Effects on electrolytes. Hyperkalaemia and hyperphosphataemia may occur in patients receiving recombinant human erythropoietin. However, hypophosphataemia has also been reported in cirrhotic patients given erythropoietin before autologous blood donation.[1]

1. Kajikawa M, *et al.* Recombinant human erythropoietin and hypophosphatemia in patients with cirrhosis. *Lancet* 1993; **341:** 503–4.

Effects on mental function. Visual hallucinations occurred in 4 patients during treatment with recombinant human erythropoietin, stopped when treatment was withdrawn, and recurred in 2 patients when erythropoietin was reinstituted.[1] Commenting on these and a further 7 cases,[2] the manufacturers considered the reaction to be extremely rare and that the contribution of concurrent medication could not be discounted. In two groups of dialysis patients treated with recombinant human erythropoietin, 15 of 134 and 2 of 103 experienced visual hallucinations.[3] Increasing age appeared to be a risk factor. Hallucination, associated with hypertension, has occurred during epoetin therapy in a patient with a history of bone marrow transplantation.[4]

4. van den Bent MJ, *et al.* Erythropoietin induced visual hallucinations after bone marrow transplantation. *J Neurol* 1999; **246:** 614–16.

Effects on the skin. Skin rashes may occur during treatment with recombinant human erythropoietin.

Pseudoporphyria cutanea tarda, a photosensitivity disorder, has been reported in 2 children undergoing peritoneal dialysis and receiving erythropoietin.[1] However, it was pointed out that this disorder has occurred in adults undergoing dialysis and the children were also receiving other potential photosensitisers.

1. Harvey E, *et al.* Pseudoporphyria cutanea tarda: two case reports on children receiving peritoneal dialysis and erythropoietin therapy. *J Pediatr* 1992; **121:** 749–52.

Effects on the spleen. Aggravation of splenomegaly was reported in 2 patients with myeloproliferative disorders after use of recombinant human erythropoietin.[1] Splenic infarction has been reported in a patient with aplastic anaemia given erythropoietin,[2] and peliosis of the spleen was discovered at autopsy in a patient with end-stage renal failure who had been receiving erythropoietin.[3]

3. Lam KY, *et al.* Peliosis of the spleen: possible association with chronic renal failure and erythropoietin therapy. *Postgrad Med J* 1995; **71:** 493–6.

Effects of subcutaneous injection. Localised pain can occur on subcutaneous injection of human recombinant erythropoietin. In comparisons of preparations it has been suggested that different excipients may affect this.[1-5] It has generally been reported that epoetin alfa preparations containing citrate buffer are more painful than those with phosphate buffer, and that epoetin beta preparations are less painful than epoetin alfa preparations.

5. Cumming MN, *et al.* Subcutaneous erythropoietin alpha (Eprex) is more painful than erythropoietin beta (Recormon). *Nephrol Dial Transplant* 1998; **13:** 817.

Treatment of adverse effects. Venesection[1] and erythropheresis[2] have been used to treat raised haematocrit and haemoglobin concentrations caused by recombinant human erythropoietin overdose. Venesection also successfully reduced the blood pressure in 4 patients with life-threatening hypertension associated with recombinant human erythropoietin treatment.[3] None of the patients had a raised haematocrit and the hypertension had been unresponsive to antihypertensive therapy.

Precautions

Epoetins should be used with caution in patients with hypertension, a history of seizures, thrombocytosis, chronic hepatic impairment, ischaemic vascular disease, or in patients with malignant tumours. Hypertension should be well controlled before treatment is started and blood pressure monitored during treatment.

Response to epoetins may be diminished by iron deficiency, infection or inflammatory disorders, haemolysis, or aluminium intoxication. Anaemia due to folic acid and vitamin B_{12} deficiencies should also be excluded, since these may also reduce the response. Patients developing sudden lack of efficacy should be investigated. If pure red cell aplasia is diagnosed treatment should be stopped and testing for epoetin antibodies considered; patients should not be transferred to another epoetin.

Patients undergoing dialysis may require increased doses of heparin in view of the increase in packed cell volume.

Platelet counts, haemoglobin concentrations, and serum-potassium concentrations should be monitored regularly.

Dosage must be carefully controlled to avoid too fast an increase in haematocrit and haemoglobin, and recommended values should not be exceeded because of the increased risks of hypertension and thrombotic events.

For reference to the uncertainty of the effect of epoetins on tumour progression and progression-free survival when used in patients with cancer, see under Anaemias in Uses and Administration, p.1063.

Abuse. The potential dangers from abuse of recombinant human erythropoietin by athletes have been reviewed.[1] Normally, optimal athletic conditioning leads to little change in red cell volume but a significant increase in plasma volume and total blood volume. In contrast, the artificial increase in the red cell mass induced by epoetin is usually accompanied by a decrease in plasma volume and no change in total blood volume. Lack of medical supervision and fluid loss during endurance events increase the risk of serious adverse consequences of these changes in blood viscosity produced by such misuse of epoetin. In one case,[2] cerebral sinus thrombosis in a cyclist was attributed to the combined use of epoetin, human growth hormone, and high doses of vitamins A and E.

Haematocrit and haemoglobin. A study[1] involving 1233 patients undergoing haemodialysis and suffering from heart failure or ischaemic heart disease found that erythropoietin in doses sufficient to increase haematocrit to 42% (within the normal range) was associated with lack of benefit and a trend towards increased mortality when compared with doses sufficient to maintain a lower haematocrit of around 30%. However, these results are difficult to interpret, since within each group, increased haematocrit was associated with lower mortality, despite the between-group differences. The possibility that intravenous iron supplementation might have contributed to these adverse results was considered, but commentators suggested that until further data were available aiming for a haematocrit of 33 to 36%, and using intravenous iron supplementation where necessary, was still appropriate.[2]

Two studies have looked at the effects of adjusting haemoglobin to different concentrations in patients with chronic renal impairment who did not yet need dialysis. In the CHOIR study[3] of 1432 patients, epoetin alfa was used to adjust haemoglobin to either 11.3 or 13.5 g per 100 mL. The risk of cardiovascular complications, particularly death and hospitalisation for congestive heart failure, was increased in the group with the higher haemoglobin target, without any additional improvement in quality of life. The CREATE study[4] included 603 patients who were treated with epoetin beta to adjust haemoglobin to either 13.0 to 15.0 g per 100 mL or 10.5 to 11.5 g per 100 mL. Although the measures for quality of life were better in the group adjusted to the higher target and there was no statistically significant difference between the groups in the risk of cardiovascular complications, there was a trend towards a more favourable outcome in the low-target group. The FDA subsequently issued a reminder[5] that in patients receiving epoetins or darbepoetin alfa, a target haemoglobin range of 10 to 12 g per 100 mL is recommended, and that haemoglobin concentrations and blood pressure should be monitored.

Resistance. Many factors may contribute to a poor response to recombinant human erythropoietin (see Precautions, above). A study in patients with anaemia of end-stage renal disease[1] found that inadequate dialysis was associated with a reduced response to erythropoietin treatment. The dialysis time and mode of dialysis may also influence response to erythropoietin therapy.[2] Antibodies to recombinant human erythropoietin have also been reported.[3,4] Delayed clinical response to recombinant human erythropoietin in a patient[5] could have been due to an inherited subclinical pyruvate kinase deficiency.

Pharmacokinetics

Epoetins exhibit some differences in their pharmacokinetics, possibly due to differences in glycosylation and in the formulation of the commercial preparations.

Epoetin alfa is slowly and incompletely absorbed after subcutaneous injection, and a relative bioavailability of about 10 to 20% has been reported. Peak concentrations after epoetin alfa intravenously are attained within 15 minutes, and within 5 to 24 hours after subcutaneous injection.

The elimination half-life of epoetin alfa after intravenous doses has been reported to be 4 to 13 hours in patients with chronic renal failure; the half-life is generally less in patients with normal renal function. An estimated elimination half-life of about 24 hours has been reported for epoetin alfa given subcutaneously.

Epoetin beta is similarly slowly and incompletely absorbed after subcutaneous injection, and its absolute bioavailability has been reported to be 23 to 42%. Peak serum concentrations are attained within 12 to 28 hours of subcutaneous doses. An elimination half-life of 4 to 12 hours has been reported after intravenous doses and a terminal half-life of 13 to 28 hours after subcutaneous doses.

Epoetin delta has a bioavailability after subcutaneous injection of between 26 and 36%, the peak serum concentration occurs after 8 to 36 hours, and the half-life in patients is about 27 to 33 hours. After intravenous injection, it has an elimination half-life of about 4 to 13 hours in patients with chronic renal failure, which is about double that measured in healthy subjects.

Epoetin zeta has a bioavailability of about 20% after subcutaneous injection, and peak serum concentrations occur after about 12 to 18 hours. The half-life after subcutaneous injection has been estimated to be about 24 hours. After intravenous injection, a half-life of about 4 hours has been measured in healthy subjects, and about 5 hours in patients with chronic renal failure; the half-life in children is about 6 hours.

Uses and Administration

Erythropoietin is a glycosylated protein hormone and a haematopoietic growth factor. It is secreted primarily by the kidneys, although a small amount is produced in extrarenal sites such as the liver. Erythropoietin regulates erythropoiesis by stimulating the differentiation and proliferation of erythroid precursors, the release of reticulocytes into the circulation, and the synthesis of cellular haemoglobin. The release of erythropoietin is promoted by hypoxia or anaemia, and up to 1000 times the normal serum-erythropoietin concentration may be reached under these conditions; this response may be impaired in some disease states such as chronic renal failure. The haematological response to erythropoietin is reduced if there is an inadequate supply of iron. For an outline of blood cell formation in general and average cell counts in adults see Haematopoiesis, p.1042.

Epoetins alfa, beta, delta, and zeta are recombinant human erythropoietins available for clinical use that have the same pharmacological actions as endogenous erythropoietin. They are used in the management of anaemia associated with chronic renal failure in dialysis and predialysis patients; they may reduce or obviate the need for blood transfusions in these patients. Epoetins alfa, beta, and zeta are also used in the management of chemotherapy-induced anaemia in patients with non-myeloid malignant disease. Epoetin alfa is used in zidovudine-related anaemia in HIV-positive patients. Epoetin beta is used in the management of anaemia of prematurity. Recombinant human erythropoietin is also being evaluated in the management of other types of normocytic-normochromic anaemias, including that associated with inflammatory disorders such as rheumatoid arthritis. In all patients, iron status should be monitored and supplementation provided if necessary.

Epoetins alfa, beta, and zeta may also be used in patients with moderate anaemia (but no iron deficiency) before elective surgery to increase the yield of blood collected for autologous blood transfusion. Epoetin alfa may also be used in such patients to reduce the need for allogeneic blood transfusion.

In the management of **anaemia of chronic renal failure** epoetin alfa, beta, or delta may be given intravenously or subcutaneously; epoetin zeta may only be given intravenously. For haemodialysis patients the dose of epoetin should be given intravenously because of the risk of pure red cell aplasia reported with subcutaneous use (see Effects on the Blood, above); it may be given during or at the end of the dialysis session using the dialysis vascular access. For predialysis and peritoneal dialysis patients, in whom intravenous access is not readily available, doses should be given subcutaneously. The aim of treatment in adults is to increase the haemoglobin concentration to 10 to 12 g per 100 mL or to increase the haematocrit to 30 to 36%. The rate of rise in haemoglobin should be gradual to minimise adverse effects such as hypertension; a rate not exceeding 2 g per 100 mL per month is suggested.

Epoetin alfa may be given subcutaneously or by intravenous injection over at least 1 minute; slow intravenous injection over 5 minutes may be used in patients who experience flu-like symptoms as adverse effects. ***Epoetin zeta*** may be given intravenously.

- In predialysis and haemodialysis patients, a recommended initial dose of epoetin alfa or zeta is 50 international units/kg three times weekly. For epoetin alfa, a higher initial dose of 50 to 100 units/kg three times weekly has been suggested in the USA.
- Doses may be increased at 4-week intervals in increments of 25 units/kg three times weekly until the target is reached.
- In patients on peritoneal dialysis an initial dose of 50 units/kg given twice weekly may be used.

Once the target is reached doses may need to be adjusted for maintenance therapy.

- The usual total weekly maintenance dose of epoetin alfa or zeta in predialysis patients is 50 to 100 units/kg given in three divided doses, and in haemodialysis patients it is about 75 to 300 units/kg given in three divided doses. In predialysis patients a total weekly dose of 600 units/kg should not be exceeded. In patients on peritoneal dialysis, the usual total weekly maintenance dose is 50 to 100 units/kg given in two divided doses.

In children, epoetin alfa or zeta may be given intravenously to those on haemodialysis.

- The initial dose is 50 units/kg three times weekly. The dose may be increased at 4-week intervals in increments of 25 units/kg three times weekly until a target haemoglobin concentration of 9.5 to 11 g per 100 mL is reached.

The usual total weekly maintenance dose given in three divided doses is:

- 225 to 450 units/kg for those weighing less than 10 kg
- 180 to 450 units/kg for those weighing 10 to 30 kg
- 90 to 300 units/kg for those weighing over 30 kg

Epoetin beta is used similarly in the management of anaemia of chronic renal failure in dialysis and predialysis patients. It may be given subcutaneously or by intravenous injection over 2 minutes. The following dosages may be used in adults and children:

- For subcutaneous injection the initial dose is 60 units/kg weekly for 4 weeks; the total weekly dose may be divided to be given in daily doses or three times a week
- For intravenous injection the initial dose is 40 units/kg three times weekly for 4 weeks; the dose may then be increased to 80 units/kg three times weekly
- Thereafter the dose of epoetin beta may be increased at 4-week intervals, for both subcutaneous and intravenous injection, in increments of 60 units/kg weekly in divided doses, until the target haemoglobin concentration or haematocrit is reached. A total weekly dose of 720 units/kg of epoetin beta should not be exceeded

For maintenance, the dose is halved initially and then adjusted every 1 to 2 weeks according to response. The weekly subcutaneous maintenance dose may be divided into 1, 3, or 7 doses; in patients stabilised on a once-weekly dose, it may be possible to adjust to a single dose every 2 weeks.

Epoetin delta is also used in the management of anaemia of chronic renal failure in dialysis and predialysis patients.

- For subcutaneous injection, the initial dose is 50 units/kg twice weekly.
- For intravenous injection, the initial dose is 50 units/kg three times weekly.
- Dosage may be adjusted by 25 to 50%, at intervals of at least 4 weeks, as required.

In adults receiving chemotherapy for **non-myeloid malignant disease**, epoetin alfa, beta, or zeta may be given by subcutaneous injection for symptomatic anaemia, usually when the haemoglobin concentration has fallen to 10 g or lower per 100 mL. The rise in haemoglobin should be gradual; a rate not exceeding 2 g per 100 mL per month, and a target haemoglobin concentration of not more than 12 g per 100 mL, are suggested.

- Epoetin alfa or zeta may be given in an initial dose of 150 units/kg three times weekly or 450 units/kg once weekly. The dose may be increased after 4 or 8 weeks, if necessary, to 300 units/kg three times weekly. If the response is still inadequate after 4 weeks at this higher dose, treatment should be stopped. Epoetin alfa may also be given in a once-weekly dose of 40 000 units, which may be increased to 60 000 units after 4 weeks if necessary.
- Epoetin beta may be given in an initial dose of 30 000 units (about 450 units/kg) weekly, as a single dose or divided into 3 to 7 doses. The dose may be doubled after 4 weeks if necessary, but treatment should be stopped if the response is still inadequate after 4 weeks at the higher dose. The total weekly dose should not exceed 60 000 units. Once the desired haemoglobin concentration has been reached, the dose should be reduced by 25 to 50% for maintenance therapy, and adjusted as necessary.

Epoetins should be stopped after the end of chemotherapy, but epoetin alfa, beta, or zeta may be continued for up to one month in the UK.

In children, epoetin alfa may be given intravenously in a single weekly dose of 600 units/kg (to a maximum of 40 000 units). The dose may be increased if necessary after 4 weeks to 900 units/kg (maximum 60 000 units).

In adult **HIV-positive patients** on zidovudine therapy, epoetin alfa may be beneficial if the endogenous serum-erythropoietin concentration is 500 milliunits/mL or less. Epoetin alfa is given by subcutaneous or intravenous injection in an initial dose of 100 units/kg three times weekly for 8 weeks. The dose may then be increased every 4 to 8 weeks by 50 to 100 units/kg three times weekly according to response. However, patients are unlikely to benefit from doses above 300 units/kg three times weekly if this dose has failed to elicit a satisfactory response.

In the management of **anaemia of prematurity** epoetin beta is given subcutaneously in a dose of 250 units/kg three times weekly. Treatment should be started as early as possible and continued for 6 weeks.

To increase the yield of **autologous blood** in adults, epoetin alfa, beta, or zeta may be used with iron supplementation. The dose depends on the volume of blood required for collection and on factors such as the patient's whole blood volume and haematocrit. Suggested regimens are:

- epoetin alfa or zeta 600 units/kg given intravenously twice weekly starting 3 weeks before surgery
- up to 800 units/kg of epoetin beta intravenously, or up to 600 units/kg subcutaneously, twice weekly for 4 weeks before surgery

To reduce the need for allogeneic blood transfusion in adults, epoetin alfa may be given in a dose of 600 units/kg subcutaneously once weekly starting 3 weeks before surgery, with a fourth dose given on the day of surgery. Alternatively, when the time before surgery is short, 300 units/kg subcutaneously daily may be given for 10 days before surgery, on the day of surgery, and for 4 days after.

Administration in neonates. Recombinant human erythropoietin may be given to neonates for anaemia of prematurity (see Anaemias, below). It is usually given by subcutaneous injection. Intravenous infusion in total parenteral nutrition solutions produced satisfactory results in a group of 20 neonates.[1] Enteral dosage in one small study[2] increased plasma-erythropoietin concentrations and peak reticulocyte counts, but in another larger study[3] it had no effect.

For a warning about diluting recombinant human erythropoietin solutions, see Stability, above.

Anaemias. Epoetins are used in normocytic-normochromic anaemias (p.1044) associated with low endogenous erythropoietin concentrations.

Anaemia associated with *chronic renal disease* is primarily a result of inadequate production of erythropoietin in the kidney. Other factors that can contribute to the anaemia include iron deficiency, blood loss associated with dialysis, and severe hyperparathyroidism. The use of epoetins in the management of renal anaemia is well established,[1,2] as consistently good results have been obtained not only for correction of anaemia but also for improvement in quality of life.[1,3] In predialysis patients, epoetins also correct anaemia, reduce the requirement for blood transfusions, and improve quality of life and exercise capacity, but there may be increased hypertension[2,4] and it is not known whether the need for dialysis is delayed.[4] Over 90% of patients with renal anaemia respond to treatment with epoetins.[1] Many factors can contribute to a poor response (see Precautions, above) and the patient should always be investigated and the cause corrected where possible. Common causes of inadequate response are iron deficiency, inflammatory disorders, chronic blood loss, hyperparathyroidism, and aluminium toxicity.[1,5]

Epoetins may be given intravenously or subcutaneously. Epoetin given subcutaneously produces lower but more sustained plasma concentrations and total weekly maintenance doses are reduced.[1,2,6] The subcutaneous route is generally used in predialysis patients and those on peritoneal dialysis,[1,2] partly because of the need to avoid venepuncture of veins that are likely to be needed for future haemodialysis access. While subcutaneous injection can also be used for haemodialysis patients, the intravenous route is preferred because of the rare risk of pure red cell aplasia reported with subcutaneous use[1] (see Effects on the Blood, above) and the ready availability of intravenous access. The dosage frequency may also be important in maximising the response to treatment, but may be influenced by the epoetin being used, route of administration, treatment phase, and patient preference. For example, giving epoetins 2 or 3 times a week may allow for a lower total weekly dose than once weekly, and may be more effective, but dosing once weekly may be more convenient for maintenance therapy.[1,2] A systematic review[7] concluded that there was no evidence to support one frequency over another in terms of maintaining target haemoglobin. See Uses and Administration, above, for examples of licensed doses, routes, and dose frequency for epoetins. Darbepoetin alfa (p.1058) is given at longer dosage intervals than epoetins and there is no difference in weekly dosage requirements between subcutaneous and intravenous routes.[2,6]

Intraperitoneal use of epoetins has also been proposed and investigated.[8,9] However, this route is rarely used because the doses must be given into a dry abdomen,[1] dose requirements are generally higher than those for intravenous or subcutaneous use, and there is the potential for more frequent episodes of peritonitis.[1,2]

Blood transfusions are often used to treat *anaemia of prematurity*, and epoetins have been investigated as a means of reducing transfusion requirements. A systematic review[10] found that although epoetin reduced transfusion needs, the effect was only modest and there was considerable variation between studies. More selective reviews of very-low-birth-weight infants (less than 1500 g) also found modest reductions in transfusion requirements, whether epoetin was started within the first week of life[11] or after one week,[12] although transfusion requirements were unlikely to be eliminated completely. Response to the late use of epoetin was also found to be dose-dependent.[12]

Factors contributing to *cancer-related anaemia* include chemotherapy, radiotherapy, and the malignancy itself. Epoetin therapy can reduce the need for blood transfusions in cancer patients[13,14] and may improve quality of life.[14,15] Guidelines for the use of epoetins in chemotherapy-induced anaemia have been issued (see Anaemia, under Bone-marrow Depression, p.639). There has, however, been some concern raised about the effect of epoetin therapy on patient survival. A placebo-controlled study of epoetin alfa to maintain normal haemoglobin concentrations (12 to 14 g per 100 mL) in patients receiving chemotherapy for metastatic breast cancer was terminated early when an increase in death was found in the epoetin group.[16] In another placebo-controlled study[17] of patients with head and neck cancer undergoing radiotherapy, epoetin beta was associated with correction of anaemia but poorer locoregional progression-free survival. In contrast, analysis of a study[18] in patients with lymphoproliferative malignancies found no effect of epoetin beta on patient survival. Two meta-analyses[14,19] found no conclusive evidence that epoetins affected tumour response or survival, but pointed out that few studies were primarily designed to assess these outcomes. Subsequently, a study of the quality of life in anaemic patients with advanced non-small cell lung cancer was stopped early, when an unplanned safety analysis suggested a reduced overall survival in patients given epoetin alfa.[20] However, two later studies did aim to investigate whether epoetin therapy influenced cancer treatment outcome and survival. One study in women treated with radiochemotherapy for advanced cervical cancer reported no positive correlation between haemoglobin increase and improvement in clinical outcomes, and could not draw a definite conclusion as to whether epoetin beta had an effect on disease progression or survival.[21] Another study, in women given chemotherapy for metastatic breast cancer, found that epoetin beta had no significant effect on overall survival.[22] Nevertheless, a further meta-analysis[23] of studies in cancer patients found that epoetin or darbepoetin alfa therapy was associated with increased risks of venous thromboembolism and death. Studies to date have generally used haemoglobin targets of 12 g and above per 100 mL, and further information is needed on the benefits and risks associated with the lower targets now advised (see Uses and Administration, above). In response to these concerns, authorities have strengthened warnings in licensed product information regarding the use of epoetins and related products in patients with cancer. The MHRA has also advised[24] that blood transfusion should be the preferred option for the management of anaemia in patients with cancer, particularly in those receiving adjuvant chemotherapy or who are being treated with curative intent. They also suggest that transfusion may be preferable in patients with advanced or metastatic cancer who have a good survival prognosis.

Epoetins are sometimes used to treat *anaemias from other causes*. Potential applications include zidovudine-induced anaemia in AIDS patients (see Effects on the Blood under Zidovudine, p.914), postpartum anaemia,[25,26] anaemia in critically ill patients,[27-29] and anaemia of chronic diseases such as rheumatoid arthritis,[30,31] inflammatory bowel disease,[32-34] and chronic heart failure.[35]

Surgery. Concern over the safety of blood transfusions and the need to conserve blood supplies has led to interest in methods of reducing blood use in surgery. Recombinant human erythropoietin has been used to increase the number of units harvested for autologous transfusion[1] and to reduce transfusion requirements.[2-4] It has also been used as an alternative to blood transfusions in Jehovah's Witnesses.[5-8]

Etamsylate *(BAN, rINN)*

Cyclonamine; E-141; Etamsilat; Etamsilatas; Etamsilato; Etamsylaatti; Etamsylát; Etamsylat; Étamsylate; Etamsylatum; Etamszilát; Ethamsylate *(USAN)*; MD-141. Diethylammonium 2,5-dihydroxybenzenesulphonate.

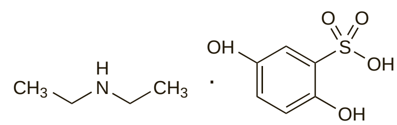
Этамзилат

$C_{10}H_{17}NO_5S = 263.3.$

CAS — 2624-44-4.

ATC — B02BX01.

ATC Vet — QB02BX01.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Etamsylate). A white or almost white, crystalline powder. It shows polymorphism. Very soluble in water; soluble in dehydrated alcohol; practically insoluble in dichloromethane; freely soluble in methyl alcohol. A 10% solution in water has a pH of 4.5 to 5.6. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Nausea, vomiting, diarrhoea, fever, headache, and skin rash have occurred after use of etamsylate. Headache and skin rashes may disappear on reduced dosage, and gastrointestinal disturbances are reduced by giving etamsylate after food. Transient hypotension has been reported following intravenous injection.

Porphyria. Etamsylate is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Pharmacokinetics

Etamsylate is absorbed from the gastrointestinal tract. It is excreted unchanged, mainly in the urine. Etamsylate is distributed into breast milk.

Uses and Administration

Etamsylate is a haemostatic that appears to maintain the stability of the capillary wall and correct abnormal platelet adhesion. It is given for the prophylaxis and control of haemorrhages from small blood vessels.

For short-term blood loss in menorrhagia a dose of 500 mg is given orally four times daily during menstruation. For the prophylaxis and treatment of periventricular haemorrhage in low birth-weight neonates 12.5 mg/kg is given by intramuscular or intravenous injection every 6 hours. For the control of haemorrhage after surgery etamsylate may be given orally to adults, or by intramuscular or intravenous injection in a dose of 250 to 500 mg; this dose may be repeated every 4 to 6 hours as necessary.

Menorrhagia. When given during menstruation to women with idiopathic menorrhagia (p.2126), etamsylate was as effective as mefenamic acid in reducing uterine blood loss in 1 study,[1] but was ineffective in another.[2] A review, which included published and unpublished results from these and 2 earlier studies, reported that etamsylate produced about a 10 to 15% reduction in menstrual blood loss.[3] Etamsylate is now considered to be less effective than other treatments for menorrhagia, and is no longer recommended.[4]

Neonatal intraventricular haemorrhage. Etamsylate is one of several drugs that have been tried in the prevention of intraventricular haemorrhage in very low birth-weight infants (p.1050). In a multicentre, placebo-controlled, double-blind study,[1] etamsylate was given in an initial dose of 12.5 mg/kg intravenously or intramuscularly within 1 hour of delivery, followed by the same dose intravenously every 6 hours for 4 days to a total dose of 200 mg/kg. Of 330 infants who had had no evidence of haemorrhage soon after delivery, the subsequent incidence of haemorrhage in the 162 who received etamsylate was reduced, particularly the more extensive grades when compared with the 168 who received placebo. Of a further 30 infants with evidence of periventricular haemorrhage before treatment, 21 were given etamsylate and 9 placebo; treatment with etamsylate limited the extension of bleeding. There was also a reduction in patent ductus arteriosus in the treated infants. However, a subsequent study using the same dosage regimen,[2] showed little benefit on short-term follow-up. It was considered that the study size may have been too small and the drug given too late; the initial dose was given within 4 hours of birth whereas, in the previous study, treatment was started within 1 hour of birth. Follow-up[3] of these infants at 2 years of age found that etamsylate had not reduced the risk of death, impairment, or disability. Developmental outcome assessments at about 4 years of age in patients from the first study[4] also found that despite the original reduction in intraventricular haemorrhage with etamsylate, it had not reduced cerebral palsy compared with the control group.

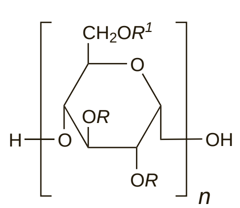
Etherified Starches ⊗

Almidón, éteres de; HES; Hydroxyethyl Starch; Hydroxyéthylamidon; Hydroxyethylamylum. 2-Hydroxyethyl ether starch.

CAS — 9005-27-0.

ATC — B05AA07.

ATC Vet — QB05AA07.



in which either *R* or *R*[1] may be either H or CH_2CH_2OH

(hetastarch)

Description. Etherified starches are starches that are composed of more than 90% of amylopectin and that have been etherified to varying extents.

- hetastarch (*BAN*, *USAN*): an average of 7 to 8 of the hydroxy groups in each 10 D-glucopyranose units of starch polymer have been converted into OCH_2CH_2OH groups
- pentastarch (*BAN*, *USAN*): an average of 4 to 5 of the hydroxy groups in each 10 D-glucopyranose units of the starch polymer have been converted to OCH_2CH_2OH groups

Etherified starches also vary in terms of average molecular weight and the position of etherification within the glucopyranose unit.

Incompatibility. Hetastarch is incompatible with many compounds including a number of injectable antibacterials.

References.

2. Wohlford JG, *et al.* More information on the visual compatibility of hetastarch with injectable critical-care drugs. *Am J Hosp Pharm* 1990; **47:** 297–8.

Adverse Effects and Precautions

Hypersensitivity reactions including anaphylactic reactions have occurred after infusion of etherified starches. Pruritus can occur after long-term use of high doses of etherified starches; the onset may be delayed until weeks after the last infusion. Serum-amylase concentrations may appear to increase during infusion of etherified starches due to formation of an enzyme-substrate complex that is only eliminated slowly.

Precautions that should be observed with plasma expanders are described under Dextran 70, p.1060, and these should be considered when etherified starches are used. There may be some interference with blood grouping and cross-matching of blood.

◊ Reviews.

Effects on the blood. Use of plasma expanders causes dilution of clotting factors and may also have direct effects on coagulation. Effects of etherified starches on the coagulation system include[1,2] a decrease in clotting factor VIII and von Willebrand factor that results in an acquired type I von Willebrand disease (see p.1051), a prolongation of the activated partial thromboplastin time, and a reduction in platelet volume. The extent of these effects appears to depend on the molecular weight and the rate of degradation *in vivo* of the starch. Etherified starches of high molecular weight that are more slowly degraded (due to a high degree of substitution or a high ratio of hydroxyethylation at the C2:C6 positions) have a greater effect on blood coagulation than medium and low molecular weight, easily degraded, etherified starches. Coagulopathy and haemorrhage have been reported with the use of solutions of etherified starches.[1,3] Serious complications such as intracranial bleeding and cerebral oedema have been reported in studies of patients with ischaemic stroke and other brain injuries who have been treated with etherified starches of various molecular weights and degrees of substitution, and several trials have been stopped prematurely as a result.[4]

Effects on the kidneys. Osmotic-nephrosis-like lesions found at biopsy in some transplanted kidneys have been attributed to use of solutions of etherified starches in the donor patient.[1] Such use has also been reported to impair immediate graft function.[2] However, another study[3] found no association between the use of these solutions in the donor patient and osmotic-nephrosis-like lesions or delayed graft function. Oliguric acute renal failure and osmotic-nephrosis-like lesions occurred in a patient who was given an etherified starch infusion during surgery for carcinoma of the tonsils.[4]

Etherified starches should be used with caution in patients with renal impairment.[5]

Effects on the skin. Pruritus has been reported after infusion of etherified starches.[1] It appears to be associated with tissue deposition of the starch although the actual mechanism by which this provokes pruritus is unresolved. The effect appears to be dose-related, which may explain the differences in reported incidences that have ranged from less than 10% to more than 60% of patients being affected. The molecular weight and degree of substitution of the etherified starch do not appear to be risk factors. The pruritus is usually generalised, but there are reports of localised pruritus affecting the trunk, extremities, anogenital area, and head and neck. It is frequently severe, persistent, and refractory to treatment, causing sleep disturbances and adversely affecting quality of life. Attacks of pruritus may be precipitated by heat, sweating, exercise, bathing, mechanical pressure, and mental stress. It typically has a delayed onset of 1 to 6 weeks after exposure to the etherified starch. Average durations of 9 to 15 weeks have been reported, but in some cases pruritus has continued for up to 2 years. The condition is generally unresponsive to treatment, although there have been reports of relief with topical capsaicin, ultraviolet therapy, or oral naltrexone.

Marked and persistent periocular swelling developed in a patient after 15 daily infusions of hetastarch.[2] Abnormal accumulation of hetastarch was found in the periocular tissues.

Pharmacokinetics

Etherified starches consist of mixtures of molecules with a range of molecular weights and with varying degrees of etherification. After intravenous infusion the molecules with a molecular weight of less than 50 000 are readily excreted unchanged by the kidney; larger molecules are metabolised and eliminated more slowly. The rate of metabolism depends upon the size of the molecule and the degree and position of etherification, with a high molecular weight, high degree of etherification, and etherification predominantly at the C2 position leading to a slower rate of metabolism and hence a longer duration of action. About 33% of a dose of high-molecular-weight hetastarch (weight average molecular weight 450 000) and about 70% of a dose of medium-molecular-weight pentastarch (weight average molecular weight 250 000) is excreted in the urine in 24 hours. Etherified starches may be distributed to various tissues; a small proportion of the dose may persist in the body for several years.

Uses and Administration

Etherified starches are plasma volume expanders used in the management of hypovolaemic shock (p.1183). Those most commonly used include high-molecular-weight hetastarch (weight average molecular weight 450 000 to 480 000) and medium-molecular-weight pentastarch (weight average molecular weight 200 000 to 250 000). Other etherified starches that are used include low-molecular-weight pentastarch and medium-molecular-weight hexastarch, which has a degree of etherification between that of pentastarch and hetastarch. A higher molecular weight hetastarch is also available. Iso-oncotic solutions of etherified starches, for example, 6% hetastarch or 6% medium-molecular-weight pentastarch, exert a similar colloidal osmotic pressure to human albumin, and when given by intravenous infusion produce an expansion of plasma volume slightly in excess of the infused volume. Hyperoncotic solutions, for example 10% medium-molecular-weight pentastarch, produce an expansion of plasma volume of about 1.5 times the infused volume. The duration of effect depends on the characteristics of the starch used; for 6% hetastarch the effect lasts for 24 to 36 hours.

Etherified starches are given intravenously as solutions in sodium chloride 0.9% or other electrolytes; concentrations used are usually 6 or 10%, although 3% solutions are also available for some. The dose and rate of infusion depend on the amount of fluid lost and degree of haemoconcentration; usual doses are in the range of 500 to 2500 mL daily, depending on the preparation used, and the infusion rate may be up to about 20 mL/kg per hour if necessary.

Hetastarch and pentastarch increase the erythrocyte sedimentation rate when added to whole blood. They are therefore used in leucapheresis procedures to increase the yield of granulocytes. Doses of 250 to 700 mL may be added to venous blood in the ratio 1 part to at least 8 parts of whole blood in such procedures. Up to 2 such procedures per week and a total of 7 to 10 have been reported to be safe.

Hetastarch and hexastarch have also been used in extracorporeal perfusion fluids.

Stroke. Haemodilution with pentastarch has been tried in patients with acute ischaemic stroke (p.1185) in an attempt to improve reperfusion of the brain by lowering blood viscosity. However, one study was terminated early when an excess mortality was noted in the haemodilution group.[1] The early fatalities occurred almost exclusively in patients with severe strokes; cerebral oedema was the main cause of death within one week of the onset of symptoms. Among the survivors neurological recovery was better among those who received haemodilution. A systematic review[2] of 18 haemodilution studies, which included 5 using etherified starches, found no benefit in terms of fatality or functional outcome with haemodilution. Factor VII

Facteur VII; Proconvertin; SPCA; Stable Factor.

ATC — B02BD05.

ATC Vet — QB02BD05.

Description. Factor VII is a plasma protein involved in blood coagulation. It may be obtained from human plasma or produced by recombinant DNA technology. The name Eptacog Alfa (Activated) is in use for a recombinant factor VIIa.

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii).

Ph. Eur. 6.2 (Human Coagulation Factor VII; Factor VII Coagulationis Humanus; Dried Factor VII Fraction BP 2008). A plasma protein fraction that contains the single-chain glycoprotein factor VII and may also contain small amounts of the activated form, the two-chain derivative factor VIIa, as well as coagulation factors II, IX, and X, and protein C and protein S. It is prepared from human plasma obtained from blood from healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation is designed to minimise activation of any coagulation factor and includes a step or steps that have been shown to remove or inactivate known agents of infection. The factor VII fraction is dissolved in a suitable liquid, passed through a bacteria-retentive filter, distributed aseptically into the final containers, and immediately frozen. The preparation is freeze-dried and the containers sealed under vacuum or under an inert gas. Heparin, antithrombin, and other auxiliary substances such as a stabiliser may be added. No antimicrobial preservative is added. The specific activity is not less than 2 international units of factor VII per mg of protein before the addition of any protein stabiliser. When reconstituted as stated on the label the resulting solution contains not less than 15 international units/mL.

