1983; **286:** 675–7.

Pain. Dihydrocodeine is used in the management of moderate to severe pain. However, dose-related increase in postoperative pain has been seen[1] in patients given 25 or 50 mg dihydrocodeine tartrate intravenously after dental surgery, and it has been proposed that dihydrocodeine might act as an antagonist in situations where acute pain was accompanied by high opioid activity.[2] Systematic review of the use of single oral doses of dihydrocodeine has indicated that these are insufficient to provide adequate relief of postoperative pain, and that dihydrocodeine is less effective than ibuprofen.[3]

BP 2008 (Dipipanone Hydrochloride). An odourless or almost odourless, white, crystalline powder. Sparingly soluble in water; freely soluble in alcohol and in acetone; practically insoluble in ether. A 2.5% solution in water has a pH of 4.0 to 6.0.

Profile

Dipipanone hydrochloride is an opioid analgesic (p.101) structurally related to methadone (p.82). Used alone it is reported to be less sedating than morphine. It is used in the treatment of moderate to severe pain.

Dipipanone hydrochloride is usually given in combination preparations with the antiemetic cyclizine hydrochloride to reduce the incidence of nausea and vomiting, but the use of such preparations is not recommended for the management of chronic pain, as the antiemetic is usually only required for the first few days of treatment. The usual oral dose of dipipanone hydrochloride is 10 mg, repeated every 6 hours. The dose may be increased if necessary in increments of 5 mg; it is seldom necessary to exceed a dose of 30 mg. After an oral dose the analgesic effect begins within an hour and lasts about 4 to 6 hours.

Preparations of dipipanone hydrochloride with cyclizine hydrochloride are subject to abuse.

NOTE. Confusingly the term dipyrone sodium also appears to be used synonymously for dipyrone itself. Dipyrone is referred to in some countries by the colloquial name 'Mexican aspirin'. The names noraminophenazonum and novaminsulfon have apparently been applied to dipyrone, but it is not clear whether these are the sodium salt.

Ph. Eur. 6.2 (Metamizole Sodium; Dipyrone BP 2008). A white or almost white crystalline powder. Very soluble in water; soluble in alcohol. Protect from light.

Adverse Effects and Precautions

Use of dipyrone is associated with an increased risk of agranulocytosis and with shock.

Effects on the blood. Data collected from 8 population groups in Europe and Israel by the International Agranulocytosis and Aplastic Anemia Study[1] revealed that there was a significant regional variability in the rate-ratio estimate for agranulocytosis and dipyrone (0.9 in Budapest to 33.3 in Barcelona). Although a large relative increase in risk between agranulocytosis and use of dipyrone was found, the incidence was less than some previous reports had suggested.

Blood dyscrasias such as agranulocytosis and granulocytopenia have continued to be reported where dipyrone remains available.[2-7]

Porphyria. Dipyrone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pharmacokinetics

After oral doses dipyrone is rapidly hydrolysed in the gastrointestinal tract to the active metabolite 4-methyl-amino-antipyrine, which after absorption undergoes metabolism to 4-formyl-amino-antipyrine and other metabolites. Dipyrone is also rapidly undetectable in plasma after intravenous doses. None of the metabolites of dipyrone are extensively bound to plasma proteins. Most of a dose is excreted in the urine as metabolites. Dipyrone metabolites are also distributed into breast milk.

Uses and Administration

Dipyrone is the sodium sulfonate of aminophenazone (p.19) and has similar properties. Because of the risk of serious adverse effects, in many countries its use is considered justified only in severe pain or fever where no alternative is available or suitable. Dipyrone has been given orally in doses of 0.5 to 4 g daily in divided doses. It has also been given by intramuscular or intravenous injection and rectally as a suppository.

A magnesium congener of dipyrone, metamizole magnesium has been used similarly to dipyrone as has the calcium congener metamizole calcium.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Enoxolone). A white or almost white, crystalline powder. It exhibits polymorphism. Practically insoluble in water; soluble in dehydrated alcohol; sparingly soluble in dichloromethane. Protect from light.

Profile

Enoxolone is a complex triterpene prepared from glycyrrhizic acid (p.2316), a constituent of liquorice (p.1740). Enoxolone is used locally in preparations for the treatment of non-infective inflammatory disorders of the skin, mouth, throat, and rectum. Enoxolone potassium (potassium glycyrrhetinate) has been used similarly.

Derivatives of enoxolone, including its aluminium salt (p.1729) and carbenoxolone (p.1714) have been used in the treatment of benign peptic ulcer disease and other gastrointestinal disorders.

◊ Enoxolone is a potent inhibitor of the enzyme 11β-hydroxysteroid dehydrogenase, which inactivates cortisol, and use with hydrocortisone has been shown in *animal* studies to potentiate the activity of hydrocortisone in skin.[1] Whether this also increased the systemic absorption and toxicity of hydrocortisone was unclear.[2] However, for reference to adverse effects attributed to systemic inhibition of cortisol when enoxolone (glycyrrhetinic acid) is produced during metabolism of ingested liquorice, see Effects on Fluid and Electrolyte Homoeostasis, p.1740.

A cream containing enoxolone with hyaluronic acid, telmesteine, and a grape extract, has been investigated with apparent benefit in the management of mild to moderate eczema.[3,4] However, topical application of enoxolone has been associated with contact dermatitis.[5]

Adverse Effects and Precautions

As for Infliximab, p.69.

Mild to moderate injection site reactions with symptoms of erythema, itching, pain, or swelling are common with etanercept. Other common reactions include headache, dizziness, asthenia, nausea and vomiting, abdominal pain, dyspepsia, and allergic reactions. Antibodies to etanercept may develop.

Etanercept should be used with caution in patients with heart failure.

Wegener's granulomatosis. The addition of etanercept to standard therapy (including cyclophosphamide or methotrexate and corticosteroids) was not shown to be effective in patients with Wegener's granulomatosis and was associated with an increased incidence of various non-cutaneous malignancies.[1] Licensed product information recommends that etanercept should not be added to therapy in patients with Wegener's granulomatosis.

Interactions

As for Infliximab, p.71. The use of etanercept with sulfasalazine has resulted in decreased white blood cell counts; however, the clinical significance of this is unknown. For an increased incidence of malignancy when etanercept was added to standard immunosuppressive therapy in patients with Wegener's granulomatosis, see above.

Pharmacokinetics

After a single subcutaneous dose of etanercept, UK licensed product information states that the mean half-life is about 70 hours, and the time to peak serum concentration 48 hours. In contrast, US information gives the half-life as 102 hours and the time to peak concentration as about 70 hours, although with a considerable range. Repeated dosing was noted to result in a two- to sevenfold increase in serum levels of etanercept in some patients.

Uses and Administration

Etanercept is a recombinant version of soluble human tumour necrosis factor (TNF) receptor that binds specifically to tumour necrosis factor (p.783) and blocks its interaction with endogenous cell-surface TNF receptors. This interaction prevents the important effect of TNF in the inflammatory processes of rheumatoid arthritis; elevated TNF levels are also found in psoriatic plaques, in the synovium of patients with psoriatic arthritis, and in the serum and synovium of patients with ankylosing spondylitis.

Etanercept is used in the treatment of moderately to severely active **rheumatoid arthritis** and active and progressive **psoriatic arthritis**. In the UK, it is licensed for use in patients who have had an inadequate response to standard disease-modifying antirheumatic drugs although, in severe rheumatoid arthritis, it may be used in patients not previously treated with methotrexate. In the USA, it is licensed to treat early rheumatoid arthritis or psoriatic arthritis, to reduce the signs and symptoms, delay structural damage, and improve physical function. In both indications, it is given as a subcutaneous injection in a dose of 25 mg twice weekly at intervals of 3 or 4 days. The equivalent weekly dose of 50 mg may also be given either as a single 50-mg injection or as two separate 25-mg injections (given at about the same time). In the UK, NICE recommends, based on guidelines from the British Society of Rheumatology, that treatment be stopped if there is no adequate response after 6 months. Etanercept is also indicated in the treatment of severely active **ankylosing spondylitis**; in the UK, its use is again limited to those who have had an inadequate response to conventional therapy. Doses are similar to those used for rheumatoid arthritis.

Etanercept is also used in the treatment of chronic, moderate to severe plaque **psoriasis**. In the UK, its use is usually limited to patients in whom other systemic treatments are not suitable. The recommended initial dose is 25 mg twice weekly. Alternatively, an initial dose of 50 mg twice weekly at intervals of 3 or 4 days may be given for 12 weeks; the dose should then be reduced to 25 mg twice weekly or 50 mg weekly. Initial doses of 25 or 50 mg once weekly have also been shown to be effective. Treatment should continue until remission is achieved, for up to 24 weeks. Etanercept should be stopped after 12 weeks in patients who show no response.

For details of uses and dosage in children, see below.

Administration in children. Etanercept is used in the treatment of moderately to severely active polyarticular **juvenile idiopathic arthritis**; UK licensed product information limits its use to those who have had an inadequate response to, or who are intolerant of, the disease-modifying antirheumatic drug methotrexate.

In the UK, it is given subcutaneously to children aged 4 years and over in a dose of 400 micrograms/kg (up to a maximum dose of 25 mg) twice weekly at intervals of 3 or 4 days. In the USA, etanercept is licensed for use in children as young as 2 years old. Similar doses are used although they are expressed as 800 micrograms/kg (up to a maximum dose of 50 mg) weekly: doses to be given as 2 separate injections may either be given on the same day or 3 to 4 days apart.

In the UK, NICE recommends, based on guidelines from the British Paediatric Rheumatology Group, that treatment be stopped in children if there is no response after 6 months, or an initial response is not maintained.

For references on the use of etanercept in juvenile idiopathic arthritis, see Rheumatoid Arthritis, below.

Asthma. TNF inhibitors such as etanercept have been investigated in the treatment of refractory asthma (p.1108).[1,2] There is some evidence that only a minority of patients will respond to such therapy, and that the benefits and risks must therefore be carefully assessed.[3]

Dementia. A small pilot study[1] and individual case reports[2] have suggested that perispinal injection of etanercept, in doses of 25 to 50 mg weekly, may improve signs of dementia in patients with Alzheimer's disease. However, randomised controlled studies are required to confirm any benefit.

Psoriasis. Etanercept is effective in patients with moderate to severe plaque psoriasis (p.1583).[1-9] It has also been successfully tried in the treatment of erythrodermic psoriasis,[10] and of plaque psoriasis in children and adolescents.[11]

Efficacy may be dose-related; in one study,[1] 25% of patients in the low-dose (25 mg once weekly) group showed at least a 75% improvement compared with 44% in the medium-dose group (25 mg twice weekly) and 59% in the high-dose group (50 mg twice weekly) after 24 weeks of etanercept treatment. However, a later multicentre study[2] in patients with chronic plaque psoriasis found that the therapeutic effect of etanercept was maintained when the dose was reduced after 12 weeks from 50 mg twice weekly to 25 mg twice weekly. An open-label extension[8] of these 2 studies found that efficacy was also sustained when patients who had received etanercept 25 mg twice weekly for at least 24 weeks had their dose altered to 50 mg once weekly.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

The presence of phenolic metabolites of etodolac in the urine may give rise to a false-positive reaction for bilirubin.

Effects on the blood. Agranulocytosis has been reported in a patient receiving etodolac.[1] Coombs-positive haemolytic anaemia due to sensitivity to etodolac metabolites has also been reported.[2]

2. Cunha PD, *et al.* Immune hemolytic anemia caused by sensitivity to a metabolite of etodolac, a nonsteroidal anti-inflammatory drug. *Transfusion* 2000; **40:** 663–8.

Effects on the gastrointestinal tract. Etodolac is reported to be a preferential inhibitor of cyclo-oxygenase 2 (COX-2) and consequently it may produce less gastric toxicity than the non-selective NSAIDs such as naproxen.[1-3]

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Etodolac is a chiral compound given as the racemate. Peak plasma concentrations of the active (S)-enantiomer and of the inactive (R)-enantiomer are usually obtained within about 2 hours of a dose by mouth but plasma concentrations of the (R)-enantiomer have been reported to greatly exceed those of the (S)-enantiomer. Both enantiomers are highly bound to plasma proteins. Both are also distributed to the synovial fluid, although the difference in their concentrations may not be as marked as the difference in plasma concentrations. The plasma half-life of total etodolac has been reported to be about 7 hours; excretion is mainly in the urine as hydroxylated metabolites and glucuronide conjugates; some may be excreted in the bile.

Uses and Administration

Etodolac, a pyrano-indoleacetic acid derivative, is an NSAID (p.99) reported to be a preferential inhibitor of cyclo-oxygenase 2 (COX-2). It is used for rheumatoid arthritis, including juvenile idiopathic arthritis, and osteoarthritis and for the treatment of acute pain.

For the treatment of rheumatoid arthritis and osteoarthritis, the recommended oral dose is initially 600 to 1000 mg daily in divided doses adjusted according to response; single daily doses of up to 600 mg may also be given. Modified-release preparations are available for once-daily use in these conditions. For doses in children, see below.

For the treatment of acute pain, the recommended dose is 200 to 400 mg every 6 to 8 hours to a maximum of 1 g daily.

Administration in children. In the USA modified-release preparations of etodolac may be given for the oral treatment of juvenile idiopathic arthritis in children aged 6 to 16 years. Doses are given once daily according to body-weight as follows:

- 20 to 30 kg: 400 mg
- 31 to 45 kg: 600 mg
- 46 to 60 kg: 800 mg
- over 60 kg: 1 g

Ph. Eur. 6.2 (Etofenamate). A yellowish viscous liquid. Practically insoluble in water; miscible with alcohol and with ethyl acetate.

Profile

Etofenamate is an NSAID (p.96) that has been applied topically in a concentration of 5 or 10% for the relief of pain and inflammation associated with musculoskeletal, joint, and soft-tissue disorders. It has also been given by deep intramuscular injection in single doses of 1 g.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Hypersensitivity reactions including anaphylaxis and angioedema have occurred in patients receiving etoricoxib; it should be stopped at the first signs of hypersensitivity. Etoricoxib should be avoided in patients with severe hepatic impairment (Child-Pugh score of 10 or more). Therapy should be stopped if persistently abnormal liver enzyme values are seen.

Etoricoxib should not be used in patients with ischaemic heart disease, peripheral arterial disease, or cerebrovascular disease. It should be used with caution in patients with significant risk factors for cardiovascular disease such as hypertension, hyperlipidaemia, and diabetes mellitus. Etoricoxib, particularly at high doses, may be associated with more frequent and severe hypertension compared with other NSAIDs and selective COX-2 inhibitors; blood pressure monitoring during etoricoxib treatment is recommended. Etoricoxib should not be used in patients with hypertension whose blood pressure is not controlled (see also Effects on the Cardiovascular System, below).

Etoricoxib is also contra-indicated in patients with inflammatory bowel disease, moderate to severe heart failure (NYHA class II to IV), and renal impairment associated with a creatinine clearance of less than 30 mL/minute. Caution is recommended when using etoricoxib in dehydrated patients; it may be advisable to rehydrate patients before giving etoricoxib.

Effects on the cardiovascular system. There have been concerns about the adverse cardiovascular effects of selective cyclo-oxygenase-2 (COX-2) inhibitors after the worldwide withdrawal of rofecoxib (see p.121). The cardiovascular safety of etoricoxib has been assessed in the MEDAL programme[1] which pooled data from 3 studies involving over 30 000 patients with either osteoarthritis or rheumatoid arthritis. Patients with osteoarthritis were given etoricoxib 60 or 90 mg daily; those with rheumatoid arthritis received 90 mg daily. In all studies, diclofenac 150 mg daily was given as the comparator; low-dose aspirin (100 mg daily or less) was also allowed where indicated. After an average treatment duration of 18 months, the rates of thrombotic events such as myocardial infarction, stroke, and sudden or unexplained death with etoricoxib were similar to those for diclofenac. (It has been suggested that diclofenac itself may increase the risk of some thrombotic events; for further details, see p.97.) The programme also found that the rate of some other non-thrombotic cardiovascular events was increased with etoricoxib: one of the 3 studies showed that there was a non-significant increase in the rate of heart failure with etoricoxib 90 mg daily compared to diclofenac; withdrawals due to oedema were also more frequent with high-dose etoricoxib than with diclofenac or etoricoxib 60 mg daily. In addition, the number of patients stopping treatment because of hypertension was higher with both doses of etoricoxib than with diclofenac. Similar results were seen in the other 2 studies.

In another study[2] that pooled pre-licensing data, the risk of thrombotic events with etoricoxib, given at a dose of at least 60 mg daily, was also found to be similar to that for placebo treatment, ibuprofen (2.4 g daily), diclofenac (150 mg daily), and naproxen (1 g daily), although there was a trend towards more events with etoricoxib than with naproxen. For details on the relative risk of thrombotic events associated with non-selective NSAIDs, see p.97.

The EMEA's Committee for Medicinal Products for Human Use (CHMP)[3] has recommended the inclusion of a warning in the labelling of etoricoxib that it must not be given to patients whose blood pressure is persistently above 140/90 mmHg and inadequately controlled; in addition, high blood pressure should be controlled before starting treatment and monitored for 2 weeks afterwards then regularly thereafter.

For discussion and advice on the use of selective COX-2 inhibitors in patients with cardiovascular or cerebrovascular disease, see under Celecoxib, p.34.

Effects on the gastrointestinal tract. It is generally accepted that the inhibition of cyclo-oxygenase-1 (COX-1) plays a role in the adverse gastrointestinal effects of the NSAIDs, and that the selective inhibition of the other isoform, COX-2, by NSAIDs such as etoricoxib may cause less gastrotoxicity than that seen with the non-selective inhibition of the traditional NSAIDs. However, licensed product information states that upper gastrointestinal perforation, ulceration, and bleeds, in some cases fatal, have occurred with etoricoxib treatment; consequently, it should be used with caution in patients with a history of, or at risk of developing, such events. In addition, etoricoxib should not be used in patients with active gastrointestinal ulceration or bleeding.

Results from controlled studies have suggested that NSAIDs selective for COX-2 were associated with a lower incidence of serious gastrointestinal effects. In a study[1] of the pooled data from 3 randomised clinical studies, etoricoxib (in doses of 60 or 90 mg daily) was associated with significantly less frequent upper gastrointestinal clinical events than diclofenac (150 mg daily). The result was attributed to the lower rate of uncomplicated ulcers with etoricoxib compared with diclofenac; there was no difference in the rate of complicated gastrointestinal events between the 2 drugs. The lower rate of uncomplicated events with etoricoxib compared with diclofenac was not affected by treatment with low-dose aspirin or proton pump inhibitors. An analysis[2] by the manufacturer, of pooled data from 10 randomised clinical studies, found that etoricoxib (in daily doses of 60, 90, or 120 mg) was associated with a lower combined risk of upper gastrointestinal perforations and bleeding, and symptomatic gastroduodenal ulcers when compared with non-selective NSAIDs (diclofenac 150 mg daily, ibuprofen 2.4 g daily, or naproxen 1 g daily) as a group. This reduced risk was seen even in patients with known risk factors for such complications such as the elderly and those with a history of gastrointestinal reactions.

Effects on the kidneys. Limited evidence of the renal toxicity of the selective cyclo-oxygenase-2 (COX-2) inhibitors such as etoricoxib suggests that such NSAIDs appear to have effects on renal function similar to those of the non-selective NSAIDs (see p.98).

Interactions

The metabolism of etoricoxib is mediated by the cytochrome P450 isoenzyme CYP3A4. Use with other drugs that inhibit or induce this isoenzyme may result in changes in plasma concentration of etoricoxib. In addition, *in vitro* studies suggest that several other isoenzymes may also mediate the main metabolic pathway of etoricoxib. Rifampicin, a potent inducer of CYP isoenzymes, has produced decreased plasma concentrations of etoricoxib.

Etoricoxib is an inhibitor of human sulfotransferase activity and has been shown to increase the plasma concentration of ethinylestradiol. Interactions with other drugs, such as oral salbutamol and minoxidil, also metabolised by this enzyme may be a possibility and licensed product information advises care with such combinations.

For interactions associated with NSAIDs in general, see p.99.

Pharmacokinetics

Etoricoxib is well absorbed from the gastrointestinal tract after oral doses. Peak plasma concentrations are reached in about 1 hour in fasted adults; food delays absorption by about 2 hours, although it has no effect on the extent of absorption. Plasma protein binding is about 92%. At steady state the half-life of etoricoxib is about 22 hours. Etoricoxib is extensively metabolised with less than 2% of a dose recovered in the urine as the parent drug. The major route of metabolism is via cytochrome P450 isoenzymes including CYP3A4 to form the 6′-hydroxymethyl derivative of etoricoxib, which is then oxidised to the 6′-carboxylic acid derivative, the major metabolite. Both are inactive or only weak cyclo-oxygenase-2 (COX-2) inhibitors. Excretion is mainly via the urine (70%) with only 20% of a dose appearing in the faeces. Studies in *animals* suggest that etoricoxib may cross the placenta and that some is distributed into breast milk.

Uses and Administration

Etoricoxib is an NSAID (p.96) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It is used in the symptomatic relief of rheumatoid arthritis, osteoarthritis, and acute gouty arthritis.

In osteoarthritis, etoricoxib is given orally in a usual dose of 30 mg once daily, increased to 60 mg once daily if necessary. The recommended dose in rheumatoid arthritis is 90 mg once daily; higher doses of 120 mg once daily are used in gouty arthritis although such doses should only be used for the acute symptomatic period and for a maximum of 8 days. For dosage recommendations in patients with hepatic impairment, see below.

Administration in hepatic impairment. The maximum oral dose of etoricoxib in patients with mild hepatic impairment (Child-Pugh score of 5 to 6), regardless of indication, is 60 mg once daily; those with moderate impairment (Child-Pugh 7 to 9) should be given a maximum of 60 mg every other day or 30 mg once daily. Etoricoxib should not be given to patients with severe hepatic impairment (Child-Pugh 10 or more).

Musculoskeletal and joint disorders. The selective cyclo-oxygenase-2 (COX-2) inhibitor etoricoxib is used in the treatment of the musculoskeletal disorders osteoarthritis and rheumatoid arthritis (see p.11 and p.11, respectively). However, in the UK, it is recommended that the use of selective COX-2 inhibitors is limited to those patients considered to be at high risk of developing serious gastrointestinal problems if given a non-selective NSAID (see p.97).

Etoricoxib is also used in gouty arthritis (p.552) and has been tried in the treatment of ankylosing spondylitis (see Spondyloarthropathies, p.13).

Pharmacopoeias. In *BP(Vet).*

BP(Vet) 2008 (Etorphine Hydrochloride). A white or almost white microcrystalline powder. Sparingly soluble in water and in alcohol; very slightly soluble in chloroform; practically insoluble in ether. A 2% solution in water has a pH of 4.0 to 5.5. Protect from light.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102. Etorphine is not used therapeutically in humans.

Etorphine hydrochloride is highly potent and rapid acting; minute amounts can exert serious effects leading to coma. It may be absorbed through skin and mucous membranes. It is thus advisable to inject an antagonist *immediately* after contamination of skin or mucous membranes with preparations containing etorphine hydrochloride and to wash the affected areas copiously. Accidental injection or needle scratch injuries should also be treated immediately by injecting an antagonist. Naloxone is preferred as the antagonist in medical treatment. However, veterinary preparations of etorphine are supplied with a preparation (*Revivon*) containing diprenorphine hydrochloride (p.1445) and this should be used for immediate first-aid antagonism if naloxone is not available.

Uses and Administration

Etorphine hydrochloride is a highly potent opioid analgesic (p.104) used for reversible neuroleptanalgesia (see Anaesthetic Techniques, p.1780) in veterinary medicine. It is given with acepromazine maleate or levomepromazine (*Immobilon*) to restrain animals and before minor veterinary surgery. The duration of action of etorphine is up to about 45 to 90 minutes depending on the species but it may be longer in man, especially if the large animal preparation is involved.

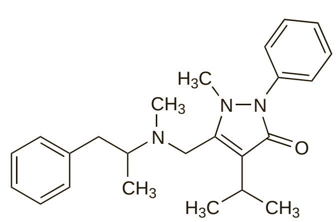
CAS — 22881-35-2.



Profile

Famprofazone has analgesic and antipyretic properties and has been given orally, usually with other analgesics.

Pharmacokinetics. On ingestion, metabolic products of famprofazone include amfetamine and metamfetamine enantiomers,[1,2] which has led to false positive results on drug testing.[3] For sporting competition famprofazone was classified by the World Anti-Doping Agency as a stimulant.[4]

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Felbinac). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in methyl alcohol.

Adverse Effects and Precautions

Mild local reactions such as erythema, dermatitis, and pruritus have occurred in patients using felbinac topically. More serious adverse effects including bullous dermatoses such as epidermal necrolysis and erythema multiforme, photosensitivity, anaphylaxis, and bronchospasm or wheeziness have also been reported. Gastrointestinal disturbances may occur.

Felbinac preparations should be avoided in patients with a history of hypersensitivity reactions to aspirin or other NSAIDs.

Incidence of adverse effects. The UK CSM had received 49 reports of adverse reactions associated with felbinac by October 1989, about 11 months after it was released on the UK market.[1] Bronchospasm or wheeziness was reported in 8 patients using felbinac gel. Four of these patients had a history of asthma of whom 3 were reported to have had a similar reaction to aspirin or other NSAIDs. Other reported reactions included skin rashes (17 cases), local application site reactions (7), and dyspepsia (6).

Uses and Administration

Felbinac, an active metabolite of fenbufen (below), is an NSAID (p.99). It is used topically in the symptomatic treatment of musculoskeletal pain including that due to soft-tissue injuries. It is applied as a 3% gel or a 3.17% foam to unbroken skin over affected areas 2 to 4 times daily. The total daily dose of gel or foam should not exceed 25 g regardless of the size or number of affected areas. Therapy should be reviewed after 14 days.

Diisopropanolamine felbinac has been used similarly.

Ph. Eur. 6.2 (Fenbufen). A white or almost white, fine crystalline powder. Very slightly soluble in water; slightly soluble in alcohol, in acetone, and in dichloromethane.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96, although the commonest adverse effects of fenbufen are skin rashes, usually occurring within the first 2 weeks of therapy, and particularly in women and in patients with sero-negative rheumatoid arthritis or psoriatic arthritis. Disorders such as epidermal necrolysis, erythema multiforme, and Stevens-Johnson syndrome have also been reported. A small number of patients who develop rash may go on to develop a severe illness characterised by pulmonary eosinophilia or allergic alveolitis. Treatment with fenbufen should be stopped immediately if a rash appears.

Breast feeding. UK licensed product information advises that fenbufen should be avoided in breast-feeding mothers, because of the presence of its metabolites in breast milk.

Effects on the blood. Haemolytic anaemia[1] and aplastic anaemia[2] have been reported in patients receiving fenbufen.

Effects on the lungs. In January 1989 the UK CSM reported that it had received 7 reports of a suspected association between rash and an allergic interstitial lung disorder in patients receiving fenbufen.[1] In 5 patients, the lung disorder was diagnosed as pulmonary eosinophilia; in the 2 other patients the pulmonary component of the reaction was described as allergic alveolitis. Several of these reactions have been reported in the literature.[2,3]

Effects on the skin. In September 1988 the UK CSM reported[1] that it was still receiving large numbers of reports of adverse reactions to fenbufen when such reports were expected to have declined. Fenbufen was the most commonly reported suspect drug in 1986 and 1987. At the time of the report more than 6000 such reports had been received, 80% concerning mucocutaneous reactions and most involving a generalised florid erythematous rash, often with pruritus. There were 178 reports of erythema multiforme, 30 of Stevens-Johnson syndrome, and 2 fatalities.

Hypersensitivity. See under Effects on the Lungs (above).

Interactions

For interactions associated with NSAIDs, see p.99.

Use of fenbufen with aspirin may result in decreased serum concentrations of fenbufen and its metabolites.

Pharmacokinetics

Fenbufen is absorbed from the gastrointestinal tract after oral use and peak plasma concentrations are reached in about 70 minutes. Fenbufen is over 99% bound to plasma proteins. It is metabolised in the liver to the active metabolites, biphenylacetic acid and 4-hydroxy-biphenylbutyric acid. Fenbufen and its metabolites are reported to have plasma half-lives of about 10 to 17 hours and are mainly eliminated as conjugates in the urine. Metabolites of fenbufen have been detected in breast milk in small amounts.

Uses and Administration

Fenbufen, a propionic acid derivative, is an NSAID (p.99). It is given for the relief of pain and inflammation associated with musculoskeletal and joint disorders such as rheumatoid arthritis, osteoarthritis, and ankylosing spondylitis in oral doses of 900 mg daily; the dose may be either 450 mg in the morning and evening or 300 mg in the morning with 600 mg in the evening.

Preparations

Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2008 (Fenoprofen Calcium). A white or almost white odourless or almost odourless crystalline powder. Slightly soluble in water and in chloroform; soluble in alcohol.

USP 31 (Fenoprofen Calcium). A white crystalline powder. Slightly soluble in water, in methyl alcohol, and in n-hexanol; practically insoluble in chloroform. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Dysuria, cystitis, haematuria, interstitial nephritis, and acute renal insufficiency have been reported with fenoprofen. Nephrotic syndrome, which may be preceded by fever, rash, arthralgia, oliguria, azotaemia, and anuria, has also occurred. Upper respiratory-tract infection and nasopharyngitis have been reported. There have been reports of severe hepatic reactions, including jaundice and fatal hepatitis.

Breast feeding. Fenoprofen is distributed into breast milk although the amount is considered by the *BNF* to be too small to be harmful to a breast-fed infant. In contrast, licensed product information does not recommend its use since safety has not been established.

Effects on the blood. Haematological adverse effects including agranulocytosis,[1] aplastic anaemia,[2] and thrombocytopenia[3,4] have been reported in patients taking fenoprofen; licensed product information also reports haemolytic anaemia.

Effects on the liver. Cholestatic jaundice and hepatitis developed in a 68-year-old woman after receiving fenoprofen 600 mg four times daily for 7 weeks. Subsequent use of naproxen and indometacin did not result in hepatotoxicity.[1] However, there has been a report of cross-hepatotoxicity between fenoprofen and naproxen.[2]

Interactions

For interactions associated with NSAIDs, see p.99.

Aspirin is reported to reduce plasma concentrations of fenoprofen.

Antiepileptics. *Phenobarbital* might increase the rate of metabolism of fenoprofen.[1] US licensed product information suggests that dosage adjustment of fenoprofen may be required when given with phenobarbital.

1. Helleberg L, *et al.* A pharmacokinetic interaction in man between phenobarbitone and fenoprofen, a new anti-inflammatory agent. *Br J Clin Pharmacol* 1974; **1:** 371–4.

Pharmacokinetics

Fenoprofen is readily absorbed from the gastrointestinal tract; bioavailability is about 85% but food and milk may reduce the rate and extent of absorption. Peak plasma concentrations occur 1 to 2 hours after a dose. The plasma half-life is about 3 hours. Fenoprofen is 99% bound to plasma proteins. About 90% of a dose is excreted in the urine in 24 hours, chiefly as the glucuronide and the glucuronide of hydroxylated fenoprofen. Fenoprofen is distributed into breast milk.

Uses and Administration

Fenoprofen, a propionic acid derivative, is an NSAID (p.99) used in the management of mild to moderate pain and for the relief of pain and inflammation associated with disorders such as osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis. It is given as the calcium salt although doses are expressed in terms of the base; fenoprofen calcium (dihydrate) 1.2 g is equivalent to about 1 g of fenoprofen. A usual oral dose is the equivalent of 300 to 600 mg of fenoprofen three or four times daily, adjusted thereafter according to response. In the USA, lower doses of 200 mg every 4 to 6 hours are recommended for mild to moderate pain. It has been recommended that the total daily dose should not exceed 3 g (UK) or 3.2 g (USA).

Incompatibility. Fentanyl citrate is incompatible with thiopental sodium and methohexital sodium.

A thick white precipitate formed in the intravenous tubing when fentanyl citrate with droperidol was given shortly after nafcillin sodium. There was no precipitate when fentanyl citrate alone was mixed with nafcillin sodium.[1]

Fentanyl citrate underwent rapid and extensive loss when admixed with fluorouracil in PVC containers.[2] The loss was due to sorption of fentanyl to the PVC as a result of the alkaline pH of the admixture, and presumably could occur from admixture of fentanyl citrate with any sufficiently alkaline drug.

See also Stability, below.

Stability. In a 48-hour study fentanyl citrate in glucose 5% or sodium chloride 0.9% was stable when stored at room temperature under usual light conditions in glass or PVC containers;[1] the concentration of fentanyl delivered by a patient-controlled system was relatively constant throughout a 30-hour study period. Fentanyl citrate injection diluted to 20 micrograms/mL with sodium chloride 0.9% was stable for 30 days at 3° or 23° in PVC reservoirs for portable infusion pumps.[2] In another study[3] fentanyl citrate diluted to 50 micrograms/mL with sodium chloride 0.9% remained stable for at least 14 days when stored at room temperature in PVC reservoirs for portable patient-controlled systems.

An admixture of fentanyl citrate and bupivacaine in sodium chloride 0.9% appeared[4] compatible and stable when stored for up to 30 days at 3° or 23° in a portable infusion pump. In another study[5] the stability of solutions containing fentanyl, bupivacaine, and adrenaline, alone and in combination was studied over a period of 56 days when stored at various temperatures in the light or in the dark in PVC bags. Both fentanyl and bupivacaine were adsorbed from solution onto the PVC for the first 3 days but thereafter concentrations of these drugs remained relatively stable; freezing appeared to slow the concentration change for bupivacaine but not for fentanyl. Solutions containing adrenaline became more acidic during the study as the adrenaline progressively deteriorated but this was greatly reduced by freezing. Autoclaving produced a further reduction in the concentration of all drugs. There was no sign of precipitation from any of the solutions studied.

An admixture of fentanyl citrate, ketamine hydrochloride, and droperidol in sodium chloride 0.9% was stable[6] for at least 30 days when stored in glass bottles at 25°; the minor decrease in the concentrations of all 3 drugs was attributed to either hydrolytic degradation or adsorption. This admixture also appeared compatible when stored in PVC bags at 4° and 25°; the small increase in drug concentrations over 30 days may be a result of water permeation and evaporation through the bags.

Fentanyl is potentially unstable in PVC containers when admixed with alkaline drugs (see Incompatibility, above).

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Fentanyl and illicitly manufactured analogues are subject to abuse (see under Precautions, below).

◊ Plasma concentrations required to produce satisfactory sedation have been reported to increase steadily in neonates receiving continuous infusions, suggesting the development of *tolerance* to the sedating effects of fentanyl.[1]

Movement disorders, extreme irritability, and symptoms characteristic of *opioid abstinence syndrome* have been reported in children after withdrawal of prolonged fentanyl infusions.[2,3] Similarly, withdrawal symptoms and, in one case, myoclonus have occurred in adults when fentanyl transdermal patches have been stopped.[4,5] Acute opioid withdrawal syndrome has also been seen in cancer patients switched from modified-release oral morphine to transdermal fentanyl despite adequate analgesia being maintained.[6]

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

Respiratory depression, which occurs especially with high doses of fentanyl, responds to naloxone (see also Effects on the Respiratory System, below). Atropine may be used to block the vagal effects of fentanyl such as bradycardia. Unlike morphine, fentanyl is reported not to cause significant histamine release. Transient hypotension may follow intravenous dosage. Muscle rigidity can occur and may require neuromuscular blockers.

Local reactions such as rash, erythema, and itching have been reported with transdermal use. Gum bleeding and irritation, and taste perversion have been reported with transmucosal use.

Effects on the cardiovascular system. For a reference to the effects of fentanyl on histamine release compared with some other opioids, see under Pethidine, p.114.

Effects on mental function. Fentanyl had some dose-related effects on mental function and motor activity in healthy subjects,[1] but immediate and delayed recall were not affected. See also under Alfentanil (p.16).

Acute toxic delirium has been reported after treatment with transdermal fentanyl.[2]

2. Kuzma PJ, *et al.* Acute toxic delirium: a uncommon reaction to transdermal fentanyl. *Anesthesiology* 1995; **83:** 869–71.

Effects on the nervous system. There have been reports of seizures with low and high doses of fentanyl or sufentanil.[1] There was, however, no EEG evidence of cortical seizure activity in a patient who had seizure-like muscle movements during a fentanyl infusion;[2] the muscle movements might have been due to myoclonus produced by depression of higher CNS inhibitory centres or to a pronounced form of opioid-induced muscle rigidity.

For a report of encephalopathy associated with prolonged use of fentanyl and midazolam in infants in intensive care, see Encephalopathy under Adverse Effects of Diazepam, p.988.

2. Scott JC, Sarnquist FH. Seizure-like movements during a fentanyl infusion with absence of seizure activity in a simultaneous EEG recording. *Anesthesiology* 1985; **62:** 812–14.

Effects on the respiratory system. Fentanyl, like other opioid agonists, causes dose-related respiratory depression; it is significant with *intravenous* fentanyl doses of more than 200 micrograms and may be more prolonged than analgesia. Anaesthesia with fentanyl may result in either prolonged or delayed respiratory depression postoperatively.[1] Consequently, patients should continue to be monitored postoperatively until spontaneous breathing has been re-established. Severe respiratory depression in a 14-month-old child after intravenous sedation with fentanyl and midazolam has also highlighted the necessity for careful monitoring when giving with other respiratory depressants.[2] If present at the end of operation respiratory depression may be reversed by an opioid antagonist such as naloxone; alternatively, a respiratory stimulant such as doxapram that does not reverse analgesia has been given.

Rigidity of the respiratory muscles (chest wall rigidity) may occur during fentanyl anaesthesia. The effects can be minimised by using a slow intravenous injection but a neuromuscular blocker may be required to allow artificial ventilation; rigidity has been reversed postoperatively by naloxone. Similar muscle rigidity induced by alfentanil could be attenuated by pretreatment with a benzodiazepine whereas small doses of neuromuscular blockers appeared to be ineffective.[3]

Coughing has been associated[4] with intravenous fentanyl; incidence was decreased with a longer injection time,[5] in light cigarette smokers,[5,6] and in older patients.[6] For the use of beclometasone and lidocaine to prevent cough associated with intravenous fentanyl in anaesthesia, see p.1518 and p.1852, respectively.

The risk of respiratory depression associated with *epidural* doses of fentanyl, a highly lipid-soluble opioid, has been considered relatively small and only slight ventilatory depression was noted[7] after a dose of 50 micrograms. However, profound delayed respiratory depression has been reported in 2 women 100 minutes[8] and 80 minutes,[9] respectively after fentanyl 100 micrograms had been given epidurally for caesarean section. No adverse effects on neonatal respiration or neurobehaviour were detected in a study[10] of neonates of mothers given epidural infusions of bupivacaine and fentanyl during labour. However, a later report[11] described 2 neonates who developed respiratory depression after their mothers were given epidural fentanyl during labour; the effect was reversed by intramuscular naloxone 400 micrograms. The authors noted that the doses of fentanyl used were higher than those in the previous study.

Respiratory depression is also a risk with *topically* applied fentanyl preparations. Severe hypoventilation with some fatalities has occurred in patients given fentanyl as a transdermal patch for minor painful conditions.[12] More recently, Health Canada had received 2 reports of fatal respiratory depression associated with the use of transdermal fentanyl patches in adolescents for relatively minor conditions (chronic headache and throat pain);[13] in both cases the respiratory depression developed within 24 hours of applying the first and only patch. Precautions

As for Opioid Analgesics in general, p.103.

Caution is advised in patients with myasthenia gravis; the effects of muscular rigidity on respiration may be particularly pronounced in these patients.

US licensed product information contra-indicates the use of standard transdermal fentanyl patches in opioid-naive patients because of the risk of fatal respiratory depression (see Effects on the Respiratory System, above and Administration, Transdermal Route, below). Similar contra-indications apply to fentanyl buccal tablets (see Administration, Transmucosal Route, below).

Absorption of fentanyl from standard transdermal patches may be increased as the temperature rises and patients should therefore avoid exposing the patch to external heat; similarly, patients with fever may require monitoring because of increased absorption. It may take 17 hours or longer for plasma concentrations of fentanyl to decrease by 50% after removal of a transdermal patch; patients who have had adverse effects should be monitored for up to 24 hours and those requiring replacement opioid therapy should initially receive low doses increased gradually thereafter. Similar advice is also given for patients receiving fentanyl via an iontophoretic drug delivery system; the mean half-life of fentanyl in this system is 11 hours.

The bioavailability of different transmucosal fentanyl preparations is not equivalent and consequently they should not be substituted on a dose-per-dose basis.

Abuse. Several synthetic analogues of fentanyl, so-called 'designer drugs', have been manufactured illicitly for recreational use, particularly in the USA. They are highly potent, and respiratory depression and death may occur very rapidly.[1] The 'fentanyls' have been smoked or snorted as well as injected intravenously.

Fentanyl analogues identified by WHO[2,3] as being subject to street abuse or likely to be abused include: alpha-methylfentanyl (also known as 'China white' or 'synthetic heroin'), 3-methylfentanyl, acetyl-alpha-methylfentanyl, alpha-methylthiofentanyl, para-fluorofentanyl, beta-hydroxyfentanyl, beta-hydroxy-3-methylfentanyl, thiofentanyl, and 3-methylthiofentanyl.

Fentanyl itself is also subject to illicit use. It is chemically unrelated to morphine and does not react in screening tests for morphine-related opioids. It has therefore been recommended[4] that fentanyl should be tested for specifically in cases with suspected opioid misuse.

Used fentanyl transdermal systems may contain significant amounts of fentanyl and have been subject to abuse. In some cases the contents of the patches have been injected intravenously; such abuse has resulted in death.[5,6] Licensed product information advises that used patches and iontophoretic transdermal systems should be folded firmly in half, adhesive side inwards to conceal the release membrane, and disposed of safely.

6. Tharp AM, *et al.* Fatal intravenous fentanyl abuse: four cases involving extraction of fentanyl from transdermal patches. *Am J Forensic Med Pathol* 2004; **25:** 178–81.

Administration. *INTRAVENOUS ROUTE.* Fentanyl is much more lipid-soluble than morphine and after standard single intravenous doses has a rapid onset and short duration of action. However, fentanyl is rapidly redistributed in the body and has a longer elimination half-life than morphine (see under Pharmacokinetics, below). Hence, with high or repeated doses, fentanyl becomes a relatively long-acting drug; to avoid accumulation patients should be monitored and doses adjusted accordingly.

Repeated intra-operative doses of fentanyl should be given with care, since not only may the respiratory depression persist into the postoperative period but it may become apparent for the first time postoperatively when the patient is away from immediate nursing attention.

TRANSDERMAL ROUTE. Fatalities have been associated with the use of standard fentanyl transdermal patches (see Effects on the Respiratory System, above). Incorrect or inappropriate use resulting in serious adverse effects and fatalities had prompted regulatory authorities to issue warnings and recommendations for changes to product labelling; in particular transdermal fentanyl patches are not appropriate for the treatment of acute or postoperative pain. Nonetheless, reports of fatalities and life-threatening adverse reactions have continued to be received[1,2] and, in December 2007, the FDA[1] reiterated that:

- fentanyl patches are indicated for the management of persistent, moderate to severe chronic pain in opioid-tolerant patients
- licensed product information must be consulted when determining the initial dose as overestimating when converting patients from another opioid analgesic can result in fatal overdose with the first dose
- use with any inhibitors of the cytochrome P450 isoenzyme CYP3A4 may result in an increase in plasma-fentanyl concentrations, which may cause potentially fatal respiratory depression; patients who are taking CYP3A4 inhibitors and using fentanyl patches for an extended period of time should be monitored and the dose of fentanyl adjusted if necessary

TRANSMUCOSAL ROUTE. The FDA[1] has received reports of serious adverse effects, including fatalities, in patients who have taken the fentanyl buccal tablets, *Fentora* (*Cephalon, USA*), resulting from inappropriate use in patients who were not opioid tolerant, misunderstanding of dosing instructions, or inappropriate substitution for other fentanyl-containing formulations. The FDA reiterated that *Fentora*:

- should only be used for breakthrough pain in opioid-tolerant cancer patients
- should not be used in those who only need an opioid on an intermittent, or as required, basis and who are not on around-the-clock opioids
- should not be used for the management of acute or postoperative pain including headaches, migraines, and pain due to injury
- should not be directly substituted for other fentanyl-containing formulations

1. FDA. Information for healthcare professionals: fentanyl buccal tablets (marketed as Fentora) (issued 26th September, 2007). Available at: http://www.fda.gov/cder/drug/InfoSheets/HCP/fentanyl_buccal.htm (accessed 24/07/08)

Breast feeding. The American Academy of Pediatrics[1] states that there have been no reports of any clinical effect in infants of breast-feeding mothers given fentanyl, and that therefore it may be considered to be usually compatible with breast feeding. The *BNF* also considers that the amount of fentanyl distributed into breast milk is too small to be harmful to a breast-fed infant. However, licensed product information states that, since fentanyl is distributed into breast milk, it should be avoided in nursing mothers because of the possibility of sedation or respiratory depression in breast-fed infants.

A study[2] using fentanyl 100 micrograms intravenously for induction of anaesthesia in 5 mothers concluded that the amount of fentanyl excreted into breast milk within 24 hours of induction was less than 0.1% of the maternal dose, and hence unlikely to affect a healthy full-term breast-feeding infant.

Children. The *BNFC* states that the half-life of fentanyl is prolonged in neonates and accumulation is likely with prolonged use; muscle rigidity may occur and the use of muscle relaxants may be required. See also under Pharmacokinetics, below.

Exercise. Opioid toxicity requiring naloxone treatment occurred in a patient who wore a fentanyl patch while engaging in vigorous outdoor exercise.[1] Physicians should be aware that along with fever and external heat sources, physical activity may cause increased absorption of transdermal fentanyl.

Handling. Avoid contact with skin and the inhalation of fentanyl citrate particles.

Interactions

For interactions associated with opioid analgesics, see p.103. Use of fentanyl with non-vagolytic neuromuscular blockers may produce bradycardia and possibly asystole.

Fentanyl is metabolised via the cytochrome P450 isoenzyme CYP3A4; use with potent inhibitors of this isoenzyme, such as ritonavir and other HIV-protease inhibitors, may increase fentanyl plasma concentrations.

Antidepressants. For reference to a possible case of serotonin syndrome associated with use of fentanyl and *SSRIs*, see Opioid Analgesics under Interactions of Fluoxetine, p.397.

Antivirals. *Ritonavir*, an inhibitor of the cytochrome P450 isoenzyme CYP3A4, might prolong fentanyl-induced respiratory depression. The plasma clearance of fentanyl was decreased, and the elimination half-life and area under the plasma concentration-time curve increased, when given with ritonavir in a study in healthy subjects.[1]

Pharmacokinetics

After parenteral doses fentanyl citrate has a rapid onset and short duration of action. After transmucosal delivery, up to 50% of the dose is rapidly absorbed from the buccal mucosa; the remainder is swallowed and slowly absorbed from the gastrointestinal tract. Some first-pass metabolism occurs via this route. The absolute bioavailability of transmucosal delivery is about half that for intravenous fentanyl but varies between formulations. Absorption is slow after transdermal application. Fentanyl is metabolised in the liver by *N*-dealkylation and hydroxylation via the cytochrome P450 isoenzyme CYP3A4. Metabolites and some unchanged drug are excreted mainly in the urine. The short duration of action is probably due to rapid redistribution into the tissues rather than metabolism and excretion. The relatively longer elimination half-life reflects slower release from tissue depots. About 80% has been reported to be bound to plasma proteins. Fentanyl appears in the CSF. It crosses the placenta and has been detected in breast milk.

◊ Marked differences in results of pharmacokinetic studies of fentanyl have been attributed[1] to differences in assay methods. The need for sensitive assay methods has been emphasised because the potency of fentanyl means that small doses are used. However, there are differences in pharmacokinetics between bolus doses and prolonged infusion with highly lipophilic drugs such as fentanyl.[2] Terminal half-lives ranging from 2 to 7 hours have been reported in healthy subjects and surgical patients. However, the duration of action of fentanyl after a single intravenous dose of up to 100 micrograms may be only 30 to 60 minutes as a result of rapid redistribution into the tissues. US licensed product information has given values for a three-compartment pharmacokinetic model with a distribution time of 1.7 minutes, a redistribution time of 13 minutes, and a terminal elimination half-life of 219 minutes. Giving repeated or large doses, or continuous infusions, may result in accumulation and a more prolonged action.

The clinical significance of secondary peak plasma-fentanyl concentrations and the possible role of entero-systemic recirculation[3] has been controversial, but some[4] considered that irregular decay curves were not unlikely for lipophilic compounds such as fentanyl, especially in patients undergoing operations and subject to large changes in blood flow. Unexpectedly high plasma-fentanyl concentrations in a patient following epidural use were thought to be a result of aortic clamping and might reflect the effect of changes in blood flow.[5]

The main metabolites of fentanyl, which are excreted in the urine, have been identified as 4-*N*-(*N*-propionylanilino) piperidine and 4-*N*-(*N*-hydroxypropionylanilino) piperidine; 1-(2-phenethyl)-4-*N*-(*N*-hydroxypropionylanilino) piperidine is a minor metabolite.[6] Fentanyl has no active or toxic metabolites.[4]

Cardiopulmonary bypass. In general, studies[1,2] indicate that serum concentrations of fentanyl during cardiopulmonary bypass decrease initially and then remain stable. The fall in concentrations has been attributed to haemodilution although adsorption to the bypass apparatus has also been found.

Children. The disposition of intravenous fentanyl 10 to 50 micrograms/kg in 14 neonates undergoing various major surgical procedures was highly variable.[1] The mean elimination half-life of 317 minutes and other pharmacokinetic parameters including volume of distribution and total body clearance were greater than reported in adults, but both pharmacodynamic and pharmacokinetic mechanisms appeared responsible for the very prolonged respiratory depression that can occur in neonates after fentanyl anaesthesia. In 9 premature neonates given fentanyl 30 micrograms/kg intravenously for induction of anaesthesia[2] the elimination half-life ranged from 6 to 32 hours, but cautious interpretation was advised because of the method of calculation.

The elderly. In one study the elimination half-life of intravenous fentanyl increased from 265 minutes in patients with a mean age of 36 years to 945 minutes in those with a mean age of 67 years.[1] The authors of another study were critical of the relatively short sampling time used and in contrast found that major fentanyl pharmacokinetic parameters did not correlate with age.[2] However, elderly patients had increased brain sensitivity to intravenous fentanyl, as shown by EEG changes[2] and lower doses might be indicated in older patients for pharmacodynamic rather than pharmacokinetic reasons.

Hepatic impairment. The pharmacokinetics of fentanyl were not affected significantly in surgical patients with cirrhosis of the liver.[1] A 1987 review[2] considered that fentanyl had not been associated with clinical problems when given to patients with liver dysfunction.

Renal impairment. Clearance of fentanyl from plasma was reported to be enhanced in surgical patients with end-stage renal disease,[1] although clearance was reduced and elimination half-life increased in patients with renal failure undergoing transplantation,[2] possibly because of the influence of uraemia on metabolism in the liver. Nevertheless, a 1987 review[2] noted that fentanyl had no active or toxic metabolites and had not been associated with clinical problems when given to patients with renal dysfunction.

Uses and Administration

Fentanyl, a phenylpiperidine derivative, is a potent opioid analgesic (p.104) chemically related to pethidine (p.113) and is primarily a μ-opioid agonist.

Fentanyl is used as an analgesic, as an adjunct to general anaesthetics, and as an anaesthetic for induction and maintenance. It is also used as a respiratory depressant in the management of mechanically ventilated patients under intensive care. When used with an antipsychotic such as droperidol it can induce a state of neuroleptanalgesia in which the patient is calm and indifferent to his surroundings and is able to cooperate with the surgeon.

Fentanyl is usually given parenterally or by the transmucosal route as the citrate, in transdermal patches as the base, or by iontophoretic transdermal delivery as the hydrochloride. Fentanyl citrate 157 micrograms and fentanyl hydrochloride 111 micrograms are each equivalent to about 100 micrograms of fentanyl. Doses are expressed in terms of the base.

It is more lipid soluble than morphine and after an intravenous injection of 100 micrograms the effects of fentanyl begin almost immediately, although maximum analgesia and respiratory depression may not occur for several minutes; the duration of action of fentanyl depends on the dose and the intensity of the pain involved, and may vary from 10 minutes to several hours.

For **premedication** the equivalent of 50 to 100 micrograms of fentanyl may be given *intramuscularly* 30 to 60 minutes before the induction of anaesthesia.

As an **adjunct** to general anaesthesia, fentanyl is usually given by *intravenous* injection. Dosage recommendations show a wide range depending on the technique.

- *Patients with spontaneous respiration* may be given 50 to 200 micrograms as an initial dose with supplements of 50 micrograms. In the USA it is recommended that doses above 2 micrograms/kg be accompanied by assisted ventilation. Significant respiratory depression follows doses of more than 200 micrograms
- *Patients whose ventilation is assisted* may be given 300 micrograms to 3.5 mg (up to 50 micrograms/kg) as an initial dose, with supplements of 100 to 200 micrograms depending on the patient's response. High doses have been reported to moderate or attenuate the response to surgical stress (see Anaesthesia, below)

Fentanyl may also be given by intravenous infusion. In ventilated patients a loading dose of about 1 microgram/kg per minute is given for the first 10 minutes followed by an infusion of about 100 nanograms/kg per minute; alternatively, the loading dose may be given as a bolus. The infusion rate should be titrated according to response and rates of up to 3 micrograms/kg per minute have been used in cardiac surgery. Infusions should be stopped about 40 minutes before the end of surgery unless artificial ventilation is to be continued postoperatively. In patients with spontaneous respiration, lower infusion rates of 50 to 80 nanograms/kg per minute are used.

Reduced doses are used in *the elderly* or debilitated patients

Similar doses to those used for premedication may also be given by *intramuscular* injection **postoperatively**, and by *intramuscular* or *slow intravenous injection* as an adjunct to **regional anaesthesia**.

For the treatment of **intractable chronic pain** in adults when opioid analgesia is indicated *transdermal* patches delivering amounts of fentanyl ranging from 12 to 100 micrograms/hour are available. In the UK, fentanyl patches may be used in strong opioid-naive patients; however, in the USA, use is restricted to patients who are already tolerant to opioid therapy of comparable potency.

- Doses should be individually titrated for each patient according to previous opioid usage. Initial dosages should not exceed 25 micrograms/hour in *opioid-naive* patients; in addition, it is recommended that these patients are initially titrated with low doses of short-acting opioids before transferring to fentanyl patches
- For *patients who have been receiving a strong opioid analgesic* the initial dose of the fentanyl patch should be based on the previous 24-hour opioid requirement. Use of a patch providing 25 micrograms of fentanyl per hour is equivalent to about 60 to 90 mg daily of oral morphine sulfate. During transfer to treatment with fentanyl patches previous opioid analgesic therapy should be phased out gradually in order to allow for the gradual increase in plasma-fentanyl concentrations
- More than one patch may be applied if doses greater than 100 micrograms/hour are required (applied at the same time to avoid confusion); additional or alternative analgesic therapy should be considered if doses greater than 300 micrograms/hour are required. Patches should be replaced every 72 hours with the new patch being applied to a different site; use of the same area of the skin should be avoided for several days
- *Elderly* or debilitated patients should be observed carefully for signs of toxicity and the dose reduced if necessary

Fentanyl patches are not appropriate for acute or postoperative pain.

A patient-activated *iontophoretic transdermal* fentanyl delivery system, *IONSYS* (*Janssen-Cilag, UK*; *Ortho-McNeil, USA*), is available for the management of acute moderate to severe **postoperative pain** in hospitalised patients. Patients should be titrated to an acceptable level of analgesia before starting therapy. *IONSYS* contains fentanyl hydrochloride and each system delivers an equivalent of 40 micrograms of fentanyl per dose over 10 minutes, to a maximum of 6 doses per hour, for 24 hours after the first dose or for 80 doses (maximum of 3.2 mg), whichever is reached first. The maximum duration of treatment is 72 hours, or 3 consecutive systems applied sequentially, with the new system being applied to a different site; only one system should be worn at a time. It should be applied to intact, non-irritated, and non-irradiated skin on the chest or upper outer arm.

A lozenge-on-a-stick dosage form of fentanyl citrate for *transmucosal* delivery is used as an analgesic in the management of **breakthrough cancer pain** in those already receiving and tolerant to opioid treatment. Lozenges containing the equivalent of 200 micrograms to up to 1.6 mg of fentanyl are available. An initial unit dose of 200 micrograms may be taken over 15 minutes for an episode of breakthrough pain and repeated once if necessary after a further 15 minutes. Doses are subsequently titrated according to response, up to a unit dose of 1.6 mg if necessary. Once the patient has been stabilised on an effective dose, no more than 4 unit doses should be taken daily.

In the USA, a buccal tablet containing fentanyl citrate for transmucosal delivery is also available and licensed for the same indication as the lozenge. Tablets containing the equivalent of 100 micrograms to up to 800 micrograms of fentanyl are available. An initial dose of 100 micrograms may be taken for an episode of breakthrough pain and repeated once if necessary after 30 minutes; thereafter, patients must wait at least 4 hours before treating another episode. Doses are subsequently titrated according to response. The dose of the maintenance opioid used for persistent pain should be re-evaluated if the patient has more than 4 episodes of breakthrough pain a day.

Caution must be exercised when switching between the lozenge and buccal tablet as the extent of absorption may be substantially different.

For details of doses in *children*, see below.

Administration. ***INHALATION ROUTE.*** In a study[1] inhaled fentanyl provided plasma concentrations similar to those after intravenous doses; use as patient-controlled analgesia was suggested. INTRANASAL ROUTE. Studies[1-3] have shown that intranasal fentanyl is as effective as the intravenous route for postoperative pain management and that it can be used in a patient-controlled analgesia system. Intranasal fentanyl has also been studied[4-6] for the management of acute pain in children. Intranasal spray formulations of fentanyl are under investigation for the treatment of breakthrough cancer pain.

INTRASPINAL ROUTE. For a discussion on the intraspinal use of fentanyl, see Postoperative Pain, below.

TRANSDERMAL ROUTE. Transdermal fentanyl is used for chronic intractable cancer pain in adults and children.[1-5]

Transdermal fentanyl is also used in the treatment of chronic non-cancer pain;[4-6] however transdermal use is contra-indicated in the management of acute or postoperative pain because the problems of dose titration in the short term increase the possibility of development of significant respiratory depression[4] (see also under Adverse Effects and under Precautions, above).

Although the licensed dosage interval for transdermal patches of fentanyl is 72 hours studies have suggested that up to about 25% of cancer patients may require more frequent application with some patients requiring fresh patches every 48 hours.[7,8] Equally, in an attempt to supply lower doses than are allowed for by existing transdermal dosage forms, patches have sometimes been cut, folded, or partially masked with non-porous dressings; the manufacturers do not recommend such practices as they consider the dose supplied will be unreliable, and there is potential for overdosage.

An iontophoretic drug delivery system containing fentanyl hydrochloride is also available for the management of acute moderate to severe postoperative pain in a hospital setting (see Postoperative Pain, below for some references).

TRANSMUCOSAL ROUTE. Transmucosal fentanyl has been tried for sedation and analgesia before anaesthesia or painful procedures in adults[1] and children[2,3] and is used for breakthrough cancer pain in opioid-tolerant patients.[4,5] It has been noted[6] that this dosage method can cause all the adverse effects of parenteral opioids; nausea and vomiting are common and potentially lethal respiratory depression can occur (see also under Precautions, above). Administration in children. Indications for fentanyl therapy in children are similar to those in adults (see above).

Fentanyl is usually given by *intravenous* injection as an **adjunct** to general anaesthesia. In the UK recommended initial doses range from 2 to 3 micrograms/kg in children aged 2 to 12 years with *spontaneous respiration*; supplements of 1 microgram/kg may be given. (The *BNFC* suggests initial doses of 1 to 5 micrograms/kg for neonates and children up to 12 years of age.) When *ventilation* is *assisted*, the initial recommended dose is also 2 to 3 micrograms/kg, with supplements of 1 microgram/kg. (The *BNFC* suggests an initial dose of 5 to 10 micrograms/kg for neonates and children up to 12 years of age, with supplements of 1 to 3 micrograms/kg.) In the USA doses are similar to those licensed in the UK.

Children may also be given fentanyl by intravenous infusion: licensed product information implies that doses are similar to those used in adults (see above) although the *BNFC* recommends that the infusion rate in ventilated patients is 1.5 micrograms/kg per hour in neonates and is 1 to 6 micrograms/kg per hour in older children.

Transdermal patches delivering amounts of fentanyl ranging from 12 to 100 micrograms/hour may be used for the treatment of **intractable chronic pain** in children aged 2 years and older who are already tolerant to opioid therapy of comparable potency. The initial dose should be based on the previous 24-hour opioid requirement. Use of a patch providing 12 micrograms of fentanyl per hour is equivalent to about 30 to 44 mg daily of oral morphine sulfate. See Uses and Administration, above for further details. Patches should be applied to the upper backs of young children to minimise the potential for removal.

Although the *transmucosal* lozenge-on-a-stick formulation is not licensed for use in children, the *BNFC* suggests a single dose of 15 to 20 micrograms/kg (maximum of 400 micrograms) for the management of **breakthrough pain** and as **premedication** in those aged 2 years and older, and who weigh more than 10 kg.

Anaesthesia. Fentanyl and its congeners alfentanil and sufentanil are shorter-acting than morphine and appear to produce fewer circulatory changes; they are preferred for use as supplements during anaesthesia with inhalational or intravenous drugs. Fentanyl is widely used as the analgesic component of balanced anaesthesia. It has been used to attenuate cardiovascular stress responses to intubation (see Anaesthesia, p.1900), and may be used in higher doses in an attempt to reduce the cardiovascular, endocrine, and metabolic changes that may accompany surgery. When attenuation of surgical stress is especially important, for example in cardiac surgery, intravenous fentanyl 50 to 100 micrograms/kg in conjunction with oxygen and a neuromuscular blocker, and sometimes up to 150 micrograms/kg, may be used for general anaesthesia. Total intravenous anaesthesia with fentanyl and propofol has been successful.[1]

Satisfactory anaesthesia has been reported[2] with high-dose fentanyl citrate (30 to 50 micrograms/kg) in *premature infants* when used as sole anaesthetic, in conjunction with pancuronium, for ligation of patent ductus arteriosus; cardiovascular stability was maintained throughout the procedure. However, others[3] found significant hypotension in preterm infants given either fentanyl 20 micrograms/kg, isoflurane, halothane, or ketamine; systolic arterial pressure was best maintained with the ketamine technique. The surgical stress response in preterm babies was abolished by the addition of fentanyl 10 micrograms/kg intravenously to an anaesthetic regimen of nitrous oxide and tubocurarine.[4] Dose responses of fentanyl in *neonatal* anaesthesia have been discussed.[5]

For details of doses in neonates and children, see above.

Neuroleptanalgesia. An injection of short-acting fentanyl 50 micrograms/mL with the longer-acting antipsychotic droperidol 2.5 mg/mL has been used for neuroleptanalgesia, premedication, and as an adjunct to anaesthesia. However, the use of such a fixed-ratio combination cannot be recommended.

PHAEOCHROMOCYTOMA. Unlike morphine and some other opioids, fentanyl and alfentanil do not release histamine and may be used safely in the anaesthetic management of patients with phaeochromocytoma.[1]

POSTOPERATIVE SHIVERING. As pethidine appears to be effective in the treatment of postoperative shivering a number of other opioids including fentanyl have also been tried. Not all opioids are necessarily effective but fentanyl has been reported to be so,[1] although information is scanty.[2]

Intensive care. Despite the short duration of action of fentanyl after single doses, rapid redistribution in the body results in an elimination half-life longer than that of morphine. Consequently fentanyl is not a short-acting drug when used for analgesia in intensive care, and may offer little advantage over morphine.[1]

Pain. ***CANCER PAIN.*** Transdermal fentanyl is used in the management of chronic intractable cancer pain; for references see Administration, Transdermal Route, above. For references to the use of transmucosal fentanyl in the management of breakthrough cancer pain, see Administration, Transmucosal Route, above.

LABOUR PAIN. Fentanyl has been reported to be an effective intravenous analgesic during active labour. Epidural fentanyl is unreliable when used alone,[1,2] although it does enhance the epidural analgesia achieved with the local anaesthetic bupivacaine. The reduction in the minimum local analgesic concentration of epidural bupivacaine for labour pain increased with increasing dose of fentanyl added to bupivacaine.[3] However, the incidence of pruritus increased significantly with fentanyl in a dose of 4 micrograms/mL and therefore the optimum dose of fentanyl may be 3 micrograms/mL for bupivacaine-sparing epidural analgesia during labour. Respiratory depression has also been reported with the combination.[4]

POSTOPERATIVE PAIN. Small intravenous bolus doses of an opioid analgesic may be injected immediately after surgery for postoperative analgesia and faster acting opioids such as fentanyl may be preferable to morphine.[1] Fentanyl has also been given by epidural injection in doses of 100 or 200 micrograms or by continuous epidural infusion in doses of 20 to 80 micrograms/hour; patient-controlled systems have been used.[2]

Epidural fentanyl or sufentanil provided effective postoperative analgesia after caesarean section with comparable adverse effect profiles.[3] The suggested optimal dose of fentanyl was 100 micrograms. For references comparing epidural fentanyl with alfentanil, see Postoperative Analgesia under Uses and Administration of Alfentanil, p.18. In a review[4] of perioperative pain management epidural opioids were considered to provide effective analgesia at lower doses than systemic opioids. Fentanyl may be given through a lumbar epidural catheter that is often inserted immediately postoperatively. After an initial loading dose of 1 to 1.5 micrograms/kg of fentanyl, infusion at the rate of 0.7 to 2 micrograms/kg per hour is begun and continued for about 48 hours on average. Some prefer to use intermittent injection. A small study[5] comparing 2 patient-controlled routes of administration found that cervical epidural fentanyl provided better postoperative pain relief at rest than intravenous fentanyl; however, there was no decrease in the total dose required and the authors considered that the benefits of epidural fentanyl did not outweigh its potential complications.

Combined opioid and local anaesthetic epidural infusions have also proved effective, for example fentanyl 1 microgram/mL with bupivacaine 0.1%; both could be infused at lower rates than either drug alone. Although a study[6] comparing bupivacaine-fentanyl combinations with each drug alone for epidural analgesia after caesarean section confirmed an additive analgesic effect for the combination, there was no demonstrable clinical benefit compared with fentanyl alone in this patient group who expect early mobilisation. However, the combination may be of greater benefit in patients for whom early ambulation is not routine.

Fentanyl has also been given by epidural injection to children for postoperative analgesia.[7]

Fentanyl has been tried by intrathecal injection for postoperative pain.[8]

As mentioned in Administration, Transdermal Route, above, an iontophoretic transdermal system for postoperative pain is also available.[9-11]

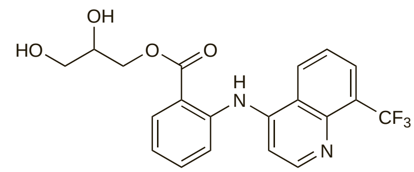
CAS — 23779-99-9.
ATC — N02BG04.
ATC Vet — QN02BG04.



Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Anaphylactic shock has been reported, and may be preceded by minor allergic manifestations; floctafenine should be stopped in any patient who develops signs suggestive of allergy (such as pruritus or urticaria). Reactions may also involve the liver. Floctafenine may cross-react with glafenine (p.62) and should not be given to patients who have had glafenine-associated reactions.

Porphyria. Floctafenine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Floctafenine is absorbed from the gastrointestinal tract; peak plasma concentrations are obtained 1 to 2 hours after ingestion. Its plasma half-life is about 8 hours. It is metabolised in the liver to floctafenic acid. It is excreted mainly as glucuronide conjugates in the urine and bile.

Uses and Administration

Floctafenine, an anthranilic acid derivative related to glafenine (p.62), is an NSAID (p.99) used in oral doses of up to 1.2 g daily, in divided doses, for the short-term relief of pain.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving flufenamic acid, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

An early study[2] found that only very small amounts of flufenamic acid were excreted into breast milk after oral doses.

Uses and Administration

Flufenamic acid, an anthranilic acid derivative related to mefenamic acid (p.80), is an NSAID (p.99). Flufenamic acid is mainly used topically in a concentration of 3 or 3.5% for the relief of pain and inflammation associated with musculoskeletal, joint, and soft-tissue disorders. Flufenamic acid and its aluminium salt have also been given orally.

Profile

Flupirtine maleate is an analgesic that has been given for the relief of pain (see Choice of Analgesic, p.2) in usual doses of 100 mg three or four times daily by mouth, or 150 mg three or four times daily as a rectal suppository; daily doses of up to 600 mg by mouth or 900 mg rectally have been used where necessary. Flupirtine has also been given by intramuscular injection as the gluconate in the management of acute pain.

There has been some interest in the potential of flupirtine to treat prion diseases such as Creutzfeldt-Jakob disease (see below).

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Minor symptoms of ocular irritation including transient burning and stinging have been reported on instillation of flurbiprofen sodium eye drops; there may be increased bleeding from ocular surgery and wound healing may be delayed. Local irritation has also followed rectal use, and local effects including a sensation of warming or burning in the mouth may be seen after using flurbiprofen lozenges.

Precautions

As for NSAIDs in general, p.98.

Breast feeding. Flurbiprofen is distributed into breast milk; however, the *BNF* and licensed product information consider the amount to be too small to be harmful to a breast-fed infant.

Herpes simplex keratitis. Whether flurbiprofen can exacerbate infection when used to treat ocular herpes simplex is unclear from *animal* studies,[1,2] but licensed product information for flurbiprofen sodium eye drops recommends that they should not be used in patients with active epithelial herpes simplex keratitis. Patients with a history of herpes simplex keratitis should also be monitored closely when undergoing treatment with these eye drops.

Interactions

For interactions associated with NSAIDs, see p.99.

Parasympathomimetics. Licensed product information for acetylcholine chloride ophthalmic preparations and for flurbiprofen sodium eye drops states that there have been reports that *acetylcholine* and *carbachol* have been ineffective when used in patients treated with topical (ophthalmic) NSAIDs.

Pharmacokinetics

Flurbiprofen is readily absorbed from the gastrointestinal tract after oral doses with peak plasma concentrations occurring about 1 to 2 hours after ingestion. Absorption after rectal doses may be more rapid. It is about 99% bound to plasma proteins and has a plasma half-life of about 3 to 6 hours. It is metabolised mainly by hydroxylation (via the cytochrome P450 isoenzyme CYP2C9) and conjugation in the liver and excreted in urine. Flurbiprofen is distributed into breast milk.

Flurbiprofen is a chiral compound given as the racemate and the above pharmacokinetic characteristics refer to the racemic mixture. Allowance may have to be made for the different activities of the enantiomers.

Uses and Administration

Flurbiprofen, a propionic acid derivative, is an NSAID (p.99). It is used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis, in soft-tissue disorders such as sprains and strains, for postoperative pain, and in mild to moderate pain including dysmenorrhoea and migraine. Flurbiprofen is also used as lozenges in the symptomatic relief of sore throat. Flurbiprofen sodium is used in eye drops to inhibit intra-operative miosis and to control postoperative inflammation of the anterior segment of the eye.

For **pain and inflammation**, flurbiprofen is given in usual oral doses of 150 to 200 mg daily in divided doses, increased to 300 mg daily in acute or severe conditions if necessary. A modified-release preparation for once-daily use is also available. Patients with dysmenorrhoea may be given an initial dose of 100 mg followed by 50 to 100 mg every four to six hours to a maximum total daily dose of 300 mg. Doses given rectally as suppositories are similar to those given by orally.

For the relief of **sore throat**, a lozenge containing 8.75 mg of flurbiprofen may be sucked or allowed to dissolve slowly in the mouth every 3 to 6 hours to a maximum daily dose of 5 lozenges. It is recommended that treatment should be limited to a maximum of 3 days.

To inhibit intra-operative miosis during **ocular surgery** one drop of flurbiprofen sodium 0.03% is instilled into the eye every 30 minutes beginning 2 hours before surgery and ending not less than 30 minutes before surgery. To control postoperative inflammation the same dosage regimen is used before ocular surgery followed 24 hours after surgery by the instillation of one drop 4 times daily for 1 to 3 weeks. Flurbiprofen sodium eye drops have also been used in the topical treatment of cystoid macular oedema.

Flurbiprofen axetil has been given in some countries by intravenous injection for severe pain.

The *R*-enantiomer, tarenflurbil, is under investigation in the management of Alzheimer's disease.

Profile

Glafenine, an anthranilic acid derivative, is an NSAID (p.96) that was used for the relief of all types of pain. However, its high incidence of anaphylactic reactions has led to its withdrawal from the market in most countries. Glafenine hydrochloride was also used.

Adverse effects and precautions. Glafenine is a common cause of anaphylaxis. There may be hepatotoxicity (sometimes fatal), nephrotoxicity, and gastrointestinal disturbances. It should be stopped at the first sign of any allergic reaction. Crystallisation of glafenine in the urinary tract has also occurred. Cross-reactivity with floctafenine has been reported.

- Co-hycodAPAP (*PEN*)—hydrocodone tartrate and paracetamol.

The following terms have been used as 'street names' (see p.vi) or slang names for various forms of hydrocodone tartrate:

Cough Syrup; Vikes.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Hydrocodone Hydrogen Tartrate 2.5-Hydrate). White or almost white, hygroscopic, crystalline powder. Freely soluble or soluble in water; sparingly soluble in alcohol; practically insoluble in cyclohexane. A 2% solution in water has a pH of 3.2 to 3.8. Store in airtight containers. Protect from light.

USP 31 (Hydrocodone Bitartrate). Fine, white crystals or crystalline powder. Soluble in water; slightly soluble in alcohol; insoluble in chloroform and in ether. pH of a 2% solution in water is between 3.2 and 3.8. Store in airtight containers. Protect from light.

Profile

Hydrocodone, a phenanthrene derivative, is an opioid analgesic (p.101) related to codeine (p.37) and has similar actions, but is more potent on a weight-for-weight basis. Hydromorphone (below) is one of the metabolites of hydrocodone.

Hydrocodone is used mainly as the tartrate in combination preparations for the relief of irritant cough, though it has no particular advantage over codeine. Hydrocodone tannate has been used similarly. Hydrocodone tartrate is also used for the relief of moderate to moderately severe pain, usually with paracetamol. The usual oral dose of hydrocodone tartrate in such combination preparations is 5 to 10 mg every 4 to 6 hours.

For details of doses in children, see below.

Hydrocodone hydrochloride is given orally and also by injection. The polistirex derivative (a hydrocodone and sulfonated diethenylbenzene-ethenylbenzene copolymer complex) is used in modified-release preparations.

Hydrocodone has also been used in the treatment of dyspnoea.

Abuse. The abuse or overuse of preparations containing hydrocodone and paracetamol has been associated with *sensorineural hearing loss.*[1,2] Cochlear implants improved the hearing loss in some of the patients.

A case of *palatal perforation* associated with intranasal abuse of a crushed preparation of hydrocodone and paracetamol has also been reported.[3]

Administration in children. Hydrocodone tartrate may be given as part of a combination preparation for the relief of irritant cough in children aged from 6 to 12 years in usual oral doses of 2.5 mg every 4 to 6 hours. Older children may be given the usual adult dose (see above).

(hydromorphone)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of hydromorphone:

Dillies; HillBilly Heroin; Hospital heroin.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Hydromorphone Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water; very slightly soluble in alcohol; practically insoluble in dichloromethane. Protect from light.

USP 31 (Hydromorphone Hydrochloride). A fine white, or practically white, odourless, crystalline powder. Soluble 1 in 3 of water; sparingly soluble in alcohol; practically insoluble in ether. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. Colour change from pale yellow to light green occurred when solutions of minocycline hydrochloride or tetracycline hydrochloride were mixed with hydromorphone hydrochloride in 5% glucose injection.[1] Mixtures of hydromorphone hydrochloride and dexamethasone sodium phosphate exhibited concentration-dependent incompatibility.[2] White cloudiness, haziness, or precipitation developed 4 hours after mixing thiopental sodium and hydromorphone hydrochloride.[3]

Stability of mixtures of fluorouracil and hydromorphone hydrochloride in 0.9% sodium chloride or 5% glucose depended on the concentration of fluorouracil present.[4] Hydromorphone hydrochloride 0.5 mg/mL with fluorouracil 1 mg/mL was stable for at least 7 days at 32° and for at least 35 days at 23°, 4°, or −20°. When the concentration of fluorouracil was increased to 16 mg/mL, hydromorphone was noted to decompose incurring unacceptable losses after 3 days at 32° or after 7 days at 23°, but was stable for at least 35 days at 4° or −20°.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

UK licensed product information contra-indicates the use of hydromorphone hydrochloride in patients with hepatic impairment; however, product information in the USA permits its cautious use although doses may need to be reduced. It should also be used with caution and given in reduced doses to those with renal impairment.

Effects on the nervous system. Myoclonus has been reported[1] in a 55-year-old man given relatively low doses of intravenous hydromorphone with a total daily dose of 4 mg on day 1 and 6 mg on day 2; symptoms resolved when the drug was stopped on day 3. A chart review[2] for neuroexcitatory symptoms in 48 patients with terminal illnesses on hydromorphone found 13 cases of agitation, 9 of myoclonus, and 4 of seizures; maximal dose and treatment duration were noted to increase the risk of neurotoxicity.

Interactions

For interactions associated with opioid analgesics, see p.103.

Alcohol. The FDA received data from pharmacokinetic studies in healthy subjects which showed that significantly higher peak plasma concentrations of hydromorphone were achieved, as a result of dose-dumping, when alcohol was ingested with once-daily hydromorphone modified-release capsules (*Palladone;*

Purdue Frederick, USA); these increases were considered potentially lethal, even in opioid-tolerant patients.[1] Subsequently, this formulation was voluntarily withdrawn by the US manufacturer in July 2005.

Pharmacokinetics

Hydromorphone hydrochloride is rapidly but incompletely absorbed from the gastrointestinal tract after oral doses; peak plasma concentrations occur within 0.5 to 1 hour. Oral bioavailability is about 50% as it undergoes extensive first-pass metabolism. Hydromorphone is about 8 to 19% bound to plasma proteins. A plasma elimination half-life of about 2.5 hours has been reported after oral or intravenous doses. Hydromorphone appears to be widely distributed in the tissues; it crosses the placenta and is distributed into breast milk. It is extensively metabolised by glucuronidation in the liver and excreted in the urine mainly as conjugated hydromorphone, dihydroisomorphine, and dihydromorphine.

Uses and Administration

Hydromorphone hydrochloride, a phenanthrene derivative, is an opioid analgesic (p.104). It is related to morphine (p.89) but with a greater analgesic potency. Hydromorphone hydrochloride is used for the relief of moderate to severe pain and for the relief of non-productive cough.

In the treatment of **pain**, hydromorphone hydrochloride is a useful alternative to morphine for subcutaneous use since its greater solubility in water allows a smaller dose volume. After injection onset of action usually occurs within 15 minutes and analgesia is reported to last for more than 5 hours; after oral doses onset of analgesia is usually within 30 minutes. It is given by subcutaneous or intramuscular injection in initial doses of 1 to 2 mg every 4 to 6 hours as necessary. It may also be given by slow intravenous injection or by intravenous or subcutaneous infusion, with doses adjusted according to individual requirements. Higher parenteral doses may be given to opioid-tolerant patients using a highly concentrated solution containing 10 mg/mL that allows smaller dose volumes. In the UK, the initial oral dose is 1.3 mg every 4 hours; thereafter the dose may be increased as necessary. In the USA, initial oral doses of 2 mg may be given every 4 to 6 hours; doses may be increased to 4 mg or more for severe pain. Modified-release preparations are available for less frequent administration, but see Alcohol, under Interactions, above. By rectum, the usual dose is 3 mg every 6 to 8 hours.

For the relief of non-productive **cough** hydromorphone hydrochloride is given, as a syrup, in doses of 1 mg repeated every 3 to 4 hours.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96. Ibuprofen may be better tolerated than other NSAIDs.

Adverse effects that may be associated with the use of ibuprofen injection in premature **neonates** include intraventricular haemorrhage, periventricular leucomalacia, bronchopulmonary dysplasia, pulmonary haemorrhage, necrotising enterocolitis, intestinal perforation, oliguria, fluid retention, and haematuria; hypoxaemia and gastrointestinal haemorrhage have also been reported. In addition ibuprofen injection should not be given to neonates with life-threatening infection, with significant renal impairment, or with known or suspected necrotising enterocolitis. Infants who are bleeding (especially gastrointestinal bleeding or intracranial haemorrhage) or who have thrombocytopenia or coagulation defects should also not be given parenteral ibuprofen, and those given it should be monitored during treatment for signs of bleeding. Renal function should be monitored and if anuria or marked oliguria is evident at the time of a scheduled second or third dose, it should be delayed until renal function has returned to normal.

Symptoms of nausea, vomiting, and tinnitus have been reported after ibuprofen overdosage. More serious toxicity is uncommon, but gastric emptying followed by supportive measures is recommended if the quantity ingested within the previous hour exceeds 400 mg/kg.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving ibuprofen, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. The *BNF* also considers the amount of ibuprofen distributed into breast milk to be too small to be harmful to a breast-fed infant. A study[2] estimated that a breast-fed infant would ingest about 0.0008% of the maternal dose. However, licensed product information for some preparations, including some topical preparations, recommends that breast feeding should be avoided during ibuprofen treatment.

Effects on the blood. Blood disorders including agranulocytosis, aplastic anaemia,[1] pure white-cell aplasia,[2] and thrombocytopenia[3] have been reported in patients taking ibuprofen. Fatal haemolytic anaemia occurred in a man taking ibuprofen and oxazepam.[4]

Effects on the cardiovascular system. For a discussion of the cardiovascular effects of NSAIDs, including ibuprofen, see p.96.

Effects on the CNS. Aseptic meningitis has occurred in patients taking NSAIDs. A review[1] of NSAID-related CNS adverse effects summarised 23 literature reports of NSAID-associated aseptic meningitis; 17 reports involved ibuprofen, 4 sulindac, 1 naproxen, and 1 tolmetin. Of the 23 reports, 11 were in patients with a diagnosis of SLE. Typically the reaction is seen in patients who have just restarted NSAID therapy after a gap in their treatment. Within a few hours of restarting the NSAID the patient experiences fever, headache, and a stiff neck; abdominal pain may be present. The patient may become lethargic and eventually comatose. Symptoms resolve if the NSAID is stopped. It is believed to be a hypersensitivity reaction but there does not appear to be cross-reactivity between NSAIDs.

Similar conclusions have also been reported more recently.[2] After experience of 2 cases, a review of the literature identified 71 episodes of ibuprofen-induced aseptic meningitis in 36 patients; 22 patients had recurrent episodes after repeated ibuprofen use. An underlying auto-immune connective tissue disorder was noted in 22 patients of whom 14 had SLE, 6 had an undifferentiated or mixed disorder, 1 had rheumatoid arthritis , and 1 had Sjögren's syndrome. In most cases, symptoms developed within 24 hours of starting ibuprofen although 1 patient had been taking ibuprofen for 2 years before the onset of symptoms. Cross-reactivity was reported in only 1 patient who had also developed aseptic meningitis with both naproxen and rofecoxib.

Effects on the gastrointestinal tract. Ibuprofen may be associated with a lower risk of upper gastrointestinal effects than some other NSAIDs, but nonetheless it can cause dyspepsia, nausea and vomiting, gastrointestinal bleeding, and peptic ulcers and perforation. Colitis and its exacerbation have occurred.[1,2]

Effects on the kidneys. Reports of adverse renal effects with ibuprofen include an increase in serum creatinine concentration,[1] acute renal failure,[2-6] and nephrotic syndrome.[7] Cystitis, haematuria, and interstitial nephritis may occur. Acute flank pain and reversible renal dysfunction has been reported in some patients treated with ibuprofen.[8,9] See also Effects on Electrolytes, above.

Effects on the liver. Raised liver transaminase values were noted in 3 patients with chronic hepatitis C infection after taking ibuprofen.[1] Values returned to normal on stopping the drug; the effect recurred in one patient who was re-exposed. Other hepatic adverse effects reported with ibuprofen include hepatitis[2] and liver failure.[3].

Effects on the skin. Skin rashes may occur during hypersensitivity reactions although serious dermatological effects attributed to ibuprofen are rare. Reports of more serious effects have included Stevens-Johnson syndrome (often associated with hepatotoxicity),[1-4] photosensitivity,[5] and bullous leukocytoclastic vasculitis.[6]

Hypersensitivity. A fatal asthma attack occurred in a 65-year-old woman, with adult-onset asthma, 30 minutes after ingestion of ibuprofen 800 mg.[1]

Overdosage. There was a substantial increase in the number of cases of ibuprofen overdose reported to the National Poisons Information Service of the UK in the 2 years after its introduction as an 'over-the-counter' medication.[1] However, no concurrent increase in severity of poisoning was found and in only 1 of 203 cases was ibuprofen thought to have caused serious problems. It was concluded that ibuprofen appeared to be much less toxic in acute overdose than either aspirin or paracetamol. Current advice is that doses below 100 mg/kg are unlikely to cause toxicity in *children*, whereas clinical features will occur in children who have ingested more than 400 mg/kg. In *adults* the dose-response effect is less clear cut, but those who have ingested less than 100 mg/kg are unlikely to require treatment.

Nonetheless, reports illustrate the complexity of major overdosage with ibuprofen. A syndrome of coma, hyperkalaemia with cardiac arrhythmias, metabolic acidosis, pyrexia, and respiratory and renal failure was reported[2] in a 17-year-old man after major overdosage with ibuprofen and minor overdosage with doxepin. Hyperkalaemia was not evident until 14 hours after hospital admission and was thought to be due to a combination of potassium replacement for initial hypokalaemia, acidosis, muscle damage, and ibuprofen-induced renal failure. A 6-year-old child developed[3] shock, coma, and metabolic acidosis after ingestion of a dose of ibuprofen equivalent to 300 mg/kg. Treatment consisting of intubation, mechanical ventilation, fluid resuscitation, gastric lavage, and activated charcoal proved successful. In another report,[4] in which a 21-month-old child had ingested the equivalent of 500 mg/kg of ibuprofen, the presenting symptoms were acute renal failure with severe metabolic acidosis. The child developed tonic-clonic seizures 46 hours after ingestion, with significant hypocalcaemia and hypomagnesaemia, which may have been exacerbated by use of sodium polystyrene sulfonate and furosemide. The seizures, which could not be controlled with diazepam, phenytoin, and phenobarbital, ceased on correction of electrolyte balance.

Pharmacokinetics

Ibuprofen is absorbed from the gastrointestinal tract and peak plasma concentrations occur about 1 to 2 hours after ingestion. Ibuprofen is also absorbed on rectal use. It is partially absorbed after topical application to the skin; some licensed product information states that percutaneous absorption from topical gel is about 5% of that from an oral dose form. Ibuprofen is 90 to 99% bound to plasma proteins and has a plasma half-life of about 2 hours. It is rapidly excreted in the urine mainly as metabolites and their conjugates. About 1% is excreted in urine as unchanged ibuprofen and about 14% as conjugated ibuprofen. There appears to be little if any distribution into breast milk.

The above figures refer to racemic ibuprofen. However, ibuprofen's disposition is stereoselective and there is some metabolic conversion of the inactive *R*-(−)-enantiomer to the active *S*-(+)-enantiomer, dexibuprofen (p.39).

Uses and Administration

Ibuprofen, a propionic acid derivative, is an NSAID (p.99). Its anti-inflammatory properties may be weaker than those of some other NSAIDs.

Ibuprofen is used in the management of mild to moderate pain and inflammation in conditions such as dysmenorrhoea, headache including migraine, postoperative pain, dental pain, musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis including juvenile idiopathic arthritis, peri-articular disorders such as bursitis and tenosynovitis, and soft-tissue disorders such as sprains and strains. It is also used to reduce fever.

Ibuprofen is also used as an alternative to indometacin in the treatment of patent ductus arteriosus.

The usual **oral** dose for painful conditions is 1.2 to 1.8 g daily in divided doses although maintenance doses of 600 mg to 1.2 g daily may be effective in some patients. If necessary the dose may be increased; in the UK the maximum recommended dose is 2.4 g daily whereas in the USA it is 3.2 g daily. Modified-release preparations of ibuprofen are available for once- or twice-daily dosing, although actual dosages vary with different preparations. Patients with rheumatoid arthritis generally require higher doses of ibuprofen than those with osteoarthritis. The recommended dose for fever reduction is 200 to 400 mg every 4 to 6 hours to a maximum of 1.2 g daily. For oral doses in children, see Administration in Children, below.

Ibuprofen may be given **parenterally** in the treatment of patent ductus arteriosus in preterm infants; for details of doses, see below.

Ibuprofen is applied **topically** as a 5% cream, foam, gel, or spray solution; a 10% gel is also available. It is also used topically as a dressing containing 500 micrograms/cm^2 of ibuprofen for the management of ulcers and superficial wounds.

Ibuprofen is usually given as the base but **derivatives**, including various salts, esters, and other complexes, have also been used. These include lysine (see Patent Ductus Arteriosus, below) and sodium salts, guaiacol and pyridoxine esters, and mabuprofen (ibuprofen aminoethanol), isobutanolammonium, and meglumine derivatives.

Ibuprofen is usually given as a racemic mixture but preparations containing only the *S*-(+)-isomer dexibuprofen (p.39) are available in some countries.

Administration in children. In the UK, the following oral doses of ibuprofen, given according to age, are recommended by the *BNFC* for the treatment of **pain**, **inflammation**, or **fever** in children:

- 1 to 3 months: 5 mg/kg 3 or 4 times daily
- 3 to 6 months: 50 mg 3 times daily
- 6 to 12 months: 50 mg 3 or 4 times daily
- 1 to 4 years: 100 mg 3 times daily
- 4 to 7 years: 150 mg 3 times daily
- 7 to 10 years: 200 mg 3 times daily
- 10 to 12 years: 300 mg 3 times daily
- 12 to 18 years: 200 to 400 mg 3 or 4 times daily increased, if necessary, to a maximum of 2.4 g daily
- in *severe* conditions in children aged between 3 months and 12 years, a dose of 30 mg/kg daily in 3 or 4 divided doses may be given

In the USA, suggested doses for children aged 6 months and over are: for fever, 5 to 10 mg/kg (depending on the severity of the fever) and for pain, 10 mg/kg; doses may be given every 6 to 8 hours up to a maximum daily dose of 40 mg/kg.

In the treatment of **rheumatic disease** including juvenile idiopathic arthritis, the *BNFC* recommends a dose of 10 mg/kg 3 or 4 times daily (maximum 2.4 g daily) in children aged 3 months and over; if necessary up to 60 mg/kg daily in 4 to 6 divided doses (maximum 2.4 g daily) may be given in systemic juvenile idiopathic arthritis.

Similar dosage regimens are also suggested by UK licensed product information; however, ibuprofen use is not generally recommended in children weighing less than 5 kg and some suggest a maximum daily dose of 500 mg in those weighing less than 30 kg. A usual daily dose in the USA for juvenile idiopathic arthritis is 30 to 40 mg/kg in divided doses.

For **post-immunisation pyrexia**, a dose of 50 mg has been recommended; a second dose may be given after 6 hours. If the pyrexia persists after the second dose, medical advice should be sought. Infants aged 2 to 3 months may also be given a 50-mg dose of ibuprofen for post-immunisation pyrexia on the advice of a doctor.

Ibuprofen or its lysine salt are also used in the treatment of **patent ductus arteriosus** in preterm infants; dosage details for this indication are given below.

Cachexia. For reference to the use of ibuprofen with megestrol to treat cancer cachexia, see p.2115.

Cystic fibrosis. In patients with cystic fibrosis (see p.166), the inflammatory response to chronic pulmonary infection with *Pseudomonas* organisms contributes to lung destruction. NSAIDs have been studied in patients with cystic fibrosis as an alternative to corticosteroids to reduce pulmonary inflammation. A systematic review[1] found evidence in support of using high-dose NSAIDs, most notably ibuprofen, to slow the progression of lung damage in patients with cystic fibrosis. However, there are limited data about the long-term safety of high doses[1] and some consider that this may have limited such use of NSAIDs;[2] others remain to be convinced that a benefit has been demonstrated.[3] The reviewers did consider that there were sufficient data to recommend that NSAIDs be temporarily stopped when intravenous aminoglycosides or other nephrotoxic drugs are used.[1]

Pain. Findings from a long-term study[1] in 585 patients (mean age of 64 years) with knee pain suggested that oral and topical ibuprofen had an equivalent analgesic effect although the former was associated with more minor adverse effects; there was no difference in the rate of major adverse effects.

Patent ductus arteriosus. Ibuprofen or its lysine salt may be given **parenterally** for the treatment of patent ductus arteriosus (p.68) in preterm infants of less than 34 weeks' gestation; doses are expressed in terms of ibuprofen. Three intravenous doses (infused over 15 minutes) are given at 24-hour intervals; the initial dose is equivalent to 10 mg/kg of ibuprofen followed by two further doses of 5 mg/kg. If, 48 hours after this course of therapy the ductus remains open, a second course may be given, but if this produces no response surgery may be necessary. Ibuprofen injection, *when given as the base*, should be used undiluted, but if necessary it may be reconstituted with sodium chloride 0.9% or glucose 5% for injection. *When given as the lysine salt*, it should be diluted with sodium chloride 0.9% or glucose 5%.

For a suggestion that ibuprofen might be a better choice than indometacin for the treatment of patent ductus arteriosus, see p.68.

Ph. Eur. 6.2 (Indometacin). A white or yellow, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol. Protect from light.

USP 31 (Indomethacin). A pale yellow to yellow-tan, crystalline powder having not more than a slight odour. It exhibits polymorphism. Practically insoluble in water; soluble 1 in 50 of alcohol, 1 in 30 of chloroform, and 1 in 40 of ether. Protect from light.

Stability. Indometacin is unstable in alkaline solution.

Indometacin Sodium *(BANM, rINNM)*

Indometacina sódica; Indométacine Sodique; Indomethacin Sodium *(USAN)*; Indomethacin Sodium Trihydrate; Natrii Indometacinum. Sodium 1-(4-chlorobenzoyl)-5-methoxy-2-methylindole-3-acetate, trihydrate.

Натрий Индометацин

Pharmacopoeias. In *US.*

USP 31 (Indomethacin Sodium). Protect from light.

Incompatibility. Indometacin sodium injection is reconstituted with preservative-free sodium chloride for injection 0.9% or preservative-free water for injection. Preparations containing glucose should not be used; reconstitution at a pH below 6 may cause precipitation of indometacin. Visual incompatibility has been reported between indometacin sodium injection and tolazoline hydrochloride,[1] 7.5 and 10% glucose injection, calcium gluconate, dobutamine, dopamine, cimetidine,[2] gentamicin sulfate, levofloxacin,[3] and tobramycin sulfate.[4] A pH below 6 may account for the visual incompatibility of indometacin sodium and several of these drugs.

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Adverse effects are more frequent with indometacin than with many other NSAIDs, the most common being gastrointestinal disturbances, headache, vertigo, dizziness, and lightheadedness. Gastrointestinal perforation, ulceration, and bleeding may also occur; rarely, intestinal strictures have been reported. Other adverse effects include depression, drowsiness, tinnitus, confusion, insomnia, psychiatric disturbances, syncope, convulsions, coma, peripheral neuropathy, blurred vision, corneal deposits and other ocular effects, oedema and weight gain, hypertension, haematuria, skin rashes, pruritus, urticaria, stomatitis, alopecia, and hypersensitivity reactions. Leucopenia, purpura, thrombocytopenia, aplastic anaemia, haemolytic anaemia, agranulocytosis, epistaxis, hyperglycaemia, hypoaldosteronism and hyperkalaemia, and vaginal bleeding have been reported. There have also been reports of hepatitis, jaundice, and renal failure. Hypersensitivity reactions may also occur in aspirin-sensitive patients. Rectal irritation and bleeding has been reported occasionally in patients who have received indometacin suppositories.

Adverse effects associated with the use of indometacin injection in premature **neonates** may also include haemorrhagic, renal, gastrointestinal, metabolic, and coagulation disorders; pulmonary hypertension, intracranial bleeding, fluid retention, and exacerbation of infection may also occur.

Effects on the blood. There were 1261 reports of adverse reactions to indometacin reported to the UK CSM between June 1964 and January 1973. These included 157 reports of blood disorders (25 fatal) including thrombocytopenia (35; 5 fatal), aplastic anaemia (17; no fatalities), and agranulocytosis or leucopenia (21; 3 fatal).[1] Subsequently, the First Report from the International Agranulocytosis and Aplastic Anemia Study confirmed a significant relationship between the use of indometacin and agranulocytosis and aplastic anaemia.[2] Neutropenia has also been noted in a premature infant with patent ductus arteriosus after use of indometacin.[3]

Although use of indometacin in 20 women being treated for premature labour did not affect maternal prothrombin or activated partial thromboplastin time, maternal bleeding time during therapy was increased.[4] However, no cases of neonatal intraventricular haemorrhage or maternal postpartum haemorrhage were seen.

Effects on cerebral blood flow. See Patent Ductus Arteriosus under Uses and Administration, below.

Effects on the eyes. Severe and irreversible retinopathy, presumably due to long-term ingestion of high doses of indometacin occurred in a 33-year-old man.[1] A summary of previous literature reports of indometacin-induced ocular effects indicated that indometacin was retinotoxic, although to what degree was uncertain. For reference to effects on the optic nerve associated with indometacin, see p.97.

1. Graham CM, Blach RK. Indomethacin retinopathy: case report and review. *Br J Ophthalmol* 1988; **72:** 434–8.

Effects on the gastrointestinal tract. Nausea, vomiting, dyspepsia, gastrointestinal lesions, and serious reactions including gastrointestinal bleeding, ulceration, and perforation have occurred in patients receiving indometacin. Although it is well established that NSAIDs can produce adverse effects on the upper gastrointestinal tract, indometacin and other NSAIDs can also affect the large intestines.[1] Giving indometacin to preterm neonates increases the risk of small bowel perforation and necrotising enterocolitis.[2-4] Risk seems to be increased in very-low-birth-weight or extremely premature infants.

4. Fujii AM. Neonatal necrotizing enterocolitis with intestinal perforation in extremely premature infants receiving early indomethacin treatment for patent ductus arteriosus. *J Perinatol* 2002; **22:** 535–40.

Effects on the joints. For references to concern that NSAIDs such as indometacin may accelerate the rate of cartilage destruction in patients with osteoarthritis, see Effects on Bone, under NSAIDs, p.96.

Effects on the kidneys. Acute renal failure,[1] nephrotic syndrome,[2] and renal papillary necrosis[3] have been reported in patients given indometacin. There have been suggestions that misoprostol might reduce the risk of indometacin-induced renal toxicity.[4,5]

Renal impairment has also occurred in **neonates** given indometacin intravenously for patent ductus arteriosus. Although rare, and usually reversible, the effect may be serious in neonates with pre-existing renal disorders.[6] Serious or fatal renal toxicity has been reported in neonates exposed to indometacin due to maternal ingestion.[7] The renal effects of prenatal indometacin may be prolonged.[8]

Precautions

As for NSAIDs in general, p.98.

Indometacin should be used with caution in patients with epilepsy, parkinsonism, or psychiatric disorders. Dizziness may affect the performance of skilled tasks such as driving. Patients on long-term indometacin therapy should be examined regularly for adverse effects, and the *BNF* particularly recommends periodic blood and ophthalmic examinations. Rectal use should be avoided in patients with proctitis and haemorrhoids.

In addition indometacin should not be given to **neonates** with untreated infection, with significant renal impairment, or with necrotising enterocolitis. Infants who are bleeding (especially gastrointestinal bleeding or intracranial haemorrhage) or who have thrombocytopenia or coagulation defects should not be given indometacin and those receiving indometacin should be monitored during treatment for signs of bleeding. Electrolytes and renal function should also be monitored and if anuria or marked oliguria is evident at the time of a scheduled second or third dose, it should be delayed until renal function has returned to normal.

False-negative results in the dexamethasone suppression test have been reported in patients taking indometacin.

Breast feeding. Convulsions in a one-week old breast-fed infant appeared to be associated with maternal ingestion of indometacin;[1] the child had normal motor and mental development at the age of 1 year and seizures had not recurred.

Indometacin has been detected in breast milk, but some workers[2,3] and the *BNF* consider that the amount is so small that it should not constitute a contra-indication to breast feeding. The American Academy of Pediatrics[4] also states that indometacin is usually compatible with breast feeding despite acknowledging the above case report of convulsions. However, licensed product information recommends that indometacin should not be used in nursing mothers.

The elderly. After a study[1] of the pharmacokinetics of indometacin in the elderly it was suggested that the maintenance dose of indometacin in elderly patients should be reduced by 25%. The total clearance of indometacin in elderly subjects had been reduced when compared with that in young subjects; this was thought to be due to reduced hepatic metabolism in the elderly.

Interactions

For interactions associated with NSAIDs, see p.99.

Anti-inflammatory doses of aspirin decrease indometacin blood concentrations by about 20%. Diflunisal decreases the renal clearance and increases plasma concentrations of indometacin. Use of diflunisal with indometacin has also resulted in fatal gastrointestinal haemorrhage, and the two should not be used together. Plasma concentrations of indometacin are likely to be increased in patients receiving probenecid.

Antibacterials. Indometacin has been reported to increase plasma concentrations of *aminoglycosides*.

Antipsychotics. Severe drowsiness and confusion have been reported in patients given *haloperidol* with indometacin.[1]

Bone modulating drugs. Indometacin has been reported to increase the bioavailability of *tiludronate*, see p.1106.

Desmopressin. The effect of desmopressin may be enhanced by indometacin.

Digoxin. In addition to increasing digoxin serum concentrations (see p.1263), combination of digoxin with indometacin has been reported to reduce the half-life of the latter in premature neonates (see Half-life under Pharmacokinetics, below).

Parasympathomimetics. The manufacturer of acetylcholine chloride ophthalmic preparations has stated that there have been reports that *acetylcholine* and *carbachol* have been ineffective when used in patients treated with topical (ophthalmic) NSAIDs.

Pharmacokinetics

Indometacin is readily absorbed from the gastrointestinal tract in adults; peak plasma concentrations are reached about 2 hours after a dose. Absorption may be slowed by food or by aluminium- or magnesium-containing antacids. In premature neonates, absorption of oral indometacin is poor and incomplete. The bioavailability of rectal suppositories in adults has been reported to be comparable with or slightly less than the bioavailability with oral dosage forms.

Indometacin is about 99% bound to plasma proteins. It is distributed into synovial fluid, the CNS, and placenta. Low concentrations have been distributed into breast milk. The terminal plasma half-life has been reported to range from 2.6 to 11.2 hours in adults. The terminal half-life in neonates has been reported to be between 12 and 28 hours (see also below). Indometacin is metabolised in the liver to its glucuronide conjugate and to desmethylindomethacin, desbenzoylindomethacin, desmethyl-desbenzoylindomethacin, and to their glucuronides. Some indometacin undergoes N-deacylation. Indometacin and its conjugates undergo enterohepatic circulation. Excretion of indometacin and its metabolites is mainly in the urine with lesser amounts appearing in the faeces.

Half-life. The plasma half-life of indometacin in premature infants can be variable but appears to be inversely proportional to post-natal age and weight.[1,2] One population model suggests that for an infant of 1.17 kg, half-life would be 22.3 hours at a post-natal age of 8 days, but 16.1 hours at 25 days (and only 11.2 hours if also receiving digoxin).[2]

Uses and Administration

Indometacin, an indole acetic acid derivative, is an NSAID (p.99). It is used in musculoskeletal and joint disorders including ankylosing spondylitis, osteoarthritis, rheumatoid arthritis, and acute gout, and in periarticular disorders such as bursitis and tendinitis. It may also be used in inflammation, pain, and oedema following orthopaedic procedures, in mild to moderate pain in conditions such as dysmenorrhoea, and it has been used in the management of postoperative pain as an adjunct to opioids, and in the treatment of fever. Indometacin is also used as the sodium salt to close patent ductus arteriosus in premature infants (see below).

The usual initial oral dose in **chronic musculoskeletal and joint disorders** is 25 mg two or three times daily increased, if required, by 25 to 50 mg at weekly intervals to 150 to 200 mg daily. To alleviate night pain and morning stiffness, up to 100 mg of the total daily dose may be given orally, or rectally as a suppository, on retiring. Alternatively, the total daily dose may be given rectally as 100 mg in the morning and at night. The total daily combined oral and rectal dose should not exceed 200 mg. In acute gout the daily dose is 150 to 200 mg in divided doses until all symptoms and signs subside; in dysmenorrhoea up to 75 mg daily has been suggested. Modified-release preparations of indometacin are available for use once or twice daily. For doses in children, see below.

Indometacin has been used as eye drops, usually of 0.1 or 0.5%, to **prevent miosis during cataract surgery**; the usual dose is 2 drops, repeated after 2 hours, on the day before surgery, then 2 drops 3 hours before and 2 drops 1 hour before surgery. The eye drops may then be instilled up to 6 times daily postoperatively to prevent **cystoid macular oedema**; treatment should be continued until inflammatory signs have disappeared. Indometacin eye drops have also been used in other inflammatory eye disorders in doses similar to those used to prevent oedema.

Meglumine indometacin and indometacin farnesil, a lipid soluble ester of indometacin ($C_{34}H_{40}ClNO_4$ = 562.1), have also been given for painful and inflammatory conditions. A complex of indometacin and L-arginine, known as indoarginine, has also been used.

Administration in children. Although indometacin is not licensed in the UK for the treatment of **rheumatic diseases** such as juvenile idiopathic arthritis in children, the *BNFC* suggests an oral dose of 0.5 to 1 mg/kg twice daily in those aged 1 month to 18 years; higher doses may sometimes be required.

Indometacin is also used in the treatment of **patent ductus arteriosus** in premature infants; see below for further details including doses.

Bartter's syndrome. The treatment of Bartter's syndrome can often be difficult (see p.1670). Blocking the kinin-prostaglandin axis with a cyclo-oxygenase inhibitor such as indometacin improves hypokalaemia and other clinical features (including growth retardation) in children with the syndrome.[1-5]

Malignant neoplasms. In common with some other NSAIDs (see p.100) it has been suggested that indometacin might possess some antineoplastic activity.[1] Some NSAIDs such as indometacin may also be of value for the differential diagnosis and the management of neoplastic fever, as they appear to be more effective in reducing this type of fever than against fever associated with infections.[2] Indometacin has also been tried for the treatment of fever and flu-like symptoms associated with interleukin-2 therapy although there has been concern over exacerbation of renal toxicity (see NSAIDs, under Interactions, p.736).

Neonatal intraventricular haemorrhage. Indometacin has been tried prophylactically to prevent the development of intraventricular haemorrhage in neonates at risk (see p.1050). Several mechanisms have been proposed for its possible action including reduction of cerebral flow as a result of vasoconstriction, reduction of oxygen free-radical damage, and accelerated maturation of blood vessels around the ventricles. Early studies[1-3] of the use of indometacin for prevention of intraventricular haemorrhage produced conflicting results. A subsequent large multicentre study[4] (the Indomethacin Intraventricular Haemorrhage Prevention Trial, IIHP) suggested that indometacin could reduce the incidence and severity of intraventricular haemorrhage, especially for the more severe forms. Neonates with a birth-weight of 600 to 1250 g were given indometacin in a dose of 100 micrograms/kg intravenously at 6 to 12 hours after delivery and then every 24 hours for 2 additional doses. There was, however, concern[5] that an unusually large number of neonates with severe intraventricular haemorrhage in the control group might have biased the findings.

A concern with the use of indometacin is the possibility that it may produce cerebral ischaemia due to its vasoconstrictor action and therefore increase the risk of developmental handicaps. Follow-up at 3 years,[6] at 4⁄ years,[7] and at 8 years of age[8] in the infants included in the IIHP study reported no adverse effects on cognitive or motor development. However, another large multicentre study[9] (the Trial of Indomethacin Prophylaxis in Preterms, TIPP) in extremely-low-birth-weight infants (less than 1000 g) found that although indometacin reduced the incidence of severe haemorrhage, it did not improve survival without neurosensory impairment at 18 months. A subsequent systematic review[10] also concluded that indometacin prophylaxis did not improve survival free of neurosensory disability although, again, the incidence of severe intraventricular haemorrhage was reduced.

Further analysis of the data from the IIHP study has suggested that indometacin might reduce intraventricular haemorrhage in boys but have little effect in girls;[11] verbal scores at ages 3 to 8 years were also higher in those boys treated with indometacin when compared to a control group of boys treated with saline; no differences in scores were noted in indometacin-treated girls and their control group. Re-analysis of data from the TIPP study[12] in extremely-low-birth-weight neonates suggested a weak gender difference in the effect of indometacin treatment when all primary outcomes such as death, cerebral palsy, cognitive delay, and severe intraventricular haemorrhage were considered; however, when outcomes were considered individually, there was a significant reduction in intraventricular haemorrhage in boys when compared with girls. The authors considered the results to be a consequence of an unfavourable effect of indometacin in girls rather than any positive effects in boys. Any true difference in effect between the sexes remains to be confirmed.

Indometacin does not appear to prevent the progression of existing haemorrhage.[13]

Patent ductus arteriosus. In the fetal circulation the ductus arteriosus connects the pulmonary artery and the descending aorta. After birth, various mechanisms, including a fall in prostaglandin concentration, trigger its closure but in some infants the ductus arteriosus fails to close, a condition known as persistent patent ductus arteriosus. This condition may be found in infants with congenital heart defects but is more commonly seen in premature neonates, especially those with respiratory distress syndrome.

- Some infants may be asymptomatic or have only slight clinical symptoms and no immediate intervention is required. In many cases spontaneous closure will occur after several months, or else surgical ligation may be performed if clinical symptoms persist.
- In some infants a patent ductus arteriosus is necessary for maintaining some oxygenation of the blood, for example in pulmonary artery atresia or transposition of the great arteries. These infants require treatment with a prostaglandin such as *alprostadil* or *dinoprostone* to maintain patency of the ductus arteriosus until surgery can be performed to correct the malformation.
- Infants with haemodynamically significant ductus arteriosus, signs of heart failure, and who require ventilation should undergo treatment to close the patent ductus arteriosus.

Initial **management** involves fluid restriction, diuretics, correction of anaemia, and support of respiration. *Chlorothiazide* and *furosemide* are diuretics commonly used. There has been concern that furosemide might delay closure in infants with respiratory distress syndrome.[1,2] A systematic review[3] concluded that this did not seem to be the case, and that the diuretic might reduce adverse renal effects of indometacin; however, the evidence for this was limited and it was felt that there was not enough evidence to support the use of furosemide in infants treated with indometacin.

If initial treatment fails to control symptoms after 24 to 48 hours then *indometacin* is generally given to promote closure of the ductus.[1,4-6] The benefits of treatment with indometacin as soon as symptoms become apparent, rather than delaying treatment until signs of congestive failure develop, have been debated.[7,8] Early treatment may significantly reduce the morbidities arising from a persistent patent ductus arteriosus.[7] However, delaying treatment until the end of the first week of life can allow for spontaneous closure and avoid the need of exposing infants to the toxic effects of indometacin.[8]

Indometacin probably leads to closure of the ductus through inhibition of prostaglandin synthesis. It is given as the sodium salt in three intravenous doses at 12- to 24-hour intervals; each dose should be infused over 20 to 30 minutes. Indometacin sodium injection is reconstituted with preservative-free sodium chloride 0.9% for injection or water for injection; glucose solutions should not be used (see Incompatibility, above). The dose of indometacin sodium (expressed as indometacin) depends upon the age of the neonate and the following doses have been suggested based upon the age at the first dose:

- less than 48 hours old: 200 micrograms/kg initially followed by two further doses of 100 micrograms/kg each
- 2 to 7 days old: three doses of 200 micrograms/kg each
- over 7 days old: 200 micrograms/kg initially followed by two further doses of 250 micrograms/kg each

If, 48 hours after this course of therapy the ductus remains open or re-opens, a second course may be used, but if this produces no response (which may be the case in 25% of infants treated[4,9]) surgery may be necessary.

Indometacin has been given orally where the injection is unavailable, but absorption of oral indometacin is poor and incomplete in premature neonates.

A decreased need for surgical closure and reduced recurrences were seen in neonates in whom standard intravenous indometacin therapy was then followed by maintenance therapy (intravenous indometacin 200 micrograms/kg daily for an additional 5 days).[10] Prolonged therapy using high doses of up to 1 mg/kg as a single dose every 12 hours has also been used with some success in a few infants who have not responded to standard regimens.[11] Similar beneficial findings were reported[12] in infants given prolonged low-dose indometacin therapy (100 micrograms/kg daily for 6 days). An additional benefit was a lower incidence of adverse effects; fewer infants had a rise in serum creatinine or urea concentrations. However, a systematic review[13] has suggested that such regimens are no more effective than the shorter standard regimens, and found an increased rather than decreased incidence of adverse effects (including a trend towards increased risk of necrotising enterocolitis[1,6]). Prolonged treatment with indometacin could not be recommended.[13] Prophylactic treatment or treatment of asymptomatic ductus with indometacin has been tried in premature infants, and there is good evidence to suggest that this is effective in reducing the risk of symptomatic patent ductus arteriosus and intraventricular haemorrhage (see above) in such patients;[7,14,15] however, prophylactic treatment has not been shown to significantly reduce the risk of short-term pulmonary complications such as bronchopulmonary dysplasia. Systematic reviews[14,15] have also found no evidence of either benefit or harm in neurological development or other longer term outcomes.

Some other NSAIDs have also been tried in the treatment of patent ductus arteriosus. Ibuprofen appears to be effective in closing a patent ductus arteriosus,[16] and it has been suggested that ibuprofen might be a better choice than indometacin as, unlike indometacin, it does not have adverse effects on renal, mesenteric, and cerebral haemodynamics. However, a recent systematic review[16] found no significant difference in the effectiveness of ibuprofen compared to indometacin and, although the risk of oliguria was reduced with ibuprofen, the risk for chronic lung disease may be increased. Ibuprofen is also effective when used prophylactically; however, there have been reports of pulmonary hypertension with such use and ibuprofen is not recommended.[17]

Oral therapy with ibuprofen has also been tried.[18]

Premature labour. The most common approach to postponing premature labour (p.2003) with drugs has historically been with a selective beta$_2$ agonist. However, as prostaglandins have a role in uterine contraction and cervical ripening and dilatation, prostaglandin synthetase inhibitors such as indometacin have also been used. Comparative studies[1,2] have shown that indometacin and ritodrine are equally effective in inhibiting uterine contractions and delaying delivery in patients in preterm labour who have intact membranes and in whom the gestational age is less than or equal to 34 weeks. In one study[2] an initial oral loading dose of indometacin 50 mg was given, followed by 25 to 50 mg orally every 4 hours until contractions stopped and then by a maintenance dose of 25 mg every 4 to 6 hours. In the other comparative study[1] indometacin was given as a 100-mg rectal suppository followed by 25 mg orally every 4 hours for 48 hours; if regular uterine contractions persisted 1 to 2 hours after the initial suppository, an additional 100-mg suppository was given before beginning oral therapy. Terbutaline was given for maintenance therapy.

Unfortunately indometacin can constrict the ductus arteriosus,[3-5] which may lead to pulmonary hypertension,[2] and has also been associated with bronchopulmonary dysplasia,[6] reduced volume of amniotic fluid (oligohydramnios)[2,4] and possible renal damage (see Effects on the Kidneys, above) in the fetus. Another complication is that prenatal indometacin exposure may increase both the incidence and severity of patent ductus arteriosus in premature infants,[7,8] as shown by the increased need for post-natal indometacin therapy and surgical ligation in such infants. However, there is evidence to suggest that there is no significant increase in the risk of neonatal complications in infants exposed to indometacin tocolysis when compared with control groups of infants who received either no treatment or tocolysis with drugs other than indometacin.[9,10]

The evidence for any overall benefit of indometacin in delaying labour is equivocal,[11-13] and it is generally reserved as a second-line tocolytic or for use with an intravenous tocolytic when an additive effect is required.

Adverse Effects, Treatment, and Precautions

Acute infusion reactions during or within 1 to 2 hours of infusion are common with infliximab, and other TNF inhibitors, particularly with the first or second dose. Symptoms include fever, chills, pruritus, urticaria, dyspnoea, chest pain, and hypertension or hypotension. Mild reactions may respond to a reduced rate of infusion or a temporary interruption. If reactions are more severe, therapy should be stopped. Pretreatment with paracetamol, corticosteroids, and antihistamines may be considered. TNF inhibitors should only be given where facilities for resuscitation are available. Delayed reactions have occurred 3 to 12 days after infliximab treatment; symptoms include myalgia, arthralgia, fever, and rash. Similar delayed reactions may also be seen when infliximab has been restarted after an extended period without treatment (see below).

Other, common, adverse effects include nausea and vomiting, abdominal pain, diarrhoea, fatigue, dizziness, headache, and back pain. Antibodies to infliximab (human antichimeric antibodies) may develop, and are associated with an increased incidence of hypersensitivity reactions. Antinuclear antibodies and anti-double-stranded-DNA antibodies have also developed with TNF inhibitor therapy. A lupus-like syndrome has occurred rarely; treatment should be stopped if it develops.

Infections are common in patients treated with infliximab or other drugs that inhibit TNF, and most often affect the upper respiratory tract and the urinary tract. TNF inhibitors have also been associated rarely with the development of serious opportunistic infections, sepsis, pneumonia, and onset or reactivation of tuberculosis (see below), particularly in patients with underlying conditions predisposing them to infections; in some cases death has resulted. TNF inhibitors should not be given to patients with severe infection, including active tuberculosis, abscesses, and opportunistic infections, and should be stopped if these develop. Patients should be evaluated for latent and active tuberculosis before beginning therapy; if evidence of latent tuberculosis is found, the risks and benefits of treatment should be considered carefully and chemoprophylaxis should be started before giving a TNF inhibitor. They should also be used with care in those with chronic infections, a history of recurrent infections, or with underlying conditions that may predispose to infections. Patients with fistulising Crohn's disease with suppurative fistulas should not be given infliximab until possible infection sources such as abscesses have been ruled out. Patients should be instructed to seek medical advice if symptoms suggestive of tuberculosis (such as persistent cough, weight loss, or low grade fever) occur. Patients should be monitored for signs of infection after stopping treatment: for adalimumab and infliximab, which both have long half-lives, monitoring should continue for 5 or 6 months, respectively; because of its relatively shorter half-life, the elimination of etanercept may be quicker.

There have been rare reports of severe hepatic reactions such as acute liver failure, jaundice, hepatitis, and cholestasis with infliximab; some cases have been fatal or required transplantation. Patients with signs or symptoms of hepatotoxicity should be evaluated and infliximab should be stopped in those patients with jaundice or marked elevations in liver enzyme values. Infliximab and other TNF inhibitors have also been associated with the reactivation of hepatitis B in chronic carriers, which has resulted in fatalities in some cases. Patients at risk of hepatitis B infection should be screened before starting treatment; it is recommended that carriers treated with a TNF inhibitor are closely monitored during, and for several months after stopping, treatment.

Blood dyscrasias, including leucopenia, thrombocytopenia, pancytopenia, and aplastic anaemia, have been reported rarely with TNF inhibitors; in some cases the outcome was fatal. They should be used with caution in patients with a history of blood dyscrasias.

Rare, and sometimes fatal, cases of interstitial lung disease including pulmonary fibrosis and pneumonitis have been reported with TNF inhibitors.

Infliximab and other TNF inhibitors are also associated with an increased incidence of malignancies including lymphoma (see also Carcinogenicity, below), although occurrences are rare. Some groups of patients treated with TNF inhibitors may already have an increased background risk of developing malignancies, regardless of drug treatment. Care has been advocated in patients with a history of malignancy.

Anaphylactic reactions have been reported rarely with TNF inhibitors. Infliximab should be avoided in patients with a history of hypersensitivity to the drug or other murine proteins.

TNF inhibitors have been associated with rare cases with seizures and clinical or radiological worsening of demyelinating disorders such as multiple sclerosis or optic neuritis; care is required in prescribing it to patients with such disorders or symptoms suggestive of their onset.

Worsening and, in some cases, new-onset heart failure has been reported with TNF inhibitors (see Effects on the Heart, below). (NYHA class III or IV). In the UK, infliximab is contra-indicated in patients with moderate to severe heart failure; however, US licensed product information advises that doses up to 5 mg/kg may be used in such patients. It should be used with caution in patients with mild heart failure (NYHA class I or II). All patients with heart failure should be closely monitored and infliximab stopped in those who develop new or worsening symptoms of heart failure. Similar recommendations are given for the TNF inhibitors adalimumab and etanercept, although UK licensed information for etanercept only advises caution in patients with heart failure.

Carcinogenicity. Malignancies, especially lymphomas, have been seen in patients treated with TNF inhibitors for rheumatoid arthritis and Crohn's disease;[1] however, the suggestion of a causal relationship is controversial. A meta-analysis[2] in 2006 identified 24 published reports of malignancies in 3493 study patients with rheumatoid arthritis who had received at least one dose of a TNF inhibitor (adalimumab or infliximab) along with 2 cases in 1512 control patients; further, unpublished, cases were also found using FDA data to give 29 malignancies in the treatment groups and 3 in the control groups. Based on these figures, there was a 3.3-fold increase in the risk of malignancy in patients receiving TNF inhibitors when compared with controls. These results have, however, been criticised[3] on a number of points including the difficulty in applying them to current practice because etanercept was not included in the analysis, and, in particular, the unexpectedly low rate of malignancies in the control groups. Other studies in patients with rheumatoid arthritis[4,5] and Crohn's disease[6] have generally concluded that the overall risk of malignancies is not significantly increased in patients taking TNF inhibitors when compared with patients who have not taken these drugs. Some studies[4,7] in patients with rheumatoid arthritis have, however, shown a possible increased risk of lymphoma with TNF inhibitor treatment, but caution in interpreting these results was recommended as they were based on a small number of cases; in addition, the background risk of lymphoma is increased in rheumatoid arthritis regardless of treatment. The risk of malignancies with TNF inhibitors requires further study.

Rare cases of hepatosplenic T-cell lymphoma have been seen in adolescents and young adults given infliximab for the treatment of Crohn's disease. In July 2006, the manufacturer was aware of 6 cases of this type of lymphoma in 5 adolescents aged 12 to 19 years and one 31-year-old adult;[8] 4 of the 6 cases occurred in males. The treatment duration ranged from 1 or 2 infusions to over 4 years of therapy; in all cases, patients were also taking or had taken azathioprine or 6-mercaptopurine. This type of lymphoma is aggressive and 5 of the above patients died. A causal relationship was not clearly established although it could neither be excluded. Further cases have since been reported.[9]

Delayed reactions. Ten of 37 patients with Crohn's disease retreated with infliximab after a 2 to 4 year period without treatment had delayed hypersensitivity reactions, of which 6 were considered serious. None of the patients had had infusion-related adverse effects with their original infliximab therapy. Adverse reactions developed in 9 of the 23 patients originally treated with a discontinued liquid formulation, and in 1 of the 14 patients who previously received the marketed formulation, leading to speculation that the formulation may have been a contributing factor.

Effects on blood lipids. A 35-year-old man with psoriatic arthritis and psoriasis developed markedly elevated triglyceride levels and a mildly increased total cholesterol level after a single infusion of infliximab;[1] tests prior to therapy had shown a mild hypertriglyceridaemia for which he had received no treatment. No further doses of infliximab were given and his triglyceride levels subsequently improved.

Effects on the CNS. Aseptic meningitis developed in a patient after his fifth injection of infliximab for rheumatoid arthritis.[1] Similar symptoms also occurred after a sixth injection.

Two patients with inflammatory bowel disease developed acute motor neuropathy with multiple conduction blocks following infliximab treatment; both patients improved after infliximab was stopped.[2] Similar adverse effects were reported in 2 further patients:[3] one was taking etanercept for rheumatoid arthritis and the other infliximab for ankylosing spondylitis. Three cases of bilateral optic neuropathy associated with infliximab therapy have also been reported.[4] Other neuropathies have been associated with TNF inhibitor treatment, including Guillain-Barré syndrome.[5]

Effects on the heart. The FDA has reported[1] on 47 patients who developed heart failure during long-term therapy with TNF antibodies (etanercept and infliximab) for arthritic conditions or Crohn's disease. Of these, 38 developed new-onset heart failure, 19 having documented risk factors for heart failure, and 9 had exacerbation of existing heart failure. The median time to new-onset heart failure was 3.5 months. However, studies[2-4] investigating a possible association between TNF inhibitors and the development of heart failure have been equivocal and further investigation is warranted.

Preliminary investigations on the use of infliximab in the treatment of moderate to severe heart failure failed to show any clinical improvement in patients given infliximab 5 mg/kg or 10 mg/kg when compared with placebo;[5] in addition, those given the higher dose had an increased risk of death or hospitalisation due to worsening heart failure.

Effects on the lungs. Infliximab treatment has been associated with a fatal exacerbation of previously asymptomatic fibrosing alveolitis in 3 patients with chronic rheumatoid arthritis;[1] all 3 patients were also taking azathioprine and prednisolone. There was no evidence of infection or other underlying causes for the decline in respiratory function.

1. Ostor AJK, *et al.* Fatal exacerbation of rheumatoid arthritis associated fibrosing alveolitis in patients given infliximab. *BMJ* 2004; **329:** 1266.

Effects on the skin. Patients with rheumatoid arthritis receiving TNF inhibitor therapy are more likely to develop adverse skin reactions than those who are not.[1] Of 289 patients taking TNF inhibitors (infliximab, etanercept, adalimumab, and lenercept), 72 (25%) reported 128 dermatological events including skin infections, eczema, drug-related eruptions, and malignancies such as actinic keratosis; of the 289 patients not taking TNF inhibitors, 37 (13%) reported dermatological events.

In another review,[2] cutaneous adverse effects were seen in 35 out of 150 patients receiving TNF inhibitors (adalimumab, etanercept, or infliximab) for rheumatic disorders; cases included dermatitis herpetiformis and leucocytoclastic vasculitis although eczematous and skin infections were more common or infectious. Perhaps unexpectedly, psoriasis-like lesions were seen in 8 patients, 6 of whom had no history of psoriasis; similar effects have also been noted in other patients with rheumatoid arthritis[3] or Crohn's disease.[4]

Rare cases of serious skin reactions have been associated with TNF inhibitor treatment.[5] Since approval in 1998, the FDA has received 15 cases of erythema multiforme, 5 cases of Stevens-Johnson syndrome, and 1 case of toxic epidermal necrolysis associated with infliximab; cases for etanercept, approved in the same year, included 13 reports of erythema multiforme, and 4 reports each of Stevens-Johnson syndrome and toxic epidermal necrolysis. For adalimumab, which was marketed late in 2002, there have been 4 cases of erythema multiforme and 2 of Stevens-Johnson syndrome.

Infection. There have been spontaneous reports of onset or reactivation of *tuberculosis* in patients treated with infliximab, including cases of miliary tuberculosis and unusual extrapulmonary disease.[1] The UK CSM noted in February 2001 that there had been 28 such reports worldwide. The US manufacturers subsequently reported[2] (in October 2001) that other serious opportunistic infections, including *histoplasmosis*, *listeriosis*, and *pneumocystosis* had occurred, and had led to some deaths; the number of reported cases of tuberculosis had risen to 84. Further opportunistic infections also continued to be reported; FDA data up to August 2002 included reports of *candidiasis*, *coccidioidomycosis*, *nocardiosis*, *aspergillosis*, and infections due to non-tuberculous mycobacteria.[3] Health Canada reported[4] in October 2004 that it had received 188 and 109 reports of infections associated with infliximab and etanercept, respectively, from January 2000 to May 2004. Of these, 10 and 2 reports were of tuberculosis associated with infliximab and etanercept, respectively. The FDA also received 25 reports of tuberculosis associated with etanercept between November 1998 and March 2002.[5] Although the majority of patients also had a history of treatment with immunosuppressants including corticosteroids, the inhibition of TNF may affect normal immune responses and predispose patients to opportunistic infections.

Guidelines[6] have been issued by the British Thoracic Society to quantify the risks of reactivation of tuberculosis with TNF inhibitors and to advise on the treatment of such infection in patients being assessed for TNF inhibitor therapy.

Interactions

Live vaccines should not be given with infliximab or other drugs that inhibit TNF as the effect of such drugs on vaccine efficacy or the risk of infection transmission is unknown. The use of TNF inhibitors with the interleukin-1 receptor antagonist anakinra may increase the risk of serious infections and neutropenia; such combinations are not recommended. A similar interaction has been seen with TNF inhibitors and the co-stimulation blocker abatacept.

Abatacept. Use of the TNF inhibitor etanercept with abatacept has resulted in an increase in the incidence of serious adverse effects including serious infections; in addition, there was no increase in clinical benefit.[1] Combinations of abatacept with TNF inhibitors are not recommended by UK licensed product information.

1. Weinblatt M, *et al.* Selective costimulation modulation using abatacept in patients with active rheumatoid arthritis while receiving etanercept: a randomised clinical trial. *Ann Rheum Dis* 2007; **66:** 228–34.

Anakinra. The incidence of serious infections, injection site reactions, and neutropenia is increased when anakinra is given with the TNF inhibitor etanercept.[1] In addition, the combination did not provide any further clinical benefit when compared to etanercept alone. Similar findings may be expected if anakinra is given with other TNF inhibitors.

Pharmacokinetics

Infliximab shows linear pharmacokinetics. It is distributed primarily in the vascular compartment and, after single doses, has a terminal elimination half-life of 8 to 9.5 days. After repeated doses, infliximab has been detected in serum for at least 8 weeks.

Uses and Administration

Infliximab is a chimeric monoclonal antibody to tumour necrosis factor α (TNF), a pro-inflammatory mediator. Elevated levels of TNF have been found in the affected tissues and fluids of patients with rheumatoid arthritis, ankylosing spondylitis, and psoriatic arthritis, and Crohn's disease and ulcerative colitis. Elevated TNF levels are also found in psoriatic plaques.

Infliximab is given by intravenous infusion over a usual period of not less than 2 hours; shorter infusion times have been used in some patients with rheumatoid arthritis (see below for further details).

Infliximab is used with methotrexate in the management of moderate to severe, active **rheumatoid arthritis** to reduce the signs and symptoms of the disease, delay structural damage, and improve physical function; in the UK it is licensed for use in patients who have had an inadequate response to standard disease-modifying antirheumatic drugs (DMARDs) although, in severe progressive cases, it may be used in patients not previously treated with methotrexate or other DMARDs; in the USA it may be used for treating early rheumatoid arthritis. Infliximab is given in a dose of 3 mg/kg, repeated at 2 and 6 weeks, then every 8 weeks thereafter. For the first 3 doses infliximab should be infused for at least 2 hours; however, UK licensed product information suggests that subsequent infusion times may be reduced to a minimum period of 1 hour in those who tolerate the initial infusions. A clinical response is usually achieved within 12 weeks of starting treatment. Patients with an inadequate response during this period or who later relapse may benefit by increasing the dose: in the UK, a maximum dose of 7.5 mg/kg every 8 weeks (with increases made in steps of 1.5 mg/kg) is recommended whereas, in the USA, a maximum dose of 10 mg/kg is allowed. Alternatively, a dose of 3 mg/kg may be given as often as every 4 weeks in such patients. Continuing therapy in those who show no response within the first 12 weeks of treatment or after dose adjustment should be carefully reconsidered: in the UK NICE recommends that infliximab be withdrawn if there is no adequate response within 6 months of starting treatment.

Patients with moderate to severe, active **Crohn's disease** unresponsive to conventional treatment may be given a single infliximab dose of 5 mg/kg. This may be followed by a maintenance regimen of additional infusions of 5 mg/kg at 2 and 6 weeks after the initial infusion and then every 8 weeks, or the drug may be readministered when signs and symptoms of the disease recur (but see below). UK licensed product information does not recommend further doses in patients who are unresponsive after the first 2 doses; in the USA, a patient is not considered to be unresponsive until 3 doses have been given. A similar regimen is used in patients with fistulising Crohn's disease although therapy should not be considered ineffective until after the third dose of infliximab. US product information suggests that doses of up to 10 mg/kg may be used in patients who relapse after an initial response. Infliximab is also used in the treatment of moderate to severe, active **ulcerative colitis** in patients unresponsive to conventional therapy; the recommended dose is 5 mg/kg given as a regimen similar to that used for Crohn's disease (see above). Therapy should not be considered ineffective until after the third dose of infliximab.

In the treatment of **ankylosing spondylitis**, UK licensed product information recommends that infliximab should only be used in patients with severe disease who have had an inadequate response to conventional treatment; however, in the USA it may be used in early treatment, to reduce the signs and symptoms. The initial dose is 5 mg/kg, repeated at 2 and 6 weeks and then every 6 to 8 weeks; if there is no response after 2 doses no further treatment should be given.

Infliximab is also used in the treatment of active and progressive **psoriatic arthritis**; in the UK, its use is limited to patients who have had an inadequate response to standard DMARD but, as before, US licensed product information allows earlier use. In the USA, it may be given with or without methotrexate; however, UK product information only recommends use without methotrexate in those patients who are intolerant of or have contra-indications to such treatment. It is given in a single dose of 5 mg/kg, repeated at 2 and 6 weeks and then every 8 weeks thereafter. Guidance issued by NICE in the UK recommends that treatment with infliximab is stopped after 12 weeks in those who show an inadequate response.

Infliximab is used in the treatment of moderate to severe plaque **psoriasis**. Its use is usually limited to patients in whom other treatments are not suitable. Infliximab is given in a dose of 5 mg/kg, repeated at 2 and 6 weeks, then every 8 weeks thereafter. Treatment should be stopped after 14 weeks (4 doses) in patients who show no response.

If the signs and symptoms of rheumatoid arthritis or Crohn's disease recur infliximab may be readministered if within 16 weeks of the last infusion. **Readministration** after a drug-free interval of more than 16 weeks may be associated with an increased risk of delayed hypersensitivity (see Delayed Reactions, above) and consequently is not recommended. Recommendations regarding the readministration of infliximab for other indications (other than those detailed above) have not been established. Limited data from readministration with a single dose of infliximab in psoriasis after an interval of 20 weeks suggest reduced efficacy and a higher incidence of mild to moderate infusion reactions when compared with the initial regimen.

For details of infliximab use in children, see below.

Administration in children. Infliximab is licensed for use in moderate to severe, active Crohn's disease in children aged 6 years and over who have not responded to conventional therapy, or who have contraindication for or are intolerant of such treatments; doses are the same as those used in adults (see above). UK licensed product information suggests that the dosage interval may be adjusted to maintain any benefits; however, further treatment is unlikely to be of use in patients not responding within the first 10 weeks.

Although unlicensed for such use in the UK, infliximab has also been used in children with fistulising Crohn's disease; the *BNFC* recommends that those aged 6 to 18 years may be treated with the same dosage regimen that is used for this indication in adults (see above).

Asthma. TNF inhibitors such as infliximab have been investigated in the treatment of refractory asthma (p.1108).[1,2] There is some evidence that only a minority of patients will respond to such therapy, and that the benefits and risks must therefore be carefully assessed.[2]

Inflammatory bowel disease. Infliximab is used in adults for the treatment of Crohn's disease[1-11] and ulcerative colitis[8,12-16] (see Inflammatory Bowel Disease, p.1697); it has also been used in children in the treatment of inflammatory bowel disease,[17-20] particularly Crohn's disease.

In the treatment of Crohn's disease, guidance issued in the UK by NICE recommends that infliximab is used in patients with severe disease when treatment with immunomodulators and corticosteroids has failed or is not tolerated, and when surgery is inappropriate.[21]

In the treatment of ulcerative colitis, guidance issued by NICE recommends against the use of infliximab in subacute manifestations of moderately to severely active disease (defined as that which would normally be managed in an outpatient setting, and does not require hospitalisation or the consideration of urgent surgical intervention).[22] The use of infliximab in acute manifestations of moderately to severely active ulcerative colitis is under review by NICE.

Leprosy. Infliximab has been used[1] in the treatment of recurrent type 2 (erythema nodosum leprosum) lepra reactions (see Leprosy, p.176). However, 2 cases of rapidly progressive leprosy developing in patients given infliximab for rheumatoid arthritis have also been described;[2] reversal (type 1) reactions occurred in both when infliximab was stopped.

Psoriasis. Infliximab is used in the treatment of moderate to severe plaque psoriasis (p.1583).[1-8] In the UK, NICE recommends[8] that it be reserved for severe cases, unresponsive to standard therapies (including ciclosporin, methotrexate, and PUVA) or where such therapies cannot be used.

Rheumatoid arthritis. TNF inhibitors play an increasingly important role in the management of rheumatoid arthritis; they tend to be reserved for patients who are unresponsive to more conventional disease-modifying drugs, although some favour use earlier in management.

Spondyloarthropathies. References to the use of infliximab in the treatment of ankylosing spondylitis and psoriatic arthritis (p.13). In the UK, NICE considers that TNF inhibitors should be reserved for severe active psoriatic arthritis unresponsive to at least 2 standard disease-modifying drugs; etanercept or adalimumab are preferred to infliximab.

Uveitis. Infliximab has been tried with some success in the treatment of uveitis (p.1515) including that associated with Behçet's syndrome (p.1499). Uveitis can also develop as a complication of other inflammatory disorders such as rheumatoid arthritis; treatment with infliximab may improve ocular symptoms in addition to its effect on the primary disorder.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

When ketoprofen is given intramuscularly there may be pain at the injection site and occasionally tissue damage. Topical preparations containing ketoprofen may cause application site reactions. Ketoprofen suppositories may cause local irritation; rectal use should be avoided in patients with a history of proctitis or haemorrhoids. Ketoprofen should be used with caution in patients with renal or hepatic impairment; it should not be used in those with severe renal impairment.

Dexketoprofen should be avoided in patients with moderate to severe renal or severe hepatic impairment, and in those with severe heart failure.

Effects on the skin. Contact and photoallergic dermatitis has been seen after topical use of ketoprofen.[1,2] A retrospective study[3] found that of the 139 cases of contact reactions to topical NSAIDs reported to the Spanish Pharmacovigilance System between 1996 and 2001, 84 involved ketoprofen (16 allergy; 68 photoallergy). Totals for other NSAIDs included piroxicam (21), etofenamate (10), piketoprofen (5), salicylates (4), fepradinol (3), diclofenac (3), indometacin (2). phenylbutazone (2), benzydamine (2), aceclofenac (1), naproxen (1), and mabuprofen (1). Analysis indicated that the number of reports for topical ketoprofen was disproportionately high in relation to its usage.

Hypersensitivity. Life-threatening asthma, urticaria, and angioedema developed in 2 aspirin-sensitive patients after taking ketoprofen 50 mg by mouth.[1] Cardiac and respiratory arrest occurred in an asthmatic patient shortly after taking ketoprofen.[2] Life-threatening asthma has also occurred after topical application of ketoprofen.[3]

There has been a report[4] of delayed skin hypersensitivity in a patient who used a topical gel containing ketoprofen. The reaction recurred on rechallenge to ketoprofen gel but not to a similar gel containing diclofenac. The authors of the report noted that the UK CSM had received 15 reports of skin reactions to ketoprofen gel, including two each of dermatitis and urticaria.

Myasthenia gravis. There has been a brief report[1] of a cholinergic crisis precipitated by a single oral dose of ketoprofen 50 mg in a patient with well-controlled myasthenia gravis. The patient had previously noted a similar but milder reaction with aspirin, but not with paracetamol.

Photosensitivity. Ketoprofen causes photosensitivity reactions[1,2] and cross-sensitivity to other drugs, notably the fibrates bezafibrate, ciprofibrate, and fenofibrate, has also been reported. The cross reactions were attributed to the benzoyl ketone structure that the drugs have in common.

Renal impairment. The elimination half-life and unbound plasma concentrations of dexketoprofen are increased in patients with renal impairment given racemic ketoprofen;[1,2] this appears to be principally attributable to impaired renal clearance of the acyl-glucuronide conjugates in a stereoselective fashion, with subsequent hydrolysis of the unstable conjugate back to the aglycone producing increased plasma-ketoprofen concentrations.[2,3] The authors of one study suggested[3] that dosage adjustments of racemic ketoprofen were indicated only for patients with moderately severe renal failure (creatinine clearance of less than 20 mL/minute).

Interactions

For interactions associated with NSAIDs, see p.99.

Probenecid delays the excretion of ketoprofen and decreases its extent of protein binding resulting in increased plasma-ketoprofen concentrations. Not unexpectedly, a similar interaction may be seen with dexketoprofen and probenecid.

Pharmacokinetics

Ketoprofen is readily absorbed from the gastrointestinal tract; peak plasma concentrations occur about 0.5 to 2 hours after an oral dose. When ketoprofen is given with food, the bioavailability is not altered but the rate of absorption is slowed. Ketoprofen is well absorbed from the intramuscular and rectal routes; only a small amount of percutaneous absorption occurs after topical application. Ketoprofen is 99% bound to plasma proteins and substantial concentrations of drug are found in the synovial fluid. The elimination half-life in plasma is about 1.5 to 4 hours. Ketoprofen is metabolised mainly by conjugation with glucuronic acid, and is excreted mainly in the urine.

Ketoprofen possesses a chiral centre. It is usually given as the racemate but its pharmacological actions appear to be due largely to the (*S*)-enantiomer, dexketoprofen. The pharmacokinetics of ketoprofen appear to exhibit little stereoselectivity (but see under Renal Impairment, above).

Uses and Administration

Ketoprofen, a propionic acid derivative, is an NSAID (p.99). Its anti-inflammatory properties may be weaker than those of some other NSAIDs. Ketoprofen is a racemic mixture; in *animal* studies the S-(+) enantiomer, dexketoprofen, has about twice the analgesic activity of ketoprofen by weight.

Ketoprofen is used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis, and in peri-articular disorders such as bursitis and tendinitis. It is also used in dysmenorrhoea, postoperative pain, in painful and inflammatory conditions such as acute gout or soft-tissue disorders, and to reduce fever. Dexketoprofen is used in the treatment of mild to moderate pain such as musculoskeletal pain, dysmenorrhoea, or dental pain.

In the treatment of rheumatic disorders a usual oral daily dose of ***ketoprofen*** is 100 to 200 mg in 2 to 4 divided doses; modified-release formulations taken once daily may also be used. Some licensed product information suggests initial oral doses of 75 mg three times daily or 50 mg four times daily increased as needed to a maximum of 300 mg daily in divided doses. Ketoprofen may also be given rectally as suppositories in a dose of 100 mg at night or 100 mg twice daily. It is recommended that the total daily combined oral and rectal dose should not exceed 200 mg. The usual oral dose for the treatment of other painful conditions including dysmenorrhoea is 25 to 50 mg every 6 to 8 hours. For details on the use of ketoprofen in patients with hepatic or renal impairment, see below.

Ketoprofen may be given by deep intramuscular injection into the gluteal muscle for acute exacerbations of musculoskeletal, joint, peri-articular and soft-tissue disorders and in the management of pain after orthopaedic surgery. Doses of 50 to 100 mg may be given every 4 hours, up to a maximum dose of 200 mg in 24 hours for up to 3 days. In some countries, ketoprofen has also been given intravenously in similar doses.

Ketoprofen may be applied as a 2.5% gel for local pain relief. Doses vary slightly between preparations: typically, they are applied 2 to 4 times daily for up to 10 days.