A white or almost white, pale yellow, green, or blue hygroscopic powder or friable solid. Store in airtight containers. Protect from light.

Eptacog Alfa (Activated) *(BAN, rINN)*

Eptacog alfa (activado); Eptacog Alfa (activé); Eptacogum Alfa (activatum). Blood-coagulation factor VII (human clone λHVII2463 protein moiety).

Эптаког Альфа (Активированный)

CAS — 102786-52-7; 102786-61-8.

ATC — B02BD08.

ATC Vet — QB02BD08.

Units

The potency of factor VII is expressed in international units and preparations may be assayed using the International Standard for blood coagulation factor VII concentrate, human (1998).

The potency of factor VIIa (activated factor VII) is expressed in international units and preparations may be assayed using the first International Standard for blood coagulation factor VIIa concentrate (1993).

Adverse Effects and Precautions

Use of eptacog alfa (activated) may be associated with minor skin reactions, fever, headache, and changes in blood pressure. Eptacog alfa (activated) should be used with caution in patients with conditions associated with circulating tissue factor, such as advanced atherosclerosis, crush injury, or septicaemia, since there is a risk of precipitating thrombosis or disseminated intravascular coagulation.

Effects on the cardiovascular system. Reports of 185 serious thromboembolic events associated with eptacog alfa (activated), that had been received by the FDA up to the end of 2004, have been reviewed.[1] Data were collected from both clinical trials and spontaneous reports. Various forms of arterial and venous thrombosis had been described, and most events were found to have occurred after its use for unlicensed indications in patients without haemophilia.

1. O'Connell KA, *et al.* Thromboembolic adverse events after use of recombinant human coagulation factor VIIa. *JAMA* 2006; **295:** 293–8.

Uses and Administration

Factor VII may be used as replacement therapy in patients with rare genetic deficiencies of factor VII.

Factor VIIa (activated factor VII) is used to treat bleeding episodes and to prevent bleeding associated with surgery in patients with haemophilia A or haemophilia B who have developed antibodies to factor VIII or factor IX, respectively, and in acquired haemophilia (see Haemophilias, p.1048). It may also be used in congenital factor VII deficiency and Glanzmann's thrombasthenia (see Inherited Haemorrhagic Disorders, p.1050). Factor VIIa may also be useful in patients with von Willebrand's disease (p.1051). Factor VIIa is given as the recombinant form, eptacog alfa (activated). Eptacog alfa (activated) 100 micrograms is equivalent to 5000 international units.

In the treatment of bleeding episodes in patients with **haemophilia**, an initial dose of eptacog alfa (activated) 90 micrograms/kg is given by intravenous bolus injection over 2 to 5 minutes. Further doses may be given as required to achieve and maintain haemostasis, initially every 2 to 3 hours. The dose may then be adjusted (effective doses have ranged from 35 to 120 micrograms/kg), or the dosing interval increased, according to response. Treatment may need to be continued for up to 3 weeks or more following serious bleeding episodes. A similar regimen may be used in patients with haemophilia when they undergo an invasive procedure or surgery, in which case the initial dose should be given immediately before the intervention.

In **factor VII deficiency**, the usual dose of eptacog alfa (activated) for treating bleeding episodes due to surgery or invasive procedures is 15 to 30 micrograms/kg every 4 to 6 hours until haemostasis is achieved.

In **Glanzmann's thrombasthenia** that is refractory to platelet transfusions, the usual dose of eptacog alfa (activated) for treating bleeding episodes or preventing bleeding due to surgery or invasive procedures is 90 micrograms/kg every 2 hours; at least 3 doses should be given.

Administration. Recombinant factor VIIa is usually given by bolus intravenous injection. The successful use of continuous infusion has been described in a few small studies and case reports.[1]

1. Stachnik JM, Gabay MP. Continuous infusion of coagulation factor products. *Ann Pharmacother* 2002; **36:** 882–91.

Haemorrhagic disorders. As well as being used in patients with haemophilia, recombinant factor VIIa has been tried or investigated in patients with bleeding of various other causes.[1] There have been reports of recombinant factor VIIa used to manage or prevent bleeding in patients receiving warfarin[2-4] or a low-molecular-weight heparin.[5] There are also a few reports of it successfully controlling bleeding associated with diffuse alveolar haemorrhage[6-8] or dengue haemorrhagic fever;[9] it has also been studied in the management of acute variceal bleeding (p.2346). In the management of massive postpartum haemorrhage (p.2003), recombinant factor VIIa is increasingly being used when standard medical and surgical therapies are inadequate. There are suggestions that it may reduce the need for blood products, control bleeding sufficiently to allow transfer of the patient to a facility where angiography and embolisation can be performed, and reduce the need for hysterectomy.[10] However, evidence consists largely of case reports and case series. Although advice has been published, based on this evidence and expert opinion,[11] the place of recombinant factor VIIa in the treatment of postpartum haemorrhage remains to be confirmed. Initial investigation of recombinant factor VIIa in the acute management of intracerebral haemorrhage was promising,[12] but a phase 3 study found that it did not reduce the rates of death or severe disability, compared with placebo.[13] Recombinant factor VIIa is also under investigation in the management of serious bleeding after surgery or trauma.[14,15]

Factor VIII

AHF; Antihaemophilic Factor; Facteur VIII.
ATC — B02BD02.
ATC Vet — QB02BD02.

Description. Factor VIII is a plasma protein involved in blood coagulation. It may be obtained from human plasma or produced by recombinant DNA technology. The names Moroctocog Alfa (see below) and Octocog Alfa (see below) are in use for recombinant factor VIII.

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Human Coagulation Factor VIII; Factor VIII Coagulationis Humanus; Dried Factor VIII Fraction BP 2008). A plasma protein fraction that contains the glycoprotein coagulation factor VIII with varying amounts of von Willebrand factor, depending on the method of preparation. It is prepared from human plasma obtained from blood from healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation includes a step or steps that have been shown to remove or inactivate known agents of infection. The factor VIII fraction is dissolved in an appropriate liquid, passed through a bacteria-retentive filter, distributed aseptically into the final containers, and immediately frozen. The preparation is freeze-dried and the containers sealed under vacuum or under an inert gas. Auxiliary substances such as a stabiliser may be added. No antimicrobial preservative is added. The specific activity is not less than 1 international unit of factor VIII:C per mg of total protein before the addition of any protein stabiliser. When reconstituted as stated on the label the resulting solution contains not less than 20 international units of factor VIII:C per mL.

A white or pale yellow hygroscopic powder or friable solid. Store in airtight containers. Protect from light.

Ph. Eur. 6.2 (Human Coagulation Factor VIII (rDNA); Factor VIII Coagulationis Humanus (ADNr)Dried Factor VIII (rDNA) BP 2008). A freeze-dried preparation of glycoproteins having the same activity as coagulation factor VIII in human plasma. It is prepared as full-length factor VIII (octocog alfa), or as a shortened two-chain structure (relative molecular mass 90 000 and 80 000), in which the B-domain has been deleted from the heavy chain (moroctocog alfa). Full-length human rDNA coagulation factor VIII contains 25 potential *N*-glycosylation sites, 19 in the B-domain of the heavy chain, 3 in the remaining part of the heavy chain (relative molecular mass 90 000) and 3 in the light chain (relative molecular mass 80 000).

Human coagulation factor VIII (rDNA) is produced by recombinant DNA technology in mammalian cell culture. Auxiliary substances such as a stabiliser may be added. A white or slightly yellow powder or friable mass. pH of the reconstituted preparation is 6.5 to 7.5. Protect from light.

USP 31 (Antihemophilic Factor). A sterile freeze-dried powder containing the factor VIII fraction prepared from units of human venous plasma that have been tested for the absence of hepatitis B surface antigen, obtained from whole-blood donors and pooled; it may contain heparin sodium or sodium citrate. It contains not less than 100 units per g of protein. Unless otherwise specified it should be stored at 2° to 8° in hermetically-sealed containers. It should be used within 4 hours of reconstitution and should be administered with equipment that includes a filter.

A white or yellowish powder. On reconstitution it is opalescent with a slight blue tinge or is a yellowish liquid.

USP 31 (Cryoprecipitated Antihemophilic Factor). A sterile frozen concentrate of human antihaemophilic factor prepared from the cryoprotein fraction, rich in factor VIII, of human venous plasma obtained from suitable whole-blood donors from a single unit of plasma derived from whole blood or by plasmapheresis, collected and processed in a closed system. It contains no preservative. It has an average potency of not less than 80 units per container. It should be stored at or below −18° in hermetically-sealed containers. It should be thawed to 20° to 37° before use; this liquid should be stored at room temperature and used within 6 hours of thawing; it should also be used within 4 hours of opening the container and administered with equipment that includes a filter.

A yellowish frozen solid. On thawing it becomes a very viscous, yellow, gummy liquid.

Moroctocog Alfa *(BAN, rINN)*

Moroctocogum Alfa; Moroktokog Alfa; Moroktokogialfa. (1—742)–(1637—1648)-Blood-coagulation factor VIII (human reduced) complex with 1649—2332-blood-coagulation factor VIII (human reduced).

Мороктоког Альфа

CAS — 284036-24-4.

Pharmacopoeias. *Eur.* (see p.vii) includes under the title Human Coagulation Factor VIII (rDNA) (see above).

Octocog Alfa *(BAN, rINN)*

Bay-w-6240; Factor VIII (rDNA); Octocogum Alfa. Blood-coagulation factor VIII (human), glycoform α.

Октоког Альфа

CAS — 139076-62-3;.

Pharmacopoeias. *Eur.* (see p.vii) includes under the title Human Coagulation Factor VIII (rDNA) (see above).

Units

The potency of factor VIII is expressed in international units and preparations may be assayed using the sixth International Standard for blood coagulation factor VIII concentrate, human (1998).

Adverse Effects and Precautions

Allergic reactions may sometimes follow the use of factor VIII preparations; the chills, urticaria, and headache experienced by some patients may be allergic manifestations. There is the possibility of intravascular haemolysis in patients with blood groups A, B, or AB receiving high doses or frequently repeated doses of factor VIII preparations due to the content of blood group isoagglutinins; also massive doses of some preparations may produce hyperfibrinogenaemia. Such risks should be reduced with more highly purified preparations.

Factor VIII preparations have been associated with the transmission of some viral infections, including hepatitis B and C, and more notably transmission of HIV. Strenuous efforts are now undertaken to screen the donor material from which factor VIII material is obtained and new methods of manufacture have also been introduced with the aim of inactivating any viruses present. Vaccination against hepatitis A and B is recommended for patients not already immune. Recombinant preparations are also available.

Some patients develop antibodies to factor VIII (see Resistance, below).

Effects on blood platelets. There have been case reports of thrombocytopenia associated with use of porcine factor VIII.[1] A retrospective study[2] of patients treated with porcine factor VIII found that the platelet count fell in 61% of 175 infusions given to 57 patients. The fall was generally clinically insignificant and platelet count appeared to recover within an hour. The effect was, however, dose-related, and larger reductions in platelet count were usually associated with intensive replacement over several days for surgery or trauma.

1. Green D, Tuite GF. Declining platelet counts and platelet aggregation during porcine VIII:C infusions. *Am J Med* 1989; **86:** 222–4.
2. Hay CRM, *et al.* Safety profile of porcine factor VIII and its use as hospital and home-therapy for patients with haemophilia-A and inhibitors: the results of an international survey. *Thromb Haemost* 1996; **75:** 25–9.

Resistance. Some patients with haemophilia A develop inhibitory antibodies to factor VIII (see Haemophilias, p.1048). The risk is highest within the first 20 to 100 treatments. Low-titre antibodies are usually transient and overcome by increased or continuing treatment with factor VIII. With high-titre highly responding antibodies, however, bleeding episodes may need to be managed with factor VIII inhibitor bypassing fraction (activated prothrombin complex concentrate), or recombinant factor VIIa. Highly responding antibodies can be eradicated by immune tolerance regimens, using regular infusion of factor concentrates over long periods, with additional immunosuppression and immuno-adsorption in some cases.[1] Postmarketing monitoring in Europe has revealed a higher number of cases of inhibitory antibodies associated with recombinant factor VIII preparations than would be expected from experience with plasma-derived products.[2] However, a review[3] by the EMEA found that, on the basis of available data, it was not possible to estimate and compare the incidence of inhibitors between different recombinant factor VIII products. They warned that recurrence of low-titre antibodies had occurred after switching from one product to another in previously treated patients with more than 100 exposure days who had a history of inhibitor development. They also requested that further investigation be undertaken by companies that market recombinant factor VIII products.

There have also been reports of lack of effect with the use of the recombinant factor VIII, moroctocog alfa, for prophylaxis, in patients who have no evidence of antibodies to factor VIII.[4]

Transmission of infections. Treatment with heat or chemicals and efforts to screen the donor material from which factor VIII and other clotting factors are obtained seem to have overcome problems with transmission of HIV and hepatitis B and C, although there is concern that non-lipid-enveloped viruses, such as human parvovirus B19 and hepatitis A, may still be transmitted. Vaccination against hepatitis A and B has been recommended for all patients who receive or may require blood products. Plasma-derived clotting factor preparations, or recombinant preparations containing added albumin, may carry a risk of transmission of variant Creutzfeldt-Jakob disease (see under Blood, p.1056). There has also been some concern about the use of human and animal products in the culture media used to manufacture recombinant clotting factor preparations, because of the theoretical risk of viral transmission from infected cell lines. Recombinant manufacturing techniques and formulations have changed over time and human and animal products are no longer used in some preparations.[1]

Pharmacokinetics

In patients with haemophilia A, factor VIII preparations have a terminal half-life of about 12 hours, whether human-derived or of recombinant origin.

◊ References.

Uses and Administration

Factor VIII is used as replacement therapy in patients with haemophilia A, a genetic deficiency of factor VIII; it may also be used in acquired haemophilia (see Haemophilias, p.1048).

Preparations of factor VIII may be derived from human plasma or recombinant sources. They are used to control bleeding episodes in the treatment of patients with haemophilia A and to prevent bleeding episodes in such patients undergoing dental and surgical procedures. They may also be used for long-term prophylaxis in patients with severe haemophilia A.

Preparations of factor VIII are given by slow intravenous injection or short infusion, and some octocog alfa preparations may also be given by continuous infusion. The dosage of factor VIII should be determined for each patient and will vary with the circumstances involving bleeding or type of surgery to be performed. In adults, a dose of 1 international unit/kg has been reported to raise the plasma concentration of factor VIII by about 2% (of normal). The response may be lower in children. A suggested formula to calculate, approximately, the dose required for a given effect is:

units = wt (kg) × 0.5 × % desired increase (of normal)

Recommended doses vary depending on the preparation used, but the following increments in plasma concentration of factor VIII have been suggested:

- for mild to moderate haemorrhage an increase to 20 to 30% of normal, usually with a single dose of 10 to 15 units/kg
- for more serious haemorrhage or minor surgery an increase to 30 to 50% of normal, by a usual initial dose of 15 to 25 units/kg followed by 10 to 15 units/kg every 8 to 12 hours if required
- for severe haemorrhage or major surgery an increase to 80 to 100% of normal may be necessary, the usual initial dose being 40 to 50 units/kg followed by 20 to 25 units/kg every 8 to 12 hours. Some octocog alfa preparations may also be given for major surgery as an initial pre-operative bolus followed by a continuous infusion, adjusted postoperatively to daily clearance and desired factor VIII concentrations

For long-term prophylaxis in severe haemophilia A, doses of 10 to 50 units/kg every 2 or 3 days, as required, may be used.

In patients with inhibitory antibodies to human factor VIII, a porcine factor VIII preparation may be used in doses of 25 to 150 units/kg depending upon the severity of the haemorrhage.

Some factor VIII concentrates also contain von Willebrand factor and these preparations may be used in the management of von Willebrand's disease (p.1051). Commercial very highly purified and recombinant factor VIII preparations do not contain appreciable amounts of von Willebrand factor and are thus ineffective.

Cryoprecipitate is an alternative source of clotting factors and contains factor VIII, factor XIII, von Willebrand factor, fibrinogen, and fibronectin. It has been used in the treatment of haemophilia A and von Willebrand's disease but safer more specific clotting factor alternatives are now available and preferred.

◊ Reviews.

2. Frampton JE, Wagstaff AJ. Sucrose-formulated octocog alfa: a review of its use in patients with haemophilia A. *Drugs* 2008; **68:** 839–53.

Administration. Surgical prophylaxis or significant haemorrhage in patients with haemophilia A is usually managed with injections of factor VIII given intravenously every 8 to 12 hours. However, continuous intravenous infusion has been used as an alternative.[1,2] It prevents wide fluctuations in factor VIII plasma concentrations and there is a progressive decrease in clearance associated with steady state. Studies have suggested that continuous infusion is as effective as bolus injection, but with a lower concentrate requirement. Concerns about continuous infusion include factor VIII stability, bacterial contamination, local irritation and thrombophlebitis, and inhibitor formation.

Factor VIII Inhibitor Bypassing Fraction

Activated Prothrombin Complex Concentrate; Anti-inhibitor Coagulant Complex; Complejo coagulante antiinhibidor del factor VIII; Faktör VIII İnhibitör Baypaslayan Fraksiyonu.

ATC — B02BD03.
ATC Vet — QB02BD03.

Adverse Effects and Precautions

Hypersensitivity reactions may follow the use of preparations with factor VIII inhibitor bypassing activity. Rapid infusion may cause headache, flushing, and changes in blood pressure and pulse rate.

It should not be given if disseminated intravascular coagulation is suspected or if there are signs of fibrinolysis. It should be used with caution in patients with liver disease. The risk of thromboembolism may be increased with the use of high doses or in patients with thrombotic risk factors.

As with other plasma-derived products, there is a risk of transmission of infection.

Safety. References.

2. Luu H, Ewenstein B. FEIBA safety profile in multiple modes of clinical and home-therapy application. *Haemophilia* 2004; **10** (suppl): 10–16.

Uses and Administration

Preparations with factor VIII inhibitor bypassing activity are prepared from human plasma and contain factors II, IX, and X, and activated factor VII; small amounts of factor VIII and factors of the kallikrein-kinin system are also present. They are used in patients with haemophilia A who have antibodies to factor VIII and in patients with acquired antibodies to factor VIII (see Haemophilias, p.1048). The dose is given intravenously and depends on the preparation used.

Factor IX

Christmas Factor; Facteur IX; Plasma Thromboplastin Component; PTC.

ATC — B02BD04.
ATC Vet — QB02BD04.

Description. Factor IX is a plasma protein involved in blood coagulation. It may be obtained from human plasma or produced by recombinant DNA technology. The name Nonacog Alfa is in use for recombinant factor IX.

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Human Coagulation Factor IX; Factor IX Coagulationis Humanus; Dried Factor IX Fraction BP 2008). A plasma protein fraction containing coagulation factor IX, prepared by a method that effectively separates it from other prothrombin complex factors (factors II, VII, and X). It is prepared from human plasma obtained from healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation is designed to maintain functional integrity of factor IX, to minimise activation of any coagulation factor, and includes a step or steps that have been shown to remove or inactivate known agents of infection. The factor IX fraction is dissolved in a suitable liquid, passed through a bacteria-retentive filter, distributed aseptically into the final containers, and immediately frozen. The preparation is freeze-dried and the containers are sealed under vacuum or under an inert gas. Heparin, antithrombin, or other auxiliary substances such as a stabiliser may be included. No antimicrobial preservative is added. The specific activity is not less than 50 international units of factor IX per mg of total protein before the addition of any protein stabiliser. The dried product is a white or pale yellow hygroscopic powder or friable solid. Store in airtight containers. Protect from light. When reconstituted as stated on the label the resulting solution contains not less than 20 international units/mL.

Ph. Eur. 6.2 (Human Prothrombin Complex; Prothrombinum Multiplex Humanum; Dried Prothrombin Complex BP 2008). It contains factor IX with variable amounts of coagulation factors II, VII, and X. It is prepared by fractionation of human plasma obtained from blood from healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation is designed in particular to minimise thrombogenicity and includes a step or steps that have been shown to remove or inactivate known agents of infection. The prothrombin complex fraction is dissolved in a suitable liquid, sterilised by filtration, distributed aseptically into final containers, and immediately frozen. The preparation is freeze-dried and the containers are sealed under vacuum or under an inert gas. No antimicrobial preservative is added. Heparin, antithrombin, and other auxiliary substances such as a stabiliser may be added. The potency of the preparation is not less than 0.6 international units of factor IX per mg of total protein before the addition of any protein stabiliser. The dried product is a white or slightly coloured, very hygroscopic, powder or friable solid. Store in airtight containers. Protect from light. When reconstituted as stated on the label the resulting solution contains not less than 20 international units/mL.

USP 31 (Factor IX Complex). A sterile freeze-dried powder consisting of partially purified factor IX fraction, as well as concentrated factor II, VII, and X fractions of venous plasma obtained from healthy human donors. It contains no preservatives. It should be stored at 2° to 8° in hermetically-sealed containers. It should be used within 4 hours after reconstitution and administered with equipment that includes a filter.

Nonacog Alfa *(BAN, USAN, rINN)*

Nonacogum Alfa; Nonakog Alfa; Nonakogialfa. Blood-coagulation factor IX (human), glycoform α; Blood-coagulation factor IX (synthetic human); .

Нонаког Альфа

CAS — 113478-33-4; 181054-95-5;.
ATC — B02BD09.
ATC Vet — QB02BD09.

Units

The activity of factor IX is expressed in terms of international units and preparations may be assayed using the third International Standard for blood coagulation factor IX concentrate, human (1996).

Adverse Effects and Precautions

Hypersensitivity reactions may follow the use of factor IX preparations and there may be chills and urticaria. Other adverse effects include nausea and vomiting, headache, and flushing particularly after rapid infusion. Intravascular coagulation and thrombosis have been reported, mainly in patients with liver disease, and factor IX should be used with care in patients at risk of thromboembolism or disseminated intravascular coagulation. The risk should be less with more highly purified preparations.

As with other plasma derivatives there is a possibility of transmitting viral infection, although selection of donors and heat or chemical treatments of products are used to minimise the risk. Vaccination against hepatitis A and B is recommended for patients not already immune.

Antibodies to factor IX may develop rarely.

Effects on the cardiovascular system. Some factor IX preparations derived from plasma contain other clotting factors in addition to factor IX (prothrombin complex concentrates), and some preparations have also contained activated clotting factors. Such preparations have the potential to produce thromboembolic complications.[1,2] Reported complications include arterial and venous thrombosis, pulmonary embolism, acute myocardial infarction, and disseminated intravascular coagulation. Risk factors in haemophiliacs include liver disease, severe muscle haemorrhages, crush injuries, immobilisation, and orthopaedic surgery. Rapid infusion of factor IX concentrates, or repeated large doses, may also increase the risk of thromboembolism. The risks of thromboembolism have been reduced with the development of more purified prothrombin complex concentrates, and highly purified factor IX preparations that do not contain other clotting factors.[1,3]

2. Najaf SM, *et al.* Myocardial infarction during factor IX infusion in hemophilia B: case report and review of the literature. *Ann Hematol* 2004; **83:** 604–7.
3. Santagostino E, *et al.* Markers of hypercoagulability in patients with hemophilia B given repeated, large doses of factor IX concentrates during and after surgery. *Thromb Haemost* 1994; **71:** 737–40.

Uses and Administration

Factor IX is used as replacement therapy in patients with haemophilia B (Christmas disease), a genetic deficiency of factor IX (see Haemophilias, p.1048).

There are two forms of factor IX preparation derived from plasma; one is of high purity, the other is rich in other clotting factors (prothrombin complex concentrates). A recombinant factor IX preparation, nonacog alfa, is also available. Preparations that contain other factors as well as factor IX may sometimes be useful for the treatment of bleeding due to deficiencies of factors II, VII, and X, as well as IX, and in the preparation of such patients for surgery; they may also be used for immediate reversal of coumarin anticoagulants and in the management of patients with haemophilia A who have antibodies to factor VIII.

Factor IX is given by slow intravenous infusion. In patients with factor IX deficiency the dosage should be determined for each patient and will vary with the preparation used and the circumstances of bleeding or type of surgery to be performed. Suggested target factor IX concentrations for patients with haemophilia B vary, but the following have been suggested:

- for mild to moderate haemorrhage the plasma concentration of factor IX should be raised to 20 to 30% of normal
- for more serious haemorrhage or minor surgery it should be raised to 30 to 60% of normal
- for severe haemorrhage or major surgery an increase to 60 to 100% of normal may be necessary

Calculation of the appropriate dose varies according to the manufacturers' recommendations.

For long-term prophylaxis in severe haemophilia B, doses of 20 to 40 international units/kg every 3 or 4 days, as required, may be used.

Factor XI

Facteur XI; Plasma Thromboplastin Antecedent; PTA.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Human Coagulation Factor XI; Factor XI Coagulationis Humanus; Dried Factor XI Fraction BP 2008). A plasma protein fraction that contains coagulation factor XI. It is prepared from human plasma obtained from blood from healthy donors; the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus. The method of preparation includes a step or steps that have been shown to remove or inactivate known agents of infection. The factor XI fraction is dissolved in a suitable liquid, distributed aseptically into the final containers, and immediately frozen. The preparation is freeze-dried and the containers sealed under vacuum or under nitrogen. Heparin, C_1-esterase inhibitor, and antithrombin III, may be added. No antimicrobial preservative is added. When reconstituted as stated on the label the resulting solution contains not less than 50 units/mL.

A white or almost white powder or friable solid. pH of the reconstituted preparation is 6.8 to 7.4. Store at a temperature of 2° to 8°. Protect from light.

Profile

Factor XI is used as replacement therapy in patients with congenital factor XI deficiency (haemophilia C; see Inherited Haemorrhagic Disorders, p.1050) for the prevention and treatment of haemorrhage. The dose is based on the degree of factor XI deficiency and the condition of the patient.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Hemoleven.

Factor XIII

Fibrin-stabilising Factor; FSF.

ATC — B02BD07.
ATC Vet — QB02BD07.

Profile

Factor XIII is used as replacement therapy in patients with a genetic deficiency of factor XIII (see Inherited Haemorrhagic Disorders, p.1050). It may also be used in patients with acquired deficiency of factor XIII (see Acquired Haemorrhagic Disorders, p.1047), and for supportive therapy in postoperative wound healing. Dosage of factor XIII is based on the degree of deficiency and the condition of the patient. For prophylaxis of haemorrhage in patients with genetic deficiency about 10 units/kg may be given intravenously once a month. The interval between doses may be shortened if spontaneous haemorrhage occurs. For pre-operative use, a dose of up to 35 units/kg may be given immediately before the operation and followed by adequate doses to maintain efficacy until the wound is healed. For the treatment of severe bleeding episodes 10 to 20 units/kg should be given daily, until bleeding stops. In acute bleeding, especially intracranial bleeding, doses of up to 50 units/kg may be needed to raise factor XIII to normal levels. Doses of at least 15 to 20 units/kg may be required for the treatment of haemorrhage in acquired factor XIII deficiency. In the promotion of postoperative wound healing, a dose of 10 units/kg may be given on the day of the operation and on each of the next 3 days. Like other clotting factor preparations (see Factor VIII, p.1067), the use of factor XIII may be associated with risks of hypersensitivity reactions, thrombosis, and viral infection transmission; inhibitors of factor XIII may occur very rarely.

Cryoprecipitate is also used as a source of factor XIII.

Factor XIII is also a component of fibrin glues (see Fibrin, p.1069).

Inflammatory bowel disease. Some patients with inflammatory bowel disease (p.1697) may be deficient in factor XIII, possibly due to increased intestinal blood loss seen in severe ulcerative colitis or increased mucosal deposition of factor XIII in Crohn's disease. Factor XIII concentrate given intravenously has produced beneficial results in 12 patients with active ulcerative colitis resistant to conventional therapy with corticosteroids and mesalazine[1] and has also been associated with healing of intractable fistulae in 3 of 4 patients with Crohn's disease.[2] However, a controlled study[3] found no benefit from factor XIII in active corticosteroid-refractory ulcerative colitis.

Preparations

Ph. Eur.: Fibrin Sealant Kit.

Proprietary Preparations (details are given in Part 3)
Arg.: Fibrogammin P; ***Austria:*** Fibrogammin; ***Belg.:*** Fibrogammin; ***Braz.:*** Fibrogammin; ***Cz.:*** Fibrogammin P†; ***Ger.:*** Fibrogammin; ***Hong Kong:*** Fibrogammin P; ***Israel:*** Fibrogammin P; ***Switz.:*** Fibrogammin; ***UK:*** Fibrogammin P.

Multi-ingredient: ***Arg.:*** Beriplast P; Tissucol; Tissucol Duo Quick†; ***Austral.:*** Tisseel Duo; ***Austria:*** Beriplast; Tissucol; Tissucol Duo Quick; ***Belg.:*** Tissucol Duo; ***Braz.:*** Beriplast P; ***Canad.:*** Tisseel; ***Chile:*** Beriplast P; ***Cz.:*** Tissucol; ***Denm.:*** Tisseel Duo Quick; ***Fin.:*** Tisseel Duo Quick; ***Fr.:*** Beriplast; Tissucol; ***Ger.:*** Beriplast; Tissucol Duo S; Tissucol-Kit; ***Gr.:*** Beriplast P; ***Hong Kong:*** Beriplast P; Tisseel; ***Hung.:*** Beriplast P; Tissucol-Kit; ***Indon.:*** Beriplast; ***Israel:*** Beriplast; Tisseel; ***Ital.:*** Beriplast; ***Mex.:*** Beriplast P; Tissucol†; ***Neth.:*** Beriplast P; Tissucol; Tissucol Duo; ***Pol.:*** Beriplast; ***Port.:*** Tissucol Duo; ***Spain:*** Beriplast P Combi; Tissucol Duo; ***Swed.:*** Tisseel Duo Quick; ***Switz.:*** Beriplast P; Tissucol; Tissucol Duo S; ***Turk.:*** Beriplast P; ***UK:*** Tisseel.

Fibrin *(rINN)*

Fibrina; Fibrine; Fibrinum.

Фибрин

Pharmacopoeias. Many pharmacopoeias have monographs for fibrin preparations, including *Eur.* (see p.vii).

Ph. Eur. 6.2 (Fibrin Sealant Kit; Fibrini Glutinum). It is composed of two components, a fibrinogen concentrate containing human fibrinogen (component 1), and a human thrombin preparation (component 2). The kit may also contain other ingredients, such as human factor XIII, a fibrinolysis inhibitor, or calcium ions. Stabilisers such as human albumin may be added. The human constituents are obtained from plasma for fractionation and the method of preparation includes a step or steps that have been shown to remove or inactivate known agents of infection. The constituents are passed through a bacteria-retentive filter and distributed aseptically into sterile containers. Containers of freeze-dried constituents are sealed under vacuum or filled with oxygen-free nitrogen or other suitable inert gas before sealing. No antimicrobial preservative is added. When thawed or reconstituted as stated on the label, the fibrinogen concentrate contains not less than 40 g/litre of clottable protein; the activity of the thrombin preparation varies over a wide range (about 4 to 1000 international units/mL). Protect from light.

Profile

Fibrin glue is prepared by mixing solutions containing fibrinogen, thrombin, and calcium ions, with the addition of aprotinin to inhibit fibrinolysis. It may also include factor XIII and other clotting components. Fibrin glue is used as a haemostatic to control haemorrhage during surgical procedures or as a spray to bleeding surfaces.

A dry artificial sponge of human fibrin, known as human fibrin foam, has been used similarly; it is prepared by clotting human thrombin with a foam of human fibrinogen solution. A collagen sponge coated with thrombin and fibrinogen is also available.

Adverse effects. Fatal neurotoxicity has been reported[1] after the use of a fibrin sealant during neurosurgical procedures. The toxicity may have been due to the presence of tranexamic acid as a stabiliser in the formulation, and such formulations should not be used in surgical operations where contact with the CSF or dura mater could occur.[2]

For rare reports of hypersensitivity reactions to aprotinin used locally as a component of fibrin sealant, see p.1055.

Fibrinogen

Factor I; Fibrinogène; Fibrinógeno; Fibrinogenum; Fibrinojen; Fibrynogen.

ATC — B02BB01; B02BC10.
ATC Vet — QB02BB01.

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii).

Ph. Eur. 6.2 (Human Fibrinogen; Fibrinogenum Humanum). It contains the soluble constituent of human plasma that is transformed to fibrin on addition of thrombin. It is obtained from plasma for fractionation and the method of preparation includes a step or steps that have been shown to remove or inactivate known agents of infection. Stabilisers, including protein such as human albumin, salts, and buffers may be added. No antimicrobial preservative is added. When dissolved in the volume of solvent stated on the label, the solution contains not less than 10 g/litre of fibrinogen.

A white or pale yellow hygroscopic powder or friable solid. Store in airtight containers. Protect from light.

Profile

Fibrinogen has been used to control haemorrhage associated with low blood-fibrinogen concentration in afibrinogenaemia or hypofibrinogenaemia although plasma or cryoprecipitate is usually preferred. Fibrinogen has also been used in disseminated intravascular coagulation (p.1048). It is a component of fibrin glue (see Fibrin, above). Recombinant human fibrinogen is under investigation.

Fibrinogen labelled with radionuclides has also been used in diagnostic procedures.

Preparations

Stability. Solutions of filgrastim must not be diluted with sodium chloride solutions as precipitation will occur. Glucose 5% solution may be used if dilution is necessary. However, filgrastim in diluted solution may be adsorbed onto glass or plastic materials and so it should not be diluted below the recommended minimum concentration (2 micrograms/mL). Also, to protect from adsorption, solutions that are diluted to concentrations of filgrastim below 15 micrograms/mL must have albumin added to give a final concentration of 2 mg/mL. For mention of the stability of filgrastim in a solution intended for enteral use in neonates, see Stability under Epoetins, p.1061.

Adverse Effects

The main adverse effects of granulocyte colony-stimulating factors such as filgrastim during short-term treatment are musculoskeletal pain and dysuria. Hypersensitivity reactions have been reported rarely. In patients receiving long-term treatment the most frequent adverse effects are bone pain and musculoskeletal pain. Other adverse effects include splenic enlargement, thrombocytopenia, anaemia, epistaxis, headache, diarrhoea, and cutaneous vasculitis. There have been reports of pulmonary infiltrates leading to respiratory failure or acute respiratory distress syndrome, and rare reports of splenic rupture. Rises in lactate dehydrogenase, alkaline phosphatase, and uric acid, are usually mild to moderate, dose-dependent, and reversible.

Colony-stimulating factors are fetotoxic in *animal* studies.

Effects on the bones. Bone mineral loss and osteoporosis have been reported in children with severe congenital neutropenia receiving granulocyte colony-stimulating factor for long periods.[1-3] However, the role of granulocyte colony-stimulating factor in producing this effect is uncertain since bone mineral loss may be a feature of the underlying disease.

Effects on the eyes. Subretinal haemorrhage resulting in irreversible loss of vision in one eye occurred in a 4-year-old girl who received filgrastim and nartograstim for chemotherapy-induced neutropenia and for mobilising peripheral blood stem cells.[1] It was postulated that the colony-stimulating factor reactivated a primary ocular inflammation probably caused by an infection. Bilateral peripapillary and macular retinal haemorrhage occurred in an adult being treated for mantle cell lymphoma.[2] It was attributed to retinal leucostasis secondary to hyperleucocytosis resulting from the use of filgrastim for stem cell mobilisation. Vision improved after cessation of filgrastim and the use of leucapheresis.

2. Salloum E, *et al.* Hyperleukocytosis and retinal hemorrhages after chemotherapy and filgrastim administration for peripheral blood progenitor cell mobilization. *Bone Marrow Transplant* 1998; **21:** 835–7.

Effects on the lungs. There have been reports of exacerbation of chemotherapy-induced pulmonary toxicity in patients receiving granulocyte colony-stimulating factor (G-CSF) with bleomycin, cyclophosphamide, or methotrexate. A systematic review[1] of 73 cases noted that the doses of the antineoplastics were below the usual toxic cumulative dose, suggesting that G-CSF may have lowered the threshold for pulmonary toxicity of these drugs. It has been proposed that G-CSF has an activating effect on neutrophils that makes them toxic to the alveolar capillary wall. The review also included 2 cases of pulmonary toxicity in non-neutropenic patients treated with G-CSF alone. The circumstances of 9 other cases suggested that neutropenic patients with a recent history of pulmonary infiltrates may be at increased risk of acute respiratory distress syndrome during neutropenia recovery. The true role of G-CSF in these cases of pulmonary toxicity remains unclear, however.

Effects on the skin. Skin reactions may occur in patients given colony-stimulating factors. In a study in women with inflammatory breast cancer, a pruritic skin reaction developed at the subcutaneous injection site in all 7 given granulocyte-macrophage colony-stimulating factor.[1] A review[2] of 8 cases of generalised pruritic maculopapular rash associated with granulocyte or granulocyte-macrophage colony-stimulating factor found that in 6 of them the rash resolved in 4 to 17 days even though therapy was continued and half the patients did not receive any treatment for the rash. A localised lichenoid reaction has been described for granulocyte colony-stimulating factor.[3] Exacerbation of psoriasis[4] and precipitation or exacerbation of neutrophilic dermatoses including Sweet's syndrome,[5-7] pyoderma gangrenosum,[8] and neutrophilic eccrine hidradenitis[9] have been reported following use of granulocyte colony-stimulating factor.

Effects on the thyroid. Reversible thyroid dysfunction has been reported in patients with pre-existing thyroid antibodies during treatment with granulocyte-macrophage colony-stimulating factor,[1] but not with granulocyte colony-stimulating factor.[2] However, clinical hypothyroidism has been reported in a patient with no history of thyroid dysfunction or thyroid antibodies during treatment with granulocyte colony-stimulating factor.[3]

Precautions

Since granulocyte colony-stimulating factors such as filgrastim can promote growth of myeloid cells *in vitro* their use in myeloid malignancies has been contra-indicated, although recently colony-stimulating factors have been used in some patients with myeloid diseases without stimulation of malignant cells. However, caution is required when they are used in patients with any pre-malignant or malignant myeloid condition. Filgrastim and lenograstim should not be used from 24 hours before until 24 hours after cytotoxic chemotherapy because of the sensitivity of rapidly dividing myeloid cells. Pegfilgrastim should not be used from 14 days before until 24 hours after chemotherapy. The safety and efficacy of granulocyte colony-stimulating factor therapy has not been established in patients receiving chemoradiotherapy, and concomitant use is generally avoided.

Granulocyte colony-stimulating factors should be used with caution in patients with sickle-cell disease. Preparations of filgrastim may contain sorbitol as an excipient; care is advisable in patients with hereditary fructose intolerance.

The complete blood count should be monitored regularly during therapy with granulocyte colony-stimulating factors. Treatment should be withdrawn in patients who develop signs of pulmonary infiltrates. Transient positive changes in bone imaging findings have occurred with growth factor therapy, and should be considered when interpreting results. Bone density should be monitored in patients with osteoporosis who are receiving long-term treatment with filgrastim.

Sickle-cell disease. Granulocytosis occurs during sickle-cell crisis (p.1044) although the role of granulocytes in vaso-occlusion has not been established. Sickle-cell crisis has occurred in patients with sickle-cell disease who have been given granulocyte colony-stimulating factor.[1-3]

3. Wei A, Grigg A. Granulocyte colony-stimulating factor–induced sickle cell crisis and multiorgan dysfunction in a patient with compound heterozygous sickle cell/β thalassemia. *Blood* 2001; **97:** 3998–9.

Pharmacokinetics

After subcutaneous injection, peak serum concentrations of filgrastim occur within about 8 hours. The serum elimination half-life of filgrastim after intravenous or subcutaneous injection is about 3.5 hours. Pegfilgrastim peak concentrations occur later, at 16 to 120 hours after subcutaneous doses. Elimination of pegfilgrastim is non-linear and clearance becomes saturated and decreases with increasing dose. It is mainly eliminated by neutrophil-mediated clearance, such that the serum concentration of pegfilgrastim declines rapidly with neutrophil recovery. It has a half-life of 15 to 80 hours after subcutaneous injection.

◊ Reviews.

Uses and Administration

Filgrastim is a granulocyte colony-stimulating factor (G-CSF), a haematopoietic growth factor that stimulates the development of granulocytes (see Haematopoiesis, p.1042). It is used to treat or prevent neutropenia in patients receiving myelosuppressive cancer chemotherapy and to reduce the period of neutropenia in patients undergoing bone marrow transplantation. It is also used to mobilise peripheral blood progenitor cells for collection and subsequent use in autologous or allogeneic peripheral blood stem cell transplantation. Filgrastim is also used in the management of chronic neutropenia (congenital, cyclic, or idiopathic), and for persistent neutropenia in patients with advanced HIV infection.

Filgrastim may be given intravenously or subcutaneously. Doses may be expressed in micrograms or in units; 10 micrograms is equivalent to 1 million units.

As an **adjunct to antineoplastic therapy**, filgrastim is given in a dose of 5 micrograms/kg daily starting not less than 24 hours after the last dose of antineoplastic. It can be given as a single daily subcutaneous injection, as a continuous intravenous or subcutaneous infusion, or as a daily intravenous infusion over 15 to 30 minutes. Treatment is continued until the neutrophil count has stabilised within the normal range which may take up to 14 days or more. A formulation of filgrastim conjugated with monomethoxy polyethylene glycol (pegfilgrastim) may also be used to reduce the incidence of neutropenia associated with antineoplastic therapy; it is given by subcutaneous injection in a single dose of 6 mg, given not less than 24 hours after the last dose of antineoplastic.

The initial dose of filgrastim following **bone marrow transplantation** is 10 micrograms/kg daily, adjusted according to response. This may be given by intravenous infusion over 30 minutes or 4 hours, or by continuous intravenous or subcutaneous infusion over 24 hours.

For **mobilisation** of peripheral blood progenitor cells for autologous peripheral blood stem cell transplantation, a dose of 10 micrograms/kg daily of filgrastim may be given subcutaneously as a single daily injection or by continuous infusion for 4 to 7 days until the last leucapheresis procedure (usually performed on days 5 to 7 as required). If filgrastim is given after myelosuppressive chemotherapy, the dose is halved to 5 micrograms/kg daily by subcutaneous injection. It is given from the first day after completion of chemotherapy until the expected neutrophil nadir is passed and the neutrophil count has recovered to the normal range, so that leucapheresis can be performed. For mobilisation of cells in healthy donors, to use in allogeneic transplantation, a dose of 10 micrograms/kg daily may be given subcutaneously for 4 or 5 days until leucapheresis (usually started on day 5).

In patients with **congenital neutropenia** the initial dose is 12 micrograms/kg daily and in patients with idiopathic or cyclic neutropenia the initial dose is 5 micrograms/kg daily. In these forms of neutropenia the dose is given subcutaneously in single or divided doses and should be adjusted according to response.

In patients with **HIV infection** and persistent neutropenia the initial dose is 1 microgram/kg daily by subcutaneous injection. The dose may be titrated up to a maximum of 4 micrograms/kg daily until a normal neutrophil count is achieved and then adjusted for maintenance according to response. Maintenance doses of 300 micrograms daily on 1 to 7 days a week have been used.

The filgrastim doses described above for patients receiving antineoplastic therapy and for chronic neutropenias may also be given to **children**. Pegfilgrastim should not be used in children or adolescents weighing less than 45 kg.

Aplastic anaemia. Colony-stimulating factors, including granulocyte colony-stimulating factors, have been tried in patients with aplastic anaemia (p.1042).

Infections. As well as stimulating the development and maturation of haematopoietic precursors, granulocyte and granulocyte-macrophage colony-stimulating factors have been found to enhance neutrophil chemotaxis and phagocytosis, enhance oxidative activity, increase microbicidal activity and antibody-mediated cellular cytotoxicity, and delay neutrophil apoptosis. Granulocyte-macrophage colony-stimulating factor also modifies macrophage and monocyte functions in inflammation and cellular immune response.[1] It has therefore been suggested that colony-stimulating factors might be useful adjuncts in the treatment of infections in non-neutropenic patients, but their clinical role is yet to be established.

The use of granulocyte colony-stimulating factor was reported[2] to reduce mortality rates in patients with septic shock due to the bacterial infection melioidosis (p.178). In small placebo-controlled studies of patients with the protozoal infection cutaneous leishmaniasis (p.824), ulcers healed faster in those treated with granulocyte-macrophage colony-stimulating factor, as an adjunct to antimony therapy, by intralesional injection[3] and topical application.[4]

However, granulocyte colony-stimulating factor does not appear to be of benefit as an adjunct in the management of pneumonia[5] (p.186). In diabetic foot infections (see Diabetic Complications, p.433) granulocyte colony-stimulating factor does not appear to affect wound healing, although there is some suggestion that it may reduce the likelihood of surgical intervention.[6]

In HIV infection (p.856), granulocyte-macrophage colony-stimulating factor has been reported to improve CD4+ cell counts.[7]

Granulocyte-macrophage colony-stimulating factor has been investigated as an adjuvant for hepatitis B vaccination in healthy subjects, patients with chronic renal failure or on haemodialysis, and in HIV-infected patients. Overall, the colony-stimulating factor appears to improve seroconversion rates and antibody titres, but further study is needed.[8]

Ischaemia. Colony-stimulating factors have been investigated for their ability to mobilise stem cells and modulate inflammation in cardiovascular disorders characterised by ischaemia. In patients with atherosclerotic coronary artery disease (p.1159) filgrastim[1] and molgramostim[2] have been tried in an attempt to promote neovascularisation; there was no cardiac benefit with the former, and although the latter promoted collateral artery growth the balance of benefit to risk was questionable, since 2 of 7 actively treated patients developed an acute coronary syndrome. Benefit has been reported in 7 patients with acute ischaemic stroke (p.1185) given filgrastim 15 micrograms/kg subcutaneously daily for 5 days in addition to the usual care given to 3 controls.[3] There was a greater improvement in neurological function in filgrastim-treated patients on 12 months of follow-up, but larger studies are required to confirm the benefit.

Neutropenia. Granulocyte colony-stimulating factors are used in the management of neutropenia. They may be used[1] long-term in the management of inherited forms of neutropenia (p.1051). They are used short-term[2-5] to treat or prevent antineoplastic-induced neutropenia (p.640) and have also been used in patients with neutropenia induced by a wide range of other drugs.[6-11] The use of colony-stimulating factors has been investigated[12] in the management of neutropenia in patients with HIV-associated infection (p.857). A controlled study[13] in 258 patients with advanced HIV infection found that prophylactic use of granulocyte colony-stimulating factor reduced the incidence of severe neutropenia and also suggested that the incidence and duration of bacterial infections was reduced.

Due to immature neutrophil production and function, neonates are susceptible to infection and preterm neonates are at particular risk. The use of colony-stimulating factors for prophylaxis or as adjuncts in the treatment of septicaemia (p.190) in neonates has been investigated in a few small trials but there is insufficient evidence of benefit to recommend the use of granulocyte or granulocyte-macrophage colony-stimulating factors in these patients. Although there is limited evidence to suggest that they may reduce mortality as adjuncts to treatment in patients with sepsis and severe neutropenia, further study is needed.[14,15] Granulocyte colony-stimulating factors have also been tried with mixed results in neonates with the rare condition of alloimmune neutropenia.[16,17]

Gelatin ⊗

Gelatina; Gélatine; Liivate; Modifiye Jelatin; Želatina; Żelatyna; Zselatin.

ATC — B02BC01 (absorbable gelatin sponge); B05AA06 (gelatin).

ATC Vet — QB02BC01 (absorbable gelatin sponge); QB05AA06 (gelatin).

Grades. Gelling grades of gelatin are usually graded by gel strength, expressed as 'Bloom value', 'Bloom strength', or 'Bloom rating'.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *Viet.* Also in *USNF.*

The gelatin described in some pharmacopoeias is not necessarily suitable for preparations for parenteral use or for other special purposes.

Ph. Eur. 6.2 (Gelatin). A purified protein obtained either by partial acid hydrolysis (type A), by partial alkaline hydrolysis (type B), or by enzymatic hydrolysis of collagen from animals (including fish and poultry); it may also be a mixture of different types. The hydrolysis leads to gelling and non-gelling product grades. Gelling grades are characterised by the gel strength (Bloom value). It is not suitable for parenteral use or for other special purposes.

A faintly yellow or light yellowish-brown solid, usually occurring as translucent sheets, shreds, powder, or granules.

Gelling grades of gelatin swell in cold water and on heating give a colloidal solution which on subsequent cooling forms a more or less firm gel. Gelatin is practically insoluble in common organic solvents. Different gelatins form aqueous solutions that vary in clarity and colour. A 1% solution in water at about 55° has a pH of 3.8 to 7.6. Protect from heat and moisture.

USNF 26 (Gelatin). It is obtained by the partial hydrolysis of collagen derived from the skin, white connective tissue, and bones of animals. Gelatin derived from an acid-treated precursor is known as Type A, and gelatin derived from an alkali-treated precursor is known as Type B.

Faintly yellow or amber sheets, flakes, or shreds, or a coarse to fine powder, the colour varying in depth according to the particle size. A solution has a slight, characteristic, bouillon-like odour. It is stable in air when dry, but is subject to microbial decomposition when moist or in solution. Gelatin swells and softens when immersed in cold water, gradually absorbing 5 to 10 times its weight of water. Soluble in hot water, in 6N acetic acid, and in a hot mixture of glycerol and water; insoluble in alcohol, in chloroform, in ether, and in fixed and volatile oils.

Incompatibility. A white precipitate was formed immediately when vancomycin injection was infused through a giving set containing modified fluid gelatin solution.[1]

1. Taylor A, Hornbrey P. Incompatibility of vancomycin and gelatin plasma expanders. *Pharm J* 1991; **246:** 466.

Adverse Effects

Hypersensitivity reactions including anaphylactic reactions have occurred after the infusion of gelatin or its derivatives. Rapid infusion of gelatin derivatives may directly stimulate the release of histamine and other vasoactive substances.

For adverse reactions associated with the topical use of gelatin, see Haemostasis under Uses and Administration, below.

Hypersensitivity. Severe anaphylactoid reactions have been reported with infusion of modified fluid gelatin solutions.[1,2] As of June 2006, the Australian Adverse Drug Reactions Advisory Committee (ADRAC)[3] had also received 70 reports of hypotension or hypersensitivity reactions associated with succinylated gelatin. Although severe hypersensitivity reactions to gelatin-based plasma expanders appear to be rare, they may be under-reported and fatalities have occurred.[2] The possibility of cross reactivity between succinylated gelatin and polygeline has also been considered; there are a few reports of patients who, after a reaction during clinical use with one plasma expander, have shown a positive skin test result to the other.[4,5] Some hypersensitivity reactions have been attributed to the use of gelatin as an excipient in vaccines[6-8] and other injectable drug products.[9] A haemostatic gelatin sponge put into place at the end of spinal surgery for a disc hernia was thought to be responsible for a delayed hypersensitivity reaction that caused oedema of the soft tissues and subsequent tingling and paresis of the lower limbs; removal of the sponge produced improvement.[10]

For reports of fatal reactions in asthmatic patients given gelatin derivatives, see Polygeline, p.1077.

Precautions

When gelatin or its derivatives are used as plasma expanders the precautions under Dextran 70 (p.1060) should be considered. There does not appear to be any interference with blood grouping and cross-matching of blood.

When gelatin is used as an absorbable haemostatic the precautions under Oxidised Cellulose (p.1075) should be considered.

Pharmacokinetics

After infusion of modified fluid gelatin (succinylated gelatin), 75% of the dose is excreted in the urine in 24 hours. The half-life is about 4 hours.

Uses and Administration

Gelatin is a protein that has both clinical and pharmaceutical uses.

Gelatin is used as a haemostatic in surgical procedures as an absorbable film or sponge and can absorb many times its weight of blood. It is also employed as a plasma volume expander similarly to the dextrans in hypovolaemic shock (p.1183). A 4% solution of a modified fluid gelatin (succinylated gelatin) has been infused in doses of 500 to 1000 mL. It may also be used in the form of a gelatin-derived polymer, see Polygeline, p.1077.

Gelatin rods may be employed to temporarily block tear outflow in the diagnosis of dry eye (p.2140).

Gelatin is used in the preparation of pastes, pastilles, suppositories, tablets, and hard and soft capsule shells. It is also used for the microencapsulation of drugs and other industrial materials. It has been used as a vehicle for injections: Pitkin's Menstruum, which consists of gelatin, glucose, and acetic acid, has been used in a modified form for heparin while hydrolysed gelatin has been used for corticotropin. Gelatin is an ingredient of preparations used for the protection of stomas and lesions.

Haemostasis. Gelatin acts as a haemostatic (p.1045) by providing a physical meshwork within which clotting can occur.

Gelatin powder may be applied dry to wound beds and may be most useful when mixed with saline or thrombin and applied to bone. Gelatin sponge can be applied dry or soaked in saline or thrombin solutions. When applied to skin wounds the gelatin liquefies within 2 to 5 days; when implanted into tissues it is absorbed within 4 to 6 weeks. Adverse reactions include an increased incidence of infection, compression of surrounding tissue due to fluid absorption, granuloma formation, and fibrosis. Generally, gelatin sponges cause little tissue reaction and can be applied to bone, dura, and pleural tissue (but see also Hypersensitivity, above).

Neonatal intraventricular haemorrhage. Plasma volume expansion in preterm neonates has been thought to help prevent neonatal intraventricular haemorrhage (p.1050). However, a study using plasma or gelatin as plasma volume expanders,[1,2] found no evidence of a decreased risk of such haemorrhage or subsequent death or disability.

Haemoglobin ⊗

Hemoglobina.

Hemoglobin Glutamer *(rINN)* ⊗

Haemoglobin Glutamer; Hemoglobina glutámero; Hémoglobine Glutamère; Hemoglobinum Glutamerum.

Гемоглобин Глутамер

ATC — B05AA10 (bovine).

ATC Vet — QB05AA10 (bovine); QB05AA90.

NOTE. The species of origin and average molecular mass should be indicated (e.g. hemoglobin glutamer-250 (bovine) indicates a polymerised haemoglobin of bovine origin with an average mass of 250 kD).

Profile

Haemoglobin has the property of reversible oxygenation and is the respiratory pigment of blood. Solutions of haemoglobin or modified haemoglobin are being investigated as blood substitutes.

Hemoglobin glutamer-250 (bovine) (HBOC-201; haemoglobin-based oxygen carrier-201) is a polymerised bovine haemoglobin that is used for the treatment of anaemia in surgical patients.

Hemoglobin glutamer-200 (bovine) (HBOC-301) is used in veterinary medicine for the treatment of anaemia in *dogs*.

Use. The structure of haemoglobin gives a non-linear oxygen dissociation curve; almost maximum oxygen saturation occurs in normal arterial blood without the need for oxygen-enriched air. Thus the use of haemoglobin solutions for emergencies appears logical. Initial *animal* experiments with haemoglobin from haemolysed erythrocytes resulted in serious renal damage but haemoglobin is not itself nephrotoxic and the development of stroma-free haemoglobin solutions reduced this toxicity. However, once released from the erythrocytes, haemoglobin loses its ability to hold 2,3-diphosphoglycerate, which is essential for the delivery of oxygen, and haemoglobin, being a small molecule, is rapidly excreted by the kidneys. Various methods have been tried to overcome these problems; formation of crosslinked haemoglobin restores the oxygen affinity to that of whole blood and conjugation, polymerisation, or microencapsulation in a lipid membrane extend the half-life. Although there is ongoing development of these preparations there are reservations concerning haemoglobin solutions as blood substitutes. Bovine blood is one source used for production but there are concerns about potential antigenicity or disease transmission; the use of outdated donated human blood is limited by availability. There is also concern about impairment of immune mechanisms. The development of recombinant human haemoglobin may overcome these problems and may allow further modification of the haemoglobin molecule.

Preparations

Proprietary Preparations (details are given in Part 3)
S.Afr.: Hemopure.

Multi-ingredient: *India:* Blosyn; Haem Up.

Interleukin-3

IL-3; Interleucina 3.

Profile

Interleukin-3 is a cytokine that acts as a colony-stimulating factor. It is under investigation in the management of myelosuppression associated with cancer chemotherapy and after bone marrow transplantation. A fusion molecule with granulocyte-macrophage colony-stimulating factor, known as milodistim (PIXY-321), has also been investigated but results have been disappointing.

Lenograstim *(BAN, USAN, rINN)*

Lenograstiimi; Lénograstim; Lenograstimum; rG-CSF. A recombinant human granulocyte colony-stimulating factor.

Ленограстим

CAS — 135968-09-1.
ATC — L03AA10.
ATC Vet — QL03AA10.

Stability. Solutions of colony-stimulating factors may be adsorbed onto glass or plastic materials. Solutions of lenograstim should not be diluted below the minimum recommended concentration for the formulation used.

Adverse Effects and Precautions

As for Filgrastim, p.1070.

Uses and Administration

Lenograstim is a granulocyte colony-stimulating factor with actions and uses similar to those of filgrastim (p.1071). It is used to treat or prevent neutropenia in patients receiving myelosuppressive cancer chemotherapy and to reduce the period of neutropenia in patients undergoing bone marrow transplantation (p.640). It is also used to mobilise peripheral blood progenitor cells for collection and subsequent use in autologous or allogeneic peripheral blood stem cell transplantation.

Lenograstim may be given for **neutropenia** in a dose of 150 micrograms/m^2 (19.2 million international units/m^2) daily to patients after bone marrow transplantation and also to patients established on antineoplastic therapy; in post-transplant patients it is given by intravenous infusion over 30 minutes or by subcutaneous injection, and in patients on antineoplastics it is given subcutaneously. Treatment is given until the neutrophil count has stabilised within the normal range, but a maximum treatment period of 28 consecutive days should not be exceeded.

For **mobilisation** of peripheral blood progenitor cells for autologous peripheral blood stem cell transplantation, a dose of 150 micrograms/m^2 (19.2 million international units/m^2) daily may be given by subcutaneous injection. It is started the day after completion of chemotherapy and given until the expected neutrophil nadir is passed and the neutrophil count has recovered to the normal range, so that leucapheresis can be performed. When used alone, a lenograstim dose of 10 micrograms/kg (1.28 million international units/kg) daily is given subcutaneously for 4 to 6 days, with leucapheresis usually performed between days 5 and 7. For mobilisation of cells in healthy donors, to use in allogeneic transplantation, a dose of 10 micrograms/kg daily may be given subcutaneously for 5 or 6 days before leucapheresis.

Leucocytes

Leucocitos.

Description. Preparations of leucocytes contain granulocytes with a variable content of red blood cells, lymphocytes, and platelets. Depending on the method of collection they may also contain dextran or hetastarch.

Adverse Effects and Precautions

Leucocyte transfusions may cause severe transfusion reactions and fever. As with other blood products, there is a risk of transmission of infection. Severe lung reactions, including fluid overload with pulmonary oedema, are a particular problem in patients with active pulmonary infections.

Red blood cell compatibility testing is necessary because of the content of red blood cells. Graft-versus-host disease may occur in immunosuppressed recipients, and can be avoided by irradiating the product before it is given.

Uses and Administration

Transfusion of leucocytes has been used in patients with severe granulocytopenia and infection which has not been controlled by treatment with appropriate antimicrobials. Transfusion of 1×10^{10} granulocytes once or twice daily has been suggested as an effective dose. Daily transfusions for at least 3 to 4 days are usually advised. Hydrocortisone and chlorphenamine may be given intravenously before transfusion to reduce the severity of adverse reactions.

Mirimostim *(rINN)*

Mirimostimum. A macrophage colony-stimulating factor; 1–214-Colony-stimulating factor 1 (human clone p3ACSF-69 protein moiety reduced), homodimer.

Миримостим

CAS — 121547-04-4.

Profile

Mirimostim is a macrophage colony-stimulating factor (M-CSF). It promotes the differentiation and proliferation of monocytes and macrophage precursors, and stimulates secretion of granulocyte and granulocyte-macrophage colony-stimulating factors (see Haematopoiesis, p.1042). Mirimostim is used in the management of neutropenia in patients receiving myelosuppressive cancer chemotherapy.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Leukoprol.

Molgramostim *(BAN, USAN, rINN)*

Molgramostiimi; Molgramostimum; Sch-39300. A recombinant human granulocyte-macrophage colony-stimulating factor; Colony-stimulating factor 2 (human clone pHG_{25} protein moiety reduced).

Молграмостим

CAS — 99283-10-0.
ATC — L03AA03.
ATC Vet — QL03AA03.

Pharmacopoeias. *Eur.* (see p.vii) includes a concentrated solution.

Ph. Eur. 6.2 (Molgramostim Concentrated Solution; Molgramostimi Solutio Concentrata). A solution of a protein having the structure of the granulocyte-macrophage colony-stimulating factor which is produced and secreted by various human blood cell types. It contains not less than 2.0 mg of protein per mL. A clear, colourless liquid. Store in airtight containers at a temperature below −65°. Protect from light.

Stability. Solutions of molgramostim may be adsorbed onto glass and plastic materials and therefore should not be diluted below the recommended minimum concentration of 7 micrograms/mL.

Adverse Effects

Granulocyte-macrophage colony-stimulating factors such as molgramostim may cause transient hypotension and flushing, bone pain and musculoskeletal pain, fever and chills, dyspnoea, rash, fatigue, and gastrointestinal effects. Antibodies have been detected. Anaphylactic reactions, pleural and pericardial effusion, and cardiac arrhythmias have been reported rarely.

Colony-stimulating factors are fetotoxic in *animal* studies.

Antibodies. Antibodies can develop in patients given recombinant granulocyte-macrophage colony-stimulating factors. The antibodies have been reported to occur more commonly, and in higher titres, in patients who are not immunocompromised compared with those who are.[1,2] Although some binding antibodies are non-neutralising and have no apparent clinical effect,[3] neutralising antibodies can reduce the efficacy of the colony-stimulating factor in repeated treatment cycles.[1,2] However, antibodies have been reported to become undetectable after a number of weeks[2] and do not appear to have long-term effects.[1] Cross-reactivity between different granulocyte-macrophage colony-stimulating factors has been reported,[1-3] and antibody formation may also be product dependent.[2]

3. Ullenhag G, *et al.* Incidence of GM-CSF antibodies in cancer patients receiving GM-CSF for immunostimulation. *Clin Immunol* 2001; **99:** 65–74.

Effects on the skin. See under Filgrastim, p.1070.

Effects on the thyroid. See under Filgrastim, p.1070.

Precautions

Since granulocyte-macrophage colony-stimulating factors such as molgramostim can promote growth of myeloid cells *in vitro* their use in myeloid malignancies has been contra-indicated, although recently colony-stimulating factors have been used in some patients with myeloid diseases without stimulation of malignant cells. However, caution is required when they are used in patients with any pre-malignant or malignant myeloid condition. They should not be used from 24 hours before until 24 hours after cytotoxic chemotherapy or radiotherapy because of the sensitivity of rapidly dividing myeloid cells.

Granulocyte-macrophage colony-stimulating factors should be used with caution in patients with pulmonary disease as they may be predisposed to dyspnoea. Treatment should be withdrawn in patients who develop signs of pulmonary infiltrates. Caution is also necessary in patients with fluid retention or heart failure as fluid retention may be aggravated.

The complete blood count should be monitored regularly during therapy.

Uses and Administration

Molgramostim is a granulocyte-macrophage colony-stimulating factor (GM-CSF), a haematopoietic growth factor that stimulates the development of white blood cells, particularly granulocytes, macrophages, and monocytes (see Haematopoiesis, p.1042). It is used to treat or prevent neutropenia in patients receiving myelosuppressive cancer chemotherapy and to reduce the period of neutropenia in patients undergoing bone marrow transplantation (p.640). It has also been used to reduce ganciclovir-induced neutropenia (see Effects on the Blood, p.879).

As an **adjunct to antineoplastic therapy**, molgramostim is given by subcutaneous injection, starting 24 hours after the last dose of antineoplastic, in a dose of 5 to 10 micrograms/kg (60 000 to 110 000 international units/kg) daily. Treatment should be continued for 7 to 10 days.

Following **bone marrow transplantation**, molgramostim may be given by intravenous infusion over 4 to 6 hours in a dose of 10 micrograms/kg (110 000 international units/kg) daily. Treatment should be begun the day after bone marrow transplantation and continued for up to 30 days depending on the neutrophil count.

For the management of **ganciclovir-induced neutropenia**, molgramostim has been given by subcutaneous injection in a dose of 5 micrograms/kg (60 000 international units/kg) daily. After 5 doses have been given the dose of molgramostim should be adjusted according to the neutrophil count.

The maximum dose for any indication should not exceed 10 micrograms/kg (110 000 international units/kg) daily.

Granulocyte colony-stimulating factors such as filgrastim (p.1070) and macrophage colony-stimulating factors such as mirimostim (p.1073) are also used.

Ischaemia. For mention of the use of molgramostim in patients with atherosclerotic coronary artery disease see under Filgrastim, p.1071.

Respiratory disorders. Pulmonary alveolar proteinosis is a rare diffuse lung disease that may result from impaired alveolar macrophage function caused by neutralising autoantibodies. It is characterised by excessive surfactant accumulation, and is usually managed with whole-lung lavage. Several months of therapy with subcutaneous granulocyte-macrophage colony-stimulating factor, typically in doses of 5 or 6 micrograms/kg daily, has been reported to induce remission in a number of these patients.[1-6] There has also been a case report[7] of the effective use of inhaled granulocyte-macrophage colony-stimulating factor.

Wounds and ulcers. Macrophages and granulocyte-macrophage colony-stimulating factors play important roles in several mechanisms essential to wound healing.[1] Recombinant granulocyte-macrophage colony-stimulating factors are being tried in non-healing wounds and ulcers (p.1585), particularly chronic venous leg ulcers. They have been given by perilesional subcutaneous injection and topical application in a few small studies and case reports with apparent promotion of wound healing.[1] In a study[2] of patients with pressure ulcers, healing was better during a 35-day period of treatment with granulocyte-macrophage colony-stimulating factor compared with placebo. However, a year after the treatment period there was no difference.[3] In a group of 3 patients with inherited disorders of neutrophil function, topical sargramostim was reported to be of benefit in wound healing.[4] In 1 case sargramostim was also given by continuous subcutaneous infusion for 72 hours into the surgical site of a gastrostomy closure. Topical molgramostim has also been used to promote healing of sickle-cell leg ulcers.[5] Molgramostim has been used as a mouthwash to relieve severe recurrent aphthous mouth ulcers in a small number of patients with AIDS.[6] There has also been some investigation of the use of granulocyte-macrophage colony-stimulating factor for oral mucositis in cancer patients, particularly those undergoing radiotherapy for head and neck cancers. Small studies of subcutaneous injection or topical application as a mouthwash have provided some optimistic results.[7,8] Comparative studies, however, have found molgramostim to be no better than hydrocortisone mouthwash[9] and perhaps only slightly better than sucralfate mouthwash.[10]

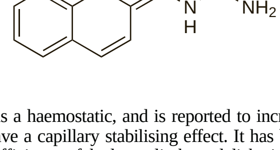
Naftazone *(BAN, rINN)*

Naftazona; Naftazonum. 1,2-Naphthoquinone 2-semicarbazone.

Нафтазон

$C_{11}H_9N_3O_2$ = 215.2.
CAS — 15687-37-3.



Profile

Naftazone is a haemostatic, and is reported to increase venous tone and have a capillary stabilising effect. It has been used in venous insufficiency of the lower limbs and diabetic retinopathy, in oral doses of 30 mg daily. It was formerly given by injection.

Preparations

Proprietary Preparations (details are given in Part 3)
Belg.: Mediaven; ***Fr.:*** Etioven; ***Switz.:*** Mediaven.

Nartograstim *(rINN)*

Nartograstimum. A recombinant human granulocyte colony-stimulating factor; *N*-L-Methionyl-1-L-alanine-3-L-threonine-4-L-tyrosine-5-L-arginine-17-L-serine colony-stimulating factor (human clone 1034).

Нартограстим

CAS — 134088-74-7.

Profile

Nartograstim is a granulocyte colony-stimulating factor with properties similar to those of filgrastim (p.1070). It has been given by intravenous or subcutaneous injection in the management of neutropenia.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Neu-Up.

Oprelvekin *(USAN, rINN)*

Oprelvekina; Oprelvékine; Oprelvekinum. 2-178-Interleukin 11 (human clone pXM/IL-11).

Опрельвекин

$C_{854}H_{1411}N_{253}O_{235}S_2$ = 19047.0.
CAS — 145941-26-0.
ATC — L03AC02.
ATC Vet — QL03AC02.

Adverse Effects and Precautions

Fluid retention may occur and lead to peripheral oedema, dyspnoea and pulmonary oedema, capillary leak syndrome, and exacerbation of pre-existing pleural effusions; caution is required when giving oprelvekin to patients with a history or signs of heart failure. Dilutional anaemia may occur. Fluid balance and electrolytes should be monitored in patients receiving long-term diuretic therapy. Transient atrial arrhythmias commonly occur; there have also been some reports of ventricular arrhythmias occurring within 2 to 7 days of starting oprelvekin. Other adverse effects include exfoliative dermatitis, blurred vision, and conjunctival injection. Hypersensitivity reactions, including anaphylaxis, have been reported with the use of oprelvekin. Papilloedema has been reported, and oprelvekin should be used with caution in patients with pre-existing papilloedema or tumours involving the CNS.

Use of oprelvekin after myeloablative chemotherapy and bone marrow transplantation is considered to be contra-indicated because of an increased incidence of adverse effects.

Fetotoxicity has been reported in *animals.*

◊ Reviews.

1. Smith JW. Tolerability and side-effect profile of rhIL-11. *Oncology (Huntingt)* 2000; **14** (suppl 8): 41–7.

Effects on the eyes. Papilloedema has been reported in patients treated with oprelvekin,[1] and was found to be a dose-limiting adverse effect in a study of safety and pharmacokinetics in children.[2]

1. Peterson DC, *et al.* Oprelvekin-associated bilateral optic disk edema. *Am J Ophthalmol* 2005; **139:** 367–8.
2. Cairo MS, *et al.* Phase I/II dose escalation study of recombinant human interleukin-11 following ifosfamide, carboplatin and etoposide in children, adolescents and young adults with solid tumours or lymphoma: a clinical, haematological and biological study. *Br J Haematol* 2005; **128:** 49–58.

Pharmacokinetics

The bioavailability of oprelvekin after subcutaneous injection is about 80%, peak serum concentrations are reached after about 3 hours, and it has a terminal half-life of about 7 hours. Oprelvekin is metabolised before excretion by the kidneys, and its clearance is reduced in renal impairment.

Uses and Administration

Oprelvekin, a recombinant human interleukin-11, is a platelet growth factor that stimulates the proliferation and maturation of megakaryocytes and thus increases the production of platelets. Oprelvekin is given by subcutaneous injection in a dose of 50 micrograms/kg daily to prevent severe thrombocytopenia and reduce the need for platelet transfusions in high-risk patients after myelosuppressive, but not myeloablative, chemotherapy for non-myeloid malignancies (see Thrombocytopenia under Treatment of Adverse Effects in Antineoplastics, p.640). The dose should be reduced in severe renal impairment (see below). The initial dose should be given 6 to 24 hours after the last dose of antineoplastic, and continued up to a maximum of 21 days. Treatment with oprelvekin should be stopped at least 2 days before starting the next planned cycle of chemotherapy.

Oprelvekin is under investigation for the treatment of Crohn's disease, rheumatoid arthritis, and chronic hepatitis C.

Administration in renal impairment. In severe renal impairment (creatinine clearance less than 30 mL/min) the recommended dose of oprelvekin is 25 micrograms/kg daily by subcutaneous injection.

Oxidised Cellulose

Cellulosic Acid; Celulosa oxidada; Oxidized Cellulose.

CAS — 9032-53-5.

ATC — B02BC02.

ATC Vet — QB02BC02.

Description. Oxidised cellulose is a sterile polyanhydroglucuronic acid, prepared by the oxidation of a suitable form of cellulose.

Pharmacopoeias. In *US* which also includes Oxidized Regenerated Cellulose.

USP 31 (Oxidized Cellulose). It contains not less than 16% and not more than 24% of carboxyl groups, calculated on the dried basis. It is a slightly off-white gauze or lint with a slight, charred odour. Insoluble in water and in acids; soluble in dilute alkalis. Store at a temperature not exceeding 8°. Protect from direct sunlight.

USP 31 (Oxidized Regenerated Cellulose). It contains 18 to 24% of carboxyl groups calculated on the dried basis. It is a slightly off-white knit fabric, with a slight odour. Insoluble in water and in dilute acids; soluble in dilute alkalis. Store at a temperature between 15° and 30°. Protect from direct sunlight.

Adverse Effects and Precautions

Foreign body reactions may occur after the use of oxidised cellulose or oxidised regenerated cellulose. Headache, burning, and stinging have been reported and sneezing has been noted after use in epistaxis. Oxidised cellulose swells on contact with a bleeding surface; this could result in tissue necrosis, nerve damage, obstruction, or vascular stenosis if packed closely, especially into bony cavities, or if wrapped tightly around blood vessels. To minimise such complications the removal of excess material should be considered after haemostasis is achieved, and oxidised cellulose should always be removed after use near the spinal cord or optic nerve. Oxidised cellulose should not be used in packing or implantation for fractures since it may interfere with bone regeneration or cause cyst formation. It should not be used as a surface dressing, except for immediate control of haemorrhage, as it inhibits epithelialisation.