Dexketoprofen is given orally as the trometamol salt. Doses are expressed in terms of the base; dexketoprofen trometamol 36.9 mg is equivalent to about 25 mg of dexketoprofen. Usual doses are 12.5 mg every 4 to 6 hours or 25 mg every 8 hours; the total daily dose should not exceed 75 mg. Elderly patients should be started on a total daily dose not exceeding 50 mg. Dose reductions are also necessary in patients with hepatic or renal impairment, see below. It is usually recommended that NSAIDs are taken with or after food to reduce any adverse gastrointestinal effects; however, licensed product information for dexketoprofen states that absorption is delayed if the drug is taken with food and therefore recommends that in acute pain dexketoprofen should be given at least 30 minutes before food.

Ketoprofen has also been used as the lysine and as the sodium salt.

Administration in hepatic or renal impairment. No specific dosage recommendations for racemic *ketoprofen* in patients with hepatic or renal impairment are given by UK licensed product information, although the drug is contra-indicated in severe renal impairment and it is advised that the dose be kept as low as possible and renal function be monitored in more moderate renal impairment (but see also Renal Impairment, above). In the USA, however, it has been recommended that patients with hepatic impairment and a serum albumin concentration of less than 3.5 g/dL should be given a maximum initial daily dose of 100 mg orally. Patients with mild renal impairment should be given a maximum daily dose of 150 mg and those with more severe impairment (GFR less than 25 mL/minute per 1.73 m^2 or end-stage renal impairment) should not exceed a maximum daily dose of 100 mg.

UK licensed product information for *dexketoprofen* recommends a reduced initial daily dose of 50 mg orally in patients with mild to moderate hepatic or mild renal impairment. Dexketoprofen should not be used in patients with severe hepatic or moderate to severe renal impairment.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Ketorolac Trometamol). A white or almost white, crystalline powder. Freely soluble in water and in methyl alcohol; slightly soluble in alcohol; practically insoluble in dichloromethane. A 1% solution in water has a pH of 5.7 to 6.7. Protect from light.

USP 31 (Ketorolac Tromethamine). A white to off-white, crystalline powder. Freely soluble in water and in methyl alcohol; slightly soluble in alcohol, in dehydrated alcohol, and in tetrahydrofuran; practically insoluble in acetone, in acetonitrile, in butyl alcohol, in dichloromethane, in dioxan, in ethyl acetate, in hexane, and in toluene. pH of a 1% solution in water is between 5.7 and 6.7. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Concern over the high incidence of reported adverse effects with ketorolac trometamol has led to its withdrawal in some countries while in others its permitted dosage and maximum duration of treatment have been reduced.

Adverse effects reported include gastrointestinal disturbances including gastrointestinal bleeding (especially in the elderly), perforation, and peptic ulceration. Hypersensitivity reactions such as anaphylaxis, rash, bronchospasm, laryngeal oedema, and hypotension have also occurred. Other adverse effects reported include drowsiness, dizziness, headache, mental and sensory changes, psychotic reactions, sweating, dry mouth, thirst, fever, convulsions, myalgia, aseptic meningitis, hypertension, dyspnoea, pulmonary oedema, bradycardia, chest pain, palpitations, fluid retention, increases in blood urea and creatinine, acute renal failure, oedema, hyponatraemia, hyperkalaemia, urinary frequency or retention, nephrotic syndrome, flank pain with or without haematuria, purpura, thrombocytopenia, epistaxis, inhibition of platelet aggregation, increased bleeding time, postoperative wound haemorrhage, haematoma, flushing or pallor, and pancreatitis. Severe skin reactions including Stevens-Johnson syndrome and Lyell's syndrome have been reported. Liver function changes may occur; hepatitis and liver failure have been reported. There may be pain at the site of injection.

Ketorolac eye drops may produce transient stinging and other minor symptoms of ocular irritation. As with some other NSAIDs used in the eye, ketorolac has been implicated in reports of corneal toxicity (see p.45).

Incidence of adverse effects. Adverse effects reported with ketorolac are mainly those common to all NSAIDs with gastrointestinal reactions being the most frequent followed by haematological, renal, hypersensitivity, and then neurological reactions. From 1990 to 1993, 97 reactions with a fatal outcome were reported worldwide.[1] The causes of death were: gastrointestinal bleeding or perforation (47 cases); renal impairment or insufficiency (20); anaphylaxis or asthma (7); haemorrhagic reactions (4); and unexplained or miscellaneous causes (19). Concern over the safety of ketorolac has led to adverse reactions being monitored closely and to the implementation of restrictions on dose and duration of treatment (see Uses and Administration, below). A postmarketing surveillance study[2] examined the risks of parenteral ketorolac in 9 900 patients given 10 272 courses of ketorolac. The results indicated a dose-response relationship with average daily ketorolac dose for both gastrointestinal bleeding and operative site bleeding, the expected major risks, and an association between gastrointestinal bleeding and therapy for over 5 days. The risk of serious gastrointestinal bleeding and operative site bleeding was higher for elderly patients [licensed product information recommends that the elderly should not receive daily parenteral doses greater than 60 mg]. Although the overall associations between ketorolac use and both gastrointestinal bleeding and operative site bleeding are small, the risk becomes clinically important as doses increase, in elderly patients, and, for gastrointestinal bleeding only, when used for longer than 5 days.

US product information has consequently emphasised that ketorolac is a potent NSAID and is indicated only for the short-term management of moderate to severe pain and not for minor or chronic painful conditions; its use carries many risks and related adverse effects can be serious especially when used inappropriately. After examining data from the above study the EU Committee for Proprietary Medicinal Products adopted the opinion that ketorolac had a narrow therapeutic margin but that it was indicated for the short-term management of moderate to severe acute postoperative pain.

Precautions

As for NSAIDs in general, p.98.

In light of the concern over the toxicity of ketorolac it has been recommended that it should not be used during pregnancy or labour and some recommend that it should not be given to mothers who are breast feeding (but see below).

Ketorolac is contra-indicated in patients with a history of hypersensitivity to aspirin or other NSAIDs, a history of asthma, nasal polyps, bronchospasm, or angioedema, a history of peptic ulceration or gastrointestinal bleeding, in patients with moderate or severe renal impairment, and in those with hypovolaemia or dehydration. Ketorolac should not be given to patients with coagulation or haemorrhagic disorders or those with confirmed or suspected cerebrovascular bleeding. It is contra-indicated as a prophylactic analgesic before surgery and for intraoperative use because of its inhibitory effects on platelets; it should also not be given postoperatively to those who have undergone procedures with a high risk of haemorrhage.

The total daily dose of ketorolac should be reduced in the elderly and in patients weighing less than 50 kg. It is recommended that patients with mild renal impairment should receive a reduced dose of ketorolac and undergo close monitoring of renal function. Ketorolac should be used with caution in heart failure, hepatic impairment and conditions leading to reduction in blood volume or in renal blood flow. Ketorolac should be withdrawn if clinical symptoms of hepatotoxicity develop.

Drowsiness and dizziness may affect the performance of skilled tasks such as driving.

Breast feeding. The concentration of ketorolac distributed into breast milk is very low and a study[1] considered that the amount ingested by the infant would probably be too small to be harmful. The American Academy of Pediatrics[2] also states that there have been no reports of any clinical effect on the infant associated with the use of ketorolac by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding. However, the *BNF* and both UK and US licensed product information recommend that ketorolac should be avoided in mothers who are breast feeding.

Interactions

For interactions associated with NSAIDs, see p.99.

Ketorolac should not be given to patients already receiving anticoagulants or to those who will require prophylactic anticoagulant therapy, including low-dose heparin. The risk of ketorolac-associated bleeding is also increased by other NSAIDs or aspirin and by pentoxifylline and use together should be avoided. Probenecid increases the half-life and plasma concentrations of ketorolac and the two drugs should not be given together.

Parasympathomimetics. Licensed product information for acetylcholine chloride ophthalmic preparations states that there have been reports that *acetylcholine* and *carbachol* have been ineffective when used in patients treated with topical (ophthalmic) NSAIDs.

Pharmacokinetics

Ketorolac trometamol is absorbed after intramuscular or oral doses. At physiological pH ketorolac trometamol dissociates to form an anionic ketorolac molecule which is less hydrophilic than the trometamol salt. The peak plasma concentration of ketorolac is reached within about 30 to 60 minutes; absorption after intramuscular injection may be slower than that after oral doses in some individuals. Ketorolac is over 99% bound to plasma proteins. It does not readily penetrate the blood-brain barrier. Ketorolac crosses the placenta and small amounts of drug are distributed into breast milk. The terminal plasma half-life is about 4 to 6 hours, but is about 6 to 7 hours in the elderly and 9 to 10 hours in patients with renal dysfunction. The major metabolic pathway is glucuronic acid conjugation; there is some *para*-hydroxylation. About 90% of a dose is excreted in urine as unchanged drug and conjugated and hydroxylated metabolites, the remainder is excreted in the faeces.

Uses and Administration

Ketorolac, a pyrrolizine carboxylic acid derivative structurally related to indometacin (p.66), is an NSAID (p.99). It is used principally as an analgesic.

Ketorolac is used intramuscularly, intravenously, or orally as the trometamol salt in the short-term management of moderate to severe **postoperative pain**. However, it should be noted that because of concerns over the high incidence of reported adverse effects with ketorolac its dosage and maximum duration of use are restricted. The recommended maximum duration for parenteral therapy is 2 days in the UK, and patients should be transferred to oral therapy as soon as possible; oral use is limited to 7 days. In the USA it is recommended that the maximum combined duration of use of parenteral and oral ketorolac should not exceed 5 days.

- In the UK the recommended initial dose by the *parenteral* route is 10 mg of ketorolac trometamol followed by 10 to 30 mg every 4 to 6 hours as required, although ketorolac may be given as often as every 2 hours in the initial postoperative period if required. The total maximum daily dose is 90 mg (60 mg in the elderly, patients with mild renal impairment, and in those weighing less than 50 kg). Intravenous injections should be given over at least 15 seconds. During transfer from parenteral to oral therapy the combined daily dose for all forms of ketorolac trometamol should not exceed 90 mg (60 mg in the elderly, patients with mild renal impairment, and in those weighing less than 50 kg) of which no more than 40 mg should be given orally.
- Regimens in use in the USA include a single intramuscular dose of 60 mg or a single intravenous dose of 30 mg, or a multiple-dose regimen comprising 30 mg every 6 hours intramuscularly or intravenously, up to a maximum of 120 mg daily. These doses should be halved in the elderly, those with renal impairment, and those weighing less than 50 kg.
- The recommended *oral* dose in the UK is 10 mg every 4 to 6 hours (every 6 to 8 hours in the elderly) to a maximum of 40 mg daily for a maximum duration of 7 days.
- In the USA the recommended oral dose is 20 mg (10 mg in the elderly, the renally impaired, and those weighing under 50 kg), followed by 10 mg every 4 to 6 hours to a maximum of 40 mg daily.

For doses in children see Administration in Children, below.

Ketorolac trometamol is used as 0.5% eye drops to relieve **ocular itching** associated with seasonal allergic conjunctivitis. Ketorolac trometamol eye drops 0.5% have also been used for the topical treatment of **cystoid macular oedema** and for the prevention and reduction of **inflammation** associated with ocular surgery. In the USA, a 0.4% eye drop is also available for postoperative ocular inflammation.

Administration in children. In the USA, children aged between 2 to 16 years may be given a single intramuscular dose of 1 mg/kg of ketorolac trometamol up to a maximum of 30 mg or a single intravenous dose of 0.5 mg/kg up to a maximum of 15 mg. In the UK, parenteral ketorolac is only recommended for those aged 16 and over; doses are as for adults (see above).

Oral ketorolac is not licensed for use in children.

Administration in renal impairment. Ketorolac is contra-indicated in patients with moderate to severe renal impairment; for suggested doses in less advanced renal impairment, see Uses and Administration, above.

Adverse Effects, Treatment and Precautions

Common adverse effects seen with leflunomide are hypertension, gastrointestinal disturbances (particularly diarrhoea), weight loss, headache, dizziness, leucopenia, asthenia, paraesthesia, joint disorders and synovitis, upper respiratory-tract infections, alopecia, eczema, and dry skin. Hypersensitivity reactions may occur and a few cases of Stevens-Johnson syndrome, erythema multiforme, toxic epidermal necrolysis, or vasculitis have been reported. Hepatotoxicity has occurred. It is usually mild and reversible but rare cases of severe, sometimes fatal, liver disease, including acute hepatic necrosis, have been seen particularly in the first 6 months of therapy. Other adverse effects that have been reported include anxiety, peripheral neuropathy, hypokalaemia, and mild hyperlipidaemia. There have been rare reports of pancytopenia, agranulocytosis, and thrombocytopenia; these effects are more common when leflunomide is given with other myelosuppressive drugs (see Interactions, below). There have been occasional reports of pancreatitis, interstitial lung disease, and severe infections, including fatal sepsis. Renal failure has also been reported.

The active metabolite of leflunomide, A-771726, has a half-life of about 2 weeks. Consequently, the adverse effects of leflunomide may continue even after therapy has been stopped. When severe reactions occur, a drug washout procedure (see below) may be required.

Leflunomide should not be given to immunocompromised patients or to patients with severe infections, hepatic or moderate to severe renal impairment, severe hypoproteinaemia, or bone-marrow dysplasia. Patients with a history of tuberculosis should be carefully monitored because of the possibility of reactivation of the infection. Intra-uterine devices should be used with caution during immunosuppressive treatment as there is an increased risk of infection. Live vaccines should be avoided for the same reason. Blood pressure should be monitored regularly during therapy.

In the UK, liver enzyme values should be checked before beginning therapy and at fortnightly intervals during the first 6 months of treatment; US licensed product information recommends monthly monitoring for the first 6 months. Subsequent monitoring should be carried out at 6- to 8-week intervals. Dosage should be reduced if moderate elevations of liver enzyme values occur (see Administration in Hepatic Impairment, below); for persistent or more severe elevations leflunomide should be stopped and washout procedures begun. Monitoring of liver enzymes should be continued after stopping therapy until they return to within the normal range. Blood counts should also be checked at the same time as liver enzyme values.

Effects on the lungs. Up to December 2006, the Australian Adverse Drug Reactions Advisory Committee had received 142 reports of respiratory symptoms with leflunomide use since its introduction in 2000.[1] Of these, 22 reports mentioned at least one of the following serious reactions: pneumonitis (8), interstitial lung disease (9), lung infiltration (4), or pulmonary fibrosis (3); it was considered that all these were likely to represent interstitial lung disease. Four patients died, but relative causality was difficult to assign as methotrexate was also given in many cases, however, several patients had been on methotrexate long-term without any problems. It was recommended that the pulmonary status of patients should be considered before starting leflunomide and monitored during treatment; if symptoms such as cough or dyspnoea develop or worsen, leflunomide may need to be stopped.

The risk of interstitial lung disease with leflunomide has also been assessed using data from a large cohort study.[2] This study found that, overall, there was a twofold increase in the risk of interstitial lung disease in patients treated with leflunomide compared with those who did not receive leflunomide. However, subgroup analysis showed that this increase was limited to those patients with a history of methotrexate use or interstitial lung disease; in those with no previous methotrexate use or no history of interstitial lung disease, there was no increased risk with leflunomide. Effects on the nervous system. Peripheral neuropathy has been associated with leflunomide use.[1-3] Up to October 2006, the Australian Adverse Drug Reactions Advisory Committee had received 659 reports of adverse reactions associated with leflunomide, 30 of which mentioned neuropathy or peripheral neuropathy;[4] leflunomide was the sole suspected drug in 24 of these cases. Recovery was noted after drug withdrawal in 6 patients, of whom 3 underwent washout procedures; however, 15 patients had not recovered at the time of the reports and there was no information on the remaining cases.

Effects on the skin. A 58-year-old woman developed lupus erythematosus 1 month after starting leflunomide 20 mg daily for treatment of Sjögren's syndrome.[1] The rash resolved within 4 weeks of stopping leflunomide but recurred on 2 separate occasions when she took the drug again.

Overdose. Unintentional overdoses with leflunomide have been reported in 2 patients. In one case, no adverse effects were seen in a 40-year-old woman who had mistakenly taken both a 100-mg and a 20-mg tablet daily for 28 days;[1] in another case, a 70-year-old man who took 100 mg weekly, in addition to 20 mg daily, for over 2 years was found to have interstitial nephritis which improved after leflunomide was stopped.[2] In both cases, the 100-mg dose was meant to be taken for 2 or 3 days only as a loading dose.

Pregnancy. Leflunomide is contra-indicated during pregnancy as its active metabolite has been shown to be teratogenic in *animals*. Pregnancy should therefore be excluded before beginning therapy, and licensed product information states that reliable contraception should be used in women of child-bearing potential (UK product information also recommends reliable contraception in men treated with leflunomide). Women wishing to become pregnant should wait for 2 years after stopping therapy, or if this is infeasible, a washout procedure (see below) should be performed and a waiting period of 6 weeks be observed from the time plasma concentrations of the metabolite fall below 20 nanograms/mL before attempting conception. A washout procedure with a waiting period of at least 3 months is recommended in men who wish to father children. Women who become pregnant during therapy should also undergo a washout procedure.

Washout procedure. If serious adverse effects occur during leflunomide therapy, licensed product information recommends that a drug washout procedure is performed. This may also be considered if a patient becomes pregnant while taking leflunomide, or if it is necessary to swap to another disease-modifying antirheumatic drug such as methotrexate.

For the washout procedure, either 8 g of colestyramine is given orally 3 times daily or 50 g of activated charcoal is given orally or via a nasogastric tube 4 times daily. Therapy is normally continued for 11 days, but should be repeated until plasma concentrations of the primary metabolite A-771726 are below 20 nanograms/mL, verified by two separate tests at least 14 days apart.

Interactions

Increased adverse effects may occur if leflunomide is given with other hepatotoxic or myelosuppressive drugs; these effects may also be seen when leflunomide treatment is followed by such drugs without a drug washout procedure (above). The risks of combined use with other disease-modifying antirheumatic drugs, particularly in the long term, have not been studied and such use is not advised in the UK; however, US licensed product information recommends that if long-term combined use is necessary, liver enzyme values and blood counts should be monitored monthly rather than every 6 to 8 weeks (see Adverse Effects, Treatment, and Precautions, above).

See above for precautions about use with live vaccines.

Anticoagulants. For reference to the effect of leflunomide on the activity of *warfarin*, see under Immunosuppressants, p.1431.

Methotrexate. Leflunomide therapy has been rarely associated with pancytopenia. Of the 18 cases (median age 65.5 years) reported in one series, 14 patients were also receiving methotrexate therapy.[1] The pancytopenia was typically severe and required hospitalisation; 5 patients had died, 4 of whom were also taking methotrexate. Time to onset of pancytopenia ranged from 11 days to 4 years. The authors concluded that the risk of pancytopenia during leflunomide treatment appeared to increase when used with methotrexate, and emphasised the importance of ongoing monitoring of blood counts.

Leflunomide therapy has also been rarely associated with interstitial lung disease including interstitial pneumonitis (see above). Up to March 2006, the Centre for Adverse Reactions Monitoring (CARM) in New Zealand[2] had received 7 reports of pneumonitis associated with leflunomide in patients who were also taking methotrexate. Of these, 4 had taken methotrexate (which is also associated with pneumonitis) for more than 1 year. Respiratory symptoms developed 12 to 36 weeks after starting leflunomide therapy; 5 patients recovered, 1 died, and another improved but had some persisting respiratory impairment.

For advice on a drug washout procedure, see above.

Pharmacokinetics

After oral doses leflunomide undergoes first-pass metabolism in the liver and gut wall to A-771726 (teriflunomide), which is responsible for the majority of the *in vivo* activity. The bioavailability of leflunomide after oral doses ranges from 82 to 95%. Peak plasma concentrations of the active metabolite may occur from 1 to 24 hours after a dose.

A-771726 is more than 99% bound to plasma proteins, mainly albumin. It is some further metabolism. About 43% of a dose is eliminated in the urine, mainly as glucuronides, and 48% is eliminated in the faeces via the bile.

A-771726 has an elimination half-life of about 2 weeks, which is thought to be mainly due to enterohepatic recycling. Colestyramine or activated charcoal are able to interrupt recycling and can therefore accelerate drug elimination.

Studies in *animals* suggest that leflunomide or its metabolites are distributed into breast milk.

Uses and Administration

Leflunomide has immunosuppressant and antiproliferative properties. It is used as a disease-modifying antirheumatic drug in the treatment of active rheumatoid arthritis. It is also used in the treatment of active psoriatic arthritis and has been investigated in the management of various solid neoplasms.

Because of the long half-life of the principal metabolite, a loading dose of leflunomide is required to reach steady-state concentrations relatively rapidly. Therapy should start with an oral loading dose of 100 mg once daily for 3 days. However, in practice, the loading dose may be omitted in those patients at an increased risk of adverse effects, particularly haematological or hepatic effects. The maintenance dose is 10 to 20 mg once daily for rheumatoid arthritis and 20 mg once daily for psoriatic arthritis. Dose adjustments may be necessary in patients who develop abnormal liver enzyme values, see below. The therapeutic effect usually starts after 4 to 6 weeks of therapy and further improvements may occur for up to 6 months.

Administration in hepatic impairment. Leflunomide is contra-indicated in patients with hepatic impairment. Patients who develop moderate elevations of liver enzyme values (defined as transaminase levels 2 to 3 times the normal upper limit) while receiving leflunomide treatment should have their dose reduced to 10 mg daily; if necessary, monitoring of liver enzyme values should also be performed at weekly intervals. If moderate elevations persist or if severe elevations occur, leflunomide should be stopped and washout procedures started (see above).

Profile

Levacetylmethadol, a diphenylheptane derivative, is a long-acting opioid analgesic (p.104); it is a derivative of methadone (p.84). It was used as the hydrochloride in the management of opioid dependence. However, the proarrhythmic effects led to its withdrawal in the EU and the USA.

Profile

Levorphanol tartrate, a phenanthrene derivative, is a potent opioid analgesic (p.101) used in the management of moderate to severe pain. The analgesic effect usually begins about 10 to 60 minutes after oral doses and lasts up to about 8 hours. A usual initial oral dose of levorphanol tartrate is 2 mg repeated in 6 to 8 hours if necessary; the dose may be increased to 3 mg every 6 to 8 hours, adjusted according to response. The maximum initial daily dose in non-opioid tolerant patients should not exceed 12 mg. Elderly or debilitated patients may require lower doses; initial doses should be reduced by 50% or more.

Levorphanol tartrate has also been given by intramuscular, subcutaneous, or slow intravenous injection for pain relief and for premedication.

Profile

Lornoxicam, an oxicam derivative, is an NSAID (p.96). It is used in musculoskeletal and joint disorders such as osteoarthritis and rheumatoid arthritis; it is also used in the treatment of other painful conditions including postoperative pain.

In the treatment of osteoarthritis and rheumatoid arthritis lornoxicam is given in an initial oral daily dose of 12 mg in two or three divided doses; if necessary the daily dose may be increased to a maximum of 16 mg.

Lornoxicam is given in oral doses of 8 to 16 mg daily for the treatment of pain. Similar doses may be given by intravenous or intramuscular injection, although in rare cases the maximum initial daily dose may be increased to 24 mg.

Profile

Loxoprofen sodium is an NSAID (p.96) given orally for the management of pain and inflammation associated with musculoskeletal and joint disorders or operative procedures. Loxoprofen sodium is given as the dihydrate although doses are expressed in terms of the anhydrous salt. Anhydrous loxoprofen sodium 10 mg is equivalent to about 11.3 mg of loxoprofen sodium dihydrate. A usual oral dose equivalent to 60 mg of the anhydrous form has been given three times daily.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Hypersensitivity reactions including anaphylaxis and angioedema have occurred in patients receiving lumiracoxib; it should be stopped at the first signs of hypersensitivity.

Lumiracoxib use, particularly at high doses, may cause severe liver toxicity (see Effects on the Liver, below) and its use is contra-indicated in patients with hepatic disease. It should also not be used in those with a history of drug-induced increases in transaminase values greater than 3 times the upper limit of normal (ULN) or in those taking other drugs known to cause clinically significant hepatic toxicity. All patients should have baseline liver function tests before starting lumiracoxib treatment; those in whom transaminases are more than 1.5 times the ULN should not start treatment. Liver function tests should be repeated monthly and lumiracoxib should be stopped in those patients with an increase in transaminases greater than 3 times the ULN; in those with an increase greater than 2 times the ULN, liver function tests should be repeated in 7 days. Patients should be advised to report any symptoms suggestive of liver toxicity such as anorexia, nausea, vomiting, abdominal pain, fatigue, dark urine, and jaundice.

Lumiracoxib should not be used in patients with ischaemic heart disease, cerebrovascular disease, or peripheral arterial disease. It should be used with caution in patients with significant risk factors for cardiovascular disease such as hypertension, hyperlipidaemia, and diabetes mellitus.

Lumiracoxib is also contra-indicated in patients with inflammatory bowel disease, moderate to severe heart failure (NYHA class II to IV), and moderate to severe renal impairment associated with a creatinine clearance of less than 50 mL/minute. Caution is recommended when using lumiracoxib in dehydrated patients; it may be advisable to rehydrate patients before giving lumiracoxib.

Effects on the cardiovascular system. There have been concerns about the adverse cardiovascular effects of selective cyclo-oxygenase-2 (COX-2) inhibitors after the worldwide withdrawal of rofecoxib (see p.121). The cardiovascular safety of lumiracoxib has been assessed in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET)[1] which involved over 18 000 patients with osteoarthritis. Lumiracoxib 400 mg daily (2 to 4 times the recommended dose) was compared against either naproxen 1 g daily, or ibuprofen 2.4 g daily; low-dose aspirin (100 mg daily or less) was also allowed where indicated. After a planned treatment duration of 1 year, the incidence of myocardial infarction, stroke, or cardiovascular death with lumiracoxib was found to be similar to that for ibuprofen or naproxen. More events were noted in the lumiracoxib versus naproxen subgroup than in the lumiracoxib versus ibuprofen group; however, this difference was not statistically significant and the authors considered that the higher number of patients with a history of vascular risk in the lumiracoxib versus naproxen subgroup could explain this finding. In addition, it was noted that the incidence of heart failure was less frequent with lumiracoxib although, again, this was not significant; however, blood pressure changes from baseline were significantly less likely with lumiracoxib than with ibuprofen or naproxen.

More recently, a meta-analysis[2] by the manufacturer (which included the above study along with other published and unpublished clinical studies of lumiracoxib in the treatment of osteoarthritis and rheumatoid arthritis) has also found no evidence that the risk of thrombotic events with lumiracoxib is significantly increased when compared to placebo, to naproxen (1 g daily), or to the NSAIDs diclofenac (150 mg daily), ibuprofen (2.4 g daily), celecoxib (up to 400 mg daily), and rofecoxib (25 mg daily) as a group.

For further details on the relative risk of cardiovascular thrombotic events with NSAIDs, see p.97.

For discussion and advice on the use of selective COX-2 inhibitors in patients with cardiovascular or cerebrovascular disease, see under Celecoxib, p.34.

Effects on the gastrointestinal tract. It is generally accepted that the inhibition of cyclo-oxygenase-1 (COX-1) plays a role in the adverse gastrointestinal effects of the NSAIDs, and that the selective inhibition of the other isoform, COX-2, by NSAIDs such as lumiracoxib may cause less gastrotoxicity than that seen with the non-selective inhibition of the traditional NSAIDs. However, licensed product information has stated that upper gastrointestinal ulceration and bleeds, in some cases fatal, have occurred with lumiracoxib treatment; consequently it should be used with caution in patients at risk of such events.

Results from controlled studies confirm that NSAIDs selective for COX-2 are associated with a lower incidence of serious gastrointestinal effects. A study[1] in patients with osteoarthritis taking lumiracoxib at supratherapeutic doses (400 mg daily) concluded that there was a lower incidence of definite or probable upper gastrointestinal ulcer complications (bleeding, perforation, or obstruction) after 12 months of treatment when compared with non-selective NSAIDS (ibuprofen 2.4 g daily or naproxen 1 g daily). The incidence of endoscopically-detected ulcers was also less with lumiracoxib than with non-selective NSAIDs. However, the use of low-dose aspirin appeared to nullify any protective gastrointestinal effect of lumiracoxib.

An analysis[2] of pooled data from 15 pre-licensing studies in patients with rheumatoid arthritis or osteoarthritis has also concluded that the risk of upper gastrointestinal ulcers and ulcer complications is less with lumiracoxib than with non-selective NSAIDs (diclofenac, naproxen, and ibuprofen).

1. Schnitzer TJ, *et al.* Comparison of lumiracoxib with naproxen and ibuprofen in the Therapeutic Arthritis Research and Gastrointestinal Event Trial (TARGET), reduction in ulcer complications: randomised controlled trial. *Lancet* 2004; **364:** 665–74.
2. Hawkey CJ, *et al.* Gastrointestinal tolerability of lumiracoxib in patients with osteoarthritis and rheumatoid arthritis. *Clin Gastroenterol Hepatol* 2006; **4:** 57–66.

Effects on the kidneys. Limited evidence of the renal toxicity of the selective cyclo-oxygenase-2 (COX-2) inhibitors such as lumiracoxib suggests that these NSAIDs appear to have effects on renal function similar to those of the non-selective NSAIDs (see p.98).

Effects on the liver. In August 2007, the regulatory authority in Australia withdrew lumiracoxib from the market after reports of hepatotoxicity.[1,2] In the 6 months since marketing, there had been 8 reports of serious adverse liver reactions resulting in 2 deaths and 2 transplantations. There was some concern that pre-licensing clinical study data seemed to suggest that those patients who developed elevated liver function tests while on lumiracoxib would recover once the drug was stopped; however, in the 8 Australian cases, some patients did not improve because of the severity of the hepatic damage.

In response to the Australian data, the MHRA in the UK reported that it had received 16 reports of suspected adverse reactions to lumiracoxib;[3] of these, one was a case of hepatotoxicity in which the patient recovered after the drug was withdrawn. Worldwide, the MHRA was aware of 11 reports of serious hepatotoxicity including 9 cases of liver failure, 2 deaths, and 3 liver transplants suspected to be at least possibly related to lumiracoxib use. The dose used in most of the cases was higher than the maximum dose of 100 mg daily that is recommended in the UK and other European countries. (Higher maximum daily doses have been licensed in other countries; in Australia, the licensed maximum dose was 400 mg daily for some conditions.) At that time in the UK, new prescribing restrictions on the use of lumiracoxib in osteoarthritis were issued (see Adverse Effects and Precautions, above) while its safety was reviewed by European regulatory authorities. However, lumiracoxib was withdrawn from the Canadian market after Health Canada noted 4 cases of severe hepatotoxicity, including 2 in Canada, associated with the 100-mg dose of lumiracoxib.[4] Following the review of the risks and benefits of lumiracoxib in October 2007, the MHRA reiterated its earlier prescribing restrictions and stated the issue of hepatotoxicity would continue to be monitored. They also advised that, worldwide up until then, there had been 19 cases of severe liver reactions, including 13 of liver failure, 2 deaths, and 3 liver transplants suspected to be possibly related to use of lumiracoxib.[5] However, in November 2007, after a further review of worldwide safety data showed an increased number of serious liver reactions with the 100-mg dose which, in some cases, occurred with short-term use, the MHRA suspended the product licence for lumiracoxib.[6] Subsequently, the EMEA[7] has recommended its withdrawal in the EU.

Interactions

For interactions associated with NSAIDs in general, see p.99. Lumiracoxib may cause liver toxicity and consequently it should not be used with other drugs known to cause clinically significant hepatotoxicity.

There is the possibility that lumiracoxib may decrease the clearance of drugs that are cytochrome P450 CYP2C9 substrates and caution is advised when it is given with CYP2C9 substrates that have a narrow therapeutic index such as phenytoin and warfarin.

Pharmacokinetics

Lumiracoxib is absorbed from the gastrointestinal tract after oral use with peak plasma concentrations reached in about 2 hours.

Protein binding is at least 98%. Lumiracoxib undergoes extensive hepatic metabolism; several enzymes appear to be involved including glucuronosyltransferase and cytochrome P450 isoenzymes. The main oxidative pathway is mediated by the CYP2C9 isoenzyme; however, this does not appear to be the major pathway. Three major metabolites have been identified: 4′-hydroxy-lumiracoxib, 5-carboxy-lumiracoxib, and 4′-hydroxy-5-carboxy-lumiracoxib. The 4′-hydroxy metabolite is active as a cyclo-oxygenase-2 (COX-2) inhibitor although it is less potent than lumiracoxib. The plasma half-life of lumiracoxib is about 4 hours. Slightly more of a dose is excreted in the urine (54%) than in the faeces (about 43%); only about 5% of a dose is excreted unchanged.

Uses and Administration

Lumiracoxib is an NSAID (p.99) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It has been withdrawn in many countries after reports of hepatotoxicity. In the UK, lumiracoxib was used in the treatment of osteoarthritis of the knee and hip in an oral dose of 100 mg once daily. Higher doses of up to 400 mg daily have been used in some countries but may be associated with an increased risk of hepatotoxicity (see Effects on the Liver, above).

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20. Anaphylactic shock has been reported in patients given lysine aspirin by injection.

Lysine aspirin, like aspirin, should not generally be given to children because of the risk of Reye's syndrome.

Hypersensitivity. For a suggestion that lysine aspirin might be more suitable than aspirin for the diagnosis of sensitivity to NSAIDs, see under Hypersensitivity on p.21.

Interactions

For interactions associated with aspirin, see p.23.

Uses and Administration

Lysine aspirin has analgesic, anti-inflammatory, and antipyretic actions similar to those of aspirin (see p.23). When given, lysine aspirin dissociates into lysine and aspirin; aspirin is then hydrolysed to salicylic acid. Lysine aspirin 900 mg is equivalent to about 500 mg of aspirin.

Lysine aspirin is used in the treatment of pain, fever, and rheumatic disorders. It is given in oral doses equivalent to 0.5 to 1 g of aspirin, repeated every 4 hours as needed up to a maximum of 3 g of aspirin daily (2 g daily in the elderly) for pain and fever. The dose for rheumatic disorders is equivalent to 3 to 6 g of aspirin daily in 3 or 4 divided doses. Lysine aspirin is also given intramuscularly or intravenously in similar doses; the maximum daily parenteral dose is equivalent to 4 g of aspirin for very severe pain and to 6 g of aspirin for rheumatic disorders.

Lysine aspirin is also used with metoclopramide in the treatment of migraine.

Lysine aspirin has also been used in the management of thromboembolic disorders.

Nasal polyps. Two long-term controlled studies[1] suggested that topical (endonasal) lysine aspirin may be effective in preventing the recurrence of nasal polyps after surgical removal (see p.1508) in both aspirin-tolerant and aspirin-sensitive patients. This effect may be attributed to the non-specific anti-inflammatory properties of lysine aspirin. Although no adverse effects were reported in this study, hypersensitivity reactions have been seen after use of salicylates in the presence of nasal polyps (see Hypersensitivity under Adverse Effects of Aspirin, p.21).

In another study[2] intranasal lysine aspirin did not show significant clinical benefit in preventing the recurrence of nasal polyps when compared with placebo. However, significant improvement at a microscopic level was noted.

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20. Magnesium salicylate should also be used with caution in renal impairment because of the risk of hypermagnesaemia.

The use of aspirin and other acetylated salicylates is generally not recommended for children because of the risk of Reye's syndrome, unless specifically indicated. Some licensed drug information extends this precaution to magnesium salicylate.

Interactions

For interactions associated with salicylates, see Aspirin, p.23.

Uses and Administration

Magnesium salicylate has analgesic, anti-inflammatory, and antipyretic actions similar to those of aspirin (see p.23). Anhydrous magnesium salicylate 1 g is equivalent to about 1.2 g of aspirin. It is used in the treatment of pain and fever and has been used in the management of inflammatory conditions such as osteoarthritis, rheumatoid arthritis, and other arthritides. Usual oral doses of magnesium salicylate, expressed in terms of anhydrous magnesium salicylate, are about 300 to 600 mg every 4 hours for pain or fever.

As for NSAIDs in general, p.96.

Incidence of adverse effects. The commonest adverse effect in 2500 patients given meclofenamate sodium was gastrointestinal disturbance.[1] Diarrhoea occurred in 11.2% of patients in double-blind studies and 32.8% of patients in long-term studies (up to 3 years). Ulcers were detected in 22 patients during therapy and skin rashes occurred in 4% of patients. Transient increases in serum aminotransferases and BUN occurred in some patients.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Meclofenamate sodium is readily absorbed when given orally. Peak plasma concentrations occur about 0.5 to 2 hours after ingestion. Meclofenamate is over 99% bound to plasma proteins. The plasma elimination half-life of meclofenamate sodium is about 2 to 4 hours. It is metabolised by oxidation, hydroxylation, dehalogenation, and conjugation with glucuronic acid and excreted in urine mainly as glucuronide conjugates of the metabolites. About 20 to 30% is recovered in the faeces. One of the metabolites, a 3-hydroxymethyl compound, is reported to be active although to a lesser extent than the parent drug.

Uses and Administration

Meclofenamic acid, an anthranilic acid derivative similar to mefenamic acid (below), is an NSAID (p.99). It is given orally as the sodium salt in musculoskeletal and joint disorders such as osteoarthritis and rheumatoid arthritis, in mild to moderate pain, and in dysmenorrhoea and menorrhagia.

Doses of meclofenamate sodium are expressed in terms of the equivalent amount of meclofenamic acid. Meclofenamic acid 100 mg is equivalent to about 113.5 mg of meclofenamate sodium. In arthritic conditions it is given in doses equivalent to 200 to 400 mg daily; daily doses are usually given in 3 or 4 divided doses. For relief of mild to moderate pain doses are 50 to 100 mg every 4 to 6 hours; the daily dose should not exceed 400 mg. The dose in the treatment of dysmenorrhoea and menorrhagia is 100 mg three times daily for up to 6 days during menstruation.

Meclofenamic acid has been given as a rectal suppository and is also used in veterinary medicine.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Treatment should be stopped if diarrhoea and rashes occur. Other effects reported include drowsiness, and effects on the blood such as thrombocytopenia, occasionally haemolytic anaemia, and rarely aplastic anaemia. Convulsions may occur on overdosage.

Mefenamic acid is contra-indicated in patients with inflammatory bowel disease. Licensed product information recommends that blood counts and liver and renal function should be monitored during long-term therapy. Drowsiness may affect the performance of skilled tasks.

Mefenamic acid may give a false positive in some tests for the presence of bile in the urine.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were given mefenamic acid, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. The *BNF* also considers that the amount of mefenamic acid distributed into breast milk is too small to be harmful to a breast-fed infant. An early study[2] confirms that the distribution of mefenamic acid into breast milk is minimal. However, licensed product information contra-indicates the use of mefenamic acid in nursing mothers.

Effects on the kidneys. Nonoliguric renal failure has occurred in elderly patients who had had diarrhoea and vomiting while taking mefenamic acid and had continued to take the drug. It is normally recommended that mefenamic acid be stopped in the event of diarrhoea and it was suggested that in these patients the gastrointestinal toxicity had led to fluid and electrolyte depletion, thus predisposing these patients to mefenamic acid's nephrotoxicity.[1] There has been a subsequent report[2] of nonoliguric renal failure in elderly patients given mefenamic acid for musculoskeletal pain.

Effects on the skin. Bullous pemphigoid, together with haemolytic anaemia and diarrhoea,[1] and fixed drug eruptions[2-4] have been associated with the use of mefenamic acid. Additionally, Stevens-Johnson syndrome, together with cholestatic hepatitis and haemolytic anaemia, in one patient has been attributed to mefenamic acid.[5] It is generally recommended that mefenamic acid should be withdrawn if skin reactions develop.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Mefenamic acid is absorbed from the gastrointestinal tract. Peak plasma concentrations occur about 2 to 4 hours after ingestion. The plasma elimination half-life is reported to be about 2 to 4 hours. Mefenamic acid is more than 90% bound to plasma proteins. It is distributed into breast milk. Mefenamic acid is metabolised by the cytochrome P450 isoenzyme CYP2C9 to 3-hydroxymethyl mefenamic acid, which may then be oxidised to 3-carboxymefenamic acid. Over 50% of a dose may be recovered in the urine, as unchanged drug or, mainly, as conjugates of mefenamic acid and its metabolites.

Uses and Administration

Mefenamic acid, an anthranilic acid derivative, is an NSAID (p.99), although its anti-inflammatory properties are considered to be minor.

It is used in mild to moderate pain including headache, dental pain, postoperative and postpartum pain, and dysmenorrhoea, in musculoskeletal and joint disorders such as osteoarthritis and rheumatoid arthritis, and in menorrhagia.

In the UK, the usual oral dose is 500 mg three times daily. US licensed product information recommends an initial dose of 500 mg followed by 250 mg every 6 hours as needed. In addition, in the USA, when mefenamic acid is used in the treatment of mild to moderate pain in adults and adolescents aged 14 years and over, it is also recommended that it should not be given for longer than 7 days at a time.

For doses of mefenamic acid in children, see below.

Administration in children. In the UK, licensed product information states that mefenamic acid may be used in children for the treatment of Still's disease (see Juvenile Idiopathic Arthritis, p.10) and fever; however, the *BNFC* does not recommend mefenamic acid for juvenile idiopathic arthritis, nor for postoperative or mild to moderate pain. A suggested oral dose of mefenamic acid for children over 6 months of age is 25 mg/kg daily in divided doses. Treatment in children should be given for no longer than 7 days unless they are receiving mefenamic acid for juvenile idiopathic arthritis.

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Incidence of adverse effects. Between September 1996, when meloxicam was first marketed in the UK, and mid-June 1998 the UK CSM had received a total of 773 reports of 1339 suspected adverse reactions for meloxicam.[1] Of all the reactions 41% were gastrointestinal and of these 18% involved gastrointestinal perforation, ulceration and/or bleeding; the mean age of the patients involved was 64 years. Although most patients recovered after withdrawal of meloxicam and/or treatment, 5 died. A total of 193 reactions involved the skin, the most common being pruritus, rash, and urticaria. There were also reports of angioedema (25), photosensitivity (12), and bullous dermatoses, including erythema multiforme and Stevens-Johnson syndrome (5). No patients died from skin reactions and most recovered after meloxicam was withdrawn. Other frequently reported reactions were neurological (mostly headache), cardiovascular (oedema and palpitations), dizziness, flushing, and fatigue. A prescription event monitoring study has also analysed events reported with meloxicam use.[2] In a cohort of 19 087 patients who had received meloxicam some time between December 1996 and March 1997, 203 patients had had 252 events considered to be suspected adverse reactions. The majority of reactions were not serious or were labelled adverse effects of meloxicam. Rare, serious suspected adverse reactions included 2 reports of thrombocytopenia and 1 each of interstitial nephritis and idiosyncratic liver abnormality. The most frequent gastrointestinal event was dyspepsia; other more serious gastrointestinal events occurring during meloxicam exposure included upper gastrointestinal bleeding (33 reports) and peptic ulcer (19 reports). However it was considered that the incidence of gastrointestinal disturbance was low in the absence of gastrointestinal risk factors. Adverse drug reactions reported during the first year of marketing of meloxicam to the Swedish Medical Products Agency suggested a similar safety profile to other NSAIDs.[3] Of the 15 reports, 6 were for gastrointestinal disturbances and 5 involved skin reactions.

Effects on the gastrointestinal tract. It is generally accepted that inhibition of cyclo-oxygenase-1 (COX-1) plays a role in the adverse gastrointestinal effects of NSAIDs, and that selective inhibition of the other isoform, COX-2, by NSAIDs such as meloxicam may cause less gastrotoxicity than that seen with the non-selective inhibition of traditional NSAIDs. However, there has been little convincing evidence that the risk of severe gastrointestinal events is lower with meloxicam than with other NSAIDs at equi-effective doses.[1] Two large multicentre studies[2,3] have reported a lower incidence of gastrointestinal adverse effects with meloxicam than with non-selective cyclo-oxygenase inhibitors (diclofenac[2] or piroxicam[3]) but in one of these[2] the dose of meloxicam given also appeared to be less effective than the reference drug. A more recent systematic review[4] also found a lower risk of serious gastrointestinal toxicity with meloxicam 7.5 mg daily when compared with diclofenac (100 or 150 mg daily), naproxen (500 mg twice daily), or piroxicam (20 mg daily); however, when given at a dose of 15 mg daily, the risk of toxicity with meloxicam was significantly lower only when compared with piroxicam.

Individual case reports of gastrointestinal toxicity with meloxicam included one of ischaemic colitis associated with high-dose (15 mg daily) meloxicam treatment.[5]

Precautions

As for NSAIDs in general, p.98.

Meloxicam should be avoided in severe hepatic impairment, in bleeding disorders, and in patients with renal failure unless receiving dialysis. Rectal use should be avoided in patients with a history of proctitis, haemorrhoids, or rectal bleeding.

Renal impairment. The pharmacokinetics of meloxicam were not substantially altered in patients with a creatinine clearance (CC) of 41 to 60 mL/minute compared with those with normal renal function.[1] In those with a CC of 20 to 40 mL/minute, total plasma-meloxicam concentrations were lower but meloxicam free fractions were higher. Such free meloxicam concentrations were similar to the other groups. On the basis of these results, it was suggested that it was not necessary to reduce meloxicam doses in patients with a CC greater than 20 mL/minute.

1. Boulton-Jones JM, *et al.* Meloxicam pharmacokinetics in renal impairment. *Br J Clin Pharmacol* 1997; **43:** 35–40.

Interactions

For interactions associated with NSAIDs, see p.99.

Colestyramine increases the clearance and decreases the half-life of meloxicam.

Pharmacokinetics

Meloxicam is well absorbed after oral or rectal doses with peak plasma concentrations reached in up to 6 hours. It is 99% bound to plasma proteins. Meloxicam has a plasma-elimination half-life of about 20 hours. It is extensively metabolised, mainly by oxidation to its major metabolite, 5′-carboxymeloxicam. *In vitro* studies suggest that the cytochrome P450 isoenzyme CYP2C9 plays an important role in the metabolism of meloxicam with CYP3A4 involved to a lesser degree. Meloxicam, in the form of metabolites, is excreted in similar amounts in the urine and in the faeces; less than 5% of a dose is excreted unchanged. The volume of distribution is increased in renal failure.

Renal impairment. For reference to the pharmacokinetics of meloxicam in renal impairment, see under Precautions, above.

Uses and Administration

Meloxicam, an oxicam derivative, is an NSAID (p.99). It is reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). Meloxicam is used in the management of rheumatoid arthritis, for the short-term symptomatic treatment of acute exacerbations of osteoarthritis, and for the symptomatic treatment of ankylosing spondylitis. It may also be used in the treatment of juvenile idiopathic arthritis.

In the treatment of rheumatoid arthritis and ankylosing spondylitis, meloxicam is given in a usual oral dose of 15 mg daily as a single dose. Those with an increased risk of adverse reactions should be started on 7.5 mg daily. A dose of 7.5 mg daily is recommended for long-term treatment in the elderly. In the treatment of acute exacerbations of osteoarthritis the usual oral daily dose of meloxicam is 7.5 mg, increased if necessary to a maximum of 15 mg daily given as a single dose.

For dosage details in children see below.

Meloxicam may be given by rectal suppository in doses similar to those used orally but use should be limited to the shortest time possible.

For the dose of meloxicam in patients with renal impairment, see below.

Administration in children. In the USA, meloxicam is used in the treatment of juvenile idiopathic arthritis in children aged 2 years and over. The recommended oral dose is 125 micrograms/kg once daily, up to a maximum of 7.5 mg daily. In the UK, licensed product information states that meloxicam should not be used in children aged under 15 years; however, the *BNFC* has suggested the following oral doses, according to body-weight, in those aged 12 to 18 years who are intolerant of other NSAIDs:

- less than 50 kg: 7.5 mg once daily
- over 50 kg: 15 mg once daily

Administration in renal impairment. Meloxicam is normally contra-indicated in patients with severe renal impairment. However, in dialysed patients, meloxicam may be given in a dose of 7.5 mg daily by mouth or by rectal suppository. No dose reduction is required in those with mild to moderate renal impairment (creatinine clearance of greater than 25 mL/min).

Musculoskeletal and joint disorders. Meloxicam is used in the treatment of osteoarthritis (see p.11), rheumatoid arthritis (see p.11) including juvenile idiopathic arthritis (p.10), and ankylosing spondylitis (see Spondyloarthropathies, p.13). However, in the UK, the use of meloxicam and other selective cyclo-oxygenase-2 (COX-2) inhibitors is limited to those patients with good cardiovascular health and at high risk of developing serious gastrointestinal problems if given a non-selective NSAID (see p.97).

Pharmacopoeias. In *Br.*

BP 2008 (Meptazinol Hydrochloride). A white or almost white powder. Very soluble in water and in methyl alcohol; freely soluble in alcohol; very slightly soluble in acetone; dissolves in dilute solutions of alkali hydroxides. Store at a temperature not exceeding 25°.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

◊ In assessing the dependence potential of meptazinol, a WHO expert committee[1] noted in 1989 that abrupt discontinuation of chronic meptazinol use precipitated only slight withdrawal signs in *animals* and that meptazinol did not suppress opioid withdrawal signs and symptoms in humans dependent on morphine. Abuse had not been reported. They considered that the likelihood of abuse was moderate and that international control was not warranted at that time.

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

Gastrointestinal adverse effects are commonly reported with meptazinol and include abdominal pain, constipation, dyspepsia, diarrhoea, and nausea and vomiting. Meptazinol is claimed to have a low incidence of respiratory depression; nonetheless, UK licensed product information states that it should not be used in patients with acute respiratory depression. There have been occasional reports of psychiatric disorders such as hallucinations, confusion, and depression. As meptazinol has both antagonist and agonist properties its effects may be only partially reversed by naloxone, but use of the latter is still recommended in overdosage.

Meptazinol has the potential to precipitate withdrawal symptoms if given to patients who are physically dependent on opioids.

Abuse. See under Dependence and Withdrawal, above.

Effects on the respiratory system. Meptazinol is said to have a relatively low potential for respiratory depression and in healthy subjects was reported to produce substantially less respiratory depression than morphine or pentazocine at usual analgesic doses.[1] However, respiratory depression does occur in anaesthetised patients given meptazinol[2] and the effects on respiration may be similar to those of morphine[3,4] or pethidine.[5,6] Compensatory mechanisms may come into play after repeated doses of meptazinol but the intravenous use of meptazinol during anaesthesia should be viewed with as much caution as with any other opioid.[6]

Respiratory arrest occurred after an *overdose* of 50 meptazinol 200-mg tablets and a quarter of a bottle of whisky.[7] Full recovery eventually followed supportive measures although spontaneous respiration was not re-established by naloxone intravenously to a cumulative total dose of 10 mg.

Interactions

For interactions associated with opioid analgesics, see p.103.

Plasma concentrations of meptazinol may be increased by ritonavir and use together should be avoided (see also p.103).

Pharmacokinetics

After oral doses of meptazinol peak plasma concentrations have been achieved within 0.5 to 2 hours, but bioavailability is low since it undergoes extensive first-pass metabolism. Systemic availability is improved after rectal doses. Peak plasma concentrations have been achieved 30 minutes after rectal or intramuscular use. Plasma protein binding has averaged only about 27%. Elimination half-lives of about 2 hours have been reported. Meptazinol is extensively metabolised in the liver and is excreted mainly in the urine as the glucuronide conjugate. Less than 10% of a dose has been recovered from the faeces. Meptazinol crosses the placenta.

The elderly. A lower clearance and longer elimination half-life has been reported for meptazinol in elderly patients, but dosage reduction was not considered warranted on pharmacokinetic grounds. Mean half-lives in elderly and young subjects were 3.39 and 1.94 hours, respectively after single oral doses[1] and 2.93 and 2.06 hours, respectively after intravenous doses.[2]

Hepatic impairment. Oral bioavailability of meptazinol appeared to be enhanced in patients with liver disease. After a single oral dose of meptazinol mean peak plasma concentrations were 184 nanograms/mL, 131 nanograms/mL, and 53 nanograms/mL in cirrhotic patients, patients with non-cirrhotic liver disease, and patients with normal liver function, respectively, although there was no evidence of accumulation after chronic dosing.[1] There were no significant differences in plasma clearance after an intravenous dose. Reduced oral doses of meptazinol might be advisable in cirrhotic patients.

Pregnancy. In women given an intramuscular injection of 100 to 150 mg during labour, meptazinol was found to cross the placenta readily but was rapidly eliminated from the neonate.[1] This contrasted with pethidine which was known to be excreted very slowly from neonates. As in the adult, elimination of meptazinol by the neonate appeared to take place mainly by conjugation with glucuronic acid.[2] A half-life of 3.4 hours, similar to that in adults, has been reported in the neonate,[3] in contrast to 22.7 hours for pethidine in neonates.

Disposition of meptazinol appears not to be significantly affected by pregnancy. Mean half-lives of 1.36 and 1.68 hours were reported in pregnant and non-pregnant women, respectively,[4] compared with 2.06 hours in men.

Uses and Administration

Meptazinol is a mixed opioid agonist and antagonist with partial opioid agonist activity at the μ_1 opioid receptor (see p.104); it also has cholinergic activity. Meptazinol is used in the treatment of moderate to severe pain. It has a shorter duration of action than morphine.

Meptazinol hydrochloride is given orally or by intramuscular or intravenous injection; doses are expressed in terms of the base. Meptazinol hydrochloride 115.6 mg is equivalent to about 100 mg of meptazinol. For the short-term treatment of moderate pain meptazinol is given in an oral dose of 200 mg every 3 to 6 hours, as required. The intramuscular dose is 75 to 100 mg given every 2 to 4 hours, as required; for obstetric pain a dose of 2 mg/kg (100 to 150 mg) may be used. Meptazinol is also given by slow intravenous injection in doses of 50 to 100 mg every 2 to 4 hours, as required.

Administration. *EPIDURAL ROUTE.* Epidural meptazinol 90 mg for postoperative pain was reported to be superior to an intramuscular dose of 90 mg.[1] However, in another study[2] a 30-mg dose was ineffective and associated with an unacceptable incidence of adverse effects. A 60-mg dose was also found to be ineffective because of its short duration of action.[3]

UK licensed product information states that the injectable formulation is not suitable for epidural or intrathecal use.

Administration in hepatic impairment. See under Pharmacokinetics, above for a suggestion that doses may need to be reduced in patients with cirrhosis.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Methadone Hydrochloride). A white or almost white, crystalline powder. Soluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Methadone Hydrochloride). Odourless colourless crystals or white crystalline powder. Soluble in water; freely soluble in alcohol and in chloroform; practically insoluble in ether and in glycerol. pH of a 1% solution in water is between 4.5 and 6.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Incompatibility. There appears to be adequate evidence that stable solutions containing methadone hydrochloride and hydroxybenzoate esters can be formulated but the risk of precipitation exists if syrup preserved with hydroxybenzoates is used to extemporaneously prepare a methadone mixture 1 mg/mL to the DTF formula.[1] An oral formulation of methadone hydrochloride 5 mg/mL containing methyl hydroxybenzoate 0.1% as preservative rather than chloroform has been reported stable for at least 4 months at room temperature.[2]

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Methadone withdrawal symptoms are similar to, but more prolonged than, those produced by morphine or diamorphine. They develop more slowly and do not usually appear until 3 to 4 days after the last dose.

Methadone is used for substitution therapy in the management of opioid dependence (see Uses and Administration, below) including neonatal abstinence syndrome (see Administration in Children, below).

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

Methadone has a more prolonged effect than morphine and readily accumulates with repeated doses. It may have a relatively greater respiratory depressant effect than morphine and, although reported to be less sedating, repeated doses of methadone may result in marked sedation. QT prolongation and torsade de pointes have been reported rarely with methadone use, particularly at doses above 100 mg daily. After gross overdosage symptoms are similar to those of morphine poisoning. Pulmonary oedema after overdosage is a common cause of fatalities among addicts.

Methadone causes pain at injection sites; subcutaneous injection causes local tissue irritation and induration.

Effects on the cardiovascular system. Methadone prolongs the QT interval and has rarely been associated with torsade de pointes. In a retrospective case series,[1] 17 patients on high-dose methadone (mean daily dose of 397 mg) developed torsade de pointes; of these, 14 had potential risk factors for arrhythmia and 6 had had their dose increased within the last month. In another study[2] torsade de pointes developed in 5 patients taking methadone (mean daily dose 268 mg); however, they all had other contributing risk factors. Other studies[3,4] did not find instances of torsade de pointes and the increase in QT interval was considered clinically insignificant; in one study,[4] the mean daily dose of methadone was 110 mg and some patients also had risk factors for arrhythmia.

For a report of QT interval prolongation in an infant born to a mother on maintenance methadone therapy for opioid addiction, see Pregnancy, below.

In a small case-controlled study of sudden cardiac deaths,[5] the prevalence of underlying cardiac disease or structural abnormalities was lower in the 22 cases with evidence of therapeutic methadone levels when compared with the 106 cases without evidence of methadone use. The authors considered that the low prevalence of cardiac risk factors in the methadone group suggested a role for methadone itself in the pathogenesis of sudden death in this group.

Effects on the endocrine system. Hypoadrenalism has been found in chronic methadone addicts. Findings consistent with deficient ACTH production and subsequent secondary hypoadrenalism have been reported[1] although there is also evidence[2] of methadone-induced primary adrenal cortical hypofunction.

Hyperprolactinaemia and galactorrhoea have also been reported.[3] See also Effects on Sexual Function, below.

Effects on the nervous system. Choreic movements occurred in a 25-year-old man on long-term methadone maintenance treatment of 45 to 60 mg daily for diamorphine addiction.[1] Similar adverse effects were seen in a 41-year-old woman taking 5 mg methadone four times daily for complex regional pain syndrome.[2] In both cases, symptoms resolved when methadone was stopped.

Effects on sexual function. Sexual performance was impaired in 29 male diamorphine addicts receiving methadone maintenance therapy.[1] The function of secondary sex organs was markedly suppressed when compared with untreated diamorphine addicts or controls and serum-testosterone concentrations were 43% lower in those on methadone. However, in a more recent study[2] in 92 opioid addicts also receiving methadone maintenance, rates of sexual dysfunction (erectile, libido, and orgasm dysfunction) were found to be similar to that of the general population. Rates of dysfunction between patients just started on methadone and those on methadone for at least 60 days were not significantly different although new patients generally had lower rates. Mean plasma levels of testosterone and prolactin were within normal ranges and although 8 individuals had low testosterone levels, only 1 case of dysfunction was reported in this group.

2. Brown R, *et al.* Methadone maintenance and male sexual dysfunction. *J Addict Dis* 2005; **24:** 91–106.

Overdosage. Most cases of methadone poisoning occur in persons not on maintenance,[1-4] particularly children or family members of maintenance patients.[1] Methadone is highly toxic to anyone who is not tolerant to opioids; 50 to 100 mg can be life-threatening in non-tolerant adults and 10 mg can be fatal in a young child.[1] Furthermore, life-threatening toxicity from oral doses as low as 5 mg has been reported in children.[2,4]

Various groups[5,6] have found that the risk of death from methadone toxicity is greatest during the first 2 weeks of maintenance therapy. This has been attributed to the difficulty in determining a safe and effective starting dose of methadone and unreliable accounts of a patient's recent drug use.

Precautions

As for Opioid Analgesics in general, p.103.

Methadone should be given with caution to patients at risk of developing prolongation of the QT interval including those with cardiac or hepatic disease, with hypokalaemia or other electrolyte imbalance, or with a family history of sudden death. It should also be used with caution in patients who are taking other potentially arrhythmogenic drugs, drugs likely to cause electrolyte imbalance, or drugs that inhibit the cytochrome P450 isoenzyme CYP3A4 (see under Interactions, below). ECG monitoring is recommended before starting methadone treatment in these patients, with a further test at dose stabilisation. ECG monitoring is also recommended before and at 7 days after dose titration above 100 mg daily in patients without recognised risk factors.

Administration. Methadone has a long half-life and accumulation may occur with repeated doses, especially in elderly or debilitated patients. An 81-year-old woman given methadone 5 mg three times daily orally for 2 days became deeply unconscious but awoke immediately when given naloxone 400 micrograms intravenously.[1]

Sudden death in 10 diamorphine addicts occurred between 2 and 6 days after starting a methadone maintenance programme.[2] The mean prescribed dose of methadone at the time of death had been about 60 mg. There was evidence of chronic persistent hepatitis in all cases and liver disease could have reduced methadone clearance resulting in higher than expected blood concentrations. Liver function tests and urine testing for the presence of drugs before entry into methadone maintenance programmes, and lower starting doses, might decrease the likelihood of such deaths. Like dextropropoxyphene, methadone has membrane stabilising activity and can block nerve conduction, and it was suggested[3] that the sudden deaths were mainly due to accumulation of methadone over several days resulting in complications such as cardiac arrhythmias or cardiovascular collapse (above). See also Overdosage, above.

Breast feeding. The American Academy of Pediatrics considers that the use of methadone in breast-feeding mothers is usually compatible with breast feeding.[1] The *BNF* also permits breast feeding by mothers on methadone maintenance although the dose should be as low as possible and the infant monitored to avoid sedation. Others have suggested that the amount of methadone in breast milk is unlikely to have any pharmacological effect on the infant.[2-8] However, in the past, there has been a report of the death of a 5-week-old breast-fed infant whose mother was on methadone maintenance.[9]

Pregnancy. Methadone is not recommended for use in labour because its prolonged duration of action increases the risk of neonatal respiratory depression.

Neonatal abstinence syndrome and low birth-weight are immediate problems in infants born to women receiving methadone for the management of opioid addiction; increased still-birth rates have also been noted.[1-3] In the neonatal period moderate to severe opioid abstinence syndrome occurred in 75% of infants in a study,[2] as well as reduced head circumference and raised systolic blood pressure. At follow-up over 18 months these children had a higher incidence of otitis media, of reduced head circumference, and of abnormal eye findings when compared with drug-free controls. Neurobehavioural abnormalities and lower scores on mental and motor developmental indices were thought to be possible predictors of later learning and behavioural problems. In a later study,[4] the use of methadone alone during pregnancy as part of a maintenance program was claimed to increase the risk of prematurity twofold, of intra-uterine growth retardation fourfold, and of microcephaly threefold when compared with a normal population. In addition, in those mothers who continued to abuse other drugs, as well as receive methadone, the risks of these events were further increased. However, an earlier study[5] has reported that methadone or diamorphine had no specific effect on intra-uterine and postnatal growth.

The relationship between maternal methadone dose and the incidence and severity of neonatal abstinence syndrome is unclear. Although a retrospective study[6] found a correlation in some pregnancies, others[7,8] did not and there was no evidence of an increased incidence of neonatal withdrawal symptoms even with high maternal doses of 100 mg or more daily.[8]

A small retrospective study[9] comparing the use of methadone during pregnancy for the treatment of chronic pain with use in maintenance therapy for opioid addiction found a lower incidence of neonatal abstinence syndrome and better growth parameters in infants born to the former group of mothers; however, a higher rate of slight prematurity was also found in this group of infants. The authors suggested that lower maternal doses and shorter durations of treatment may account for the favourable findings, in addition to better maternal health, nutrition, and socio-economic status.

Clinically significant prolongation of the QT interval has been reported[10] in an infant born to a mother taking methadone 50 mg daily for maintenance therapy; the infant had mild withdrawal symptoms and follow-up at 2 months of age was normal.

Interactions

For interactions associated with opioid analgesics, see p.103.

Methadone is metabolised in the liver mainly via the cytochrome P450 isoenzyme CYP3A4; the isoenzymes CYP2B6, CYP2D6, CYP2C9, CYP2C19, and CYP1A2 are also thought to be involved. Consequently, use with other drugs that induce or inhibit these isoenzymes may result in changes in plasma concentrations of methadone and, possibly adverse effects. There is a risk of cardiac events in patients receiving methadone who are also taking drugs that affect cardiac conduction or electrolyte balance.

◊ Drugs that *acidify* or *alkalinise* the urine may have an effect on methadone pharmacokinetics since body clearance is increased at acidic pH and decreased at alkaline pH.[1]

1. Nilsson M-I, *et al.* Effect of urinary pH on the disposition of methadone in man. *Eur J Clin Pharmacol* 1982; **22:** 337–42.

Antibacterials. Withdrawal symptoms have been reported in patients maintained on methadone when they were given the enzyme inducer *rifampicin*.[1-3] Conversely, the use of *ciprofloxacin*, which inhibits CYP1A2 and CYP3A4, has resulted in signs of methadone toxicity.[4]

Antidepressants. *SSRIs* such as fluoxetine[1] and fluvoxamine[1,2] may enhance the effects of some opioid analgesics; such interactions may lead to methadone toxicity. *St John's wort* reduced the plasma-methadone concentration to dose ratios by 47% in 4 patients on methadone maintenance therapy for opioid addiction; 2 patients reported symptoms suggestive of a withdrawal syndrome.[3]

Antiepileptics. Opioid withdrawal symptoms have been reported in patients maintained on methadone when they were given *carbamazepine*,[1,2] *phenobarbital*,[3] or *phenytoin*.[4,5] Conversely, methadone-induced respiratory depression developed in a patient on carbamazepine, gabapentin, and methadone for neuropathic pain, after carbamazepine was stopped.[6]

Antifungals. Use of methadone with *fluconazole* has been reported[1] to increase serum concentrations of methadone although the authors considered that for patients being treated for opioid dependence the interaction was unlikely to require adjustment of the methadone dose. However, respiratory depression has been reported[2] after intravenous doses of fluconazole were given to a 60-year-old man also taking oral methadone for pain relief in advanced gastric cancer. Although a randomised placebo-controlled study[3] found that giving *voriconazole* to patients on methadone maintenance therapy for opioid addiction was generally safe and well tolerated, the authors recommended monitoring and possible dose reduction of methadone when the 2 drugs are used together. Similar recommendations are also given in the licensed product information for voriconazole.

Antivirals. The potential for interaction between antiretrovirals and methadone has been reviewed.[1] Available evidence for HIV-protease inhibitors suggests that *atazanavir*, *indinavir*, and, possibly, *saquinavir* alone have no effect on plasma concentrations of methadone; *amprenavir*, *nelfinavir*, *ritonavir*, and *ritonavir-boosted saquinavir* may reduce plasma-methadone concentrations but the effect is unlikely to be clinically significant. *Lopinavir-ritonavir* may also reduce methadone concentrations and, although most studies found the interaction to be insignificant, one study reported opioid withdrawal symptoms in some patients. Unpublished data [also referred to in the licensed product information] on *tipranavir* (boosted with ritonavir) in healthy, opioid-naive subjects suggest that it may decrease plasma-methadone; licensed product information for tipranavir recommends that patients are monitored for symptoms of opioid withdrawal.

The NNRTIs *nevirapine* and *efavirenz* have both been reported to reduce plasma-methadone levels and withdrawal symptoms have occurred when they were given to patients receiving methadone. Conversely, *delavirdine* may increase methadone concentrations although the effect is unlikely to be clinically significant. Methadone possibly increases plasma concentrations of the NRTI *zidovudine* (see p.915).

Gastrointestinal drugs. Histamine H_2-antagonists such as *cimetidine* (see p.103) may enhance the effects of some opioid analgesics; such interactions may lead to methadone toxicity.

Grapefruit juice. Grapefruit juice, an inhibitor of the cytochrome P450 isoenzyme CYP3A4, has been shown to modestly increase the bioavailability of methadone;[1] although no symptoms of methadone toxicity were seen in the studied patients, the authors commented that such effects may occur in patients with reduced opioid tolerance, particularly when starting methadone treatment.

Pharmacokinetics

Methadone hydrochloride is readily absorbed from the gastrointestinal tract and from subcutaneous or intramuscular injections. It is widely distributed in the tissues, diffuses across the placenta, and is distributed into breast milk. It is extensively protein bound. Methadone is metabolised in the liver, mainly by *N*-demethylation and cyclisation, and the metabolites are excreted in the bile and urine. Metabolism is primarily catalysed by CYP3A4, although other cytochrome P450 isoenzymes also play a role (see Interactions, above). It has a prolonged half-life and is subject to accumulation.

◊ In reviews of the pharmacokinetics of methadone[1-5] particular reference has been made to its long elimination half-life, accumulation after repeated doses, and wide interindividual variations.

Methadone is rapidly absorbed after oral doses and has high oral bioavailability. Peak plasma concentrations have been reported 1 to 5 hours after a single tablet by mouth. It undergoes considerable tissue distribution and protein binding is reported to be 60 to 90% with α_1-acid glycoprotein being the main binding protein in plasma. Metabolism to the major metabolite 2-ethylidine-1,5-dimethyl-3,3-diphenylpyrrolidine and the minor metabolite 2-ethyl-3,3-diphenyl-5-methylpyrroline, both of them inactive, occurs in the liver. These metabolites are excreted in the faeces and urine with unchanged methadone. Other metabolites, including methadol and normethadol, have also been described. The liver may also serve as a major storage site of unchanged methadone which is taken up, bound non-specifically by the liver, and released again mainly unchanged. Urinary excretion of methadone is pH-dependent, the lower the pH the greater the clearance.

In addition to marked interindividual variations there are differences in the pharmacokinetics of methadone after single or multiple doses. Elimination half-lives vary considerably (a range of 15 to 60 hours has been quoted) and may be much longer than the 18 hours reported following a single dose. Careful adjustment of dosage is necessary with repeated doses.

Most studies have been in addicts. Plasma concentrations have been found to vary widely during methadone maintenance therapy with large differences between patients and wide fluctuations in individual patients. These variations in kinetics have also been seen in cancer patients.

Administration. Methadone is considerably more lipid-soluble than morphine. A study of plasma concentrations and analgesia after intramuscular injection indicated that more rapid and greater relief of pain might be achieved if lipid-soluble opioid analgesics were injected into the deltoid rather than the gluteal muscle; there was no significant difference in absorption of morphine from the two sites.[1]

Other routes investigated in pharmacokinetic studies include continuous intravenous infusion[2] and continuous epidural infusion.[3] Rectal administration[4] has also been studied.

Hepatic impairment. Overall hepatic dysfunction does not seem unduly to disrupt methadone metabolism[1] and it has been suggested[2] that maintenance dosage of methadone need not be changed in stable chronic liver disease, although abrupt changes in hepatic status might result in substantial alterations in methadone disposition requiring dosage adjustments.

In a study of patients on methadone maintenance therapy[2] apparent terminal half-life of methadone was prolonged from a mean of 18.8 hours in those with healthy livers to 35.5 hours in patients with severe chronic liver disease. However, plasma concentrations were not increased in such patients.

Pregnancy. Plasma concentrations of methadone were reduced in methadone-maintained pregnant women, probably due to enhanced metabolism.[1,2] It was suggested that the dose of methadone might need to be increased in such patients.

Renal impairment. The urinary excretion of methadone was reduced in renal failure,[1] but plasma concentrations were within the usual range and faecal excretion accounted for the majority of the dose. Very little methadone was removed by peritoneal dialysis or haemodialysis.

Uses and Administration

Methadone hydrochloride, a diphenylheptane derivative, is an opioid analgesic (p.104) that is primarily a μ opioid agonist. Single doses of methadone have a less marked sedative action than single doses of morphine. Methadone is a racemic mixture and levomethadone (p.77) is the active isomer.

Methadone hydrochloride is used in the treatment of moderate to severe pain; it may be of use for those patients who experience excitation or exacerbation of pain with morphine. Methadone is also used in the management of opioid dependence. It has a depressant action on the cough centre and has been used as a cough suppressant in terminal illness, although the *BNF* discourages this use because of the risks of accumulation.

For **pain relief** starting oral doses of methadone hydrochloride may range from 2.5 to 10 mg given every 6 to 8 hours or longer and thereafter adjusted as necessary. Methadone may also be given parenterally. In the UK, the subcutaneous and intramuscular routes are licensed with the intramuscular route being recommended for prolonged use; US licensed product information states that the intravenous, intramuscular, and subcutaneous routes may be used although it gives doses for the intravenous route only. Initial dose ranges for parenteral routes are similar to those used orally; however, if transferring between oral and parenteral methadone, US product information states that the initial conversion dose should be based on the guide that 10 mg of oral methadone is equivalent to about 5 mg of parenteral methadone. The analgesic effect of methadone begins about 10 to 20 minutes after parenteral injection and about 30 to 60 minutes after oral doses, the effect of a single dose usually lasting about 4 hours. As accumulation occurs with repeated doses, the effects become more prolonged. Consequently, to avoid the risk of opioid overdose, it is recommended that in prolonged use methadone should not be given more than twice daily.