Oxidised cellulose should be used as the dry material since moistening will reduce its ability to absorb blood. Silver nitrate or other escharotic chemicals should not be applied before use as cauterisation might inhibit absorption of oxidised cellulose. Thrombin is inactivated by the low pH of oxidised cellulose; it is recommended that oxidised cellulose should not be impregnated with other haemostatics or antibacterials.

Uses and Administration

Oxidised cellulose and oxidised regenerated cellulose are absorbable haemostatics (p.1045). When applied to a bleeding surface, they swell to form a gelatinous mass which aids in the formation of a clot. It is gradually absorbed by the tissues, usually within 7 to 14 days. These materials also have a weak bactericidal action. They are used in surgery as adjuncts in the control of moderate bleeding where suturing or ligation is impracticable or ineffective; they should not be used to control haemorrhage from large arteries. The gauze, lint, or knitted material should be laid on the bleeding surface or held firmly against the tissues until haemostasis is achieved; removal should then be considered (see Adverse Effects and Precautions, above). Oxidised cellulose should be used as the dry material as moistening will reduce its ability to absorb blood.

Arg.: Gelifundol†; ***Austria:*** Gelifundol; ***Cz.:*** Gelifundol†; ***Ger.:*** Gelifundol†; ***Hong Kong:*** Gelifundol†; ***Hung.:*** Gelifundol†; ***S.Afr.:*** Gelifundol†; ***Thai.:*** Gelifundol.

Pegzerepoetin Alfa ⊗

Methoxy Polyethylene Glycol-Epoetin Beta; Pegserepoetin Alfa; R-744; Ro-50-3821. 1-165-Erythropoietin (human) monoamide with α-(3-carboxypropyl)-ω-methoxypoly(oxy-1,2-ethanediyl).

CAS — 677324-53-7.

ATC — B03XA03.

ATC Vet — QB03XA03.

Adverse Effects and Precautions

As for Epoetins, p.1061.

Pharmacokinetics

In patients with chronic renal impairment, pegzerepoetin alfa is absorbed after subcutaneous injection with an absolute bioavailability of about 60%. It has a terminal elimination half-life of about 134 hours after intravenous injection and about 140 hours when given subcutaneously. Haemodialysis does not affect the pharmacokinetics of pegzerepoetin alfa.

Uses and Administration

Pegzerepoetin alfa is described as a continuous erythropoietin receptor activator (CERA). It has similar properties to the epoetins (p.1062), but a longer duration of action. Pegzerepoetin alfa is used in the treatment of anaemia associated with chronic renal failure (see Normocytic-normochromic Anaemia, p.1044). A starting dose of 600 nanograms/kg is given once every 2 weeks as a single intravenous or subcutaneous injection. The dose may be adjusted by about 25%, at monthly intervals, so that the rate of rise of haemoglobin is between 1 and 2 g per 100 mL each month. When the target haemoglobin concentration of between 11 and 12 g per 100 mL has been achieved, a maintenance dose of pegzerepoetin alfa may be given once monthly; this is equal to twice the dose that had been given once every 2 weeks.

Pegzerepoetin alfa is also under investigation in the treatment of anaemia in patients with non-myeloid malignant disease receiving chemotherapy.

Cz.: Mircera; ***Fr.:*** Mircera; ***Port.:*** Mircera; ***UK:*** Mircera; ***USA:*** Mircera.

Plasma

Pharmacopoeias. Many pharmacopoeias have monographs, including *Eur.* (see p.vii).

Ph. Eur. 6.2 (Human Plasma for Fractionation; Plasma Humanum ad Separationem). The liquid part of human blood remaining after separation of the cellular elements from whole blood or collected in an apheresis procedure; it is intended for the manufacture of plasma-derived products. It is obtained from healthy donors and is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus.

A light yellow to green, clear or slightly turbid liquid, without visible signs of haemolysis. Frozen plasma should be stored at or below −20°; it may still be used for fractionation if the temperature is between −20° and −15° for not more than a total of 72 hours without exceeding −15° on more than one occasion as long as the temperature is at all times −5° or lower.

Ph. Eur. 6.2 (Human Plasma (Pooled and Treated for Virus Inactivation); Plasma Humanum Coagmentum Conditumque ad Exstinguendum Virum). A frozen or freeze-dried, sterile, non-pyrogenic preparation obtained from human plasma derived from donors belonging to the same ABO blood group. The plasma used complies with the requirements for Human Plasma for Fractionation (above). The method of preparation is designed to minimise activation of any coagulation factor and includes a step or steps that have been shown to inactivate known agents of infection.

The frozen preparation, after thawing, is a clear or slightly opalescent liquid free from solid and gelatinous particles. The freeze-dried preparation is an almost white or slightly yellow powder or friable solid.

Adverse Effects and Precautions

As for Blood, p.1056, though with a low risk of transmitting cell-associated viruses. However, the production of blood products using plasma from UK donors has been phased out due to the possible risk of transmission of Creutzfeldt-Jakob disease.

Uses and Administration

Fresh frozen plasma contains useful amounts of clotting factors. It should be reserved for patients with proven abnormalities in blood coagulation. Indications include congenital deficiencies in clotting factors for which specific concentrates are unavailable, severe multiple clotting factor deficiencies (for example in patients with liver disease), rapid reversal of the action of coumarin anticoagulants, and disseminated intravascular coagulation. It may be used after massive blood transfusion when there is evidence of coagulation deficiency but its value for routine prophylaxis against abnormal bleeding tendencies in patients receiving massive blood transfusions is contentious except where clotting abnormalities have been confirmed. It has also been used in the treatment of thrombotic thrombocytopenic purpura and as a source of plasma proteins.

The amount of fresh frozen plasma transfused depends on the required level of clotting factors. A unit of fresh frozen plasma refers to the quantity of plasma obtained from 1 unit of whole blood; this generally represents a volume of about 250 mL, including anticoagulant.

Fresh frozen plasma should not be used as a volume expander or as a nutritional source.

Therapeutic plasma exchange or plasmapheresis (see below) are used in a wide variety of disorders.

Plasma is used to prepare blood products including albumin, antithrombin III, blood clotting factors, immunoglobulins, and platelets. Other preparations include cryoprecipitate depleted plasma, which is deficient in fibrinogen, factor VIII, von Willebrand factor, cryoglobulin, and fibronectin, and single donor plasma, which is not frozen. A solvent-detergent-treated plasma preparation is available.

Hereditary angioedema. For a mention of fresh frozen plasma being used in hereditary angioedema, see p.1081.

Neonatal intraventricular haemorrhage. Plasma volume expansion in preterm neonates has been thought to help prevent neonatal intraventricular haemorrhage (p.1050). However, a study using plasma or gelatin as plasma volume expanders,[1,2] found no evidence of a decreased risk of such haemorrhage or subsequent death or disability.

Plasma exchange. Therapeutic plasma exchange or plasmapheresis are procedures in which plasma is selectively removed from the body while the cellular constituents of blood are retained. Although the two terms are commonly used synonymously, plasmapheresis generally involves the removal of small volumes of plasma, whereas plasma exchange removes larger volumes which must be replaced with a suitable fluid.

They have been tried in a number of disorders, including many with an immunological basis, when conventional treatment has not been successful. The aim is removal or reduction of those constituents of plasma causing or aggravating a disease or replacement of deficient plasma factors if the deficiency is the cause of the disorder.

Volume and frequency of plasma exchange is determined by the pathophysiology of the undesirable plasma constituent. For example, removal of antibody usually requires exchange of 1.5 times the estimated plasma volume (3 to 4 litres) repeated daily or on alternate days until the desired reduction is obtained. The replacement fluid used depends on the volume and the condition being treated; albumin solutions, plasma expanders, or sodium chloride 0.9% are frequently used, whereas in conditions where there is deficiency of a plasma factor replacement of blood components such as immunoglobulins may be required. Fresh frozen plasma has been used as a replacement fluid but is associated with a high incidence of adverse effects and is generally reserved for the management of thrombotic thrombocytopenic purpura.

Technological developments, such as the use of specific adsorbents and the use of multiple filters with different pore sizes, may enable removal of only the desired constituent and avoid removal and subsequent replacement of total plasma.

Thrombotic microangiopathies. Thrombotic thrombocytopenic purpura and haemolytic-uraemic syndrome are both syndromes characterised by intravascular platelet clumping.[1-6] Thrombocytopenia also occurs and fragmentation of erythrocytes, partly caused by the red cells passing through areas of the microvasculature occluded by the platelet aggregation, leads to microvascular haemolytic anaemia. In **thrombotic thrombocytopenic purpura** (TTP) the platelet aggregation is extensive and obstructs the vessels of various organs producing ischaemia or even infarction. The CNS, notably the brain, is often the area predominantly affected although some degree of renal involvement may occur. It is an uncommon disorder; adult women, in whom the condition presents as a chronic relapsing illness, are slightly more frequently affected. It may be associated with abnormalities of von Willebrand factor due to deficiency or impaired activity of a protease, ADAMTS-13.[5,6]

In **haemolytic-uraemic syndrome** (HUS) the platelet aggregation is relatively less widespread and less severe and mainly affects the renal microvasculature although extra-renal manifestations may also occur. The primary consequences are hypertension and acute renal insufficiency or ultimately, if untreated, renal failure. Most cases of HUS occur in early childhood and follow a diarrhoeal illness caused by *Shigella dysenteriae* or *Escherichia coli*. However, the condition is becoming increasingly recognised in adults, particularly the elderly. Some cases may be drug induced. With appropriate symptomatic therapy HUS is typically a self-limiting disease with spontaneous recovery although fatalities have been known.

The supportive **management** of both syndromes follows similar lines.[1,3,4] In HUS, or TTP with renal symptoms, special attention needs to be directed towards the prevention of renal failure. Hypovolaemia should be corrected, with careful control of fluid and electrolyte balance and hypertension. Haemodialysis will be needed if renal failure develops. Severe anaemia requires blood transfusion, but platelet transfusion should be avoided.

Plasma exchange (see above) is considered to be the mainstay of therapy for TTP.[1-6] The optimal regimen has not been determined, but it is usually performed daily. There is also some debate about the preferred fluid replacement; plasma exchange using cryosupernatant (the plasma remaining after cryoprecipitate is prepared, and which is depleted of von Willebrand factor) may be more efficacious than fresh frozen plasma.[3] When plasma exchange is not available, infusion of fresh frozen plasma may be used.[1,3] In HUS, there is some debate over the use of plasma exchange or infusion. Some consider that these have no proven benefit in HUS[2,3] but others[1] have challenged this belief.

Antiplatelet therapy and corticosteroids are often given, although neither has been adequately investigated and antiplatelets such as ticlopidine and clopidogrel have been reported to cause TTP (see p.1411). Aspirin and dipyridamole have been used, but are not recommended when profound thrombocytopenia is present because of the potential bleeding risk, without proven benefit. However, low-dose aspirin may be used when platelet counts have recovered after plasma exchange in TTP.[1,3] Some reports have described improved outcome in both syndromes with corticosteroids.[7] They are often used with plasma exchange in TTP.[1,3,4] However, a randomised, double-blind trial[8] in children with HUS failed to show any difference between oral corticosteroids and placebo in terms of haematological or neurological recovery, although renal function appeared to improve more rapidly in those receiving corticosteroids.

Other drugs may also be tried, particularly in refractory TTP. Some treatments that have been reported to be beneficial in case reports or small series include normal immunoglobulin,[1,4] azathioprine,[1] ciclosporin,[1,3] cyclophosphamide,[3] and vincristine.[1-4] The monoclonal antibody, rituximab, is under investigation.[2] The use of a protein-A immuno-adsorption column may be considered in the management of TTP associated with malignancy or bone marrow transplantation.[3] Epoprostenol may be tried in order to inhibit platelet-endothelial interactions but again has not been subject to controlled studies; anecdotal evidence presents both favourable and negative results.[9] Alteplase has been used successfully in one patient with HUS.[10] Splenectomy may also be considered.[1,3,4]

Plasma Protein Fraction ⊗

Fracción proteica del plasma.

Pharmacopoeias. Many pharmacopoeias have monographs, including *US.*

USP 31 (Plasma Protein Fraction). A sterile preparation of serum albumin and globulin obtained by fractionating material (blood, plasma, or serum) from healthy human donors, the source material being tested for the absence of hepatitis B surface antigen. It contains 5% of protein; not less than 83% of the total protein is albumin; not more than 17% is alpha and beta globulins; not more than 1% has the electrophoretic properties of gamma globulin. It contains sodium acetyltryptophanate with or without sodium caprylate as a stabilising agent but no antimicrobial preservative. It contains 130 to 160 mmol/litre of sodium, and not more than 2 mmol/litre of potassium. A solution in 0.15M sodium chloride containing 1% protein has a pH between 6.7 and 7.3. It should be used within 4 hours of opening the container.

Profile

Plasma protein fraction consists mainly of albumin with a small proportion of globulins; it does not contain blood-clotting factors. It has properties and uses similar to those of other albumin solutions (p.1052). It is given intravenously as a solution containing 5% of total protein. The amount of plasma protein fraction given will depend upon the clinical condition of the patient. For hypovolaemic shock an initial infusion of up to 500 mL for adults has been suggested at a rate not normally exceeding 10 mL/minute. A suggested dose in infants and small children for shock with dehydration is up to 33 mL/kg given at a rate of up to 5 to 10 mL/minute. In hypoproteinaemia, 1 to 1.5 litres of a 5% solution will provide 50 to 75 g of protein. Patients with normal blood volume may require slow infusion to prevent excessive volume expansion.

As with other albumin solutions, plasma protein fraction should not be used for parenteral nutrition.

Preparations

USP 31: Plasma Protein Fraction.

Platelets

Plaquetas.

Pharmacopoeias. Many pharmacopoeias have monographs, including *US.*

USP 31 (Platelets). The portion of blood that contains platelet cells derived from human whole blood from which red blood cells and a portion of the plasma are removed by centrifugation, sedimentation, or apheresis. Platelets derived from whole blood may be pooled from multiple donors to form one dose of platelets. The source blood for platelets must be tested for syphilis, hepatitis B, human T-cell lymphotropic virus (HTLV) Type I and Type II, hepatitis C, and HIV Type 1 and Type 2.

Platelets derived from whole blood should have a minimum of 5.5×10^{10} platelet cells suspended in a volume of 40 to 70 mL of original plasma. Platelets produced by apheresis should have a minimum of 3.0×10^{11} platelet cells suspended in 100 to 500 mL of original plasma or in an approved additive solution.

Platelets derived from whole blood or by apheresis may be further processed by filtration for removal of leucocytes, or by irradiation to inactivate lymphocytes.

The names of the different platelet preparations are:

- Platelets—prepared from a single unit of whole human blood within 8 hours of collection
- Platelets, Pooled—individual platelet units derived from whole human blood and pooled by aseptic techniques, labelled with a unique identifying number related to the number of individual units pooled, and with an expiry date of 4 hours after pooling of the individual units
- Platelets, Pheresis—prepared by apheresis from a single donor
- Platelets, Leukocyte Reduced—prepared from whole blood, either by centrifugation or by sedimentation, and filtered to yield less than 8.3×10^5 white blood cells in the final container
- Platelets, Pheresis, Leukocyte Reduced—contains less than 5×10^6 white blood cells, prepared by apheresis, with or without a filter

Platelets may be stored in plasma or in an approved additive solution at 20° to 24° with continuous gentle agitation for no more than 5 days after date of preparation. The pH must be greater than 6.2 throughout the storage period.

USP 31 (Platelet Concentrate). It contains the platelets taken from plasma obtained, in a single procedure, by whole blood collection, plasmapheresis, or plateletpheresis from a single suitable human donor. The platelets are suspended in a specified volume (20 to 30 mL, or 30 to 50 mL) of the original plasma. The suspension contains not less than 5.5×10^{10} platelets per unit in not less than 75% of the units tested. It should be stored in hermetically-sealed sterile containers at 20° to 24° (30 to 50 mL volume), or at 1° to 6° (20 to 30 mL volume) except during transport when the temperature may be 1° to 10°. The expiration time is not more than 72 hours from the time of collection of the source material. Continuous gentle agitation must be maintained if stored at 20° to 24°. The suspension must be used within 4 hours of opening the container and should be administered with equipment that contains a filter.

Adverse Effects and Precautions

Transmission of infection has been associated with the transfusion of blood products including platelets (p.1056). Since platelets are stored at room temperature there is increased risk of bacterial infection after transfusion. Transfusion reactions including fever and urticaria are not uncommon. Recipients of multiple transfusions of platelet concentrates from random donors may develop antibodies to HLA which result in impaired responsiveness to subsequent transfusions.

Use of leucocyte-depleted platelet concentrates reduces the incidence of transfusion reactions and of HLA sensitisation. Platelet concentrates prepared from Rh(D)-positive donors should generally not be given to Rh(D)-negative women of child-bearing potential. Ideally platelet concentrates should also be ABO-compatible with the recipient.

ABO compatibility. Platelets express the ABO blood group antigens and the plasma component of platelet concentrates may contain alloantibodies from the donor (see Blood Groups, p.1057). Ideally, ABO-identical platelet concentrates should be used, but ABO-compatible concentrates are often used and incompatible concentrates may be used in an emergency. However, the use of ABO-mismatched platelets can reduce the efficacy of the platelet transfusion. Also, acute haemolytic reactions can occur after infusion of mismatched platelets if the infused plasma contains high antibody titres or the volume of plasma infused is large. Some have suggested that screening donors for high antibody titres should be routine in order to avoid this, but there is no consensus as to the definition of critical titre. There have been mixed reports on whether the use of ABO-mismatched platelets has an effect on the recipient's long-term clinical course.

Reviews.

1. Lozano M, Cid J. The clinical implications of platelet transfusions associated with ABO or Rh(D) incompatibility. *Transfus Med Rev* 2003; **17:** 57–68.

HLA antibodies. Platelets obtained from single donors have been used in patients receiving multiple transfusions of platelet concentrates to reduce the formation of antibodies to HLA. Some practitioners suggest[1] that patients who are likely to need long-term platelet support should be typed for HLA A and B antigens and screened for HLA antibodies. Leucocyte-depleted platelets and UVB-irradiated platelets have also been tried. A study[2] in 530 patients found that the incidence of platelet refractoriness was reduced from 13% of those patients receiving pooled platelet concentrates to 3% and 5% of those receiving leucocyte-depleted and UVB-irradiated platelets, respectively. A meta-analysis[3] of this and earlier small studies also concluded that leucocyte depletion reduced the risk of alloimmunisation and platelet refractoriness. Some guidelines[4] have nonetheless considered that there is no convincing evidence of clinical benefit from routine use.

Uses and Administration

Blood platelets assist in the haemostatic process (p.1045) by aggregating to form a platelet thrombus, and by releasing factors involved in initiating coagulation.

Transfusions of platelet concentrates are given to patients with thrombocytopenic haemorrhage (see p.1051). They are also given prophylactically to reduce the frequency of haemorrhage in thrombocytopenia associated with the chemotherapy of neoplastic disease (see p.640).

Polygeline *(BAN, pINN)* ⊗

Poligelina; Polygéline; Polygelinum.

Полигелин

CAS — 9015-56-9.

ATC — B05AA10.

Description. Polygeline is a polymer prepared by cross-linking polypeptides derived from denatured gelatin with a di-isocyanate to form urea bridges.

Incompatibility. Intravenous preparations of polygeline contain calcium ions and are incompatible with citrated blood.

Adverse Effects

As for Gelatin, p.1072.

Hypersensitivity. Fatal reactions after polygeline infusion have been reported in 2 patients with bronchial asthma.[1,2] Both patients were undergoing epidural analgesia with bupivacaine and polygeline was given to correct hypotension that had not responded to infusion of crystalloids. One patient developed focal seizures.[2] Both patients developed refractory bronchospasm and cardiac arrhythmias and died despite intensive resuscitation attempts.

Licensed drug information recommends that prophylaxis with histamine H_1- and H_2-antagonists should be given to patients with known allergic conditions such as asthma. Similar advice has been offered[3] for patients undergoing anaesthesia and receiving polygeline following findings of an increased incidence of severe histamine-related reactions in such patients. Nevertheless, severe respiratory distress developed in an asthmatic patient given polygeline under spinal anaesthesia despite premedication with bronchodilators and antihistamines.[4]

There is a possibility of cross reactivity between polygeline and succinylated gelatin (see Gelatin, p.1072).

3. Lorenz W, *et al.* Incidence and clinical importance of perioperative histamine release: randomised study of volume loading and antihistamines after induction of anaesthesia. *Lancet* 1994; **343:** 933–40.
4. Kathirvel S, *et al.* Severe life threatening reaction to Haemaccel in a patient with bronchial asthma. *Eur J Anaesthesiol* 2001; **18:** 122–3.

Precautions

Precautions that should be observed with plasma expanders are described under Dextran 70, p.1060, and should be considered when polygeline is used for this purpose.

Polygeline preparations contain calcium ions and therefore should be used with caution in patients being treated with cardiac glycosides.

Pharmacokinetics

Like gelatin, polygeline is excreted mainly in the urine. The half-life is about 5 to 8 hours.

Renal impairment. In a study[1] in 52 patients with normal or impaired renal function given 500 mL of polygeline 3.5% about 50% of the dose was excreted in the urine within 48 hours in those with normal renal function. Excretion of polygeline in those with renal impairment, based on the patient's glomerular filtration rate (GFR), was found to be:

- GFR 31 to 90 mL/minute: unimpaired
- GFR 11 to 30 mL/minute: slightly reduced
- GFR 2 to 10 mL/minute: reduced to 27% in 48 hours
- GFR 0.5 to 2 mL/minute: reduced to 9.3% in 48 hours

The mean half-life of the elimination phase was 505 minutes in those with adequate renal function, increasing to 985 minutes in those with end-stage renal failure. Polygeline 500 mL of 3.5% solution could be given twice weekly for 1 to 2 months even in patients with total anuria.

1. Köhler H, *et al.* Elimination of hexamethylene diisocyanate cross-linked polypeptides in patients with normal or impaired renal function. *Eur J Clin Pharmacol* 1978; **14:** 405–12.

Uses and Administration

Polygeline is a plasma volume expander used as a 3.5% solution with electrolytes in the management of hypovolaemic shock (p.1183). The rate of infusion depends on the condition of the patient and does not normally exceed 500 mL in 60 minutes although it may be greater in emergencies. Initial doses for hypovolaemic shock usually consist of 500 to 1000 mL; up to 1500 mL of blood loss can be replaced by polygeline alone. Patients losing greater volumes of blood will require blood transfusion as well as plasma expanders.

Polygeline is also used in extracorporeal perfusion fluids, as a perfusion fluid for isolated organs, as fluid replacement in plasma exchange, and as a carrier solution for insulin. For plasma exchange, up to 2 litres of polygeline may be given as sole replacement fluid.

Protein C

Autoprothrombin IIA; Factor XIV; Proteína C.

ATC — B01AD12.

ATC Vet — QB01AD12.

Drotrecogin Alfa (Activated) *(BAN, rINN)*

Drotrecogina alfa (activada); Drotrécogine Alfa (activé); Drotrecoginum Alfa; Drotrecoginum Alfa (activatum); Drotrekogiini-alfa; Drotrekogin Alfa; LY-203638.

Дротрекогин Альфа (activated)

CAS — 98530-76-8.
ATC — B01AD10.
ATC Vet — QB01AD10.

Incompatibility. In a simulated Y-site study,[1] only 6 of 34 drugs were found to be both physically and chemically compatible with drotrecogin alfa (activated); these were ceftriaxone, cisatracurium, fluconazole, glyceryl trinitrate, potassium chloride, and vasopressin. Drugs found to be incompatible were adrenaline hydrochloride, albumin, amiodarone hydrochloride, ampicillin with sulbactam, ceftazidime, ciclosporin, ciprofloxacin, clindamycin, dobutamine hydrochloride, dopamine hydrochloride, fosphenytoin, furosemide, gentamicin sulfate, heparin sodium, imipenem with cilastatin, insulin, levofloxacin, magnesium sulfate, metronidazole, midazolam hydrochloride, nitroprusside sodium, noradrenaline acid tartrate, piperacillin with tazobactam, potassium phosphate, ranitidine hydrochloride, ticarcillin with clavulanic acid, tobramycin sulfate, and vancomycin hydrochloride.

1. Mann HJ, *et al.* Physical and chemical compatibility of drotrecogin alfa (activated) with 34 drugs during simulated Y-site administration. *Am J Health-Syst Pharm* 2004; **61:** 2664–71. Correction. *ibid.* 2005; **62:** 1134.

Adverse Effects and Precautions

As with other plasma-derived products, protein C preparations carry a risk of transmission of infection. Hypersensitivity reactions have been reported infrequently. Antibodies to protein C may develop in patients treated for congenital protein C deficiency.

Drotrecogin alfa (activated) may increase the risk of severe bleeding episodes. When used in patients with severe sepsis, it is therefore contra-indicated in those who are at low risk for death, such as those with single-organ failure, especially after surgery. It is also contra-indicated in patients with active internal bleeding and in those in which bleeding could be associated with a high risk of death or significant morbidity. Drotrecogin alfa (activated) should be used with caution when there is any other increased risk of bleeding. Drotrecogin alfa (activated) should be stopped 2 hours before any invasive surgery or procedure with an inherent risk of bleeding; it may be restarted 12 hours after major invasive procedures or surgery, or immediately after uncomplicated less invasive procedures, if adequate haemostasis has been achieved.

Effects on the blood. The safety data from early clinical studies and spontaneous reports during clinical use of drotrecogin alfa (activated) have been reviewed.[1] The overall rate of serious bleeding events was 5.3% during the 28-day study period. Serious bleeding events that were considered to be probably related to the use of drotrecogin alfa (activated) occurred in between 2.1% and 2.8% of patients, and often during the infusion period. Risks associated with serious bleeding events were invasive procedures and severe thrombocytopenia; meningitis may also be a risk factor for intracranial haemorrhage. It was recommended that drotrecogin alfa (activated) should not be used when the platelet count is less than 30 000/mm^3.

A subsequent large, multicentre randomised study in patients with severe sepsis, but a low risk of death (the ADDRESS study), confirmed the increased incidence of bleeding in patients with single organ failure who had undergone recent surgery (within 30 days); these patients also had an increased death rate (see Severe Sepsis, below).

1. Bernard GR, *et al.* Safety assessment of drotrecogin alfa (activated) in the treatment of adult patients with severe sepsis. *Crit Care* 2003; **7:** 155–63.

Interactions

When oral anticoagulants such as warfarin are started in patients receiving protein C replacement therapy, a transient hypercoagulable state may occur because of the rapid suppression of vitamin K-dependent protein C activity. An initial low dose of the oral anticoagulant should be increased gradually, and protein C replacement continued, until anticoagulation is stabilised. The risk of bleeding may be increased if tissue plasminogen activator and protein C are used together.

The risk of bleeding with drotrecogin alfa (activated) may be increased if it is used with other drugs that affect haemostasis, such as thrombolytics, oral anticoagulants, antiplatelet drugs, glycoprotein IIb/IIIa-receptor antagonists, and prostacyclins. Low doses of heparin for venous thromboembolism prophylaxis may be used with drotrecogin alfa (activated) without increased risk of serious bleeding. However, in a study of patients with severe sepsis who were already receiving prophylactic heparin, the risks of death and serious adverse events were increased if heparin was stopped when drotrecogin alfa (activated) was started; the reason for this was unclear.

Pharmacokinetics

During continuous infusion for the management of severe sepsis, steady-state plasma concentrations of drotrecogin alfa (activated) are reached in about 2 hours. It is inactivated by plasma protease inhibitors and rapidly cleared from the circulation, falling to below measurable limits within about 2 hours of stopping the infusion.

Uses and Administration

Protein C is an endogenous inhibitor of blood coagulation (see Haemostasis and Fibrinolysis, p.1045). A preparation of protein C purified from human plasma is used in the management of thromboembolic disorders in patients with congenital deficiency of protein C. The dose should be adjusted according to response in protein C activity. Licensed UK product information suggests an initial dose of 60 to 80 international units/kg. In the USA, an initial dose of 100 to 120 international units/kg is suggested for acute episodes and short-term prophylaxis of thromboembolism, followed by 3 doses of 60 to 80 units/kg every 6 hours, then maintenance doses of 45 to 60 units/kg every 6 or 12 hours. Doses of 45 to 60 units/kg every 12 hours are suggested for long-term prophylaxis. As a solution of 100 international units/mL it is given by intravenous injection at a maximum rate of 2 mL/minute.

Drotrecogin alfa (activated) is a recombinant activated protein C that is used in the management of severe sepsis in high-risk patients with multiple organ failure. It is given by intravenous infusion in a dose of 24 micrograms/kg per hour for 96 hours. Treatment should be started within 48 hours, and preferably within 24 hours, of the onset of sepsis-induced organ dysfunction.

For the use of protein C and drotrecogin alfa (activated) in children, see below.

Administration in children. Dosage regimens of protein C used for children and neonates with protein C deficiency are the same as those used in adults (see above). However, for children weighing less than 10 kg the rate of injection should not exceed 0.2 mL/kg per minute.

Drotrecogin alfa (activated) is not licensed for use in children under 18 years of age (see also Severe Sepsis, below).

Severe sepsis. Severe sepsis (sepsis associated with acute organ dysfunction; see Septicaemia, p.190) involves a systemic inflammatory response, inappropriate coagulation, and impaired fibrinolysis. These contribute to the development of disseminated intravascular coagulation (DIC) and microvascular thrombosis (p.1048). Endogenous protein C becomes depleted as it is activated in an attempt to restore homoeostasis. In the small number of cases that have been reported,[1-3] protein C replacement appeared to improve rate of survival and clinical outcome in the management of purpura fulminans and DIC in severe meningococcaemia. Protein C has also been used in a few patients with purpura fulminans associated with sepsis caused by other organisms such as *Streptococcus pneumoniae*.[4]

Drotrecogin alfa (activated) has been studied in the management of severe sepsis and found to reduce morbidity and mortality, but with an increased risk of serious bleeding events[5-9] (see also Effects on the Blood, above). Pooled study data suggested that earlier treatment (within 24 hours of first organ dysfunction) was associated with more benefit than later treatment,[10] and subgroup analysis suggested that the benefits were greatest in those at greater risk of death.[11] A subsequent large, multicentre randomised study[12] (the ADDRESS trial) examined the effects of drotrecogin alfa (activated) in patients with severe sepsis but a low risk of death (APACHE II score less than 25, or single organ failure). The study was terminated early, as interim analysis indicated that there was no benefit from active therapy, and in the subgroup of patients with single organ failure who had undergone surgery within the last 30 days, those given the drug appeared to have a higher mortality rate than those assigned to placebo. Various regulatory bodies have issued guidance restricting the use of drotrecogin alfa (activated) to high-risk patients under specialist care.[13-15]

Similar results to those in adults have been reported in initial studies of drotrecogin alfa (activated) in children.[16,17] However, a large placebo-controlled study was stopped early when an interim analysis found that drotrecogin alfa (activated) was highly unlikely to show an improvement over placebo in the primary end-point of composite time to complete organ failure resolution over 14 days.[18] The analysis also found an increase in the rate of CNS bleeding in the drotrecogin alfa (activated) group. The efficacy of drotrecogin alfa (activated) does not appear to depend on the identity of the infective organism.[19]

Red Blood Cells ⊗

Eritrocitos.

Pharmacopoeias. Many pharmacopoeias have monographs, including *US.*

USP 31 (Red Blood Cells). It is the portion of blood that contains haemoglobin and is derived from human whole blood (from which plasma and platelets are removed by centrifugation, sedimentation) or by apheresis. Red blood cells may be further processed by addition of red cell preservatives, irradiation to inactivate lymphocytes, filtration for removal of leucocytes, washing to remove proteins, freezing and thawing, or rejuvenation using validated and approved procedures.

For preparations derived from whole blood, one unit (dose) of Red Blood Cells contains a minimum of 50 g of haemoglobin. One unit of Red Blood Cells, Leukocytes Reduced contains a minimum of 42.5 g of haemoglobin and has a residual leucocyte count of less than 5×10^6. One unit of Red Blood Cells, Deglycerolized contains a minimum of 40 g of haemoglobin. One unit of Red Blood Cells, Leukocytes Reduced and Deglycerolized contains a minimum of 34 g of haemoglobin and has a residual leucocyte count of less than 5×10^6.

For preparations derived by apheresis, one unit (dose) of Red Blood Cells, Pheresis contains a mean haemoglobin content of 60 g of haemoglobin. One unit of Red Blood Cells, Pheresis, Leukocytes Reduced contains a mean haemoglobin content of 51 g of haemoglobin and has a residual leucocyte count of less than 5×10^6.

Red blood cells should be stored in the original container, or transferred to an equivalent container using a technique that does not compromise sterility. An approved additive solution may be added after removal of the plasma. Liquid red blood cells is stored at 1° to 6°. Frozen red blood cells is stored at or below −65°.

Red blood cells in Anticoagulant Citrate Dextrose Solution, Anticoagulant Citrate Phosphate Dextrose Solution, or in Anticoagulant Citrate Phosphate Dextrose-Dextrose Solution may be stored for up to 21 days at 1° to 6° after the blood has been drawn. Red blood cells in Anticoagulant Citrate Dextrose Phosphate Adenine Solution may be stored for up to 35 days at 1° to 6°. Red blood cells may be stored in an approved additive solution for up to 42 days at 1° to 6°.

Frozen red blood cells prepared with low glycerol content (20%) may be stored at or below −120° for not later than 10 years from years from the date of collection. Frozen red blood cells prepared with high glycerol content (40%) may be stored at or below −65° for not later than 10 years from years from the date of collection. If the frozen red blood cells is processed for freezing or for thawing, in an open system, the expiry date for the thawed red blood cells is 24 hours after removal from −65° storage, provided it is then stored at the temperature of unfrozen red blood cells.

Dark red in colour when packed and may show a slight creamy layer on the surface and a small supernatant layer of yellow or opalescent plasma.

Adverse Effects and Precautions

As for Blood, p.1056.

Antibody formation. Patients with sickle-cell anaemia frequently require repeated transfusions of red blood cells. Alloimmunisation is a common problem in these patients, and has the potential to cause haemolytic transfusion reactions.[1] Alloantibodies were detected in 32 of 107 black patients with sickle-cell anaemia who had received red cell transfusions compared with 1 of 19 non-black patients who had received transfusions for other chronic anaemias.[2] The incidence of antibody formation was related to the number of transfusions received. An analysis of the red cell phenotypes suggested that the high rate of alloimmunisation among patients with sickle-cell anaemia could be due to racial differences between donors and recipients. Alloimmunisation can also occur in thalassaemia patients who are given transfusions,[3] and the incidence in these patients may also be affected by racial differences between donors and recipients.[4] Erythrocyte autoantibody formation has also been reported.[1,3]

4. Ho H-K, *et al.* Alloimmunization in Hong Kong southern Chinese transfusion-dependent thalassemia patients. *Blood* 2001; **97:** 3999–4000.

Uses and Administration

Transfusions of red blood cells are given for the treatment of severe anaemia without hypovolaemia (p.1042).

Red blood cells are also used for exchange transfusion in babies with haemolytic disease of the newborn (p.2204). Red cells may be used with volume expanders for acute blood loss of less than half of the blood volume; if more than half of the blood volume has been lost, whole blood should be used.

Other red blood cell products are available. Concentrated red cells in an optimal additive solution containing sodium chloride, adenine, glucose, and mannitol has reduced viscosity and an extended shelf-life. Leucocyte-depleted red cells may be used in patients who have developed antibodies to previous transfusions or in whom development of antibodies is undesirable. Frozen, thawed, and washed red cell concentrates in which plasma proteins are removed in addition to leucocytes and platelets may be used in patients with rare antibodies.

Preparations

USP 31: Red Blood Cells.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: *Arg.:* Vulnofilin Compuesto†.

Romiplostim *(USAN, rINN)*

AMG-531; Romiplostimum. L-Methionyl[human immunoglobulin heavy constant gamma 1-(227 *C*-terminal residues)-peptide (Fc fragment)] fusion protein with 41 amino acids peptide, (7-7′:10,10′)-bisdisulfide dimer.

Ромиплостим

CAS — 267639-76-9.

Profile

Romiplostim is a protein that acts as an agonist at the thrombopoietin receptor to stimulate platelet production, although it has no sequence homology with endogenous thrombopoietin. It is under investigation in the treatment of chronic idiopathic thrombocytopenic purpura.

◊ References.

1. Bussel JB, *et al.* AMG 531, a thrombopoiesis-stimulating protein, for chronic ITP. *N Engl J Med* 2006; **355:** 1672–81. Correction. *ibid.*; 2054.
2. Kuter DJ, *et al.* Efficacy of romiplostim in patients with chronic immune thrombocytopenic purpura: a double-blind randomised controlled trial. *Lancet* 2008; **371:** 395–403.

Sargramostim *(BAN, USAN, rINN)*

BI-61.012; rhu GM-CSF; Sargramostimum. A recombinant human granulocyte-macrophage colony-stimulating factor; 23-L-Leucinecolony-stimulating factor 2 (human clone pHG_{25} protein moiety).

Сарграмостим

CAS — 123774-72-1.

ATC — L03AA09.

ATC Vet — QL03AA09.

Pharmacopoeias. In *US.*

USP 31 (Sargramostim). A single chain, glycosylated polypeptide of 127 amino acid residues expressed from *Saccharomyces cerevisiae*. The glycoprotein primarily consists of three molecular species having relative molecular weights of about 19 500, 16 800, and 15 500 due to different levels of glycosylation. Sargramostim has the property of generating granulocyte, macrophage, and mixed granulocyte macrophage colonies from haematopoietic progenitor cells found in bone marrow. Store in sealed containers at a temperature of −20° or below.

Stability. Solutions of sargramostim may be adsorbed onto glass or plastic materials and so albumin must be added to give a final concentration of 1 mg/mL to solutions that are diluted to concentrations of sargramostim below 10 micrograms/mL.

Adverse Effects and Precautions

As for Molgramostim, p.1073.

Uses and Administration

Sargramostim is a granulocyte-macrophage colony-stimulating factor with actions and uses similar to those of molgramostim (p.1074). It is used to treat or prevent neutropenia in patients receiving myelosuppressive cancer chemotherapy and to reduce the period of neutropenia in patients undergoing bone marrow transplantation (p.640). It is also used after bone marrow transplantation when engraftment is delayed or has failed. Sargramostim may be used to mobilise peripheral blood progenitor cells for collection and subsequent use in autologous peripheral blood stem cell transplantation, as well as after transplantation to improve engraftment.

As an **adjunct to antineoplastic therapy**, sargramostim is given by intravenous infusion over 4 hours in a dose of 250 micrograms/m^2 daily for up to 42 days as required.

After **bone marrow transplantation**, sargramostim may be given in a dose of 250 micrograms/m^2 daily by intravenous infusion over 2 hours. When engraftment is delayed or has failed, a course of sargramostim 250 micrograms/m^2 daily for 14 days may be used. The dose can be repeated after a 7-day interval if engraftment has not occurred. A third course of 500 micrograms/m^2 daily for 14 days may be tried after another 7-day interval if needed, but further dose escalation is unlikely to be of benefit.

For **mobilisation** of peripheral blood progenitor cells a dose of 250 micrograms/m^2 daily is given by continuous intravenous infusion over 24 hours or by subcutaneous injection, with leucapheresis usually starting on day 5. The same dosing regimen may be used after peripheral blood stem cell transplantation, until neutrophil recovery.

HIV infection and AIDS. Sargramostim has been evaluated in the management of HIV infection (p.856). There is some evidence to suggest that it might help to decrease and suppress viral load, and increase CD4+ cell counts, by enhancing the activity of antiretroviral drugs and increasing the resistance of monocytes to HIV infection.[1-3] However, in a study[4] of patients who were medically stable but had incompletely controlled HIV replication, sargramostim did not have a significant antiviral effect and there was only a trend towards increased CD4+ counts. The effect of molgramostim has been studied in a small trial[5] in which it was found to blunt viral rebound following interruption of HAART.

5. Fagard C, *et al.* A controlled trial of granulocyte macrophage-colony stimulating factor during interruption of HAART. *AIDS* 2003; **17:** 1487–92.

Inflammatory bowel disease. A small dose-escalating study[1] reported a beneficial effect from the use of sargramostim in Crohn's disease (see Inflammatory Bowel Disease, p.1697). A subsequent larger placebo-controlled study[2] in moderate to severe active disease found that the rate of response to sargramostim was not significantly different from that of placebo. Although disease severity and quality of life improved in the sargramostim group, later unpublished study results were said to be disappointing, and in June 2007 the manufacturer declared that it would not be investigating sargramostim any further in Crohn's disease.

Wounds and ulcers. See under Molgramostim (p.1074) for mention of the use of sargramostim in the promotion of wound healing.

Preparations

USP 31: Sargramostim for Injection.

Proprietary Preparations (details are given in Part 3)
USA: Leukine.

Thrombin *(rINN)*

Factor IIa; Thrombine; Thrombinum; Trombin; Trombina.

Тромбин

CAS — 9002-04-4.
ATC — B02BC06; B02BD30.
ATC Vet — QB02BC06; QB02BD30.

Pharmacopoeias. Many pharmacopoeias have monographs, including *US.*

USP 31 (Thrombin). A sterile, freeze-dried powder derived from bovine plasma containing the protein substance prepared from prothrombin through interaction with added thromboplastin in the presence of calcium. It is capable, without the addition of other substances, of causing the clotting of whole blood, plasma, or a solution of fibrinogen. It should be stored at 2° to 8°. Once reconstituted, solutions should be used within a few hours of preparation. The label should state that the prepared solution should not be injected into or otherwise allowed to enter large blood vessels.

A white to greyish, amorphous substance dried from the frozen state.

Thrombin Alfa *(USAN, rINN)*

Human thrombin (recombinant, glycosylated); Thrombine Alfa; Thrombinum Alfa; Trombina Alfa. Human thrombin (recombinant, glycofrom α).

Тромбин Альфа

CAS — 869858-13-9.

Adverse Effects and Precautions

Hypersensitivity reactions, including anaphylaxis, have occurred rarely. Thrombin solutions must not be injected into blood vessels.

Antibody formation. Exposure to thrombin preparations of bovine origin has led to the development of antibodies to bovine thrombin and factor V with cross-reactivity, in some cases, to human factors. The presence of inhibitors to human factors may produce bleeding abnormalities and interfere with clotting measurements. Platelet infusions, fresh frozen plasma, and activated prothrombin complex concentrates have been used in the management of acute haemorrhagic complications, though often with limited success. Treatments that have been tried, in order to reduce the antibody titre, have included corticosteroids, ciclosporin, antineoplastics, intravenous immunoglobulin, and plasmapheresis.[1,2] Despite the availability of preparations containing virus-inactivated human fibrinogen the use of bovine thrombin is reported to be widespread and cases of acquired factor V inhibitor continue to occur.[3]

2. Streiff MB, Ness PM. Acquired FV inhibitors: a needless iatrogenic complication of bovine thrombin exposure. *Transfusion* 2002; **42:** 18–26.
3. Kirkeby KM, Aronowitz P. Acquired factor V inhibitor: a common and avoidable complication of topical bovine thrombin application. *Am J Med* 2005; **118:** 805.

Uses and Administration

Thrombin is a protein substance produced *in vivo* from prothrombin that converts soluble fibrinogen into insoluble fibrin thus producing coagulation.

Thrombin of either human or bovine origin is applied topically to control bleeding from capillaries and small venules. It is applied directly to the bleeding surface either as a solution or dry powder. It may also be used with absorbable gelatin sponge during surgical procedures. Thrombin alfa, a recombinant human thrombin, is used similarly.

Thrombin is a component of fibrin glue (p.1069).

Pseudoaneurysm. An acute pseudoaneurysm is an arterial rupture, contained by fibromuscular tissue, that communicates with the artery via a narrow neck. Insertion-site femoral pseudoaneurysm can occur as a result of procedures such as cardiac catheterisation and peripheral angiography. It is usually treated with ultrasound-guided compression, but this time-consuming technique causes discomfort for both the patient and the staff carrying out the procedure, and may be of limited success for large pseudoaneurysms and patients receiving anticoagulation. Surgical repair may be required in some patients. As an alternative to pressure or surgery, thrombin has been given by ultrasound-guided percutaneous injection. In reported series,[1-4] complete thrombosis of the pseudoaneurysm sac occurred in more than 90% of patients with one injection of bovine thrombin. Bovine thrombin has also been used when compression has failed,[4,5] and a comparative study[6] in 30 patients found thrombin to be more successful than compression. Human thrombin has also been used successfully.[7] A retrospective review[8] concluded that bovine and human thrombin were equally effective. The successful use of autologous thrombin in a few patients has also been described.[9]

Thrombomodulin Alfa *(rINN)*

ART-123; Thrombomoduline Alfa; Thrombomodulinum Alfa; Trombomodulina alfa. 1–498-Thrombomodulin (human clone TMP26/TMJ1 protein moiety reduced).

Тромбомодулин Альфа

CAS — 120313-91-9.

Profile

Endogenous thrombomodulin is a transmembrane protein found on the surface of endothelial cells, which acts as a thrombin receptor. Thrombomodulin-bound thrombin activates protein C, which then inactivates clotting factors and so limits coagulation.

Thrombomodulin alfa, a recombinant form of thrombomodulin, is under investigation in the prophylaxis of venous thromboembolism and the treatment of disseminated intravascular coagulation.

Thromboplastin

Cytozyme; Thrombokinase; Tromboplastina; Tromboplastyna.

Profile

Tissue thromboplastin (tissue factor; factor III) is a membrane glycoprotein that is released from damaged tissue and initiates coagulation. The term thromboplastin may also be applied to other related substances with similar activity. Commercial preparations may contain tissue extracts comprising a variety of such substances.

Preparations of thromboplastin have been used as haemostatics.

A preparation of thromboplastin derived from rabbit brain is used in the determination of the prothrombin time for the control of anticoagulant therapy (for further details see Uses and Administration of Warfarin Sodium, p.1432).

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Clauden.

Thrombopoietin

Trombopoyetina.

Profile

Thrombopoietin is a naturally occurring colony-stimulating factor that regulates thrombopoiesis (see Haematopoiesis, p.1042). Recombinant thrombopoietin, and a form of recombinant thrombopoietin conjugated with polyethylene glycol (pegacaristim, PEG-megakaryocyte growth and development factor, PEG-rHuMGDF), are under investigation. They have been studied in the management of thrombocytopenia (p.1051) in patients receiving myelosuppressive or myeloablative chemotherapy, and in patients with myelodysplastic syndrome or HIV-associated thrombocytopenia. There is also some interest in the use of recombinant forms of thrombopoietin in stem cell mobilisation regimens and to increase platelet counts in healthy apheresis donors. However, some results have been disappointing and there are reports of neutralising antibody development.

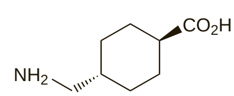
Tranexamic Acid *(BAN, USAN, rINN)*

Acide tranexamique; Ácido tranexámico; Acidum tranexamicum; AMCA; *trans*-AMCHA; CL-65336; Kyselina tranexamová; Traneksaamihappo; Traneksamik Asit; Traneksamo rūgštis; Tranexámsav; Tranexamsyra. *trans*-4-(Aminomethyl)cyclohexanecarboxylic acid.

Транексамовая Кислота

$C_8H_{15}NO_2$ = 157.2.

CAS — 1197-18-8.
ATC — B02AA02.
ATC Vet — QB02AA02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.*

Ph. Eur. 6.2 (Tranexamic Acid). A white or almost white, crystalline powder. Freely soluble in water and in glacial acetic acid; practically insoluble in alcohol and in acetone. A 5% solution in water has a pH of 7.0 to 8.0.

Incompatibility. Solutions of tranexamic acid are incompatible with benzylpenicillin.

Adverse Effects

Tranexamic acid appears to be well tolerated. It can produce dose-related gastrointestinal disturbances. Hypotension has occurred, particularly after rapid intravenous dosage. Thrombotic complications have been reported in patients receiving tranexamic acid, but these are usually a consequence of its inappropriate use (see Precautions, below). There have been a few instances of transient disturbance of colour vision associated with use of tranexamic acid; in such cases the drug should be stopped. Hypersensitivity skin reactions have also been reported.

Effects on the eyes. Tranexamic acid has been associated with retinopathy[1] and visual impairment.[2] A haemodialysis patient developed almost total loss of vision within 2 weeks of starting daily tranexamic acid injections after emergency surgery for a bleeding peptic ulcer. Vision was largely restored within a few days of stopping tranexamic acid,[2] although some impairment persisted in conditions of poor light. The patient had experienced visual impairment previously when given tranexamic acid. The authors noted that doses of tranexamic acid should be reduced in patients with renal impairment undergoing dialysis.

A patient undergoing regular peritoneal dialysis for Epstein's syndrome developed ligneous conjunctivitis, gingival hyperplasia, and peritoneal protein loss associated with the use of tranexamic acid.[3]

2. Kitamura H, *et al.* Tranexamic acid-induced visual impairment in a hemodialysis patient. *Clin Exp Nephrol* 2003; **7:** 311–14.
3. Diamond JP, *et al.* Tranexamic acid-associated ligneous conjunctivitis with gingival and peritoneal lesions. *Br J Ophthalmol* 1991; **75**: 753–4.

Effects on the skin. A widespread, patchy rash with associated blisters, considered on skin biopsy to be a fixed-drug eruption, occurred in a 33-year-old woman.[1] Tranexamic acid, which she had taken for 8 years and which had been well tolerated, was identified as the cause. Desensitisation was unsuccessful. Tranexamic acid was also suspected as being the cause of a fixed-drug eruption in a 36-year-old woman.[2] Pruritic, vesicle-bullous lesions appeared within a few hours of starting tranexamic acid and the lesions resolved completely 3 days after stopping therapy even though other drug treatment was continued.

1. Kavanagh GM, *et al*. Tranexamic acid (Cyklokapron)-induced fixed-drug eruption. *Br J Dermatol* 1993; **128:** 229–30.
2. Carrión-Carrión C, *et al.* Bullous eruption induced by tranexamic acid. *Ann Pharmacother* 1994; **28:** 1305–6.

Precautions

Tranexamic acid should not be used in patients with active intravascular clotting because of the risk of thrombosis. Patients with a predisposition to thrombosis are also at risk if given antifibrinolytic therapy. Haemorrhage due to disseminated intravascular coagulation should therefore not be treated with antifibrinolytic compounds unless the condition is predominantly due to disturbances in fibrinolytic mechanisms; tranexamic acid has been used when the latter conditions are met, but with careful monitoring and anticoagulant cover.

Lysis of existing extravascular clots may be inhibited in patients receiving tranexamic acid. Clots in the renal system can lead to intrarenal obstruction, so caution is required in patients with haematuria. Doses of tranexamic acid should be reduced in patients with renal impairment. Licensed product information recommends that regular eye examinations and liver function tests should be performed if tranexamic acid is used long term.

Some studies have suggested that tranexamic acid when given to patients after a subarachnoid haemorrhage increases the incidence of cerebral ischaemic complications (see Haemorrhagic Disorders under Uses, below).

Rapid intravenous dosage may be associated with adverse effects (see above).

Interactions

Drugs with actions on haemostasis should be given with caution to patients on antifibrinolytic therapy. The potential for thrombus formation may be increased by oestrogens, for example, or the action of the antifibrinolytic antagonised by compounds such as thrombolytics.

Retinoids. Antifibrinolytics should be used with caution in patients receiving oral *tretinoin* as thrombotic events have been reported in patients being treated with tranexamic acid and tretinoin (see Antifibrinolytics, p.1619).

Pharmacokinetics

Tranexamic acid is absorbed from the gastrointestinal tract with peak plasma concentrations occurring after about 3 hours. Bioavailability is about 30 to 50%. Tranexamic acid is widely distributed throughout the body and has very low protein binding. It diffuses across the placenta and is distributed into breast milk. Tranexamic acid has a plasma elimination half-life of about 2 hours. It is excreted in the urine mainly as unchanged drug.

Uses and Administration

Tranexamic acid is an antifibrinolytic drug that inhibits breakdown of fibrin clots. It acts primarily by blocking the binding of plasminogen and plasmin to fibrin; direct inhibition of plasmin occurs only to a limited degree. Tranexamic acid is used in the treatment and prophylaxis of haemorrhage associated with excessive fibrinolysis. It is also used in the prophylaxis of hereditary angioedema.

Tranexamic acid is given by mouth and by slow intravenous injection or continuous infusion. Parenteral dosage is usually changed to oral after a few days. Alternatively, an initial intravenous injection may be followed by continuous infusion.

For short-term use in **haemorrhage**, oral doses are 1 to 1.5 g (or 15 to 25 mg/kg) 2 to 4 times daily. When given by slow intravenous injection doses are 0.5 to 1 g (or 10 mg/kg) 3 times daily. Tranexamic acid is given by continuous infusion at a rate of 25 to 50 mg/kg daily.

Tranexamic acid is given for prolonged periods in **hereditary angioedema** in doses of 1 to 1.5 g by mouth 2 or 3 times daily.

Children may be given doses of 25 mg/kg orally or 10 mg/kg intravenously, usually 2 or 3 times daily, depending on the indication.

Reduced doses are recommended for patients with renal impairment (see below).

Solutions of tranexamic acid have been applied topically, for example as a bladder irrigation or mouthwash.

Administration in renal impairment. Licensed drug information recommends reduced doses of tranexamic acid for patients with renal impairment, based on the serum-creatinine concentration (SCC):

- SCC 120 to 250 micromoles/litre: 15 mg/kg twice daily orally, or 10 mg/kg twice daily intravenously
- SCC 250 to 500 micromoles/litre: 15 mg/kg once daily orally, or 10 mg/kg once daily intravenously
- SCC higher than 500 micromoles/litre: 7.5 mg/kg once daily or 15 mg/kg once every 48 hours orally, or 5 mg/kg once daily or 10 mg/kg once every 48 hours intravenously (some products contra-indicate use in severe renal impairment)

Haemorrhagic disorders. Tranexamic acid and aminocaproic acid are structurally related synthetic antifibrinolytic drugs that block the binding of plasminogen and plasmin to fibrin, thereby preventing dissolution of the haemostatic plug.[1,2] A plasma concentration of tranexamic acid of 5 to 10 micrograms/mL has been considered necessary for effective inhibition of fibrinolysis.[2]

Antifibrinolytics are used to control haemorrhage that is considered to be caused by excessive fibrinolysis. Antifibrinolytic therapy may also be indicated in the prevention of rebleeding in some haemorrhagic conditions, the rationale being to retard dissolution of the haemostatic plug formed in response to vascular injury.

In haemorrhage caused by a congenital or acquired deficiency of blood coagulation factors, haemostatic drugs have a secondary role and may be useful in reducing requirements of factor concentrates. In patients with haemophilias (p.1048) antifibrinolytics may be added to coagulation factor replacement before dental surgery, and used in the prevention and treatment of mucosal bleeding after the procedure. The route depends on the severity of the coagulation factor deficiency and the procedure to be undertaken; for example, tooth extraction will probably require more prophylactic cover than dental scaling. Regimens therefore vary,[3-7] but an initial oral or intravenous dose of tranexamic acid may be followed by oral use, or topical 5% mouthwash continued for up to 7 days after dental procedures. Tranexamic acid has been used similarly in patients with von Willebrand's disease[4] (p.1051). An approach using tranexamic acid mouthwashes has also been used to reduce the risk of bleeding after oral surgery in patients on anticoagulant therapy.[8,9] Tranexamic acid may prove beneficial in patients with other congenital bleeding disorders such as α_2-antiplasmin deficiency.[10] Aminocaproic acid has been tried in a few patients with hereditary haemorrhagic telangiectasia with mixed results.[11] Tranexamic acid has been reported to be effective in the control of epistaxis in these patients; reports generally describe oral use,[12,13] but tranexamic acid has also been applied directly as nasal drops.[14]

Tranexamic acid and aminocaproic acid have each been used in an attempt to prevent rebleeding in patients with subarachnoid haemorrhage (see Stroke, p.1185), particularly if surgery is to be delayed. However, while rebleeding may be reduced, there can be an increase in the incidence of cerebral ischaemic complications resulting in little overall improvement in outcome.[15] Paradoxically, rebleeding has been noted in patients given high doses of aminocaproic acid after subarachnoid haemorrhage (see Effects on the Blood under Aminocaproic Acid, p.1053).

Tranexamic acid has been used to control gastrointestinal haemorrhage, e.g. due to peptic ulcer disease (p.1702) or oesophageal varices (see Variceal Haemorrhage under Monoethanolamine, p.2346). In a meta-analysis[16] of 6 studies, involving a total of 1267 patients given tranexamic acid for acute upper gastrointestinal haemorrhage, treatment with tranexamic acid was associated with a 20 to 30% decrease in the rate of rebleeding, a 30 to 40% decrease in the need for surgery, and a 40% decrease in mortality. However, the validity of one study included in the analysis has been disputed,[17,18] and it is not the usual treatment in these patients.

Tranexamic acid or aminocaproic acid have been suggested to control bleeding in many other conditions. These include haemorrhage after surgical or other procedures including prostatectomy, bladder surgery, and cervical conisation. They may be used to reduce perioperative blood loss and allogeneic transfusion requirements.[19-23] They may also be effective in other conditions associated with excessive fibrinolysis such as menorrhagia (see below), epistaxis, and placental abruption.

Hereditary angioedema. Hereditary angioedema, formerly known as hereditary angioneurotic oedema, is a rare autosomal dominant disease caused by either a deficiency of complement C1 esterase inhibitor or, more rarely, a lack of functioning inhibitor.[1-6] The disease presents as episodic attacks of oedema, usually of the extremities and face, and often involving the gastrointestinal mucosa producing abdominal pain. A non-pruritic rash may also occur. A few patients develop life-threatening laryngeal oedema. Attacks generally last about 1 to 3 days and may occur as frequently as weekly or there may be years between attacks. The first attack may occur at any age although initial presentation in childhood is most common. Trauma, especially dental surgery, illness, and emotional stress may provoke an attack although often there is no precipitating factor.

Treatment of the acute attack is essentially supportive. If laryngeal oedema is present adrenaline, antihistamines, and corticosteroids may be given (as for Anaphylaxis, p.1205) even though patients with hereditary angioedema often fail to respond adequately to them. The mainstay of treatment of an acute attack is replacement therapy with complement C1 esterase inhibitor. Fresh frozen plasma has been used although there is a risk of initially exacerbating the oedema due to the presence of other complements in the plasma. Tracheostomy or tracheal intubation may be necessary.

Once the acute attack has subsided most patients will not require further treatment, but those who experience life-threatening attacks, repeated episodes of swelling around the face or neck, or incapacitating attacks require long-term **prophylactic therapy**. A synthetic androgen (danazol or stanozolol) or an antifibrinolytic (aminocaproic acid or tranexamic acid) is effective for long-term prophylaxis.[1,2,4,6] Danazol and stanozolol raise serum concentrations of C1 esterase inhibitor possibly by enhancing its synthesis in the liver.[2,6] Aminocaproic acid and tranexamic acid may act by inhibiting plasmin activation.[7] A synthetic androgen is often preferred because these seem to be more effective than antifibrinolytics. In children, however, androgens are generally avoided because of their adverse effects. Nevertheless, they have been used in children, with close monitoring, when antifibrinolytics have been ineffective.[3] In exceptional circumstances, long-term prophylaxis with twice weekly C1 esterase inhibitor may be indicated for adults when antifibrinolytics and androgens are ineffective, not tolerated, or contra-indicated.[6]

Short-term prophylaxis may be used in situations expected to provoke an attack, such as surgery or dental work. Complement C1 esterase inhibitor is given within 24 hours before the procedure, or fresh frozen plasma may be used if this is not available. Alternatively, a synthetic androgen or antifibrinolytic may be used, but these must be started several days before the procedure and continued for 2 days after.

Investigational therapies for the management of hereditary angioedema include a recombinant complement C1 esterase inhibitor, icatibant acetate (a bradykinin receptor antagonist), and ecallantide (an inhibitor of human plasma kallikrein).

Menorrhagia. Tranexamic acid is used in women with menorrhagia (p.2126) who do not require contraception or hormonal therapy. It reduces uterine blood loss in such women when used during menstruation.[1-3] A comparative trial[1] found tranexamic acid 1 g by mouth every 6 hours to be more effective than the NSAID mefenamic acid, a commonly used treatment for the condition, and etamsylate. It is also more effective than cyclical norethisterone[2] (although less so than a progesterone-releasing intra-uterine device[3]). A review,[4] which included these and some other studies, reported that tranexamic acid reduces menstrual blood loss by about 34 to 59% over 2 to 3 cycles.

von Willebrand Factor

Facteur Willebrand humain (human von Willebrand factor); Factor humanus von Willebrandi (human von Willebrand factor); Factor VIII-related Antigen; vWF.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Human von Willebrand Factor). A preparation of a plasma protein fraction that contains the glycoprotein von Willebrand factor with varying amounts of coagulation factor VIII, depending on the method of preparation. It is prepared from human plasma obtained from blood from healthy donors: the plasma is tested for the absence of hepatitis B surface antigen and antibodies against HIV-1 and HIV-2 and hepatitis C virus.

When reconstituted as stated on the label, the potency is not less than 20 international units of von Willebrand factor per mL. It is a white or pale yellow, hygroscopic powder or friable solid. Store in airtight containers. Protect from light.

Profile

von Willebrand factor is used in the treatment and prophylaxis of bleeding in von Willebrand's disease (p.1051), usually when desmopressin is ineffective or contra-indicated. It is generally contained in plasma concentrate preparations with factor VIII, but highly purified preparations that contain very little factor VIII are also available in some countries. Dosage depends on the extent and source of bleeding. Hypersensitivity reactions may occur rarely, and as for other plasma-derived preparations, the risk of transmission of infective agents cannot be totally excluded.

The processes of bone turnover, and the regulation of body calcium, are intimately connected. The concentration of calcium in plasma is normally kept within a narrow range (p.1667). It is regulated by the absorption and excretion of calcium, and also by modulation of the normal resorption and formation of bone and hence the movement of calcium to and from the skeletal reservoir. The endogenous substances parathyroid hormone, calcitonin, and vitamin D, are involved in the regulation of calcium homoeostasis.

Drugs described in this chapter affect bone resorption or formation, with effects on serum calcium. They include:

- bisphosphonates
- bone morphogenetic proteins
- calcitonins
- cinacalcet hydrochloride
- gallium nitrate
- parathyroid hormone
- strontium ranelate
- teriparatide

The inorganic fluoride salts, which can promote bone formation when given in appropriate doses, are discussed in the chapter on Nutritional Agents (see Sodium Fluoride, p.1962).

Bone and Bone Disease

The skeleton acts as mechanical support and protection to softer tissues and organs. It is also important in electrolyte homoeostasis, acting as a reservoir of certain ions and minerals such as calcium, phosphorus, and magnesium.

Bone has two components: an organic matrix, called **osteoid**, consisting mainly of collagen, and a mineral phase deposited through that matrix; the latter, comprising about 70% of the skeletal mass, is composed chiefly of hydroxyapatite (a complex crystalline salt of calcium and phosphate). There are two structural forms known in mature bone, namely cortical (lamellar) bone, which has a dense, continuous structure, and trabecular (cancellous) bone, which has a 'spongy' structure of linked plates and is associated with high bone turnover and growth. The peripheral or appendicular parts of the skeleton are mainly cortical bone, while the axial or central parts, such as the spine and pelvis, contain substantial amounts of trabecular bone.

Bone is a dynamic tissue: once new bone has been laid down it is subject to a continual process of formation and resorption called **remodelling**. Remodelling takes place along bone surfaces and is carried out by bone cells (osteoclasts and osteoblasts) that originate in the marrow and share common origins with blood cells. Stimulated by physical or chemical signals, **osteoclasts** dig a cavity into the bone (bone resorption); they are then replaced by **osteoblasts** that synthesise new osteoid to fill the cavity (bone formation) and may help to promote its subsequent mineralisation. The actions of these two types of bone cell are closely linked, and agents that suppress resorption ultimately decrease bone formation too. However, at any given time there is a deficit in potential bone mass, the **remodelling space**, which represents sites of bone resorption that have not yet been filled in. Any stimulus that affects bone turnover by altering the recruitment of osteoblasts and osteoclasts to remodelling will result in an increase or decrease in the remodelling space, until a new steady state is achieved, and this will be seen as a decrease or increase in bone mass. Lifelong accumulation of remodelling deficits leads to age-related bone loss.

Bone also contains **osteocytes**, which are cells derived from osteoblasts thought to be involved in the movement of minerals.

Bone cells are controlled by systemic hormones including parathyroid hormone, 1,25-dihydroxycholecalciferol (calcitriol), calcitonin, and local regulators such as bone morphogenetic proteins and cytokines. A local signalling system involving the protein RANKL (receptor activator of nuclear factor-kappa B ligand), which induces osteoclast differentiation and activation and promotes bone resorption, and the protein osteoprotegerin, which inhibits osteoclast formation and prevents bone resorption, is mediated via the receptor RANK found on osteoclasts and their precursors.

Bone diseases may be due to defects in the production of osteoid or its mineralisation, or to an imbalance in resorption and formation of bone. Bone balance can be affected by diverse stimuli such as dietary insufficiency, hormones, including sex hormones, and drugs such as corticosteroids.

Hypercalcaemia of malignancy

About 10% of patients with cancer develop hypercalcaemia of malignancy, which is typically severe and progressive.[1,2] The condition is thought to be mediated usually by parathyroid hormone-related protein released from tumour tissue, which acts both locally and systemically to enhance osteoclastic bone resorption and increase renal tubular calcium reabsorption. Increased levels of parathyroid hormone-related protein have been found in hypercalcaemic patients, especially those with solid tumours, regardless of the existence of bone metastases.[3,4] Other causes of hypercalcaemia of malignancy include the activation of osteoclasts by the local release of bone-resorbing cytokines such as interleukin-1, interleukin-6, tumour necrosis factors, and growth factors;[3,4] this mechanism occurs particularly in those with myeloma.[4] The RANKL signalling system may play an important role.[5] Some lymphomas secrete active vitamin D, enhancing osteoclastic bone resorption and intestinal calcium absorption. Rarely, ectopic secretion of parathyroid hormone may cause hypercalcaemia.[6]

Bisphosphonates are the preferred drugs for **treating** hypercalcaemia once the patient has been adequately rehydrated with intravenous sodium chloride 0.9% (see Hypercalcaemia, p.1668). It has been recommended[6] that therapy be begun as soon as possible, since a response is only seen after 2 to 4 days; in about 60 to 90% of patients serum calcium concentrations normalise within 4 to 7 days, and responses last for up to 3 weeks.[6] There is some evidence that bisphosphonates may be less effective in patients with high initial levels of parathyroid hormone-related protein; in addition, they have no effect on the renal tubular resorption of calcium.[2] There is no consensus as to the best bisphosphonate to choose. Pamidronate has been widely used and is considered by many to be the drug of choice.[7] A systematic review,[2] which noted that aminobisphosphonates were most effective in this condition, considered low-dose clodronate less effective than pamidronate although no difference was seen at higher doses. Others have queried the existence of a dose response for clodronate;[1] the fact it can be given subcutaneously, or orally (after intravenous therapy) may be useful.[1,4] Etidronate, which can also be given orally, is also less effective than pamidronate,[7,8] and prolonged therapy may cause osteomalacia. Alendronate has been found to be as effective as clodronate, and superior to etidronate.[2] Studies with neridronate, olpadronate, and risedronate have been more limited;[1] incadronate has also been used.[2] However, newer aminobisphosphonates such as ibandronate and zoledronate may be the most effective option, with longer durations of response and more convenient dosage than pamidronate.[1,4] In patients unresponsive to low initial doses of bisphosphonates, some recommend larger doses;[6] alternatively, other drugs may be considered.

Calcitonin has a rapid onset of action, and is particularly useful in life-threatening hypercalcaemia.[1,7] This effect, however, is short-lived, and calcitonin is generally used as adjunctive therapy.[1] When given with bisphosphonates, calcitonin reduces serum calcium more rapidly than bisphosphonates given alone.[4]

Plicamycin, a cytotoxic antibiotic with particular activity against osteoclasts, has been used to obtain a rapid (within 24 hours) and sustained reduction in plasma-calcium concentrations in severe hypercalcaemia. However, it is highly toxic and its use no longer recommended.[1,5] Gallium nitrate also inhibits bone resorption; initial studies in patients with hypercalcaemia associated with malignancy have indicated beneficial effects,[3] but bisphosphonates are still likely to be preferred.[4,5]

Corticosteroids are useful in hypercalcaemia associated with corticosteroid-sensitive haematological malignancies such as lymphoma or myeloma.[1,4,6] In addition they may be useful to overcome renal tubular resistance to calcitonin[9] but otherwise are not usually effective.[10] There have been individual reports of beneficial results using somatostatin analogues such as octreotide for the treatment of hypercalcaemia of malignancy.

Malignant neoplasms

The bisphosphonates and calcitonins are used to control the hypercalcaemia that often accompanies malignant disease (see above). Bisphosphonates are also used in metastatic bone disease (p.660) to control bone pain and to reduce skeletal complications such as fractures. Evidence of the ability of bisphosphonates to prevent the development of bone metastases is conflicting. Bisphosphonates have been found to be effective in reducing the skeletal complications of multiple myeloma (p.658) and are recommended in those patients with bone disease.

Osteogenesis imperfecta

Osteogenesis imperfecta (brittle bone syndrome) is a heterogeneous inherited disorder of connective tissue characterised by bone fragility, osteopenia, short stature, joint laxity, teeth defects, and hearing abnormalities.[1,2] It is often classified into 4 forms, I-IV, which vary in clinical severity, and radiological and genetic aspects;[1] some distinguish 3 further forms, V, VI, and VII.[2]

Orthopaedic treatment and physical activity programmes form the basis of therapy: at present there is no curative drug therapy.[1-3] Calcitonins were commonly used in management, but their use has declined.[1] Beneficial effects have been reported with growth hormone, especially in moderate forms of the disease.[1] Bisphosphonates have yielded substantial improvements in chronic pain, bone mineral density, fracture rate and mobility,[3,4] without significant adverse effects, and may be especially beneficial in severe osteogenesis imperfecta.[1] Cyclic intravenous pamidronate has been the most widely used bisphosphonate, but benefit has also been reported with intermittent intravenous neridronate,[5,6] as well as daily oral clodronate,[7] and daily oral olpadronate.[8] Alendronate and zoledronate are under investigation.[4] Bisphosphonates may also be useful for associated immobilisation hypercalcaemia.[9] Immobilisation can also result in calcium and vitamin D deficiency, and prophylactic supplementation may be useful.[3] Bone marrow transplantation and the potential of antisense gene therapy are being investigated.[1,2]

Osteomalacia and rickets

Osteomalacia occurs in adults when there is impaired mineralisation of the bone matrix, and rickets occurs in children due to defective mineralisation of the cartilaginous growth plate.[1-3] Generally the inadequate bone mineralisation results from deficiency or abnormal metabolism of vitamin D,[1,2,4] calcium deficiency,[1,5] or phosphate deficiency or depletion.[1-3] Several hereditary disorders are associated with the development of rickets including vitamin D-pseudodeficiency rickets (vitamin D-dependent rickets), in which there is impaired synthesis of 1,25-dihydroxycholecalciferol (Type I) or receptor resistance to 1,25-dihydroxycholecalciferol (Type II), and X-linked hypophosphataemic rickets.[2,6] Osteomalacia also occurs in renal osteodystrophy[2] associated with chronic renal failure (see below). Oncogenic osteomalacia is a rare form characterised by hypophosphataemia and renal phosphate wasting caused by a tumour, usually mesenchymal.[2,3] Some drugs including various antiepileptics (p.496), etidronate, and aluminium salts, can interfere with bone mineralisation and cause osteomalacia. Osteomalacia may present with generalised or local bone pain, polyarthralgias, or muscle weakness.[2] Rickets characteristically causes skeletal deformities, epiphyseal enlargement, muscle hypotonia, and teeth defects.[1-4,6]

Treatment of osteomalacia and rickets is mainly aimed at correcting any underlying deficiency.[2] Vitamin D substances, calcium, or phosphate supplements can be given orally as appropriate but doses require careful individual adjustment to maintain calcium and phosphate concentrations within normal limits.[2,5] Vitamin D requirements are probably greater in those with reduced calcium intake, and calcium requirements greater in those with limited sunlight exposure and dietary vitamin D intake.[5] A variety of forms or analogues of vitamin D are available (see p.1986). For the treatment of simple vitamin D deficiency colecalciferol or ergocalciferol are generally preferred.[4] If malabsorption is suspected, larger doses or parenteral use may be necessary, but where large doses are required it may be preferable to use one of the more potent forms of vitamin D such as calcitriol.[2] Simple calcium deficiency may be a more important cause of rickets than vitamin D deficiency in some populations. A study in African children with rickets found that their calcium intake was low and that they responded better to calcium supplementation, with or without vitamin D, than to vitamin D alone.[5]

Type I vitamin D-pseudodeficiency rickets requires replacement therapy with calcitriol. In Type II disease, resistance to calcitriol treatment may be so extreme that only very large supplements of calcium may be effective. X-linked hypophosphataemic rickets is considered to be best treated with combined phosphate supplementation and calcitriol.[3] There has also been some interest in the use of growth hormone in children with hypophosphataemic rickets.[7] A form of hypophosphataemic rickets, rickets of prematurity (see under Osteomalacia, p.1684), may occur in small, premature infants fed exclusively on breast milk, and phosphate supplementation plus calcium and vitamin D has been suggested in such cases. Prophylaxis of calcium or vitamin D deficiencies through adequate dietary intake or supplementation is controversial given difficulties in definitive requirements (see Human Requirements under Calcium, p.1677, and Human Requirements, p.1988, and Osteomalacia, p.1990, under vitamin D).