Methadone is used as part of the treatment of **opioid dependence**, although prolonged use of methadone itself may result in dependence. Initially, methadone hydrochloride is given in doses sufficient to suppress signs of opioid withdrawal but avoid toxicity; the *BNF* and US licensed product information recommended a starting dose of 10 to 40 mg daily. Subsequent dose adjustments should be made cautiously because of the risks of accumulation; the *BNF* suggests adjusting the dose in steps of 10 mg to a maximum weekly increase of 30 mg. Once the dose has been stabilised, patients may choose to receive prolonged therapy with a carefully selected methadone dose for each individual; most patients in such maintenance programmes are stabilised on once-daily doses of 60 to 120 mg. Alternatively, detoxification may be appropriate with the dose of methadone being gradually decreased until total withdrawal is achieved. Methadone is usually given orally for the treatment of dependence although parenteral routes may be used, particularly when oral therapy is not possible; the doses stated above may be given orally or parenterally. In the UK, oral treatment is commonly given as a mixture containing 1 mg/mL of methadone hydrochloride.

For details of doses in children, see below.

For the control of intractable **cough** associated with terminal lung cancer, methadone hydrochloride is usually given in the form of a linctus in a dose of 1 to 2 mg every 4 to 6 hours, but reduced to twice daily on prolonged use.

Administration. Although duration of action after single doses of methadone is similar to that of morphine, it increases considerably with multiple dosing of methadone because of the long elimination half-life (see under Pharmacokinetics, above). The minimum effective dose of methadone can be difficult to titrate for the individual patient. A fixed 10-mg oral dose with a flexible patient-controlled dosage interval has been used in patients with chronic cancer pain.[1] Dosage not more frequently than every 4 hours during the first 3 to 5 days, followed by a fixed dose every 8 to 12 hours depending on the patient's requirements, was advised.

A suggested initial dose for patients who need to switch from oral morphine to methadone because of poor pain control is one tenth of the total daily dose of morphine, but not greater than 100 mg, given at intervals determined by the patient, typically every 8 hours.[2]

When switching from oral to parenteral use it was suggested[3] that the dose of methadone should be halved and adjusted thereafter as necessary.

Evidence of the prolonged effect of methadone was demonstrated when a single intravenous bolus dose of 20 mg resulted in postoperative analgesia lasting about 25 hours.[4] An initial 2-hour loading intravenous infusion of methadone 100 to 200 micrograms/kg per hour to provide rapid analgesia followed by infusion at a lower maintenance rate of 10 to 20 micrograms/kg per hour for continuous pain relief has been used in burn patients.[5] Methadone has also been given by continuous subcutaneous infusion for severe cancer pain[6,7] although this route has been associated with local tissue irritation and induration. Epidural methadone has been used successfully in doses of up to 5 mg for analgesia in association with bupivacaine.[8,9] Intermittent and continuous epidural infusion of methadone has also been tried[10] in postoperative analgesia.

A small case series[11] found topical methadone powder to be effective for pain relief of open, exudative wounds.

Administration in children. Methadone is not licensed for use in children. However, it has been tried[1] intravenously in children aged 3 to 7 years to prevent postoperative **pain**; a dose of 200 micrograms/kg was given perioperatively followed postoperatively by 50 micrograms/kg every 10 minutes until the patient was both comfortable and adequately alert. Methadone has also been tried[2] orally for the treatment of severe pain in hospitalised children; daily doses ranged from 200 to 600 micrograms/kg for up to 6 weeks.

Methadone is used for the management of **neonatal abstinence syndrome** (p.102). The *BNFC* suggests an initial oral dose of 100 micrograms/kg increased by 50 micrograms/kg every 6 hours until symptoms are controlled; once stabilised, the total daily dose is given in 2 divided doses for maintenance. When withdrawing methadone, the dose should be reduced over 7 to 10 days.

Cancer pain. Methadone is used as an alternative to morphine in the treatment of severe cancer pain (p.5). A better understanding of its pharmacokinetics and of equianalgesic doses may address early concerns about the risk of cumulative toxicity associated with prolonged use. However, its long terminal half-life makes it less suitable for the treatment of breakthrough pain.

Methadone has been given by the oral, rectal, and parenteral routes.

Opioid dependence. The treatment of opioid dependence is discussed on p.101. In the UK, oral liquid preparations of methadone hydrochloride 1 mg/mL are widely used for this purpose. It is important to note that these preparations are 2.5 times **stronger** than Methadone Linctus (BP 2008), and although some are licensed for analgesia in severe pain, many are licensed for the treatment of opioid dependence only. Methadone Oral Solution (1 mg/mL) (BP 2008) is available as a ready-to-use solution or may be prepared from Methadone Hydrochloride Oral Concentrate. However, most commercially available preparations in the UK still follow an earlier formula formerly listed in the Drug Tariff Formulary (DTF):

Methadone Mixture 1 mg/mL
methadone hydrochloride 10 mg
Green S and Tartrazine Solution (BP 1980) 0.02 mL
Compound Tartrazine Solution (BP 1980) 0.08 mL
syrup, unpreserved 5 mL
chloroform water, double-strength to 10 mL.

Some commercially available forms of DTF Methadone Mixture 1 mg/mL use a preservative system based on hydroxybenzoate esters rather than chloroform; however, syrup preserved with hydroxybenzoate esters may be unsuitable for extemporaneous dispensing (see under Incompatibility, above).

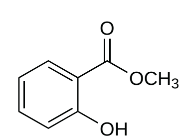
CAS — 119-36-8.



NOTE. Methyl salicylate and methyl salicylate liniment have been known previously as oil of wintergreen, wintergreen, and wintergreen oil. Wintergreen oil has also been known as sweet birch oil.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *Viet.* Also in *USNF.*

Ph. Eur. 6.2 (Methyl Salicylate). A colourless or slightly yellow liquid. Very slightly soluble in water; miscible with alcohol, and with fatty and essential oils. Protect from light.

USNF 26 (Methyl Salicylate). It is produced synthetically or is obtained from the leaves of *Gaultheria procumbens* (Ericaceae) [wintergreen] or from the bark of *Betula lenta* (Betulaceae) [sweet or black birch]. The source of the methyl salicylate must be indicated on the label.

A colourless, yellowish, or reddish liquid having the characteristic odour of wintergreen. Slightly soluble in water; soluble in alcohol and in glacial acetic acid. Store in airtight containers.

Storage. Certain plastic containers, such as those made from polystyrene, are unsuitable for liniments or ointments containing methyl salicylate.

Adverse Effects, Treatment, and Precautions

Salicylate intoxication can occur after ingestion or topical application of methyl salicylate (see Overdosage, below).

Overdosage. Ingestion of methyl salicylate poses the threat of severe, rapid-onset salicylate poisoning because of its liquid concentrated form and lipid solubility.[1] It is readily absorbed from the gastrointestinal tract and most is rapidly hydrolysed to free salicylate. The symptoms, which may appear within 2 hours of ingestion, are similar to those of salicylate poisoning in general (see Adverse Effects of Aspirin, p.20), although methyl salicylate is expected to be more toxic because of its lipid solubility. There have been reports of fatalities after ingestion of as little as 4 mL in a child and 6 mL in an adult, although the adult lethal dose is estimated to be 30 mL.[1] Topical Chinese herbal medicinal preparations may contain methyl salicylate in variable amounts, and salicylate poisoning has been reported in a 40-year-old man after a total body application of such a preparation.[2] Salicylate poisoning has also been reported in a woman who had attempted suicide by ingesting Red Flower Oil, a topical Chinese herbal oil.[3] The authors also noted that some patients took small amounts of this preparation orally in an attempt to enhance its analgesic effects.

3. Chan TH, *et al.* Severe salicylate poisoning associated with the intake of Chinese medicinal oil ('Red Flower Oil'). *Aust N Z J Med* 1995; **25:** 57.

Percutaneous absorption. Like other salicylates, methyl salicylate may be absorbed through intact skin.[1] Percutaneous absorption is enhanced by exercise, heat, occlusion, or disruption of the integrity of the skin. The amount absorbed will also be increased by application to large areas of skin.

Results from a study in healthy subjects showed that a considerable amount of salicylic acid may be absorbed through the skin after topical application of products containing methyl salicylate.[2] Both the rate and extent of absorption increased after repeated application; the bioavailability of the ointment preparation used in the study increased from 15% after the second dose to 22% after the third to eighth dose. The authors recommend that topical analgesic preparations containing methyl salicylate or other salicylates should be used with caution in patients at increased risk of developing salicylate adverse effects (see Precautions of Aspirin, p.22).

Results from another study[3] showing high tissue to plasma ratios after topical application of a methyl salicylate formulation suggest that direct penetration and not recirculation in the blood is responsible for the salicylate concentrations found. The results also showed that methyl salicylate is extensively metabolised to salicylic acid in the dermal and subcutaneous tissues after topical application.

However, for a study suggesting limited absorption from a patch preparation containing camphor, menthol, and methyl salicylate, see Menthol, p.2340.

Interactions

Absorption of methyl salicylate through the skin can occur after excessive topical application (see above), and interactions would be expected to be as for other salicylates (see Interactions of Aspirin, p.23).

Anticoagulants. Potentiation of *warfarin* anticoagulation has been reported[1-3] after topical application of methyl salicylate preparations.

Uses and Administration

Methyl salicylate is a salicylic acid derivative that is irritant to the skin and is used topically in rubefacient preparations for the relief of pain in musculoskeletal, joint, and soft-tissue disorders. It is also used for minor peripheral vascular disorders such as chilblains and as an ingredient in inhalations for the symptomatic relief of upper respiratory-tract disorders.

Wintergreen oil is also used in aromatherapy.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Morphine Sulphate). A white or almost white, crystalline powder. Soluble in water; very slightly soluble in alcohol; practically insoluble in toluene. Protect from light.

USP 31 (Morphine Sulfate). White, feathery, silky crystals, cubical masses of crystals, or a white crystalline powder. Is odourless and when exposed to air it gradually loses water of hydration. It darkens on prolonged exposure to light. Soluble 1 in 16 of water and 1 in 1 of water at 80°; soluble 1 in 570 of alcohol and 1 in 240 of alcohol at 60°; insoluble in chloroform and in ether. Store in airtight containers at a temperature up to 40° as permitted by the manufacturer. Protect from light.

Incompatibility. Incompatibility data for morphine has been extensively studied[1,2] and may depend on many factors such as the formulation used, and order and ratio of mixing; however, most studies are usually only short term and contain few details on mixing the same drugs in a variety of different situations.

Morphine salts are sensitive to changes in pH and morphine is liable to be precipitated out of solution in an alkaline environment. Compounds incompatible with morphine salts include aminophylline and sodium salts of barbiturates and phenytoin. Other incompatibilities, sometimes attributed to particular formulations, have included:

- Aciclovir sodium—precipitate noted 2 hours after admixture with morphine sulfate solution[3]
- Chlorpromazine hydrochloride injection—precipitation was considered to be due to chlorocresol present in the morphine sulfate injection[4]
- Doxorubicin—addition of morphine sulfate 1 mg/mL to doxorubicin hydrochloride liposomal injection 400 micrograms/mL in dextrose 5% resulted in turbidity changes[5]
- Fluorouracil—immediate precipitate formed after admixture of fluorouracil 1 or 16 mg/mL with morphine sulfate 1 mg/mL in dextrose 5% or sodium chloride 0.9%[6]
- Furosemide—precipitate noted 1 hour after admixture with morphine sulfate solution[3]
- Haloperidol—immediate precipitation seen after admixture of haloperidol and morphine sulfate solution[7]
- Heparin sodium—incompatibility has been reported from straightforward additive studies.[1] Another study[8] indicated that morphine sulfate and heparin sodium were only incompatible at morphine sulfate concentrations greater than 5 mg/mL and that this incompatibility could be prevented by using 0.9% sodium chloride solution as the admixture diluent rather than water
- Pethidine hydrochloride—incompatibility has been noted after admixture with morphine sulfate[1,9]
- Prochlorperazine edisilate—immediate precipitation was attributed to phenol in the morphine sulfate injection formulation[10,11]
- Promethazine hydrochloride—cloudiness was reported to develop when 12.5 mg of promethazine hydrochloride was drawn into a syringe containing morphine sulfate 8 mg.[12] Others[9] have noted no incompatibility
- Ranitidine hydrochloride—crystal needles and/or sticky spots observed in admixtures of morphine hydrochloride and ranitidine hydrochloride in various ratios stored at different temperatures[13]
- Tetracyclines—colour change from pale yellow to light green occurred when solutions of minocycline hydrochloride or tetracycline hydrochloride were mixed with morphine sulfate in 5% glucose injection[14]

Stability. ***INTRAVENOUS PREPARATIONS.*** Solutions of morphine sulfate for intravenous infusion appear to be relatively stable. In a study[1] solutions containing 40 micrograms/mL and 400 micrograms/mL retained more than 90% of their initial concentration of morphine sulfate when stored at 4° or 23° for 7 days, whether or not they were protected from light. Solutions prepared from commercially available injection or from powder, in 0.9% sodium chloride or 5% glucose, and stored in PVC bags or glass bottles did not differ in stability from one another. In a further study[2] 10 mg/mL or 5 mg/mL solutions of morphine sulfate in glucose or sodium chloride and stored in portable infusion pump cassettes retained more than 95% of their initial concentration when kept at 23° for 30 days. A 0.9% solution of sodium chloride containing morphine sulfate 2 mg/mL was stable for 6 weeks when stored in polypropylene syringes at ambient temperatures in the light or dark but a similar solution which also contained 0.1% sodium metabisulfite lost 15% of its potency during the same period.[3] Stability of such a solution with or without sodium metabisulfite was considered to be unacceptable when stored in glass syringes in the dark.[4]

A more recent review[5] (which included some of the above studies) has concluded that the degradation of morphine solutions is not affected by oxygen, light, diluent type, salt form, or morphine concentration when stored under normal conditions; it was considered that morphine solutions could be stored for at least 3 months without stability problems.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Dependence associated with morphine and closely related μ-agonists appears to result in more severe withdrawal symptoms than that associated with κ-receptor agonists. With morphine, withdrawal symptoms usually begin within a few hours, reach a peak within 36 to 72 hours, and then gradually subside.

Morphine is used for substitution therapy in the management of neonatal abstinence syndrome (see Administration in Children, below).

Effects on the nervous system. Myoclonus, often associated with hyperalgesia, has been reported in patients with advanced malignant disease treated with morphine.[1-5] It appears to be uncommon with typical oral doses of morphine and is more often associated with high intravenous and spinal doses. Neuroexcitatory metabolites of morphine are often implicated in the development of myoclonus;[2,4,5] however, other possible mechanisms such as drug interactions cannot be ruled out.[4-6]

It has been reported that myoclonus induced by morphine can be successfully controlled using a benzodiazepine such as midazolam.[7] Indeed, some researchers[8] consider benzodiazepines to be the drugs of choice: clonazepam, diazepam, and lorazepam were most frequently used. Dantrolene[5,8] and gabapentin[9] have also been tried.

Breast feeding. Measurable blood concentrations of morphine have been detected in 2 breast-fed infants whose mothers received oral or intrathecal morphine during and after their pregnancies; however, no adverse effects were reported in either of these infants.[1,2] In a group of 7 women given patient-controlled analgesia with intravenous morphine after caesarean delivery, the concentrations of morphine and its metabolite morphine-6 glucuronide in the colostrum were found to be very small.[3] Although no infants were breast fed during the study, it was considered that the effects of maternal morphine on breast-fed infants would be negligible.[3] The American Academy of Pediatrics[4] also states that the use of morphine is usually compatible with breast feeding.

Hepatic impairment. In view of its hepatic metabolism, caution is generally advised when giving morphine to patients with hepatic impairment (but see under Pharmacokinetics, below). The *BNF* advises that use should be avoided or the dose reduced because of the risk of precipitating a coma, although it is also noted that many patients with hepatic impairment tolerate morphine well. Others have considered that severe hepatic impairment may affect morphine metabolism but less severe impairment does not.[1]

The mean elimination half-life of morphine in 12 patients with cirrhosis was almost twice that in 10 healthy subjects after administration of a modified-release oral morphine preparation (*MST-Continus; Napp, UK*) and peak serum concentrations were almost three times as high.[2] Patients with cirrhosis had a greater degree of sedation but none developed encephalopathy. It was recommended that the dose for modified-release preparations should be reduced and that it be given less often when patients have cirrhosis.

In a later study[3] 15 patients with liver cancer were given the same oral morphine preparation and compared with 10 healthy subjects from the previous study; the area under the serum concentration-time curve of morphine was increased three- to fourfold in those with cancer. The elimination half-life of morphine was also prolonged in patients with primary cancer when compared with healthy subjects and those with secondary metastatic disease. Adverse effects were more frequent in the primary cancer group and included 2 cases of respiratory depression; the authors commented that altered blood-brain transportation may have been partly responsible for such effects.

Phaeochromocytoma. Morphine and some other opioids can induce the release of endogenous histamine and thereby stimulate catecholamine release making them unsuitable for use in patients with phaeochromocytoma. For further details, see p.103.

Renal impairment. Severe and prolonged respiratory depression has occurred in patients with renal impairment given morphine. Toxicity in 3 such patients was attributed to the accumulation of the active metabolite morphine-6-glucuronide.[1] Plasma concentrations of this metabolite were found[2] to be ten times higher than normal in a 7-year-old girl with haemolytic uraemic syndrome given morphine intravenously although the half-life of morphine was also prolonged. Plasma concentrations of morphine-6-glucuronide were also reported[3] to be persistently increased 19 days after stopping morphine by intravenous infusion in a 17-year-old girl with normal renal function. The authors of the report suggested that alterations in bowel flora after antibacterial therapy or inhibition of morphine-3-glucuronide glucuronidation by lorazepam might be responsible. It has also been reported[4] that accumulation of morphine can occur in renal failure, although to a lesser extent than accumulation of metabolites (see also under Pharmacokinetics, below).

Interactions

For interactions associated with opioid analgesics, see p.103.

US licensed product information for some once-daily modified-release preparations of morphine sulfate states that patients must not ingest alcohol, including alcohol-containing medicines, at the same time due to the risk of rapid release and absorption of a potentially fatal dose of morphine; *in-vitro* studies showed that alcohol accelerated the release of morphine.

◊ For references to myoclonus associated with morphine and the concurrent use of other drugs, see Effects on the Nervous System under Adverse Effects, above.

Antibacterials. There is some evidence[1] that the potent enzyme inducer *rifampicin* can reduce the serum concentration of morphine and decrease its analgesic effect; induction of the enzymes responsible for conversion of morphine to the active glucuronide metabolite did not seem to occur.

Benzodiazepines. An additive sedative effect is to be expected between opioid analgesics and benzodiazepines and has been reported with morphine and *midazolam.*[1]

Local anaesthetics. Prior use of epidural *chloroprocaine*, when compared with lidocaine, has been reported to reduce the duration[1] and efficacy[2] of epidural morphine analgesia. However, a later study[3] found no such effects; the authors suggested that findings from the previous 2 studies were due to breakthrough pain caused by the early resolution of chloroprocaine anaesthesia occurring before the maximum onset of morphine analgesia.

Metoclopramide. Reports on the effects of metoclopramide on morphine have included an increased rate of onset and degree of sedation when oral metoclopramide was given with modified-release morphine[1] and antagonism of the effects of morphine on gastric emptying by intravenous metoclopramide.[2]

Tricyclic antidepressants. Both *clomipramine* and *amitriptyline* significantly increased the plasma availability of morphine when given to cancer patients taking oral morphine solution.[1] It was noted however that the potentiation of the analgesic effects of morphine by these drugs might not be confined to increased bioavailability of morphine; the dose of tricyclic to use with morphine in the treatment of cancer pain should be decided by clinical evaluation rather than by pharmacokinetic data.

Pharmacokinetics

Morphine salts are well absorbed from the gastrointestinal tract but have poor oral bioavailability since they undergo extensive first-pass metabolism in the liver and gut. After subcutaneous or intramuscular injection morphine is readily absorbed into the blood. The majority of a dose of morphine is conjugated with glucuronic acid in the liver and gut to produce morphine-3-glucuronide and morphine-6-glucuronide. The latter is considered to contribute to the analgesic effect of morphine, especially with repeated oral doses. Morphine-3-glucuronide on the other hand can antagonise the analgesic action and might be responsible for the paradoxical pain seen in some patients given morphine. Other active metabolites include normorphine, codeine, and morphine ethereal sulfate. Enterohepatic circulation probably occurs. Morphine is distributed throughout the body but mainly in the kidneys, liver, lungs, and spleen, with lower concentrations in the brain and muscles. Morphine crosses the blood-brain barrier less readily than more lipid-soluble opioids such as diamorphine, but it has been detected in the CSF as have its highly polar metabolites morphine-3-glucuronide and morphine-6-glucuronide. Morphine diffuses across the placenta and traces also appear in breast milk and sweat. About 35% is protein bound. Mean plasma elimination half-lives of about 2 hours for morphine and 2.4 to 6.7 hours for morphine-3-glucuronide have been reported.

Up to 10% of a dose of morphine may eventually be excreted, as conjugates, through the bile into the faeces. The remainder is excreted in the urine, mainly as conjugates. About 90% of total morphine is excreted in 24 hours with traces in urine for 48 hours or more.

◊ Much has been published on the metabolism and disposition of morphine and its relevance to the clinical use of morphine, in particular the analgesic effect of repeated oral doses and the relative potency of oral to parenteral doses. There has been uncertainty as to the contributions in man of first-pass metabolism in the liver and gut,[1-4] the possible role of renal metabolism,[2,3,5,6] the analgesic activity and clinical importance of the metabolite morphine-6-glucuronide,[2,7-21] and enterohepatic circulation.[2,9] There has also been interest in the effects of the metabolite morphine-3-glucuronide.[21-24]

Administration. There have been many studies on the pharmacokinetics of morphine given by various routes and methods. These include the buccal route (see below), modified-release oral preparations,[1,2] the rectal route,[3,4] the topical route,[5] the pulmonary route,[6,7] continuous subcutaneous compared with intravenous infusion,[8] and the intraspinal route.[9-13]

Slow dural transfer of morphine and its prolonged presence in the CSF appear to correlate with its slow onset and long duration of action by epidural and intrathecal injection.[14] More lipid-soluble opioids, such as diamorphine and pethidine, enter and leave the CSF more rapidly than morphine.

The pharmacokinetics of morphine given by 5 different routes—intravenous bolus injection and oral, sublingual, buccal, and modified-release buccal tablets—were studied[15] with particular reference to morphine-6-glucuronide, the active metabolite. This metabolite occurred in large quantities after intravenous doses and plasma concentrations rapidly exceeded those of morphine. After oral doses morphine-6-glucuronide and morphine-3-glucuronide were present in quantities similar to those seen after intravenous morphine; morphine concentrations in plasma were very low and the mean morphine-6-glucuronide to morphine area under the curve ratio was 9.7 to 1. There was delayed absorption with attenuation and delay of peak morphine and metabolite plasma concentrations after sublingual or buccal dosage.

Compared with oral doses, concentrations of morphine were higher and those of its glucuronides lower when morphine was given rectally,[16] suggesting avoidance of first-pass metabolism.

Morphine was not absorbed systemically when applied topically to ulcers although some absorption may occur when a large surface area is involved.[5]

BUCCAL ROUTE. Conflicting results from studies on buccal morphine may reflect differences in formulation[1] and hence absorption. Some[2] reported equivalent analgesia with buccal and intramuscular morphine although others[3] found marked interindividual variability with mean peak serum concentrations of morphine some eight times lower after a buccal tablet than after an intramuscular injection and occurring a mean of 4 hours later. Morphine sulfate in aqueous solution has been reported to be moderately well absorbed from the buccal mucosa.[4] Absolute bioavailability for morphine was estimated to be 23.8% after an oral solution, 22.4% after a modified-release oral tablet (*MST Continus; Napp, UK*), and 20.2% after a modified-release buccal tablet, with maximum plasma-morphine concentrations at 45 minutes, 2.5 hours, and 6 hours respectively; mean ratios of area under the plasma concentration-time curve for morphine-6-glucuronide to morphine in plasma were 11:1 after buccal and oral morphine compared with 2:1 for intravenous morphine.[5] There was considerable inter-subject variation in plasma concentrations of the morphine metabolites, morphine-3-glucuronide and morphine-6-glucuronide after buccal doses of morphine as a modified-release formulation,[6] and lack of pain relief was subsequently reported with this buccal formulation.[7] Poor absorption of morphine from modified-release buccal tablets when compared with intramuscular injection was also reported;[8] bitterness of the tablets, leading to their premature removal, and poor dissolution may have contributed.

Children. The pharmacokinetics of morphine in *children* are generally considered similar to those in adults;[1-3] in both an elimination half-life of about 2 hours has been reported after intravenous administration of morphine. In *neonates*, however, clearance is generally reduced[4-7] and pharmacokinetics are more variable.[8-10] Studies[7,11] have found significantly higher plasma concentrations of morphine and a significantly lower morphine-6-glucuronide to morphine ratio in neonates when compared with older infants and children; however, the morphine-6-glucuronide to morphine-3-glucuronide ratio remains constant irrespective of age.[7] Elimination half-lives of 6.7 and 10 hours have been reported in term and preterm infants, respectively after a single intravenous dose of morphine, with nearly 80% of the dose remaining unbound.[10] The reduced clearance, which is dependent on gestational age and birth weight,[12,13] and higher morphine concentrations are probably due to reduced metabolism in neonates as well as immature renal function: the capacity to conjugate morphine by glucuronidation is reduced in preterm infants,[6,8,9] and some premature neonates may lack the capacity entirely.[9]

The elderly. The pharmacokinetics of morphine were compared[1] in 7 healthy elderly (60 to 69 years) and 13 healthy young (24 to 28 years) subjects, after a single intravenous injection of morphine sulfate 10 mg per 70 kg. Although the terminal rate of drug disappearance from plasma was faster in the elderly group, apparent volume of distribution at steady state was about half that of the young group and plasma clearance was reduced.

Hepatic impairment. The liver is a major site of morphine metabolism and therefore hepatic impairment could be expected to affect elimination (see under Precautions, above). There is some evidence that in cirrhosis glucuronidation might be relatively spared compared with other metabolic processes and that some extrahepatic metabolism may occur. Several studies have served to illustrate these points:

- Hepatic extraction of morphine was impaired in cirrhotic patients, but less than expected[1]
- Morphine metabolism was minimal during the anhepatic phase of liver transplantation, but increased markedly when the new liver was reperfused[2]
- Morphine metabolism was virtually complete after liver transplantation with only 4.5% unchanged morphine being excreted in the urine 24 hours after administration[3]
- Morphine elimination was reduced when hepatic blood flow was impaired[4]

Renal impairment. Only a small amount of morphine is excreted unchanged in the urine. There are conflicting reports of morphine accumulation in patients with renal impairment; some for,[1,2] others against.[3-5] It does seem clear though that morphine metabolites accumulate in such patients[5-9] including those on peritoneal dialysis;[10] the half-life of the active metabolite morphine-6-glucuronide was reported to be prolonged and its clearance reduced when morphine-6-glucuronide was given to patients with renal impairment.[11] Opioid intoxication[12] and a prolonged opioid effect[13] in patients with renal failure has been associated with morphine-6-glucuronide (see also under Precautions, above).

Uses and Administration

Morphine, a phenanthrene derivative, is the main alkaloid of opium (p.105). It is now commonly obtained from whole opium poppies (*Papaver somniferum*) which are harvested as poppy straw; a concentrate of poppy straw is known as CPS.

Morphine is an opioid analgesic (p.104) with agonist activity mainly at μ opioid receptors and perhaps at κ and δ receptors. It acts mainly on the CNS and smooth muscle. Although morphine is mainly a CNS depressant it has some central stimulant actions which result in nausea and vomiting and miosis. Morphine generally increases smooth muscle tone, especially the sphincters of the gastrointestinal and biliary tracts.

Morphine may produce both physical and psychological dependence (see p.101) and should therefore be used with discrimination. Tolerance may also develop.

Morphine is used for the relief of moderate to severe pain, especially that associated with cancer, myocardial infarction, and surgery. In addition to relieving pain, morphine also alleviates the anxiety associated with severe pain and it is useful as a hypnotic where sleeplessness is due to pain. It is also used in the management of neonatal abstinence syndrome (see Administration in Children, below).

Morphine reduces intestinal motility but its role, if any, in the symptomatic treatment of diarrhoea is very limited. It also relieves dyspnoea associated with various conditions, including that due to pulmonary oedema resulting from left ventricular failure. It is an effective cough suppressant, but codeine is usually preferred as there is less risk of dependence; morphine may however be necessary to control intractable cough associated with terminal lung cancer. Morphine has been used pre-operatively as an adjunct to anaesthesia for pain relief and to allay anxiety. It has also been used in high doses as a general anaesthetic in specialised procedures such as open-heart surgery.

Morphine is usually **administered** as the sulfate, although the hydrochloride and the tartrate are used in similar doses. Doses are expressed as the salts. Dosage routes include the oral, subcutaneous, intramuscular, intravenous, intraspinal, and rectal routes. Subcutaneous injections are considered unsuitable for oedematous patients. Parenteral doses may be intermittent injections or continuous or intermittent infusions adjusted according to individual analgesic requirements.

Doses should generally be reduced in the elderly or debilitated or in patients with hepatic or renal impairment (see also under Precautions, above).

For **pain**:

- *Oral* doses are usually in the range of 5 to 20 mg every 4 hours and may be given as an aqueous solution of the hydrochloride or sulfate, as modified-release granules or tablets, or as tablets. With modified-release preparations the 24-hour dose is usually given as a single dose or in 2 divided doses; in the USA, a modified-release preparation (*MS Contin, Purdue*) that allows dosing every 8 or 12 hours is also available. With all modified-release preparations, additional doses of a conventional formulation may be needed if breakthrough pain occurs. As with the other routes, high oral doses may be required for effective analgesia in palliative care.
- Morphine is sometimes given *rectally* generally as suppositories in doses of 10 to 30 mg every 4 hours. Oral modified-release preparations have also been used rectally although such use is unlicensed in the UK and is generally not recommended except, possibly, in some emergency situations.
- The usual dose by *subcutaneous* or *intramuscular* injection is 10 mg every 4 hours but may range from 5 to 20 mg.
- Doses of up to 15 mg have been given by slow *intravenous* injection, sometimes as a loading dose for continuous or patient-controlled infusion. For continuous intravenous administration maintenance doses have generally ranged from 0.8 to 80 mg/hour, although some patients have required and been given much higher doses. Similar doses have been given by continuous subcutaneous infusion.
- For myocardial infarction, the *BNF* recommends that 10 mg may be given by intravenous injection at a rate of 2 mg/minute followed by a further 5 to 10 mg if necessary; half this dose should be used in elderly or debilitated patients.
- Intraspinal doses are in the region of 5 mg for an initial *epidural* injection; if pain relief is unsatisfactory after one hour, further doses of 1 to 2 mg may be given up to a total dose of 10 mg per 24 hours. The recommended initial dose for continuous epidural infusion is 2 to 4 mg per 24 hours increased if necessary by further doses of 1 to 2 mg. A modified-release formulation of liposomal morphine sulfate for lumbar epidural use is also available for the treatment of pain after major surgery; doses range from

10 to 20 mg, depending on the type of surgery, and should be given before the operation, or after clamping of the umbilical cord if used during caesarean section. It is intended for single-use only and no other drugs should be administered into the epidural space for at least the next 48 hours.

- *Intrathecal* use of morphine and its salts has tended to be less common than epidural. Doses of 200 micrograms to 1 mg have been injected intrathecally on a single occasion.

For details of doses in children see below.

In **acute pulmonary oedema** 5 to 10 mg may be given by intravenous injection at a rate of 2 mg/minute.

For the control of intractable **cough** associated with terminal lung cancer, morphine oral solution is given in an initial dose of 5 mg every 4 hours.

Administration. *CONTINUOUS INFUSION.* Both acute and chronic pain have been controlled satisfactorily by continuous intravenous or subcutaneous infusions of morphine sulfate[1-3] but diamorphine hydrochloride or hydromorphone hydrochloride may be preferred for subcutaneous infusion because their greater solubility in water allows a smaller dose volume. Continuous subcutaneous infusions may be preferred to continuous intravenous infusions.[4] Continuous subcutaneous infusion may be less effective than epidural morphine for relief of postoperative pain;[5] however, it was still considered to provide simple and relatively effective analgesia with a low rate of adverse effects.

INTRA-ARTICULAR ROUTE. Intra-articular injection of morphine into the knee at the end of arthroscopy has been reported to provide some degree of postoperative pain relief;[1,2] such pain relief may be more pronounced than that produced by the same dose given intravenously[1] or intramuscularly.[2] The effect appears to be due to the action of morphine on peripheral opioid receptors[2] although a systemic effect has not been completely excluded.[1]

There have been conflicting results on whether addition of morphine to intra-articular bupivacaine improves analgesia[3,4] and a systematic review[5] concluded that from the few well-controlled studies there was no evidence of an added analgesic effect of morphine compared with saline alone.

Doses of morphine reported to have been injected intra-articularly have ranged from 1 to 10 mg.

INTRANASAL ROUTE. An intranasal formulation of morphine is under investigation for the relief of acute pain.

INTRASPINAL ROUTE. Morphine is given epidurally and intrathecally to relieve both acute and chronic pain. However, reviews on the role of spinal opioids have generally concluded that they should be reserved for pain not controlled by more conventional routes.[1-3] When converting from conventional routes it has been suggested that 1% of the total daily dose could be tried as the daily intrathecal dose and 10% as the epidural dose.[3] Conversion from intrathecal to oral dosage has also been investigated.[4]

Intrathecal morphine may be delivered continuously via an implanted programmable infusion pump for the long-term management of chronic non-malignant and cancer pain.

PATIENT-CONTROLLED ANALGESIA. Morphine is one of the most frequently used opioid analgesics for patient-controlled analgesia (see p.4). Most experience has been with the intravenous route, but the intramuscular, subcutaneous, oral, pulmonary, and epidural[1] routes have also been used. Reasonable initial settings recommended for intravenous use have been a demand dose of 1 to 2 mg of morphine sulfate (or its equivalent) and a lockout interval of 5 to 10 minutes.[2]

PULMONARY ROUTE. For reference to the use of nebulised morphine see Dyspnoea, below.

Administration in children. Opioid analgesics are used in children in the management of moderate to severe **pain** (see p.3); morphine is the most widely used opioid for severe pain in children and is the standard against which other opioids are compared. Morphine may be given to children requiring acute analgesia as a result of surgery or invasive procedures. It may also be given for chronic non-malignant pain and is the opioid of choice for the oral treatment of severe pain in palliative care. Its analgesic and sedative properties are useful in the management of children in intensive care (see p.957); morphine is considered to be a more rational choice than fentanyl in settings where long-term infusions are required. Respiratory depression with morphine treatment is a risk in all children; however, neonates (and particularly those who are breathing spontaneously) may have an enhanced susceptibility because of the pharmacokinetic differences of morphine in this age group (see above).

The following initial doses are recommended by the *BNFC*; doses should thereafter be adjusted according to response:

- By subcutaneous or intramuscular injection, neonates may be given 100 micrograms/kg every 6 hours; those aged 1 to 6 months, 100 to 200 micrograms/kg every 6 hours; 6 months to 2 years, 100 to 200 micrograms/kg every 4 hours; 2 to 12 years, 200 micrograms/kg every 4 hours; 12 to 18 years, 2.5 to 10 mg every 4 hours
- By intravenous injection over at least 5 minutes, neonates may be given 50 micrograms/kg every 6 hours; those aged 1 to 6 months, 100 micrograms/kg every 6 hours; 6 months to 12 years, 100 micrograms/kg every 4 hours; 12 to 18 years, 2.5 mg every 4 hours

  The following doses given by slow intravenous injection are suggested as loading doses for continuous intravenous infusion: neonates may be given 25 to 100 micrograms/kg; those aged 1 to 6 months, 100 to 200 micrograms/kg; 6 months to 12 years, 100 to 200 micrograms/kg; 12 to 18 years, 2.5 to 10 mg. The loading dose may be followed by an infusion given in a dose dependent on the patient's age: neonates, 5 to 40 micrograms/kg per hour; 1 to 6 months, 10 to 30 micrograms/kg per hour; 6 months to 18 years, 20 to 30 micrograms/kg per hour
- By mouth or rectum, infants aged 1 to 12 months may be given 80 to 200 micrograms/kg every 4 hours; those aged 1 to 2 years, 200 to 400 micrograms/kg every 4 hours; 2 to 12 years, 200 to 500 micrograms/kg, to a maximum of 20 mg, every 4 hours; 12 to 18 years, 5 to 20 mg every 4 hours. In *palliative care*, modified-release oral preparations may be used; they are given as a single daily dose or in 2 divided doses
- By continuous subcutaneous infusion, children aged 1 to 3 months may be given 10 micrograms/kg per hour; those aged 3 months to 18 years, 20 micrograms/kg per hour

Intraspinal doses of morphine that have been tried[1] in children are as follows:

- Caudal epidural block, 100 micrograms/kg
- Thoracic or lumbar epidural block, 50 micrograms/kg
- Intrathecal doses of 20 or 30 micrograms/kg have provided satisfactory postoperative pain relief, but respiratory depression occurred in 10 and 25%, respectively

Guidelines[2] for analgesia in children in Accident and Emergency departments in the UK recommend the use of intravenous morphine as an alternative to, or after initial treatment with, intranasal diamorphine for *severe pain* such as that associated with large burns, long bone dislocation, appendicitis, or sickle-cell crisis, but it should be used with caution if there is risk of depression of airway, breathing, or circulation.

In the UK, morphine is also used in the management of **neonatal abstinence syndrome** (p.102) under specialist supervision. The *BNFC* recommends an initial oral dose of 40 micrograms/kg (increase dose if necessary) every 4 hours until symptoms are controlled; the dosage frequency should be reduced gradually over 6 to 10 days until a dose of 40 micrograms/kg once daily is achieved after which the drug should be stopped.

Cancer pain. Morphine is the opioid of choice for moderate to severe cancer pain (p.5); guidelines for its use issued by the European Association for Palliative Care[1] include:

- the optimal route for use is by mouth. For best effect, both conventional (for dose titration) and modified-release (for maintenance) dosage forms are required
- the simplest method of dose titration is with conventional morphine dosage every 4 hours, and the same dose for breakthrough pain. This 'rescue dose' may be given as often as required, up to hourly. The total daily dose of morphine should be reviewed each day and the regular dose adjusted to take into account the amount needed for breakthrough pain
- if pain returns consistently before the next dose is due the regular dose should be increased. Conventional formulations do not generally need to be given more often than every 4 hours, and modified-release products should be given according to the intended duration of the preparation (usually every 12 or 24 hours). Patients stabilised on regular oral morphine require continued access to a rescue dose for breakthrough pain
- if a conventional formulation of morphine is not available and treatment is started with modified-release morphine, changes to the regular dose should not be made more often than every 48 hours, which means that dose titration will be prolonged
- for patients taking conventional morphine preparations every 4 hours, a double dose at bedtime is effective to prevent pain disturbing sleep
- if patients are unable to take morphine orally the preferred alternative route is subcutaneous. There is no indication for intramuscular morphine for cancer pain since subcutaneous dosage is simpler and less painful
- when converting dosage, the relative potency of oral to subcutaneous morphine is between about 1:2 and 1:3, so 20 to 30 mg of oral morphine is equianalgesic to 10 mg by subcutaneous injection
- in patients who need continuous parenteral morphine the preferred route is by subcutaneous infusion. However, intravenous infusion may be preferred:

  in patients who already have an indwelling intravenous line

  in those with generalised oedema

  if erythema, soreness, or sterile abscess develop during subcutaneous dosage

  in patients with coagulation disorders

  where peripheral circulation is poor
- when converting dosage, the relative potency of oral to intravenous morphine is also between about 1:2 and 1:3
- the buccal, sublingual, and nebulised routes of administration are not recommended in the absence of evidence for clinical advantage over more usual routes
- a small proportion of patients develop intolerable adverse effects with oral morphine (in conjunction with adjuvant non-opioid analgesics as appropriate) before achieving adequate pain relief. In such patients a change to an alternative opioid, or a change in the route should be considered. Although switching between opioids complicates pain management, adequate pain relief for some may depend on the use of alternative drugs, the use of intraspinal routes, or non-drug methods of pain control

Similar recommendations are given in guidelines issued by the US National Comprehensive Cancer Network.[2]

Dyspnoea. In the treatment of dyspnoea (p.104), doses of morphine tend to be smaller than those used for pain relief. Morphine hydrochloride or sulfate may be given as an oral solution in carefully titrated doses, starting at a dose of 5 mg every 4 hours; as little as 2.5 mg every 4 hours may be sufficient for opioid-naive patients.[1] In acute pulmonary oedema, 5 to 10 mg may be given by slow intravenous injection. In patients already receiving morphine for pain relief the following doses have been suggested:[2]

- mild dyspnoea: 25 to 50% of usual analgesic dose
- moderate dyspnoea: 50 to 100% of usual analgesic dose
- severe dyspnoea: 100% or more of usual analgesic dose

Patients have also obtained relief from subcutaneous injection.[3] Although it has been reported that a low dose of nebulised morphine (mean dose 1.7 mg) improved exercise endurance in patients with dyspnoea due to advanced chronic lung disease,[4] several subsequent studies[5-7] have failed to obtain significant improvements with doses up to 40 mg. It is considered that current evidence does not support the use of nebulised morphine for breathlessness.[1,8-10] Furthermore, bronchospasm can be a problem, particularly at high doses, and there is no consensus on the optimal dose, schedule, or method of dose titration.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96. Nabumetone is contra-indicated in patients with severe hepatic impairment.

Effects on the gastrointestinal tract. Like other NSAIDs nabumetone can produce adverse effects on the gastrointestinal tract, although some studies have produced favourable comparisons with ibuprofen[1] or naproxen.[2] A recent review[3] noted that limited comparative data suggest that nabumetone has a similar gastrointestinal adverse effect profile to that of selective COX-2 inhibitors. It has been suggested[4] that nabumetone may be a preferential inhibitor of cyclo-oxygenase-2 (COX-2) but the significance of this in determining its adverse effects is uncertain.

Effects on the lungs. Pulmonary fibrosis developed in a 68-year-old woman taking nabumetone 1.5 g; symptoms appeared after 2 weeks of therapy and worsened during the next 6 weeks.[1] There was rapid resolution on stopping nabumetone and treatment with oral corticosteroids.

1. Morice A, *et al.* Pulmonary fibrosis associated with nabumetone. *Postgrad Med J* 1991; **67:** 1021–2.

Effects on the skin. Pseudoporphyria characterised by blistering on the neck and hands developed in a 36-year-old woman taking nabumetone and auranofin for rheumatoid arthritis.[1] Stopping auranofin had no effect on the blistering which only resolved once nabumetone was withdrawn. The authors of the report stated that the UK CSM had received 3 additional reports of pseudoporphyria suspected to be caused by nabumetone.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Nabumetone is well absorbed from the gastrointestinal tract. Plasma concentrations after oral doses are too small to be measured, as it undergoes rapid and extensive first-pass metabolism in the liver to the principal active compound 6-methoxy-2-naphthylacetic acid (6-MNA) and other inactive metabolites. 6-MNA is more than 99% bound to plasma proteins. It diffuses into synovial fluid, crosses the placenta, and is distributed into breast milk. There is considerable interindividual variation in the plasma elimination half-life of 6-MNA, especially in the elderly; some reported mean values at steady state include 22 to about 27 hours for young adults and about 25 and 34 hours in elderly patients. 6-MNA eventually undergoes further metabolism by *O*-methylation and conjugation. About 80% of a dose is excreted in the urine as inactive or conjugated metabolites and less than 1% as unchanged 6-MNA.

Uses and Administration

Nabumetone is a non-active prodrug whose major metabolite is an NSAID (p.99) structurally similar to naproxen (p.92). It is used for the relief of pain and inflammation associated with osteoarthritis and rheumatoid arthritis in a usual oral dose of 1 g taken as a single dose in the evening; if necessary 0.5 to 1 g may be given additionally in the morning. It has been recommended that a dose of 1 g daily should not be exceeded in elderly patients and that 500 mg daily may be satisfactory in some cases.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

◊ A WHO expert committee considered in 1989 that the likelihood of nalbuphine abuse was low to moderate and was not great enough to warrant international control.[1] Abuse had been reported infrequently and the withdrawal syndrome produced when naloxone was given after continuous nalbuphine dosage was less severe than that in morphine dependence. Subsequently, there have been occasional reports of abuse[2,3] including misuse among athletes.[4,5]

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

Headache may occur. Nausea and vomiting occur less than with other opioids. Hallucinations and other psychotomimetic effects are rare and have been reported less frequently than with pentazocine. As nalbuphine has both antagonist and agonist activity its effects may be only partially reversed by naloxone, but use of the latter is still recommended in nalbuphine overdose.

Effects on the respiratory system. Nalbuphine produces similar respiratory depression to morphine at equianalgesic doses, but there is a ceiling effect with nalbuphine and, unlike morphine, respiratory depression does not increase appreciably with higher doses.[1] In a cumulative-dose study[2] a plateau effect was seen with nalbuphine above a total dose of 30 mg per 70 kg intravenously. Similar ventilatory depression has been noted[3] with single intravenous doses of nalbuphine of 15, 30, or 60 mg per 70 kg; naloxone failed to reverse the depression at the highest dose.

Precautions

As for Opioid Analgesics in general, p.103.

Nalbuphine may precipitate withdrawal symptoms if given to patients physically dependent on opioids.

The dose of nalbuphine should be reduced in patients with hepatic or renal impairment.

Abuse. See under Dependence and Withdrawal, above.

Pregnancy. When nalbuphine is used for analgesia during labour there is more placental transfer and sedation in mothers and their infants than with pethidine.[1] There have also been reports of bradycardia and respiratory depression in neonates whose mothers received nalbuphine during labour.[2,3] It was considered that nalbuphine should be given with caution during labour, especially by the intravenous route. Some[2] have recommended subcutaneous dosage and advised that nalbuphine should not be given around the expected time of delivery.

Interactions

For interactions associated with opioid analgesics, see p.103.

Pharmacokinetics

There appears to be considerable first-pass metabolism of nalbuphine after oral doses. On intramuscular injection nalbuphine has been reported to produce peak plasma concentrations after 30 minutes. It is metabolised in the liver and is excreted in the urine and faeces as unchanged drug and conjugates. Nalbuphine crosses the placenta and small amounts are distributed into breast milk.

Uses and Administration

Nalbuphine hydrochloride, a phenanthrene derivative, is an opioid analgesic (p.104). It has mixed opioid agonist and antagonist activity. It is used for the relief of moderate to severe pain and as an adjunct to anaesthesia. Nalbuphine hydrochloride is reported to act within 15 minutes of subcutaneous or intramuscular injection or within 2 to 3 minutes of intravenous injection and generally to produce analgesia for 3 to 6 hours. It is given subcutaneously, intramuscularly, or intravenously. Intravenous infusion as part of a patient-controlled analgesia system has also been used.

The usual adult dose of nalbuphine hydrochloride for **pain** relief is 10 to 20 mg every 3 to 6 hours as required.

As an adjunct in balanced **anaesthesia** a usual dose is 0.3 to 3 mg/kg given intravenously over 10 to 15 minutes at induction. Maintenance doses of 250 to 500 micrograms/kg may be given as intravenous boluses if required.

Action. Nalbuphine is generally described as a mixed agonist and antagonist acting mainly as an agonist at κ opioid receptors and as an antagonist or partial agonist at μ receptors. It has shown antagonist activity similar to that seen with naloxone in opioid-dependent subjects.[1] Nalbuphine is structurally related to naloxone and oxymorphone. Pharmacologically nalbuphine is qualitatively similar to pentazocine, but nalbuphine is a more potent antagonist at μ opioid receptors, is less likely to produce psychotomimetic effects such as hallucinations, and is reported to produce no significant cardiovascular effects in patients with ischaemic heart disease. It differs from pure μ agonists such as morphine in that its analgesic, sedative, and respiratory depressant actions are subject to a 'ceiling' effect and may not increase proportionately with dose.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Suppositories containing naproxen may cause rectal irritation and occasional bleeding.

Naproxen should be used with caution in renal impairment, and use is not recommended in patients whose creatinine clearance is less than 20 mL/min.

Breast feeding. The American Academy of Pediatrics[1] states that there have been no reports of any clinical effect on the infant associated with the use of naproxen by breast-feeding mothers, and that therefore it may be considered to be usually compatible with breast feeding. The *BNF* also considers that the amount of naproxen distributed into breast milk is too small to be harmful to a breast-fed infant; however, some licensed product information recommends that breast feeding should be avoided during naproxen therapy.

In a study[2] of a breast-fed infant only 0.26% of the mother's dose was recovered from the infant.

Effects on the cardiovascular system. For a discussion of the possible cardiovascular effects of naproxen, see p.96.

Effects on the CNS. Aseptic meningitis has been associated with naproxen therapy;[1,2] attacks may be recurrent and cross-sensitivity with other NSAIDs has occurred.[2]

There has been a report[3] of a patient with Parkinson's disease whose symptoms had previously been well controlled but who deteriorated when she was given naproxen. She improved on withdrawal of naproxen and the effect was confirmed by rechallenge. It was noted that the UK CSM had recorded a case of parkinsonism associated with a combined preparation of naproxen and misoprostol and 12 other reports of tremor or ataxia precipitated by naproxen.

Effects on the eyes. Keratopathy, characterised by whorl-like corneal opacities, occurred in a woman taking naproxen; complete regression occurred after stopping the drug.[1] There has also been a report of exacerbation of glaucoma in a 65-year-old woman given naproxen.[2]

Effects on the gastrointestinal tract. Gastrointestinal adverse effects are among the most frequently reported during short- and long-term treatment with naproxen. Acute proctocolitis associated with the use of naproxen has been reported.[1] Oesophageal ulceration reported in 7 patients[2] may have arisen due to incorrect consumption (such as taking the dosage without fluids or lying down after a dose) but other causes could not be dismissed.

Effects on the kidneys. Acute renal failure,[1] renal papillary necrosis,[2,3] interstitial nephritis,[4] and hyperkalaemia[1] have been reported in patients receiving naproxen. As with other NSAIDs, renal adverse effects occur more frequently in patients with certain risk factors such as volume depletion, diuretic therapy, heart failure, and pre-existing renal dysfunction.[1]

Effects on the salivary glands. For reference to salivary gland swelling associated with naproxen therapy, see Hypersensitivity, below.

Effects on the skin. Cutaneous reactions reported in patients receiving naproxen include erythema nodosum,[1] lichen planus,[2] toxic pustular skin eruption,[3] bullous dermatosis,[4] and fixed drug eruption.[5] Photodermatitis, characterised by vesicle formation or increased skin fragility on sun-exposed skin, has been reported in adults[6-8] and children.[9,10]

A relapse of subacute cutaneous lupus erythematosus was reported to be possibly associated with naproxen.[11]

Hypersensitivity. In an early case-report in 11 aspirin-sensitive asthmatic patients, all developed reactions (rhinorrhoea, tightness of chest, wheezing, dyspnoea) after taking naproxen in doses of 40 to 80 mg.[1] More recently, angioedema occurred after a single dose of naproxen in a patient known to be aspirin-sensitive.[2] Hypersensitivity to individual NSAIDs is believed to be closely linked to the extent to which these drugs inhibit prostaglandin (see under Aspirin, p.21). There may therefore be a dose threshold below which no detectable symptoms occur. Such an effect has been reported[3] in a patient previously stabilised on naproxen for about one year who had a hypersensitivity reaction after a dosage increase.

A hypersensitivity reaction characterised by pulmonary infiltrates with eosinophilia[4,5] has been reported in patients taking naproxen. There has also been a report of a generalised hypersensitivity reaction with acute eosinophilic colitis in a 57-year-old woman treated with naproxen for osteoarthritis.[6] Bilateral swelling of the major salivary glands, a generalised rash, and eosinophilia suggestive of a hypersensitivity response was reported in another patient after use of naproxen.[7] Leukocytoclastic vasculitis with peripheral neuropathy and nephritis has also been noted in a 62-year-old woman after naproxen treatment.[8]

Parkinsonism. For a report of a patient whose symptoms of Parkinson's disease were exacerbated by naproxen, see Effects on the CNS, above.

Interactions

For interactions associated with NSAIDs, see p.99.

The excretion of naproxen is delayed by probenecid resulting in raised plasma concentrations of naproxen.

Antiepileptics. For the effect of naproxen on the protein binding of *valproic acid*, see p.510.

Pharmacokinetics

Naproxen and naproxen sodium are readily absorbed from the gastrointestinal tract. Peak plasma concentrations are attained about 1 to 2 hours after ingestion of naproxen sodium and in about 2 to 4 hours after ingestion of naproxen. Food reduces the rate but not the extent of absorption. Naproxen and naproxen sodium are also well absorbed rectally. At therapeutic concentrations naproxen is more than 99% bound to plasma proteins. Plasma concentrations of naproxen increase proportionally with dose up to about 500 mg daily; at higher doses there is an increase in clearance caused by saturation of plasma proteins. Naproxen diffuses into synovial fluid; it crosses the placenta and is distributed into breast milk in small amounts. Naproxen has a plasma elimination half-life of about 12 to 17 hours. About 95% of a dose is excreted in urine as naproxen and 6-*O*-desmethylnaproxen and their conjugates. Less than 5% of a dose appears in the faeces.

Uses and Administration

Naproxen, a propionic acid derivative, is an NSAID (p.99).

Naproxen is used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis including juvenile idiopathic arthritis. It is also used in dysmenorrhoea, headache including migraine, postoperative pain, soft-tissue disorders, acute gout, and to reduce fever. Naproxen is usually given *orally* as the free acid or as the sodium salt. The doses in the licensed product information are expressed in terms of the free acid or the sodium salt as appropriate for an individual preparation; however, the doses given below are expressed in terms of the equivalent amount of free acid only. Each 550 mg of naproxen sodium is equivalent to about 500 mg of naproxen.

In the treatment of **rheumatic disorders**, the usual dose of naproxen or naproxen sodium is the equivalent of 500 mg to 1 g of naproxen daily either as a single dose or in 2 divided doses. US licensed product information states that patients who tolerate lower doses may have their dosage increased to 1.5 g daily for a period of up to 6 months, if required. For dosage in children, see below.

In **other painful conditions** such as dysmenorrhoea and acute musculoskeletal disorders the usual regimen is the equivalent of 500 mg of naproxen initially, followed by 250 mg every 6 to 8 hours, up to a maximum daily dose of 1.25 g on the first day and 1 g thereafter.

In **acute gout** an initial dose equivalent to 750 mg of naproxen followed by 250 mg every 8 hours is used.

For the treatment of **migraine**, the equivalent of 750 mg of naproxen can be given at the first symptom of an impending attack and, if necessary, this may be followed after at least half an hour by further doses of 250 to 500 mg throughout the day to a total maximum daily dose of 1250 mg. See below for a suggested dose for the prophylaxis of migraine.

Naproxen has been given *rectally* in similar doses to those used orally.

Naproxen has also been used as the piperazine, aminobutanol, and lysine salts, and as naproxen cetrimonium. Naproxen is available in a combination pack with misoprostol (p.2013) for patients at risk of NSAID-induced peptic ulceration. Alternatively, packs containing naproxen with lansoprazole capsules are available in some countries for such patients.

Administration in children. In the treatment of juvenile idiopathic arthritis (p.10), US licensed product information recommends an oral dose of about 10 mg/kg daily of naproxen in 2 divided doses for children aged 2 years and over. In addition, higher doses may also be used: the *BNFC* suggests a dose of 5 to 10 mg/kg twice daily in children aged 1 month to 18 years which may be increased to 10 to 15 mg/kg twice daily (maximum of 1 g daily) for short-term use in severe disease.

Headache. An NSAID such as naproxen is among the drugs tried first for the symptomatic treatment of various types of headache including migraine (p.616) and tension-type headache (p.617). An NSAID given at the onset of symptoms can successfully treat an acute attack of migraine.[1] Co-treatment with a triptan may provide additional benefit and a preparation containing both sumatriptan succinate and naproxen sodium has recently been developed.[2,3]

NSAIDs also appear to be effective for the prophylaxis of migraine, although propranolol is generally preferred. Studies have indicated that naproxen sodium 550 mg [equivalent to 500 mg of naproxen] given twice daily may be useful for reducing the number of attacks suffered.[4-6]

Malignant neoplasms. Some NSAIDs such as naproxen may be of value both for the differential diagnosis and the management of neoplastic fever[1-4] as they appear to be more effective in reducing this type of fever than against fever associated with infections. However, the reliability of naproxen in the diagnosis of neoplastic fever has been questioned.[5] In a group of 72 patients, naproxen decreased body temperature in 55% of patients with neoplastic disorders and 38% of patients with other conditions. Thus, the sensitivity of the test was calculated as 55% and its specificity as 62%, which the authors considered to be too low to be reliable.

Adverse Effects and Treatment

Adverse effects occurring with nefopam include gastrointestinal disturbances, such as nausea and vomiting, sweating, drowsiness, insomnia, urinary retention, dizziness, hypotension, tremor, paraesthesia, palpitations, lightheadedness, nervousness, confusion, blurred vision, headache, dry mouth, syncope, angioedema, allergic reactions, and tachycardia. Euphoria, hallucinations, and convulsions have occasionally been reported, as has temporary pink discoloration of the urine. Symptoms of overdosage have included CNS and cardiovascular toxicity.

Effects on the urinary tract. In January 1989, the UK CSM[1] reported that it had received 53 reports in which nefopam was associated with the development of urinary retention or symptoms of hesitancy, poor stream, or dribbling. In one case there was a history of prostatism.

Overdosage. There have been reports of fatal overdoses with nefopam.[1-3] One report[1] also provided details of 9 other patients who recovered with routine supportive treatment.

3. Tracqui A, *et al.* Fatal overdosage with nefopam (Acupan). *J Anal Toxicol* 2002; **26:** 239–43.

Precautions

Nefopam is contra-indicated in patients with a history of convulsive disorders. It should be used with caution in the elderly and in patients with glaucoma, urinary retention, or impaired hepatic or renal function.

Abuse. Abuse of parenteral nefopam has been reported in 3 patients with a history of chronic pain.[1] Psychostimulant-like symptoms such as agitation, impatience, and violence, were noted in 2 of the patients; antimuscarinic effects were also seen. All 3 patients were found to be psychologically dependent; in 2 who attempted to stop nefopam, withdrawal symptoms were noted.

1. Villier C, Mallaret MP. Nefopam abuse. *Ann Pharmacother* 2002; **36:** 1564–6.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving nefopam, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

Studies in 5 healthy nursing mothers given nefopam for post-episiotomy pain indicated that nefopam was present in human milk in an equivalent concentration to that in plasma.[2] It was calculated that on a body-weight basis a breast-fed infant would receive less than 3% of the maternal dose.

Interactions

It has been recommended that nefopam should not be given to patients receiving MAOIs and should be used cautiously in those receiving tricyclic antidepressants. The adverse effects of nefopam may be additive to those of other drugs with antimuscarinic or sympathomimetic activity.

Pharmacokinetics

Nefopam is absorbed from the gastrointestinal tract. Peak plasma concentrations occur 1 to 3 hours after a dose by mouth and up to 1 hour after intramuscular injection. About 73% is bound to plasma proteins. Nefopam is distributed into breast milk. It has an elimination half-life of about 4 hours. It is extensively metabolised and excreted mainly in urine, in which less than 5% of a dose is excreted unchanged. About 8% of a dose is excreted via the faeces.

Uses and Administration

Nefopam hydrochloride is a non-opioid analgesic considered to act centrally, although its mechanism of action is unclear. It also has some antimuscarinic and sympathomimetic actions. Nefopam hydrochloride is used for the relief of moderate acute and chronic pain. The usual oral dose range is 30 to 90 mg three times daily; the recommended initial dose is 60 mg (or 30 mg in elderly patients) three times daily. Nefopam hydrochloride may also be given in doses of 20 mg by intramuscular injection, repeated every 6 hours if necessary; it has been recommended that the patient should always be lying down when receiving the injection and should remain so for 15 to 20 minutes afterwards. It has also been given by slow intravenous injection in doses of 20 mg every 4 hours up to a maximum of 120 mg daily.

Hiccup. In two case series[1,2] involving 10 patients in total, hiccups refractory to standard therapy stopped after treatment with intravenous nefopam. For the management of intractable hiccups see under Chlorpromazine, p.976.

Ph. Eur. 6.2 (Niflumic Acid). A pale yellow, crystalline powder. Practically insoluble in water; soluble in alcohol and in methyl alcohol; freely soluble in acetone.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Fluoride-associated osteosis has been reported with prolonged use. Niflumic acid should be stopped if hypersensitivity skin reactions appear.

Effects on the skin. From a case-control study[1] of children admitted to a hospital emergency department in Italy it was calculated that the odds-ratio of users of niflumic acid, or its derivative morniflumate, developing serious cutaneous reactions was 4.9. Given this figure and the fact that safer drugs were available the authors considered that there was no indication for which niflumic acid was required in children. However, a large cohort study[2] involving 193 727 children aged between 0 and 14 years found that niflumic acid was not associated with a higher risk of mucocutaneous reactions when compared with other NSAIDs or paracetamol. The authors of the later study suggested that the conclusions of the original study may have been confounded because there was no adjustment for age or indication.

Uses and Administration

Niflumic acid, a nicotinic acid derivative, is an NSAID (p.99). It has been used in inflammatory and musculoskeletal and joint disorders in usual oral doses of about 250 mg three or four times daily; up to 1500 mg daily has been used in severe disorders. It has also been used topically as a 3% cream or ointment or 2.5% gel. The morpholinoethyl ester, morniflumate (p.86), has similar uses.

Niflumic acid glycinamide has been used topically in inflammatory mouth disorders.

Ph. Eur. 6.2 (Nimesulide). A yellowish crystalline powder. It exhibits polymorphism. Practically insoluble in water; slightly soluble in dehydrated alcohol; freely soluble in acetone.

Profile

Nimesulide is an NSAID (p.96) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It may be given in oral doses of up to 100 mg twice daily for inflammatory conditions, fever, pain, and dysmenorrhoea; use in the EU is limited to a maximum of 15 days due to reports of hepatotoxicity (see Adverse Effects, below). It has also been given rectally in a dose of 200 mg twice daily or applied topically as a 3% gel. Nimesulide betadex (nimesulide betacyclodextrin complex) has been used similarly.

Adverse effects. Although *thrombocytopenia* is a common feature in patients infected with HIV, a group of workers considered that thrombocytopenia in one of their patients was related to the use of nimesulide.[1]

There have been reports[2-4] of *hepatotoxicity* after treatment with nimesulide. Data from spontaneous reports has also suggested that nimesulide may be associated with a higher risk of hepatotoxicity than other NSAIDs.[4] A cohort study[5] involving about 400 000 users of NSAIDs in one region of Italy between 1997 and 2001 found that those taking nimesulide were 1.3 times more likely to develop hepatotoxicity than users of other NSAIDs and 1.9 times more likely to suffer severe liver injury. In May 2007 the Irish regulatory authority withdrew nimesulide from the Irish market after concerns about hepatotoxicity.[6] Since being licensed in 1995, nimesulide had generated 53 adverse reaction reports involving liver toxicity, including 9 cases of liver failure, 3 of which resulted in death and 6 in liver transplantation; there had also been 1 other liver-related fatality. The EMEA[7] subsequently recommended that treatment with nimesulide should be limited to 15 days.

There have been reports[8,9] of *toxic pustuloderma* (acute generalised exanthematous pustulosis) after receiving oral nimesulide. *Fixed drug eruptions* have also been seen.[10]

An infant developed hypotension and hypothermia after inadvertently taking an *overdose* of 8 times the recommended daily dose of nimesulide.[11] The patient recovered after gastric lavage with activated charcoal and supportive therapy.

Pregnancy. Irreversible *end-stage renal failure* has been reported in a neonate born to a mother who received nimesulide as a tocolytic from the 26th to the 32nd week of pregnancy.[1] Others have reported neonatal renal failure associated with nimesulide.[2] *Premature closure of the ductus arteriosus* leading, in some cases, to *persistent pulmonary hypertension* has also been seen in 10 neonates whose mothers self-medicated with nimesulide during the third trimester of pregnancy.[3]

Premature labour. Nimesulide has been tried as an alternative to indometacin to delay labour in patients with a history of preterm delivery (p.2003). Nimesulide was given from 16 to 34 weeks of gestation and a successful delivery started 6 days after withdrawal.[1] There appeared to be no adverse effect on fetal renal function or the ductus arteriosus. The authors suggested that fetal prostaglandin synthesis might be mainly mediated through cyclo-oxygenase-1 (COX-1) and that a relatively selective COX-2 inhibitor such as nimesulide might produce fewer adverse effects on the fetus than other non-selective NSAIDs. However, in a small study short-term effects on the fetus were similar for nimesulide, indometacin, and sulindac.[2]

Adverse effects have been reported in some neonates whose mothers received nimesulide during their pregnancies, see above.

NOTE. Use of the term 'synthetic capsaicin' to describe nonivamide has arisen from the use of nonivamide as an adulterant for capsaicin and capsicum oleoresin.

Profile

Nonivamide is a synthetic analogue of capsaicin (p.32) that is used in topical preparations for the relief of muscular and rheumatic pain.

Nonivamide has also been used as a food flavour and in 'pepper sprays' for law enforcement and self defence.

Adverse Effects and Treatment

The commonest adverse effects of NSAIDs are generally gastrointestinal disturbances, such as gastrointestinal discomfort, nausea, and diarrhoea; these are usually mild and reversible but in some patients peptic ulceration and severe gastrointestinal bleeding may occur. It is generally agreed that inhibition of cyclo-oxygenase-1 (COX-1) plays an important role in the gastrointestinal effects of NSAIDs; the selective inhibition of COX-2 improves gastrointestinal tolerance.

CNS-related adverse effects include headache, vertigo, dizziness, nervousness, tinnitus, depression, drowsiness, and insomnia. Hypersensitivity reactions may occur occasionally and include fever, angioedema, bronchospasm, and rashes. Hepatotoxicity and aseptic meningitis, which occur rarely, may also be hypersensitivity reactions. Some patients may experience visual disturbances.

Haematological adverse effects of NSAIDs include anaemias, thrombocytopenia, neutropenia, eosinophilia, and agranulocytosis. Unlike aspirin, inhibition of platelet aggregation is reversible with other NSAIDs.

Some NSAIDs have been associated with nephrotoxicity such as interstitial nephritis and nephrotic syndrome; renal failure may be provoked by NSAIDs especially in patients with pre-existing renal impairment. Haematuria has also occurred. Long-term use or abuse of analgesics, including NSAIDs, has been associated with nephropathy.

Fluid retention may occur, rarely precipitating heart failure in susceptible patients. Other cardiovascular adverse effects of NSAIDs, including those selective for COX-2 inhibition, are discussed in detail below.

Other adverse effects include photosensitivity. Alveolitis, pulmonary eosinophilia, pancreatitis, Stevens-Johnson syndrome, and toxic epidermal necrolysis are other rare adverse effects. Induction or exacerbation of colitis has also been reported.

Further details concerning the adverse effects of the individual NSAIDs may be found under their respective monographs.

Incidence of adverse effects. The relative toxicity of NSAIDs is a subject of debate.[1] Attempts have been made to rank these drugs according to their toxicity on various body systems.[2] The toxicity of selective cyclo-oxygenase-2 (COX-2) inhibitors has also been reviewed.[3] For further details see below under individual headings.

Effects on the blood. The UK CSM has provided data on the reports it had received between July 1963 and January 1993 on agranulocytosis and neutropenia.[1] Several groups of drugs were commonly implicated, among them NSAIDs for which there were 133 reports of agranulocytosis (45 fatal) and 187 of neutropenia (15 fatal). The most frequently implicated NSAID was phenylbutazone with 74 reports of agranulocytosis (39 fatal) and 40 of neutropenia (4 fatal).

Effects on bone. Prostaglandins have been shown to play an important role in the bone-healing process and, consequently, the decrease in prostaglandin levels produced by NSAID use may impair the healing process.[1] Under experimental conditions, many NSAIDs including the cyclo-oxygenase-2 (COX-2) inhibitors have been shown to reduce healing.[1] However, clinical evidence of such an effect is rare.[2] There is also concern that some NSAIDs such as indometacin may accelerate the rate of cartilage destruction in patients with osteoarthritis.[3,4]

Effects on the cardiovascular system. ***BLOOD PRESSURE.*** A meta-analysis[1] of 50 randomised studies of the effects of NSAIDs on blood pressure in a total of 771 patients found that NSAIDs had elevated mean supine blood pressure by 5 mmHg. Piroxicam, indometacin, and ibuprofen had produced the greatest increase but the effect was only found to be statistically significant for piroxicam. Aspirin, sulindac, and flurbiprofen produced the smallest elevation in blood pressure while the effect of tiaprofenic acid, diclofenac, and naproxen was intermediate. The increase was more marked in studies in which patients had received antihypertensive therapy than in those where such treatment had not been used. NSAIDs had antagonised all antihypertensive therapy but the effect had been greater against beta blockers and vasodilators than against diuretics. An earlier meta-analysis of intervention studies had produced similar results.[2] Of the 1324 patients who had received NSAIDs, increases in mean arterial pressure were greatest in hypertensive patients who had taken either indometacin, naproxen, or piroxicam, although results were only significant for indometacin and naproxen. Sulindac and aspirin had minimal effects on mean arterial pressure.

It has been suggested that the use of NSAIDs in the elderly may increase the risk of the need for antihypertensive therapy.[3] A study[3] of 9411 patients aged 65 years or older who had just started treatment with antihypertensives found that 41% had used NSAIDs in the previous year compared with 26% of 9629 control patients not being treated with antihypertensives.

Heart failure. The recent use of NSAIDs has been associated with an increased risk of developing heart failure in elderly patients.[1] A case-control study[2] found that the use of an NSAID in the previous week doubled the odds of being admitted to hospital with heart failure; this risk was increased tenfold in those with a history of heart disease. The study also suggested an association between both high-dose and long drug plasma half-life and an increased risk of heart failure.

Thrombotic events. After the introduction of the selective cyclo-oxygenase-2 (COX-2) inhibitors, concerns arose that the risk of thrombotic events such as myocardial infarction and stroke might be increased in patients treated with these selective NSAIDs, and their safety was continuously reviewed by some regulatory bodies. Subsequently, clinical study data confirmed that there was a small increased risk of these events with the COX-2 inhibitors which prompted the general world-wide withdrawal of rofecoxib (see p.121) and valdecoxib (see p.132). For those selective NSAIDs that remained, prescribing restrictions were imposed (for further details, see under Celecoxib, p.34).

Concerns have also been raised that the increased risk of thrombotic events seen with the selective COX-2 inhibitors may also apply to the non-selective NSAIDs. After a review of data available at the time, the FDA[1] reported in April 2005 that the use of non-selective NSAIDs may potentially increase cardiovascular risk. In August 2005, the UK CSM advised that any cardiovascular risk with the non-selective NSAIDs was likely to be small and associated with continuous long-term treatment and higher doses;[2] no changes to current prescribing practices were recommended. This advice was endorsed a few months later by the EMEA in Europe.[3] However, new information has since become available and, in October 2006, the EMEA updated its advice.[4] Based on data which included the MEDAL programme[5] and reviews of several important epidemiological studies[6-8] the following points were made:

- the results from the MEDAL programme suggest that *diclofenac* (150 mg daily) has a risk of thrombotic events similar to that of etoricoxib (60 mg or 90 mg daily); however, further issues need to be considered before this can be considered conclusive
- based on study and epidemiological evidence, diclofenac, particularly at a high dose (150 mg daily), may be associated with an increased risk of thrombotic events
- clinical study data suggest that high-dose *ibuprofen* (2.4 g daily) is associated with an increased risk of thrombotic events; however, overall, epidemiological studies do not support an increased risk with low-dose ibuprofen (1.2 g daily or less)
- *naproxen* (1 g daily) may be associated with a lower risk for thrombotic events than the COX-2 inhibitors, but a small risk cannot be excluded; overall, there is no evidence of a cardioprotective effect
- for all *other non-selective NSAIDs* there are insufficient data to assess the thrombotic risk and consequently an increased risk cannot be excluded; a small increase in absolute risk seems most likely when used in high doses and for long-term treatment

It has been suggested that NSAIDs may reduce the cardioprotective effect of aspirin, but see under Interactions of Aspirin, p.23.