Osteoporosis

Osteoporosis is a disease characterised by low bone mass and microarchitectural deterioration of bone tissue, leading to enhanced bone fragility and risk of fracture, particularly of the long bones (distal forearm and neck of the femur) and the vertebrae.[1-9] Although bone formation outstrips resorption in youth, accumulated small deficits from remodelling (see Bone and Bone Disease, above) result in a gradual loss of bone mass after the third or fourth decades.[2-4,6,10] Primary osteoporosis is therefore usually an age-related disease. It can affect both sexes, though women are at greater risk because bone loss is accelerated, to a variable degree, after the menopause.[1-3,5,6,10,11] Osteoporosis can also be secondary to chronic endocrine or metabolic conditions[1,5,6,10-12] such as hyperparathyroidism (p.1087), hyperthyroidism (p.2165), diabetes mellitus (p.431), Cushing's syndrome (p.2344), malabsorption syndromes, anorexia nervosa, or inflammatory bowel disease (p.1697) affecting calcium and vitamin D absorption. Other conditions associated with bone loss and osteoporosis include osteogenesis imperfecta (p.1083), rheumatoid arthritis (p.11), complex regional pain syndrome (p.6), chronic renal disease, and multiple myeloma (p.658); osteoporosis may also follow organ and tissue transplantation or prolonged immobilisation. Other secondary causes include the use of drugs[1,5,6,10,11] such as corticosteroids (p.1491), thyroid hormones, anticonvulsants, gonadorelin analogues (p.2106), and heparin (p.1302).

Risk factors for osteoporosis include non-modifiable predictors of low bone mineral density (BMD), such as female sex, increased age, Caucasian or Asian race, while other factors are potentially modifiable but may be independent of BMD, such as cigarette smoking, alcohol consumption, low body-weight, and physical inactivity. Other factors include early menopause, prolonged amenorrhoea, high caffeine intake, and nutritional deficiencies such as low calcium intake and vitamin D deficiency.[1,3,6,10,13] The most important risk factors for osteoporosis-related fracture are a previous history of low-trauma fracture as an adult (40 years of age or older) and low BMD.[1,3,4]

Patients are usually asymptomatic until fractures occur,[6,13] and up to two-thirds of vertebral fractures may also be asymptomatic.[1,6] Fractures can result in pain, deformity (kyphosis, loss of height), and disability.[1] Currently, the most reliable method of assessing osteoporosis and fracture risk is measurement of BMD, usually by dual energy X-ray absorptiometry.[1,3,4,6,14] WHO have defined osteoporosis as a BMD 2.5 standard deviations or more below the young adult mean, and severe or established osteoporosis as this BMD in the presence of one or more fragility fractures.[3] There is no universally agreed policy on screening for osteoporosis, but measurement of BMD should be considered in those thought to be at risk of osteoporosis if the result is likely to affect treatment decisions.[2,3,7,10,15,16]

Since osteoporosis is defined in terms of BMD, the distinction between clinical consequences, such as fractures, and risk, is blurred. Thus, differences between prevention and treatment are increasingly difficult to define; objectives are similar and interventions the same.[3] Goals in management are to prevent fractures, optimise skeletal development to maximise peak BMD at skeletal maturity, stabilise BMD and prevent bone loss, preserve structural skeletal integrity, and to decrease morbidity and mortality from fractures.[1,4] Secondary causes of osteoporosis should be identified and treated as appropriate.[4]

General **non-pharmacological** measures include:

- ensuring adequate dietary calcium and vitamin D intake (see under Human Requirements, p.1677 and p.1988), especially during growth.[1,3,4,17] Supplementation may be necessary, see below.
- regular weight-bearing exercise; during growth this optimises peak bone mass,[3,4,16,17] but is also beneficial in pre- and postmenopausal women in terms of increasing BMD and reducing the risk of fractures.[1,4,16,18] However, exercise does not appear to prevent fractures in postmenopausal women during the first 2 years of exercise.[19]
- lifestyle modifications such as smoking cessation (p.2354) and moderation of caffeine and alcohol intake.[1,3,9,18,20]
- interventions to reduce or prevent falls and injuries; measures to protect the patient should falls occur may also be considered.[1,16,18,20]
- Supportive therapy in the acute phase of a fracture, including pain relief, surgery or appropriate orthopaedic management.[17]

Pharmacological treatment aims to increase bone mass, either by inhibiting bone resorption, or by stimulating bone formation through anabolic effects.[1,21] While many drugs are used, not all have been well evaluated for their effect on fracture rates, and there is little comparative data.[22] Furthermore, many studies have been conducted in postmenopausal osteoporotic women, and evaluation in postmenopausal women with normal BMD, osteopenic women with no fracture, or men, is limited.[3,16]

- Calcium and vitamin D supplementation is accepted baseline adjunctive treatment for osteoporosis and may also be used as a prophylactic measure.[4,7,17,21] Calcium supplementation has a small but positive effect on BMD and tends to reduce the incidence of vertebral fractures. Low vitamin D status has been associated with reduced BMD, and increased risk of falls and hip fracture in elderly people; however, differences in baseline vitamin D concentrations make comparison of studies difficult.[8] Vitamin D supplementation appears to reduce the risk of hip and non-vertebral fractures,[7,8] especially in those with vitamin D deficiency. Excessive vitamin D should be avoided, as this may decrease BMD.[2] Studies of supplementation with calcium plus vitamin D show equivocal results on fracture rates.[8] However, daily calcium with vitamin D supplementation is recommended for elderly institutionalised people with limited exposure to sunlight.[15,16,18]
- Bisphosphonates are antiresorptive drugs that are used first-line for the treatment and prevention of osteoporosis.[4,15,16,20] While aminobisphosphonates and non-nitrogen-containing bisphosphonates differ in their effect on BMD,[14,23] no comparative studies have been done and BMD changes do not necessarily correlate with fracture reduction;[23] some consider effect on fracture rates to be similar.[14]

  There is good evidence that alendronate or risedronate, given orally, can prevent bone loss,[4,11] improve BMD,[1,4,6] and reduce the risk of both vertebral and non-vertebral fractures.[1,2,8,9,13,21] These effects are seen within 1 year of starting treatment,[24] and effects on BMD persist for some while after stopping the drug, particularly with alendronate.[14] Evidence for other bisphosphonates is more patchy: oral or intravenous ibandronate,[11] and intravenous pamidronate[6] or zoledronate[1,11] have all been shown to increase BMD at the spine and hip. Oral ibandronate has been shown to decrease vertebral fracture risk in women with osteoporosis, as well as non-vertebral fracture risk in those with severe disease.[11,25] Intravenous ibandronate has been associated with a reduction in the incidence of new fractures.[11] In a controlled study,[26] a once-yearly infusion of zoledronate given over a 3-year period significantly reduced the risk of vertebral, hip, and other fractures. BMD at the hip, femoral neck, and lumbar spine also increased significantly compared with placebo. Oral cyclical etidronate has been shown to decrease the risk of vertebral fractures,[1,3] (as has oral clodronate[17]), but evidence for an effect on non-vertebral fractures is less clear.[17] In the UK, NICE[27] recommends the use of bisphosphonates for the secondary prevention of osteoporotic fragility fractures in postmenopausal women. Alendronate, etidronate, or risedronate may be given to all women aged 75 years and older, to women aged between 65 and 74 years with confirmed osteoporosis, and to postmenopausal women younger than 65 with very low BMD or with confirmed osteoporosis and one or more additional age-independent risk factors.
- Calcitonins are antiresorptive agents with an adjunctive or second-line role in the treatment of osteoporosis; calcitonin (salmon) is given by subcutaneous injection or intranasally as a spray. Both routes have been found to increase spinal BMD;[1,4,5] decreases in vertebral[4,28] fracture risk have been seen with the nasal spray, although

the beneficial effect on nonvertebral fracture may be less than with bisphosphonates.[29] It has been suggested that the analgesic effects of calcitonins may be valuable in patients with acute pain due to osteoporotic fractures,[2,3,15,21] the analgesia being achieved within 2 weeks.[6]

- In postmenopausal women, HRT (p.2077) was initially considered first-line,[28] as its antiresorptive action has been shown to preserve BMD and decrease hip and vertebral fracture risk.[1,2,21] However, results from the Women's Health Initiative and Million Women studies suggested that long-term use of HRT could increase the risk of breast and some other cancers (see p.2071), while not reducing cardiovascular risk or improving cognitive function. The UK CSM has thus recommended that HRT no longer be considered as a first-line therapy for the prevention of osteoporosis in women aged over 50 years and at increased risk of fractures;[30] it remains an option for those intolerant of or refractory to other therapies, and for prevention of osteoporosis in women with premature menopause until the age of 50. It has been suggested that treatment not exceed 5 years,[21] although others suggest treatment of 7 to 10 years in order to maximise effect in those women considered at greater benefit than risk with HRT.[2] A large study found that women who had stopped using HRT more than 5 years previously had similar hip fracture risk to those who had never used HRT. However, those who had stopped using HRT within the previous 5 years had a higher risk of hip fracture than in those who had never taken HRT.[31]
- Raloxifene is a selective oestrogen receptor modulator (SERM) that partially mimics the effects of oestrogen in bone and the cardiovascular system, but without the stimulatory effects on the endometrium and breast.[3] Raloxifene significantly increases BMD in postmenopausal women and reduces vertebral fracture risk in those women with osteoporosis,[32] although it may exacerbate cardiovascular problems.[11,15] Risk of non-vertebral fracture is not affected,[3,15] and some consider SERMs less effective than the bisphosphonates.[6] NICE recommends raloxifene[27] for the secondary prevention of osteoporotic fragility fractures in women unable to take bisphosphonates or who have had an unsatisfactory response to bisphosphonate treatment.
- Combination therapy of HRT or raloxifene with bisphosphonates has increased BMD but with no effects on fracture reduction.[17]
- Tibolone is a synthetic steroid with combined oestrogenic, progestogenic, and androgenic properties, that increases BMD comparably to HRT, relieves vasomotor symptoms, and does not cause endometrial proliferation.[3] However, there are limited data on fracture prevention, and some do not recommend its use for treatment of osteoporosis.[21] A large study[33,34] of the treatment of osteoporosis in postmenopausal women was stopped early when it was found that although tibolone reduced the risk of fracture there was an increased risk of stroke. However, the full results of this study are yet to be published.
- Fluoride has a direct anabolic effect on the osteoblast, stimulating bone formation; it has been given as sodium fluoride or sodium monofluorophosphate in the treatment of osteoporosis.[3,35] However, increases in lumbar BMD with fluoride have not resulted in decreased vertebral fracture rate, and may even be associated with increased bone fragility and an increase in non-vertebral fractures.[3,36] Thus fluoride is not widely recommended for osteoporosis management; fluoride water concentrations should be taken into account if it is used.[3]
- Parathyroid hormone and its analogue teriparatide also have anabolic effects on bone, and increase BMD at the spine.[20,21] Daily subcutaneous injections of teriparatide reduced the risk of vertebral and non-vertebral fractures in postmenopausal women with osteoporosis.[4,35] Teriparatide has also been shown to increase lumbar and femoral BMD, and reduce non-vertebral fractures to a greater extent than alendronate.[5] The response to parathyroid hormone may be modified by previous or concurrent treatment with antiresorptive drugs.[8] Combination therapy with alendronate offered no advantage over parathyroid hormone (or teriparatide) monotherapy in terms of changes in BMD. However, after 1 year of parathyroid hormone monotherapy, BMD gains were maintained or increased when followed with alendronate therapy, but lost if followed by placebo.[37] NICE recommends teriparatide as an option for the secondary prevention of osteoporotic fragility fractures in women aged 65 years and older who have had an unsatisfactory response to bisphosphonates or who are intolerant to bisphosphonates, and who have an extremely low BMD (4 standard deviations or more below the mean) or a very low BMD (3 standard deviations or more) plus one or more additional risk factors.[27]
- Strontium ranelate has both anabolic and resorptive properties.[17] It has been found to increase BMD at the spine and hip, and reduce new vertebral, non-vertebral, and hip fractures in postmenopausal women with osteoporosis.[9,11]
- Anabolic steroids such as nandrolone have been found to increase BMD similarly to HRT, but adverse effects and limited data on fracture reduction efficacy have limited their use.[3,16]
- There is some suggestion that HMG-CoA reductase inhibitors (statins) can stimulate bone formation and have the potential to reduce fracture risk, but data are conflicting, and further trials are needed.[35,38,39]
- Thiazide diuretics reduce urinary calcium excretion and observational studies have found patients to have a higher BMD and fewer hip fractures;[3] however, effects are small and therapy is likely to be restricted to an adjunctive preventative role.[1,3,5]
- Ipriflavone is a synthetic isoflavone that may inhibit bone resorption; results on BMD from trials are conflicting, and data on fracture reduction lacking.[1,3]
- Vitamin K plays a role in bone metabolism, and is licensed in some countries in the management of osteoporosis; it has been suggested that vitamin K substances should be given to patients at risk of reduced bone mineralisation.[40] A systematic review and meta-analysis found that vitamin K supplementation was associated with increased BMD and a reduced fracture incidence, especially of the hip;[41] however, routine supplementation is not considered justified until these results are confirmed in a large randomised study with fractures as primary outcome.
- Potential anabolic agents in the management of osteoporosis include growth hormone and insulin-like growth factor I.[5,35] Novel antiresorptive agents under investigation include cathepsin K inhibitors, cytokine inhibitors,[5,21] the RANKL monoclonal antibody denosumab,[42] and osteoprotegerin.[5,43]

There is less evidence to guide decisions on the management of osteoporosis in **men**[3,44] than in postmenopausal women. Calcium and vitamin D intake or supplementation, nutritional and lifestyle advice are similar to that for women.[44-46] In hypogonadal men with osteoporosis, testosterone replacement therapy should be used.[3,44,45] In eugonadal men, there are concerns regarding the potential long-term adverse effects of exogenous testosterone.[44,46] Therefore, in men with idiopathic osteoporosis, bisphosphonates may be the treatment of choice.[45] Alendronate has been found to increase BMD at all sites and decrease vertebral fracture rates in men with osteoporosis,[45] and there have been some reports of beneficial effects on lumbar BMD have been reported with cyclical etidronate. Preliminary results with risedronate indicate favourable increases in lumbar BMD and a decrease in vertebral fracture risk.[44]

Beneficial effects on both lumbar and femoral BMD have been reported with teriparatide; its effect on BMD when used alone was found to be greater than when used with alendronate, or that of alendronate alone.[45] While efficacy in fracture prevention is lacking, it may be considered second-line for patients unable to take bisphosphonates.[44] Nasal calcitonin (salmon) has been found to increase lumbar BMD in men with idiopathic osteoporosis,[45] but most similarly reserve its use for those who cannot tolerate bisphosphonates.[44,46]

Of the other available drugs, fluoride has increased BMD and decreased vertebral but not non-vertebral fractures.[45] Thiazide diuretics have been reported to be of benefit, but data on BMD and fracture risk are conflicting; they may be given as adjunctive therapy in men with hypercalciuria.[44] Use of growth hormone in men with idiopathic osteoporosis has led to gains in BMD in a small uncontrolled study.[46]

Paget's disease of bone

Paget's disease of bone (osteitis deformans) is a progressive bone disease of unknown aetiology, characterised by excessive and disorganised bone resorption and formation.[1-4] It may affect single (monostotic) or multiple bones (polyostotic);[1,2,5] the most commonly affected bones include the pelvis, femur, lumbar spine, skull, and tibia.[2,4,5] Although its prevalence appears to be decreasing,[1,2,4,6] Paget's disease occurs in about 3% of the population over 40 years of age[1] and its frequency increases with age.[1,2] Patients may be asymptomatic, but some present with musculoskeletal and bone pain, or with bone weakness and deformity that can result in fractures.[2-4,7] Other complications include hearing loss, osteoarthritis, spinal stenosis, nerve compression (especially of the spinal cord), cranial nerve palsies, and rarely, hydrocephalus or brainstem compression. Cardiac output increases due to increased skeletal vascularity, but high-output heart failure is rare, as is malignant transformation to osteosarcoma.[2-4]

Patients who are asymptomatic may require no treatment;[5,8] however treatment is warranted, in those patients with biochemical markers of active disease or in whom the sites of disease are associated with a risk of progression and future complications.[4,8] Drug therapy is guided by monitoring biochemical improvement in disease activity.[2,6]

Bone pain may be treated with analgesics or NSAIDs, or with drugs that reduce bone resorption, such as the calcitonins and bisphosphonates.[2,4,5]

Bisphosphonates are indicated for persistent bone pain, or to prevent further progression of the disease, especially if complications such as spinal-cord compression are present or there is a risk of such complications.[3,8] Disease activity may be reduced for several months, or years, after bisphosphonate therapy has ceased.[8] However, while bone turnover is suppressed, and osteolytic lesions may be healed, the underlying disorder is not cured; data on long-term effects of bisphosphonates on fractures, bone deformity, or osteoarthritis are limited and they may theoretically exacerbate hearing loss.[2]

Initial experience was with etidronate,[1,6,8] but it is less effective than the newer drugs, and with high doses or prolonged treatment can affect bone mineralisation;[4,6,8] while some still consider it effective,[8] others consider it to have little place in the management of Paget's disease.[3,6,9] Clodronate appears to provide a higher and more sustained response than etidronate.[8] Pamidronate, more effective at healing lesions than etidronate, also gives a prolonged response, although its effects may diminish due to resistance.[8] Alendronate or risedronate both reduce biochemical markers of disease activity with sustained remission,[4,8,9] are more effective than etidronate,[9] and overcome resistance to pamidronate;[3] risedronate may be useful after incomplete response to etidronate.[8] Tiludronate is also more effective than etidronate, with no effect on bone mineralisation, no reported resistance,[1,8] and may be a viable option for those patients unable to tolerate other bisphosphonates.[4] Neridronate has been reported to be beneficial in those patients with resistance to etidronate and clodronate.[8] Preliminary studies indicate suppression of disease activity with ibandronate.[6] Olpadronate and zoledronate have shown benefit in refractory disease, and some suggest zoledronate should be a first-line option.[7]

Bisphosphonates have superseded calcitonins,[1,3,5,6,8] which have a short-lived effect and which generally are less effective in suppressing bone turnover and improving bone pain.[2] Calcitonins may still have a role in those patients for whom bisphosphonates are intolerable or ineffective;[5,6] however, resistance to both bisphosphonates and calcitonins may occur.[1,4]

Plicamycin, a cytotoxic antibiotic with particular activity against osteoclasts, is highly effective in the treatment of Paget's disease of bone.[8] However, it is associated with severe toxicity and is therefore now avoided or reserved for patients refractory to other drugs.[4,6,8]

Studies with gallium nitrate, another inhibitor of bone resorption, have indicated beneficial effects in the treatment of Paget's disease of bone, but long-term haematological safety has not been established,[1,8] and routine use is not recommended.[6] Ipriflavone has also been reported to be of benefit, but remains investigational for Paget's disease.[8]

In selected patients, orthopaedic surgery for a fracture, knee or hip replacement, spinal stenosis, or correction of a bone deformity may be appropriate.[4,6,8] A calcitonin or bisphosphonate may be given for up to 3 months before surgery in order to reduce bone vascularity and minimise blood loss during the operation,[2,4,8] although this effect has not been verified in studies.[6] Such treatment also helps to prevent development of hypercalcaemia due to prolonged immobilisation.[4]

Renal osteodystrophy

Patients with chronic renal failure (p.1672) may develop complex changes to bone known as renal osteodystrophy[1-6] as part of the wider metabolic derangement know as chronic kidney disease-mineral and bone disorder (CKD-MBD).[7,8] These are often classified according to the state of bone turnover[1,3,5] and bone biopsy is the gold standard for diagnosis and classification.[2-6] Progressive renal failure is associated with hypocalcaemia, hyperphosphataemia, and some decrease in vitamin D metabolism, which increase the production of parathyroid hormone. This leads to secondary hyperparathyroidism (see below) and **high bone turnover** disease.[1,3-5] This manifests as *osteitis fibrosa*,[1,3-5] a condition characterised by increased osteoclastic and osteoblastic activity, woven and irregular osteoid, and bone marrow fibrosis.[2-6] **Low bone turnover** disease includes *osteomalacia* (see above) and *adynamic bone disease*.[1-5] These are characterised by defective mineralisation, decreased bone formation, and an absence of osteoclasts and osteoblasts; osteoid seams are wider or increased in osteomalacia, but normal or decreased in adynamic bone disease.[1-4,9] Osteomalacia, associated with vitamin D deficiency or aluminium toxicity (which has adverse effects on bone, see p.1706), is decreasing in incidence with the removal of aluminium from dialysate solutions and decreasing use of aluminium-containing phosphate binders.[1-3,5,10] The pathogenesis of adynamic bone disease is not fully understood; its increasing incidence is thought to be due to suppression of parathyroid hormone secretion caused by increased exposure to calcium salts, as phosphate binders or in dialysate fluid, and vitamin D analogues.[1-6,9,10] Risk factors for its development include elderly age, diabetes mellitus, and peritoneal dialysis.[1-3,5,9] **Mixed uraemic osteodystrophy** has features of both high bone turnover with hyperparathyroidism, and defective bone mineralisation or osteomalacia.[1-6]

Patients with renal osteodystrophy may develop **osteopenia** or **osteoporosis**.[11]

Treatment is aimed at preventing bone disease by controlling the plasma concentrations of phosphate, calcium, parathyroid hormone, and correcting vitamin D deficiency; it should therefore be begun early in the course of renal impairment.[1,2,4,5]

- *Hyperphosphataemia* (p.1669) is initially controlled with a low-phosphate diet but many patients, especially those on dialysis, also need an oral phosphate binder to complex with dietary phosphate in the gastrointestinal tract and reduce its absorption.[1,4]

  Calcium salts such as the carbonate or acetate are effective phosphate binders and have been found to suppress parathyroid hormone concentrations.[1,2,4,12] Calcium citrate is not recommended, because it increases intestinal aluminium absorption.[3,4,12] Calcium salts also raise plasma-calcium concentrations but hypercalcaemia can occur.[4,9] The use of dialysis fluids with a lower calcium content has been suggested for these patients.[4] Use of calcium can also contribute to the development of adynamic bone disease[1,9] and precipitate exogenous calcium deposition in the soft tissues;[1,9,12] coronary artery calcification is a particular problem contributing to cardiac mortality in patients with chronic renal failure.[2-4,13] Hyperphosphataemia or use of vitamin D can exacerbate calcification.[4,12,13]

  Aluminium-based phosphate binders have been given but relatively large doses are required and, as mentioned above, aluminium accumulation can lead to osteomalacia and adynamic bone disease in patients with impaired renal function; their use is no longer generally recommended.[2,3,12] Magnesium carbonate also binds phosphate, but may cause hypermagnesaemia and interfere with bone mineralisation.[2] Dialysate magnesium content may need to be reduced.[4]

  Other phosphate binders that do not contain calcium or aluminium have been tried. Sevelamer is a cationic polymer capable of binding phosphate[2,3] without affecting serum calcium.[4] It has been shown to be equivalent to calcium-based binders,[2,3,12] and is effective in dialysis patients.[1] It has been reported to reduce calcium scores in the coronary artery when compared with calcium salts.[4] Lanthanum carbonate is a cation with a high affinity for phosphate and similar efficacy to calcium carbonate.[3] It has been used effectively in dialysis patients but long-term potential toxic effects are as yet undetermined.[4]

- Vitamin D compounds that do not require renal hydroxylation, such as calcitriol or its synthetic analogue, alfacalcidol, are used to correct *hypocalcaemia* and to contribute to the control of *secondary hyperparathyroidism*;[1,4] calcium supplements may also occasionally be required. Oversuppression of parathyroid hormone concentration should be avoided to deter the development of adynamic bone disease.[1] Calcitriol is given orally at first, but may also be given intravenously or intraperitoneally to patients on dialysis;[2,4-6] doses are adjusted according to response but the effect should be carefully monitored as hypercalcaemia and hyperphosphataemia may develop.[1,4,5] Use of alfacalcidol in the early stages of renal failure, before dialysis is required, has been reported to improve subclinical bone disease.[1] Newer vitamin D analogues suppress parathyroid activity but with potentially less effect on serum calcium and phosphate;[2-4,13] these include doxercalciferol, maxacalcitol, paricalcitol, and falecalcitriol (see Hyperparathyroidism, p.1989).

  Calcimimetics increase the sensitivity of the calcium-sensing receptor of the parathyroid cells.[3] Cinacalcet has reduced parathyroid hormone concentrations[2] without inducing hypercalcaemia or hyperphosphataemia[13] in dialysis patients.

  Patients with hyperparathyroidism unresponsive to drug therapy, or who develop hypercalcaemia (which may itself further aggravate the decline in renal function), may require sub-total or total parathyroidectomy.[2-4] There is a risk of inducing a low turnover bone state; hyperparathyroidism can also recur after surgery.[4] Bone mineral density improves after surgery.[2]

  Bisphosphonates can be used in the acute management of hypercalcaemia,[2] but seem to be of little use in the long-term treatment of hyperparathyroidism. They may be effective in increasing bone mineral density in haemodialysis patients.[3] Some, however, consider their use is unjustified, even in those with documented osteopenia or osteoporosis, and that they may exacerbate adynamic bone disease due to their effects on bone mineralisation.[11]

- *Adynamic bone disease* is treated by stimulating parathyroid hormone-driven bone turnover and mineralisation.[2,3] Calcium and vitamin D supplementation may need to be reduced or stopped, and dialysate calcium concentrations reduced.[2,9] Aluminium deposition needs to be excluded; the use of aluminium-based phosphate binders is clearly undesirable in these patients.[2,9] On bone biopsy, if aluminium accumulation is evident, chelation with desferrioxamine may be considered.[2,4]
- *Osteomalacia* may respond to vitamin D treatment.[2]
- Treatment of mixed uraemic osteodystrophy involves management of both hyperparathyroidism and mineralisation defects.[2]

Rickets

See Osteomalacia and Rickets, above.

Parathyroid Disorders

Parathyroid hormone, secreted by the parathyroid gland, maintains concentrations of ionised calcium in extracellular fluid within normal limits. It acts directly on the kidney to enhance renal reabsorption of calcium, to increase phosphate excretion, and to promote the conversion of vitamin D to its active metabolite, 1,25-dihydroxycholecalciferol, which in turn, enhances calcium absorption from the gastrointestinal tract. Parathyroid hormone also acts on bone, to accelerate bone resorption and the release of calcium and phosphate into the extracellular fluid. Secretion of parathyroid hormone is primarily regulated by the extracellular concentration of ionised calcium; hypocalcaemia stimulates secretion whereas hypercalcaemia has an inhibitory effect. 1,25-Dihydroxycholecalciferol can also suppress parathyroid hormone secretion.

Disorders of parathyroid hormone secretion cause a disruption of calcium homoeostasis and in the long-term, may result in bone disease.

Hyperparathyroidism

Primary hyperparathyroidism is a disorder of parathyroid hormone hypersecretion usually caused by adenomas or hyperplasia of the parathyroid glands; parathyroid carcinoma is a rare cause.[1-4] Patients are often asymptomatic, or have non-specific constitutional symptoms such as fatigue, weakness, anorexia, or bone pain.[3-6] About 20% of patients present with nephrolithiasis, overt bone disease, or neuromuscular weakness.[5] Symptoms and signs of hypercalcaemia (p.1668) may occur;[3,5] hypercalcaemia is usually mild or even intermittent, and severe hypercalcaemia is rare.[7]

Secondary hyperparathyroidism is common in chronic renal failure (p.1672). Other causes of hypocalcaemia or vitamin D deficiency resulting in increased parathyroid hormone secretion include dietary deficiencies or malabsorption, or lack of exposure to sunlight.[1,3] While patients may also be asymptomatic, manifestations can include arthritis, bone pain, myopathy, tendon rupture, or complications such as coronary artery calcification and calciphylaxis; symptoms of the underlying cause can occur.[3]

Tertiary hyperparathyroidism results from autonomous hypersecretion by the parathyroid gland in patients with long-standing secondary hyperparathyroidism, and often occurs after kidney transplantation.[1,3]

Surgical parathyroidectomy is the treatment of choice for symptomatic primary hyperparathyroidism.[1-4,6,8] In patients with asymptomatic primary hyperparathyroidism, no treatment may be necessary, and patients are monitored for serum calcium, serum creatinine, and bone mineral density;[3,5,6,9] the timing of any surgical intervention has been subject to debate.[1,2,4]

In patients for whom surgery is not an option, hypercalcaemia must be controlled. Restriction of dietary calcium is not generally recommended, as this may raise parathyroid hormone levels further.[3,5,6,9,10] While vitamin D supplementation may be reasonable in patients with low concentrations of 1,25-dihydroxycholecalciferol, high doses can worsen hypercalcaemia and cause hypercalciuria.[5] Oral phosphate supplements have been given in the short-term to alleviate hypercalciuria and hypercalcaemia; intravenous use is no longer recommended.[9] The more potent bisphosphonates can be used in the acute management of hypercalcaemia,[9] but seem to be of little benefit in the long-term treatment of hyperparathyroidism.[1,9] However, bisphosphonates such as alendronate may be of use in those patients with low bone mineral density.[3,5,8-12] Although calcitonins have a rapid hypocalcaemic effect it is usually short-lived;[9] they are therefore generally given as adjunctive therapy with a bisphosphonate.[2] Oestrogens have been reported to increase bone mineral density in postmenopausal women with primary hyperparathyroidism, and to have a small effect on calcium concentrations;[5] however, the high doses needed, and the risks associated with HRT, generally preclude their use.[3,5,6] Raloxifene, a selective oestrogen receptor modulator, may be an alternative, having been found to decrease serum calcium and bone turnover in a small, short-term trial.[13] Calcium receptor agonists (calcimimetics) may be of benefit in primary hyperparathyroidism by increasing the sensitivity of the calcium-sensing receptor.[5,8-10] In a small dose-finding study,[14] cinacalcet decreased serum calcium and lowered parathyroid hormone concentrations without increasing urinary calcium excretion in all dose groups. A larger, placebo-controlled trial by the same group found that cinacalcet rapidly normalised serum calcium and modestly decreased parathyroid hormone concentrations; this effect was sustained over 52 weeks.[15] Use of parathyroid hormone peptides to induce autoantibodies against parathyroid hormone resulted in improvement in hypercalcaemia in a woman with parathyroid carcinoma.[16]

Treatment of secondary hyperparathyroidism is usually aimed at the underlying cause of the hypocalcaemia;[1] early treatment of patients with chronic renal failure can prevent or delay its onset. Treatment is based on appropriate vitamin D replacement and reduction of hyperphosphataemia.[1,3] Oral phosphate binders bind dietary phosphate in the gastrointestinal tract reducing its absorption.[1,3] These have included calcium salts such as the carbonate and acetate, which raise serum calcium but carry the risk of inducing hypercalcaemia. Aluminium hydroxide also binds phosphate, but can cause osteomalacia (p.1084) and adynamic bone disease (see Renal Osteodystrophy, above). Sevelamer is a polymer that does not contain calcium or aluminium, and is capable of binding phosphate.[3] Vitamin D compounds that do not require renal hydroxylation for activation, such as calcitriol or its analogue alfacalcidol, are used to lower parathyroid hormone, but the high doses required can induce hypercalcaemia and hyperphosphataemia;[3] newer analogues include doxercalciferol, falecalcitriol, maxacalcitol, and paricalcitol (see p.1989). Cinacalcet is also given orally in the treatment of secondary hyperparathyroidism in patients with chronic kidney disease and on haemodialysis. In a placebo-controlled study,[17] cinacalcet lowered parathyroid hormone levels and reduced serum calcium and phosphate concentrations.

In patients refractory to medical therapy for secondary hyperparathyroidism, parathyroidectomy may be an option; percutaneous ethanol injection has been used as an alternative.[3,10] Kidney transplantation (p.1813) may cause regression of secondary hyperparathyroidism in some patients, but the condition recurs in about a third of renal graft recipients.[1] Tertiary hyperparathyroidism is usually treated with surgery.[1,3]

Hypoparathyroidism

Hypoparathyroidism occurs when there is a deficiency of parathyroid hormone secretion. This may be due to damage or destruction of the glands, e.g. by surgery[1] or disease.[2] Hypoparathyroidism can also arise from auto-immune disease, agenesis of the parathyroid glands (DiGeorge syndrome), defective synthesis of parathyroid hormone (familial hypoparathyroidism), or mutations of the parathyroid and renal calcium-sensing receptors (autosomal dominant hypocalcaemic hypercalciuria) leading to defective regulation of parathyroid hormone secretion.[1,2] Other factors that may lead to a deficiency in parathyroid hormone include hypomagnesaemia and parathyroid adenomas. Where the deficiency results from resistance to parathyroid hormone the condition is termed **pseudohypoparathyroidism**.[1] Parathyroid hormone, as teriparatide, is used in the differential diagnosis of hypoparathyroidism and pseudohypoparathyroidism.

Hypoparathyroidism leads to hypocalcaemia and hyperphosphataemia,[1,3] although in some patients these may not become significant until there is an increased calcium demand, as in pregnancy. Vitamin D deficiency also develops.[1,3] Clinical features reflect the underlying cause of the hypoparathyroidism, but if it occurs rapidly, hypocalcaemia can be acute, with consequent paraesthesia, tetany, and seizures.[1] In chronic hypoparathyroidism, chronic hypocalcaemia may cause cataracts and visual impairment.[1] Hypomagnesaemia and metabolic alkalosis may also occur.[3]

Treatment is aimed at correcting the hypocalcaemia (p.1668) that results mainly from decreased renal tubular calcium resorption.[3] In patients with acute hypocalcaemic tetany parenteral doses of calcium salts, along with either oral or parenteral calcitriol, may be necessary.[1,3] In those with chronic hypocalcaemia treatment is usually with oral calcium, such as calcium carbonate (which has the advantage of binding phosphate), and vitamin D compounds such as calcitriol (which increase the intestinal absorption of calcium).[1,3] Calcium concentrations and renal function require careful monitoring as resultant hypercalcaemia can cause hypercalciuria, nephrolithiasis, and renal damage.[1] Thiazide diuretics may also minimise renal calcium losses.[3] Efficacy of treatment may vary depending on the underlying cause.[1,2]

Teriparatide has been shown to be effective in the treatment of chronic hypoparathyroidism. In 2 studies comparing it with calcium and calcitriol treatment,[4,5] teriparatide maintained serum calcium in the normal range, and decreased urine calcium excretion.

Parathyroid tissue transplantation is rarely possible as allografts require immunosuppression. Autografting may result in recurrence of pre-parathyroidectomy hyperparathyroidism.[1] However, good results have been reported after transplantation of parathyroid cells, depleted of antigen-bearing cells, in a few patients with postsurgical hypoparathyroidism.[6,7]

Alendronate

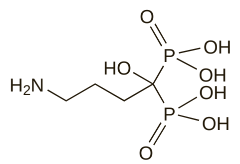
ATC — M05BA04.
ATC Vet — QM05BA04.

Alendronic Acid *(BAN, rINN)*

Acide Alendronique; Ácido alendrónico; Acidum Alendronicum; AHButBP; Alendronihappo; Alendronik Asit; Alendronsyra; Aminohydroxybutylidene Diphosphonic Acid. 4-Amino-1-hydroxybutane-1,1-diylbis(phosphonic acid).

Алендроновая Кислота

$C_4H_{13}NO_7P_2$ = 249.1.
CAS — 66376-36-1.
ATC — M05BA04.
ATC Vet — QM05BA04.



Alendronate Sodium *(USAN, rINNM)*

Alendronat Sodyum; Alendronate de Sodium; Alendronato sódico; G-704650; L-670452; MK-0217; MK-217; Monosodium alendronate; Natrii alendronas; Natrii Alendronas Trihydricus; Natrio alendronatas; Natriumalendronaatti; Natriumalendronat; Nátrium-alendronát; Nátrium-alendronát trihydrát; Sodium Alendronate *(BANM)*; Sodium, alendronate de. Sodium trihydrogen (4-amino-1-hydroxybutylidene)diphosphonate trihydrate.

Натрий Алендронат

$C_4H_{12}NNaO_7P_2,3H_2O$ = 325.1.
CAS — 121268-17-5.
ATC — M05BA04.
ATC Vet — QM05BA04.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Sodium Alendronate). A white or almost white crystalline powder. Soluble in water; practically insoluble in dichloromethane; very slightly soluble in methyl alcohol. A 1% solution in water has a pH of 4.0 to 5.0.

USP 31 (Alendronate Sodium). A white, free-flowing powder. Soluble in water; practically insoluble in alcohol, in acetone, in acetonitrile, in chloroform, and in isopropyl alcohol; very slightly soluble in dimethyl sulfoxide, in methyl alcohol, and in propylene glycol.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. Gastrointestinal symptoms such as abdominal pain, dyspepsia, diarrhoea or constipation are the most frequent adverse effects with alendronate. Severe oesophageal reactions such as oesophagitis, erosions, ulceration, and stricture have occurred (see below); patients should be advised to stop taking the tablets and seek medical attention if they develop symptoms such as dysphagia, new or worsening heartburn, pain on swallowing, or retrosternal pain. Peptic ulceration has also been reported.

Alendronate should not be given to patients with abnormalities of the oesophagus or other factors that might delay oesophageal emptying, or those unable to stand or sit upright for at least 30 minutes. It should be used with caution in patients with upper gastrointestinal abnormalities. To minimise the risk of oesophageal reactions:

- patients should be instructed to swallow alendronate tablets whole with plenty of water (not less than 200 mL), in an upright position (standing or sitting). Mineral water with a high concentration of calcium should be avoided
- tablets should be taken on rising for the day, on an empty stomach, at least 30 minutes before breakfast and any other oral medication
- patients should remain upright after taking the tablets (the *BNF* recommends standing or sitting upright for at least 30 minutes), and should not lie down before eating the first meal of the day
- alendronate should not be taken at bedtime, or before getting up for the day

Hypocalcaemia should be corrected before starting alendronate therapy, and other disorders affecting mineral metabolism such as vitamin D deficiency or hypoparathyroidism should also be treated; serum calcium in these patients should be monitored during therapy.

Effects on the eyes. For reports of ocular effects with the bisphosphonates, including alendronate, see under Bisphosphonates, p.1090.

Effects on the heart. For a report of a possible association between alendronate and atrial fibrillation, see Effects on the Heart, under Bisphosphonates, p.1090.

Effects on the kidneys. Renal failure has been associated with the aminobisphosphonates, including alendronate, see under Bisphosphonates, p.1091.

Effects on the liver. Hepatitis[1,2] and hepatocellular damage with raised liver enzyme concentrations[3,4] have been reported after therapy with alendronate.

1. Lieverse RJ. Hepatitis after alendronate. *Neth J Med* 1998; **53:** 271–2.
2. Carrère C, *et al.* Hépatite aiguë sévère imputable á l'alendronate. *Gastroenterol Clin Biol* 2002; **26:** 179–80.
3. Halabe A, *et al.* Liver damage due to alendronate. *N Engl J Med* 2000; **343:** 365.
4. de la Serna Higuera C, *et al.* Lesión hepatocelular inducida por alendronato. *Gastroenterol Hepatol* 2001; **24:** 244–6.

Effects on mental state. Auditory hallucinations and red-coloured visual disturbances were reported[1] in a patient taking alendronate for osteoporosis.

1. Coleman CI, *et al.* Alendronate-induced auditory hallucinations and visual disturbances. *Pharmacotherapy* 2004; **24:** 799–802.

Effects on the musculoskeletal system. A 63-year old woman given alendronate 70 mg once weekly for osteoporosis developed diffuse severe myalgia and transient acute symmetrical polyarthritis 12 hours after ingestion. Symptoms did not recur after stopping the drug.[1] From the initial marketing of alendronate up until November 2002, the FDA had received reports of severe bone, joint, and/or muscle pain in 118 patients, including a child given the drug in error. Of 83 patients for whom information was available, 55 improved after stopping alendronate; in most of these improvement was gradual, although some experienced immediate relief. Nine of these 83 patients had recurrence of pain when given alendronate again. It was suggested that pain might tend to be under-reported since it is subjective, and might be attributed to underlying osteoporosis.[2] As of May 2006, 7 cases of synovitis linked to alendronate use had been reported in New Zealand; in one case, severe synovitis caused carpal tunnel syndrome that required urgent decompression.[3]

Concerns have been raised about potential oversuppression of bone turnover during long-term therapy with alendronate. In a report on 9 patients who developed spontaneous non-spinal fractures while taking alendronate, fracture healing was absent or incomplete in 6 patients who continued therapy for between 3 months and 2 years after fracture onset. When alendronate was stopped, fracture healing was still incomplete in 4 patients after 8 to 12 months. Use of estrogen (in 3 cases) or the presence of glucocorticoid-induced osteoporosis (in 2) may have contributed to the development of bone turnover suppression in some, but 4 patients had received alendronate as monotherapy; duration of therapy was also considered to be a factor as bone suppression might be cumulative.[4]

Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including alendronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

Effects on the oesophagus. Between September 1995 and March 1996 the UK CSM had received 10 reports of adverse effects on the oesophagus in patients receiving alendronate sodium.[1] Of these, 4 were of oesophageal reflux, 4 of oesophagitis, and 2 of oesophageal ulceration. As of March 1996, worldwide an estimated 475 000 patients had received alendronate and 199 patients had oesophageal reactions reported to the manufacturer, of which 51 were serious or severe.[2] Endoscopic findings included erosions, ulcerations, exudative inflammation, and thickening of the oesophagus. Bleeding was rare, and oesophageal perforation was not reported. Most oesophageal reactions occurred within 1 week to 2 months of starting alendronate therapy. Recovery occurred when alendronate was stopped; however, it was considered important that patients be followed up for the possible development of strictures.[2] In about 60% of the cases where the information was available, alendronate had not been taken in accordance with the precautions for use (see above).

The CSM subsequently noted[3] that it had continued to receive reports of reactions; by July 1998 there had been 97 reports in the UK, in 1 case associated with a fatality. It was estimated that 1 to 2% of patients might experience oesophageal reactions even when following the precautions for use. Some have reported a much higher incidence of unacceptable upper gastrointestinal symptoms in clinical practice.[4] However, a large placebo-controlled trial of alendronate did not find any increase in upper gastrointestinal events in patients taking alendronate.[5]

Hypersensitivity. Allergic reactions to bisphosphonates do occur but appear to be rare, see p.1091.

Interactions

As for the bisphosphonates in general, p.1091.

Pharmacokinetics

Like other bisphosphonates, alendronate is poorly absorbed after oral doses. Absorption is decreased by food, especially by products containing calcium or other polyvalent cations. Bioavailability is about 0.4% when taken half an hour before food, reduced from 0.7% in the fasting state; absorption is negligible when taken up to 2 hours after a meal. Plasma protein binding is about 78%. Bisphosphonates do not appear to be metabolised. About half of the absorbed portion is excreted in the urine; the remainder is sequestered to bone for a prolonged period.

Uses and Administration

Alendronate is an aminobisphosphonate with general properties similar to those of the other bisphosphonates (p.1091). It is a potent inhibitor of bone resorption and is given in the management of osteoporosis either alone or with vitamin D. Alendronate is used for the treatment of Paget's disease of bone. It has also been given in the treatment of bone metastases and hypercalcaemia of malignancy.

Alendronate is given orally as the sodium salt, but doses are expressed in terms of alendronic acid; alendronate sodium 1.3 mg is equivalent to about 1 mg of alendronic acid. The specific instructions given in Adverse Effects and Precautions, above should be followed to minimise adverse effects and permit adequate absorption.

The usual dosage for the treatment of **osteoporosis** in men and women is 10 mg daily. Postmenopausal women may be given 5 mg daily for prophylaxis. It may also be given once weekly to postmenopausal women in a dose of 70 mg for treatment of osteoporosis, or 35 mg for prophylaxis. Men with osteoporosis may be treated with 70 mg once weekly.

For the treatment and prevention of corticosteroid-induced osteoporosis a dose of 5 mg daily is given; postmenopausal women who do not take HRT should be given 10 mg daily.

In adults with **Paget's disease** of bone the usual dose is 40 mg daily for 6 months; treatment may be repeated if necessary after an interval of a further 6 months.

Alendronate has also been given by intravenous infusion.

Administration. Alendronate once-weekly was considered to be therapeutically equivalent to once-daily dosing in both the treatment[1,2] and prevention[3] of osteoporosis, although the treatment study[1] was considered[4,5] to lack information about other drugs being taken and reasons for withdrawal, and studied bone mineral density, not fracture. Tolerability of a once-weekly regimen was comparable to placebo in one study[6] and to once-daily dosing in another;[7] a review[5] concluded that weekly dosage carried a lower risk of upper gastrointestinal symptoms.

6. Greenspan S, *et al.* Tolerability of once-weekly alendronate in patients with osteoporosis: a randomized, double-blind, placebo-controlled study. *Mayo Clin Proc* 2002; **77:** 1044–52.
7. Simon JA, *et al.* Patient preference for once-weekly alendronate 70 mg versus once-daily alendronate 10 mg: a multicenter, randomized, open-label, crossover study. *Clin Ther* 2002; **24:** 1871–86.

Administration in renal impairment. Elimination of alendronate is reduced in *rats* with kidney failure and is likely to be reduced in patients with renal impairment. Licensed product information makes the following recommendations for oral dosage based on creatinine clearance (CC):

- mild to moderate renal impairment (CC greater than 35 mL/minute): no dose adjustment needed
- severe renal impairment (CC less than 35 mL/minute): use is not recommended due to lack of experience with alendronate in this population

Charcot neuroarthropathy. Six months of treatment with once-weekly alendronate has been reported[1] to improve signs and symptoms of Charcot neuroarthropathy (a sometimes painful deformity in limbs that have lost sensory innervation).

1. Pitocco D, *et al.* Six-month treatment with alendronate in acute Charcot neuroarthropathy: a randomized controlled trial. *Diabetes Care* 2005; **28:** 1214–15.

Complex regional pain syndrome. Osteoporosis is one of the features of complex regional pain syndrome (p.6). Bisphosphonates may be of benefit in controlling associated pain in some patients. In a small study,[1] intravenous alendronate 7.5 mg daily for 3 days significantly improved pain, tenderness, swelling, and motion compared with placebo.

1. Adami S, *et al.* Bisphosphonate therapy of reflex sympathetic dystrophy syndrome. *Ann Rheum Dis* 1997; **56:** 201–4.

Gaucher disease. In a placebo-controlled study of patients with Gaucher disease (p.2249), the addition of oral alendronate 40 mg daily to enzyme therapy increased lumbar bone mineral density, but had no effect on focal lesions;[1] the authors concluded that alendronate may be useful adjunctive therapy especially in those patients at risk of osteopenic fracture.

1. Wenstrup RJ, *et al.* Gaucher disease: alendronate disodium improves bone mineral density in adults receiving enzyme therapy. *Blood* 2004; **104:** 1253–7.

Hypercalcaemia. Bisphosphonates are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated. A randomised dose-response study[1] found that single intravenous doses of alendronate 5 mg or more effectively lowered serum-calcium concentrations in patients with tumour-induced hypercalcaemia. Alendronate has also been used to treat hypercalcaemia associated with vitamin D intoxication in children.[2,3]

3. Doneray H, *et al.* Intragastric alendronate therapy in two infants with vitamin D intoxication: a new method. *Clin Toxicol* 2008; **46:** 300–2.

Hyperparathyroidism. Bisphosphonates have been used to inhibit bone resorption in the treatment of hypercalcaemia associated with hyperparathyroidism (p.1087), but seem to be of little benefit for long-term treatment. In patients with primary hyperparathyroidism, oral alendronate significantly increased bone mineral density, especially at the lumbar spine; virtually all of this gain appeared to occur within the first year of treatment. Alendronate is considered to be useful in those patients for whom parathyroidectomy is not possible.[1-4]

3. Chow CC, *et al.* Oral alendronate increases bone mineral density in postmenopausal women with primary hyperparathyroidism. *J Clin Endocrinol Metab* 2003; **88:** 581–7.
4. Khan AA, *et al.* Alendronate in primary hyperparathyroidism: a double-blind, randomized, placebo-controlled trial. *J Clin Endocrinol Metab* 2004; **89:** 3319–25.

Osteoporosis. Bisphosphonates are used for the prevention and treatment of osteoporosis (p.1084). Alendronate significantly increases bone mineral density (BMD) of the lumbar spine and femoral neck in **postmenopausal women** with osteoporosis;[1,2] it increases vertebral BMD in postmenopausal women without osteoporosis, but not quite to the same extent as HRT.[1]

Continuous long-term therapy appears to be more effective than short-term treatment in terms of skeletal benefits,[1-4] but a residual effect on BMD remains for several years after stopping treatment,[3-5] despite resumption of bone loss after withdrawal of alendronate.[4-6] Studies[7,8] in early postmenopausal women suggested that a *higher initial dosage* might be more effective in terms of BMD gain and residual effect.

The effect of alendronate on fracture risk may depend on *baseline bone mineral density*.[2] Treatment reduced the incidence of new vertebral and nonvertebral fractures in women with prior fractures; in women without prior fractures, alendronate reduced the incidence of clinical fractures in those with osteoporosis,[9] but not in those with higher BMD.[10] A systematic review[11] found that alendronate showed a clinically important benefit in the secondary prevention of all osteoporotic fractures; statistically significant reductions in vertebral, non-vertebral, hip, and wrist fractures were seen. No significant reductions were found for primary prevention of osteoporotic fractures, but the reduction in vertebral fractures with alendronate was deemed to be clinically important.

Alendronate is also used in **men** with osteoporosis; in a 2-year randomised study, 10 mg daily by mouth was found to increase vertebral and nonvertebral BMD and help prevent vertebral fractures.[12] Alendronate at 70 mg weekly by mouth also increased BMD significantly in osteoporotic men after 1 year when compared to placebo; fracture incidence, not a primary end-point, was similar in both groups.[13]

Alendronate also increases bone mass density in men and women receiving oral **corticosteroids** at doses equivalent to at least 7.5 mg prednisone daily,[14,15] and may be of some benefit in reducing bone loss after heart[16] and liver[17] **transplantation**.

In men with prostate cancer given androgen deprivation therapy, BMD of the spine and hip significantly improved in those given once-weekly alendronate compared with those given calcium and vitamin D supplementation alone.[18]

Limited available data suggest that alendronate may be safe and effective for patients with HIV who have decreased BMD.[19]

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. Alendronate, at oral doses of 40 mg daily for 6 months, has been shown to be more effective than both etidronate and placebo in the treatment of Paget's disease,[1] although an earlier study[2] found a more sustained reduction in biochemical markers with an oral dose of 80 mg daily.

Bisphosphonates

Bifosfonatos; Biphosphonates; Diphosphonates.

Bisphosphonates are analogues of pyrophosphate, in which the central oxygen atom is replaced by a carbon atom with two further substituents—see Figure 1, p.1090. Like pyrophosphate they have a strong affinity for bone. The bisphosphonates are used chiefly for their antiresorptive and hypocalcaemic properties (see Uses and Administration, below).

Adverse Effects, Treatment, and Precautions

Bisphosphonates may cause gastrointestinal disturbances including abdominal pain, nausea and vomiting, and diarrhoea or constipation. Peptic ulceration has been reported. Existing gastrointestinal problems may be exacerbated, and oral bisphosphonates should generally be given with care or avoided if acute upper gastrointestinal inflammation is present. Gastrointestinal disturbances may be more frequent with aminobisphosphonates such as alendronate, ibandronate, and risedronate; oesophagitis has also occurred. General

The symbol † denotes a preparation no longer actively marketed

precautions to minimise the risk of oesophageal reactions, (see under Alendronate, p.1088) should be observed.

Disturbances in serum electrolytes may occur, most commonly hypocalcaemia and hypophosphataemia. Existing hypocalcaemia or other disturbances of bone and mineral metabolism should be effectively treated before starting bisphosphonate therapy. Adequate intake of calcium and vitamin D is important, and supplementation may be needed if dietary intake is insufficient. Bisphosphonates may cause musculoskeletal pain (which can be severe and incapacitating), osteonecrosis of the jaw (see also Dental Care, below), ocular disturbances, and headache. Hypersensitivity reactions have occurred rarely; angioedema, rashes, urticaria, and pruritus have been reported. Other rare adverse effects include blood disorders such as anaemia, thrombocytopenia, leucopenia and disturbances in liver enzyme values.

Transient fever and flu-like symptoms have been reported, usually at the start of treatment, and are common with infusions of ibandronate, pamidronate, and zoledronate. There may be local reactions, including thrombophlebitis, after parenteral doses. Dizziness, vertigo, asthenia, peripheral oedema, paraesthesia, taste disturbances, and joint disorders have also occurred.

Impairment of renal function has been reported with bisphosphonates, particularly when given parenterally. As a result their use should generally be avoided in patients with moderate to severe renal impairment and they should be used with care in those with lesser degrees of renal impairment.

Etidronate interferes with bone mineralisation, especially at higher doses, which can result in osteomalacia and an increased incidence of fracture. Etidronate should be stopped if a fracture occurs, until healing is complete. It has also been associated with a flare in bone pain in some patients with Paget's disease. Impaired mineralisation is much less marked at usual doses of other bisphosphonates.

Overdosage with bisphosphonates would be likely to result in symptoms of hypocalcaemia; if necessary, parenteral infusion of a calcium salt could be given. Giving milk or antacids, to bind the bisphosphonate and minimise absorption, has been suggested for oral overdosage.

There is little clinical experience with bisphosphonates in pregnancy and they are generally contra-indicated; bisphosphonates have been associated with skeletal abnormalities in the fetus when given to pregnant *animals.*

Dental care. Osteonecrosis of the jaw has been reported in patients given bisphosphonates (see Effects on the Musculoskeletal System, below). Of the published cases most were associated with intravenous therapy in cancer patients, although some have followed oral therapy in patients with osteoporosis. In many cases the effect followed dental surgery. The Adverse Drug Reactions Advisory Committee in Australia has recommended that all patients scheduled to receive intravenous bisphosphonates should have a dental review,[1] and that any dental procedures be completed before beginning the drug.[1,2] Furthermore, health professionals should be aware of the presenting clinical features of osteonecrosis.[2] In the UK, the Commission on Human Medicines has recommended that a dental review should be considered before bisphosphonate treatment in patients with risk factors such as cancer, chemotherapy, corticosteroid therapy, or poor oral hygiene.[3] Licensed information for some bisphosphonates has been amended in a number of countries to include similar warnings.[4]

Effects on the ears. For mention of ototoxicity associated with the use of etidronate in 2 patients with pre-existing otosclerosis, and a recommendation that such patients be monitored when given bisphosphonates, see p.1097. For similar effects with pamidronate, see p.1101.

Effects on the eyes. Ocular effects have been associated with bisphosphonates and although reactions to pamidronate appeared to be rare, the manufacturers were aware of 23 cases up to September 1993 that were possibly associated with the drug.[1] The reactions included anterior uveitis in 7 patients and unilateral episcleritis or scleritis in 3. In one previously reported case,[2] bilateral iritis was associated with risedronate and subsequently pamidronate in a patient who had earlier received etidronate without ill-effect. There have been subsequent reports of unilateral and bilateral scleritis with pamidronate, requiring the drug to be stopped.[3] Anterior[3,4] and posterior[5] uveitis have continued to be reported, and more recently, diplopia with conjunctival swelling and eyelid oedema.[6,7] Similarly, alendronate[8-11] and zoledronate[12] have been associated with scleritis and anterior uveitis. Scleritis,[13] episcleritis,[14] and uveitis[15] have also been reported with risedronate, and bilateral anterior uveitis with clodronate.[16] Non-specific conjunctivitis and abnormal or blurred vision have occurred with most of the bisphosphonates, including etidronate.[13] Dry eye, sore eye, and conjunctivitis were the most frequently reported ophthalmological events assessed as related to risedronate therapy in a prescription-event monitoring study in England.[17] The Australian Adverse Drug Reactions Advisory Committee was aware of 38 reports of serious ocular reactions to bisphosphonates as of April 2004; these were associated with pamidronate or alendronate in 18 cases each, and risedronate or zoledronate in 1 case each.[15] Most reports were of inflammatory reactions such as uveitis, iritis, scleritis, episcleritis, or optic neuritis, and occurred a median of 3 weeks after starting therapy. The risk might be higher with intravenous bisphosphonates, but the frequency of reports was thought to relate mostly to usage.[15] Acute retinal pigment epitheliitis has been reported after an intravenous infusion of zoledronate.[18] Patients who have ocular pain or vision loss while taking bisphosphonates should have the drug stopped and be referred to an ophthalmologist.[13]

Effects on the heart. In a study of once-yearly zoledronate for the treatment of postmenopausal osteoporosis, the number of patients who had arrhythmia in the zoledronate group was significantly higher than that in the placebo group.[1] An increased incidence of serious atrial fibrillation was also seen in the zoledronate group. Fifty patients in the zoledronate group had serious atrial fibrillation, compared with 20 patients in the placebo group. Among the 50 patients, the events occurred more than 30 days after infusion in 47 patients, by which time zoledronate would be undetectable in the circulation. The mechanism by which bisphosphonates might cause arrhythmia or atrial fibrillation is unclear; little or no effect on serum calcium concentrations was seen when measured 9 to 11 days after zoledronate infusion. In an analysis[2] of a randomised study of alendronate in postmenopausal women with osteoporosis, 47 serious atrial fibrillation adverse events were reported in the alendronate group, compared with 31 events among those receiving placebo. There was no increased risk of all atrial fibrillation adverse events.

Although the observed association might have been due to chance,[1] it was felt that the possibility of an increased risk of atrial fibrillation with bisphosphonates should be explored.[2] Two case-control studies examining the association[3,4] came to opposite conclusions as to whether bisphosphonate treatment increased the risk of atrial fibrillation. In the UK, the MHRA stated in July 2008 that any risk appeared low and the balance of risk and benefit for bisphosphonates remained favourable.[5] The FDA in the USA, which came to similar preliminary conclusions, was said to be seeking additional data for a more detailed analysis.

Effects on the kidneys. Renal failure was associated with the intravenous use of etidronate in 2 patients with hypercalcaemia of malignancy.[1] One had been given a high dose (1 g) by short intravenous infusion on two successive days and the other had an elevated serum-creatinine concentration before treatment. A third patient given clodronate, who also developed renal failure, also had a slightly raised serum-creatinine concentration beforehand. Others[2] commented that with smaller doses of etidronate or clodronate (up to 300 mg daily) by intravenous infusion over 2 to 3 hours, renal impairment had not been seen in more than 40 patients treated. They noted a trend towards raised creatinine concentrations which was reversed when etidronate infusions were stopped. Another group[3] found increased serum-creatinine concentrations after the first infusion of etidronate when compared with placebo, but not after subsequent infusions. An overdose of parenteral etidronate led to acute renal failure in one patient.[4] Pamidronate has been associated with nephrotoxicity,[5] proteinuria,[6] acute tubular necrosis,[7,8] and collapsing focal segmental glomerulosclerosis.[9] Over a period of 2 years, 72 cases of renal failure associated with intravenous zoledronate were reported to the FDA.[10] Of 7 cases reported over the course of 3.5 years in France, 3 patients recovered completely, and 1 partially, after stopping zoledronate. Two fatalities were reported, but comorbidities prohibited a direct causal link to zoledronate; the outcome in the remaining case was unknown.[11] Six cases of acute tubular necrosis have been reported with zoledronate;[12] all patients had received pamidronate on previous occasions, and most had mildly raised baseline serum creatinine. While pamidronate may have potentiated the renal toxicity seen with zoledronate, the authors noted that the patterns of nephrotoxicity differ between the 2 drugs. Reports to the Australian Adverse Drug Reactions Advisory Committee have suggested that renal failure or renal impairment may occur more often with zoledronate than with other bisphosphonates. While the deterioration in renal function with zoledronate was acute, in many cases it appeared to be unrelated to the infusion rate; patients may also have been predisposed to renal impairment.[13] There has also been a report of acute renal failure with alendronate treatment in a patient with myeloma,[14] and with tiludronate in a patient treated for hypercalcaemia of malignancy.[15]

Effects on the musculoskeletal system. Osteonecrosis of the jaw has been reported with the use of some bisphosphonates.[1-8] The majority of reports have been in cancer patients treated with intravenous bisphosphonates who were also receiving chemotherapy and corticosteroids. However, osteonecrosis has also been reported in patients receiving oral bisphosphonates for osteoporosis or Paget's disease. Most cases have been associated with dental procedures such as tooth extraction, and many patients had local infection including osteomyelitis.[6,7,9,10] Presenting features may include altered local sensation, maxillofacial pain, toothache, denture sore spots, loose teeth, exposed bone or impaired healing, recurrent or persistent soft tissue infection in the oral cavity, and marked oral odour.[7] A history of underlying dental problems, such as infection, dental extraction, or maxillofacial surgery may exacerbate the problem.[1] Other predisposing factors include oral trauma, periodontitis, and poor dental hygiene.[11] For recommendations on dental care in patients prescribed intravenous bisphosphonates see above.

Length of exposure was found to correlate with development of osteonecrosis,[9,12,13] although some cases have occurred only a few months after bisphosphonate use.[9] There is also some evidence for a dose-response relationship.[8] Furthermore, the type of bisphosphonate used may affect the risk; intravenous use of bisphosphonates containing an aminoterminal group of a nitrogen-containing side-chain appear to present the highest risk,[9] and there is some suggestion that the risk may be higher with zoledronate than with pamidronate.[1,12] The incidence appears to be higher in patients with multiple myeloma,[1,9,12] and elderly myeloma patients may be at increased risk.[9,13]

The mechanism by which bisphosphonates induce osteonecrosis has not been fully elucidated. Avascular necrosis of the hip has been reported; it is possible that osteonecrosis may be a systemic bone disease with initial manifestation in the jaw.[13] A case of osteonecrosis of the auditory canal has been reported;[14] the patient had concurrent osteonecrosis of the jaw.

No effective treatment is known and there is no consensus on management. Stopping bisphosphonate therapy does not necessarily promote healing of the necrotic process;[8,9,13] recovery of normal osteoclast function and bone turnover may be too gradual for this measure to have clinical significance.[10] However, there have been anecdotal reports of healing and complete resolution of lesions several months after cessation of therapy.[10] Treatment is directed towards control of pain and infection and careful local debridement of necrotic bone, but not wide excision of lesions.[8,10]

Effects on the respiratory system. Bronchospasm induced by bisphosphonates has been reported in 2 patients who were aspirin-sensitive asthmatics. The first patient complained of shortness of breath and wheezing 10 minutes after the start of an infusion of clodronate while the second developed similar symptoms 2 days after the start of cyclical therapy with etidronate by mouth. Oral rechallenge in both patients resulted in a fall in the forced expiratory values at 1 second.[1] The reaction in these 2 patients was not considered to be immune-mediated. Risedronate reportedly induced bronchiolitis obliterans organising pneumonia in a patient with sarcoidosis.[2]

For a report of fatal cardiorespiratory failure secondary to acute respiratory distress syndrome caused by etidronate, see Effects on the Skin, under Etidronate, p.1097.

2. Arai T, *et al.* Risedronate induced BOOP complicated with sarcoidosis. *Thorax* 2005; **60:** 613–14.

Hypersensitivity. Bisphosphonates may rarely cause hypersensitivity reactions such as angioedema, urticaria, and pruritus. Reports include a severe allergic reaction to medronate disodium when given as a radiopharmaceutical,[1] and mild skin rashes in 2 patients given oral pamidronate.[2] There has also been a report of erythroderma with lesions of the mucous membranes associated with use of clodronate in one patient,[3] and severe epidermal necrosis may have been associated with tiludronate in another.[4] A possibly drug-related rash has also been reported in a patient receiving alendronate.[5] Other cutaneous reactions reported with alendronate include urticaria,[6] erythematous papules and petechiae,[7] gyrate erythema,[8] and drug-induced lichen planus;[9] licensed product information states that Stevens-Johnson syndrome has been reported. Two patients with cutaneous reactions to pamidronate or clodronate were able to continue oral clodronate after desensitisation.[10] Licensed product information states that zoledronate has been associated with rare reports of hypersensitivity, including angioedema and bronchoconstriction, and very rarely, with anaphylaxis.

Interactions

The bisphosphonates are not well absorbed from the gastrointestinal tract, and dosage with food further impairs their absorption.

Compounds containing aluminium, calcium, iron, or magnesium, including antacids and mineral supplements and some osmotic laxatives, can also impair the absorption of bisphosphonates given by mouth.

It has been suggested that the use of certain bisphosphonates with NSAIDs may result in an increased incidence of gastrointestinal or renal adverse effects.

There may be additive hypocalcaemic effects with aminoglycosides.

Aminoglycosides. Severe hypocalcaemia has been reported after treatment with *amikacin*,[1] or *netilmicin*[2] in patients who had previously received clodronate. In both cases, signs of aminoglycoside toxicity were evident; clodronate had been withdrawn in one patient upon starting the aminoglycoside,[1] and in the other several weeks before.[2] Bisphosphonates and aminoglycosides can induce hypocalcaemia by different mechanisms and the effects of both drugs may persist for several weeks; care should be taken when giving them together.[1,2]

Pharmacokinetics

The bisphosphonates are poorly absorbed after oral doses, with bioavailabilities in the fasting state ranging from about 0.7% (alendronate; risedronate) to up to 6% (etidronate; tiludronate). Absorption is reduced by food, especially by products containing calcium or other polyvalent cations. They have a high affinity for bone, with about 50% of an absorbed dose sequestered to ossified tissues and retained in the body for prolonged periods. Excretion is in the urine, as unchanged drug; they do not appear to be metabolised.

Uses and Administration

The bisphosphonates inhibit bone resorption and thus have a hypocalcaemic effect. They are pyrophosphate analogues that have a high affinity for the hydroxyapatite of bone, and that inhibit bone resorption by osteoclasts; because of the coupling of resorption and formation this results in an overall reduction in remodelling and bone turnover (see Bone and Bone Disease, p.1083). Their antiresorptive potency varies widely. The bisphosphonates also inhibit the formation and dissolution of hydroxyapatite crystals and thus have the potential to interfere with bone mineralisation. The degree to which the bisphosphonates inhibit mineralisation in clinical practice varies; etidronate is the most potent inhibitor of those now in general clinical use.

Because bone resorption increases plasma-calcium concentrations, the bisphosphonates are used as adjuncts to the treatment of severe hypercalcaemia, especially when associated with malignancy. They are also used in disorders associated with excessive bone resorption and turnover, such as Paget's disease of bone and osteoporosis, as well as in the management of bone metastases. Etidronate has been used in the prevention and treatment of ectopic ossification.

The affinity of bisphosphonates for bone allows complexes labelled with radioactive technetium-99m (see p.2055) to be used diagnostically as bone scanning agents.

Bisphosphonates have been given by intravenous infusion or orally. In the latter case food should be avoided for a suitable period before and after a dose, especially foods with a high calcium content such as milk.

Complex regional pain syndrome. Osteoporosis is one of the features of complex regional pain syndrome (p.6). Bisphosphonates may be of benefit in controlling associated pain in some patients.

Ectopic ossification. Bisphosphonates that are potent inhibitors of mineralisation such as etidronate have been advocated for prevention of ectopic ossification (p.100), but they do not prevent the formation of the osteoid matrix, and delayed mineralisation may occur once they are withdrawn.

Hypercalcaemia. In patients with severe symptomatic hypercalcaemia restoration and maintenance of adequate hydration and urine flow is essential, and helps to reduce plasma-calcium concentrations by promoting calcium diuresis. In hypercalcaemia of malignancy (p.1083) therapy with inhibitors of bone resorption such as the bisphosphonates is used. Although sustained, the action of bisphosphonates is not particularly rapid; they may be used with a calcitonin where both rapid and prolonged diminution of plasma-calcium concentration is desired.

Hyperparathyroidism. Bisphosphonates have been used to inhibit bone resorption in the treatment of hypercalcaemia associated with hyperparathyroidism (p.1087), but seem to be of little benefit for long-term treatment.

Juvenile idiopathic arthritis. Bisphosphonates may have a role[1] in preventing low bone mineral density and fragility fractures in children with juvenile idiopathic arthritis (p.10).

1. Thornton J, *et al.* Systematic review of effectiveness of bisphosphonates in treatment of low bone mineral density and fragility fractures in juvenile idiopathic arthritis. *Arch Dis Child* 2006; **91:** 753–61.

Malignant neoplasms of the bone. There is good evidence that some bisphosphonates are of benefit in **treatment** of patients with metastatic bone disease (p.660) not only to control bone pain[1,2] and to manage the attendant hypercalcaemia, but also to reduce skeletal complications such as fractures.[2-8] Maximum benefit in terms of skeletal events occurs only after 6 months of treatment.[9] It has been suggested that given the strength of the evidence, treatment with bisphosphonates should be begun at first diagnosis of bone metastases, and continued until no longer clinically relevant.[2,10] While some continue treatment despite disease progression, others advocate changing to a more potent bisphosphonate, or stopping treatment altogether.[9] Starting bisphosphonates in women with breast cancer without evidence of bone metastases is not recommended.[11]

There are concerns over the development of osteonecrosis of the jaw with bisphosphonate treatment (see Effects on the Musculoskeletal System, under Adverse Effects, above), and a possibly increased incidence in patients with multiple myeloma. Some have recommended[12,13] that monthly intravenous bisphosphonate therapy continue for 2 years in myeloma patients. After 2 years, therapy can be stopped in those who have achieved a complete response or who are in a stable plateau phase. If disease is still active, frequency of infusion can be decreased to once every 3 months. However, others recommend stopping therapy after 1 year in those with a complete response or very good partial response. For those with a poorer response and ongoing active bone disease, bisphosphonates may be continued for up to 2 years.[14] In newly diagnosed patients, pamidronate is favoured over zoledronate as data suggest the risk of osteonecrosis may be higher with the latter.[12-14] However, routinely switching patients from zoledronate to pamidronate is not recommended, as no data suggest that this will prevent osteonecrosis. Multiple myeloma patients without evidence of skeletal involvement should not routinely be given bisphosphonates.[12]

There is also much interest in the use of bisphosphonates to **prevent** the development of bone metastases;[2,4,5,8] however, preliminary evidence of their efficacy is conflicting. Specific references may be found under the individual drugs.

Osteogenesis imperfecta. Bisphosphonates have been tried in osteogenesis imperfecta (p.1083), but orthopaedic treatment and physical activity programmes form the basis of therapy.

Osteoporosis. Bisphosphonates are used first-line in the prevention and treatment of osteoporosis (p.1084). Alendronate, risedronate and cyclical etidronate are used orally; clodronate and ibandronate have been used both orally and parenterally, and ibandronate, pamidronate, and zoledronate by intermittent intravenous infusion. Generally, in the management of **postmenopausal** osteoporosis, bisphosphonates increase bone mineral density (BMD) at both the spine and hip and reduce vertebral fractures; effect on non-vertebral fractures varies.[1,2] Treatment in women at highest risk, with prevalent fractures or low BMD, is considered most effective.[2] In the UK, NICE[3] recommends the use of bisphosphonates for the secondary prevention of osteoporotic fragility fractures in postmenopausal women. Alendronate, etidronate, or risedronate may be given to all women aged 75 years and older, to women aged between 65 and 74 years with confirmed osteoporosis, and to postmenopausal women younger than 65 with very low BMD or with confirmed osteoporosis and one or more additional age-independent risk factors. Data also suggest that the more severe the osteoporosis, the greater the benefit, and since bone density continues to decline with age, and vertebral fracture incidence rises after age 75, some consider it more beneficial in older women.[4] However, others have expressed concern about a possible increase in brittleness of bones with long-term bisphosphonate treatment.[5]

Although there is less evidence for the efficacy of bisphosphonates for the treatment of idiopathic osteoporosis in **men**, some consider them the treatment of choice. A systematic review[6] stated that, while further evaluation of bisphosphonate therapy in **children** with secondary osteoporosis is warranted, evidence does not support their use as standard therapy.

Bisphosphonates are also considered effective at prevention and treatment of **corticosteroid-induced** osteoporosis.[7] Fracture risk (see p.1491) may also be reduced although a systematic review was inconclusive in this respect.[7]

A meta-analysis of bisphosphonate use in the early **post-transplant** period found that they were effective in reducing BMD decline at the lumbar spine; however, prolonged and more intensive treatment may increase the risk of adynamic or low bone turnover disease.[8]

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease.

Bone Morphogenetic Proteins

BMP; Proteínas morfogenéticamente óseas.

Костные Морфогенетические Белки

ATC — M05BC01 (BMP-2); M05BC02 (BMP-7).

Dibotermin Alfa *(BAN, USAN, rINN)*

Dibotermina alfa; Dibotermine Alfa; Diboterminum Alfa; hrBMP-2; rhBMP-2. Human recombinant bone morphogenetic protein 2.

Диботермин Альфа

CAS — 246539-15-1.

ATC Vet — QM05BC01.