Effects on the CNS. A literature review[1] revealed that headache, hearing loss, and tinnitus are the most frequent CNS adverse effects in patients taking NSAIDs. Aseptic meningitis had occurred rarely in patients using NSAIDs such as naproxen, sulindac, or tolmetin, but the most common reports were in patients with SLE who were receiving ibuprofen (see also p.64).

Reports of psychosis appear to be rare[1,2] and have involved indometacin or sulindac, but in some reviewers' experience it was probably under-reported and was typically seen in elderly patients given indometacin.[1]

Adverse CNS effects have also been reported with the selective cyclo-oxygenase-2 (COX-2) inhibitors.[2]

The role of NSAIDs in the development of cognitive decline in the elderly is unclear. They have been associated with memory impairment and attention deficits in elderly patients,[1,3] especially when given in high doses;[4] however, some authors have also reported that long-term NSAID use may reduce the rate of cognitive decline[4,5] or the risk of developing Alzheimer's disease[6-8] (see also Dementia, under Uses and Administration, below).

Effects on electrolytes. See Effects on the Kidneys, below.

Effects on the eyes. Ocular effects such as blurred vision occur rarely in patients taking NSAIDs. Other more serious effects on the eyes associated with NSAIDs also appear to be rare. In the USA the National Registry of Drug-Induced Ocular Side Effects analysed 144 reports they received of possible adverse optic nerve reactions associated with the use of NSAIDs.[1] Of the 24 cases of papilloedema with or without pseudotumor cerebri more than half were associated with propionic acid derivatives, but it was considered that the data indicated that, on rare occasions, most NSAIDs could cause this effect; the number of reports for individual drugs was: 7 for ibuprofen, 5 each for indometacin and naproxen, 3 for meclofenamate, and 1 each for diflunisal, ketoprofen, sulindac, and tolmetin. Almost two-thirds of the 120 cases of optic or retrobulbar neuritis were also associated with propionic acid derivatives; the number of reports for individual drugs was: ibuprofen 43, naproxen 17, indometacin 9, benoxaprofen 8, phenylbutazone 8, piroxicam 8, zomepirac 7, sulindac 6, fenoprofen 5, oxyphenbutazone 3, meclofenamate 2, tolmetin 2, diflunisal 1, and ketoprofen 1.

Ocular adverse effects have also been reported with the selective Cyclo-oxygenase-2 (COX-2) inhibitors.[2]

There have been reports of severe corneal toxicity associated with the use of some topical NSAIDs, such as diclofenac and ketorolac, in the eye (see p.45).

Effects on fertility. Reversible infertility has been reported in women on long-term NSAIDs.[1-3] Prostaglandins are considered to be involved in the processes of ovulation and it is thought that NSAIDs may compromise ovulation via inhibition of cyclo-oxygenase-2 (COX-2). Women trying to become pregnant may need to avoid treatment with NSAIDs.

Effects on the gastrointestinal tract. NSAIDs can cause clinically important damage of the gastrointestinal tract, increasing the incidence of bleeding in the upper gastrointestinal tract and of perforation, although serious complications and death are relatively infrequent. They have also been associated with damage to the distal small intestine and colon.[1-3]

The complex **mechanisms** involved are not fully understood, although it is generally accepted that the inhibition of cyclo-oxygenase-1 (COX-1) plays a role in gastrointestinal toxicity and that the selective COX-2 inhibitors are less gastrotoxic than the traditional NSAIDs (see below).[4-8] The gastric mucosa is damaged both by local and systemic effects of NSAIDs.[5] The local effect is pH-dependent and varies between individual drugs. The systemic effect is pH-independent, can occur with any route of administration, and is less drug specific; it is this effect that is thought to involve COX-1 inhibition.

Risk factors continue to be studied and so far the most important patient-related factors for upper gastrointestinal toxicity are old age, a history of peptic ulcers or bleeding of the gastrointestinal tract, and concomitant use of corticosteroids.[9] It has also been suggested that risk is increased in children.[10] *Helicobacter pylori* infection exacerbates the risk of ulceration, but patients remain at increased risk even if infection is eradicated.[11] Duration of therapy is not thought to influence the risk for serious events; a cohort study[12] found that the risk of gastrointestinal bleeding or perforation with NSAIDs was constant throughout treatment, and risk quickly declines after NSAID withdrawal.[13]

Several studies[14-17] have been conducted on the **relative toxicity** of oral NSAIDs on the upper gastrointestinal tract and various rankings of these drugs have been discussed.[18-22] The UK CSM[20] examined 10 epidemiological studies for 7 oral non-aspirin NSAIDs and also examined the spontaneous reports they had received of gastrointestinal effects associated with NSAIDs. The CSM concluded that:

- azapropazone was associated with the *highest* risk of gastrointestinal reactions
- ibuprofen carried the *lowest* risk (but this may be related to dose, see below)
- piroxicam, ketoprofen, indometacin, naproxen, and diclofenac had an *intermediate* risk; it was considered that the risk for piroxicam might be higher than for the other NSAIDs with intermediate toxicity

A later update[23] by the CSM confirmed these findings.

The relative gastrointestinal toxicity of NSAIDs has also been reviewed by the EMEA[21] using data from epidemiological studies and spontaneous adverse drug reaction reports. Available evidence suggested that piroxicam and ketoprofen, particularly in high doses, were associated with the greatest risk of gastrointestinal toxicity when compared to diclofenac, etodolac, ibuprofen, indometacin, meloxicam, nabumetone, naproxen, and nimesulide. No firm conclusions were made for the other NSAIDs although there was weak evidence to suggest that the risk of toxicity was slightly higher for indometacin and naproxen than for diclofenac and ibuprofen. As a result of this review the EMEA carried out a full benefit-risk assessment for piroxicam and subsequently placed restrictions on its systemic usage (see p.118).

In a systematic review[24] of controlled epidemiological studies that found a relation between NSAID use and hospital admission for gastric haemorrhage or perforation, the low risk of serious gastric toxicity with ibuprofen appeared to be attributable mainly to the low doses used clinically; higher doses of ibuprofen were associated with a similar risk to indometacin and naproxen. For reference to an association between aspirin and the most severe gastric lesions compared with other NSAIDs, see p.21.

Results from controlled studies have confirmed that the **selective COX-2 inhibitors** are associated with a lower incidence of serious gastrointestinal effects, such as bleeding, perforation, and obstruction, than the traditional NSAIDs[25] (see also Celecoxib, p.35 for further details). However, since the risk of such effects is inherently low in those with no history of peptic ulcer disease, the general prescribing of selective COX-2 inhibitors to all patients requiring an NSAID is questioned, particularly in the light of concerns about their cardiovascular effects (see Thrombotic Events, above). In the UK, the use of selective COX-2 inhibitors is limited to patients with good cardiovascular health and at high risk of developing serious gastrointestinal problems if given a non-selective NSAID. High-risk patients include the elderly, those already receiving gastrotoxic drugs, and those with existing gastrointestinal disorders.

There has been concern that **topical** use of NSAIDs may also be associated with gastrointestinal toxicity but a case-controlled study[26] concluded that this route was not associated with significant upper gastrointestinal bleeding or perforation.

Apart from the selection of an NSAID with a lower risk for gastrointestinal toxicity, other methods used for the **prevention** or **treatment** of NSAID-associated ulceration are discussed under the treatment of peptic ulcer disease on p.1702.

Effects on the kidneys. NSAIDs can produce renal disorders on systemic or topical use,[1] some of which are due to their inhibition of prostaglandin synthesis.[2,3] In the presence of renal vasoconstriction the vasodilator action of prostaglandins increases renal blood flow and thereby helps to maintain renal function.[4,5] Patients whose renal function is being maintained by prostaglandins are therefore at risk from NSAIDs. Such patients include those with impaired circulation, the elderly, those on diuretics, and those with heart failure or renal vascular disease.[2,4] Other risk factors for renal impairment with NSAIDs include dehydration, cirrhosis, surgery, sepsis,[6] and a history of gout or hyperuricaemia.[6,7] The half-life of an NSAID may be a more important determinant of the risk of developing functional renal impairment than the ingested dose.[7] Evidence of renal toxicity due to cyclo-oxygenase-2 (COX-2) selective inhibitors is less extensive; however, such NSAIDs appear to have effects on renal function similar to those of the non-selective NSAIDs.[8,9]

ACE inhibitors and angiotensin receptor antagonists can also produce renal impairment and combined use with NSAIDs should be undertaken with great care.[10,11] The Australian Adverse Drug Reactions Advisory Committee[10] stated in August 2003 that over 50% of cases of renal failure reported to the committee were associated with use of NSAIDs, ACE inhibitors, or diuretics (alone or together); where all these were taken together the fatality rate for reported cases of renal failure was 10%.

Prostaglandin inhibition may also lead to salt and water retention particularly when there is pre-existing hypertension or sodium depletion.[4] NSAIDs, therefore, tend to counteract the action of diuretics and antihypertensives.[2,4] There have been isolated reports of severe hyponatraemia and other symptoms resembling the syndrome of inappropriate antidiuretic hormone secretion in patients taking NSAIDs.[12,13]

Potassium homoeostasis is less dependent on prostaglandins and hyperkalaemia occurs infrequently with NSAIDs.[3] It is more likely to occur in patients with specific risk factors such as those receiving potassium supplements or potassium-sparing diuretics.[3] Indometacin appears to be the main NSAID implicated.

NSAIDs may cause acute interstitial nephritis, perhaps involving an allergic response,[2,3,14] and it may progress to interstitial fibrosis or papillary necrosis.[3,15]

Analgesic abuse or prolonged excessive use can produce nephropathy, a condition characterised by renal papillary necrosis and chronic interstitial nephritis, and, eventually, renal failure.[16] Phenacetin, a para-aminophenol derivative, has long been recognised as being one of the main drugs responsible for analgesic nephropathy,[17,18] but nephropathy has also been associated with the long-term use of NSAIDs and paracetamol without phenacetin.[19]

Effects on the liver. A retrospective study involving over 220 000 adults who were either using, or had used, NSAIDs identified a small excess risk of serious, acute non-infectious liver injury; in current users there was a twofold increase in risk and there was a predominance of the cholestatic type of liver injury among such patients. Nonetheless, admissions to hospital for liver injury had been rare.[1] In a review[2] of cohort and case-control studies describing an association between NSAIDs and liver disease, the strongest evidence emerged for sulindac. There were also a significant number of reports of hepatotoxicity on rechallenge with diclofenac. Evidence of hepatotoxicity for other NSAIDs was weak, although the risk appeared to be high when they were used with other hepatotoxic drugs. However, the overall incidence of liver disease with NSAIDs was very low.

A later review has also concluded that NSAID-induced hepatotoxicity is an uncommon event.[3] Nevertheless, an increased risk of hepatotoxicity has been associated with the selective cyclo-oxygenase-2 (COX-2) inhibitor lumiracoxib which led to its subsequent withdrawal in many countries (see p.78). For similar reasons, nimesulide has been withdrawn in some countries and its use is limited in others (see p.95).

Effects on the lungs. Adverse pulmonary effects such as pneumonitis, alveolitis, pulmonary infiltrates, and pulmonary fibrosis, often suggestive of an allergic or immune reaction, have been reported with a number of NSAIDs. For references, see under individual monographs.

Effects on the pancreas. A review[1] of drug-induced pancreatitis considered that sulindac was amongst the drugs for which a definite association with pancreatitis had been established. There had been isolated reports of pancreatitis with ketoprofen, mefenamic acid, and piroxicam but any association was considered to be questionable. A more recent population-based, case-controlled study found a substantial variation in the risk of pancreatitis between individual NSAIDs.[2] The increase in risk was highest for diclofenac and ketoprofen (adjusted odds ratios of 5.0 and 4.8, respectively), with indometacin and ibuprofen showing smaller but nonetheless significant increases (odds ratios of 3.6 and 1.5, respectively). Of the other NSAIDs studied (celecoxib, etodolac, naproxen, and rofecoxib), all showed a small but non-significant increase in risk of pancreatitis in current NSAID users.

Effects on the skin. The diverse cutaneous reactions to NSAIDs including those selective for cyclo-oxygenase-2 (COX-2) inhibition have been reviewed.[1-3]

Of 250 children attending a rheumatology clinic 34 (13.6%) were found to have 4 or more facial scars of unknown origin.[4] This number of scars was found in 22.2% of the 116 children who had received naproxen and in 9.2% of the 87 who had received other NSAIDs. Children affected were more likely to have light skin and blue or green eyes. It was not known whether this was a form of phototoxic reaction but pseudoporphyria-like eruptions associated with NSAIDs, and naproxen in particular (see p.93), have been reported.[5,6]

Concern by the EMEA over the serious nature of skin reactions associated with piroxicam has led to restrictions on the systemic use of piroxicam in the EU (see p.118).

Hypersensitivity. NSAIDs have produced a wide range of hypersensitivity reactions in susceptible individuals; the most common include skin rashes, urticaria, rhinitis, angioedema, bronchoconstriction, and anaphylactic shock. Hypersensitivity to NSAIDs appears to occur more frequently in patients with asthma or allergic disorders but other risk factors have been identified (for further details see under Aspirin, p.21). The occurrence of aspirin sensitivity in patients with asthma and nasal polyps has been referred to as the 'aspirin triad'. There is considerable cross-reactivity between aspirin and other NSAIDs and it is generally recommended that patients who have had a hypersensitivity reaction to aspirin or any other NSAID should avoid all NSAIDs. For references to hypersensitivity reactions associated with NSAIDs, see under individual monographs. See also Effects on the Skin (p.73) for a report suggesting that ketoprofen is more allergenic than other topical NSAIDs.

Overdosage. In general, symptoms of NSAID poisoning are mild, and usually include nausea and vomiting, headache, drowsiness, blurred vision, and dizziness. There have been isolated case reports of more serious toxicity, including seizures, hypotension, apnoea, coma, and renal failure, although usually after ingestion of substantial quantities. Seizures are a particular problem with mefenamic acid overdosage.

Treatment of NSAID overdosage is entirely supportive. Gastric lavage and activated charcoal may be of benefit within 1 hour of ingestion of a potentially toxic amount. Multiple doses of activated charcoal may be useful in enhancing elimination of NSAIDs with long half-lives such as piroxicam and sulindac. Forced diuresis, haemodialysis, or haemoperfusion are unlikely to be of benefit for NSAID overdosage, although haemodialysis may be required if oliguric renal failure develops.

Precautions

All NSAIDs are contra-indicated in patients with active peptic ulceration; in addition, the non-selective NSAIDs should be used with caution, if at all, in patients with a history of such disorders. To reduce the risk of gastrointestinal effects, NSAIDs may be taken with or after food or milk. Histamine H_2-antagonists, proton pump inhibitors such as omeprazole, or misoprostol may be used for a similar purpose in high-risk patients taking non-selective NSAIDs (see Peptic Ulcer Disease, p.1702). However, food, milk, and such measures may reduce the rate and extent of drug absorption. The UK CSM recommends that NSAIDs associated with the lowest risk of gastrointestinal toxicity (see Effects on the Gastrointestinal Tract, under Adverse Effects, above) should be tried first in the lowest recommended dose, and not more than one oral NSAID should be used at a time; selective inhibitors of cyclo-oxygenase-2 (COX-2) should be reserved for patients at highest risk of ulcer, perforation, or bleeding, and after assessment of cardiovascular risk. There is no evidence to justify the use of gastroprotective drugs with selective inhibitors of COX-2 to further reduce the risk of gastrointestinal effects.

All NSAIDs are contra-indicated in severe heart failure; furthermore selective COX-2 inhibitors should not be used in patients with moderate heart failure, ischaemic heart disease, peripheral arterial disease, or cerebrovascular disease. NSAIDs should be used with caution in patients with hypertension; the selective COX-2 inhibitors should also be used with caution in patients with left ventricular failure, oedema, or a history of cardiac failure, and in patients with risk factors for developing heart disease.

NSAIDs should be used with caution in patients with infections, since symptoms such as fever and inflammation may be masked (for the suggestion that they should not be used in children with varicella see below). They should also be used with caution in patients with asthma or allergic disorders. NSAIDs (including topical NSAIDs) are contra-indicated in patients with a history of hypersensitivity reactions to such drugs, including those in whom attacks of asthma, angioedema, urticaria, or rhinitis have been precipitated by aspirin or any other NSAID.

Other general precautions to be observed include use in patients with haemorrhagic disorders or impaired renal or hepatic function. Patients undergoing therapy with some NSAIDs may need to be monitored for the development of blood, kidney, liver, or eye disorders. NSAIDs should be used with caution in the elderly and may need to be given in reduced doses.

Some NSAIDs can interfere with thyroid function tests by lowering serum-thyroid hormone concentrations.

Further details concerning the precautions of the individual NSAIDs may be found under their respective monographs.

Pregnancy. Most licensed product information recommends avoidance of NSAIDs during pregnancy, unless the proposed benefit outweighs the risks, but in many cases published data on use of the drugs in pregnancy is scanty or absent, making an informed decision difficult. Use of NSAIDs during pregnancy may delay the onset of labour and increase its duration.

Use of NSAIDs during the third trimester of pregnancy may result in the *premature closure of fetal ductus arteriosus*. A recent meta-analysis[1] suggested that the short-term use of NSAIDs was associated with a fifteen fold increase in the risk of premature closure when compared to either placebo or other non-NSAIDs. There was insufficient data to predict the outcome of long-term NSAID treatment in late pregnancy; however, it seemed likely that the risk of premature closure would be even greater with such treatment.

Results from a case-control interview study[2] suggested that prenatal ingestion of aspirin or other NSAIDs might be implicated in *persistent pulmonary hypertension* of the newborn. The authors suggested that these drugs may be responsible for gestational structural or functional alterations of the pulmonary vasculature. However, the primary cause might also have been the underlying disorder for which the NSAIDs or aspirin were ingested. They were unable to pinpoint in which trimester the drugs might have their proposed action. A more recent study[3] has found that persistent pulmonary hypertension of the newborn is significantly associated with *in-utero* NSAID exposure, particularly to aspirin, ibuprofen, and naproxen. Fetal exposure to an NSAID was confirmed by meconium analysis.

The risk of *miscarriage* may be increased with NSAID use;[4,5] however, this observation remains to be confirmed. One study[4] also found no association between NSAID use and congenital abnormalities, low birth weight, or preterm birth.

Renal impairment. The *BNF* recommends that NSAIDs in general should be given at the lowest effective dose in patients with mild renal impairment and that renal function should be carefully monitored; they should be avoided if possible in patients with moderate to severe renal impairment.

Varicella. The French regulatory authorities noted in July 2004 that after the report of 3 cases of septic shock, 1 fatal, in children treated with NSAIDs for fever and pain, pharmacovigilance studies had discovered a number of other cases of severe complications relating to infection of the skin lesions of chickenpox in NSAID-treated children.[1] Although these, and a few reports in the literature[2,3] could not establish a causal relation, it was considered prudent to avoid the use of NSAIDs in children with chickenpox, and licensed product information for the relevant drugs was to be modified appropriately.[1] More recently, a nested case-control study[4] of nearly 250 000 patients with chickenpox or shingles in the UK General Practice Research Database found an increased risk of severe skin and soft tissue complications associated with the use of NSAIDs, mostly in children with chickenpox.

Interactions

Interactions involving NSAIDs include enhancement of the effects of oral anticoagulants (especially by azapropazone and phenylbutazone) and increased plasma concentrations of lithium, methotrexate, and cardiac glycosides. The risk of nephrotoxicity may be increased if given with ACE inhibitors, ciclosporin, tacrolimus, or diuretics. Effects on renal function may lead to reduced excretion of some drugs. There may also be an increased risk of hyperkalaemia with ACE inhibitors and some diuretics, including potassium-sparing diuretics. The antihypertensive effects of some antihypertensives including ACE inhibitors, beta blockers, and diuretics may be reduced. Convulsions may occur due to an interaction with quinolones. NSAIDs may increase the effects of phenytoin and sulfonylurea antidiabetics.

Use of more than one NSAID together (including aspirin) should be avoided because of the increased risk of adverse effects. The risk of gastrointestinal bleeding and ulceration associated with NSAIDs is increased when used with corticosteroids, the SSRIs, the SNRI venlafaxine, the antiplatelets clopidogrel and ticlopidine, iloprost, erlotinib, sibutramine, or, possibly, alcohol, bisphosphonates, or pentoxifylline. There may be an increased risk of haematotoxicity if zidovudine is used with NSAIDs. Ritonavir may increase the plasma concentrations of NSAIDs. Licensed product information for mifepristone advises of a theoretical risk that prostaglandin synthetase inhibition by NSAIDs or aspirin may alter the efficacy of mifepristone. There have been occasional reports of increased adverse effects when NSAIDs were given with misoprostol although such combinations have sometimes been used to *decrease* the gastrointestinal toxicity of NSAIDs.

Further details concerning the interactions of the individual NSAIDs may be found under their respective monographs.

Uses and Administration

Given as single doses or in short-term intermittent therapy NSAIDs can relieve mild to moderate pain. However, it may take up to 3 weeks of use before their anti-inflammatory effects become evident. The combined analgesic and anti-inflammatory effects make them particularly useful for the symptomatic relief of painful and/or inflammatory conditions including rheumatic disorders such as rheumatoid arthritis, osteoarthritis, and the spondyloarthropathies, and also in peri-articular disorders, and soft-tissue rheumatism. Some NSAIDs are used in the management of dental or post-operative pain. Some NSAIDs, but not aspirin or other salicylates, are also used to treat acute gouty arthritis.

Generally, it is felt that there are only small differences in anti-inflammatory activity between the various NSAIDs and choice is largely empirical. Responses of individual patients vary widely. Thus, if a patient fails to respond to one NSAID, another drug may be successful. However, it has been recommended that NSAIDs associated with a low risk of gastrointestinal toxicity should generally be preferred and the lowest effective dose used. Treatment with NSAIDs that are selective inhibitors of cyclo-oxygenase-2 (COX-2), such as celecoxib, is limited in the UK to those patients with a history of serious gastrointestinal problems or considered to be at high risk of developing such problems if given a non-selective NSAID (see Effects on the Gastrointestinal Tract, above).

NSAIDs are usually given orally, with or after food, although some such as diclofenac, ketoprofen, ketorolac, parecoxib, piroxicam, and tenoxicam can be given intramuscularly; diclofenac, ketorolac, parecoxib, and tenoxicam can also be given intravenously. Some NSAIDs are applied topically or given rectally as suppositories.

Several NSAIDs are used in ophthalmic preparations for the inhibition of intra-operative miosis, control of postoperative ocular inflammation, and prevention of cystoid macular oedema.

Action. Cyclo-oxygenases play an important role in the biosynthesis of prostaglandins (p.2374). Non-selective NSAIDs inhibit both cyclo-oxygenase-1 (COX-1) and cyclo-oxygenase-2 (COX-2); the idea that inhibition of COX-1 is associated with adverse gastrointestinal effects while inhibition of COX-2 is associated with anti-inflammatory activity,[1-6] led to the development[7] of preferential or selective inhibitors of COX-2. Meloxicam and nimesulide are preferential inhibitors of COX-2, (i.e. they have a higher selectivity for COX-2 than COX-1 but are not exclusive COX-2 inhibitors); etodolac and nabumetone are also claimed to have preference for COX-2 although there is less evidence for this. Drugs with a very high selectivity for COX-2 are also available; celecoxib and parecoxib are two examples. Although the selective inhibition of COX-2 may be associated with reduced gastrointestinal toxicity, adverse effects associated with such inhibition have been noted in other body systems, see Thrombotic Events under Effects on the Cardiovascular System, and Effects on the Kidneys, above.

There is evidence that NSAIDs may also have a central mechanism of action that augments the peripheral mechanism.[6]

Many NSAIDs possess centres of chirality within their molecular structure, with different chiral forms (enantiomers) having different degrees of pharmacological activity.[8,9] For example, indometacin, its analogues, and some arylpropionic acids are chiral drugs with the S(+)-enantiomer in most cases showing the dominant pharmacological activity. However, the ratio of S/R activity varies between drugs and between *animal* species. NSAIDs are generally used clinically as the racemate with only a few currently being given as the (S)-enantiomer (for example, dexibuprofen and dexketoprofen). The chirality of a drug may have subtle effects on its toxicity and interactions, and it may be more desirable to use a drug as its active enantiomer.[9]

Colic pain. Prostaglandins have been implicated in the aetiology of biliary colic (p.5), and some NSAIDs such as diclofenac, indometacin, and ketoprofen have been used to relieve such pain.

Dementia. A systematic review[1] of observational studies suggested that the risk of developing dementia (p.362) is lower in patients who are taking NSAIDs. However, a randomised trial[2] found no benefit from treatment with naproxen or rofecoxib in patients with existing mild to moderate Alzheimer's disease. Another systematic review[3] has suggested that the beneficial effects of NSAIDs seen in some studies are likely to be due to biases such as recall introduced by the study's design; the benefit of NSAIDs in preventing dementia or cognitive impairment was 50% in studies with prevalent (pre-existing) dementia cases, which decreased to 20% in studies of incident dementia cases (those developing during the study period), and was absent in those which used cognitive decline as an end-point. Further studies are needed to determine the role of NSAIDs in dementia.[4,5]

Diabetes insipidus. NSAIDs such as indometacin have been used in the treatment of diabetes insipidus; for some references, see p.68.

Ectopic ossification. Ectopic ossification (heterotopic ossification) is a condition in which mature bone develops in non-skeletal tissues, commonly the connective tissue of muscles. It occurs after local trauma, for example after joint dislocation or surgery such as total hip replacement, and also after neurological damage such as severe head or spinal cord injuries.[1,2] Ectopic bone formation usually starts about 2 weeks after the injury, though symptoms, which include localised pain, fever, swelling, erythema, and restriction of movement, may not appear for 8 to 12 weeks.[1,3] Neurogenic ectopic ossification may develop even several years after spinal cord injury.[3] A congenital form of ectopic ossification, myositis ossificans progressiva (fibrodysplasia ossificans progressiva), also occurs but is rare. The principal complications of ectopic ossification are loss of joint mobility and function.[1,2]

Ectopic ossification should be distinguished from the calcification of soft tissue which may occur in connective tissue disorders or in parathyroid disorders as a result of high circulating concentrations of calcium and or phosphate; in these conditions calcification occurs without bone formation.

Surgical resection can improve joint motion[1,3] in patients with ectopic ossification, but may be associated with severe complications and poor outcome, and ossification may recur postoperatively.[3] Delaying surgery as long as possible until bone formation has decreased may lessen the likelihood of these complications,[1] although earlier surgery may prevent fibrous ankylosis and muscle contracture.[3] Although there is no consensus on treatment, early, regular and cautious physiotherapy is recommended to mobilise joints;[1-3] aggressive manipulation may cause further ossification.

Prophylactic measures include radiotherapy or drug therapy. While prophylaxis does not always prevent the development of ectopic ossification, it can decrease its occurrence and severity. Prophylactic measures should be begun as early as possible and with regard to orthopaedic surgery may be started before the operation. Prophylaxis is also required if mature ectopic bone is to be surgically excised in order to minimise the rate of recurrence. Low-dose radiotherapy is as effective as high-dose, and pre-operative irradiation is as effective as postoperative.[4] Studies suggest that NSAID prophylaxis is of similar efficacy to radiotherapy.[4] NSAIDs appear to significantly reduce the incidence of ectopic bone formation,[2-5] possibly by inhibiting inflammation and suppressing mesenchymal cell proliferation.[3] While controversy exists as to duration and doses, indometacin is considered the NSAID of choice by some; naproxen, tenoxicam, and diclofenac may also be of benefit.[4] Ibuprofen has been tried; however, a recent study[6] has found that, although it significantly reduced the rate of ectopic bone formation, there were no clinical benefits 6 to 12 months after surgery. Bisphosphonates that inhibit the mineralisation of the deposited bone, such as etidronate, have also been used but they do not prevent the formation of the osteoid matrix. Also when etidronate is stopped, some mineralisation can occur, resulting in delayed ectopic or rebound ossification, though it is usually less severe. Prolonged treatment may be needed.[2,3] A systematic review,[7] however, found insufficient evidence to recommend the use of etidronate for the treatment of acute ectopic ossification.

Eye disorders. Miosis resistant to conventional mydriatics often develops during ocular surgery, possibly due to release of prostaglandins and other substances associated with trauma. NSAIDs, which are prostaglandin synthetase inhibitors, are therefore used prophylactically as eye drops before ocular surgery to ameliorate intra-operative miosis but there has been some doubt that the effect they produce is of clinical significance. Those commonly used include diclofenac, indometacin, and flurbiprofen. These drugs do not possess intrinsic mydriatic properties.

Some NSAIDs are used topically or systemically in inflammatory ocular disorders, including inflammation and cystoid macular oedema following ocular surgery (see below). Topical NSAIDs are also effective analgesics when used in the management of corneal abrasions. However, their role in the treatment of macular oedema associated with uveitis (p.1515) is less clear. NSAIDs are also used in the treatment of scleritis (see p.1512). Diclofenac and ketorolac have also both been used in the management of seasonal allergic conjunctivitis (see p.564).

POSTOPERATIVE INFLAMMATORY OCULAR DISORDERS. Corticosteroids are used topically for the control of **postoperative ocular inflammation** but caution is required as they can delay wound healing and mask postoperative infection. They should only be used for short periods as they can cause glaucoma in susceptible individuals. Topical NSAIDs have also been tried and appear to be as effective as corticosteroids in controlling signs of inflammation after ocular surgery,[1] but there has been some concern about reports of corneal toxicity (see p.45).

Cystoid macular oedema may follow cataract or retinal detachment surgery due to a disturbance of the blood-retinal barrier. A number of NSAIDs,[1-7] including diclofenac, flurbiprofen, indometacin, and ketorolac are used topically with or without corticosteroids to prevent or relieve cystoid macular oedema. NSAIDs such as indometacin are also used systemically in its management. However, a recent systematic review[6,7] has found insufficient evidence for the efficacy of NSAIDs (topical and oral) in acute or chronic cystoid macular oedema after cataract surgery although topical ketorolac may have a positive effect in chronic disease.

Fever. Paracetamol, salicylates, and some other NSAIDs are the main antipyretics used to control fever (p.10). Paracetamol is usually the antipyretic of choice in infants and children but ibuprofen is an effective alternative; alternation of the two may be better than either alone, although this is controversial. Salicylates are generally contra-indicated in these patients because of the possible link between their use and the development of Reye's syndrome (see under Adverse Effects of Aspirin, p.22).

Gout. NSAIDs are the drugs usually used first for the treatment of acute attacks of gout (p.552). Since the drug treatment of chronic gout can lead to the mobilisation of urate crystals from established tophi to produce acute attacks, NSAIDs may also be used for the prophylaxis of acute gout during the first few months of urate-lowering therapy.

Headache. An NSAID is often tried first for the symptomatic treatment of various types of headache including migraine (p.616) and tension-type headache (p.617). NSAIDs may also be effective prophylactic drugs for migraine, although propranolol is generally preferred. Paroxysmal hemicrania, a rare variant of cluster headache (p.616), responds to indometacin.

Kidney disorders. Although NSAIDs can produce adverse effects on the kidney (see above) they may have a role in the management of some types of glomerular kidney disease (p.1504). They may be of use for the control of proteinuria due to nephrotic syndrome except when there is overt renal failure.

Malignant neoplasms. An early study by the American Cancer Society[1] suggested that regular use of aspirin might reduce the risk of developing fatal cancer of the oesophagus, stomach, colon, or rectum. Death rates due to other gastrointestinal cancers did not appear to be affected. Some studies[2-11] appear to support this reduced risk of colorectal cancer (see Prophylaxis, under Malignant Neoplasms of the Gastrointestinal Tract, p.666) in regular users of aspirin or other NSAIDs, particularly in high-risk patients, conclusions that were cautiously endorsed by a systematic review.[12] However, other studies[13,14] have found no evidence of an association between the use of aspirin or NSAIDs and the incidence of colorectal cancer, although the authors suggest that these results may be explained by the short treatment period and the low dose of aspirin used. Although a subsequent review[15] prepared for the US Preventive Services Task Force (USPSTF) indicated that cyclo-oxygenase-2 (COX-2) inhibitors and NSAIDs reduce the incidence of colonic adenomas and that NSAIDs also reduce the incidence of colorectal cancer, the USPSTF issued a statement[16] that, because of the adverse cardiovascular and gastrointestinal effects associated with these agents, their use to prevent colorectal cancer could not be recommended in those at average risk of colorectal cancer.

The potential role that inhibition of COX-2 may play in the management of cancer has been discussed[17,18] and a recent study[19] has found that regular use of aspirin appears to reduce the risk of colorectal cancers that overexpress COX-2 but not those with weak or absent expression of COX-2.

A large case-control study,[20] using data held on the UK general practice research database, has examined information on NSAID use and the development of common cancers. This study also found that the use of NSAIDs (including aspirin) may protect against cancer of the oesophagus, stomach, colon, and rectum. However, the study failed to show any decrease in risk of non-gastrointestinal cancers. More recently, 2 meta-analyses[21,22] have also suggested that aspirin and NSAID use reduce the risk of other gastrointestinal cancers such as oesophageal or stomach cancer. In addition, one analysis[21] considered the effect of NSAID and aspirin use on non-gastrointestinal cancers: aspirin use showed a chemoprotective effect in pancreatic cancer although this was not significant statistically; there was also a slight, but nonetheless significant, reduction in the risk of breast cancer associated with both aspirin and NSAID use. The results for other sites, namely ovary, lung, bladder, and prostate, suggested no effect or possibly a slight reduced risk. The authors considered that it was unclear if any potential benefit in non-gastrointestinal cancers may be offset by the known adverse effects associated with the long-term use of these drugs particularly in those cancers with a low incidence.

Treatment with sulindac (see Gastrointestinal Disorders, p.127) has been found to reduce the number of polyps in patients with familial adenomatous polyposis, a condition which predisposes to development of colorectal cancer. Celecoxib has similar effects (see p.36) and it is now licensed for use in such patients.

Menstrual disorders. Menorrhagia (p.2126) is thought to be associated with abnormalities of prostaglandin production. Treatment with NSAIDs such as ibuprofen, mefenamic acid, or naproxen during menstruation, can reduce uterine blood loss by an average of 30% in women with menorrhagia. There does not appear to be any evidence that one NSAID is more effective than another.

NSAIDs are usually the first choice for the pain of dysmenorrhoea (p.6). Mefenamic acid may have a theoretical advantage over other NSAIDs in being able to inhibit both the synthesis and the peripheral action of prostaglandins, but clinical studies have not shown fenamates to be more effective, and systematic review has suggested that ibuprofen may have the best risk/benefit ratio.

Migraine. See Headache, above.

Orthostatic hypotension. Fludrocortisone is usually the first drug tried in the treatment of orthostatic hypotension (p.1530) when nonpharmacological treatment has failed. NSAIDs such as flurbiprofen, ibuprofen, or indometacin may be used alone or added to treatment if the response is inadequate.

Pain. NSAIDs have a similar analgesic effect to aspirin and paracetamol in single doses but, in regular full dosage, they have both a lasting analgesic and an anti-inflammatory effect. They are used in the management of mild to moderate pain (see Choice of Analgesic, p.2) and are of particular value in pain due to inflammation. NSAIDs may be of benefit for inflammatory pain in infants and children (p.3), although paracetamol is generally the preferred non-opioid analgesic in this age group. NSAIDs may be used in the treatment of acute low back pain (p.7) if paracetamol fails to provide adequate pain relief. NSAIDs may also be used as an adjunct to opioids in the management of severe pain such as cancer pain (p.5) and are particularly effective in bone pain of malignant origin. NSAIDs may be used for postoperative analgesia (p.4), and are of particular value after day-case surgery because of their lack of sedative effects. They are not usually considered to be strong enough as the sole analgesic after major surgery, but may be used with stronger analgesics and may allow dosage reduction of opioids. The pain of mild sickle-cell crises (p.9) may be controlled by analgesics such as NSAIDs or less potent opioids, for example codeine or dihydrocodeine; NSAIDs may be used with more potent opioids such as morphine for severe crises.

Dependence and tolerance are not a problem with non-opioid analgesics such as NSAIDs, but there is a ceiling of efficacy, above which, increasing the dose has no further therapeutic effect.

Rheumatic disorders. NSAIDs provide symptomatic relief for rheumatic disorders such as rheumatoid arthritis (p.11) and spondyloarthropathies (p.13), but they do not alter the course of the disease and additional antirheumatic drugs may need to be given to prevent irreversible joint damage. NSAIDs may also be used as an alternative to paracetamol for osteoarthritis (p.11). Short-term use of oral NSAIDs may help to relieve pain and reduce inflammation of soft-tissue rheumatism (p.13); topical formulations of some NSAIDs are also used.

Scleroderma. NSAIDs should be used with caution in scleroderma (p.1817) because of the risk of exacerbating renal and other problems.

Dependence and Withdrawal

Repeated use of opioids is associated with the development of psychological and physical dependence. Although this is less of a problem with legitimate therapeutic use, dependence may develop rapidly when opioids are regularly abused for their euphoriant effects. Drug dependence of the opioid type is characterised by an overwhelming need to keep taking the drug (or one with similar properties), by a physical requirement for the drug in order to avoid withdrawal symptoms, and by a tendency to increase the dose owing to the development of tolerance.

Abrupt withdrawal of opioids from persons physically dependent on them precipitates a withdrawal syndrome, the severity of which depends on the individual, the drug used, the size and frequency of the dose, and the duration of drug use. Withdrawal symptoms may also follow the use of an opioid antagonist such as naloxone or a mixed agonist and antagonist such as pentazocine in opioid-dependent persons. Neonatal abstinence syndrome may occur in the offspring of opioid-dependent mothers and these infants can suffer withdrawal symptoms at birth.

Opioid analgesics can be classified according to the receptors at which they act (see Uses and Administration, below) and withdrawal syndromes are characteristic for a receptor type. Cross-tolerance and cross-dependence can be expected between opioids acting at the same receptors. Dependence associated with morphine and closely related μ-agonists appears to result in more severe withdrawal symptoms than those associated with κ-receptor agonists. Onset and duration of withdrawal symptoms also vary according to the duration of action of the specific drug. With morphine and diamorphine *withdrawal symptoms* usually begin within a few hours, reach a peak within 36 to 72 hours, and then gradually subside; they develop more slowly with methadone. Withdrawal symptoms include yawning, mydriasis, lachrymation, rhinorrhoea, sneezing, muscle tremor, weakness, sweating, anxiety, irritability, disturbed sleep or insomnia, restlessness, anorexia, nausea, vomiting, loss of weight, diarrhoea, dehydration, leucocytosis, bone pain, abdominal and muscle cramps, gooseflesh, vasomotor disturbances, and increases in heart rate, respiratory rate, blood pressure, and temperature. Some physiological values may not return to normal for several months after the acute withdrawal syndrome.

Withdrawal symptoms may be terminated by a suitable dose of the original or a related opioid. Tolerance diminishes rapidly after withdrawal so that a previously tolerated dose may prove fatal.

For a discussion of the treatment of opioid dependence and neonatal abstinence syndrome, see below.

Diagnosis. Naloxone (p.1455) and other opioid antagonists have been used to diagnose opioid dependence.

Treatment of opioid dependence. The treatment of opioid dependence has been the subject of a number of reviews and discussions.[1-10]

Planned withdrawal (**detoxification**) may be effected slowly or rapidly. The usual method in many countries is to replace the drug of dependence with *methadone* (an opioid agonist) given as a liquid oral preparation, and then gradually withdraw the methadone if possible. Methadone is suitable for withdrawal therapy because it can be given orally and its long half-life allows once daily use. Oral *diamorphine* has been used similarly to methadone; reefers containing diamorphine have also been used in some centres. *Dihydrocodeine* tablets have been used successfully. The partial opioid agonist *buprenorphine*, given sublingually, is another alternative to methadone in the treatment of opioid dependence, and withdrawal symptoms may possibly resolve more quickly than with methadone.[11] However, it should only be given to patients with moderate dependence; those dependent on high doses of opioids may experience withdrawal symptoms when given buprenorphine. The methadone derivative *levacetylmethadol* was a more recent introduction but its proarrhythmic effects have led to its use being suspended.

Iatrogenic opioid dependence may occur in patients receiving μ-agonists such as morphine, fentanyl, or pethidine for the management of acute pain or in an intensive care setting for more than 5 to 10 days. Methadone has been used successfully to manage opioid withdrawal in adult intensive care patients.[12] However, some[13] avoid using methadone to manage withdrawal in children because of the stigma of its associations with managing withdrawal in drug addicts. In physically dependent but non-addicted patients, gradual weaning using the same opioid that was used therapeutically is preferred where possible, although in some cases, it may be necessary to change to a different opioid because of ease of use, duration of action, and ability to taper the dose; virtually any opioid can be used.[13]

Other drugs used in the management of opioid withdrawal include alpha$_2$-adrenoceptor agonists such as *clonidine* and opioid antagonists such as *naltrexone* and *naloxone*. Clonidine may help to suppress symptoms of opioid withdrawal, such as anxiety, insomnia, and muscle aches. It appears to be more effective when used in the control of symptoms after abrupt withdrawal than when used during gradual withdrawal of methadone. Hypotension may limit its usefulness in some patients. The clonidine analogue *lofexidine* may produce similar results to those obtained with clonidine and appears to be less sedating and hypotensive.[14]

Naltrexone and naloxone block the euphoriant effects of opioids although their use as monotherapy in detoxification is limited by unacceptable opioid withdrawal effects. Naltrexone may be used with alpha$_2$-adrenoceptor agonists such as clonidine or lofexidine to ameliorate symptoms but there are insufficient data to determine whether such combinations reduce the duration of withdrawal treatment or increase the rate of transfer to maintenance therapy with an opioid antagonist.[15] Naloxone and naltrexone are also being used in the relatively new technique of rapid or ultra rapid opioid detoxification,[16-18] which is achieved while the patient is heavily sedated or under *general anaesthesia* and hence unaware of any unpleasant withdrawal symptoms. However, although detoxification may be achieved within 24 hours and has a high initial success rate, the technique itself is not without risks and it does not obviate the need for maintenance treatment (see below).

Concomitant counselling and other psychosocial services have been shown to be important in the outcome of withdrawal therapy.[19,20] Detoxification alone does not ensure long-term abstinence.

A number of other drugs may be of use as **adjuncts** in the management of withdrawal symptoms. *Diphenoxylate* with atropine or *loperamide* may be used for the control of diarrhoea. *Promethazine* has been used for its antiemetic and sedative actions. Beta blockers such as *propranolol* may be of use for patients with pronounced somatic anxiety symptoms. *Benzodiazepines* or *clomethiazole* can be given to relieve anxiety and associated insomnia but only short courses should be used in order to minimise the risk of dependence and abuse.

Long-term **maintenance** treatment (stabilisation treatment) with an opioid is sometimes used, in conjunction with psychosocial support, to enable the patient to acquire some form of social stability. *Methadone* is most commonly used; the use of *diamorphine* although feasible[21,22] is controversial[23] and is advocated by only a few individual centres. *Buprenorphine* is another possibility.[24] The use of methadone for maintenance has been reviewed.[25-27] *Naltrexone* can be effective in maintaining abstinence in opioid addicts after detoxification, especially after rapid or ultra rapid detoxification. It is considered that naltrexone would probably be of most use in highly motivated addicts with good sociological and psychological support to discourage impulsive use of opioids.[1,28,29]

The problems associated with the management of the **pregnant** patient with opioid dependence have been discussed.[30] The aim should be to stabilise the patient first using *methadone* since acute withdrawal can result in fetal death. Drug withdrawal is best done slowly during the second trimester. It has been suggested that if patients present during the final trimester and cannot be detoxified, maintenance with *diamorphine* might be preferable to the use of methadone as it might produce less severe withdrawal symptoms in the neonate.[31] The management of neonatal abstinence syndrome is discussed below.

NEONATAL ABSTINENCE SYNDROME. Infants born to opioid-dependent mothers may suffer withdrawal, with signs including CNS hyperirritability, gastrointestinal dysfunction, respiratory distress, yawning, sneezing, mottling, and fever. Onset of symptoms is partly dependent on the drug and varies from shortly after birth to 2 weeks of age, although most symptoms appear within 72 hours. Some symptoms may persist for 3 months or more.

The American Academy of Pediatrics (AAP)[1] recommended that treatment of the neonate with abstinence syndrome should be primarily supportive and considered that many infants with signs of drug withdrawal could be managed in this way. They advised adoption of abstinence scoring methods to judge the need for drug therapy, although such systems do not appear to have been validated. Drugs that have been used for opioid withdrawal include paregoric (a USP 31 preparation containing opium), diluted tincture of opium, morphine, methadone, diazepam, chlorpromazine, phenobarbital, and clonidine. Naloxone should not routinely be given to infants of opioid-dependent mothers because of the risk of seizures with abrupt opioid withdrawal. The AAP[1] made no definite recommendations but considered that, when appropriate, specific drug therapy should be used for treatment of withdrawal symptoms. Thus for opioid withdrawal, tincture of opium was the preferred drug. Others favour treatment with oral morphine solution.[2] The *BNFC* notes that although morphine is widely used and the dose can be easily adjusted, methadone may provide smoother control of symptoms.

Practice varies widely and evidence for the efficacy of particular drugs in the management of neonatal abstinence syndrome is scanty and difficult to compare.[3,4] It has been suggested that diazepam may be less useful than phenobarbital or paregoric but the use of paregoric (which contains both camphor and alcohol) has been questioned. In the UK, chlorpromazine has also been widely used[5] although a systematic review[6] found insufficient evidence to support such use. The authors[6] also found that phenobarbital may reduce the severity of withdrawal symptoms in those receiving an opioid; there was insufficient evidence to support the use of clonidine.

Adverse Effects

In usual doses the commonest adverse effects of opioid analgesics are nausea, vomiting, constipation, drowsiness, and confusion; tolerance to these (except constipation) generally develops with long-term use. Micturition may be difficult and there may be ureteric or biliary spasm; the latter may be associated with alterations in liver enzyme values. There is also an antidiuretic effect. Dry mouth, dizziness, sweating, facial flushing, headache, vertigo, bradycardia, tachycardia, palpitations, orthostatic hypotension, hypothermia, restlessness, changes of mood, decreased libido or potency, hallucinations, and miosis also occur. These effects tend to occur more commonly in ambulant patients than in those at rest in bed and in those without severe pain. Raised intracranial pressure occurs in some patients. Muscle rigidity has been reported after high doses. The euphoric activity of opioids has led to their abuse. For a discussion of opioid dependence, see above.

Larger doses of opioids produce respiratory depression and hypotension, with circulatory failure and deepening coma. Convulsions may occur, especially in infants and children. Rhabdomyolysis progressing to renal failure has been reported in overdosage. Death may occur from respiratory failure. Toxic doses of specific opioids vary considerably with the individual and regular users may tolerate large doses. The triad of coma, pinpoint pupils, and respiratory depression is considered indicative of opioid overdosage; dilatation of the pupils occurs as hypoxia develops. Pulmonary oedema after overdosage is a common cause of fatalities among opioid addicts.

Morphine and some other opioids have a dose-related histamine-releasing effect which may be responsible in part for reactions such as urticaria and pruritus as well as hypotension and flushing. Contact dermatitis has been reported and pain and irritation may occur on injection. Anaphylactic reactions after intravenous injection have been reported rarely.

◊ The adverse effects associated with individual opioid analgesics may reflect to some extent their activity at specific opioid receptors (see Uses and Administration, below) or may result from a direct toxic effect.[1,2] Some adverse effects of pure opioid agonists, such as the respiratory depressant effect of morphine, are dose related, whereas agonist-antagonists such as buprenorphine, butorphanol, and nalbuphine exhibit a 'ceiling effect' as the dose increases.

The type and extent of adverse effects experienced in practice may depend on whether or not opioid-sensitive pain is present, whether the opioid analgesic is being given for the control of chronic severe pain or acute pain, and the route used. In a review[3] of the use of opioids in *chronic pain* it was noted that, despite worries to the contrary, respiratory depression and dependence liability are not generally a problem when appropriate doses are used to treat opioid-sensitive pain. In fact the presence of opioid-sensitive pain appears to protect against the respiratory depressant effect, although it may occur if the source of opioid-sensitive pain is removed (e.g. by surgery) without adequate reduction in opioid dosage. The adverse effects of opioid analgesics when used in advanced cancer have also been discussed.[4] Constipation was considered to be the most troublesome adverse effect; significant respiratory depression was rarely seen with recommended regimens, since pain antagonises the central depressant effects of morphine.

In the context of *acute postoperative pain* opioid-induced respiratory depression is of concern but short-term postoperative use is unlikely to cause dependence (although see Treatment of Opioid Dependence, above for references to iatrogenic physical dependence).[5] It was hoped that giving opioids by the *spinal route* would result in fewer adverse effects, especially respiratory depression. In postoperative pain relief with spinal opioids, the incidence of adverse effects is said to be low when patients are properly monitored.[6] However, some[7] have reported pruritus, nausea and vomiting, and urinary retention to be common and respiratory depression to occur; more seriously the appearance of respiratory depression could be considerably delayed. These effects were more common with morphine, but all opioid analgesics had the propensity to produce respiratory depression when given spinally.[7] Delayed respiratory depression has been attributed to the poor lipid solubility of morphine, but does occur after other opioids. Some have considered that despite earlier worries, potentially fatal late respiratory depression was as rare with the spinal route as postoperative respiratory depression with the conventional route.[8,9] Disputes regarding the frequency of respiratory depression associated with even conventional use of opioid analgesics might be due to the methods used for measuring respiratory effects.[10] The incidence of ventilatory depression has been reported to be higher after intrathecal than epidural use of morphine.[11]

Effects on the cardiovascular system. For reference to histamine release and cardiovascular effects following the intravenous administration of some opioids see under Pethidine, p.114.

Effects on the endocrine system. Endogenous opioid peptides may have a role in the regulation of endocrine function. Like endorphin and enkephalins, morphine has been found to stimulate prolactin release[1] and synthetic analogues of morphine are reported to have similar properties; long-term intrathecal opioids (morphine or hydromorphone) have been reported to produce hypogonadotrophic hypogonadism, adrenal insufficiency, and growth hormone deficiency, although tolerance to the effects on prolactin develops with long-term use.[2] Opioids such as morphine are also part of a large group of drugs implicated in causing hyperglycaemia.[3]

Treatment of Adverse Effects

Activated charcoal may be given orally in conscious patients if a substantial overdose has been ingested within 1 hour provided that the airway can be protected (see below); it should be considered in all patients if a substantial amount of a modified-release preparation has been ingested.

Intensive supportive therapy may be required to correct respiratory failure and shock. In addition, the specific antagonist naloxone is used for rapid reversal of the severe respiratory depression and coma produced by excessive doses of opioid analgesics (see p.1454). Since naloxone has a shorter duration of action than many opioids patients who have already responded should be kept under close observation for signs of relapse and repeated injections given according to the respiratory rate and depth of coma. Alternatively, in situations where repeated administration is required, such as where a longer acting opioid is known or suspected to be the cause of symptoms, a continuous intravenous infusion of naloxone, adjusted according to response, may be used. All patients should be observed for at least 6 hours after the last dose of naloxone.

The use of opioid antagonists such as naloxone in persons physically dependent on opioids may induce withdrawal symptoms.

Activated charcoal. The National Poisons Information Service in the UK considers the benefit of gastric decontamination in the management of overdosage with opioid analgesics to be uncertain. However, it is suggested that oral activated charcoal may be considered if given within 1 hour of ingestion and the quantity of opioid analgesic is substantial or, for these specific drugs, exceeds the following amount:

- buprenorphine: 100 micrograms/kg (adult); 100 micrograms/kg (child)
- codeine: 350 mg (adult); 5 mg/kg (child)
- dihydrocodeine: 420 mg (adult); 3 mg/kg (child)
- methadone: any amount in an opioid-naive patient or more than the prescribed daily dose if on methadone therapeutically
- tramadol: 500 mg (adult); 10 mg/kg (child)

Constipation. For reference to the use of opioid antagonists, particularly naloxone, to relieve opioid-induced constipation without compromising analgesic control in patients receiving long-term therapy with opioids, see Reversal of Opioid Effects under Uses and Administration of Naloxone, p.1454.

Precautions

Opioid analgesics are generally contra-indicated in acute respiratory depression and obstructive airways disease, although opioids such as morphine are used in some forms of dyspnoea (see below). They are also contra-indicated or should be used with great caution in acute alcoholism, convulsive disorders, head injuries, and conditions in which intracranial pressure is raised. They should not be given to comatose patients.

Opioid analgesics should be given with caution or in reduced doses to patients with hypothyroidism, adrenocortical insufficiency, asthma or decreased respiratory reserve, renal or hepatic impairment, prostatic hyperplasia, hypotension, shock, inflammatory or obstructive bowel disorders, or myasthenia gravis. Dosage should be reduced in elderly or debilitated patients.

Opioid analgesics should be given with great care to infants, especially neonates. Their use during labour may cause respiratory depression in the neonate. Babies born to opioid-dependent mothers may suffer withdrawal symptoms (see Neonatal Abstinence Syndrome, above).

Therapy with opioid analgesics should be stopped gradually in patients who may have developed physical dependence, to avoid precipitating withdrawal symptoms (see Dependence, above). Opioid analgesics with some antagonist activity, such as buprenorphine, butorphanol, nalbuphine, or pentazocine, may precipitate withdrawal symptoms in physically dependent patients who have recently used pure agonists such as morphine.

Drowsiness may affect the ability to perform skilled tasks; those so affected should not drive or operate machinery.

Asthma. Opioids appear to be safe and may be used with caution in controlled asthma; however, they should be avoided during acute exacerbations.[1]

Biliary-tract disorders. It is usually recommended that opioids such as morphine should either be avoided in patients with biliary disorders or that they should be given with an antispasmodic. Morphine can cause an increase in intrabiliary pressure as a result of effects on the sphincter of Oddi[1] and may therefore be expected to exacerbate rather than relieve pain in patients with biliary colic (p.5) or other biliary-tract disorders. Biliary-type pain after cholecystectomy has also been associated with codeine[2] and morphine.[3]

Morphine caused a more marked delay in gallbladder emptying than pethidine, pentazocine, or butorphanol in a study[4] in healthy subjects; this was considered confirmation that morphine should be avoided in biliary disorders. In another study[5] fentanyl and sufentanil did not constrict the common bile duct like morphine; they may be suitable for perioperative pain control in patients in whom spasm of the common bile duct is undesirable. The suggestion that pethidine should be preferred to morphine in patients with acute pancreatitis (p.9), because of its lesser effect on the bile duct, has been questioned.[6]

Children. Children under 6 months of age may be more sensitive to opioids; neonates in particular may be more sensitive to respiratory depression with morphine than adults. Pharmacokinetic differences may contribute to this increased sensitivity. Nonetheless, neonates can be treated with opioids such as morphine (see p.90) if receiving respiratory support.

Older infants and children can be treated effectively with morphine or other opioid analgesics and from the age of 5 or 6 months morphine metabolism follows the course seen in adults.

For a discussion of the choice of analgesic in children see p.3. The use of opioids for sedation and analgesia in neonates in intensive care is mentioned on p.957.

The elderly. Ageing can affect the pharmacokinetics and pharmacodynamics of opioids although the net effects of these changes on opioid analgesia in the elderly remain unclear.[1] Practical recommendations include careful review of indication for opioid use both initially and at regular intervals thereafter, starting opioids cautiously at lower doses and with longer dosing intervals, and regular consideration given to dose reduction and drug substitution or discontinuation. If possible, further drugs should not be prescribed to manage the adverse effects of opioids.

Hepatic impairment. The pharmacokinetics of opioids may be altered in patients with hepatic dysfunction. A review[1] of opioid use in this patient group considered that opioids such as morphine and hydromorphone that are metabolised by glucuronidation were relatively safe when compared with those metabolised by cytochrome P450 isoenzymes; the half-lives of glucuronidated opioids were found to be maintained until late disease whereas the prolonged half-lives seen with opioids metabolised by P450 isoenzymes were not accurately predicted by disease severity. It was also recommended that oral immediate-release or parenteral, short-acting opioids were preferable to long-acting preparations such as transdermal or modified-release formulations.

Phaeochromocytoma. Morphine and some other opioids can induce the release of endogenous histamine and thereby stimulate catecholamine release. Both diamorphine[1] and pethidine[2] have been reported to cause hypertension when given to patients with phaeochromocytoma and histamine-releasing opioids should be avoided in such patients. Alfentanil, like fentanyl, does not release histamine and may be the opioid of choice in the anaesthetic management of patients with phaeochromocytoma.[3]

Renal impairment. A literature review[1] concluded that codeine and morphine are best avoided in patients with renal failure and/or on dialysis; hydromorphone may be used with caution and monitoring, and use of fentanyl and methadone appeared to be safe. Similar recommendations have been made for patients with end-stage renal disease who are not undergoing dialysis.[2] See also under the individual monographs.

Interactions

As serious and sometimes fatal reactions have followed use of pethidine in patients receiving MAOIs (including moclobemide), pethidine and related drugs are contra-indicated in patients taking MAOIs or within 14 days of stopping such treatment; other opioid analgesics should be avoided or given with extreme caution (for further details, see p.418). Life-threatening reactions have also been reported when selegiline, a selective inhibitor of monoamine oxidase type B, has been given with pethidine. The depressant effects of opioid analgesics are enhanced by other CNS depressants such as alcohol, anaesthetics, anxiolytics, hypnotics, tricyclic antidepressants, and antipsychotics. Cyclizine may counteract the haemodynamic benefits of opioids. Cimetidine inhibits the metabolism of some opioids, especially pethidine.

The actions of opioids may in turn affect the activities of other drugs. For instance, their gastrointestinal effects may delay absorption as with mexiletine or may be counteractive as with cisapride, metoclopramide, or domperidone. Opioid premedicants such as papaveretum have been reported to reduce serum concentrations of ciprofloxacin.

Alcohol. Rapid release or dose-dumping of hydromorphone from a modified-release preparation (*Palladone; Purdue Frederick, USA*) has been associated with the ingestion of alcohol (for further details, see under Interactions of Hydromorphone, p.63). Health Canada[1] has warned that this interaction may occur with all modified-release formulations of opioid analgesics. Licensed product information for some modified-release preparations of morphine sulfate also warns against such use (see Interactions of Morphine, p.88).

Antivirals. Interactions between opioid analgesics and *HIV-protease inhibitors* or *reverse transcriptase inhibitors* are complex, and the results of the limited number of studies and reports *in vivo* have not always borne out predictions about the nature of potential interactions.

- Substantial **decreases** in the area under the plasma concentration-time curve (AUC) and in the plasma concentration have been reported for pethidine when given with *ritonavir*; however, plasma concentrations of the toxic metabolite norpethidine are greatly **increased**, and licensed product information for ritonavir counsels against such combined use. Ritonavir is predicted to reduce plasma concentrations of morphine. Plasma concentrations of methadone may be reduced if given with HIV-protease inhibitors although the effect may not be clinically significant. The NNRTIs *nevirapine* and *efavirenz* have also been reported to reduce plasma-methadone levels and withdrawal symptoms have occurred when given to patients receiving methadone. (For further details on the interactions of methadone with antivirals, see p.84.) In addition, efavirenz has been reported to decrease the AUC of buprenorphine (see p.30).
- In contrast, an **increase** in AUC and in elimination half-life of fentanyl has been reported in subjects also receiving ritonavir (see p.57). Licensed product information for ritonavir also considers that increased plasma concentrations of buprenorphine (p.30), dextropropoxyphene, and tramadol, with an increased likelihood of opioid toxicity, may occur if these drugs are given during ritonavir treatment. Licensed information for meptazinol also states that increased plasma concentrations of meptazinol have been noted when given with ritonavir. The NNRTI *delavirdine* has been reported to increase the plasma concentrations of buprenorphine (see p.30) and methadone (p.84).

Histamine H_2-antagonists. Histamine H_2-antagonists may enhance the effects of some opioid analgesics. *Cimetidine* was reported to alter the clearance and volume of distribution of pethidine[1] whereas *ranitidine* did not.[2] Morphine has been considered less likely to interact with cimetidine than pethidine because of differences in metabolism. In a study[3] cimetidine did not affect the disposition of morphine in healthy subjects. A later study[4] in patients undergoing major surgery suggested that pre- or postoperative intravenous cimetidine did not significantly affect outcomes such as morphine consumption and incidence of adverse effects when compared with placebo. Nevertheless, there have been isolated reports of possible interactions between morphine and H_2-antagonists; apnoea, confusion, and muscle twitching have been associated with cimetidine plus morphine,[5] and confusion associated with ranitidine plus morphine.[6] There has also been a report[7] of a patient receiving regular analgesia with oral methadone and subcutaneous morphine who became unresponsive 6 days after starting cimetidine for prophylaxis of peptic ulcer; treatment with naloxone was required.

Uses and Administration

Opioid analgesics possess some of the properties of naturally occurring or **endogenous opioid peptides**. Endogenous opioid peptides are widely distributed in the CNS and are also found in other parts of the body. They appear to function as neurotransmitters, modulators of neurotransmission, or neurohormones. Their presence in the hypothalamus suggests a role in the regulation of endocrine function. Opioids have been shown to stimulate the release of some pituitary hormones, including prolactin and growth hormone, and to inhibit the release of others, including corticotropin.

Endogenous peptides include the enkephalins, endorphins, and dynorphins; their polypeptide precursors may also be precursors for non-opioid peptides. Proenkephalin is the precursor of met- and leu-enkephalin; pro-opiomelanocortin is the precursor of beta-endorphin, beta-lipotrophin, melanocyte-stimulating hormone, and corticotropin; and prodynorphin is the precursor of dynorphins and neoendorphins.

Pharmacologically the opioid analgesics are broadly similar; qualitative and quantitative differences may be dependent on their interaction with **opioid receptors**. There are several types of opioid receptor and they are distributed in distinct patterns through the central and peripheral nervous systems. The three main types in the CNS were originally designated μ (mu), κ (kappa), and δ (delta) although they have been reclassified as OP_3, OP_2, and OP_1, respectively. Activities attributed to the stimulation of these receptors have been as follows:

- μ—analgesia (mainly at supraspinal sites), respiratory depression, miosis, reduced gastrointestinal motility, and euphoria; μ_1 (supraspinal analgesia) and μ_2 (respiratory depression and gastrointestinal activity) subtypes have been postulated
- κ—analgesia (mainly in the spinal cord); less intense miosis and respiratory depression, dysphoria and psychotomimetic effects
- δ—less certain in man, but probably analgesia; selective for enkephalins
- Other receptors include σ (sigma) and ε (epsilon) receptors. The psychotomimetic effects of agonist-antagonists such as pentazocine that are poorly antagonised by naloxone have been thought by some to be mediated by σ receptors

Opioids act at one or more of these receptors as full or partial agonists, or as antagonists. Morphine and similar opioid agonists (sometimes called μ agonists) are considered to act primarily at μ and perhaps at κ and δ receptors. Opioid agonist-antagonists such as pentazocine appear to act as κ agonists and μ antagonists whereas buprenorphine is a partial agonist at μ receptors with some antagonist activity at κ receptors. The opioid antagonist naloxone acts at μ, κ, and δ receptors.

In addition to differing affinities for particular receptors the degree of activation once bound also differs. The full agonist morphine produces maximum activation at the μ receptor and its effects increase with dose, whereas partial agonists and agonist-antagonists may demonstrate a 'ceiling effect' in that above a certain level their effects do not increase proportionately with dose.

Other differences between opioid analgesics may relate to their lipid solubility and pharmacokinetics; speed of onset and duration of action may influence the choice of analgesic.

Opioid analgesics were traditionally classified as weak or strong opioids; however this classification has largely been replaced by the one used in the WHO three-step analgesic ladder (see Cancer Pain, p.5). In this system opioids are divided into those that are used for **mild to moderate pain** and those that are used for **moderate to severe pain**. Examples of opioids in the first group include codeine, dextropropoxyphene, and dihydrocodeine; such opioids are distinguished by the existence of a ceiling effect and are often used with non-opioid analgesics. The principal opioid for the treatment of moderate to severe pain is morphine. Others include diamorphine, fentanyl, methadone, and pethidine.

In addition to the relief of pain, opioids are used in **anaesthesia** for premedication, induction, or maintenance; however, pre-operative use is generally limited to patients who require control of existing pain. In balanced anaesthesia they are used with an anaesthetic and a neuromuscular blocker. When used with an antipsychotic they can produce a state of mild sedation with analgesia called neuroleptanalgesia.

Some opioids are used for analgesia, sedation, and suppression of respiration in the management of mechanically ventilated patients under **intensive care** (p.957).

Opioids such as codeine, hydrocodone, and hydromorphone are used for the suppression of **cough**; for intractable cough in terminal illness morphine may be used.

Opioids may relieve some forms of **dyspnoea**; morphine and diamorphine are probably the most commonly used in the UK, but dihydrocodeine, hydrocodone, and oxymorphone have also been tried.

Methadone and buprenorphine are used in the treatment of opioid **dependence** (see above).

Anaesthesia. Opioid analgesics have been given intravenously as supplements during general anaesthesia with inhalational or intravenous drugs. They have also been widely used as premedication before surgery to reduce anxiety, for smooth induction of anaesthesia, to reduce overall anaesthetic requirements, and to provide postoperative pain relief. Such use of opioids is now rare and is restricted to patients already in pain or to those who will experience pain before induction of anaesthesia. Very high doses of morphine have been infused intravenously to produce anaesthesia for cardiac surgery, but shorter acting drugs such as fentanyl and related opioids are generally used now; some may prefer agonist-antagonist opioids. Sedation and respiratory depression may be prolonged necessitating assisted ventilation; reversal of these effects can be achieved by opioid antagonists such as naloxone. For a discussion of the various drugs used to achieve and maintain conditions suitable for surgery, including the use of opioids in the induction and maintenance of anaesthesia, see p.1780. Opioid analgesics, most commonly fentanyl, have been used with an antipsychotic to induce a state known as neuroleptanalgesia in which the patient is calm and indifferent to the surroundings yet is responsive to commands. For a brief discussion of neuroleptanalgesia and similar anaesthetic techniques, see p.1780.

POSTOPERATIVE SHIVERING. Pethidine appears to be effective in the treatment of postoperative shivering (see p.1779) but not all opioids are necessarily effective.

Cough. Opioids are used to suppress cough (p.1547). Pholcodine (p.1570) and dextromethorphan (p.1555), which lack classical analgesic activity and have fewer adverse effects, are the most commonly used opioids. Of the analgesic opioids, codeine is the most widely used as a cough suppressant. However, these opioids are seldom sufficiently potent to be effective in severe cough. Morphine and diamorphine are used for the relief of intractable cough in terminal illness, although morphine is now preferred. Methadone has also been used but should be avoided as it has a long duration of action and tends to accumulate.

Cough suppressants containing codeine or similar opioids are generally not recommended for use in children, and should be avoided in those under 2 years of age.

Diarrhoea. Oral rehydration therapy, which is the treatment of choice for acute diarrhoea (p.1694), prevents dehydration, but it does not necessarily shorten the duration of the diarrhoea. Preparations containing codeine, morphine, or other opioids have therefore been used for their antimotility action as adjuncts in the management of acute diarrhoea. However, the WHO considers that such antidiarrhoeal drug therapy is of limited value, and should never be given to children. Furthermore opioids should not be used in conditions where inhibition of peristalsis should be avoided, where abdominal distension develops, or in diarrhoeal conditions such as severe ulcerative colitis or antibiotic-associated colitis.

Dyspnoea. Dyspnoea (a subjective feeling of abnormally uncomfortable, difficult, or laboured breathing) is associated with diseases that interfere with oxygenation of the blood. It is best relieved by treatment of the underlying disorder (the treatment of dyspnoea associated with asthma and chronic obstructive pulmonary disease is discussed on p.1108 and p.1112, respectively). Where this is impossible or ineffective, symptomatic management is required.

Oxygen may reduce dyspnoea in some patients even if dyspnoea is not related to hypoxia. A flow of air directed across the face by a fan can also be effective. Despite the hazards of using benzodiazepines in patients with any form of respiratory depression or pulmonary insufficiency (see under Precautions of Diazepam, p.989), drugs such as diazepam, lorazepam, or midazolam may be helpful in patients with advanced cancer who have rapid shallow respiration, especially when this is associated with anxiety.[1-3] Levomepromazine is occasionally used as an alternative.

Opioids may relieve some forms of dyspnoea,[2,4,5] such as those due to acute left ventricular failure, pulmonary oedema, and malignant chest disease. Guidelines[6] (based on the findings of systematic reviews[7]) issued for the management of dyspnoea in palliative care recommend that opioids should be considered in patients with severe and unrelieved dyspnoea. The cause of dyspnoea should be established since the use of opioids is generally not advised, or only with extreme caution, in patients with obstructive airways disease whose dyspnoea may be relieved by other means. In the UK, morphine and diamorphine are probably the most commonly used opioids for dyspnoea, but dihydrocodeine, hydrocodone, and oxymorphone have also been tried. It is unclear if all opioids are equally effective.[5]

Nebulised morphine, hydromorphone, or fentanyl have been tried for the management of dyspnoea, and there are anecdotal reports of benefit, especially in palliative care, but evidence from controlled studies to date does not support such use.[2-4,8-11] See also under Morphine, p.90.

In patients with advanced cancer and intractable dyspnoea unresponsive to the above measures, chlorpromazine may be useful to relieve air hunger and sedate dying patients who have unrelieved distress;[1] midazolam may be used as an alternative. Promethazine has also been used. High doses of a corticosteroid such as dexamethasone may help to relieve dyspnoea in patients with airways obstruction due to a tumour by reducing oedema around the tumour.

Pain. Opioid analgesics are used for the relief of acute and chronic pain (see Choice of Analgesic, p.2). Not every type of pain responds; neuropathic pain, for example, may not be alleviated by opioid therapy. For further discussion of specific pain states and the role of opioid analgesics in their treatment see p.5 onwards.

There has also been interest in the local analgesic effects of opioids themselves.[1,2]

The use of opioid analgesics in opioid-dependent patients receiving maintenance treatment with an opioid is the subject of much debate; however, some consider such use to be appropriate in the management of acute pain in these patients and recommendations have been issued.[3]

HEADACHE. Opioid analgesics such as codeine are sometimes included in oral compound analgesic preparations used in the initial treatment of migraine (see p.616) or tension-type headache (see p.617), but are best avoided, especially in patients who experience frequent attacks.

Restless legs syndrome. Some opioids may be beneficial in the treatment of restless legs syndrome (see Sleep-associated Movement Disorders, p.958), although evidence is scanty.

Sedation. In addition to their analgesic action opioids have been used for their sedative properties. Mention of this use of opioids can be found in the discussions of anaesthesia (p.1780), endoscopy (p.956), and intensive care (p.957).

Tetanus. Opioid analgesics can be used to provide analgesia and additional sedation in patients undergoing treatment for tetanus (p.196 and p.1901). Opioids such as fentanyl, morphine, and sufentanil have also been given to control the sympathetic overactivity in such patients.[1-3]

Chin., Eur., and *US* include a monograph for prepared or powdered opium. *Eur.* also contains monographs for standardised opium dry extract or standardised opium tincture. *Jpn* includes prepared opium and a diluted opium powder containing 1% of anhydrous morphine.
Ph. Eur. 6.2 (Opium, Raw; Opium BP 2008). The air-dried latex obtained by incision from the unripe capsules of *Papaver somniferum* L. It has a characteristic odour and a blackish-brown colour. It should contain not less than 10% of anhydrous morphine, not less than 2% of anhydrous codeine, and not more than 3% of anhydrous thebaine. Protect from light.
Ph. Eur. 6.2 (Opium, Prepared; Opii Pulvis Normatus). Raw opium powdered and dried at a temperature not exceeding 70°. It is a yellowish-brown or dark brown powder and contains 9.8 to 10.2% of morphine and not less than 1.0% of codeine, calculated with reference to the dried drug. The content may be adjusted by adding a suitable excipient or raw opium powder.
USP 31 (Opium). The air-dried milky exudate obtained by incising the unripe capsules of *Papaver somniferum* (Papaveraceae). Externally it is pale olive-brown or olive-grey; internally it is reddish-brown. It has a very characteristic odour and a very bitter taste. It yields not less than 9.5% of anhydrous morphine.
USP 31 (Powdered Opium). Opium dried at a temperature not exceeding 70°, and reduced to a very fine light brown or moderately yellowish-brown powder that yields not less than 10% and not more than 10.5% of anhydrous morphine. It may contain any of the permitted diluents with the exception of starch.

Profile

Opium is the air-dried latex obtained by incision from the unripe capsules of *Papaver somniferum* (Papaveraceae). It contains morphine, codeine, and thebaine and a variable mixture of other alkaloids including noscapine and papaverine. The exuded latex is dried and manipulated to form cakes of uniform composition, variously shaped according to the country of origin, and known in commerce as Turkish, Indian, or European opium.

Opium has the properties of opioid analgesics (p.101). Its analgesic and sedative actions are due mainly to its content of morphine (p.89). It acts less rapidly than morphine since opium appears to be more slowly absorbed; the relaxing action of the papaverine and noscapine on intestinal muscle makes it more constipating than morphine.

Opium is intended only as the starting material for the manufacture of galenical preparations and is not dispensed as such. It is used as Prepared Opium (Ph. Eur. 6.2), as Powdered Opium (USP 31), as Opium Tincture (BP 2008 or USP 31), or as Camphorated Opium Tincture (BP 2008) or Paregoric (USP 31) in various oral preparations. These have included Opiate Squill Linctus (BP 2008) (Gee’s linctus) for cough.

Paregoric (USP 31) has been advocated in the USA for the treatment of neonatal abstinence syndrome.

NOTE. Do not confuse papaveretum with papaverine (p.2191).

Pharmacopoeias. In *Br.*
BP 2008 (Papaveretum). It contains 80.0 to 88.4% of anhydrous morphine hydrochloride, 8.3 to 9.2% of papaverine hydrochloride, and 6.6 to 7.4% of anhydrous codeine hydrochloride. A white or almost white crystalline powder. Soluble in water, sparingly soluble in alcohol. A 1.5% solution in water has a pH of 3.7 to 4.7. Protect from light.

Profile

The opium alkaloids are the prototypical opioid analgesics (p.101). Mixtures of opium alkaloids such as papaveretum have the analgesic and sedative properties of morphine (p.89) and are used in the treatment of moderate to severe pain including postoperative and severe chronic pain. They may also be used for pre-operative sedation and as an adjunct to anaesthesia. Papaveretum (BP 2008) 15.4 mg contains the equivalent of about 10 mg of the major component, anhydrous morphine.

- In the UK, papaveretum formerly contained the hydrochlorides of morphine, codeine, noscapine, and papaverine. However, because of concern over the potential genotoxicity of noscapine (p.1566) UK preparations containing papaveretum were reformulated to exclude the noscapine component and the name papaveretum was redefined in the BP 1993 to reflect this change of formulation. It is possible that in other countries the term papaveretum is still being used to describe a mixture containing noscapine.

Doses. Papaveretum is generally given by subcutaneous or intramuscular injection in doses of 7.7 to 15.4 mg every 4 hours if necessary. The initial dose in the elderly or debilitated patients should not exceed 7.7 mg.

In the treatment of pain and as an adjunct in anaesthesia, papaveretum may also be given intravenously in doses of one-quarter to one-half the corresponding subcutaneous or intramuscular dose. For pre-operative medication papaveretum is given intramuscularly or subcutaneously sometimes with hyoscine hydrobromide.

For details of doses in children, see below.

Oral preparations containing papaveretum with aspirin have been given for the management of moderate to severe pain.

◊ Papaveretum has been confused with papaverine (p.2191) and in one such case[1] a patient became unconscious after self-injection of papaveretum in mistake for papaverine.

Administration in children. Papaveretum may be given to children in the treatment of moderate to severe pain including postoperative and severe chronic pain. It is also used for pre-operative sedation and as an adjunct to anaesthesia. Papaveretum is generally given by subcutaneous or intramuscular injection every 4 hours if necessary, according to age as follows:
- neonates: 115 micrograms/kg
- 1 to 12 months: 154 micrograms/kg
- 1 to 6 years: 1.93 to 3.85 mg
- 6 to 12 years: 3.85 to 7.7 mg

Older children may be given the usual adult dose (see above).

In the treatment of pain and as an adjunct to anaesthesia papaveretum may also be given intravenously in doses of one-quarter to one-half the corresponding subcutaneous or intramuscular dose.

Diagnosis and testing. False-positive results for testing of benzodiazepines in urine have been reported in patients taking oxaprozin.[1] The manufacturer[2] has commented that the interaction occurs with some immunoassay tests and that thin-layer chromatography can successfully discriminate between benzodiazepines and oxaprozin. False-positive results for a fluorescence polarisation immunoassay for phenytoin have also been reported in patients receiving oxaprozin.[3]

Effects on the liver. Fatal fulminant hepatitis occurred[1] in a 56-year-old woman who had received 600 to 1200 mg of oxaprozin daily for about 6 weeks. In another patient symptomatic hepatitis developing during oxaprozin use resolved on stopping the drug.[2]

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Oxaprozin is slowly but extensively absorbed from the gastrointestinal tract; it is 99% bound to plasma proteins, mainly albumin. Peak plasma concentrations are reached after about 2 to 3 hours. At steady state, the biological half-life is about 44 hours. Oxaprozin is metabolised mainly in the liver by microsomal oxidation and conjugation with glucuronic acid to form inactive metabolites which are excreted in the urine (65%) and faeces (35%).

Uses and Administration

Oxaprozin, a propionic acid derivative, is an NSAID (p.99). It is used in the treatment of osteoarthritis and rheumatoid arthritis in a usual oral dose of 1.2 g given once daily, although in osteoarthritis, patients with low body-weight or mild disease should be given an initial dose of 600 mg once daily. The recommended maximum daily dose is 1.8 g or 26 mg/kg, whichever is the lower.

Administration in children. Oxaprozin is given orally in the treatment of juvenile idiopathic arthritis (p.10) in children aged 6 years and over. Doses are expressed in terms of body-weight and may be given once daily:

- 22 to 31 kg: 600 mg
- 32 to 54 kg: 900 mg
- 55 kg and over: 1200 mg

Administration in renal impairment. US licensed product information for oxaprozin recommends that the initial oral dose in patients with severe renal impairment or on dialysis is 600 mg once daily. The dose may be increased to 1.2 g once daily, if necessary.

Dependence and Withdrawal

As for Opioid Analgesics in general, p.101.

Oxycodone has been subject to abuse (see under Adverse Effects, Treatment, and Precautions, below).

◊ Takotsubo-like cardiomyopathy developed in a 61-year-old woman when her dose of oxycodone was inadvertently and greatly reduced 7 days after surgery for degenerative osteoarthritis.[1] The patient had a chronic history of opioid dependence and had been treated with oxycodone (80 mg daily) and hydromorphone (4 mg every 3 hours as needed) for several months before surgery; postoperatively, her dose of oxycodone had been increased to 120 mg daily with additional doses for breakthrough pain.

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

UK licensed product information contra-indicates the use of oxycodone in patients with moderate to severe hepatic impairment or severe renal impairment; however, product information in the USA permits its cautious use in patients with severe hepatic or severe renal impairment although doses may need to be reduced.

Abuse. Oxycodone hydrochloride modified-release tablets have been subject to abuse.[1-3] The crushed tablets have been inhaled or injected by addicts and in some cases this has resulted in fatalities.

Hepatic impairment. The clearance and elimination of oxycodone were prolonged in 6 women with end-stage liver cirrhosis awaiting liver transplantations.[1] Significant ventilatory depression also occurred. Pharmacokinetic values after successful transplantation were similar to those previously reported for healthy adults. It was recommended that, when giving oxycodone to patients with end-stage liver disease, the dosing frequency should be reduced and the dose lowered.

Interactions

For interactions associated with opioid analgesics, see p.103.

Antidepressants. For reference to possible cases of serotonin syndrome associated with use of oxycodone and *SSRIs*, see Opioid Analgesics under Interactions of Fluoxetine, p.397.

Pharmacokinetics

Oxycodone is absorbed from the gastrointestinal tract; oral bioavailability is about 60 to 87% due to lower pre-systemic and/or first-pass metabolism compared with other opioids. About 45% is bound to plasma proteins. It is metabolised to noroxycodone, via cytochrome P450 isoenzymes of the CYP3A family, and, to a lesser extent, to oxymorphone (p.107) via CYP2D6. Both metabolites undergo glucuronidation and are excreted with unchanged drug in urine. The elimination half-life of oxycodone is reported to be 2 to 4 hours. Oxycodone crosses the placenta and is distributed into breast milk.

Uses and Administration

Oxycodone, a phenanthrene derivative, is an opioid analgesic (p.104). Oxycodone hydrochloride is given orally or by subcutaneous or intravenous injection for the relief of moderate to severe pain.

A usual oral starting dose for opioid-naive patients in severe pain is 5 mg every 4 to 6 hours increased thereafter as necessary according to response. For patients who have been receiving a strong opioid analgesic the initial dose of oxycodone should be based on the daily opioid requirement; UK licensed product information suggests that 10 mg of oral oxycodone is equivalent to about 20 mg of oral morphine. Most patients do not require more than 400 mg daily. Preparations containing oxycodone hydrochloride and aspirin, ibuprofen, or paracetamol are also used. Oxycodone hydrochloride may also be given orally as a modified-release preparation every 12 hours.

For details of doses in children, see below.

Intravenous doses of oxycodone hydrochloride range from 1 to 10 mg, given over 1 to 2 minutes, and repeated not more often than every 4 hours; a dose of 2 mg/hour is the recommended starting dose as an intravenous infusion. The intravenous route may also be used for patient-controlled analgesia. When given subcutaneously, the starting dose is 5 mg every 4 hours; subcutaneous infusions should be started at 7.5 mg daily in opioid-naive patients. When transferring between oral and parenteral oxycodone, UK licensed product information advises that, as a guide, 2 mg of oral oxycodone is equivalent to about 1 mg of parenteral oxycodone.

Oxycodone has been given rectally as suppositories containing 30 mg of oxycodone (as the pectinate) or 10 or 20 mg of oxycodone hydrochloride; the dose may be repeated every 6 to 8 hours.

For doses in patients with hepatic or renal impairment, see below.

Oxycodone terephthalate is also used orally.

Administration in children. Although oxycodone hydrochloride is not licensed in the UK for use in children under 18 years old, the *BNFC* suggests that it may be given for the treatment of moderate to severe pain in palliative care. Those aged from 1 month to 12 years may be given initial oral doses of 200 micrograms/kg (up to 5 mg) every 4 to 6 hours increased thereafter as necessary according to response; older children may be given the usual adult dose (see above). Oxycodone hydrochloride may also be given orally as a modified-release preparation every 12 hours to those aged 8 years and older.

Administration in hepatic or renal impairment. The plasma concentrations of oxycodone may be increased in patients with hepatic or renal impairment and consequently dosage adjustment may be necessary in such patients. In the UK, licensed product information recommends that the oral starting dose for adult patients with mild hepatic impairment or mild to moderate renal impairment should be 2.5 mg given every 6 hours; it contra-indicates the use of oxycodone in those with moderate to severe hepatic impairment or severe renal impairment. US product information permits the cautious use of oxycodone in adult patients with severe hepatic or severe renal impairment.

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

For details on the use of oxymorphone in patients with hepatic or renal impairment see below.

Interactions

For interactions associated with opioid analgesics, see p.103.

Licensed product information for a modified-release preparation of oxymorphone hydrochloride (*Opana ER; Endo, USA*) states that patients must not ingest alcohol, including alcohol-containing medicines, at the same time due to the risk of increased plasma concentrations and a potentially fatal overdose of oxymorphone.

Pharmacokinetics

Oxymorphone hydrochloride is absorbed from the gastrointestinal tract after oral doses, but bioavailability is only about 10% because of first-pass metabolism. Absorption is increased after a high-fat meal. About 10% is bound to plasma proteins. Oxymorphone is extensively metabolised in the liver by glucuronidation and less than 1% of a dose appears in the urine and faeces as unchanged drug. With regard to its major metabolites between 33 and 38% of a dose is excreted in the urine as oxymorphone-3-glucuronide and less than 1% as 6-OH-oxymorphone. Oxymorphone crosses the placenta.

Uses and Administration

Oxymorphone hydrochloride, a phenanthrene derivative, is an opioid analgesic (p.101) with actions and uses similar to those of morphine (p.86), apart from a lack of cough suppressant activity. Oxymorphone is given orally, parenterally, or rectally for the relief of moderate to severe pain, including pain in obstetrics, and is reported to provide analgesia for 3 to 6 hours. It may also be used parenterally for premedication, as an adjunct to anaesthesia, and to relieve dyspnoea due to pulmonary oedema resulting from left ventricular failure.

A usual *oral* starting dose for opioid-naive patients is 10 to 20 mg of oxymorphone hydrochloride every 4 to 6 hours adjusted thereafter as necessary; some patients may be started on lower doses of 5 mg. For patients who have been receiving a strong opioid analgesic the initial dose of oxymorphone should be based on the daily opioid requirement; licensed product information suggests that 10 mg of oral oxymorphone is equivalent to about 30 mg of oral morphine and recommends giving half the calculated equivalent dose of oxymorphone initially. Oxymorphone hydrochloride may also be given orally as a modified-release preparation every 12 hours. Oral preparations of oxymorphone should be taken on an empty stomach.

Oxymorphone hydrochloride is given by *intramuscular* or *subcutaneous injection* in initial doses of 1 to 1.5 mg, repeated every 4 to 6 hours as necessary; 500 micrograms may be given by intravenous injection. The usual dose for analgesia during labour is 0.5 to 1 mg intramuscularly. When transferring between oral and parenteral oxymorphone, licensed product information advises that, as a guide, 10 mg of oral oxymorphone is equivalent to about 1 mg of parenteral oxymorphone.

Oxymorphone hydrochloride is also given *rectally* as a suppository in a dose of 5 mg every 4 to 6 hours.

Administration in hepatic impairment. Advice on the use of oxymorphone in patients with hepatic impairment is conflicting. Licensed product information for one range of preparations (*Opana* and *Opana ER tablets; Endo, USA*) recommends caution in patients with mild hepatic impairment; these patients should be started on the lowest oral dose and titrated slowly thereafter. In addition, it is stated that oxymorphone is contra-indicated in those with moderate or severe impairment. However, licensed information for another oxymorphone preparation (*Numorphan injection and suppositories; Endo, USA*) only recommends caution in hepatic disease although lower doses (unspecified) are advised in those patients with severe impairment.

Administration in renal impairment. In patients with moderate to severe renal impairment, the bioavailability of oxymorphone was found to increase by over 50%; consequently, it is recommended that oxymorphone is given with caution and in reduced doses (unspecified) to those with a creatinine clearance of less than 50 mL/minute.

Profile

Oxyphenbutazone, a metabolite of phenylbutazone (p.117), is an NSAID (p.96). It has been applied topically to the eye as an anti-inflammatory ointment in conditions such as episcleritis. Oxyphenbutazone was used systemically in disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis but such use is no longer considered justified because of the risk of severe haematological adverse effects (see also Effects on the Blood, under Phenylbutazone, p.117).

The piperazine salt has also been used.

Porphyria. Oxyphenbutazone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Ph. Eur. 6.2 (Paracetamol). A white or almost white, crystalline powder. Sparingly soluble in water; freely soluble in alcohol; very slightly soluble in dichloromethane. Protect from light.

USP 31 (Acetaminophen). A white odourless crystalline powder. Soluble 1 in 20 of boiling water, 1 in 10 of alcohol, and 1 in 15 of 1*N* sodium hydroxide. Store in airtight containers. Protect from light. Protect from moisture and heat.

Adverse Effects and Treatment

Adverse effects of paracetamol are rare and usually mild, although haematological reactions including thrombocytopenia, leucopenia, pancytopenia, neutropenia, and agranulocytosis have been reported. Skin rashes and other hypersensitivity reactions occur occasionally. Hypotension has been reported rarely with parenteral use.

Overdosage with paracetamol can result in severe liver damage and sometimes acute renal tubular necrosis. Prompt treatment with acetylcysteine or methionine is essential and is discussed under Overdosage, below.

Effects on the respiratory tract. The results of a case-control study[1] have suggested that the frequent (daily or weekly) use of paracetamol may be associated with asthma. However, the UK CSM has commented that the results of this study do not alter any advice regarding the use of paracetamol and that it remains a safe and effective pain killer for many patients including asthmatics.

Subsequently, a further study and a review have found an increase in the prevalence of asthma[2,3] and COPD[2] with frequent (daily or weekly) use of paracetamol. A link between paracetamol use in pregnancy and asthma in children has also been suggested (see Pregnancy under Precautions, below). However, another review[4] stated that there have been very few actual reports of paracetamol causing asthma; furthermore, bronchospasm is not a recognised feature of paracetamol overdosage. The review concluded that a strong link between paracetamol use and asthma was unlikely.

Hypersensitivity. Reactions characterised by urticaria, dyspnoea, and hypotension have occurred after use of paracetamol in adults[1-4] and children.[5,6] Angioedema has also been reported.[7] Fixed drug eruptions, confirmed by rechallenge, have been described,[8-11] and toxic epidermal necrolysis has occurred.[12]

Overdosage. Acute ***oral*** overdosage with paracetamol, whether accidental or deliberate, is relatively common and can be extremely serious because of the narrow margin between therapeutic and **toxic doses**. Ingestion of as little as 10 to 15 g of paracetamol by adults may cause severe hepatocellular necrosis and, less often, renal tubular necrosis. Patients should be considered at risk of severe liver damage if they have ingested more than 150 mg/kg of paracetamol or 12 g or more in total, whichever is the smaller. The risk of severe toxicity after acute paracetamol overdose appears to be less in children than in adults at comparable doses; however, chronic use of supratherapeutic doses in children has resulted in unintentional overdoses and severe hepatotoxicity.[1,2]

Patients receiving enzyme-inducing drugs or those with a history of alcohol abuse are at special risk of hepatic damage, as may be patients suffering from malnutrition such as those with anorexia or AIDS. It has also been suggested that fasting may predispose to hepatotoxicity.[3]

Early **signs** of overdosage (very commonly nausea and vomiting although they may also include lethargy and sweating) usually settle within 24 hours. Abdominal pain may be the first indication of liver damage, which is not usually apparent for 24 to 48 hours and sometimes may be delayed for up to 4 to 6 days after ingestion. Liver damage is generally at a maximum 72 to 96 hours after ingestion. Hepatic failure, encephalopathy, coma, and death may result. Complications of hepatic failure include acidosis, cerebral oedema, haemorrhage, hypoglycaemia, hypotension, infection, and renal failure. Prothrombin time increases with deteriorating liver function and some recommend that it be measured regularly. However, as both paracetamol[4] and acetylcysteine[5] can independently affect prothrombin time in the absence of hepatic injury, the use of prothrombin time as a marker for hepatotoxicity has been questioned and it has been recommended that treatment decisions are based on the entire liver biochemistry.[6]

Acute renal failure with acute tubular necrosis may develop, even in the absence of severe liver damage. Other non-hepatic symptoms that have been reported following paracetamol overdosage include myocardial abnormalities and pancreatitis.

The **mechanism** of toxicity in overdosage with paracetamol is thought to be the production of a minor but highly reactive metabolite, *N*-acetyl-*p*-benzoquinoneimine (NABQI) by cytochrome P450 isoenzymes (mainly CYP2E1 and CYP3A4)[2] in the liver and kidney. The amount of NABQI produced after normal doses of paracetamol is usually completely detoxified by conjugation with glutathione and excreted as mercaptopurine and cysteine conjugates. In paracetamol overdosage, tissue stores of glutathione become depleted, allowing NABQI to accumulate and bind to sulfhydryl groups within hepatocytes causing cell damage. Substances capable of replenishing depleted stores of glutathione, such as acetylcysteine or methionine, are therefore used as antidotes in paracetamol overdosage. Acetylcysteine may also be involved in the repair of damaged tissue.

Treatment of oral paracetamol overdosage. The management of paracetamol overdosage as practised in the UK and US has been the subject of numerous reviews.[3,6-13] Guidelines have also been issued in the UK by the Paracetamol Information Centre.[14] Separate consensus guidelines have also been issued by clinical toxicologists in Australia and New Zealand.[15]

Prompt treatment is essential, even when there are no obvious symptoms, and all patients should be admitted to hospital; full supportive measures should also be instituted.

- Activated charcoal may be used to reduce gastrointestinal absorption, if it can be given within 1 hour of the overdose, and if more than 150 mg/kg of paracetamol has been ingested. However, if acetylcysteine or methionine is to be given by mouth the charcoal is best cleared from the stomach to prevent it reducing the absorption of the antidote.
- There is little evidence that gastric lavage is of benefit in those who have overdosed solely with paracetamol.
- The plasma-paracetamol concentration should be determined as soon as possible, but not within 4 hours of ingestion, to ensure that peak concentrations are recorded. The risk of liver damage is determined by comparison with a nomogram reference line on a plot of plasma-paracetamol concentration against hours after ingestion. A semi-logarithmic plot or a linear plot may be used, see Figure 1 (p.109) and Figure 2 (p.109). Generally, antidote treatment is required if the patient's plasma-paracetamol concentration is higher than the appropriate line (but see below).
- Patients receiving enzyme-inducing drugs such as carbamazepine, phenytoin, phenobarbital, rifampicin, and St John's wort, or those with malnutrition or a history of alcohol abuse, are considered at high risk, and should receive an antidote even if their plasma-paracetamol concentrations are up to 50% below the standard reference line.
- Plasma-paracetamol concentrations measured more than 15 hours after ingestion are not reliable indicators of hepatic toxicity. Furthermore, the nomogram may not be suitable for use when patients have taken modified-release preparations of paracetamol.[16-18] Some suggestions for modified strategies for the use of the Rumack-Matthew nomogram in the face of overdosage with modified-release preparations have been made.[19-21]
- Plasma-paracetamol concentrations and the Rumack-Matthew nomogram are also of little value in patients who have taken repeated supratherapeutic doses or multiple overdoses of paracetamol over a short period of time: such patients should be considered at serious risk and given antidote treatment.
- Deaths from liver failure have occurred in patients presenting with plasma-paracetamol concentrations below the treatment line: suggested explanations include inadequate patient histories and a need for a lower treatment threshold.[22]
- If there is any doubt about timing or the need to treat, then a patient **should** be treated with an antidote. In some centres, patients who have ingested 150 mg/kg or more of paracetamol are treated regardless of plasma-paracetamol concentrations.[23]
- Antidote treatment should be started as soon as possible after suspected paracetamol ingestion and should not be delayed while awaiting the results of plasma assays. Once the results become available, treatment may be stopped if the initial concentration was below the nomogram reference line. However, if the initial concentration is above the reference line, the full course of antidote must be given and should not be stopped when subsequent plasma concentrations fall below the reference line.

Choice of antidote. Acetylcysteine (p.1548) is usually the antidote of choice but the route of administration varies, and the best protocol has yet to be determined.[6,24] Intravenous use has been associated with anaphylactic reactions but is the preferred route in the UK because of fears that oral absorption might be reduced by vomiting or activated charcoal. However, in the USA the oral route is also used, and is clearly effective. The use of methionine (p.1450) by mouth is licensed in the UK, despite the same risks of impaired absorption due to vomiting or activated charcoal. It is cheaper and easier to give than intravenous acetylcysteine and may be used in situations where a patient cannot be transferred to hospital, provided it is given within 10 to 12 hours of the overdose and the patient is not vomiting.

Acetylcysteine is most effective when given during the first 8 hours after taking the overdose and the effect diminishes progressively thereafter. It used to be believed that starting treatment more than 15 hours after overdosage was of no benefit and might aggravate the risk of hepatic encephalopathy. However, late treatment was subsequently shown to be safe,[25] and studies of patients treated up to 36 hours after ingestion suggest that benefit may be obtained up to and possibly beyond 24 hours.[26,27] Furthermore, giving intravenous acetylcysteine to patients who had already developed fulminant hepatic failure has been shown to reduce morbidity and mortality.[28]

- An initial dose of 150 mg/kg of acetylcysteine in 200 mL of glucose 5% is given intravenously over 15 minutes in the UK, or over 60 minutes in the USA. This is followed by an intravenous infusion of 50 mg/kg in 500 mL of glucose 5% over the next 4 hours and then 100 mg/kg in one litre over the next 16 hours. Sodium chloride 0.9% may be used where glucose 5% is unsuitable. The volume of intravenous fluids should be modified for children. If an anaphylactoid reaction develops, the infusion should be stopped and an antihistamine given; it may be possible to continue the acetylcysteine infusion at a slower rate.

Notes for the use of this chart:
1. The time coordinates refer to time after ingestion.
2. Plasma-paracetamol concentrations drawn before 4 hours may not represent peak concentrations.
3. The graph should be used only in relation to a single acute ingestion.
4. The solid line 25% below the standard nomogram is included to allow for possible errors in plasma assays and estimated time from ingestion of an overdose.
5. The solid line 50% below the standard nomogram is to assess the possible hepatic toxicity in patients receiving enzyme-inducing drugs or with malnutrition or a history of alcohol abuse.
6. The value of such charts is uncertain if the patient is first seen 15 hours or more after ingestion, or has taken modified release preparations of paracetamol.

- In the USA, acetylcysteine may also be given orally as an alternative to parenteral treatment. It is given as an initial dose of 140 mg/kg as a 5% solution followed by 70 mg/kg every 4 hours for an additional 17 doses. Some[29] have suggested increasing the loading dose of oral acetylcysteine when it is given after activated charcoal, whereas others[30] have found that the efficacy of acetylcysteine is not reduced by use of activated charcoal beforehand and consider a larger acetylcysteine dose unnecessary.

Methionine, like acetylcysteine, is most effective when given as early as possible after paracetamol overdosage. However, it is not as effective if treatment is delayed[31-33] and hepatic damage is more frequent and severe if treatment with methionine is started more than 10 hours after ingestion; it may also precipitate hepatic encephalopathy.

- The usual oral dose of methionine in adults and children over 6 years is 2.5 g every 4 hours for 4 doses starting less than 10 to 12 hours after ingestion of the paracetamol and provided the patient is not vomiting. Children under 6 years should be given 1 g every 4 hours for 4 doses. It has also been given intravenously.

The literature relating to the use of methionine in paracetamol poisoning is, in general, imprecise as to the form of methionine used. In the UK, the doses quoted above refer to DL-methionine. Preparations containing both methionine and paracetamol (co-methiamol) have been formulated for use in situations where overdosage may occur. However, the issue of whether methionine should be routinely added to paracetamol preparations is contentious for medical and ethical reasons.

Histamine H_2-antagonists. It has been suggested that since cimetidine blocks the hepatic cytochrome P450 mixed function oxidase system, it might be of use as an adjunct to acetylcysteine for patients whose production of the toxic metabolite of paracetamol is increased due to enzyme induction. Although there have been several anecdotal reports claiming benefit for cimetidine in patients with paracetamol poisoning, there is no current evidence to support these claims.[6,10,11,34]

Liver transplantation may be considered as a last recourse in some patients.

After maternal **overdosage during pregnancy** fetal metabolism of paracetamol that crosses the placenta can produce sufficient hepatotoxic metabolites to cause fetal hepatotoxicity. Limited data from case reports and a case series suggest that early treatment with oral or intravenous acetylcysteine can be safe and effective in such cases.[35]

There is little information available on overdosage when paracetamol is given as an ***intravenous infusion***. The standard nomogram may not be appropriate in determining treatment from plasma-paracetamol concentrations after intravenous overdose, as it is based on data from acute paracetamol ingestion rather than intravenous administration. The National Poisons Information Service in the UK recommends that the need for antidote treatment should be based on the total administered dose of paracetamol and/or any resultant hepatic impairment.

Pancreatitis. Drug-induced pancreatitis associated with paracetamol was reported[1] to be a rare reaction only occurring in patients taking more than recommended doses. In a retrospective study of data from 814 patients who had taken paracetamol overdoses, hyperamylasaemia was detected in 246, and was more common and more severe in patients transferred to a specialist unit because of more severe poisoning.[2] However, acute pancreatitis was diagnosed only in 33 cases.

Precautions

Paracetamol should be given with care to patients with impaired kidney or liver function. It should also be given with care to patients with alcohol dependence.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving paracetamol, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. The *BNF* also considers that the amount of paracetamol distributed into breast milk is too small to be harmful to a breast-fed infant.

Pharmacokinetic studies in 12 nursing mothers given a single dose of paracetamol showed that peak paracetamol concentrations in breast milk of 10 to 15 micrograms/mL were achieved in 1 to 2 hours. Plasma concentrations were determined in 2 mothers; a breast milk/plasma ratio of about 1 was reported.[2] Similar findings have been reported from other studies.[3,4]

Hepatic impairment. A short review[1] concluded that there was evidence that paracetamol could be and had been used safely in patients with liver disease. Studies had also shown that although the half-life of paracetamol was prolonged in such patients, glutathione concentrations in those taking recommended doses were not depleted to the critical levels that would enable accumulation of paracetamol's hepatotoxic metabolite. The *BNF* warns that large doses should be avoided.

Pregnancy. Paracetamol is generally considered to be the analgesic of choice in pregnant patients. However, the frequent use of paracetamol (defined as most days or daily use) in late pregnancy may be associated with an increased risk of persistent wheezing in the infant[1] which may persist into childhood[2] (but see also Effects on the Respiratory Tract, above). The authors emphasised that the number of pregnant women taking frequent doses was very small and they recommended that *infrequent* paracetamol should remain the analgesic of choice in pregnancy.

Renal impairment. Caution is recommended when giving paracetamol to patients with renal impairment. Plasma concentrations of paracetamol and its glucuronide and sulfate conjugates are increased in patients with moderate renal failure and in patients on dialysis.[1-3] It has been suggested that paracetamol itself may be regenerated from these metabolites.[1,2] There are conflicting data on whether the conjugates of paracetamol accumulate in patients with renal impairment receiving multiple doses.[2,3]

Interactions

The risk of paracetamol toxicity may be increased in patients receiving other potentially hepatotoxic drugs or drugs that induce liver microsomal enzymes. The absorption of paracetamol may be accelerated by drugs such as metoclopramide. Excretion may be affected and plasma concentrations altered when given with probenecid. Colestyramine reduces the absorption of paracetamol if given within 1 hour of paracetamol.

Antibacterials. The plasma-paracetamol concentrations considered an indication for antidote treatment (see under Overdosage, above) should be halved in patients receiving enzyme-inducing drugs such as *rifampicin*. Severe hepatotoxicity at therapeutic doses or moderate overdoses of paracetamol has been reported in patients receiving *isoniazid*, alone[1-3] or with other drugs for tuberculosis.[4]

Anticoagulants. For the effects of paracetamol on oral anticoagulants, see under Warfarin, p.1427.

Antiepileptics. The plasma-paracetamol concentrations considered an indication for antidote treatment (see under Overdosage, above) should be halved in patients receiving enzyme-inducing drugs such as *carbamazepine*, *phenobarbital*, *phenytoin*, or *primidone*.

Antivirals. For reports of adverse effects on the liver associated with use of paracetamol with antiviral drugs, see under Interferon Alfa, p.888 and Zidovudine, p.915.

Probenecid. Pretreatment with probenecid can decrease paracetamol clearance and increase its plasma half-life.[1] Although urinary excretion of the sulfate and glucuronide conjugates of paracetamol are reduced, that of paracetamol is unchanged.

Pharmacokinetics

Paracetamol is readily absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 10 to 60 minutes after oral doses. Paracetamol is distributed into most body tissues. It crosses the placenta and is present in breast milk. Plasma-protein binding is negligible at usual therapeutic concentrations but increases with increasing concentrations. The elimination half-life of paracetamol varies from about 1 to 3 hours.

Paracetamol is metabolised mainly in the liver and excreted in the urine mainly as the glucuronide and sulfate conjugates. Less than 5% is excreted as unchanged paracetamol. A minor hydroxylated metabolite (*N*-acetyl-*p*-benzoquinoneimine), is usually produced in very small amounts by cytochrome P450 isoenzymes (mainly CYP2E1 and CYP3A4) in the liver and kidney. It is usually detoxified by conjugation with glutathione but may accumulate after paracetamol overdosage and cause tissue damage.

Uses and Administration

Paracetamol, a para-aminophenol derivative, has analgesic and antipyretic properties and weak anti-inflammatory activity. Paracetamol is given orally or as a rectal suppository for mild to moderate pain and for fever (p.10). It may also be given by intravenous infusion for the short-term treatment of moderate pain, particularly after surgery, and of fever. Paracetamol is often the analgesic or antipyretic of choice, especially in the elderly and in patients in whom salicylates or other NSAIDs are contra-indicated. Such patients include asthmatics, those with a history of peptic ulcer, and children.

The usual **oral** dose is 0.5 to 1 g every 4 to 6 hours up to a maximum of 4 g daily. Paracetamol may also be given as suppositories in a **rectal** dose of 0.5 to 1 g every 4 to 6 hours, up to 4 times daily.

Paracetamol is also given by **intravenous** infusion over 15 minutes; dosage may be calculated by weight as follows:

- patients weighing over 50 kg, single doses of 1 g every 4 or more hours, to a maximum of 4 g daily
- from 33 to 50 kg, single doses of 15 mg/kg every 4 or more hours, to a maximum of 60 mg/kg or 3 g daily (whichever is less)

For doses in children or in renal impairment, see below.

Administration in children. In the UK, the licensed **oral** doses in children are:

- 3 months to 1 year: 60 to 120 mg
- 1 to 5 years: 120 to 250 mg
- 6 to 12 years: 250 to 500 mg

These doses may be given every 4 to 6 hours when necessary up to a maximum of 4 doses in 24 hours.

In younger children the *BNFC* suggests the following doses:

- neonates 28 to 32 weeks postmenstrual age (gestational age at birth plus chronological age): 20 mg/kg as a single dose then 10 to 15 mg/kg every 8 to 12 hours if necessary up to a maximum of 30 mg/kg daily
- neonates over 32 weeks postmenstrual age: 20 mg/kg as a single dose then 10 to 15 mg/kg every 6 to 8 hours if necessary up to a maximum of 60 mg/kg daily
- 1 to 3 months of age: 30 to 60 mg every 8 hours if necessary

The *BNFC* also suggests higher doses for use in children with more ***severe*** symptoms:

- 1 to 3 months: 20 mg/kg as a single dose followed by 15 to 20 mg/kg every 6 to 8 hours if necessary up to a maximum of 60 mg/kg daily
- older children: 20 mg/kg every 6 hours to a maximum of 90 mg/kg daily for 48 hours or longer if necessary followed by 15 mg/kg every 6 hours. Usual adult maximum doses (see above) should not be exceeded

For ***post-immunisation pyrexia***, a dose of 60 mg has been recommended for children 2 to 3 months of age. If necessary a second dose may be given after six hours; if the pyrexia persists after that dose, medical advice should be sought.

UK licensed **rectal** doses, which may be given to children every 4 to 6 hours, up to 4 times daily are:

- 1 to 5 years: 125 to 250 mg
- 6 to 12 years: 250 to 500 mg

The *BNFC* suggests the following rectal doses in younger children:

- neonates 28 to 32 weeks postmenstrual age: 20 mg/kg as a single dose then 15 mg/kg every 12 hours if necessary to a maximum of 30 mg/kg daily
- neonates over 32 weeks postmenstrual age: 30 mg/kg as a single dose then 20 mg/kg every 8 hours if necessary to a maximum of 60 mg/kg daily
- 1 to 3 months of age: 30 to 60 mg every 8 hours
- 3 to 12 months of age: 60 to 125 mg every 4 to 6 hours if necessary to a maximum of 4 doses in 24 hours

The *BNFC* also suggests higher rectal doses for use in children with more ***severe*** symptoms:

- 1 to 3 months: 30 mg/kg as a single dose followed by 20 mg/kg every 8 hours to a maximum of 60 mg/kg daily
- older children: 40 mg/kg as a single dose followed by 20 mg/kg every 4 to 6 hours to a maximum of 90 mg/kg daily for 48 hours or longer, if necessary, before reducing to 15 mg/kg every 6 hours. Usual adult maximum doses (see above) should not be exceeded

Doses by **intravenous** infusion in children, given over 15 minutes, are:

- full-term neonates and other children below 10 kg: single doses of 7.5 mg/kg every 4 or more hours, to a maximum of 30 mg/kg daily; intravenous paracetamol has not been studied in premature neonates
- between 10 and 33 kg: single doses of 15 mg/kg every 4 or more hours, to a maximum of 60 mg/kg or 2 g daily (whichever is less)
- from 33 to 50 kg: single doses of 15 mg/kg every 4 or more hours, to a maximum of 60 mg/kg or 3 g daily (whichever is less)
- over 50 kg: usual adult doses (see above)

The intravenous solution may be diluted to a minimum strength of one-tenth of its original concentration in sodium chloride 0.9% or glucose 5%; the diluted solution should be used within 1 hour of preparation.

It has been suggested[1] that the recommended doses of paracetamol for children may result in subtherapeutic blood concentrations, and that an initial loading dose should be given, followed by regular doses up to the recommended maximum daily dose. However, the appropriate maximum daily dose remains controversial, and there is obvious concern given the risks of overdosage.

Administration in renal impairment. In patients with a creatinine clearance of 30 mL/minute or less it is recommended that the interval between each intravenous paracetamol dose is increased to 6 hours.

Headache. Non-opioid analgesics such as paracetamol, aspirin, and other NSAIDs are often tried first for the symptomatic treatment of various types of headache including migraine (see p.616) and tension-type headache (see p.617). These drugs given at the onset of symptoms can successfully treat an acute attack of migraine. However, absorption may be poor due to gastric stasis which is commonly present in migraine. For this reason dispersible and effervescent preparations and compound preparations containing drugs such as metoclopramide which relieve gastric stasis have been advocated.

Pain. Paracetamol is used in the management of mild to moderate pain (see Choice of Analgesic, p.2). It is of similar potency to aspirin, but with weak anti-inflammatory activity. Paracetamol may also be used as an adjunct to opioids in the management of severe pain such as cancer pain (p.5). Paracetamol is the preferred choice for pain in children (p.3) because of the association of aspirin with Reye's syndrome in this age group (see p.22). In the treatment of rheumatic disorders, a weak anti-inflammatory effect limits the role of paracetamol. However, it may be of benefit for simple pain control in rheumatoid arthritis (p.11) and ankylosing spondylitis (see under Spondyloarthropathies, p.13), although these patients usually require the additional anti-inflammatory effects provided by NSAIDs. Synovial inflammation is usually only a minor component of osteoarthritis (p.11), and paracetamol is generally recommended as first choice of treatment before NSAIDs are tried. Paracetamol is useful for the relief of acute low back pain (p.7).

Dependence and tolerance are not a problem with non-opioid analgesics such as paracetamol, but there is a ceiling of efficacy, above which increasing the dose has no further therapeutic effect.

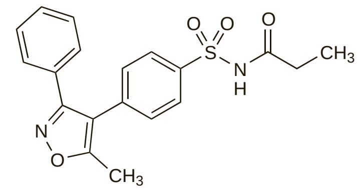
CAS — 198470-84-7 (parecoxib); 197502-82-2 (parecoxib sodium).

ATC — M01AH04.

ATC Vet — QM01AH04.



(parecoxib)

Incompatibility. Parecoxib sodium should not be mixed with products other than those recommended in licensed product information (see Uses and Administration, below). In particular, the use of lactated Ringer's solution with or without glucose will cause parecoxib to precipitate. Parecoxib should also not be given in the same syringe as opioids. The use of sterile water for injection is not recommended as the resulting solution is not isotonic.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Hypersensitivity reactions, including anaphylaxis and angioedema and serious skin reactions, have been reported with valdecoxib and may therefore occur with parecoxib, a prodrug of valdecoxib (see also p.132). Parecoxib should be stopped at the first signs of hypersensitivity. Some of these reactions occurred in patients with a history of allergic reactions to sulfonamides and the use of parecoxib is contra-indicated in such patients.

Parecoxib should be avoided in patients with severe hepatic impairment (Child-Pugh score of 10 or more), inflammatory bowel disease, and moderate to severe heart failure (NYHA class II to IV). It should not be used in patients with ischaemic heart disease, peripheral arterial disease, or cerebrovascular disease. It should also not be used after coronary artery bypass graft surgery as there may be an increased risk of adverse effects such as myocardial infarction, deep-vein thrombosis, pulmonary embolism, stroke, renal impairment, deep surgical infections, and sternal wound complications. This may apply especially in obese patients or those with a history of cerebrovascular disease. Parecoxib should be used with caution in patients with significant risk factors for cardiovascular disease such as hypertension, hyperlipidaemia, and diabetes mellitus. Caution is also recommended when using parecoxib in dehydrated patients; rehydration may be advisable before giving parecoxib.

Effects on the cardiovascular system. There have been concerns about the adverse cardiovascular effects of selective cyclo-oxygenase-2 (COX-2) inhibitors after the general worldwide withdrawal of rofecoxib (see p.121). The short-term use of parecoxib after coronary artery bypass graft surgery has been associated with an increased risk of adverse effects such as myocardial infarction, deep-vein thrombosis, pulmonary embolism, and stroke.[1] When compared with patients in the placebo group, the risk of such effects was almost 4 times greater in those given intravenous parecoxib for 3 days followed by oral valdecoxib for the next 7 days.

For discussion and advice on the use of selective COX-2 inhibitors in patients with cardiovascular or cerebrovascular disease, see under Celecoxib, p.34.

1. Nussmeier NA, *et al.* Complications of the COX-2 inhibitors parecoxib and valdecoxib after cardiac surgery. *N Engl J Med* 2005; **352:** 1081–91.

Effects on the gastrointestinal tract. It is generally accepted that the inhibition of cyclo-oxygenase-1 (COX-1) plays a role in the adverse gastrointestinal effects of the NSAIDs, and that the selective inhibition of the other isoform, COX-2, by NSAIDs such as parecoxib may cause less gastrotoxicity than that seen with the non-selective inhibition of the traditional NSAIDs. However, licensed product information reports that upper gastrointestinal perforation, ulceration, and bleeds have occurred with parecoxib treatment and therefore it should be used with caution in patients with a history of such events.

Effects on the kidneys. Increasing evidence of the renal toxicity of the selective cyclo-oxygenase-2 (COX-2) inhibitors such as parecoxib suggests that such NSAIDs appear to have effects on renal function similar to those of the non-selective NSAIDs (see p.98).

Up to June 2004, the Australian Adverse Drug Reactions Advisory Committee had received 20 reports of adverse reactions associated with parecoxib.[1] Of these, 13 mentioned renal impairment with raised creatinine levels and/or oliguria; acute renal failure was reported in 4 of the 13 cases and multiple doses of parecoxib had been given in 6 cases. (In Australia, parecoxib was approved for single-dose use only because of safety concerns about multiple doses.)

Interactions

For interactions associated with NSAIDs, see p.99.

Parecoxib is rapidly hydrolysed to its active metabolite, valdecoxib; the metabolism of valdecoxib is mainly mediated by the cytochrome P450 isoenzymes CYP3A4 and CYP2C9. Consequently, caution is recommended when using parecoxib with inhibitors of such isoenzymes. Licensed product information advises that the dose of parecoxib should be reduced if given with fluconazole, a CYP2C9 inhibitor; however, dose adjustment of parecoxib is not generally necessary when giving with ketoconazole, a CYP3A4 inhibitor, despite increased plasma concentrations of valdecoxib. The effects of enzyme inducers such as carbamazepine, dexamethasone, phenytoin, and rifampicin have not been studied; theoretically, the metabolism of valdecoxib may be increased by these drugs.

Valdecoxib has been noted to increase the plasma levels of dextromethorphan, a CYP2D6 substrate, and therefore caution is recommended when giving parecoxib with drugs that are metabolised via CYP2D6 and that have a narrow therapeutic index. Such drugs include flecainide, metoprolol, and propafenone. Valdecoxib may also affect the plasma levels of drugs that are metabolised via CYP2C19: an increase in the plasma levels of omeprazole was seen in patients using valdecoxib.

Pharmacokinetics

On intravenous or intramuscular injection, parecoxib is rapidly hydrolysed in the liver to its active metabolite, valdecoxib, and propionic acid; the plasma half-life of parecoxib is about 22 minutes. Plasma protein binding is about 98%. Valdecoxib is also extensively metabolised in the liver; pathways involved include those via the cytochrome P450 isoenzymes CYP3A4 and CYP2C9, and glucuronidation. Another active metabolite has been identified but it is not considered to contribute a significant clinical effect. Excretion is mainly via the urine with about 70% of a dose appearing as inactive metabolites. Less than 5% of a dose appears as unchanged valdecoxib in the urine. No unchanged parecoxib is found in the urine with only trace amounts in the faeces. The elimination half-life of valdecoxib is about 8 hours.

Uses and Administration

Parecoxib is an NSAID (p.99) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It is a prodrug of valdecoxib (p.132) and is used for the short-term treatment of postoperative pain in patients aged 18 years and over. Parecoxib is given as the sodium salt although doses are expressed as the base; 42.4 mg of parecoxib sodium is equivalent to about 40 mg of parecoxib. The recommended dose is 40 mg given by intravenous or slow intramuscular injection; this may be followed by 20 or 40 mg every 6 to 12 hours as required. The maximum daily dose is 80 mg. Elderly patients weighing less than 50 kg should begin treatment with half the usual dose, repeated to a maximum of 40 mg daily. Doses may need to be reduced in hepatic impairment, see below.

Parecoxib should be reconstituted with either sodium chloride 0.9%, glucose 5%, or sodium chloride 0.45% with glucose 5%; no other solvents are recommended in licensed product information. In addition the reconstituted solution may only be injected into intravenous lines delivering sodium chloride 0.9%, glucose 5%, sodium chloride 0.45% with glucose 5%, or lactated Ringer's solution. (See above for details on incompatibilities.)

Administration in hepatic impairment. Licensed product information in the UK states that no dosage adjustment is generally necessary for parecoxib in patients with *mild* hepatic impairment (Child-Pugh score 5 or 6). For those with *moderate* impairment (Child-Pugh score 7 to 9) parecoxib should be given at half the usual dose (see above), repeated to a maximum dose of 40 mg daily. Use in patients with *severe* impairment (Child-Pugh score 10 and over) is not recommended as there is no clinical experience in such patients.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Pentazocine is subject to abuse.

◊ Pentazocine does produce physical dependence, but withdrawal symptoms are substantially less severe than with morphine. It does not typically produce drug-seeking behaviour of the same degree or intensity as morphine or other prototypic μ agonists, nor does it substitute for morphine in dependent subjects.[1] Pentazocine injection has been abused,[2] but street abuse, especially in the USA, has more often involved the intravenous use of crushed tablets of pentazocine and tripelennamine ('T's and Blues').[3-5] A decreased incidence of pentazocine abuse in the USA appeared to coincide with the introduction of oral tablets incorporating naloxone,[1] the rationale being that naloxone antagonises the effect of pentazocine if illicitly injected, but has no effect when taken orally. Some continued to abuse the new pentazocine/naloxone formulation;[6] intravenous abuse in one woman, who was unaware of the reformulation, resulted in opioid withdrawal symptoms and severe hypertension.[7] A 1989 report from the WHO committee[1] rated the likelihood of abuse of pentazocine as moderate, based on its pharmacological profile, dependence potential, and actual abuse. The committee considered that it should continue to be scheduled as a psychotropic substance rather than a narcotic drug.

Adverse Effects

As for Opioid Analgesics in general, p.102.

Pentazocine may cause hallucinations and other psychotomimetic effects such as nightmares and thought disturbances. High doses may result in hypertension and tachycardia; increased aortic and pulmonary artery pressure with an increase in cardiac work has followed intravenous use in patients with myocardial infarction. Like morphine it causes respiratory depression, but pentazocine is said to have a 'ceiling' effect and the depth of respiratory depression does not increase proportionately with higher doses.

Rare adverse effects with pentazocine have included agranulocytosis and serious skin reactions such as erythema multiforme and toxic epidermal necrolysis.

Pentazocine injections may be painful. Local tissue damage may occur at injection sites particularly after subcutaneous injection or multiple doses; there have been reports of muscle fibrosis associated with intramuscular injections.

Effects on the blood. There have been reports of agranulocytosis associated with pentazocine.[1-3]

3. Sheehan M, *et al.* Pentazocine-induced agranulocytosis. *Can Med Assoc J* 1985; **132:** 1401.

Effects on the CNS. Oculogyric crisis has been associated with the use of pentazocine.[1]

1. Burstein AH, Fullerton T. Oculogyric crisis possibly related to pentazocine. *Ann Pharmacother* 1993; **27:** 874–6.

Effects on the skin. Toxic epidermal necrolysis in a 62-year-old man was attributed to pentazocine;[1] he had taken 50 to 75 mg every 4 hours for 8 days. His severe uraemia was attributed to fluid loss through the skin.

1. Hunter JAA, Davison AM. Toxic epidermal necrolysis associated with pentazocine therapy and severe reversible renal failure. *Br J Dermatol* 1973; **88:** 287–90.

Treatment of Adverse Effects

As for Opioid Analgesics in general, p.102.

As pentazocine has both opioid agonist and antagonist activity its effects may not be completely reversed by naloxone, but use of the latter is still recommended in pentazocine overdosage.

Precautions

As for Opioid Analgesics in general, p.103.

Pentazocine has weak opioid antagonist actions and may precipitate withdrawal symptoms if given to patients who are physically dependent on opioids. It should generally be avoided after myocardial infarction and in patients with heart failure or arterial or pulmonary hypertension.

When frequent injections are needed, pentazocine should be given intramuscularly rather than subcutaneously and the injection sites should be varied.

Abuse. See under Dependence and Withdrawal, above.

Porphyria. Pentazocine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with opioid analgesics, see p.103.

Tobacco smoking. Smokers metabolised about 40% more pentazocine than non-smokers, although there was large inter-subject variation;[1] tobacco smoking might induce liver enzymes responsible for drug oxidation.

1. Vaughan DP, *et al.* The influence of smoking on the inter-subject variation in pentazocine elimination. *Br J Clin Pharmacol* 1976; **3:** 279–83.

Pharmacokinetics

Pentazocine is well absorbed from the gastrointestinal tract; after an oral dose, peak plasma concentrations occur in 1 to 3 hours and the half-life is reported to be about 2 to 3 hours. After intramuscular injection, peak plasma concentrations are reached in 15 minutes to 1 hour and the half-life is about 2 to 5 hours. About 50 to 75% has been reported to be bound to plasma proteins. Pentazocine undergoes extensive first-pass metabolism in the liver; oral bioavailability is low with only about half of a dose reaching the systemic circulation. Metabolites and a small amount of unchanged drug are excreted in the urine. It crosses the placenta and is distributed into breast milk.

Hepatic impairment. Clearance of pentazocine was significantly reduced and terminal half-life and oral bioavailability increased in cirrhotic patients when compared with healthy subjects.[1]

1. Neal EA, *et al.* Enhanced bioavailability and decreased clearance of analgesics in patients with cirrhosis. *Gastroenterology* 1979; **77:** 96–102.

Uses and Administration

Pentazocine, a benzomorphan derivative, is an opioid analgesic (p.104) that has mixed opioid agonist and antagonist actions. Agonist activity is thought to be mainly at κ opioid receptors (with possibly some σ receptor activity); it acts as a weak antagonist or partial agonist at μ receptors. Pentazocine is used for the relief of moderate to severe pain including the pain of labour. Combined preparations with paracetamol or aspirin may also be used in the treatment of moderate pain. It may also be used for pre-operative sedation and as an adjunct to anaesthesia. Its analgesic effect declines more rapidly than that of morphine.

Pentazocine is given orally as the hydrochloride; doses may be expressed as either the base or the salt. Pentazocine is also given parenterally and rectally as the lactate; doses are expressed in terms of the base. Pentazocine 100 mg is equivalent to about 112.8 mg of pentazocine hydrochloride or 131.6 mg of pentazocine lactate.

A usual oral dose is the equivalent of 50 to 100 mg of pentazocine or pentazocine hydrochloride every 3 to 4 hours after food, to a maximum of 600 mg daily.

The usual initial dose by subcutaneous, intramuscular, or intravenous injection is the equivalent of pentazocine 30 mg as a single dose. Thereafter, the dose may be adjusted according to response; in some patients 45 to 60 mg by subcutaneous or intramuscular injection may be required. In the USA single intravenous doses of not more than 30 mg are advised. Doses may be repeated every 3 to 4 hours; it should not be necessary to exceed 360 mg daily. Also if frequent injections are needed, the intramuscular route should be used rather than the subcutaneous route, and the injection sites should be varied. In obstetric analgesia 30 mg may be given as a single dose by intramuscular injection during labour; alternatively, 20 mg may be given by intravenous injection as soon as contractions occur at regular intervals and repeated 2 or 3 times at intervals of 2 to 3 hours if necessary.

For details of doses in children, see below.

Pentazocine is given rectally in suppositories usually in a dose equivalent to pentazocine 50 mg up to 4 times daily.

As a deterrent to abuse a combined oral preparation of pentazocine hydrochloride and naloxone hydrochloride is available in some countries.

Administration in children. In the UK, pentazocine is licensed for the relief of moderate to severe pain in children and doses may be repeated every 3 to 4 hours if necessary. Those aged 6 to 12 years may be given a usual oral dose of 25 mg. Children aged 1 to 12 years may be given doses of up to 1 mg/kg by subcutaneous or intramuscular injection or up to 500 micrograms/kg by intravenous injection.

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of pethidine:
Bam; Peth.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Pethidine Hydrochloride). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. Store in airtight containers. Protect from light.

USP 31 (Meperidine Hydrochloride). A fine white odourless crystalline powder. Very soluble in water; soluble in alcohol; sparingly soluble in ether. pH of a 5% solution in water is about 5. Protect from light.

Incompatibility. Solutions of pethidine hydrochloride are acidic. They are incompatible with barbiturate salts and loss of clarity was also seen in an early additive study[1] with other drugs including aminophylline, heparin sodium, meticillin sodium, morphine sulfate, nitrofurantoin sodium, phenytoin sodium, sodium iodide, sulfadiazine sodium, and sulfafurazole diolamine. Colour change from pale yellow to light green occurred when solutions of minocycline hydrochloride or tetracycline hydrochloride were mixed with pethidine hydrochloride in 5% glucose injection.[2] In the same study an immediate precipitate occurred on admixture with cefoperazone sodium or mezlocillin sodium; with nafcillin sodium an immediate cloudy appearance cleared on agitation. Incompatibility has also been seen between pethidine hydrochloride and aciclovir sodium, imipenem, furosemide,[3] liposomal doxorubicin hydrochloride,[4] and idarubicin.[5] Solutions of cefazolin sodium[6] and pethidine hydrochloride mixed in 5% glucose injection turned light yellow after storage for 5 days at 25°; the admixture was stable for at least 20 days at 4°.

Stability. Pethidine hydrochloride injection 100 mg/mL was stable[1] for at least 24 hours at room temperature when diluted to a concentration of 300 mg/litre in glucose 5% and 4% and in sodium chloride injection (0.9%) and sodium chloride injection (0.9%) diluted 1 in 5.

Accelerated stability studies using elevated temperatures and humidities to simulate tropical conditions classified pethidine hydrochloride as a 'less stable drug substance'.[2] It was suggested that during quality assurance of preparations containing pethidine hydrochloride particular attention should be paid to their stability.

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Doses of pethidine as large as 3 or 4 g daily have been taken by addicts. As tolerance to the CNS stimulant and antimuscarinic effects is not complete with these very large doses, muscle twitching, tremor, mental confusion, dilated pupils, and sometimes convulsions may be present.

Withdrawal symptoms appear more rapidly than with morphine and are of shorter duration.

For the abuse of pethidine analogues, see under Precautions, below.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

The effects on smooth muscle may be relatively less intense than with morphine and constipation occurs less frequently. Local reactions often follow injection of pethidine; general hypersensitivity reactions occur rarely. Pethidine given intravenously may increase the heart rate. After overdosage, symptoms are generally similar to those of morphine poisoning. However, stimulation of the CNS and convulsions may also occur, especially in tolerant individuals or after toxic oral doses; these have been attributed mainly to the metabolite norpethidine.

Incidence of adverse effects. The incidence of adverse effects in hospitalised patients receiving pethidine was monitored by the Boston Collaborative Drug Surveillance Program.[1] Adverse reactions to oral pethidine were reported in 16 of 366 patients and mainly involved the gastrointestinal tract. After pethidine by injection 102 of 3268 patients had adverse effects, the CNS being involved in 38.

More recently, 20 adverse reactions were identified in a chart review of 141 patients given pethidine and considered to be at high risk of developing toxicity;[2] high-risk patients were defined as those with renal impairment (creatinine clearance 50 mL/minute or less), those receiving patient-controlled analgesia (PCA) with pethidine, and those given intravenous pethidine in doses of over 200 mg daily for several days. The most common adverse reactions were confusion and anxiety; other reported adverse effects included nervousness, seizures, and hallucinations. Patients who developed adverse reactions were significantly older, more likely to be taking a benzodiazepine, and had longer hospital stays than those without adverse effects. Out of the 20 reports, 16 adverse effects were noted in the 123 patients who received pethidine via a PCA pump; cumulative doses for patients using PCA were found to be a significant risk factor in the development of adverse effects.

Effects on the cardiovascular system. Histamine release was more frequent after pethidine than after morphine, fentanyl, or sufentanil given intravenously for the induction of anaesthesia.[1] Increased plasma-histamine concentrations occurred in 5 of 16 patients given pethidine in a mean dose of 4.3 mg/kg and were generally accompanied by hypotension, tachycardia, erythema, and increased plasma-adrenaline concentrations. Only 1 of 10 given morphine and none of those receiving fentanyl or sufentanil showed evidence of histamine release. All of the histamine releasers were young women.

Effects on the nervous system. CNS excitatory effects of pethidine such as tremors, muscle twitches, and convulsions have been associated with toxic doses and have been attributed to the metabolite norpethidine. Accumulation of norpethidine may occur if large doses of pethidine are repeated at short intervals (including for patient-controlled analgesia) and is especially likely when renal function is impaired.[1-13]

Precautions

As for Opioid Analgesics in general, p.103.

Pethidine should also be given cautiously to patients with a history of convulsive disorders or supraventricular tachycardias.

Abuse. A synthetic analogue of pethidine, MPPP (1-methyl-4-phenyl-4-propionoxypiperidine), manufactured illicitly for recreational use, achieved notoriety when it was accidentally contaminated with MPTP (1-methyl-4-phenyl-1,2,3,6-tetrahydropyridine) leading to an epidemic of parkinsonism among intravenous drug abusers.[1] WHO has also identified another analogue, PEPAP (1-phenylethyl-4-phenyl-4-acetoxypiperidine) as being liable to abuse.[2]

Breast feeding. No adverse effects have been seen in breast-feeding infants whose mothers were given pethidine, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding.

The elderly. Pethidine had a slower elimination rate in elderly compared with young patients and a reduction in total daily dose might be necessary in elderly patients receiving repeated doses of pethidine.[1] Another study concluded that age-related changes in disposition were not sufficient to warrant modification of pethidine dosage regimens.[2]

Phaeochromocytoma. Pethidine provoked episodes of hypertension in a patient with phaeochromocytoma; the effect was suppressed by labetalol.[1] Like other histamine-releasing opioids, pethidine should be used with caution in such patients.

1. Lawrence CA. Pethidine-induced hypertension in phaeochromocytoma. *BMJ* 1978; **1:** 149–50.

Pregnancy and the neonate. Pethidine has been widely used for analgesia during labour. It rapidly crosses the placenta and like other opioid analgesics may cause respiratory depression in the neonate, although perhaps less so than morphine. Respiratory depression varies according to the timing and size of the maternal dose.

Fetal depression was not apparent when delivery occurred within 1 hour of giving pethidine, but was present in 6 of 24 infants delivered 1 to 3 hours after injection and in all of 5 infants delivered 3 to 6 hours after injection.[1] However, higher blood concentrations of pethidine were seen in infants delivered within 1 hour of an intramuscular dose of pethidine compared with those delivered 1 to 4 hours after injection. The role of pethidine metabolites was uncertain. It has also been reported[2] that depressed neonatal responses persisted for the first 2 days of life; depression was dose-related being greatest with the highest dose of pethidine (75 to 150 mg within 4 hours of delivery). Neonates appear able to metabolise pethidine, although probably more slowly than adults.[3] The amounts of pethidine and norpethidine excreted by the neonate increased significantly with the maternal dose-delivery interval for intervals of up to 5 hours and most of the placentally transferred pethidine should be excreted by the third day. Elimination of pethidine took up to 6 days in the neonates in another study.[4]

Further references on the transplacental transfer of pethidine can be found in Pregnancy under Pharmacokinetics, below.

Neither psychological nor physical effects were found in 5-year-olds born to mothers who had received pethidine during labour.[5] Neonatal behaviour does not appear to have been affected significantly by pethidine, although it has been acknowledged that the relationship between maternal analgesia in labour and subsequent infant behaviour is by no means simple.[6] The results of early studies that suggested an excess of cases of cancer in children whose mothers received pethidine during labour have been refuted by a later and larger study.[7]

Renal impairment. Caution is necessary when pethidine is given to patients with renal impairment; UK licensed product information recommends that it should be avoided in those with severe impairment, whereas US product information suggests to use reduced doses. Evidence of CNS excitation, including seizures and twitches, in 2 patients with renal insufficiency given multiple doses of pethidine was attributed to accumulation of the metabolite norpethidine; both patients had high norpethidine : pethidine plasma concentration ratios.[1]

Interactions

For interactions associated with opioid analgesics, see p.103.

Very severe reactions, including coma, severe respiratory depression, cyanosis, and hypotension have occurred in patients receiving MAOIs (including moclobemide and selegiline) and given pethidine. There are also reports of hyperexcitability, convulsions, tachycardia, hyperpyrexia, and hypertension. Pethidine should not be given to patients receiving MAOIs or within 14 days of their discontinuation. Use of pethidine with phenothiazines has produced severe hypotensive episodes and may prolong the respiratory depression due to pethidine.

Plasma concentrations of norpethidine are increased by ritonavir, with a resultant risk of toxicity; use together should be avoided (see also p.103).

Antibacterials. See MAOIs below for interactions between pethidine and *isoniazid* and *linezolid*.

Antidepressants. For reference to possible cases of serotonin syndrome associated with use of pethidine and *SSRIs*, see Opioid Analgesics under Interactions of Fluoxetine, p.397. See also MAOIs, below.

Barbiturates. Opioid analgesics and barbiturates can be expected to have additive CNS depressant effects. Prolonged sedation with pethidine in the presence of *phenobarbital* has also been attributed to induction of *N*-demethylation of pethidine, resulting in the enhanced formation of the potentially neurotoxic metabolite norpethidine.[1,2]

Histamine H_2-antagonists. See under Opioid Analgesics, p.103.

MAOIs. Some of the most serious interactions involving pethidine have been with non-selective MAOIs and have been manifest as enhanced depressant effects or hyperexcitability (see Interactions, above). However, a life-threatening interaction has also been reported between pethidine and *selegiline*, a selective monoamine oxidase type B inhibitor.[1] Also, symptoms suggestive of a mild serotonin syndrome developed in a 73-year-old woman taking *moclobemide* (a reversible inhibitor of monoamine oxidase type A), nortriptyline, and lithium after she was given pethidine intravenously.[2]

Use of the antibacterial *isoniazid* with pethidine led to a drop in blood pressure and lethargy in a 54-year-old man.[3] Serotonin syndrome developed in a 27-year-old man after the use of pethidine with *linezolid*;[4] symptoms resolved when pethidine was stopped. The authors of both studies attributed the interaction to the inhibitory action of isoniazid and linezolid on monoamine oxidase.

Phenothiazines. *Prochlorperazine* prolonged the respiratory depressant effect of pethidine in healthy subjects.[1] Enhanced CNS depression and hypotension were reported when healthy subjects were given *chlorpromazine* in addition to pethidine; there was evidence of increased *N*-demethylation of pethidine.[2]

2. Stambaugh JE, Wainer IW. Drug interaction: meperidine and chlorpromazine, a toxic combination. *J Clin Pharmacol* 1981; **21:** 140–6.

Phenytoin. The hepatic metabolism of pethidine appears to be enhanced by phenytoin; use together resulted in reduced half-life and bioavailability in healthy subjects; blood concentrations of norpethidine were increased.[1]

1. Pond SM, Kretschzmar KM. Effect of phenytoin on meperidine clearance and normeperidine formation. *Clin Pharmacol Ther* 1981; **30:** 680–6.

Pharmacokinetics

Pethidine hydrochloride is absorbed from the gastrointestinal tract, but only about 50% of the drug reaches the systemic circulation because of first-pass metabolism. Absorption after intramuscular injection is variable. Peak plasma concentrations have been reported 1 to 2 hours after oral doses. It is about 60 to 80% bound to plasma proteins.

Pethidine is metabolised in the liver by hydrolysis to pethidinic acid (meperidinic acid) or demethylation to norpethidine (normeperidine) and hydrolysis to norpethidinic acid (normeperidinic acid), followed by partial conjugation with glucuronic acid. Norpethidine is pharmacologically active and its accumulation may result in toxicity. Pethidine is reported to have a plasma elimination half-life of about 3 to 6 hours in healthy subjects; the metabolite norpethidine is eliminated more slowly, with a half-life reported to be up to about 20 hours. Both pethidine and norpethidine appear in the CSF. At the usual values of urinary pH or if the urine is alkaline, only a small amount of pethidine is excreted unchanged; urinary excretion of pethidine and norpethidine is enhanced by acidification of the urine. Pethidine crosses the placenta and is distributed into breast milk.

Administration. The elimination half-life of pethidine was prolonged and plasma clearance decreased when given perioperatively compared with postoperatively.[1]

During labour the pharmacokinetics of pethidine may depend on how it is given. In a comparison of intramuscular injection at different sites, absorption of pethidine from the gluteus muscle was impaired and the deltoid muscle was preferred.[2]

No statistically significant differences were found in pharmacokinetic parameters for deltoid and gluteal intramuscular injections in elderly postoperative patients.[3] However, substantial interpatient variability was noted for both sites, and the authors suggested that more rapid and predictable routes such as intravenous injection may be more appropriate for postoperative use in the elderly.

Hepatic impairment. The terminal half-life of pethidine was prolonged to about 7 hours in cirrhotic patients compared with 3 hours in healthy subjects, which was attributed to impairment of the drug-metabolising activity of the liver.[1] Another study concluded that although impaired hepatic metabolism might confer relative protection from norpethidine toxicity in patients with cirrhosis, there might be an increased risk of cumulative toxicity because of slow elimination of the metabolite.[2]

Renal impairment. Plasma protein binding of pethidine was reported to be decreased in renal disease and ranged from 58.2% in healthy subjects to 31.8% in anuric patients.[1] The same workers also reported prolonged elimination of pethidine in patients with renal dysfunction.[2]

Uses and Administration

Pethidine, a phenylpiperidine derivative, is a synthetic opioid analgesic (p.104) that acts mainly as a μ opioid agonist. Pethidine is used for the relief of most types of moderate to severe acute pain including the pain of labour. It is more lipid soluble than morphine and has a less potent and shorter lasting analgesic effect; analgesia usually lasts for 2 to 4 hours. Its short duration of action and accumulation of its potentially neurotoxic metabolite norpethidine on repeated dosage make it unsuitable for the management of chronic pain. Pethidine has a weaker action on smooth muscle than morphine and its lower potential to increase biliary pressure may make it a more suitable opioid analgesic for pain associated with biliary colic and pancreatitis (but see Biliary-tract Disorders, p.103). It is also used for premedication and as an adjunct to anaesthesia. It has been given with phenothiazines such as promethazine to achieve basal narcosis. Pethidine has little effect on cough or on diarrhoea.

For the relief of **pain**, pethidine hydrochloride is given in oral doses of 50 to 150 mg every 4 hours if necessary. It may also be given by intramuscular or subcutaneous injection in doses of 25 to 100 mg and by slow intravenous injection in doses of 25 to 50 mg repeated after 4 hours. For *postoperative* pain, the *BNF* suggests that the subcutaneous or intramuscular doses may be given every 2 to 3 hours if necessary.

In *obstetric analgesia* 50 to 100 mg may be given by intramuscular or subcutaneous injection as soon as contractions occur at regular intervals. This dose may be repeated after 1 to 3 hours if necessary up to a maximum of 400 mg in 24 hours.

For **premedication** 25 to 100 mg may be given intramuscularly about 1 hour before surgery. It may also be given subcutaneously in similar doses. As an **adjunct to anaesthesia** 10 to 25 mg may be given by slow intravenous injection.

For details of doses in children, see below.

Administration. In addition to the conventional routes pethidine has been given epidurally,[1-4] intraperitoneally,[5,6] and intrathecally.[7-9] It has also been given by various routes as a patient-controlled system.[10-13] However, some consider that the use of pethidine should be avoided for patient-controlled analgesia because of the increased risk of norpethidine-induced seizures[14] (see also Incidence of Adverse Effects and Effects on the Nervous System, above).

Administration in children. Pethidine is used for the relief of moderate to severe acute pain and for premedication in children.

For the relief of **pain**, the *BNFC* suggests that children aged 2 months to 12 years may be given pethidine hydrochloride 0.5 to 2 mg/kg orally or by subcutaneous or intramuscular injection every 4 to 6 hours if necessary; older children up to 18 years of age may be given 50 to 100 mg orally, or 25 to 100 mg intramuscularly or subcutaneously, every 4 to 6 hours if necessary. Injection solutions may be given orally if needed, to achieve a suitable dose. Pethidine may also be given by intravenous injection in doses of 0.5 to 1 mg/kg to neonates and children up to 12 years of age, repeated every 10 to 12 hours if necessary in those up to 2 months of age and every 4 to 6 hours if necessary in older children; those aged 12 to 18 years may be given the usual adult intravenous dose (see above) repeated every 4 to 6 hours if necessary. An intravenous injection of 1 mg/kg as a loading dose followed by continuous intravenous infusion of 100 to 400 micrograms/kg per hour adjusted according to response may also be given to those aged 1 month and over.

For **premedication**, UK licensed product information recommends that 1 to 2 mg/kg is given intramuscularly about 1 hour before surgery.

Eclampsia and pre-eclampsia. See Lytic Cocktails under Sedation, below.

Pain. Pethidine produces prompt but short-lasting analgesia, and may be preferred to morphine when rapid control of acute pain is required. It has been widely used in obstetrics to control the pain of labour (although the *BNF* notes that morphine or other opioids are often preferred for obstetric pain), and for postoperative pain relief after caesarean section or other surgical procedures.

In a study of patients with intractable pain the minimum effective analgesic blood concentration ranged from 100 to 820 nanograms/mL (median 250 nanograms/mL) in 15 of 16; the remaining patient failed to obtain analgesia with pethidine. Additional measures were considered necessary[1] if the minimum effective concentration exceeded 400 nanograms/mL.

Pethidine has traditionally been given by intermittent intramuscular injection in the treatment of acute pain, but inconsistent pain relief can be expected because of fluctuating blood-pethidine concentrations;[2] continuous intravenous infusion might be more effective for acute pain. SICKLE-CELL CRISIS. Concern has been expressed over the continued use of pethidine for analgesia in painful crises in sickle-cell disease. Control of pain may be inadequate and doses commonly used to manage crises may lead to accumulation of the neuroexcitatory metabolite of pethidine and precipitate seizures.[1,2] See also Effects on the Nervous System, above.

LYTIC COCKTAILS. Lytic cocktails consisting of chlorpromazine, pethidine, and/or promethazine have been given intravenously in some countries for the management of pre-eclampsia and imminent eclampsia. However, the use of phenothiazines is generally not recommended late in pregnancy, and other treatments are preferred for hypertension (see Hypertension in Pregnancy, under Hypertension, p.1171); the management of eclampsia, which is the convulsive phase, is discussed on p.470.

Lytic cocktails have also been used for sedation and analgesia in children, by intramuscular or occasionally intravenous injection. However, there is a high rate of therapeutic failure as well as serious adverse effects with such combinations, and the American Academy of Pediatrics[1] had recommended that alternative sedatives and analgesics should be considered. Lytic cocktails are not the most appropriate means of sedation for short procedures since patients must be monitored for about 1 hour before the procedure while the drugs take effect, and for even longer during the recovery period.[2]

Adverse Effects and Precautions

Phenacetin may cause methaemoglobinaemia, sulfhaemoglobinaemia, and haemolytic anaemia.

Prolonged use of large doses of analgesic mixtures containing phenacetin has been associated with the development of renal papillary necrosis (see Effects on the Kidneys, p.98) and transitional-cell carcinoma of the renal pelvis.

Porphyria. Phenacetin is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Uses and Administration

Phenacetin, a para-aminophenol derivative, has analgesic and antipyretic properties. It was usually given with aspirin, caffeine, or codeine but is now little used because of adverse haematological effects and nephrotoxicity.

Adverse Effects and Precautions

Phenazone is liable to give rise to skin eruptions and in susceptible individuals even small doses may have this effect. Hypersensitivity reactions and nephrotoxicity have been reported. Large oral doses may cause nausea, drowsiness, coma, and convulsions.

Effects on the blood. Phenazone can cause haemolytic anaemia in certain individuals with a deficiency of G6PD.[1] Episodes of agranulocytosis were reported[2] in 6 women using a cream containing phenazone; all recovered on withdrawal.

Porphyria. Phenazone is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

Phenazone affects the metabolism of some other drugs and its own metabolism is affected by other drugs that increase or reduce the activity of liver enzymes.

Pharmacokinetics

Phenazone is absorbed from the gastrointestinal tract and peak plasma concentrations are obtained within 1 to 2 hours of ingestion. It is distributed throughout the body fluids with concentrations in the saliva and breast milk reaching about the same levels as those in plasma. Less than 10% is bound to plasma proteins and it has an elimination half-life of about 12 hours. Phenazone is metabolised in the liver to 3 major metabolites 3-hydroxymethylphenazone, 4-hydroxyphenazone, and norphenazone. Phenazone, 3-hydroxymethylphenazone, and glucuronidated metabolites are all excreted in the urine. A small portion may be eliminated via the bile.

Uses and Administration

Phenazone is an NSAID (p.99) and has been given orally; phenazone and caffeine citrate and phenazone salicylate have similarly been given orally as analgesics.

Solutions containing about 5% of phenazone have been used topically as ear drops in disorders such as acute otitis media (but see below).

Phenazone is used as a test for the activity of drug-metabolising enzymes in the liver.

Otitis media. There appears to be no justification[1] for the inclusion of phenazone in topical preparations used in treating acute otitis media (p.182). It is presumably included in such preparations because it is believed to have a local anti-inflammatory and, therefore, analgesic action. It would, however, seem unlikely that phenazone would have any action on the skin of the intact tympanic membrane and, therefore, on the pain which is due primarily to the stretching and distention of the membrane.

(phenazopyridine)

Pharmacopoeias. In *Pol.* and *US*.

USP 31 (Phenazopyridine Hydrochloride). A light or dark red to dark violet crystalline powder. Is odourless or with a slight odour. Soluble 1 in 300 of cold water, 1 in 20 of boiling water, 1 in 59 of alcohol, 1 in 331 of chloroform, and 1 in 100 of glycerol; very slightly soluble in ether. Store in airtight containers.

Removal of stains. Phenazopyridine stains may be removed from fabric by soaking in a 0.25% solution of sodium dithionite.

Adverse Effects

Phenazopyridine hydrochloride has caused gastrointestinal adverse effects, headache, and rashes. Hepatotoxicity, haemolytic anaemia, methaemoglobinaemia, and acute renal failure have also been reported, generally associated with overdosage or with therapeutic doses in patients with renal impairment. Crystal deposits of phenazopyridine have formed in the urinary tract.

Abnormal coloration of body tissues or fluids may occur. Urine is tinged either orange or red and underclothes are apt to be stained.

Effects on the CNS. A case of aseptic meningitis, with distinct episodes of fever and confusion, was associated with the use of phenazopyridine.[1]

1. Herlihy TE. Phenazopyridine and aseptic meningitis. *Ann Intern Med* 1987; **106:** 172–3.

Overdosage. Report of a 2-year-old child who developed cyanosis and methaemoglobinaemia after ingesting at most three 200-mg tablets of phenazopyridine hydrochloride.[1]

Precautions

Phenazopyridine hydrochloride is contra-indicated in patients with renal impairment or severe hepatitis and should be used with caution in those with G6PD deficiency. Treatment should be stopped if the skin or sclerae become discoloured; this may indicate accumulation as a result of impaired renal excretion. Phenazopyridine may interfere with urinalysis based on colour reactions or spectrometry.

Staining of contact lenses may occur.

Pharmacokinetics

Phenazopyridine hydrochloride is absorbed from the gastrointestinal tract. It is excreted mainly in the urine; up to 65% may be excreted as unchanged phenazopyridine and 18% as paracetamol.

Uses and Administration

Phenazopyridine is an azo dye that exerts an analgesic effect on the mucosa of the urinary tract and is used to provide symptomatic relief of pain and irritability in conditions such as cystitis and prostatitis (see p.2178 and p.2181, respectively), and urethritis (p.199). Phenazopyridine hydrochloride has been given in usual oral doses of about 200 mg three times daily after food. If given with an antibacterial for the treatment of urinary-tract infections (p.199), treatment should usually not exceed 2 days, although lower doses have been given as part of a combined preparation for at least a week.

Urinary-tract infections. There is currently no well-substantiated role for phenazopyridine in the treatment of urinary-tract infections and its adverse effects are potentially serious.[1]

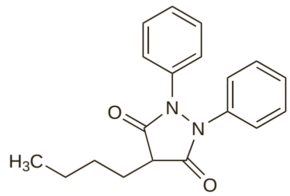
ATC — M01AA01; M02AA01.
ATC Vet — QM01AA01; QM02AA01.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*
Ph. Eur. 6.2 (Phenylbutazone). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; it dissolves in alkaline solutions. Protect from light.
USP 31 (Phenylbutazone). A white to off-white, odourless, crystalline powder. Very slightly soluble in water; soluble in alcohol; freely soluble in acetone and in ether. Store in airtight containers.

Profile

Phenylbutazone, a pyrazolone derivative, is an NSAID (p.96). However, because of its toxicity and in particular its adverse haematological reactions (see Effects on the Blood, below), it is not used as a general analgesic or antipyretic. Although phenylbutazone is effective in almost all musculoskeletal and joint disorders including ankylosing spondylitis, acute gout, osteoarthritis, and rheumatoid arthritis, it should only be used in acute conditions where less toxic drugs have failed. Initial oral doses of up to 600 mg daily in divided doses have been used in the treatment of rheumatic disorders although up to 800 mg daily may be required in acute gout. After 1 to 3 days, the dose should be reduced to the minimum effective amount, which may be as little as 200 mg daily; treatment should be given for the shortest period possible, up to a usual maximum of 1 week. Reduced doses are recommended in elderly patients.

In some countries phenylbutazone has also been given as a rectal suppository and applied topically for musculoskeletal pain and in soft-tissue injury. It has also been given intramuscularly as the sodium salt. Other salts of phenylbutazone that have been used in musculoskeletal, joint, and soft-tissue disorders include the calcium, megallate, and piperazine salts.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were given phenylbutazone, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. However, when phenylbutazone had been available in the UK the *BNF* had advised that phenylbutazone should be avoided during breast feeding as small amounts are distributed into breast milk.

Effects on the blood. Both phenylbutazone[1-3] and oxyphenbutazone[1,3] are well known for their adverse effects on the blood and especially for fatal agranulocytosis and aplastic anaemia. Leucopenia, pancytopenia, haemolytic anaemia, and thrombocytopenia may also occur. The UK CSM[4] noted that between July 1963 and January 1993 it had received 74 reports of agranulocytosis (39 fatal) associated with phenylbutazone and 40 reports of neutropenia (4 fatal). Up-to-date figures were not provided on oxyphenbutazone, but it is considered to be more toxic to the bone marrow than phenylbutazone.[1]

Adverse Effects and Treatment

As for NSAIDs in general, p.96.

Local irritation and occasionally bleeding may occur with piroxicam suppositories and there may be pain and occasionally tissue damage at the injection site on intramuscular use. Application site reactions have also occurred with topical preparations of piroxicam.

Piroxicam is considered to be associated with an intermediate risk of gastrointestinal effects although there is some suggestion that the risk may be higher than for other intermediate-risk NSAIDs (p.97).

◊ A report[1] of the adverse reactions associated with piroxicam in South Africa during 1981-86 included two reactions, paraesthesia and hair loss, not previously recorded in the literature.

1. Gerber D. Adverse reactions of piroxicam. *Drug Intell Clin Pharm* 1987; **21:** 707–10.

Effects on the blood. Decreases in haemoglobin and haematocrit not associated with obvious gastrointestinal bleeding, have occurred in patients taking piroxicam. Thrombocytopenia, thrombocytopenic purpura,[1] and aplastic anaemia[2] have been described in patients on piroxicam.

2. Lee SH, *et al.* Aplastic anaemia associated with piroxicam. *Lancet* 1982; **i:** 1186.

Effects on electrolytes. Reversible hyperkalaemic hyperchloraemic acidosis has been reported[1,2] in patients receiving piroxicam. Severe hyponatraemia and symptoms resembling the syndrome of inappropriate antidiuretic hormone secretion have also been associated with piroxicam.[3]

Effects on the kidneys. Acute nephropathy with characteristic features of Henoch-Schönlein purpura,[1] acute renal failure,[2] uraemia with hyperkalaemia, and acute interstitial nephritis[3] have been associated with systemic use of piroxicam. Nephrotic syndrome and interstitial nephritis have followed topical use of piroxicam gel.[4]

2. Paterson D, *et al.* Piroxicam induced submassive necrosis of the liver. *Gut* 1992; **33;** 1436–8.

Effects on the skin. As with other NSAIDs, rash has occurred in patients taking piroxicam. Phototoxic reactions have been described.[1] Serious skin reactions attributed to piroxicam therapy include toxic epidermal necrolysis,[2] pemphigus vulgaris,[3] erythema multiforme,[4] and Stevens-Johnson syndrome.[5] Fixed drug eruptions have also been reported.[6]

Concern by the EMEA over the serious nature of skin reactions associated with piroxicam has led to restrictions on the systemic use of piroxicam in the EU (see below).

Overdosage. Details of 16 patients who were considered to have taken an overdosage of piroxicam alone were reported[1] to the National Poisons Information Service of the UK. Thirteen patients (including 5 children) had no symptoms after doses estimated to be up to 300 to 400 mg; 2 patients complained of dizziness and blurred vision after 200 to 300 mg; the last patient, who claimed to have taken 600 mg presented in coma, regained consciousness within one hour, and had recovered fully within 24 hours. Severe multisystem toxicity has been reported in a 2-year-old child after ingestion of 100 mg of piroxicam.[2]

Precautions

As for NSAIDs in general, p.98.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were given piroxicam, and the American Academy of Pediatrics considers[1] that it is therefore usually compatible with breast feeding. The *BNF* also considers the amount excreted into breast milk to be too small to be harmful to a breast-fed infant.

Piroxicam appears in breast milk in concentrations of about 1% of those in the maternal plasma.[2] Similar data are also included in the licensed product information although it does not recommend piroxicam use during breast feeding as clinical safety has not been established.

Porphyria. Piroxicam has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with NSAIDs, see p.99.

Use of aspirin with piroxicam results in decreased plasma concentrations of piroxicam to about 80% of normal. The UK licensed product information for ritonavir suggests that use of piroxicam with ritonavir may result in increased plasma concentrations of piroxicam and an increased risk of toxicity; it recommends that use together should be avoided.

Pharmacokinetics

Piroxicam is well absorbed from the gastrointestinal tract; peak plasma concentrations are reached 3 to 5 hours after an oral dose. Piroxicam is more rapidly absorbed after intramuscular use; it is also absorbed to some degree after topical application. Piroxicam is 99% bound to plasma proteins. It has been detected in breast milk. Piroxicam has a long plasma elimination half-life of about 50 hours. Because of this, steady-state concentrations are not reached for 7 to 12 days. It is metabolised in the liver by hydroxylation and conjugation with glucuronic acid and excreted mainly in the urine with smaller amounts in the faeces. Enterohepatic recycling occurs. Less than 5% of the dose is excreted unchanged in the urine and faeces.

Piroxicam betadex dissociates in the gastrointestinal tract to its components piroxicam and betadex (p.2291). Piroxicam absorption from piroxicam betadex is more rapid than that of unmodified piroxicam; peak plasma concentrations of piroxicam are reached 30 to 60 minutes after an oral dose. Betadex is not absorbed but is metabolised in the colon to various sugars.

Uses and Administration

Piroxicam, an oxicam derivative, and piroxicam betadex are NSAIDs (p.99). Piroxicam betadex may have a more rapid onset of therapeutic effect due to its enhanced solubility (see Pharmacokinetics above). Both have been used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, rheumatoid arthritis including juvenile idiopathic arthritis, in soft-tissue disorders, in acute gout, and in postoperative pain but systemic usage in the EU is now restricted (see below) to chronic painful and inflammatory conditions.

In rheumatic disorders a usual initial oral dose of *piroxicam* is 20 mg daily as a single dose. Daily maintenance doses may vary between 10 and 30 mg given in single or divided doses; use of doses in excess of 20 mg daily for more than a few days is associated with an increased risk of gastrointestinal adverse effects. Piroxicam has been given in similar doses as a rectal suppository or on a short-term basis by intramuscular injection.

For dosage in children, see below.

Piroxicam is also used in the local treatment of a variety of painful or inflammatory conditions as a topical gel in a concentration of 0.5% applied three or four times daily; treatment should be reviewed after 4 weeks. A 1% gel is also available. Piroxicam has been used in some countries as a 0.5 or 1% cream and as eye drops in a concentration of 0.5%.

Doses of piroxicam betadex are expressed in terms of the equivalent amount of piroxicam. Piroxicam betadex 191.3 mg is equivalent to about 20 mg of piroxicam. In rheumatic and acute musculoskeletal disorders *piroxicam betadex* is given in an oral dose equivalent to 20 mg of piroxicam daily as a single dose. This dose may be reduced to 10 mg daily in elderly patients.

Other salts or compounds that have also been used include piroxicam cinnamate (cinnoxicam), piroxicam choline, and piroxicam pivalate.

◊ Following a review[1] of the benefit-risk balance for piroxicam the EMEA placed restrictions on its systemic use and stated that:

- *its use in acute painful and inflammatory conditions should be abandoned*
- *its use should be limited only to the symptomatic relief of osteoarthritis, rheumatoid arthritis, and ankylosing spondylitis*
- *it should not be used as a first-line treatment*
- *the dose should be limited to 20 mg daily*
- *treatment should be reviewed within 14 days of starting*
- *it should only be started by doctors experienced in treating chronic painful and inflammatory conditions*
- *use with a gastroprotective drug should be considered*
- *it should not be given to patients at risk of gastrointestinal disorders associated with bleeding or to those who have had skin reactions to other drugs*
- *it should not be used with another NSAID or an anticoagulant*

Administration in children. In the UK, piroxicam may be used in children aged 6 years or over with juvenile idiopathic arthritis (p.10). The usual oral dose is:

- less than 15 kg: 5 mg once daily
- 16 to 25 kg: 10 mg once daily
- 26 to 45 kg: 15 mg once daily
- 46 kg or over: 20 mg once daily

UK licensed product information states that only the dispersible tablets are recommended for use in children.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Propacetamol Hydrochloride). A white or almost white crystalline powder. Freely soluble in water; slightly soluble in dehydrated alcohol; practically insoluble in acetone. Protect from moisture.

Profile

Propacetamol hydrochloride, a para-aminophenol derivative, is hydrolysed to paracetamol (p.108) in the plasma. It has been given intramuscularly or intravenously in usual doses of 1 to 2 g every 4 hours up to 4 times daily if necessary, to a maximum dose of 8 g daily, for the treatment of pain (see Choice of Analgesic, p.2) and fever (p.10). For doses in children, see below.

Administration in children. In some countries propacetamol is used intravenously in the treatment of pain and fever in neonates and children.[1,2] Doses range from 20 to 30 mg/kg given over 15 minutes up to 4 times daily, not exceeding a maximum daily dose of 120 mg/kg propacetamol (equivalent to a daily dose of 60 mg/kg of paracetamol).

Adverse effects. Occupational contact dermatitis has been reported in healthcare professionals after preparing injections of propacetamol.[1-3]

Propacetamol is the hydrochloride of *N*,*N*-diethylglycine ester with paracetamol and the results of a study[4] have suggested that allergic reactions to propacetamol are related to sensitisation to the activated ester rather than to paracetamol itself.

Profile

Propyphenazone, a pyrazolone derivative related to phenazone (p.116), has analgesic and antipyretic properties. It has been given orally and as a rectal suppository in the treatment of pain and fever. The usual oral adult dose is 0.5 to 1 g up to four times daily. There have been some reports of severe hypersensitivity reactions in patients receiving propyphenazone.

Porphyria. Propyphenazone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

(remifentanil)

Incompatibility. Remifentanil hydrochloride should not be mixed in the same intravenous solution as blood products. UK licensed product information states that it should not be mixed with lactated Ringer's injection with or without 5% glucose; however, in the USA the product literature states that remifentanil hydrochloride is stable for 4 hours at room temperature after reconstitution and dilution to 20 to 250 micrograms/mL with lactated Ringer's injection and for 24 hours if lactated Ringer's with 5% glucose is used. Incompatibilities have been reported between chlorpromazine hydrochloride 2 mg/mL and remifentanil 25 micrograms/mL (as the hydrochloride) in 5% glucose and cefoperazone sodium 40 mg/mL or amphotericin B 0.6 mg/mL and remifentanil 250 micrograms/mL (as the hydrochloride) in 5% glucose.[1]

Administration. Remifentanil hydrochloride injections containing glycine should not be given by the epidural or intrathecal routes.

Hepatic impairment. Although the pharmacokinetics of remifentanil are not changed in patients with severe hepatic impairment, such patients may be more sensitive to the respiratory depressant effects and should be monitored with doses titrated to individual requirements.

Renal impairment. The pharmacokinetics of remifentanil are not changed in patients with severe renal impairment (a creatinine clearance of less than 10 mL/minute) and licensed product information states that the carboxylic acid metabolite is unlikely to accumulate to clinically active concentrations in such patients after remifentanil infusions given for up to 3 days. Dosage adjustment is considered to be unnecessary. This is supported by pharmacokinetic studies[1,2] in intensive care patients with renal impairment given remifentanil infusions at a rate of 100 to 150 nanograms/kg per minute for up to 3 days.

Interactions
For interactions associated with opioid analgesics, see p.103.

Pharmacokinetics
After parenteral doses remifentanil hydrochloride has a rapid onset and short duration of action. Its effective biological half-life is about 3 to 10 minutes and is independent of dose. Remifentanil is about 70% bound to plasma proteins, mainly to α_1-acid glycoprotein. It is hydrolysed by non-specific esterases in blood and tissues to an essentially inactive carboxylic acid metabolite. About 95% of a dose of remifentanil is excreted in the urine as the metabolite. Studies in *animals* suggest that remifentanil may cross the placenta and is distributed into breast milk.

◊ Licensed product information for remifentanil gives values for a three-compartment pharmacokinetic model with a rapid distribution half-life of 1 minute, a slower distribution half-life of 6 minutes, and a terminal elimination half-life of 10 to 20 minutes.

Uses and Administration
Remifentanil, an anilidopiperidine derivative, is an opioid analgesic (p.104) related to fentanyl (p.58). It is a short-acting μ-receptor opioid agonist used for analgesia during induction and/or maintenance of general anaesthesia. It is also used to provide analgesia into the immediate postoperative period, and may be used as the analgesic component of local or regional anaesthesia with or without benzodiazepine sedation. Remifentanil is also used to provide analgesia and sedation in mechanically ventilated patients under intensive care.

Remifentanil is given intravenously as the hydrochloride, usually by infusion. Its onset of action is within 1 minute and the duration of action is 5 to 10 minutes. Doses are expressed in terms of the base; remifentanil hydrochloride 1.1 mg is equivalent to about 1 mg of remifentanil. Initial doses for anaesthesia in elderly patients should be half the recommended adult doses and then titrated to individual requirements. Obese patients may require doses based on their ideal (lean) bodyweight. For details of doses in children, see below.

When used to provide **analgesia** during *induction* of anaesthesia an intravenous infusion is given in doses of 0.5 to 1 micrograms/kg per minute. An additional initial intravenous bolus of 1 microgram/kg may be given over 30 to 60 seconds particularly if the patient is to be intubated less than 8 minutes after the start of the infusion.

For provision of analgesia during *maintenance* of anaesthesia in ventilated patients, usual infusion doses range from 0.05 to 2 micrograms/kg per minute depending on the anaesthetic drug employed and adjusted according to response. Supplemental intravenous boluses of 0.5 to 1 micrograms/kg may be given every 2 to 5 minutes in response to light anaesthesia or intense surgical stress. The infusion dosage in spontaneous respiration is initially 0.04 micrograms/kg per minute adjusted according to response within a usual range of 0.025 to 0.1 micrograms/kg per minute. Bolus doses are not recommended during spontaneous ventilation.

For continuation of analgesia into the immediate *postoperative* period typical doses by intravenous infusion have ranged from 100 to 200 nanograms/kg per minute; supplemental intravenous bolus doses are not recommended during the postoperative period.

To provide **analgesia and sedation** in ventilated patients under intensive care, remifentanil is given as an intravenous infusion at an initial rate of 100 to 150 nanograms/kg per minute. Doses should then be titrated to provide adequate analgesia and sedation; a period of 5 minutes should be allowed between dose adjustments. Additional sedative drugs should be given to those patients inadequately sedated with remifentanil infusions of 200 nanograms/kg per minute. An increase in the rate of remifentanil infusion may be necessary if additional analgesia is required to cover stimulating or painful procedures such as wound dressing. Doses of up to 750 nanograms/kg per minute have been given to some patients. Bolus doses of remifentanil are not recommended in intensive care.

Remifentanil is also used as an analgesic in patients receiving monitored anaesthesia care. In the USA, it may be given intravenously in a single dose of 1 microgram/kg 90 seconds before the local anaesthetic; alternatively, a dose of 100 nanograms/kg per minute may be given as an intravenous infusion, starting 5 minutes before the local anaesthetic, which should be reduced to 50 nanograms/kg per minute after the local anaesthetic. Subsequent adjustments of 25 nanograms/kg per minute at 5-minute intervals may be made to maintain a balanced analgesia.

Remifentanil has a very rapid offset of action and no residual opioid action remains 5 to 10 minutes after stopping an infusion. When appropriate, alternative analgesics should be given before stopping remifentanil, in sufficient time to provide continuous and more prolonged pain relief.

Administration in children. Remifentanil hydrochloride, given by continuous intravenous infusion, is used for analgesia during maintenance of general anaesthesia in children. Usual infusion doses (expressed as the base) for those aged from 1 to 12 years range from 0.05 to 1.3 micrograms/kg per minute depending on the anaesthetic drug employed and adjusted according to response; supplemental intravenous boluses of 1 microgram/kg may be given over at least 30 seconds. US licensed product information also states that neonates and children aged up to 2 months may be given infusion doses of 0.4 to 1 micrograms/kg per minute with supplemental boluses of 1 microgram/kg. Similar doses are suggested in the *BNFC* for use in neonates although in the UK remifentanil is not licensed for use in children under 1 year of age.

Profile

Rofecoxib is an NSAID (p.96) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It was given orally for symptomatic relief in the treatment of osteoarthritis and rheumatoid arthritis, and in the management of acute pain, dysmenorrhoea, and migraine but was generally withdrawn worldwide after reports of cardiovascular adverse effects (see below).

Rofecoxib has been applied topically in some countries.

Effects on the cardiovascular system. As of February 2001, the UK CSM had received a small number of reports of *myocardial infarction* or *ischaemia* associated with the selective cyclo-oxygenase-2 (COX-2) inhibitors.[1] At that time it noted that COX-2 inhibitors such as rofecoxib did not possess the intrinsic antiplatelet activity associated with aspirin, and consequently did not provide protection against ischaemic cardiac events. Data from a large, randomised study also showed the incidence of myocardial infarction to be greater in patients taking rofecoxib than in those taking naproxen.[2] Postmarketing surveillance of rofecoxib continued to provide further case reports of adverse cardiovascular effects. In addition, results of the then unpublished APPROVe study of rofecoxib for prevention of adenomatous polyposis indicated that the risk of myocardial infarction and stroke was markedly increased in patients receiving the drug compared to those on placebo; however, this difference was only apparent after 18 months of treatment. As a result, the study was stopped early and, in September 2004, the manufacturer generally withdrew rofecoxib worldwide. The cardiovascular findings from the APPROVe study were published in 2005;[3] the results showed a twofold increase in the risk of adverse cardiovascular events in patients receiving rofecoxib 25 mg daily when compared with those on placebo. More recently, 1-year follow-up data for patients in the APPROVe study has been released. In a statement from the manufacturer,[4] it is noted that in the year after rofecoxib was stopped there was no statistically significant difference in the risk of confirmed thrombotic cardiovascular events in those patients who had previously taken rofecoxib compared with those who had been given placebo; however, when data from both the on- and off-treatment periods were considered together, the difference in the risk of cardiovascular events between the rofecoxib and the placebo groups remained significant. Combined data from the on- and off-treatment periods also showed that there was an increased risk of confirmed heart attacks and ischaemic strokes in the rofecoxib group when compared to the placebo group. (The data for ischaemic stroke were later published.[5]) Similar data, suggesting a 1.5-fold increase in risk of thrombotic events with rofecoxib, were reported from a study of adjuvant use for colorectal cancer.[6] A cumulative meta-analysis also indicated an increased risk of myocardial infarction in patients receiving rofecoxib.[7]

Subsequent investigation by US and European regulatory authorities has confirmed that other COX-2 inhibitors are also associated with some increased cardiovascular risk (see under Celecoxib, p.34), as are some non-selective NSAIDs (see Thrombotic Events, p.97).

A review[8] of prospective studies evaluating the effect of selective COX-2 inhibitors on blood pressure was unable to determine if there was any association between the use of these drugs and blood pressure elevations. Of the studies considered, a randomised study in elderly, hypertensive patients with osteoarthritis has suggested that the risk of developing *increased systolic blood pressure* is greater in those patients receiving rofecoxib than in those receiving celecoxib.[9] However, the manufacturers of rofecoxib have pointed out that the trial used doses of rofecoxib greater than those recommended for elderly or hypertensive patients.

USP 31 (Salicylamide). A white practically odourless crystalline powder. Slightly soluble in water and in chloroform; soluble in alcohol and in propylene glycol; freely soluble in ether and in solutions of alkalis.

Profile

Salicylamide is a salicylic acid derivative (see Aspirin, p.20) but is not hydrolysed to salicylate; it is almost completely metabolised to inactive metabolites during absorption and on first pass through the liver. It is given in usual oral doses of 325 to 650 mg or more, usually with other analgesics, three or four times daily for pain and fever. Salicylamide has also been applied topically in rubefacient preparations in concentrations of up to about 5% for the relief of muscular and rheumatic pain.

Pain. Preparations containing willow bark extract have been tried with some success in the treatment of musculoskeletal disorders such as low back pain[1-3] and osteoarthritis.[4] However, the quality of reporting in trials is generally poor and further studies are needed to establish their place in therapy.

Profile

Salol is a salicylic acid derivative (see Aspirin, p.20). It was formerly used as an intestinal antiseptic, but effective doses were toxic owing to the liberation of phenol. It is used in oral preparations containing methenamine for the treatment of lower urinary-tract infections.

Salol has been used topically as a sunscreen.

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20.

The use of aspirin and other acetylated salicylates is generally not recommended for children because of the risk of Reye's syndrome, unless specifically indicated. Some licensed product information extends this precaution to salsalate.

Effects on the gastrointestinal tract. Salsalate is associated with less faecal blood loss than aspirin and has been reported to cause fewer gastric lesions than piroxicam.[1] However, small-bowel ulcerations were reported in a patient when salsalate was added to a regimen of ranitidine and metoclopramide which had been prescribed for duodenal ulcer.[2]

Effects on the mouth. Ulcerated lesions on the tongue of a 77-year-old man were caused by taking salsalate tablets incorrectly.[1] The patient had placed the tablets under his tongue rather than swallowing them whole, resulting in prolonged, direct contact with the tongue.

1. Ruscin JM, Astroth JD. Lingual lesions secondary to prolonged contact with salsalate tablets. *Ann Pharmacother* 1998; **32:** 1248.

Interactions

For interactions associated with salicylates, see Aspirin, p.23.

Pharmacokinetics

Salsalate is insoluble in acidic gastric fluids but is soluble in the small intestine. One molecule of salsalate is hydrolysed to 2 molecules of salicylic acid; hydrolysis occurs both in the small intestine and after absorption of the parent compound. Additional details on the pharmacokinetics of salicylic acid are provided in aspirin (see p.23). Not all of the absorbed salsalate is hydrolysed and about 13% of salsalate is excreted as glucuronide conjugates in the urine; thus, the amount of salicylic acid available from salsalate is less than that from aspirin when the two drugs are given in equimolar equivalents of salicylic acid.

Uses and Administration

Salsalate is a salicylic acid derivative that has analgesic, anti-inflammatory, and antipyretic actions similar to those of aspirin (see p.23). It is used for pain and fever and also in inflammatory disorders such as osteoarthritis and rheumatoid arthritis. A usual oral dose is up to 3 g daily given in divided doses with food.

Ph. Eur. 6.2 (Sodium Aurothiomalate). A mixture of monosodium and disodium salts of (2*RS*)-2-(aurosulphanyl)butanedioic acid. It contains 44.5 to 46.0% of gold and 10.8 to 11.8% of sodium, calculated with reference to the dried substance. A fine, pale yellow, hygroscopic powder. Very soluble in water; practically insoluble in alcohol and in dichloromethane. A 10% solution in water has a pH of 6.0 to 7.0. Store in airtight containers.

USP 31 (Gold Sodium Thiomalate). A mixture of the mono-sodium and disodium salts of gold thiomalic acid [(aurothio)succinic acid] ($C_4H_4AuNaO_4S$ = 368.1 and $C_4H_3AuNa_2O_4S$ = 390.1) that has a gold content of 44.8 to 49.6%, and 49.0 to 52.5% calculated on the dried alcohol-free and glycerol-free material. pH of a 10% solution in water is between 5.8 and 6.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

Reports show a wide range for the incidence of adverse effects of sodium aurothiomalate. However, some consider that with careful treatment about one-third of patients will experience adverse effects. It is also considered that about 5% of patients will experience severe adverse effects and that some of the effects will be fatal. The most common effects involve the skin and mucous membranes with pruritus (an early sign of intolerance) and stomatitis (often with a metallic taste) being the most prominent. Rashes with pruritus often occur after 2 to 6 months of intramuscular treatment and may require stopping therapy. Other reactions affecting the skin and mucous membranes include erythema, maculopapular eruptions, erythema multiforme, urticaria, eczema, seborrhoeic dermatitis, lichenoid eruptions, alopecia, exfoliative dermatitis, glossitis, pharyngitis, vaginitis, photosensitivity reactions, and irreversible pigmentation (chrysiasis).

Toxic effects on the blood include eosinophilia, thrombocytopenia, leucopenia, agranulocytosis, and aplastic anaemia.

Effects on the kidneys include mild transient proteinuria which may lead to heavy proteinuria, haematuria, and nephrosis.

Other effects reported include pulmonary fibrosis, dyspnoea, toxic hepatitis, cholestatic jaundice, peripheral neuritis, encephalitis, psychoses, fever, and gastrointestinal disorders including enterocolitis. Gold deposits may occur in the eyes. Vasomotor or nitritoid reactions, with weakness, flushing, palpitations, and syncope, may occur after injection of sodium aurothiomalate. Local irritation may also follow injection.

Sometimes there is an initial exacerbation of the arthritic condition.

Some adverse effects of gold have an immunogenic component.

Effects on the blood. Blood disorders such as eosinophilia, leucopenia, granulocytopenia, and thrombocytopenia have occurred in patients receiving gold therapy. Eosinophilia has been reported to be the most frequent haematological abnormality.[1] It has been estimated that thrombocytopenia develops in 1 to 3% of patients receiving gold salts.[2]

Fatal consumption coagulopathy occurred in 4 children after the second injection of sodium aurothioglucose or sodium aurothiomalate.[3]

Effects on the cardiovascular system. Vasomotor or nitritoid reactions associated with gold compounds are usually transient and self-limiting and although they may be mild there have been isolated reports of associated complications such as myocardial infarction, stroke, transient ischaemic attack, and transient monocular visual loss.[1] Most reactions have been associated with sodium aurothiomalate (a reported incidence of 4.7%) but they have also occurred with auranofin and sodium aurothioglucose. Tachyphylaxis usually occurs to the reactions and most patients are able to continue treatment but paradoxically in some the severity increases with repeated doses; 2.8% of patients receiving sodium aurothiomalate may require a change of treatment due to recurrent reactions. It is important to distinguish such reactions from true anaphylactic reactions to gold.[1] Patients taking ACE inhibitors may be at increased risk of nitritoid reactions.[2,3] Transfer of the patient to sodium aurothioglucose or reduction of the dose by 50%, injection in the recumbent position, and observation for 20 minutes have been recommended for the next few injections after a reaction.[2]

Effects on the kidneys. Proteinuria developed in 21 patients while receiving a standard regimen of sodium aurothiomalate.[1] The severity of the proteinuria varied greatly and in 11 it increased for 4 months after treatment was stopped. Eight patients were considered to have developed the nephrotic syndrome. The median duration of proteinuria was 11 months, resolving in all 21 patients when treatment was withdrawn; at 24 months 3 patients were still experiencing proteinuria and it was not until 39 months that all were free of the condition. Renal biopsy indicated several types of kidney damage.

Effects on the lungs. 'Gold lung' is the term used to describe symptoms of dyspnoea on exertion, weakness, dry cough, and malaise that are seen rarely in patients on gold treatment.[1] Such symptoms usually develop some weeks or months after starting gold treatment and are associated with cumulative doses of several hundred milligrams although, very rarely, they have been seen with cumulative doses of less than 100 mg.[2] Pulmonary insufficiency may eventually develop and there have been occasional fatalities.[3] The pulmonary lesions usually subside on withdrawal of gold therapy, although persistent symptoms have been reported.

Nonbacterial thrombotic endocarditis associated with gold-induced pulmonary disease has also been reported.[4] This was considered to be a manifestation of gold-induced immune complex deposition.

Effects on the nails. Effects on the nervous system. Neurological complications with gold salts are infrequent but may include peripheral neuropathy, Guillain-Barré syndrome, myokymia (repeated involuntary contractions of muscle fibre), and encephalopathy. Some reports[1-6] are given below.

Effects on the skin. Chrysiasis is a distinctive pigmentation that develops in light-exposed skin of patients receiving parenteral gold salts. In a study[1] of 31 patients with chrysiasis who were receiving intramuscular sodium aurothiomalate for rheumatoid arthritis, it was noted that visible changes developed above a threshold equivalent to 20 mg/kg gold content. The severity of the pigmentation depended upon cumulative dose. Focal aggregates of gold are deposited in the reticular and papillary dermis with no obvious increase in melanin. The pigmentation is permanent but benign, although the cosmetic effects may cause some patients distress. Prevention of chrysiasis is difficult but avoidance of exposure to sunlight may be helpful.

Hypersensitivity. Many adverse effects associated with gold treatment have an immunological basis. Patients with contact allergy to gold may exhibit a flare-up, associated with cytokine release, when given sodium aurothiomalate intramuscularly.[1] Small amounts of nickel have been detected in sodium aurothiomalate injection[2] and in sodium aurothioglucose injection[3] and it has been suggested that gold therapy may also exacerbate or induce hypersensitivity to nickel.[2-4]

Anaphylaxis may occur occasionally[5] but vasomotor or 'nitritoid' reactions (see Effects on the Cardiovascular System, above) may produce similar symptoms.

Treatment of Adverse Effects

The treatment of the adverse effects of gold is usually symptomatic and most effects resolve when gold therapy is withdrawn. In severe cases a chelator such as dimercaprol (p.1444) may be used.

Precautions

Gold therapy is contra-indicated in exfoliative dermatitis, SLE, necrotising enterocolitis, and pulmonary fibrosis. It should be used with caution in the elderly and in renal or hepatic impairment; use is contra-indicated if renal or hepatic disorders are severe. Patients with a history of haematological disorders or who have previously shown toxicity to heavy metals should not be given gold salts, nor should any severely debilitated patient.

It is recommended that diabetes mellitus and heart failure should be adequately controlled in any patient before gold is given. Patients with a history of urticaria, eczema, or colitis should be treated with caution. Patients with a poor sulfoxidation status may be more susceptible to adverse effects of sodium aurothiomalate.

Use of gold compounds with other therapy capable of inducing blood disorders should be undertaken with caution, if at all.

Because of the risk of vasomotor reactions, patients should remain recumbent for about 10 minutes after each injection.

Urine should be tested for albumin before each injection and a full blood count carried out. Patients receiving gold compounds either orally or parenterally should be warned to report the appearance of sore throat or tongue, metallic taste, pruritus, rash, buccal ulceration, easy bruising, purpura, epistaxis, bleeding gums, unexplained bleeding, menorrhagia, pyrexia, indigestion, diarrhoea, or unexplained malaise. The development of breathlessness or cough should also be reported. Effects such as eosinophilia, proteinuria, pruritus, and rash arising during gold treatment should be allowed to resolve before therapy is continued.

Licensed product information recommends that annual chest X-rays should be carried out.

Breast feeding. The American Academy of Pediatrics considers that gold compounds are usually compatible with breast feeding.[1]

Gold has been detected in breast milk[2-4] and found bound to the red blood cells of breast-fed babies.[3,4] In a report[2] of a breast-fed infant it was calculated that the weight-adjusted dose of gold received by the infant exceeded that received by the mother although the infant exhibited no ill-effects during 100 days of breast feeding and developed normally thereafter. Nonetheless, because of the relatively high exposure it was recommended that breast-fed infants should be closely monitored.

Porphyria. Sodium aurothiomalate has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Although healthy neonates have been born after *in utero* exposure to gold compounds,[1,2] *animal* studies and a report[1] of malformation in a child born to a woman treated with sodium aurothiomalate led to a suggestion that gold might possibly have teratogenic effects. Licensed product information advises that sodium aurothiomalate should be avoided during pregnancy.

Interactions

There is an increased risk of toxicity when gold compounds are given with other nephrotoxic, hepatotoxic, or myelosuppressive drugs. Use of gold compounds with penicillamine may increase the risk of haematologic or renal adverse reactions.

ACE inhibitors. For a possible increased risk of nitritoid reactions when gold compounds are given to patients taking ACE inhibitors, see Effects on the Cardiovascular System, above.

Penicillamine. For a discussion on the effects of previous therapy with gold salts affecting penicillamine toxicity, see p.1458.

Pharmacokinetics

Sodium aurothiomalate is absorbed readily after intramuscular injection and 85 to 95% becomes bound to plasma proteins. With doses of 50 mg weekly a steady-state serum concentration of gold of about 3 to 5 micrograms/mL is reached in 5 to 8 weeks. It is widely distributed to body tissues and fluids, including synovial fluid, and accumulates in the body.

The serum half-life of gold is about 5 to 6 days but this increases after successive doses and after a course of treatment, gold may be found in the urine for up to 1 year or more owing to its presence in deep body compartments. Sodium aurothiomalate is mainly excreted in the urine, with smaller amounts in the faeces.

Gold has been detected in the fetus when sodium aurothiomalate was given to the mother. Gold is distributed into breast milk.

Uses and Administration

Sodium aurothiomalate and other gold compounds are used mainly for their anti-inflammatory effect in active progressive rheumatoid arthritis and progressive juvenile idiopathic arthritis; they may also be beneficial in psoriatic arthritis. They are generally used as disease-modifying antirheumatic drugs in patients whose symptoms are unresponsive to or inadequately controlled by NSAIDs alone.

Sodium aurothiomalate therapy should only be undertaken where facilities are available to carry out the tests specified under Precautions, above.

Sodium aurothiomalate is given by deep intramuscular injection; the area should be gently massaged and, due to the possibility of vasomotor reactions, the patient should remain recumbent for 10 minutes and kept under close observation for 30 minutes after each injection. In the UK, 10 mg is given in the first week to test the patient's tolerance. If satisfactory, this may be followed by doses of 50 mg at weekly intervals until signs of remission occur; the dosage interval is then increased to 2 weeks until full remission occurs and then increased gradually to every 4 to 6 weeks. Treatment may be continued for up to 5 years after remission.

Improvement may not be seen until a total dose of 300 to 500 mg has been given. If no major improvement has occurred after a total of 1 g has been given (excluding the test dose) therapy should be stopped; alternatively in the absence of toxicity, 100 mg may be given weekly for a further 6 weeks; should there be no response at this dose other forms of therapy should be tried. In patients who relapse while receiving maintenance therapy, the interval between doses should be reduced to one week and should not be increased again until control has been obtained; however, if no response is obtained within 2 months, alternative treatment should be used. It is important to avoid complete relapse since a second course of gold therapy is not usually effective.

For doses in juvenile idiopathic arthritis, see Administration in Children, below.

NSAIDs may be continued when sodium aurothiomalate therapy is begun.

Other gold compounds that have been used include auranofin (p.25), aurothioglucose (p.26), aurotioprol (p.26), gold keratinate (p.62), and sodium aurotiosulfate (below).

Administration in children. For children with progressive juvenile idiopathic arthritis the suggested initial weekly dose of sodium aurothiomalate is 1 mg/kg by deep intramuscular injection to a maximum of 50 mg weekly (one-tenth to one-fifth of the calculated initial weekly dose may be given for 2 to 3 weeks to test the patient's tolerance). Weekly doses should continue until signs of remission occur, at which point the dosage interval may be increased to fortnightly. With full remission, the dosage interval may again be increased gradually to every 4 weeks. If no improvement has occurred after 20 weeks, the dose could be raised slightly or another antirheumatic drug tried. For the view that use of gold compounds is no longer appropriate to treat juvenile idiopathic arthritis see Rheumatic Disorders, below.

Asthma. For comment on the use of parenteral gold compounds in the treatment of asthma, see under Auranofin, p.26.

Pemphigus and pemphigoid. Corticosteroids are the main treatment for blistering in pemphigus and pemphigoid (p.1582). Intramuscular gold therapy has been used concomitantly to permit a reduction in corticosteroid dosage although evidence for the steroid-sparing effect is lacking;[1,2] it has been suggested that gold therapy should be reserved for patients who cannot tolerate corticosteroids or in whom they are contra-indicated.[1]

Rheumatic disorders. Gold compounds are among the disease-modifying antirheumatic drugs (DMARDs) that may be used in the treatment of rheumatoid arthritis (p.11). Although toxicity has now reduced its popularity, intramuscular gold has long been used for the treatment of rheumatoid arthritis[1-4] and is often the standard against which the efficacy of other treatments is measured. Oral gold is less toxic but is also much less effective. It is unclear if there are differences between available intramuscular forms, but a study[5] in 120 patients converted from aurothioglucose to aurothiomalate found that 29 withdrew from the latter drug within 12 months, mostly because of lack of efficacy or the development of adverse effects not seen with the previous drug.

Gold compounds have also been used in the treatment of juvenile idiopathic arthritis (p.10); however, the *BNFC* states that gold is no longer used for this indication.

Gold compounds may also be of benefit in psoriatic arthritis (see under Spondyloarthropathies, p.13).

Adverse Effects, Treatment, and Precautions

As for Aspirin, p.20.

Although sodium salicylate has been used in the treatment of rheumatic fever, its high sodium content may cause problems in patients with cardiac complications.

The use of aspirin and other acetylated salicylates is generally not recommended for children because of the risk of Reye's syndrome, unless specifically indicated. Some licensed drug information extends this precaution to sodium salicylate.

Effects on the eyes. Retinal haemorrhages were reported in a 60-year-old woman taking sodium salicylate 6 g daily by mouth for 2 months and in a 10-year-old girl taking sodium salicylate, 4 g daily by mouth, for 40 days.[1] In both cases the haemorrhages gradually resolved after the treatment was stopped.

Interactions

For interactions associated with salicylates, see Aspirin, p.23.

Uses and Administration

Sodium salicylate is a salicylic acid derivative that has analgesic, anti-inflammatory, and antipyretic actions similar to those of aspirin (p.23). Sodium salicylate 1 g is equivalent to about 1.1 g of aspirin. It is used in the treatment of pain, fever, and in rheumatic disorders such as osteoarthritis and rheumatoid arthritis. The usual oral dose of sodium salicylate for pain or fever is 325 to 650 mg every four hours as required. The oral dose for rheumatic disorders is 3.6 to 5.4 g daily in divided doses. Sodium salicylate has also been used in the symptomatic treatment of rheumatic fever but its high sodium content may cause problems in patients with cardiac complications.

Sodium salicylate has also been given by intravenous infusion and topically.

Breast feeding. Concentrations of sufentanil were similar in colostrum and serum in 7 women given sufentanil by continuous epidural infusion during the first postoperative day after caesarean section. In the light of its poor oral availability such an amount was not considered to be a hazard to the breast-fed infant, and a maternal dose of 5 micrograms/hour epidurally was considered to be safe for such infants.[1]

Effects on the cardiovascular system. For a reference to the effects of sufentanil on histamine release compared with some other opioids, see under Pethidine, p.114.

Effects on the nervous system. There have been reports of tonic-clonic movements or seizures in a few patients receiving sufentanil.[1] There was no evidence of cortical seizure activity in a patient whose EEG was recorded,[2] suggesting that the observed myoclonus was not a convulsion or seizure.

Effects on the respiratory system. Sufentanil, like other opioid agonists, causes dose-related respiratory depression. There have been reports of significant respiratory depression associated with chest wall rigidity in the early postoperative period after anaesthesia with intravenous sufentanil.[1,2] Respiratory depression has also been reported after intrathecal sufentanil for postoperative analgesia[3] and labour pain.[4]. A retrospective chart review[3] of a 6-year period, during which 4870 patients received intrathecal sufentanil for the management of labour pain, found that the case above was the only one of respiratory arrest reported in the group.

The elderly. The pharmacokinetics of sufentanil in elderly patients have been variable in different studies, but a review[1] considered that there had been no evidence overall for differences between the elderly and younger adults. Nevertheless, as with fentanyl, reduced initial doses have been advised in the elderly.

Handling. Avoid contact with skin and the inhalation of particles of sufentanil citrate.

Obesity. The elimination half-life and volume of distribution of sufentanil were increased in obese subjects.[1,2] Licensed product information recommends that for obese patients more than 20% above ideal body-weight the dosage of sufentanil should be determined on the basis of the patients' lean body-weight.

Interactions

Benzodiazepines. For the effects of using opioids such as sufentanil with benzodiazepines, see Analgesics under Interactions of Diazepam, p.989.

Pharmacokinetics

After parenteral doses sufentanil citrate has a rapid onset and short duration of action. The terminal elimination half-life of sufentanil is about 2.5 hours. It is extensively bound to plasma proteins (about 90%). It is metabolised in the liver and small intestine by *N*-dealkylation and *O*-demethylation and the inactive metabolites are excreted in the urine and faeces. About 80% of a dose is excreted within 24 hours and 2% is eliminated as unchanged drug. Sufentanil crosses the placenta and is distributed into breast milk.

◊ The pharmacokinetics of sufentanil have been reviewed.[1,2] Sufentanil is very lipid-soluble. Like alfentanil it is highly bound to plasma proteins, mainly to α_1-acid glycoprotein. The elimination half-life lies between that of alfentanil and fentanyl. The manufacturers of sufentanil have given values for a three-compartment pharmacokinetic model with a distribution half-life of 1.4 minutes, a redistribution half-life of 17.1 minutes, and an elimination half-life of 164 minutes. Accumulation may be relatively limited when compared with fentanyl. In practice the pharmacokinetics of sufentanil may vary according to the age and condition of the patient and the procedures undertaken. For example, the elimination half-life of sufentanil has been reported to be longer in patients undergoing cardiac surgery (595 minutes),[3] in hyperventilated patients (232 minutes),[4] in those undergoing abdominal aortic surgery (more than 12 hours),[5] and in ventilated intensive care patients under sedation (25.5 hours).[6]

Children. Neonates (up to 1 month old) had a significantly lower plasma clearance rate and greater elimination half-life than infants (1 month to 2 years), children, and adolescents.[1] Others[2] have found that infants and small children (1 month to 3 years) with cardiac disease had higher clearance rates and shorter elimination half-lives than reported for adults. Older children (aged 2 to 8 years) with no history of cardiac, renal, or hepatic disease have also been noted to have shorter elimination half-lives and higher clearance rates than adults.[3]

Hepatic impairment. Because of the efficient hepatic extraction and clearance of sufentanil[1] liver dysfunction might be expected to affect its pharmacokinetics. However, elimination kinetics and plasma protein binding were found to be similar in cirrhotic and non-cirrhotic patients after a single dose of sufentanil.[2]

Uses and Administration

Sufentanil, a phenylpiperidine derivative, is an opioid analgesic (p.104) related to fentanyl (p.58). It is highly lipid-soluble and more potent than fentanyl. Sufentanil is used as an analgesic adjunct in anaesthesia and as a primary anaesthetic in procedures requiring assisted ventilation. It has a rapid onset and recovery is considered to be more rapid than with fentanyl. It is also used as an analgesic in the management of postoperative pain and labour pain.

Sufentanil is given as the citrate either intravenously by slow injection or as an infusion, or epidurally. Doses are expressed as the base; sufentanil citrate 15 micrograms is equivalent to about 10 micrograms of sufentanil. Lower initial doses are advised in the elderly and debilitated patients. For obese patients more than 20% above ideal body-weight the dosage of sufentanil should be determined on the basis of the patient's lean body-weight. For details of doses in children, see below. In all patients supplementary maintenance doses should be based on individual response and length of procedure. Doses of up to the equivalent of 8 micrograms/kg of sufentanil produce profound analgesia. Higher doses produce a deep level of anaesthesia but are associated with prolonged respiratory depression and assisted ventilation may be required in the postoperative period.

When used as an analgesic **adjunct to anaesthesia** with nitrous oxide and oxygen for surgical procedures lasting up to 8 hours, the total *intravenous* dosage should not exceed 1 microgram/kg per hour. It is customary to give up to 75% of the dose before intubation followed as necessary during surgery by additional injections of 10 to 50 micrograms or by a suitable continuous or intermittent infusion given so that the total hourly dose is not exceeded. Thus, for an operation lasting 1 to 2 hours the total dose would be 1 to 2 micrograms/kg with 0.75 to 1.5 micrograms/kg being given before intubation.

When used as a **primary anaesthetic** in major surgery *intravenous* doses of 8 to 30 micrograms/kg are given with 100% oxygen; doses of 25 to 30 micrograms/kg block sympathetic response including catecholamine release and are indicated in procedures such as cardiovascular surgery or neurosurgery. Anaesthesia may be maintained by additional injections of 0.5 to 10 micrograms/kg or by a suitable continuous or intermittent infusion given so that the total dosage for the procedure does not exceed 30 micrograms/kg.

In postoperative **pain**, sufentanil is given *epidurally* in an initial dose of 30 to 60 micrograms, which should provide analgesia for 4 to 6 hours. Additional boluses of up to 25 micrograms may be given at intervals of not less than 1 hour if necessary.

Sufentanil is also given *epidurally* for the relief of pain during labour and delivery. Recommended doses are 10 to 15 micrograms given with 10 mL of bupivacaine 0.125% (or its equivalent) with or without adrenaline;

the dose may be repeated twice at not less than one-hour intervals until delivery. The total dose of sufentanil should not exceed 30 micrograms.

Administration. Sufentanil is usually given intravenously, but the epidural route is also used (see below). Intranasal (see Anaesthesia, Pain, and Sedation, below), intrathecal (see below), and sublingual use (see Pain, below) have also been tried.

EPIDURAL. In a laboratory assessment of epidural sufentanil in healthy subjects,[1] a dose of 50 micrograms produced analgesia for 2 to 3 hours; analgesia was intensified and prolonged, and respiratory and other adverse effects, especially drowsiness, were reduced by the addition of adrenaline. Epidural sufentanil or fentanyl provided effective postoperative analgesia following caesarean section with comparable adverse effect profiles.[2] Sufentanil doses of 20 and 30 micrograms showed equivalent efficacy and provided greater analgesia for a longer duration than a dose of 10 micrograms. Addition of sufentanil to local anaesthetics such as bupivacaine during labour has considerably reduced the local anaesthetic requirements[3] and improved the quality of epidural analgesia.[4] Combination of sufentanil with a local anaesthetic (ropivacaine or bupivacaine) has been used for patient-controlled epidural analgesia (PCEA),[5-9] although an early study suggested that PCEA with sufentanil alone had little advantage over patient-controlled analgesia with intravenous morphine.[10]

Effective analgesia has been achieved in children with epidural sufentanil.[11]

INTRATHECAL. Sufentanil, alone or in combination, has been given intrathecally for labour pain: a combination of sufentanil, bupivacaine, and adrenaline given intrathecally provided excellent analgesia during labour and had a more rapid onset, a longer duration of action, and reduced local anaesthetic requirements compared with epidural administration.[1] Intrathecal sufentanil and bupivacaine provided shorter duration of analgesia when given during the advanced stages of labour compared with early labour.[2] There has been some concern about the effect of intrathecal use on fetal heart rate. An early study[3] found no significant difference in the heart rate when intrathecal sufentanil was compared with epidural bupivacaine; however, a more recent study[4] reported that high-dose intrathecal sufentanil (7.5 micrograms) when given on its own increased the risk of fetal heart rate abnormalities when compared with low-dose intrathecal sufentanil (2.5 micrograms) given with bupivacaine and adrenaline. Nonetheless, there was no evidence of a difference in adverse neonatal outcomes between the groups.

A small study in patients undergoing hip replacement found that intrathecal sufentanil 7.5 micrograms produced better and longer lasting analgesia than the same dose given intravenously.[5]

Intrathecal sufentanil has also been tried in the treatment of chronic pain.[6]

Administration in children. Although experience of paediatric use is limited, sufentanil citrate is licensed for the induction and maintenance of anaesthesia in children under 12 years of age undergoing cardiovascular surgery. Intravenous doses of 10 to 25 micrograms/kg are given with 100% oxygen with maintenance doses of up to 25 to 50 micrograms.

Anaesthesia. Sufentanil, like fentanyl (p.59), appears to produce fewer circulatory changes than morphine, which may offer some advantages in cardiovascular surgery.

Premedication with sufentanil given intranasally has been tried in children[1-3] and in adults.[4]

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Sulindac). A yellow, polymorphic, crystalline powder. Very slightly soluble in water and in ether; sparingly soluble in alcohol; soluble in dichloromethane; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Sulindac). A yellow, odourless or practically odourless, crystalline powder. Practically insoluble in water and in hexane; slightly soluble in alcohol, in acetone, in chloroform, and in methyl alcohol; very slightly soluble in ethyl acetate and in isopropyl alcohol.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96. Urine discoloration has occasionally been reported with sulindac.

Sulindac metabolites have been reported as major or minor components in renal stones. It should therefore be used with caution in patients with a history of renal stones and such patients should be kept well hydrated while receiving sulindac.

UK licensed product information recommends that patients with hepatic impairment should not be given sulindac; in the USA, however, licensed information states that patients with poor hepatic function may be given a reduced dose of sulindac with close monitoring. The dose of sulindac may also need to be reduced in those with renal impairment. Licensed information recommends that sulindac is not used in patients with advanced renal disease, but this appears to be based on a lack of data in such patients.

Effects on the blood. Agranulocytosis,[1] thrombocytopenia,[2] haemolytic anaemia,[3] and aplastic anaemia[4] have been reported in patients taking sulindac.

Effects on the kidneys. Sulindac-induced renal impairment, interstitial nephritis, and nephrotic syndrome have been reported.[1] It has been suggested that sulindac, as a prodrug, may not inhibit renal prostaglandin synthesis in therapeutic doses. However, this potentially important therapeutic advantage has not been uniformly seen in short-term studies in patients with renal dysfunction.[2-4]

There have been reports of renal stones consisting of between 10 and 90% of sulindac metabolites developing in patients given sulindac.[5]

Effects on the liver. Hepatotoxicity reported in patients receiving sulindac includes hepatocellular injury and cholestatic jaundice.[1,2] Symptoms of hypersensitivity including rash, fever, or eosinophilia have been reported in 35 to 55% of patients with sulindac-induced liver damage;[2] in these patients the liver damage occurred usually within 4 to 8 weeks of beginning sulindac therapy. For reference to a report citing the strongest evidence for an association of sulindac with liver disease compared with other NSAIDs, see under NSAIDs, p.98.

Effects on the lungs. For reference to pneumonitis associated with sulindac therapy, see Hypersensitivity, below.

Effects on the skin. Toxic epidermal necrolysis has occurred in patients taking sulindac.[1] In a patient toxic hepatitis and the Stevens-Johnson/toxic epidermal necrolysis syndrome resulted in death.[2]

An unusual pernio-like reaction affecting the toes, which was also confirmed by rechallenge, has been reported.[3]

Interactions

For interactions associated with NSAIDs, see p.99.

Dimethyl sulfoxide reduces plasma concentrations of the active metabolite of sulindac and use of the two drugs together has also resulted in peripheral neuropathy. Diflunisal and aspirin are reported to reduce the plasma concentration of the active metabolite of sulindac. Unlike other NSAIDs, sulindac is reported not to reduce the antihypertensive effects of drugs such as thiazide diuretics, but nevertheless licensed product information recommends that blood pressure be closely monitored in patients taking antihypertensives with sulindac.

Pharmacokinetics

Sulindac is absorbed from the gastrointestinal tract. It is metabolised by reversible reduction to the sulfide metabolite, which appears to be the active form, and by irreversible oxidation to the sulfone metabolite. Peak plasma concentrations of the sulfide metabolite are achieved in about 2 hours. The mean elimination half-life of sulindac is about 7.8 hours and of the sulfide metabolite about 16.4 hours. Sulindac and its metabolites are over 90% bound to plasma proteins. About 50% is excreted in the urine mainly as the sulfone metabolite and its glucuronide conjugate, with smaller amounts of sulindac and its glucuronide conjugate; about 25% appears in the faeces, primarily as sulfone and sulfide metabolites. Sulindac and its metabolites are also excreted in bile and undergo extensive enterohepatic circulation.

Uses and Administration

Sulindac is an NSAID (p.99) structurally related to indometacin (p.68); its activity appears to be due to its sulfide metabolite. Sulindac is used in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis, and also in the short-term management of acute gout and peri-articular conditions such as bursitis and tendinitis. It has also been used to reduce fever.

A usual initial oral dose of sulindac is 150 or 200 mg twice daily, reduced according to response; the maximum recommended daily dose is 400 mg. Licensed product information recommends that the treatment of peri-articular disorders should be limited to 7 to 14 days; for acute gout, 7 days of therapy is usually adequate.

Sulindac sodium has been given by rectal suppository.

Administration in hepatic or renal impairment. The dose of sulindac may need to be reduced in patients with hepatic or renal impairment but see Adverse Effects and Precautions, above..

Gastrointestinal disorders. In placebo-controlled studies[1,2] sulindac 150 to 200 mg twice daily for 6 to 9 months has reduced the number and size of polyps in patients with familial adenomatous polyposis but the effect may be incomplete and in a study[2] only polyps less than 2 mm in size regressed. In addition, the size and number of polyps has been reported[1] to increase on stopping treatment. The benefit of long-term therapy has therefore been studied. Reduced effectiveness has been seen[3] with long-term use but others[4] have reported management of recurrences by adjustment of maintenance dosage; there seemed to be individual variations in sensitivity to sulindac with respect to prevention of polyp recurrence although an average maintenance dose of 200 mg daily appeared to be needed.[4]

There is evidence[5] that sulindac alters the ratio of apoptosis of surface cells relative to those lying deeper in the crypt of rectal mucosa, thus altering epithelial homoeostasis. Whether sulindac prevents malignant degeneration is unknown but there have been reports[6-8] of patients who developed rectal cancer during or after long-term therapy for adenomatous polyposis. A more recent, placebo-controlled trial[9] has also reported that sulindac did not reduce the development of adenomas in patients with familial adenomatous polyposis. Some[1,9] consider that sulindac is unlikely to replace surgery as primary therapy for familial adenomatous polyposis.

A sulfone metabolite of sulindac, exisulind (p.720) has also been investigated for the treatment of familial adenomatous polyposis.

Sulindac has also been reported to have produced beneficial effects in a patient with duodenal polyps associated with Gardner's syndrome[10] but a placebo-controlled study has suggested that it may not be effective against sporadic type colonic polyps.[11]

Premature labour. The most common approach to postponing premature labour (p.2003) with drugs has historically been with a selective beta$_2$ agonist. However, as prostaglandins have a role in uterine contraction and cervical ripening and dilatation, prostaglandin synthetase inhibitors such as indometacin have also been used. Sulindac has also been tried[1,2] as an alternative to indometacin as it appears to have little placental transfer and may therefore have fewer fetal adverse effects.[1] However, the authors of a subsequent study suggested that sulindac had many of the same adverse fetal effects as indometacin and its use could only be described as investigational.[3] A study[4] using relatively low doses of sulindac (100 mg twice daily) did not note any significant fetal or maternal adverse effects but also found the drug to be ineffective in extending gestation or improving outcome.

Superoxide Dismutase

SOD; Superóxido dismutasa.

Description. Superoxide dismutase represents a group of water-soluble protein congeners widely distributed in nature which catalyse the conversion of superoxide radicals to peroxide. Several different forms exist, which vary in their metal content; forms containing copper or copper and zinc are common.

Orgotein *(BAN, USAN, rINN)*

Bovine Superoxide Dismutase; Orgoteiini; Orgoteína; Orgotéine; Orgoteinum; Ormetein.

Орготеин

CAS — 9016-01-7.
ATC — M01AX14.
ATC Vet — QM01AX14.

Description. Orgotein is a superoxide dismutase produced from beef liver as Cu-Zn mixed chelate. Mol. wt about 33 000 with a compact conformation maintained by about 4 gram-atoms of chelated divalent metal.

Pegorgotein *(USAN, rINN)*

Pegorgoteína; Pégorgotéine; Pegorgoteinum; PEG-SOD; Win-22118.

Пэгорготеин

CAS — 155773-57-2.

Description. Pegorgotein is a superoxide dismutase conjugated with polyethylene glycol to prolong its duration of action.

Sudismase *(rINN)*

Sudismasa; Sudismasum.

Судизмаза

CAS — 110294-55-8.

Description. Sudismase is a human *N*-acetylsuperoxide dismutase produced by recombinant DNA technology and containing a copper and zinc prosthetic group.

Adverse Effects

Anaphylaxis and other hypersensitivity reactions, sometimes fatal, have been reported with orgotein. Local reactions and pain may occur at the site of injection of orgotein.

Uses and Administration

Superoxide dismutases have anti-inflammatory properties. Orgotein, a bovine derived superoxide dismutase, has been given by local injection, into the joints for degenerative joint disorders, but hypersensitivity reactions have limited its use. It has also been tried for the amelioration of adverse effects from radiotherapy. Forms of human superoxide dismutase derived by recombinant DNA technology have been developed.

Superoxide dismutases are also under investigation for their free-radical scavenging properties in a variety of conditions including the prevention of bronchopulmonary dysplasia in neonates.

Bronchopulmonary dysplasia. Use of sudismase in premature infants treated for respiratory distress syndrome did not prevent development of bronchopulmonary dysplasia (p.1500) in the first month.[1] However, treated infants subsequently showed a lower incidence of severe respiratory disease and hospitalisations in the first year, suggesting a reduction in chronic lung injury. The antioxidant was given intratracheally in a dose of 5 mg/kg every 48 hours as long as intubation and ventilation were necessary. A systematic review[2] was unable to reach a firm conclusion about the efficacy of superoxide dismutases in preventing chronic lung disease.

Motor neurone disease. A small percentage of patients with familial amyotrophic lateral sclerosis (see Motor Neurone Disease, p.2380) have been shown to have a mutation in the gene encoding for the enzyme copper-zinc superoxide dismutase but there has been no consensus as to whether patients with this mutation should be given superoxide dismutase supplements.[1]

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Tenoxicam). A yellow, polymorphic, crystalline powder. Practically insoluble in water; very slightly soluble in dehydrated alcohol; sparingly soluble in dichloromethane; it dissolves in solutions of acids and alkalis. Protect from light.

Stability. An admixture of tenoxicam 0.02% and ceftazidime 0.5% (as the sodium salt) in glucose injection 5% appeared stable when stored for up to 120 hours at 25° in glass bottles;[1] when stored in PVC bags, the admixture was stable for up to 72 hours at 25° and for up to 144 hours at 4°.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Incidence of adverse effects. Adverse effects associated with tenoxicam have been reviewed.[1] The majority of adverse effects relate to the gastrointestinal tract (11.4%), nervous system (2.8%), or skin (2.5%).

Gastrointestinal disturbances including nausea and vomiting (14.7%) and dyspepsia (2.3%), surgical site bleeding (4.3%), wound infection (2.7%), dizziness (5.7%), and headache (10.7%) were the most common adverse effects reported in a placebo-controlled study involving 1001 patients following the perioperative use of oral and intravenous tenoxicam.[2] It was noted, however, that the incidence of dizziness, nausea and vomiting, and headache was greater in the placebo group and that the difference in the incidence of dyspepsia between the 2 groups was not significant.

Effects on the kidneys. A review[1] of the effects of tenoxicam on renal function concluded that tenoxicam could be given at normal recommended doses to elderly patients or those with mild to moderate renal impairment who were not at high risk of renal failure or receiving potentially nephrotoxic therapy. Data from the manufacturer's database[1] on 67 063 patients, including 17 005 over 65 years of age, who had received tenoxicam indicated that there had been 45 adverse events relating to urinary system function, described as severe in 7. The prevalence of adverse events was similar in elderly and non-elderly patients, the most common effects being dysuria and renal pain.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Tenoxicam is well absorbed after oral doses; peak plasma concentrations occur within about 2 hours in fasting subjects; this may be delayed to about 6 hours when tenoxicam is given with food but the extent of absorption is not affected. It is also rapidly absorbed when given by intramuscular injection. Tenoxicam is about 99% protein bound and penetrates synovial fluid. The plasma elimination half-life ranges from 42 to 81 hours; with daily dosage, steady-state concentrations are reached within 10 to 15 days. Tenoxicam is completely metabolised to inactive metabolites which are excreted mainly in the urine; there is some biliary excretion of glucuronide conjugates of the metabolites.

Uses and Administration

Tenoxicam, a piroxicam (p.117) analogue, is an NSAID (p.99). It is used in the symptomatic management of musculoskeletal and joint disorders such as osteoarthritis and rheumatoid arthritis, and also in the short-term management of soft-tissue injury. Tenoxicam is given as a single oral daily dose usually of 20 mg. In acute musculoskeletal disorders treatment for up to 7 days is usually sufficient but in severe cases it may be given for up to a maximum of 14 days. Doses similar to those given orally have been given by intramuscular or intravenous injection for initial treatment for 1 or 2 days. Tenoxicam has also been given by rectal suppository.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tiaprofenic Acid). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol, in acetone, and in dichloromethane. Protect from light.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Tiaprofenic acid may cause cystitis, bladder irritation, and other urinary-tract symptoms (see below). It should not be given to patients with active urinary-tract disorders or prostatic disease or a history of recurrent urinary-tract disorders. It should be stopped immediately if urinary-tract symptoms occur and urinalysis and urine culture performed.

Tiaprofenic acid is contra-indicated in patients with severe hepatic or renal impairment.

Breast feeding. Although tiaprofenic acid is distributed into breast milk, the amount is considered by the *BNF* to be too small to be harmful to a breast-fed infant. Licensed product information also states that exposure to tiaprofenic acid via breast milk is unlikely to be of pharmacological significance; however, it is recommended that either treatment or breast feeding is stopped as necessary.

Effects on the urinary tract. Cystitis and bladder irritation have been associated with the use of tiaprofenic acid.[1-6] In August 1994 the UK CSM stated[4] that since the introduction of tiaprofenic acid in the UK in 1982 they had received 69 reports of cystitis and 32 other reports of urinary-tract symptoms associated with tiaprofenic acid including frequency, dysuria, and haematuria whereas only 8 cases of cystitis had been reported for all other NSAIDs combined. Analysis of spontaneous reports received by WHO[7] confirmed that cystitis was more commonly associated with tiaprofenic acid than with other NSAIDs. The Australian Adverse Drug Reactions Advisory Committee had received similar reports.[3] Since the 1994 warning, the CSM[8] had received reports of a further 74 cases of cystitis, but the majority of these had occurred before the warning was issued. The duration of treatment in patients affected had varied considerably. Most patients recovered when tiaprofenic acid was withdrawn.

The CSM recommended that tiaprofenic acid should not be given to patients with urinary-tract disorders and that it should be stopped in patients who develop urinary-tract symptoms. Patients should be advised that if they develop symptoms such as urinary frequency, nocturia, urgency, or pain on urination, or have blood in their urine they should stop taking tiaprofenic acid and consult their doctor. Older patients may be at increased risk.[9]

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Tiaprofenic acid is absorbed from the gastrointestinal tract with peak plasma concentrations being reached within about 1.5 hours after oral doses. It has a short elimination half-life of about 2 hours and is highly bound to plasma proteins (about 98%). Excretion of tiaprofenic acid and its metabolites is mainly in the urine in the form of acyl glucuronides; some is excreted in the bile. Tiaprofenic acid crosses the placenta and is distributed into breast milk.

Uses and Administration

Tiaprofenic acid, a propionic acid derivative, is an NSAID (p.99). It is used for the relief of pain and inflammation in musculoskeletal and joint disorders such as ankylosing spondylitis, osteoarthritis, and rheumatoid arthritis, in peri-articular disorders such as fibrositis and capsulitis, and in soft-tissue disorders such as sprains and strains. The usual oral dose is 600 mg daily given in 2 or 3 divided doses; in patients with cardiac, hepatic, or renal impairment, licensed product information suggests that the dose is reduced to 200 mg twice daily. A modified-release preparation may be available for once-daily use. Tiaprofenic acid has also been given rectally. It has been given intramuscularly as the trometamol salt in acute conditions.

Adverse Effects, Treatment, and Precautions

As for Opioid Analgesics in general, p.102.

Overdosage. Cyanosis, respiratory depression, and seizures developed in a 28-year-old woman after an overdose of a combination preparation of tilidine and naloxone.[1] The authors commented that the amount of naloxone included in the preparation, in order to prevent abuse, was insufficient to prevent respiratory depression after severe overdose.

Porphyria. Tilidine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with opioid analgesics, see p.103.

Pharmacokinetics

Tilidine is absorbed from the gastrointestinal tract. It is metabolised and excreted in the urine mainly as metabolites nortilidine (nortilidate) and bisnortilidine (bisnortilidate). Nortilidine is responsible for the analgesic activity of tilidine.

Uses and Administration

Tilidine hydrochloride is an opioid analgesic (p.104). It is used in the control of moderate to severe pain.

Tilidine hydrochloride may be given in usual oral doses of up to 50 mg four times daily. It has been given as a suppository, or by intravenous, intramuscular, or subcutaneous injection. Tilidine has also been given as the phosphate in modified release tablets. As a deterrent to abuse combined oral preparations of tilidine hydrochloride with naloxone hydrochloride are available in some countries.

Ph. Eur. 6.2 (Tolfenamic Acid). A white or slightly yellow crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol and in dichloromethane; soluble in dimethylformamide. It dissolves in dilute solutions of alkali hydroxides. Protect from light.

Adverse Effects, Treatment, and Precautions

As for NSAIDs in general, p.96.

Dysuria, most commonly in males and probably due to local irritation of the urethra by a metabolite, has been reported. Tremor, euphoria, and fatigue have also occurred. Tolfenamic acid is contra-indicated in patients with significant hepatic or renal impairment.

Breast feeding. Although tolfenamic acid is distributed into breast milk, the amount is considered by the *BNF* and licensed product information to be too small to be harmful to a breast-fed infant.

Effects on the lungs. Pulmonary infiltration has been associated with tolfenamic acid treatment in 6 patients.[1]

1. Strömberg C, *et al.* Pulmonary infiltrations induced by tolfenamic acid. *Lancet* 1987; **ii:** 685.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Tolfenamic acid is readily absorbed from the gastrointestinal tract. Peak plasma concentrations are reached about 60 to 90 minutes after an oral dose. Tolfenamic acid is about 99% bound to plasma proteins. The plasma half-life is about 2 hours. Tolfenamic acid is metabolised in the liver; the metabolites and unchanged drug are conjugated with glucuronic acid. About 90% of an ingested dose is excreted in the urine and the remainder in the faeces. Tolfenamic acid is distributed into breast milk.

Uses and Administration

Tolfenamic acid, an anthranilic acid derivative related to mefenamic acid (p.80), is an NSAID (p.99). In the treatment of acute attacks of migraine tolfenamic acid is given in a usual oral dose of 200 mg when the first symptoms appear; if a satisfactory response is not obtained this dose may be repeated once after 1 to 2 hours. Tolfenamic acid has also been given for the relief of mild to moderate pain in disorders such as dysmenorrhoea, rheumatoid arthritis, or osteoarthritis in doses of 100 to 200 mg three times daily.

Interactions

For interactions associated with NSAIDs, see p.99.

Pharmacokinetics

Tolmetin is almost completely absorbed from the gastrointestinal tract and peak plasma concentrations are attained about 30 to 60 minutes after ingestion. It is extensively bound to plasma proteins (over 99%) and has a biphasic plasma half-life of about 1 to 2 hours and 5 hours, respectively. Tolmetin penetrates synovial fluid and very small amounts are distributed into breast milk. It is excreted in the urine as an inactive dicarboxylic acid metabolite and its glucuronide and as tolmetin glucuronide with small amounts of unchanged drug.

Uses and Administration

Tolmetin sodium is an NSAID (p.99). It is used in musculoskeletal and joint disorders such as osteoarthritis and rheumatoid arthritis, including juvenile idiopathic arthritis. It is given orally as the sodium salt although doses are expressed in terms of the base; tolmetin sodium dihydrate 122.5 mg is equivalent to about 100 mg of tolmetin.

For the treatment of rheumatoid arthritis and osteoarthritis, the usual initial oral dose is the equivalent of 400 mg of tolmetin three times daily. Doses should be adjusted after 1 to 2 weeks according to response; maintenance doses of 600 mg to a maximum of 1800 mg daily in divided doses have been used.

For dosage details in children, see below.

Tolmetin as the free acid has been applied as a topical gel.

Administration in children. For the treatment of juvenile idiopathic arthritis in children aged 2 years and over, tolmetin sodium is given in initial oral doses equivalent to 20 mg/kg of tolmetin daily in three or four divided doses; maintenance doses of 15 mg/kg to a maximum of 30 mg/kg daily have been used.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tramadol Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in methyl alcohol; very slightly soluble in acetone. Protect from light.

Incompatibility. Some manufacturers state that tramadol hydrochloride injection 50 mg/mL is incompatible with injections of diazepam, diclofenac sodium, flunitrazepam, glyceryl trinitrate, indometacin, midazolam, piroxicam, and phenylbutazone if mixed in the same syringe. A study[1] also found tramadol hydrochloride injection (diluted to 400 micrograms/mL) to be incompatible with aciclovir and clindamycin when mixed together.

Stability. Oral suspensions of tramadol hydrochloride 5 mg/mL, prepared by mixing crushed tablets with a strawberry syrup and *Ora-Plus* (1:1) or with *Ora-Sweet* and *Ora-Plus* (1:1) were found to be stable for at least 90 days when stored either in the refrigerator or at room temperature.[1] Oral suspensions containing tramadol hydrochloride 7.5 mg/mL and paracetamol 65 mg/mL, prepared by mixing the crushed tablets of a combination preparation with the above vehicles, were also found to be stable for at least 90 days when stored under similar conditions.[2]

Dependence and Withdrawal

As for Opioid Analgesics, p.101.

Tramadol may have lower potential for producing dependence than morphine.

◊ A WHO expert committee[1] considered in 2003 that the available information on tramadol was not sufficient to warrant international control. Studies in *animals* indicated that tramadol produced little tolerance, had mild withdrawal symptoms, and a lower abuse potential than codeine and pentazocine. Subsequently, when reviewed in 2006, the committee[2] considered that, despite an increase in its use, tramadol continued to show a low level of abuse and concluded that there was not sufficient evidence to justify a further review.

Nevertheless, there have been reports[3-8] of dependence and abuse, particularly in opioid-dependent persons, and of withdrawal symptoms. In October 1996, the UK CSM[9] commented that since June 1994 they had received reports of drug dependence in 5 patients and withdrawal symptoms associated with tramadol in 28 patients, which corresponded to a reporting rate of about 1 in 6000. Doses in excess of the recommended maximum of 400 mg daily had been taken by 5 of the patients. The duration of treatment before onset of these effects ranged from 10 to 409 days (average 3 months). Withdrawal symptoms reported were typically those of opioid withdrawal in general. A more recent report from the Swedish Medical Products Agency[10] stated that between 1996 to 2005 they had received 71 reports of withdrawal symptoms associated with tramadol; treatment duration ranged from 1 week to over 3 years at daily doses of between 50 mg to 2 g.

Adverse Effects and Treatment

As for Opioid Analgesics in general, p.102.

Tramadol may produce fewer typical opioid adverse effects such as respiratory depression and constipation. In addition to hypotension, hypertension has occasionally occurred.

Effects on the CNS. The UK CSM[1] commented in February 1995 that since June 1994 they had received reports of 15 patients who had experienced *confusion* and/or *hallucinations* while taking tramadol. The majority of the reactions developed 1 to 7 days after starting treatment and in most patients resolved rapidly on withdrawal. It was noted that psychiatric reactions comprised about 10% of all reactions reported with tramadol.

In a later comment[2] in October 1996, the CSM noted that 27 reports of *convulsions* and one of worsening epilepsy had been received, which corresponded to a reporting rate of about 1 in 7000. Of the 5 patients receiving intravenous tramadol, 2 had been given doses equivalent to 1.45 and 4 g daily, well in excess of those recommended (see also Overdosage, below). Of the patients receiving oral tramadol, the majority were taking other drugs known to cause convulsions, including tricyclic antidepressants and SSRIs. A similar pattern has been reported in the USA[3] and Australia.[4-6]

A debilitating CNS-mediated reaction to an initial dose of tramadol has been described in a patient.[7] Symptoms, which lasted about 4 hours, included ataxia, dilatation of the pupils, numbness in all limbs, tremulousness, and dysphoria. Although the exact mechanism of the reaction was not known, it was suggested that since the patient was an extensive metaboliser with very high activity of the cytochrome P450 isoenzyme CYP2D6, high concentrations of the active *O*-desmethyl metabolite were the cause. The patient recovered with no sequelae. It is possible that this represents a case of the *serotonin syndrome*, since tramadol is known to be associated with this condition, particularly at high doses or when given with other drugs that raise serotonin concentrations.[4]

Effects on the respiratory system. Respiratory depression has been reported after tramadol infusion anaesthesia,[1] although in a postoperative study[2] tramadol had no significant respiratory depressant effect when equianalgesic doses of morphine, pentazocine, pethidine, piritramide, and tramadol were compared.

2. Fechner R, *et al.* Clinical investigations on the effect of morphine, pentazocine, pethidine, piritramide and tramadol on respiration. *Anasth Intensivmed* 1985; **26:** 126–32.

Overdosage. In a multicentre case series,[1] 126 cases of tramadol toxicity were reported between October 1995 and August 1996; of these, 87 involved exposure to tramadol alone. Common symptoms included lethargy, nausea, tachycardia, and agitation; seizures were also noted. Respiratory depression was seen in only 2 patients. The inhibitory effects of tramadol on monoamine reuptake, rather than its opioid effects, was considered to result in much of its toxicity. A similar pattern of toxicity has also been seen in a more recent report.[2] In 190 tramadol-only exposures reported between January 1999 and July 2001, the main symptoms of overdosage were CNS depression, nausea and vomiting, tachycardia, and seizures. Again, the incidence of respiratory depression was rare, with only 1 case reported.

Precautions

As for Opioid Analgesics in general, p.103.

Tramadol should be used with caution in patients with renal or hepatic impairment and should be avoided if renal impairment is severe. Removal by haemodialysis is reported to be minimal at 7%.

Tramadol should be used with care in patients with a history of epilepsy or those susceptible to seizures. See also Effects on the CNS under Adverse Effects, above.

Abuse. See under Dependence and Withdrawal, above.

Anaesthesia. Licensed product information warns against using tramadol during very light planes of general anaesthesia because of possible intra-operative awareness, although it may be used intra-operatively provided anaesthesia is maintained with a potent volatile or intravenous anaesthetic. Intra-operative awareness was reported in 65% of a group of 20 patients when used to provide analgesia during light general anaesthesia with nitrous oxide and intermittent enflurane.[1] However, in a study[2] of 51 patients given tramadol during stable light continuous isoflurane-nitrous oxide anaesthesia there was no clinically significant lightening of anaesthesia and others have commented that during extensive use of tramadol intra-operatively over several years, there had not been any incidence of recall in any patient treated at their clinic.[3]

Interactions

For interactions associated with opioid analgesics, see p.103.

Carbamazepine is reported to diminish the analgesic activity of tramadol by reducing serum concentrations.

The risk of seizures is increased if tramadol is used with other drugs that have the potential to lower the seizure threshold. See also Effects on the CNS under Adverse Effects, above.

Tramadol inhibits reuptake of noradrenaline and serotonin and enhances serotonin release and there is the possibility that it may interact with other drugs that enhance monoaminergic neurotransmission including lithium, tricyclic antidepressants, and SSRIs; it should not be given to patients receiving MAOIs or within 14 days of their discontinuation.

◊ Metabolism of tramadol is mediated by the cytochrome P450 isoenzyme CYP2D6. Use with specific inhibitors of this enzyme, such as *quinidine*, may increase concentrations of tramadol and lower concentrations of its active metabolite but the clinical consequences of this effect are unclear.

Anticoagulants. For reports of the effect of tramadol on oral anticoagulants, see Analgesics under Interactions of Warfarin, p.1427.

Antidepressants. For reference to possible cases of serotonin syndrome associated with use of tramadol and *SSRIs*, see Opioid Analgesics under Interactions of Fluoxetine, p.397.

5-HT$_3$-receptor antagonists. The pre-operative use of *ondansetron* has been noted to reduce the postoperative analgesic efficacy of tramadol.[1,2] In one study,[1] the cumulative dose of tramadol was up to 35% greater in those patients who also received ondansetron compared to those who received no antiemetic. In addition there was no difference in the incidence of postoperative nausea and vomiting between the two groups.

Pharmacokinetics

Tramadol is readily absorbed after oral doses but is subject to some first-pass metabolism. Mean absolute bioavailability is about 70 to 75% after oral use and 100% after intramuscular injection. Plasma protein binding is about 20%. Tramadol is metabolised by *N*- and *O*-demethylation via the cytochrome P450 isoenzymes CYP3A4 and CYP2D6 and glucuronidation or sulfation in the liver. The metabolite *O*-desmethyltramadol is pharmacologically active. Tramadol is excreted mainly in the urine, predominantly as metabolites. Tramadol is widely distributed, crosses the placenta, and appears in small amounts in breast milk. The elimination half-life is about 6 hours.

Uses and Administration

Tramadol hydrochloride is an opioid analgesic (p.104). It also has noradrenergic and serotonergic properties that may contribute to its analgesic activity. Tramadol is used for moderate to severe pain.

Tramadol hydrochloride is given by mouth, intravenously, or rectally as a suppository. The intramuscular route has also been used. It may also be given by infusion or as part of a patient-controlled analgesia system.

Usual oral doses are 50 to 100 mg every 4 to 6 hours. Tramadol hydrochloride may also be given orally as a modified-release preparation once or twice daily. The total oral daily dosage should not exceed 400 mg. Preparations containing tramadol hydrochloride with other analgesics such as paracetamol are also used.

A dose of 50 to 100 mg may be given every 4 to 6 hours by intramuscular or intravenous injection over 2 to 3 minutes, or by intravenous infusion. For the treatment of postoperative pain, the initial dose is 100 mg followed by 50 mg every 10 to 20 minutes if necessary to a total maximum (including the initial dose) of 250 mg in the first hour. Thereafter, doses are 50 to 100 mg every 4 to 6 hours up to a total daily dose of 600 mg.

Usual rectal doses by suppository are 100 mg up to 4 times daily.

For details of doses in children and in patients with hepatic or renal impairment, see below.

Administration in children. In the UK, tramadol hydrochloride is licensed for the management of moderate to severe pain in children 12 years of age and older; usual adult doses may be given (see above). However, in some other European countries it is licensed in younger children although the age range permitted can vary: for example, in *France*, a usual dose in those aged 3 years and over is 1 to 2 mg/kg orally, which may be repeated 3 or 4 times daily, whereas in *Germany*, similar doses are permitted in children as young as 1 year old. Tramadol has also been given parenterally to children in doses similar to those used orally.

Administration in hepatic or renal impairment. A dosage interval of 12 hours is recommended for tramadol usage in severe hepatic impairment. The dosage interval should also be increased to 12 hours in patients with a creatinine clearance (CC) less than 30 mL/minute; in the USA licensed product information suggests that the maximum oral dose should not exceed 200 mg daily in these patients. Tramadol should not be given to patients with more severe renal impairment (CC less than 10 mL/minute).

Pharmacopoeias. In *US.*

USP 31 (Trolamine Salicylate). A compounded mixture of trolamine and salicylic acid in propylene glycol. pH of a 5% solution in water is between 6.5 and 7.5. Store in airtight containers in a cool place.

Profile

Trolamine salicylate is a salicylic acid derivative used similarly to methyl salicylate (p.85) in topical rubefacient preparations in a concentration of 10 to 20% for the relief of muscular and rheumatic pain. It has also been used as a sunscreen.

Percutaneous absorption. In contrast to methyl salicylate, which undergoes considerable absorption and produces high subcutaneous and dermal concentrations of salicylic acid after application to intact skin, concentrations of salicylic acid after topical application of trolamine salicylate were substantially lower in tissue[1] and undetectable in serum.[2]

Profile

Valdecoxib is an NSAID (p.96) reported to be a selective inhibitor of cyclo-oxygenase-2 (COX-2). It was given orally in the treatment of osteoarthritis and rheumatoid arthritis, and for the pain of dysmenorrhoea. The risk of serious skin reactions with valdecoxib, in addition to its cardiovascular adverse effects (see below), prompted its general withdrawal worldwide in April 2005.

Effects on the cardiovascular system. The short-term use of parecoxib and valdecoxib after coronary artery bypass graft surgery has been associated with an increased risk of adverse effects such as myocardial infarction, deep-vein thrombosis, pulmonary embolism, and stroke.[1] When compared with patients in the placebo group, the risk of such effects was almost 4 times greater in those who had received intravenous parecoxib for 3 days followed by oral valdecoxib for the next 7 days. Those patients who received oral valdecoxib only for 7 days postoperatively had a non-significant increase in risk for adverse cardiovascular effects.

The adverse cardiovascular effects associated with valdecoxib treatment were one of the reasons the drug was generally withdrawn in April 2005.

1. Nussmeier NA, *et al.* Complications of the COX-2 inhibitors parecoxib and valdecoxib after cardiac surgery. *N Engl J Med* 2005; **352:** 1081–91.

Effects on the skin. Toxic epidermal necrolysis developed in a patient who took valdecoxib for 8 days, despite stopping the drug at the first signs of a rash and starting treatment with oral prednisolone;[1] the patient had a history of hypersensitivity to sulfonamides. Health Canada[2] noted in January 2004 that it had received 5 reports of serious cutaneous adverse reactions associated with valdecoxib over less than 1 year from marketing of the drug in December 2002. However, none of these were erythema multiforme, Stevens-Johnson syndrome, or toxic epidermal necrolysis although such reactions had been reported to other regulatory authorities. In December 2004, the EMEA[3] stated that it had received reports of all 3 reactions, as well as exfoliative dermatitis; most of them had occurred within the first 2 weeks of starting treatment and the incidence rate appeared greater for valdecoxib than other selective COX-2 inhibitors. The EMEA also noted that use of parecoxib (a prodrug of valdecoxib, see p.111) had been associated with erythema multiforme.

The increased risk of serious skin reactions with valdecoxib treatment was one of the reasons the drug was generally withdrawn in April 2005.

Adverse Effects and Precautions

The most common adverse effects reported with ziconotide have included dizziness, nausea and vomiting, nystagmus, abnormal gait, blurred vision, headache, elevated creatine kinase levels, and asthenia. Cognitive impairment, particularly confusion and impaired memory, is also very common, and typically develops after several weeks of treatment. Severe CNS symptoms such as hallucinations, paranoid reactions, speech disorders, aphasia, and decreased alertness may occur but convulsions, stroke, delirium, encephalopathy, and coma have been reported less commonly. Creatine kinase may be elevated, and monitoring of blood concentrations is recommended, but clinical myopathy or rhabdomyolysis is uncommon. Ziconotide may cause or exacerbate depression. Patients with a history of psychosis should not be treated with ziconotide.

Uses and Administration

Ziconotide is a synthetic form of a peptide derived from the venom of the cone shell *Conus magus* (a sea snail). It is reported to be a neurone-specific calcium-channel blocker. Ziconotide is given as a continuous intrathecal infusion in the management of severe chronic pain in patients who are intolerant of or refractory to more conventional treatments (see Choice of Analgesic, p.2).

Ziconotide is given intrathecally as the acetate; doses may be expressed in terms of the base or the acetate. In the EU, the initial dose (expressed in terms of the base) is 2.4 micrograms daily adjusted according to response, in increments of up to 2.4 micrograms, to a maximum daily dose of 21.6 micrograms. Licensed product information recommends that the interval between dose increases is at least 2 days. In the USA, the initial dose (expressed in terms of the acetate) should be no more than 2.4 micrograms daily, adjusted according to response. Dose increases of up to 2.4 micrograms two or three times a week are permitted, over a period of at least 3 weeks, up to a maximum daily dose of 19.2 micrograms.

Ziconotide has been tried in other conditions such as head trauma.

This chapter describes the important helminth or worm infections that occur in man (see Table 1, p.135) and the anthelmintics used to treat them.

Choice of Anthelmintic

Helminth infections are among the most common infections in man, affecting a large proportion of the world's population, mainly in tropical regions. In developing countries they pose a large threat to public health, and contribute to the prevalence of malnutrition, anaemia, eosinophilia, and pneumonia. Helminth infections causing severe morbidity include lymphatic filariasis (a cause of elephantiasis), onchocerciasis (river blindness), and schistosomiasis. These infections can affect the majority of populations in endemic areas with major economic and social consequences. WHO is making strenuous efforts to control a number of these infections in endemic areas. Control of these infections in both individuals and populations depends not only on the use of chemotherapeutic agents but also on preventing transmission by advice on food preparation and hygiene, the provision of adequate sanitation and sewage treatment (especially where sewage is used as fertiliser), the provision of safe potable water supplies, and effective vector control.

The worms that cause infection in man generally fall either into the phylum Nematoda, which includes the nematodes or roundworms, or into the phylum Platyhelminthes, which includes the cestodes or tapeworms and the trematodes or flukes.

The **nematodes** (or roundworms) are a large group of worms, some of which are capable of producing infections in man. In many cases man is the primary (definitive) host but human infections caused by parasites for which animals are the primary hosts also occur. Nematodes do not generally multiply in man; strongyloidiasis is an exception as re-infection can occur without environmental re-exposure. Nematode infections are most common in warm, moist climates, but some species of nematode can tolerate cool or arid conditions and infective forms can persist in the environment for long periods. An understanding of the life cycle of the infective species is necessary for diagnostic tests to be made at appropriate times, usually to coincide with the infective stage of the cycle, and for the choice of appropriate control measures.

The nematode infections can be divided into filarial infections, intestinal infections, and tissue infections.

Filarial nematodes are endemic in large areas of the tropics and produce considerable morbidity. The adult worms may live for several years, releasing large numbers of motile embryos known as microfilariae into the blood or skin, depending on the species. Transmission is usually by biting insects, which form the intermediate host. In some endemic areas multiple infections with filarial nematodes are common.

Filarial nematode infections include:

- loiasis
- lymphatic filariasis
- mansonella infections
- onchocerciasis.

Intestinal nematode infections (roundworms) are very common especially in developing countries in the tropics and subtropics. Children are particularly at risk and these infections contribute to morbidity through malnutrition, vitamin deficiencies, diarrhoea, anaemia, and pneumonia. Poor sanitation and sewage disposal perpetuate infections with soil-borne nematodes. Often several different worm infections are endemic in the same region, resulting in mixed infections. When this occurs, broad-spectrum anthelmintics may be used to reduce the overall infection burden in the population (see under Ascariasis, below).

Intestinal nematode infections include:

- angiostrongyliasis
- ascariasis
- capillariasis
- enterobiasis
- hookworm infections
- strongyloidiasis
- trichostrongyliasis
- trichuriasis.

The *tissue nematodes* represent a miscellaneous group causing a variety of pathological conditions in man. In cutaneous larva migrans and toxocariasis, the nematodes have a primary animal host and the human disease is caused by infection with infective larvae which do not subsequently mature in man. Trichinosis and gnathostomiasis affect a number of carnivorous animals and man is an incidental host. Syngamosis is primarily an infection of domestic fowl and wild birds although infection in man has been reported rarely. In dracunculiasis, man is the primary (definitive) host. Although these diseases are not generally fatal they cause a considerable degree of morbidity and treatment is complicated by the lack of effective, non-toxic systemic anthelmintics.

Tissue nematode infections include:

- angiostrongyliasis
- cutaneous larva migrans
- dracunculiasis
- gnathostomiasis
- syngamosis
- toxocariasis
- trichinosis.

The **cestodes** (flatworms, segmented worms, or tapeworms) cause infection in man in most parts of the world. Man may be the primary host, harbouring the adult worm in the intestine, or an intermediate host carrying the larval form. With the exception of *Hymenolepis nana* the adult worms do not usually multiply within the same host. However, larval forms may be produced and, as with infection or ingestion of these forms, systemic infection may develop.

Cestode infections include:

- cysticercosis
- diphyllobothriasis
- echinococcosis
- hymenolepiasis
- taeniasis.

Trematode (or fluke) infections are caused by parasitic worms of the class Trematoda. There are 4 categories of fluke which are pathogenic in man; the blood flukes *Schistosoma* spp., the intestinal flukes *Fasciolopsis, Heterophyes, Metagonimus,* and *Nanophyetus* spp., the liver flukes *Clonorchis*, *Fasciola*, and *Opisthorchis* spp., and the lung flukes *Paragonimus* spp. Symptoms are usually only seen in heavy infections and commonly include fever, pain, and eosinophilia.

Trematode infections include:

- intestinal fluke infections
- liver fluke infections
- lung fluke infections
- schistosomiasis.

Ancylostomiasis

See under Hookworm Infections, below. Larvae of *Ancylostoma* spp. are also a cause of cutaneous larva migrans (see below).

Angiostrongyliasis

Two forms of angiostrongyliasis are recognised and both are due to accidental infection with species of the animal nematode *Angiostrongylus.*

Infection with the larvae of the rat lungworm *A. cantonensis* causes an eosinophilic meningoencephalitis. Transmission follows ingestion of raw or undercooked snails or crustaceans, or of contaminated vegetables. The disease is generally self-limiting.

Intestinal infection with *A. costaricensis* can cause eosinophilic gastro-enteritis. It most commonly occurs in children after ingestion of vegetables contaminated by infected slugs. Surgical resection of the affected bowel may be necessary. Mebendazole and albendazole have been tried in the management of both these infections. However, anthelmintic drugs have not been shown to be effective and in *A. cantonensis* infection, severe host reaction to the dying larvae may result. Most patients will in fact have a self-limited course and recover completely. Symptomatic treatment with analgesics, corticosteroids, and removal of CSF may relieve pressure in *A. cantonensis* meningitis.[1]

Ascariasis

Ascariasis is an infection caused by *Ascaris lumbricoides*, the common or giant roundworm. The term roundworm is also applied to nematodes in general. It is usually an infection of the small intestine but on rare occasions there may be severe ectopic infections. It is commonly found in the tropics and especially in rural areas. Eggs are excreted in the faeces and can remain viable in moist soil for several years. On ingestion of mature eggs the larvae hatch and penetrate the intestinal wall. They migrate in the bloodstream via the liver to the lungs where they enter the alveoli. The larvae then move up the bronchial tree and are swallowed. The mature adult develops in the intestines, and it has been estimated that a gravid female is produced about 2 months after infection. The life span of the adult worm is 1 to 2 years. Ascariasis may be asymptomatic. When symptoms of intestinal infection do occur they include anorexia, abdominal pain, and diarrhoea; nutritional deficiency may result. The pulmonary stage may cause pneumonitis and bronchospasm often accompanied by eosinophilia. Heavy infections can cause intestinal or biliary obstruction. Migration of the worm from the small intestine can produce ectopic infection of the genito-urinary tract, lungs, liver, or heart. Such infections are rare but serious.

Treatment is with a benzimidazole carbamate derivative such as albendazole or mebendazole[1-3] with both drugs being equally highly effective. Pyrantel embonate[3] and levamisole are alternatives, while the potential of nitazoxanide for the treatment of ascariasis is being investigated.[1] Ivermectin has also been used.[2] Such broad-spectrum therapy can be useful if the patient is suffering from a mixed intestinal nematode infection. Drugs such as tiabendazole

NOTE: Infections due to worms marked with an asterisk may occur in temperate climates. Infections due to other worms are generally limited to tropical or localised areas, but may occur in travellers who have visited those areas.

with little or no activity against *Ascaris* should be avoided for the initial treatment of mixed infections since they may stimulate the worm to migrate to a different body site. Mass treatment programmes may be necessary in endemic areas to reduce the overall burden of disease.[1]

Capillariasis

Capillariasis is caused by infection with *Capillaria philippinensis,* a nematode endemic in the Philippines and southern Thailand. Infection in man is through eating raw or undercooked freshwater fish containing infective larvae. The larvae mature in the intestines and the adults produce both eggs and infective larvae so that auto-infection occurs and heavy infections can result. Symptoms are mostly gastrointestinal, with abdominal pain, vomiting, and severe prolonged diarrhoea leading to cachexia and muscle wasting. The infection has a mortality rate of between 20 and 30% if untreated. Prolonged treatment with mebendazole or, alternatively, albendazole, is necessary.[1]

Clonorchiasis

See under Liver Fluke Infections, below.

Cutaneous larva migrans

Cutaneous larva migrans (creeping eruption) occurs when man becomes infected with the larvae of animal hookworms, usually *Ancylostoma braziliense* or *A. caninum*, hookworms of cats and dogs. Other hookworms may also be involved or may cause other infections (see Hookworm Infections, below). The larvae penetrate the skin and then migrate causing characteristic trails in the skin. This migration can persist for several months and can be a source of intense pruritus. Occasionally larvae migrate to the lungs causing eosinophilia and pulmonary symptoms. Albendazole or ivermectin may be given by mouth and may be better tolerated than oral tiabendazole; tiabendazole can also be applied topically but is of limited value for multiple lesions.

Infection with *Gnathostoma spinigerum* or *Strongyloides stercoralis* can also cause cutaneous larva migrans (see Gnathostomiasis and Strongyloidiasis, below). Ocular and visceral larva migrans are features of toxocariasis (see below).

Cysticercosis

Infection with the pork tapeworm, *Taenia solium* may result in taeniasis (intestinal infection with adult tapeworms—see below) or cysticercosis (tissue infection with larval forms). Cysticercosis may develop after ingestion of *T. solium* eggs in food or water contaminated with infected human faecal material, or as a result of auto-infection in intestinal carriers of adult tapeworms. Ingested eggs release larvae that may penetrate the intestinal wall to be carried via the bloodstream to skeletal muscles, heart, eyes, brain, and spinal cord where they form encapsulated cysts (cysticerci). Human cysticercosis is associated with poverty and endemic in areas where hygiene is poor and sanitation inadequate.

Infection is typically subclinical, but symptoms may develop when the encysted larvae die and elicit an inflammatory reaction. Clinical features depend on the number, size, location, and stage of development of the cysticerci, as well as on the host's immune response. Cysts in the CNS (**neurocysticercosis**) may result in seizures and headaches, and are a common cause of epilepsy in endemic areas. Other symptoms include confusion, attention deficit, and ataxia. Hydrocephalus and intracranial hypertension may result from obstruction of CSF flow. Cysts in the spinal cord, eyes, or heart may also cause serious morbidity.

Treatment of neurocysticercosis consists of managing seizures with antiepileptics. Antiepileptics can usually be discontinued if patients have been seizure-free for more than 2 years.[1]

The use of anthelmintics in the treatment of neurocysticercosis remains controversial.[1-3] Live cysticerci usually do not provoke seizures whereas dead or dying parasites can elicit an inflammatory response, seizures, and transient neurological effects, hence treatment does not necessarily reduce seizure frequency. Patients with viable or degenerating parenchymal cysts and those with extraparenchymal cysts (such as subarachnoid cysts, including giant cysts and racemose forms) may benefit from anthelmintics.[1,3,4] Anthelmintics are of little or no benefit in patients with inactive, calcified lesions, and are contra-indicated in patients with cysticercotic encephalitis as they may exacerbate intracranial hypertension.[1,2] A double-blind, placebo-controlled study in patients with seizures due to viable parenchymal cysts confirmed that albendazole therapy (with dexamethasone) was safe and decreased the burden of parasites and the number of generalised seizures.[5] Albendazole is now considered to be the drug of choice, but praziquantel may also be used.[1,4,6] Adjunctive corticosteroids are recommended for parenchymal infections if there are numerous cysts, or if neurological symptoms or intracranial hypertension develops after starting treatment. Patients with subarachnoid cysticercosis should also be given adjunctive corticosteroids. However, use of corticosteroids with praziquantel may be complicated by a pharmacokinetic interaction— see Corticosteroids, under Interactions of Praziquantel p.154 for further details. If hydrocephalus is present, surgical removal of cysts or ventricular shunting may be indicated.[1] Detailed consensus guidelines for the treatment of neurocysticercosis have been developed.[2]

Prevention of infection with *T. solium* is possible by avoiding ingestion of undercooked pork and food and water contaminated with human faeces. Ideally, prevention measures should include adequate sanitation, sewage treatment, and abattoir inspection. Those already infected with *T.solium* and their close contacts should be treated with anthelmintics in order to interrupt or reduce the cycle of direct person-to-person transmission. Universal or selected treatment of human taeniasis with praziquantel has significantly reduced the prevalence in areas where *T. solium* infection is endemic.[3,7]

Diphyllobothriasis

Diphyllobothriasis is an intestinal infection with the fish tapeworm *Diphyllobothrium latum* and other *Diphyllobothrium* spp. and is acquired in man through ingestion of raw, infected, freshwater fish. The infection is rarely symptomatic. However, because the adult worm competes for vitamin B_{12}, some patients may develop megaloblastic anaemia with its associated neurological symptoms. Concentrations of other vitamins may also be reduced. Treatment is with a single dose of praziquantel; niclosamide is an alternative.[1] Vitamin supplements should also be given to correct any deficiencies.

Dracunculiasis

Dracunculiasis (dracontiasis, guinea-worm infection) is caused by infection with the nematode *Dracunculus medinensis*. It has been endemic in parts of Africa and Asia but is increasingly coming under control and the hope is that it will soon be eradicated.[1] The disease is transmitted through drinking water containing larvae that develop in freshwater crustaceans. The larvae penetrate the intestinal mucosa and mature in connective tissue. The adult female migrates to the subcutaneous tissues, normally of the legs, after about 1 year. Ulceration of the overlying skin releases larvae which are ingested by the crustacean host to complete the life cycle. The first symptom is the lesion caused by the emerging worm, although a generalised hypersensitivity reaction may also occur. Secondary infection is a common complication.

The most effective method of controlling dracunculiasis is by provision of safe drinking water. The WHO eradication campaign is based on health education, and the provision of safe water by measures including water treatment with pesticides such as temefos and encouraging the use of domestic filters.

There is no effective direct drug therapy against any stage in man. The traditional treatment is removal of the adult worm by gentle traction sometimes over several weeks. Metronidazole or tiabendazole may provide symptomatic benefit in the management of dracunculiasis although they have no direct anthelmintic effect. They are thought to act by weakening the anchorage of the worms within the subcutaneous tissues, thus allowing them to be removed more quickly.

Echinococcosis

Echinococcosis, or hydatid disease, in man is infection with the larval stage of the cestode *Echinococcus granulosus* or *E. multilocularis*. These two species cause distinct forms of the disease known as cystic echinococcosis and alveolar echinococcosis respectively. Various animals are involved in the transmission of the disease, man becoming infected through ingestion of eggs from contaminated faeces. The eggs hatch in the intestine and the embryos penetrate the intestinal wall and invade body organs, usually the liver. The embryo develops into a cyst which slowly increases in size and may remain intact for many years. Symptomatic infection usually only occurs when the cyst is large enough to cause obstruction or to compress adjacent structures, or if rupture occurs. Where possible, surgical removal of the intact cyst is the first line of treatment.

In **cystic echinococcosis**, drugs may be given locally or systemically before surgery to kill infective larvae within the cyst and reduce the risk of further infection. They are also given postoperatively if a cyst ruptures during surgery. Local injection of a larvicidal agent such as alcohol, cetrimide, or hypertonic saline has been used. Chemotherapy is also used as an adjunct or when surgery is not possible. The preferred drug for associated systemic treatment is albendazole. Mebendazole may be used, although some have suggested it is not as effective as albendazole. Praziquantel has also been reported to be effective. Albendazole may be a suitable alternative to surgery as initial treatment in uncomplicated cases; use with cimetidine (to inhibit its metabolism) may increase its effectiveness.

A further option when surgery is not possible is the PAIR (puncture/aspiration/injection/re-aspiration) procedure which consists of ultrasound-guided cyst puncture followed by aspiration of the cyst fluid, local injection of alcohol or hypertonic saline into the cyst, and re-aspiration of the cyst contents. Concomitant chemotherapy is recommended.

E. multilocularis infection (**alveolar echinococcosis**) is more invasive and is characterised by a tumour-like infiltrative growth; it usually requires both surgery and long-term treatment with a benzimidazole, such as albendazole, although some patients have improved on albendazole alone.

Enterobiasis

Enterobiasis is an infection with *Enterobius vermicularis* (pinworm, threadworm). It is one of the few intestinal nematodes which is common in temperate climates and is particularly common in young children. Like trichuriasis it is an infection of the large intestine and transmission follows ingestion or inhalation of mature eggs. The larvae mature in the gut in about 2 months. The eggs are not released into the gut contents but the mature female migrates to the anus at night and lays its eggs on the perianal and perineal skin. The eggs become infective within 6 hours. Diagnosis is based on detecting eggs around the anus. The most common symptom is perianal itching but many infections are asymptomatic. Rarely ectopic disease such as appendicitis or salpingitis may occur. The adult worm has a life span of about 6 weeks and, if re-infection can be prevented, the infection is self-limiting. While additional hygiene measures can prevent re-infection, treatment of the whole family with an anthelmintic should remain the main therapeutic response; more than one course may be required.

Treatment is with a benzimidazole carbamate derivative, such as albendazole or mebendazole, or with pyrantel embonate.[1] Such broad-spectrum therapy can be useful if the patient is suffering from a mixed intestinal nematode infection. Other anthelmintics used in enterobiasis include piperazine or pyrvinium embonate.

Fascioliasis

Fasciolopsiasis

Gnathostomiasis

Gnathostomiasis is an infection with, in most cases, the larval form of the nematode *Gnathostoma spinigerum*, although other *Gnathostoma* spp. have been identified. *G. spinigerum* inhabits the stomach of cats and dogs. Eggs shed in their faeces are ingested by freshwater crustaceans and hatch into larvae which are ingested by fish or other animals; man acquires the infection by consumption of the raw or undercooked flesh of these secondary hosts. Once ingested the larva penetrates the gut wall and migrates via the liver to other tissues including skin, eyes, and CNS. Rarely, dermal infiltration may result in cutaneous larva migrans (above).

The preferred treatment of gnathostomiasis is surgical removal of the gnathostome but this is rarely possible. Albendazole or, alternatively, ivermectin, may be used.[1]

Heterophyiasis

See under Intestinal Fluke Infections, below.

Hookworm infections

Infections with the hookworms *Ancylostoma duodenale* (ancylostomiasis) and *Necator americanus* (necatoriasis) are a major cause of iron-deficiency anaemia in large areas of the tropics and sub-tropics, especially in rural communities. Eggs deposited in warm moist soil hatch into larvae which develop further into the infective form. Infection is normally by penetration through the skin although it may be by ingestion. The larvae migrate to the lungs and are subsequently swallowed and mature to the adult form in the small intestine. Eggs appear in the faeces about 6 to 8 weeks after infection and the adult worm may live for several years. *A. duodenale* larvae are capable of remaining dormant in the tissues, only maturing to the adult when climatic conditions are favourable. Symptoms correspond to the stage of infection. Visitors to endemic areas may develop intense pruritus, erythema, and papulovesicular eruption at the site of infection, known as ground itch. Migration through the lungs during the first infection may cause pneumonitis and bronchospasm with accompanying eosinophilia. The main symptoms of intestinal infection are iron-deficiency anaemia and severe hypoalbuminaemia. In addition, abdominal pain, diarrhoea, and weight loss may occur.

Treatment is usually with a benzimidazole carbamate derivative such as mebendazole or albendazole,[1-3] and such broad-spectrum therapy can also be useful if the patient has a mixed intestinal nematode infection. Albendazole may be more effective than mebendazole.[4] Other anthelmintics used in hookworm infections include levamisole or pyrantel embonate,[2-4] but these may be less effective against *N. americanus* than against *A. duodenale*. Iron-deficiency anaemia caused by hookworm infections responds rapidly to oral iron therapy; folic acid supplements may be necessary in some patients. Mass treatment programmes may be necessary in endemic areas to reduce the overall burden of infection.[2,5]

Hymenolepiasis

Hymenolepiasis is an infection of the intestine with *Hymenolepis nana*, or dwarf tapeworm. Infection is acquired through ingestion of eggs in contaminated food or water or on hands and can be passed directly from person to person. It is more common in children. Clinical symptoms occur in heavy infections and include diarrhoea and abdominal pain. Treatment is with a single dose of praziquantel. Nitazoxanide may be used as an alternative.[1]

Intestinal fluke infections

The intestinal fluke infections **fasciolopsiasis**, **heterophyiasis**, **metagonimiasis**, and **nanophyetiasis** are caused by *Fasciolopsis buski*, *Heterophyes heterophyes* and some other *Heterophyes* spp., *Metagonimus yokogawai*, and *Nanophyetus salmincola* respectively. Fasciolopsiasis, heterophyiasis, and metagonimiasis are endemic in the Far East and Southeast Asia, and heterophyiasis is also common in the Middle East. Nanophyetiasis has occurred increasingly in the Pacific Northwest of the USA. Fasciolopsiasis is caused by the ingestion of infected aquatic plants, while undercooked or raw infected fish are the sources of *H. heterophyes*, *M. yokogawai*, and *N. salmincola* infections.

Fasciolopsiasis is usually asymptomatic, but heavy infections can cause diarrhoea, abdominal pain, and, rarely, intestinal obstruction and an allergic oedematous reaction. Metagonimiasis is also generally asymptomatic but may cause mild diarrhoea, while pain and mucous diarrhoea are common in heterophyiasis. Similar gastrointestinal symptoms plus eosinophilia occur in nanophyetiasis. Eggs of *M. yokogawai* and *H. heterophyes* may rarely penetrate the bowel wall and enter the bloodstream to be deposited in various organs, leading to serious complications such as heart failure or fatal embolism in the heart or brain.

Treatment of intestinal fluke infections is with praziquantel.[1,2]

Liver fluke infections

Fasciola hepatica, *Opisthorchis viverrini*, *O. felineus*, and *Clonorchis sinensis* are liver flukes transmitted by the ingestion of infected aquatic plants, grasses or water (*F. hepatica*), or raw or undercooked fish (*Opisthorchis* spp., *C. sinensis*). **Fascioliasis** is primarily a disease of sheep and cattle and human infections may occur wherever these animals are raised, whereas **clonorchiasis** and **opisthorchiasis** are seen mainly in Southeast Asia and eastern Europe.

Fascioliasis in the acute phase is usually characterised by fever, gastrointestinal symptoms, pain due to liver enlargement, and marked eosinophilia, but these symptoms decline as the worms enter their final habitat in the bile ducts. Acute symptoms occur rarely with clonorchiasis and opisthorchiasis and infections tend to be asymptomatic for many years. Adult flukes live in the bile ducts and symptoms of biliary-tract obstruction appear after repeated or heavy infections with liver flukes. Cholangiocarcinoma (bile-duct cancer) is now generally accepted to be associated with liver fluke infection although its exact pathogenesis is unclear.

Praziquantel is used for the treatment of most liver fluke infections.[1,2] Bithionol is more effective than praziquantel in fascioliasis and has been the preferred treatment, although in the USA the CDC considers triclabendazole to be the treatment of choice; dehydroemetine has also been used, and nitazoxanide[2] may be effective.

Praziquantel remains the treatment of choice for clonorchiasis and opisthorchiasis.[1,2] Albendazole is a suggested alternative for clonorchiasis.[2]

Loiasis

Loiasis is an infection with the filarial nematode *Loa loa* which occurs in areas of Central and West Africa. It is transmitted by the biting tabanid fly *Chrysops*. The infective larvae mature to adult worms which migrate through subcutaneous tissues and occasionally the subconjunctiva. Symptoms include pruritus, swelling, and pain, with occasional subcutaneous swellings, often on the arms or legs, that are characteristic of the disease. Passage of a worm through the subconjunctiva produces intense conjunctivitis. Eosinophilia may be severe, especially in visitors from non-endemic areas. Other complications include renal disease, endomyocardial fibrosis, encephalopathy, and peripheral neuropathy.

Diethylcarbamazine is used for treatment;[1] it is effective against the microfilariae, larval forms, and a proportion of adult worms. In some cases, treatment has been associated with acute encephalitis, particularly in patients with heavy microfilaraemia. It has been assumed that this is related to blockage of capillaries in the brain and meninges and for this reason small doses of diethylcarbamazine are given initially, with a corticosteroid and antihistamine, gradually increasing to full therapeutic doses over several days. However this does not eliminate the risk of encephalitis entirely and the role of the microfilariae in this syndrome has been questioned. Albendazole may be useful where diethylcarbamazine cannot be used, but repeated courses may be needed.[1] Some consider that ivermectin could be used[1] but, as with diethylcarbamazine, there is concern over its potential neurotoxic effects in patients with heavy microfilaraemia.

Diethylcarbamazine is also used for prophylaxis[1] but it has been suggested that it should be reserved for subjects at high risk of exposure. Vector control is regarded as impractical and methods aimed at reducing contact with the vector such as window screens and protective clothing are recommended.

Lung fluke infections

The lung fluke infection **paragonimiasis** is caused by *Paragonimus* spp., commonly *P. westermani*, and occurs in Asia, Africa, and Central or South America. The disease is transmitted by the ingestion of raw infected freshwater crabs or crayfish, or from drinking infected water.

The flukes mature in the lungs where they cause local necrosis, haemorrhage, inflammation, and fibrosis. Symptoms of paragonimiasis include fever, pain, and chest complaints, but most light to moderate infections are asymptomatic. The worms may also develop at other sites, particularly the brain where they can cause epilepsy, symptoms of cerebral tumours, or cerebral embolism, which may be fatal.

Treatment is with praziquantel or bithionol.[1] Triclabendazole has been studied.

Lymphatic filariasis

Lymphatic filariasis is a parasitic disease caused by filarial nematodes. The three species of filariae that cause lymphatic filariasis are *Wuchereria bancrofti* (bancroftian filariasis), *Brugia malayi*, and *B. timori* (brugian filariasis, also known as Malayan and Timorian filariasis respectively). Adult worms produce larvae (microfilariae) which enter the peripheral bloodstream and through mosquito vectors infective larvae may be transmitted from person to person. The larvae migrate from the skin to the lymphatic system where they mature into adult worms that may live for several years. Development of lymphatic filariasis requires multiple bites from infected mosquitoes over a prolonged period of time (months to years); consequently, people living in endemic areas are at greatest risk of developing the disease.

Filarial infection is usually contracted in childhood and most infections are initially asymptomatic, although nearly all those infected will have some degree of subclinical lymphatic and kidney damage. Infection may remain occult or species- and body-site-dependent symptoms may follow. Acute inflammatory reactions to immature and dead or dying adult worms in the lymphatic system are referred to as *adenolymphangitis*, and are characterised by episodic attacks of fever, malaise, and inflammation of the inguinal lymph nodes, testis, and spermatic cord, and focal lymphoedema. These acute episodes usually resolve spontaneously after about a week, but can recur several times a year. *Chronic filariasis* may develop 10 to 15 years after initial symptoms and results from recurrent inflammation with subsequent damage to the lymphatic system, leading to impaired lymph drainage and lymphoedema. Manifestations include mild to massive enlargement of the legs, arms, breasts, or genitals (testicular hydrocele or swelling of the vulva), chyluria, and elephantiasis (grossly swollen limbs with thickened, hard, rough, and fissured skin). Lymphangitis may result from secondary bacterial infections.

Occult filariasis refers to filarial infection in which microfilariae are not detected in the peripheral blood but may be found in other body fluids and tissues. It is rare and is thought to result from a hypersensitivity reaction to filarial antigens. Clinical manifestations include tropical pulmonary eosinophilia, glomerulopathies, endomyocardial fibrosis, filarial arthritis, and filarial granulomas in the breast.

There is no entirely satisfactory **treatment** for individuals with lymphatic filariasis. Current treatments are effective against microfilariae, and thus prevent disease transmission, but have little or no effect on the adult worms and do not halt the progression of symptoms once the disease has developed. Diethylcarbamazine removes circulating microfilariae and is partially effective against the adult worm and is considered the treatment of choice.[1] Treatment may trigger acute lymphangitis, and diethylcarbamazine should not be given during an acute episode as it may cause further worm death and thus exacerbate the inflammatory response. Ivermectin is only active against microfilariae and is mainly used in areas also endemic for onchocerciasis or loiasis. Albendazole plus either of these two drugs is considered to increase their effectiveness and such combinations are recommended for mass treatment programmes.[2] However, systematic reviews of randomised studies[3,4] found insufficient evidence to either confirm or reject the observation that albendazole with diethylcarbamazine or ivermectin is more effective than either drug given alone. Secondary infections with bacteria and fungi occur in poorly vascularised tissues and therefore rigorous hygiene, skin care, physiotherapy, and other measures to promote lymph flow in the affected areas are recommended; in some cases antibiotics are needed. Large hydroceles and scrotal elephantiasis are generally not reversible with drug therapy and usually require surgical intervention after a treatment course with diethylcarbamazine.

Filaria have been shown to contain *Wolbachia* endobacteria which are essential for larval development and adult worm fertility and viability. This symbiotic dependency has provided a new approach in the treatment of filariasis, and oral doxycycline for 8 weeks has resulted in a reduction in adult worms and prolonged reduction in microfilaraemia.[5]

Tropical pulmonary eosinophilia responds to a 3-week course of diethylcarbamazine but patients may relapse and require re-treatment. Filarial arthritis responds rapidly to treatment with diethylcarbamazine.

In communities where lymphatic filariasis is endemic **mass treatment** of the entire community is the basis of the Global Programme to Eliminate Lymphatic Filariasis.[2] The primary goal is to eliminate microfilariae from the blood of infected individuals thereby interrupting transmission. The programme recommends a single dose of 2 drugs (albendazole plus either diethylcarbamazine or ivermectin) given once-yearly for 4 to 6 years.[2,3] Albendazole plus ivermectin is used in areas where onchocerciasis or loiasis are also endemic. An alternative approach is the use of diethylcarbamazine-medicated salt for 6 to 12 months throughout the community at risk.

Ongoing **vector control** should be carried out before or during peak transmission season, in order to consolidate the effects of mass chemotherapy. People living in or visiting endemic areas are advised to sleep under a mosquito net and use mosquito repellent on exposed skin between dusk and dawn.

Mansonella infections

Infections with the filarial nematodes *Mansonella perstans*, *M. ozzardi*, and *M. streptocerca* are generally asymptomatic but symptoms including malaise, fever, joint pain, and meningeal symptoms have been described. Infection is transmitted by biting midges and flies. Treatment with diethylcarbamazine may be effective depending on the infecting species (although it has no effect in *M. ozzardi* infections[1]). Mebendazole may be effective alone[1] or with levamisole or diethylcarbamazine[2] in *M. perstans*; albendazole is considered the drug of choice in this infection.[1] Ivermectin has been suggested for *M. ozzardi* infections[1] and may be the drug of choice for *M. streptocerca.*

Onchocerciasis

Onchocerciasis (river blindness) is a parasitic disease caused by infection with the filarial nematode *Onchocerca volvulus*. It is endemic in large areas of West and Central Africa, areas of Latin America, and Yemen. It is particularly prevalent near fast flowing rivers, the breeding ground of the blackfly which is the vector of the parasite. After infection, the larvae mature into adult worms in fibrous nodules, usually in the subcutaneous tissue. The adult female worms release large numbers of microfilariae which migrate from the nodules into other tissues, most notably the skin and the eyes. Death of microfilariae in the eyes causes severe inflammation and scarring that may lead to lesions in the eyes and impaired vision. There is some evidence that antigens released from symbiotic *Wolbachia* bacteria within the microfilariae also play a role.[1-3] Repeated infection over several years may result in irreversible blindness. In the skin the dying microfilariae trigger a subcutaneous inflammatory response that causes intense itching. Over time the skin becomes swollen and thickened (lizard skin) and may lose some of its elasticity and pigment (leopard skin).

Onchocerciasis is controlled either by treating the infected patient, thereby reducing the transmission of the infection from the human host to the vector, or by interrupting the transmission from vector to human. The drug of choice for the **treatment** of onchocerciasis is ivermectin.[2-5] A single oral dose of ivermectin rapidly eliminates microfilariae from the skin and more gradually eliminates them from the cornea and anterior chamber of the eye.[4] It has little effect on the adult worms although it suppresses release of microfilariae for several cycles. Ivermectin therefore only controls the disease; it does not cure or eradicate it. Control of the disease in endemic areas relies upon the use of ivermectin every 12 months in Africa (and every 6 months in Central and South America) and this may be combined with vector control (below). Because the adult worms live for about 15 years, treatment will need to be continued for many years. Ivermectin is donated by *Merck* through the Mectizan Expert Committee (MEC) for human use in *community-wide mass treatment programmes* in all countries in which onchocerciasis is endemic, where it is given to all but pregnant women, breast-feeding mothers of recently born babies, children weighing less than 15 kg, and those unable to walk or otherwise seriously ill.[6] For further details, see under Ivermectin, p.146. Increasing the frequency of the standard doses of ivermectin to every 3 months appears to increase efficacy compared with annual treatments.[7] Evidence from Ghana suggests that ivermectin-resistant populations of parasites are emerging and that its ability to suppress skin microfilariae repopulation is reduced over time in some communities.[8]

In areas where onchocerciasis and loiasis are co-endemic, care should be taken because ivermectin may cause serious adverse effects, including encephalopathy, in some patients with high *Loa loa* microfilaraemias (see Incidence of Adverse Effects, under Ivermectin, p.145). The Mectizan Expert Committee and the Technical Consultative Committee[9] have implemented recommendations for ivermectin mass treatment programmes of onchocerciasis in areas co-endemic for loiasis.

Before the introduction of ivermectin in 1988, diethylcarbamazine was the usual treatment for onchocerciasis, but it is no longer recommended by WHO.[4] The major limitations to its use are the severe allergic reaction (the Mazzotti reaction) associated with its microfilaricidal action, aggravation of existing ocular lesions or precipitation of new ones, and the need to give repeated courses of treatment for continued suppression of the disease.[4] Suramin has also been used in the treatment of onchocerciasis and is effective against adult worms.[4] However, its use is restricted because of its toxicity. Moxidectin is an anthelmintic used in veterinary medicine and is currently being evaluated for human use.[10] Amocarzine has also been evaluated in onchocerciasis.[4]

Recently it has been shown that adult worms contain *Wolbachia* endobacteria, which are essential for adult worm fertility and viability. This symbiotic dependency on *Wolbachia* has provided a new approach in the treatment of onchocerciasis. Treatment with oral doxycycline daily for 6 weeks has been shown to sterilise adult worms for the 4-month study period.[11] When given with a single dose of ivermectin, embryogenesis is interrupted for at least 18 months.[12] The long doxycycline treatment regimen is not suitable for mass treatment programmes, but it may be used with ivermectin for treatment of patients who permanently leave an endemic area.

In non-endemic areas ivermectin may be given every 3 to 6 months depending on the recurrence of symptoms or presence of microfilariae.

Vector control with larvicides, continued for the life span of an adult worm, is used to interrupt the transmission of infection and was the main strategy for onchocerciasis control before the introduction of ivermectin. However, despite initial success fly re-invasion became a problem, as the flight range of the vector was longer than expected.[13]

Schistosomiasis

Schistosomiasis (bilharziasis) is a parasitic infection caused by *Schistosoma* spp., largely *S. mansoni*, *S. japonicum*, and *S. haematobium*, and to a lesser extent *S. intercalatum* and *S. mekongi*. The disease is seen mainly in Africa, Asia, South America, and the Caribbean, where it is a hazard to individuals exposed to fresh water containing the intermediate host, infected freshwater snails.

Free-swimming cercariae are released from the snail and penetrate human skin causing a pruritic papular rash in sensitised individuals (swimmer's itch). Parasites mature in the lungs and liver within about 6 weeks, then migrate to the blood vessels, the bladder, or intestines. Mature female worms produce eggs which are excreted in urine or stools, or become lodged in tissues, and immunological reaction to these eggs results in disease. The acute reaction to egg deposition has been termed Katayama fever, a self-limiting but sometimes fatal illness resembling serum sickness and most frequently seen in *S. japonicum* infection. The chronic phase of infection is often asymptomatic for many years, but usually results in granuloma formation and fibrosis in tissues where eggs are deposited, such as the liver, lungs, intestines, or urinary tract, the site depending on the infecting species.

Praziquantel is used for the treatment of chronic schistosomiasis[1-6] and is effective against all species of schistosomes. Metrifonate and oxamniquine have been used as alternatives against *S. haematobium*[1,2] and *S. mansoni*[1,3-5] respectively. Artemisinin derivatives used alone or in combination with praziquantel are also under investigation for *S. mansoni* infection[6-8] and *S. haematobium*.[9]

Niclosamide is used as a molluscicide for the treatment of water in schistosomiasis control programmes. Copper sulfate or sodium pentachlorophenate have also been used but to a lesser extent.

Schistosomiasis vaccines are in development.

Strongyloidiasis

Strongyloidiasis[1] is an infection of the small intestine caused by *Strongyloides stercoralis*, known as threadworm in the USA. It generally occurs in the tropics and subtropics and can also occur in some areas of South and East Europe, Japan, and the USA. In contrast with other intestinal nematodes, the eggs of *S. stercoralis* hatch before leaving the gastrointestinal tract, and can cause autoinfection, particularly in immunocompromised patients. Larvae reaching the soil can either mature into free-living adults or remain in an infective larval stage. Infective larvae cause infection by penetrating the skin. The larvae migrate to the lungs, move up the bronchial tree to be swallowed, and finally penetrate the mucosa of the small intestine where they mature. Eggs are deposited about 28 days after initial infection.

Infection may be asymptomatic, but commonly patients have symptoms relating to the stages of infection. Penetration of larvae through the skin causes intense pruritus and an erythematous rash. The rash may follow the course of migration and is one of the causes of cutaneous larva migrans (above). An inflammatory response to migration through the lungs may be seen and may include pneumonitis and bronchospasm. In heavy infections, which are most common in immunocompromised patients as a result of autoinfection, massive pulmonary invasion can occur resulting in fatal alveolar haemorrhage. Abdominal symptoms include colicky pain, diarrhoea, and vomiting, leading to nutritional deficiencies and weight loss. Eosinophilia may also be present. Disseminated disease may occur in immunocompromised patients and produce severe pulmonary and abdominal symptoms, shock, encephalopathy, meningitis, and Gram-negative septicaemia. Since strongyloidiasis is commonly fatal in these patients, vulnerable patients from endemic areas should be screened regularly and treated promptly at the first sign of infection.

Ivermectin is considered to be the treatment of choice.[1,2] Tiabendazole was widely used, and still is in some countries, but albendazole is more effective and better tolerated. Mebendazole has also been suggested but it must be given for longer periods than albendazole since it has only a limited effect on migrating larvae. A combination of ivermectin and albendazole has been suggested in disseminated disease.[2] These broad-spectrum anthelmintics (except tiabendazole) are also useful if the patient is suffering from a mixed intestinal nematode infection.

Syngamosis

Syngamosis, or gapeworm infection, is caused by *Syngamus* and *Mammomonogamus* spp. and is mainly an infection of domestic fowl and wild birds and mammals, although infection in man has been reported very rarely.[1-6] Man may become infected by eating foods contaminated with infective larvae which penetrate the intestinal wall and migrate to the lungs, where they mature into adult worms. The major symptom is cough, due to irritation of the bronchi and increased mucus production. The infection may be confused with asthma. Tiabendazole and mebendazole have been used successfully to treat the infection in man.

Taeniasis

Taeniasis is an infection of the intestine with beef tapeworm, *Taenia saginata*, or pork tapeworm, *T. solium*, acquired through ingestion of contaminated raw or undercooked meat. The larval form of *T. solium* can cause the systemic infection cysticercosis (see above).

Infection with the adult worm usually produces symptoms only when the worm reaches a size that can cause obstruction or related problems. Segments of the worm containing eggs may be excreted in the faeces so maintaining the cycle of reproduction. Treatment is with a single dose of praziquantel,[1] which has the advantage of also being active, in higher doses, against the larval form of *T. solium*. Niclosamide is also effective but is only active against adult worms.

1. Abramowicz M, ed. *Drugs for parasitic infections*. 1st ed. New Rochelle NY: The Medical Letter, 2007.

Toxocariasis

Toxocariasis[1] is infection with the larval form of *Toxocara canis* or, less commonly, *T. cati*. The adult worms live in the intestines of dogs and cats respectively, and man becomes infected when eggs excreted in animal faeces are ingested. Once ingested the eggs hatch and the larvae migrate from the intestine to other organs, most commonly the liver, lung, and eye. Most infections are asymptomatic but two clinical syndromes, ocular larva migrans and visceral larva migrans, can occur, usually in children.

Ocular larva migrans occurs when larvae invade the eye causing a granuloma which may impair vision and can cause blindness. There is no specific treatment.[2] Anthelmintics such as albendazole or tiabendazole, corticosteroids, ocular surgery, and laser photocoagulation have been used but assessment of their efficacy is difficult because of the variable natural course of the disease.

The clinical symptoms of visceral larva migrans depend upon the organs involved but commonly include cough, wheezing, fever, and hepatomegaly. Encephalitis and seizures may occur and there is usually eosinophilia. Acute infection normally resolves without treatment.[3] However, severe or prolonged infections may be treated with albendazole;[4] mebendazole or tiabendazole have also been used.[1,4]

Trichinosis

Trichinosis (trichinellosis) is an infection caused by *Trichinella spiralis.* Man becomes infected through ingestion of raw or undercooked meat, usually pork, containing infective larvae. The larvae mature into adult worms in the small intestine and the mature females deposit larvae which migrate in the blood to skeletal muscle and sometimes to the myocardium. Symptoms usually occur only in heavy infections. Invasion of the intestines by the maturing adult worms can cause diarrhoea, abdominal pain, and vomiting followed about a week later by hypersensitivity reactions to the migrating larvae. These may include eosinophilia, fever, muscle pain, periorbital oedema and, more rarely, encephalitis, myocarditis, or pneumonia which may be fatal.

All patients with confirmed or suspected infection should be treated to prevent the continued production of larvae. Albendazole or mebendazole are considered to be the anthelmintics of choice. A corticosteroid should be given for severe hypersensitivity reactions.[1]

Trichostrongyliasis

Trichostrongyliasis is an infection of the small intestine caused by *Trichostrongylus* spp. including *T. colubriformis*. *Trichostrongylus* spp. are normally parasites of herbivores, but infections in man have been found. They have a similar life cycle to *Ancylostoma duodenale* (see Hookworm Infections, above). Pyrantel embonate, albendazole, or mebendazole are recommended for the treatment of trichostrongyliasis.[1] Successful treatment with ivermectin has occurred in areas where widespread use of benzimidazole carbamate derivatives in grazing animals has led to resistance to these drugs.[2]

Trichuriasis

Trichuriasis is an infection of the large intestine with *Trichuris trichiura*, sometimes known as whipworm. Distribution is worldwide, but most infections occur in the tropics and subtropics. Eggs are excreted in the faeces and can remain viable in the soil for extended periods. Under optimum conditions the eggs become infective in about 2 to 4 weeks. After ingestion, larvae are released from the eggs and develop within the wall of the small intestine for about 3 to 10 days, before migrating to the lumen of the large intestine where they remain attached to the mucosal lining. Eggs are detectable in the faeces about 1 to 3 months after infection. Trichuriasis is often asymptomatic, but heavy infection can result in anaemia, diarrhoea, and rectal prolapse.

Treatment is with a benzimidazole carbamate derivative such as albendazole or mebendazole[1-3] and such broad-spectrum therapy can be useful if the patient is suffering from a mixed intestinal nematode infection. Ivermectin[2] and nitazoxanide[4] are alternatives. However, a systematic review[3] considered the treatment of trichuriasis to be unsatisfactory with current drugs.

Adverse Effects and Precautions

As for Mebendazole, p.148.

Incidence of adverse effects. Although generally well-tolerated, the following adverse reactions were reported in the first phase of WHO-coordinated studies[1] involving 30 patients given *high-dose* therapy with albendazole for the treatment of cystic echinococcosis (hydatid disease): raised serum-transaminase levels (2 patients), reduced leucocyte counts (1), gastrointestinal symptoms (1), allergic conditions (1), and loss of hair (1). Treatment was stopped in a further patient with alveolar echinococcosis because of depressed bone-marrow activity. In the second phase of these studies,[2] of 109 patients given albendazole for cystic echinococcosis, 20 had adverse effects; similar findings were reported with mebendazole. The range of effects with albendazole was: elevation of transaminases (5 patients), abdominal pain and other gastrointestinal symptoms (7), severe headache (4), loss of hair (2), leucopenia (2), fever and fatigue (1), thrombocytopenia (1), and urticaria and itching (1). Albendazole had to be withdrawn in 5 patients because of adverse effects, although in 3 the withdrawal was only temporary.

Effects on growth. A multiple-dose regimen of albendazole in children with asymptomatic trichuriasis has been reported to be associated with impaired growth in those with low levels of infection.[1] However it was considered that this should not prevent the use of single doses in mass treatment programmes.[2]

2. Winstanley P. Albendazole for mass treatment of asymptomatic trichuris infections. *Lancet* 1998; **352:** 1080–1.

Effects on the liver. In a series of 40 patients given albendazole for echinococcosis, 7 developed abnormalities in liver function tests during therapy.[1] Six had a hepatocellular type of abnormality attributable to albendazole; the seventh had cholestatic jaundice which was probably not due to albendazole. See also Incidence of Adverse Effects, above for reports of raised serum-transaminase levels.

Albendazole should only be used in the treatment of echinococcosis if there is constant medical supervision with regular monitoring of serum-transaminase concentrations and of leucocyte and platelet counts. Patients with liver damage should be treated with reduced doses of benzimidazole carbamates, if at all.[2]

Pregnancy. Albendazole is teratogenic in some *animals* and there are no adequate and well controlled studies in human pregnancy. Albendazole is therefore usually contra-indicated during pregnancy and licensed product information cautions against becoming pregnant while taking albendazole or within one month of completing treatment.

Interactions

Anthelmintics. The plasma concentration of albendazole sulfoxide has been increased by *praziquantel*,[1] although the practical consequences of this were considered uncertain.

1. Homeida M, *et al.* Pharmacokinetic interaction between praziquantel and albendazole in Sudanese men. *Ann Trop Med Parasitol* 1994; **88:** 551–9.

Antiepileptics. *Phenytoin*, *carbamazepine*, and *phenobarbital* appear to induce the oxidative metabolism of albendazole via the cytochrome P450 isoenzyme CYP3A by roughly the same extent, resulting in significantly reduced concentrations of albendazole sulfoxide. This interaction is likely to be clinically significant when albendazole is used to treat systemic worm infections, and increased doses of albendazole would be needed.[1] The interaction is probably not clinically significant when albendazole is used for intestinal worm infections.

Corticosteroids. Plasma concentrations of the active metabolite of albendazole (albendazole sulfoxide) were reported to be raised by about 50% in a study in 8 patients receiving *dexamethasone*.[1]

Histamine H_2-antagonists. Concentrations of albendazole sulfoxide have been found to be raised in bile and hydatid cyst fluid when albendazole was given with *cimetidine*, which may increase effectiveness in the treatment of echinococcosis.[1]

Pharmacokinetics

Absorption of albendazole from the gastrointestinal tract is poor but may be enhanced by a fatty meal. Albendazole rapidly undergoes extensive first-pass metabolism. Its principal metabolite albendazole sulfoxide has anthelmintic activity and a plasma half-life of about 8.5 hours. Albendazole sulfoxide is widely distributed throughout the body including into the bile and the CSF. It is about 70% bound to plasma protein. Albendazole sulfoxide is eliminated in the bile; only a small amount appears to be excreted in the urine.

Uses and Administration

Albendazole is a benzimidazole carbamate anthelmintic structurally related to mebendazole (p.148) and with similar activity. It is used in relatively high doses in the treatment of the cestode infections cysticercosis and echinococcosis (hydatid disease). In some countries albendazole is used in the treatment of single and mixed intestinal nematode infections including ascariasis, enterobiasis, hookworm, strongyloidiasis, and trichuriasis. It may also be used in the treatment of angiostrongyliasis, capillariasis, gnathostomiasis, and trichostrongyliasis. Albendazole may be effective in the treatment of the tissue nematode infections cutaneous larva migrans, toxocariasis, and trichinosis and has been tried in loiasis, and, with other anthelmintics, in mass treatment programmes in areas where lymphatic filariasis is endemic. For discussions of these infections and their treatment, see under Choice of Anthelmintic (p.134), and under the individual headings below.

In the treatment of **echinococcosis**, albendazole is given orally with meals in a dose of 400 mg twice daily for 28 days for patients weighing over 60 kg. A dose of 15 mg/kg daily in two divided doses (to a maximum total daily dose of 800 mg) is used for patients weighing less than 60 kg. For cystic echinococcosis, the 28-day course may be repeated after 14 days without treatment to a total of 3 treatment cycles. For alveolar echinococcosis, cycles of 28 days of treatment followed by 14 days without treatment may need to continue for months or years.

In the treatment of **neurocysticercosis**, US licensed product information recommends doses of albendazole for parenchymal cysts similar to the doses used in echinococcosis (see above); the recommended duration of treatment is 8 to 30 days. Current expert opinion also favours similar doses of 15 mg/kg daily but with a duration of treatment of only 8 days for parenchymal disease and about 1 month for subarachnoid disease. For further information on dosage regimens, see Cysticercosis, below.

Albendazole is given orally, usually as a single dose, in the treatment of single or mixed **intestinal nematode infections**. The usual dose for adults and children aged 2 years or over with ascariasis, enterobiasis, hookworm infections, or trichuriasis is 400 mg as a single dose. In enterobiasis, the dose may be repeated in 1 to 4 weeks. Some consider that children of 1 to 2 years of age may be given 200 mg for enterobiasis. In strongyloidiasis, 400 mg is given once or twice daily for 3 consecutive days; this may be repeated after 3 weeks if necessary.

Albendazole has also been used to treat **giardiasis** (p.824); suggested doses are 400 mg daily by mouth for 5 days.

Ascariasis. Albendazole is used as an alternative to mebendazole in the treatment of ascariasis (p.134). Both drugs are equally highly effective with a cure rate greater than 98% reported for albendazole in one study.[1]

Capillariasis. Albendazole in a dose of 400 mg daily for 10 days has been suggested[1] as an alternative to mebendazole for the treatment of capillariasis (p.135).

Cutaneous larva migrans. Albendazole has been reported[1-4] to be effective in the treatment of cutaneous larva migrans (p.135) and is an alternative to tiabendazole or ivermectin. Albendazole, generally in a dose of 400 mg daily for three[1] or five[2] days, has alleviated the discomfort of cutaneous larva migrans; treatment for seven days may be more effective and has not been associated with an increased incidence of adverse effects.[4] A single dose of 400 mg has also been effective.[3] An ointment containing albendazole 10%, applied 3 times a day for 10 days, was reported to be effective in treating cutaneous larva migrans in 2 young children.[5]

Cysticercosis. The use of anthelmintics in the treatment of neurocysticercosis (see Cysticercosis, p.135) remains controversial, but if indicated albendazole is considered to be the drug of choice.[1-3] The dose of albendazole originally used was the same as that used in echinococcosis, typically about 15 mg/kg daily orally for 1 month. There is now some evidence that shorter courses of treatment may be appropriate in some forms of neurocysticercosis. A study[4] confirmed that a 10-day course of albendazole 400 mg twice daily, together with dexamethasone, was safe and decreased the burden of parasites and the number of generalised seizures in patients with viable parenchymal cysts. Albendazole has also been reported to be effective for extraparenchymal infection, such as subarachnoid, ventricular,[2,5,6] and spinal cord cysticercosis,[2] but the longer treatment period of 1 month with a dose of 15 mg/kg daily is usually used. Alternatively, a higher dose of albendazole for a shorter time may be considered. A study[5] of 36 patients with subarachnoid and intraventricular cysticercosis found that 30 mg/kg daily for 8 days was safe and more effective than 15 mg/kg daily for 8 days, both regimens being given with corticosteroids.

Echinococcosis. Albendazole is used in the treatment of echinococcosis (p.136) as an adjunct to, or instead of, surgery. It is generally preferred to mebendazole.

Hookworm infections. Hookworm infections (p.136) are commonly treated with benzimidazole carbamates such as albendazole. In 77 patients with light necatoriasis (*Necator americanus* infection) albendazole, in a single 400-mg dose, produced an 84% cure rate and an 82% reduction in egg count in those patients not cured.[1] In another study,[2] although the cure rate was only 56.8% after a single 400-mg dose of albendazole this was superior to treatment with mebendazole which had a cure rate of 22.4%. A further study[3] comparing albendazole with mebendazole and pyrantel in the treatment of necatoriasis also found albendazole to be the most effective.

Albendazole is given in mass treatment programmes to reduce the overall burden of infection.[1,4]