Eptotermin Alfa *(rINN)*

Eptotermina alfa; Eptotermine Alfa; Eptoterminum Alfa; hrBMP-7; OP-1; Osteogenic Protein-1. Human recombinant bone morphogenetic protein 7.

Эптотермин Альфа

CAS — 129805-33-0.

ATC Vet — QM05BC02.

Profile

Bone morphogenetic proteins (BMPs) are growth factors that promote ectopic bone formation and can be extracted from demineralised bone matrix. Several have been identified and developed for use in orthopaedic and reconstructive surgery; some have been produced by recombinant technology.

Eptotermin alfa is a recombinant form used in adults for the treatment of non-union of tibia of at least 9 months duration in cases where autograft has failed or is unfeasible. Dibotermin alfa, another recombinant form, is used as an adjunct to standard care for the treatment of acute tibia fractures in adults, as an implant containing 12 mg. The implant is also indicated for anterior lumbar spine fusion, as a substitute for bone grafting, in adults with degenerative disc disease who have had at least 6 months of non-operative treatment. Dibotermin alfa is also used as an alternative to bone grafting for sinus augmentation, and for localised alveolar ridge augmentations for defects associated with extraction sockets. Osteogenin (BMP-3) is under investigation.

Adverse effects. The FDA issued a warning in July 2008 that use of recombinant human bone morphogenetic protein products in cervical spine fusion had been associated with at least 38 reports of swelling of neck and throat tissue, with resultant compression of the airway or vulnerable neurological structures. Complications were often life-threatening, and had required respiratory support and/or tracheotomy in some cases. The use of alternative treatments or enrollment in approved clinical studies was recommended when treating cervical spine problems.[1]

Calcitonins

Calcitoninas.

ATC — H05BA01 (salmon synthetic); H05BA02 (pork natural); H05BA03 (human synthetic).

ATC Vet — QH05BA01 (salmon synthetic); QH05BA02 (pork natural); QH05BA03 (human synthetic).

Calcitonin (Human)

Calcitonina (humana); Calcitonin-human; Human Calcitonin.

$C_{151}H_{226}N_{40}O_{45}S_3$ = 3417.8.
CAS — 21215-62-3.
ATC — H05BA03 (human synthetic).
ATC Vet — QH05BA03 (human synthetic).

Description. Calcitonin (human) is a synthetic polypeptide comprising 32 amino acids in the same linear sequence as in naturally occurring human calcitonin.

Calcitonin (Pork) *(BANM)*

Calcitonina (cerdo).
CAS — 12321-44-7.
ATC — H05BA02 (pork natural).
ATC Vet — QH05BA02 (pork natural).

NOTE. The synonym thyrocalcitonin and the CAS number 9007-12-9 have been used for calcitonin that is often of pork origin.
Description. Calcitonin (pork) is a polypeptide hormone obtained from pork thyroid.

Calcitonin (Salmon) *(BAN)*

Calcitonina (salmón); Calcitonin-salmon; Calcitoninum salmonis; Kalcitonin lososí; Kalcytonina łososiowa; Kalsitoniini (lohi); Kalsitonin (Somon); Lašišų kalcitoninas; Laxkalcitonin; Lazac-kalcitonin; Salcatonin; Salkatonin; Salmon Calcitonin; SCT-1; SMC-20-051.

$C_{145}H_{240}N_{44}O_{48}S_2$ = 3431.9.
CAS — 47931-85-1.
ATC — H05BA01 (salmon synthetic).
ATC Vet — QH05BA01 (salmon synthetic).

NOTE. There may be some confusion between the terms Salcatonin and Calcitonin (Salmon) (Salmon Calcitonin; Calcitonin-salmon) although in practice these names appear to be used for the same substance.

- The Ph. Eur. 6.2 defines Calcitonin (Salmon) as a polypeptide having the structure determined for salmon calcitonin I. It is available as an acetate.
- Calcitonin (Salmon)/Salcatonin (*BAN*) is defined as a *component* of natural salmon calcitonin. The BP 2008 defines Calcitonin (Salmon)/Salcatonin as a synthetic polypeptide having the structure determined for salmon calcitonin I.
- In the USA, Calcitonin (*USAN*) includes calcitonin (human) and calcitonin (salmon) and there Salcatonin is understood to be a synthetic polypeptide structurally similar to natural salmon calcitonin (Calcitonin Salmon (Synthesis)). The US manufacturers use Calcitonin-salmon for a synthetic polypeptide with the same structure as calcitonin of salmon origin.

Pharmacopoeias. In *Chin, Eur.* (see p.vii), and *US..*
Ph. Eur. 6.2 (Calcitonin (Salmon)). A white or almost white powder. It is obtained by chemical synthesis or by a method based on recombinant DNA (rDNA) technology. Freely soluble in water. Store at 2° to 8°. If the substance is sterile store in a sterile, airtight, tamper-proof container. Protect from light.
USP 31 (Calcitonin Salmon). It is a polypeptide that has the same sequence as that of the hormone that regulates calcium metabolism and is secreted by the ultimobranchial gland of salmon. It is produced from either synthetic processes or microbial processes using recombinant DNA (rDNA) technology. One mg of acetic acid-free, anhydrous calcitonin salmon is equivalent to 6000 USP units. Store in airtight containers at a temperature of 2° to 8°, or maintain in a frozen state. Protect from light.

Elcatonin *(rINN)*

[Aminosuberic Acid 1,7]-eel Calcitonin; [Asu^{1,7}]-E-CT; Carbocalcitonin; Elcatonina; Elcatonine; Elcatoninum. 1-Butyric acid-7-(L-2-aminobutyric acid)-26-L-aspartic acid-27-L-valine-29-L-alanine-calcitonin (salmon).

Элькатонин

$C_{148}H_{244}N_{42}O_{47}$ = 3363.8.
CAS — 60731-46-6.
ATC — H05BA04.
ATC Vet — QH05BA04.

Description. Elcatonin is a synthetic analogue of eel calcitonin.

Pharmacopoeias. In *Jpn.*

Incompatibility. Like some other peptide drugs, calcitonin may be adsorbed onto the plastic of intravenous giving sets; it has been suggested that solutions for intravenous infusion should contain some protein to prevent the sorption and consequent loss of potency (see under Administration, below).

Units

0.8 units of calcitonin, porcine, are contained in one ampoule of the second International Standard Preparation (1991).

128 units of calcitonin, salmon, are contained in approximately 20 micrograms of freeze-dried purified synthetic salmon calcitonin, with mannitol 2 mg in one ampoule of the second International Standard Preparation (1989).

17.5 units of calcitonin, human, are contained in one ampoule of the second International Standard Preparation (1991).

88 units of calcitonin, eel, are contained in one ampoule of the first International Standard Preparation (1989).

Potency of calcitonins is estimated by comparing the hypocalcaemic effect, in *rats*, with that of the standard preparation, and is expressed in international or MRC units which are considered to be equivalent. One manufacturer states that 100 international units by this assay is equivalent to 1 mg of porcine or human calcitonin, and to 25 micrograms of salmon calcitonin although other, slightly different, equivalencies have been cited for other preparations. However, although 1 unit of pork calcitonin, 1 unit of salmon calcitonin, and 1 unit of human calcitonin should give the same response in humans this is not necessarily the case. Doses of calcitonin that have been considered approximately equivalent in practice are:

- 80 units of pork calcitonin
- 50 units of salmon calcitonin
- 500 micrograms of human calcitonin

Clinically, doses of pork and salmon calcitonin are expressed in units whereas those of human calcitonin can be expressed by weight, probably a reflection of its purity.

Adverse Effects, Treatment, and Precautions

Calcitonins may cause nausea, vomiting, diarrhoea, dizziness, flushing, and tingling of the hands. These reactions are dose dependent, usually transient, and occur more often with intravenous doses. Other adverse effects have included skin rash, an unpleasant taste, abdominal pain, urinary frequency, and tremor. A diabetogenic effect has been reported rarely. Inflammatory reactions at the injection site have been reported with some calcitonins, and rhinitis and other local reactions have been reported with nasal formulations. Transient hypocalcaemia may occur after injections of calcitonin, and use is contra-indicated in patients with hypocalcaemia.

Calcitonins should be given with care to patients with renal impairment (see below) or heart failure. If children receive calcitonin it should preferably be for short periods and bone growth should be monitored.

Circulating antibodies may develop after several months of use but resistance does not necessarily follow (see also below). In patients with suspected sensitivity, a skin test has been advised before use as hypersensitivity reactions, including anaphylaxis, have occurred.

Calcitonin has inhibited lactation in *animals*.

Nausea and vomiting may be reduced by giving doses at bedtime or by giving an antiemetic beforehand.

Calcitonin (pork) may contain trace amounts of thyroid hormones, but clinical effects are unlikely in most patients.

Antibody formation. Long-term treatment with heterologous calcitonins may lead to the formation of neutralising antibodies. This appears to be common in patients given calcitonin (pork) or, to a lesser extent, calcitonin (salmon). Calcitonin (human) is less immunogenic than pork or salmon, but a study[1] has also detected antibodies to human calcitonin in 1 of 33 women with postmenopausal osteoporosis after 6 months of therapy.

The degree to which such antibodies affect therapeutic activity is uncertain. Some studies have suggested a significant loss of therapeutic activity in patients who developed neutralising antibodies to calcitonin (salmon),[2] or a restoration in activity after a switch from salmon to human calcitonin in such patients;[3] equally, others have presented evidence that the activity of calcitonin (salmon) was not reduced by the development of antibodies to the drug.[4]

Effect on glucose metabolism. A single subcutaneous injection of calcitonin (salmon) has been reported to increase blood-glucose concentrations,[1] but long-term treatment with calcitonins was considered unlikely to cause diabetes.[2] Nevertheless, deterioration in diabetic control has been noted in a patient given calcitonin (pork)[3] and postprandial release of insulin was abolished by intravenous salmon calcitonin in 8 patients with duodenal ulcers.[4]

Interactions

There is a theoretical possibility that dosage adjustments of cardiac glycosides or calcium-channel blockers may be required in patients who are given injections of calcitonin, because of the effects of the latter on serum calcium.

Pharmacokinetics

Calcitonins are rapidly inactivated when given orally. After injection, calcitonins are quickly metabolised, primarily in the kidneys but also in blood and peripheral tissues. Bioavailability has been reported to be about 70%; plasma protein binding is about 30 to 40%. The inactive metabolites and a small proportion of unchanged drug are excreted in the urine. The elimination half-life after injection of calcitonin (human) is stated to be 60 minutes and that of calcitonin (salmon) about 70 to 90 minutes.

Calcitonins are also absorbed through the nasal and rectal mucosa. Although figures have varied widely, about 3% of an intranasal dose of calcitonin (salmon) is reported to be bioavailable compared with the same dose given by intramuscular injection, with peak plasma concentrations occurring after about 30 to 40 minutes compared with 15 to 25 minutes after the parenteral dose. Elimination half-life has been reported to be about 16 to 43 minutes.

◊ After the *subcutaneous injection* of 19.9 micrograms of synthetic calcitonin (salmon) in 16 healthy subjects,[1] absorption was rapid with an absorption half-life of 23.4 minutes. The maximum mean plasma concentration was 384 picograms/mL at 60 minutes after which excretion was fairly rapid with an elimination half-life of 87 minutes. These results and those from previously reported investigations of salmon, human, and porcine calcitonin could not easily be compared, especially since different assay methods had been used. Nevertheless it was concluded that bioavailability from subcutaneous and intramuscular injection sites was good; that dosage may need to be adjusted in renal insufficiency because of low metabolic clearance rate; and that the higher potency of calcitonin (salmon) is due to higher intrinsic activity at the receptor site rather than to pharmacokinetic differences. The US manufacturers have cited a half-life of 1.02 hours after a single subcutaneous injection of calcitonin (human) 500 micrograms. The plasma elimination half-life of elcatonin was about 4.8 hours after *intramuscular injection* in healthy subjects.[2]

Calcitonins are absorbed on *intranasal* or *rectal* dosage. Peak plasma concentrations of calcitonin (salmon) were achieved after 20 to 60 minutes when given by nasal spray in doses ranging from 200 to 400 units.[3] In another study[4] calcitonin (salmon) 200 units, repeated once after 3 hours, was given by nasal spray or suppository to healthy subjects. Absorption was prompt and the total amount absorbed was similar with either route. However, whereas intranasal dosage produced low peaks with calcitonin (salmon) still detectable in the blood after 3 to 5 hours, rectal dosage produced peak plasma concentrations about 6 to 8 times higher but the drug was undetectable within 2 hours; plasma concentrations were lower than those found after injection. Another group[5] found calcitonin (human) to be poorly absorbed when given intranasally to healthy subjects. Absorption from nasal powder or spray solutions was improved by the presence of the surfactants dihydrofusinate or glycocholate.

Investigations carried out in 4 osteoporotic patients[6] suggested that the rectal calcitonin (salmon) could provide 65% of the bioavailability of intramuscular doses.

A study of an *oral* formulation of calcitonin (salmon) in healthy subjects evaluated different oral doses in comparison to intravenous dosing, and found 1.2 mg orally to be comparable to 10 micrograms intravenously, in terms of bioavailability and efficacy.[7]

Uses and Administration

Calcitonin is a hormone produced by mammalian thyroid parafollicular cells or the ultimobranchial gland in non-mammalian vertebrates. In man its secretion and biosynthesis are regulated by the plasma-calcium concentration. It has a hypocalcaemic action that is due primarily to inhibition of osteoclastic bone resorption; of less importance is a direct effect on the kidneys resulting in increased urinary excretion of calcium and phosphorus. Calcitonin contains 32 amino acids; the sequence varies according to the species. Synthetic calcitonin (salmon) and synthetic calcitonin (human) are in clinical use; calcitonin (salmon) is the most potent. Naturally occurring calcitonin (pork) has been used and elcatonin, a synthetic derivative of eel calcitonin, is available in some countries.

Calcitonins are used in the treatment of diseases characterised by high bone turnover such as Paget's disease of bone. They are also given as an adjunct in the treatment of severe hypercalcaemia, especially that associated with malignancy. Some calcitonins are used in the management of osteoporosis.

Calcitonins are generally given by subcutaneous or intramuscular injection; some have been given intranasally, rectally, or by intravenous infusion or slow intravenous injection.

In **Paget's disease of bone** the usual dose range for calcitonin (salmon) is 50 units three times weekly to 100 units daily in single or divided doses by subcutaneous or intramuscular injection. Calcitonin (human) is usually given by subcutaneous or intramuscular injection; doses range from 500 micrograms two to three times weekly, to 250 or 500 micrograms daily; severe cases may require up to 1 mg daily in divided doses.

As an adjunct to the treatment of **hypercalcaemia**, calcitonins have a rapid effect which is greatest in patients with an increased bone turnover. Calcitonin (salmon) may be given by subcutaneous or intramuscular injection in a dose of 4 units/kg every 12 hours, increased if necessary after one or two days to 8 units/kg every 12 hours, up to a maximum of 8 units/kg every 6 hours after a further two days. Alternatively, 100 units every 6 to 8 hours may be given, increased after one or two days to a maximum of 400 units every 6 to 8 hours. Doses greater than 8 units/kg every 6 hours are considered to have no additional benefit. In the emergency treatment of hypercalcaemic crisis, calcitonin (salmon) has also been given intravenously: a suggested dose is up to 10 units/kg diluted in 500 mL of sodium chloride 0.9% and given by slow intravenous infusion over at least 6 hours (see also under Administration below for the problems of intravenous dosage). Calcitonin (human) 500 micrograms every 6 hours has also been given by slow intravenous injection for hypercalcaemia of malignancy.

Calcitonin (salmon) is used in the treatment of **postmenopausal osteoporosis** in a dose of 200 units daily intranasally by nasal spray, alternating nostrils each day. In some countries it has also been given in a dose of 100 units daily or every other day by subcutaneous or intramuscular injection. Supplementary calcium (equivalent to at least 600 mg of elemental calcium daily) and, if necessary, vitamin D (400 units daily) should also be given.

Calcitonin (salmon) is also used for the prevention of acute bone loss due to sudden **immobilisation** such as in patients with recent osteoporotic fractures. The recommended dose is 100 units daily (or 50 units twice daily) by subcutaneous or intramuscular injection, for 2 to 4 weeks. The dose may be reduced to 50 units daily at the start of remobilisation; treatment is maintained until patients are fully mobilised.

Calcitonin (salmon) has also been used for the control of **bone pain due to malignant neoplasms** although in the EU such use is no longer considered appropriate.

Oral formulations of calcitonin (salmon) are being studied.

Administration. Calcitonins have poor oral bioavailability and are usually given by subcutaneous or intramuscular injection. To improve patient acceptability, especially in diseases requiring long-term drug therapy, alternative routes have been investigated:[1]

- calcitonin (salmon) has proved effective when given **intranasally** in usual doses of 50 to 200 units daily (for references, see Osteoporosis below), and intranasal products for osteoporosis are available.
- suppositories containing 300 units of calcitonin (salmon) have been used **rectally** in the management of hypercalcaemia; one suppository being given three times daily (total daily dose of 900 units).[2,3] Daily doses of 100 units of calcitonin (salmon) by suppository have been tried in postmenopausal osteoporosis[4] and in patients with bone pain.[5]
- calcitonins have been given by **intravenous infusion**, but this is rarely necessary and may cause more adverse effects. If intravenous use is essential, it has been suggested[6] that some protein must be present in the solution to prevent adsorption onto the plastic of the giving set. However, in practice this does not seem to be the case; in the UK, manufacturer's recommendations are for dilution with normal saline, while acknowledging that such dilution results in a loss of potency, and dosage is adjusted accordingly. Presumably dilution with a protein-containing solution would allow lower doses to be used. The manufacturers do specify that solutions for infusion should be prepared immediately before use and that glass or hard plastic containers should not be used.

Novel formulations of an orally active calcitonin have been investigated; one such formulation using a low-molecular-weight carrier, was considered effective and well-tolerated in a Phase I study.[7]

7. Buclin T, *et al.* Bioavailability and biological efficacy of a new oral formulation of salmon calcitonin in healthy volunteers. *J Bone Miner Res* 2002; **17:** 1478–85.

Administration in renal impairment. Calcitonins are metabolised mainly in the kidneys and pharmacokinetic studies (see above) have indicated that the dosage of calcitonins may need to be reduced in patients with renal insufficiency, but there have been no specific guidelines.

Charcot neuroarthropathy. In a small study in patients with acute Charcot neuroarthropathy, intranasal calcitonin with calcium supplementation significantly reduced bone turnover compared with calcium supplementation alone.[1]

1. Bem R, *et al.* Intranasal calcitonin in the treatment of acute Charcot neuroosteoarthropathy: a randomized controlled trial. *Diabetes Care* 2006; **29:** 1392–4.

Hypercalcaemia. Calcitonins can be used in addition to rehydration and diuresis in the management of moderate to severe symptomatic hypercalcaemia (p.1668), including that of malignancy (p.1083). Because of their rapid effect, they may be particularly useful in life-threatening hypercalcaemia. However, although they have a rapid effect it is usually short-lived; calcitonins are therefore generally given as an adjunct with other therapy such as a bisphosphonate.

Malignant neoplasms of the bone. Calcitonins may be useful adjuvants in the treatment of malignant disease involving the bone (p.660), not only to correct hypercalcaemia of malignancy (p.1083), but perhaps to relieve bone pain and osteolysis. A systematic review[1] concluded however that available evidence did not support the use of calcitonin for metastatic bone pain; the review was limited to only a few studies. Other therapeutic measures were recommended until further studies are done. In the EU, the use of injectable calcitonins for metastatic bone pain is no longer recommended.

1. Martinez-Zapata MJ, *et al.* Calcitonin for metastatic bone pain. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2006 (accessed 18/04/08).

Osteogenesis imperfecta. There have been reports[1,2] of beneficial effects with calcitonins in the treatment of osteogenesis imperfecta (p.1083), but their use has declined in favour of bisphosphonates.

1. Castells S, *et al.* Therapy of osteogenesis imperfecta with synthetic salmon calcitonin. *J Pediatr* 1979; **95:** 807–11.
2. Nishi Y, *et al.* Effect of long-term calcitonin therapy by injection and nasal spray on the incidence of fractures in osteogenesis imperfecta. *J Pediatr* 1992; **121:** 477–80.

Osteoporosis. Calcitonins may be used in the prevention and treatment of osteoporosis (p.1084). In the treatment of **postmenopausal** osteoporosis they are usually second-line agents; however, because of their analgesic effect, they may be useful for the initial treatment of those with bone pain due to vertebral crush fractures.[1] Calcitonin (salmon) nasal spray has been shown to significantly reduce the risk of vertebral fractures in women with established osteoporosis,[2] although the study has been criticised[3] for a high drop-out rate. Any effect on hip fracture is unestablished.[1,2] In the management of **corticosteroid**-induced osteoporosis, calcitonin appears to maintain bone mineral density (BMD) at the lumbar spine, but not at the femoral neck. Effects on prevention of fractures have not been established.[1,4] Nasal calcitonin (salmon) has been found to increase lumbar spine BMD in **men** with idiopathic osteoporosis.[1]

4. Cranney A, *et al.* Calcitonin for preventing and treating corticosteroid-induced osteoporosis. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2000 (accessed 22/02/05).

Paget's disease of bone. Calcitonins may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. However, the bisphosphonates have largely superseded the calcitonins in this role.

Pain. In addition to bone pain associated with malignancy and with bone disorders such as Paget's disease, calcitonins may also have other analgesic properties. Beneficial results have been seen in various painful conditions, including complex regional pain syndrome (p.6), and particularly with intranasal salmon calcitonin.[1] Salmon calcitonin 100 or 200 units intravenously has also provided relief[2] from phantom limb pain (p.9) after amputation. A small double-blind crossover study of intravenous calcitonin in amputee patients with phantom limb pain found it was ineffective, however, in contrast to ketamine.[3] Intranasal calcitonin at a dose of 200 units also provided only transient relief of phantom limb sensation after spinal cord injury in a patient refractory to clomipramine;[4] the authors speculated that optimal dosage may not have been used and noted that all previous studies were in amputees.

For a discussion on pain and its management, see p.2.

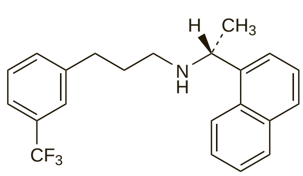
Cinacalcet Hydrochloride *(BANM, USAN, rINNM)*

AMG-073 (cinacalcet); Cinacalcet, Chlorhydrate de; Cinacalceti Hydrochloridum; Hidrocloruro de cinacalcet; KRN-1493. *N*-[(1*R*)-1-(Naphthalen-1-yl)ethyl]-3-[3-(trifluoromethyl)phenyl]-propan-1-amine hydrochloride.

Цинакальцета Гидрохлорид

$C_{22}H_{22}F_3N,HCl$ = 393.9.
CAS — 364782-34-3.
ATC — H05BX01.
ATC Vet — QH05BX01.



(cinacalcet)

Adverse Effects and Precautions

Hypocalcaemia and adynamic bone disease can occur; serum calcium and intact parathyroid hormone concentrations should be monitored regularly, especially in patients with a history of seizure disorders or hepatic impairment. Other adverse effects of cinacalcet include gastrointestinal disturbances, myalgia, dizziness, paraesthesia, hypertension, asthenia, anorexia, rashes, and non-cardiac chest pain. There have been isolated reports of hypotension, worsening heart failure, or both, in patients with impaired cardiac function. Hypersensitivity reactions have been reported rarely.

Interactions

Cinacalcet is partly metabolised by cytochrome P450 isoenzymes CYP3A4 and CYP1A2. Concentrations of cinacalcet have almost doubled when given with the CYP3A4 inhibitor ketoconazole. Dose adjustments of cinacalcet may be required if therapy with strong inhibitors or inducers of CYP3A4 is started, or stopped. Plasma levels of cinacalcet may be lower in smokers due to induction of CYP1A2-mediated metabolism, and dose adjustments may be necessary if patients start or stop smoking. Cinacalcet is a strong inhibitor of cytochrome P450 isoenzyme CYP2D6; exposure to amitriptyline, desipramine, and nortriptyline has been increased when given with cinacalcet.

Pharmacokinetics

Peak plasma concentrations are obtained 2 to 6 hours after an oral dose of cinacalcet, and are substantially increased if given with food. Clearance from plasma is biphasic, with a terminal half-life of about 30 to 40 hours. Cinacalcet is approximately 93 to 97% bound to plasma proteins. It is rapidly and extensively metabolised by cytochrome P450 isoenzymes CYP3A4 and CYP1A2. Metabolites are renally excreted, with 80% of the dose recovered in the urine, and 15% in the faeces.

Uses and Administration

Cinacalcet is a calcimimetic agent that increases the sensitivity to extracellular calcium of the calcium-sensing receptors of the parathyroid gland, which regulate parathyroid hormone secretion; this results in a reduction in parathyroid hormone secretion as well as a decrease in serum calcium. Cinacalcet hydrochloride is given orally in the treatment of secondary hyperparathyroidism in patients with chronic kidney disease on dialysis, as well as for the reduction of hypercalcaemia in patients with parathyroid carcinoma or primary hyperparathyroidism (where parathyroidectomy is not an option). Doses are expressed in terms of the base; cinacalcet hydrochloride 33 mg is equivalent to about 30 mg of cinacalcet.

In the treatment of **secondary hyperparathyroidism**, the initial dose is 30 mg once daily, increased at intervals of 2 to 4 weeks by 30 mg to a maximum of 180 mg daily.

For the treatment of **hypercalcaemia** in patients with parathyroid carcinoma or primary hyperparathyroidism, cinacalcet is given in an initial dose of 30 mg twice daily, increased sequentially at intervals of 2 to 4 weeks to a maximum of 90 mg three or four times daily.

Динатрий Клодронат

$CH_2Cl_2Na_2O_6P_2,4H_2O$ = 360.9.
CAS — 22560-50-5.
ATC — M05BA02.
ATC Vet — QM05BA02.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Clodronate Disodium Tetrahydrate). A white or almost white, crystalline powder. Freely soluble in water; practically insoluble in alcohol; slightly soluble in methyl alcohol. A 5% solution in water has a pH of 3.0 to 4.5.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. Gastrointestinal symptoms with oral clodronate may be reduced by giving it in divided doses rather than as a single daily dose. Reversible increases in liver enzyme values and serum parathyroid hormone have occurred; transient moderate leucopenia has been reported. Monitoring of hepatic and renal function, white cell counts, and serum calcium and phosphate is advised. Clodronate has precipitated bronchospasm, even in patients with no history of asthma. Transient proteinuria has been reported immediately after intravenous infusion.

Effects on the eyes. For reports of ocular effects associated with the bisphosphonates, including clodronate, see under Bisphosphonates, p.1090.

Effects on the kidneys. For mention of renal failure developing in a patient with slightly raised serum-creatinine concentrations who subsequently received an intravenous infusion of clodronate, see under Bisphosphonates, p.1091.

Effects on the musculoskeletal system. Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including clodronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

Effects on the respiratory system. For a report of bronchospasm in an aspirin-sensitive asthmatic, induced by an infusion of clodronate, see p.1091.

Hypersensitivity. Allergic reactions to bisphosphonates are rare. For published reports of cutaneous reactions associated with clodronate, see p.1091.

Interactions

As for the bisphosphonates in general, p.1091.

Aminoglycosides. Severe hypocalcaemia has been reported after treatment with *amikacin*[1], or *netilmicin*[2] in patients who had previously received clodronate. In both cases, signs of aminoglycoside toxicity were evident; clodronate had been withdrawn in one patient upon starting the aminoglycoside,[1] and in the other several weeks before.[2] Bisphosphonates and aminoglycosides can induce hypocalcaemia by different mechanisms and the effects of both drugs may persist for several weeks; care should be taken when giving them together.[1,2]

1. Mayordomo JI, Rivera F. Severe hypocalcaemia after treatment with oral clodronate and aminoglycoside. *Ann Oncol* 1993; **4:** 432–3.
2. Pedersen-Bjergaard U, Myhre J. Severe hypocalcaemia after treatment with diphosphonate and aminoglycoside. *BMJ* 1991; **302:** 295. Correction. *ibid.*; 791.

Pharmacokinetics

Like other bisphosphonates, clodronate is poorly absorbed after oral doses. Absorption is decreased by food, especially by products containing calcium or other polyvalent cations. Bioavailability is only 1 to 4%, and may differ appreciably between different oral formulations. On absorption or intravenous dosage it is cleared rapidly from the blood with a reported plasma half-life of only about 2 hours, but has a high affinity for bone. Binding to serum plasma proteins is low. Clodronate is not metabolised. Over 70% of an intravenous dose is excreted unchanged in the urine within 24 hours, the remainder being sequestered to bone tissue.

Bioavailability. Enhanced bioavailability tablets of clodronate disodium are available in some countries, the licensed dose of which is less than the dose of the standard formulations (see below). However, an open, randomised, crossover study in 88 subjects found that a 1040-mg dose of the enhanced tablet formulation provided only 52% of the bioavailable dose of 1600 mg of the standard capsule formulation.[1]

1. Lapham G, *et al.* Bioavailability of two clodronate formulations. *Br J Hosp Med* 1996; **56:** 231–3.

Uses and Administration

Clodronate is a bisphosphonate with general properties similar to those of the other bisphosphonates (p.1091). It inhibits bone resorption, but appears to have less effect on bone mineralisation than etidronate at comparable doses. Clodronate is used, generally as the disodium salt, as an adjunct in the treatment of severe hypercalcaemia associated with malignancy. In addition, it is used in the management of osteolytic lesions and bone pain associated with skeletal metastases. Doses are expressed in terms of anhydrous clodronate disodium; 125 mg of clodronate disodium tetrahydrate is equivalent to about 100 mg of anhydrous substance.

Clodronate is given by slow intravenous infusion, diluted in sodium chloride 0.9% or glucose 5%, or orally, as a single daily dose or in 2 divided doses; food should be avoided for at least 1 hour before or 1 hour after an oral dose. Clodronate disodium is available in capsules of 400 mg and standard tablets of 800 mg. Tablets of clodronate disodium 520 mg are also available in some countries, and have a greater bioavailability than the capsules or standard tablets; one such tablet of clodronate disodium 520 mg is equivalent to about two capsules each containing clodronate disodium 400 mg or one 800-mg standard tablet (but see Bioavailability, above).

In the management of osteolytic lesions, hypercalcaemia, and bone pain associated with **skeletal metastases** in patients with breast cancer or multiple myeloma, clodronate disodium 1.6 g daily (4 capsules or 2 standard tablets) is given orally, and may be increased if necessary to a maximum of 3.2 g daily. Alternatively a dose of 1.04 g (2 tablets) daily, increased if necessary up to 2.08 g daily, may be given as enhanced bioavailability tablets.

In **hypercalcaemia of malignancy** clodronate disodium is given by intravenous infusion over not less than 2 hours in a dose of 300 mg in 500 mL of infusion solution daily on successive days until normocalcaemia is achieved (usually within 5 days); duration of treatment should not exceed 10 days. Alternatively, it may be given as a single intravenous infusion of 1.5 g in 500 mL of infusion solution over a period of 4 hours. Once serum-calcium concentrations have been reduced to an acceptable level, maintenance therapy may be given orally in similar doses to those used for initial oral treatment of metastases. If hypercalcaemia recurs, the intravenous dose may be repeated.

Administration. In Italy, clodronate is also used *intramuscularly*.[1,2] The usual dose for maintenance therapy of hypercalcaemia is 100 mg daily for 2 to 3 weeks; in the prevention and treatment of postmenopausal osteoporosis, 100 mg is given every 7 to 14 days. However, injection into the gluteal muscle caused local hardening; severe pain at the injection site may limit prolonged use of this route.[1] In Canada, clodronate has been given *subcutaneously* in doses of 1500 mg in 50 to 250 mL of infusion solution over 2 to 3 hours, to treat hypercalcaemia associated with malignancy. The chest and abdomen were the sites most frequently used; pain was the most common adverse effect.[3]

2. Filipponi P, *et al.* Intermittent versus continuous clodronate administration in postmenopausal women with low bone mass. *Bone* 2000; **26:** 269–74.
3. Roemer-Bécuwe C, *et al.* Safety of subcutaneous clodronate and efficacy in hypercalcaemia of malignancy: a novel route of administration. *J Pain Symptom Manage* 2003; **26:** 843–8.

Administration in renal impairment. A pharmacokinetic study[1] found that renal clearance of intravenous clodronate was highly dependent on renal function. While recommending caution in interpreting these results for patients with malignancy or severe bone disease, the authors recommended the following dose adjustments based on creatinine clearance (CC):

- CC 50 to 80 mL/minute: up to 25% reduction in dose
- CC 12 to 49 mL/minute: 25 to 50% dose reduction
- CC less than 12 mL/minute: 50% dose reduction

However, some manufacturers recommend that *intravenous* infusion of clodronate should be avoided in patients with moderate to severe renal impairment (serum creatinine greater than 440 micromoles/litre). Others recommend, where multiple infusions are given, adjustment according to creatinine clearance (CC) as follows:

- mild renal impairment (CC 50 to 80 mL/minute): 25% reduction in dose
- moderate renal impairment (CC 10 to 50 mL/minute): 25 to 50% dose reduction
- severe impairment (CC below 10 mL/minute): contra-indicated

For the *oral* route the following adjustments may be made:

- CC between 10 and 30 mL/minute: 50% dose reduction
- CC below 10 mL/minute (or serum creatinine greater than 440 micromoles/litre): contra-indicated

Complex regional pain syndrome. Osteoporosis is one of the features of complex regional pain syndrome (p.6). Bisphosphonates may be of benefit in controlling associated pain in some patients. In a small study,[1] intravenous clodronate 300 mg daily for 10 days significantly improved pain, tenderness, swelling, and motion compared with placebo.

1. Varenna M, *et al.* Intravenous clodronate in the treatment of reflex sympathetic dystrophy syndrome: a randomized, double blind, placebo controlled study. *J Rheumatol* 2000; **27:** 1477–83.

Hypercalcaemia. Bisphosphonates are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated. Clodronate has been shown to be effective[1-4] in the treatment of malignant hypercalcaemia. A small dose-response study[3] found low-dose clodronate for mild cases to be as effective as high-dose clodronate for moderate to severe cases of tumour-induced hypercalcaemia.

Malignant neoplasms of the bone. Bisphosphonates are of benefit in some patients with metastatic bone disease (p.660) not only to manage bone pain and hypercalcaemia, but to reduce skeletal complications such as fractures. Clodronate is licensed for such use in many countries. Studies in breast cancer patients with bone metastases found that clodronate reduced the incidence of fractures,[1,2] and delayed the time to onset of new bone events.[2,3] Whether bisphosphonates can prevent the development of new skeletal metastases is unclear. Results of studies using clodronate to reduce skeletal metastases in women with breast cancer have been conflicting,[1,4-6] and one study in women with node-positive disease actually suggested an increase in concomitant visceral metastases.[5] Overall, the studies appeared limited by duration, and further data are needed.[7] In a trial of patients with multiple myeloma,[8] oral clodronate was found to slow the progression of skeletal disease, especially in those patients with less overt disease at diagnosis; the authors suggested starting clodronate early in the course of the disease.

Osteogenesis imperfecta. Clodronate has been reported to be of benefit in a boy with osteogenesis imperfecta (p.1083) type I. Starting at 13⁄ years old he was given oral clodronate 400 mg daily for 5 years, and sustained no new low-trauma fractures during this time. Treatment was stopped for 8 months, but bone mineral density remained below normal limits. Clodronate was restarted at 800 mg daily and given with no untoward effects, until the patient was 22 years old, 8 years after initial referral.[1]

1. Ashford RU, *et al.* Oral clodronate as treatment of osteogenesis imperfecta. *Arch Dis Child* 2003; **88:** 945.

Osteoporosis. Bisphosphonates are used for the prevention and treatment of osteoporosis (p.1084). Clodronate is licensed for this use in some countries. Studies of its use in daily oral doses, or intermittent intravenous infusions,[1] or intramuscular injections (at 7-, 10- or 14-day intervals)[1,2] found increases in bone mineral density at various sites in postmenopausal women with osteoporosis or low bone mass. A large study[3] in postmenopausal women with vertebral osteopenia found that oral clodronate 800 mg daily prevented bone loss in the lumbar spine and femoral trochanter, but not the femoral neck; this dose has been shown to reduce vertebral fracture risk in women with postmenopausal or secondary osteoporosis.[4] The risk of vertebral fractures was also reduced in patients with arthritis receiving corticosteroids, who were given intramuscular clodronate once weekly.[5] Oral clodronate may be of benefit in reducing bone loss after heart transplantation,[6] but the benefits of intravenous clodronate in a small prospective study in patients receiving parenteral nutrition (who are at high risk of osteoporosis) were uncertain.[7]

7. Haderslev KV, *et al.* Effect of cyclical intravenous clodronate therapy on bone mineral density and markers of bone turnover in patients receiving home parenteral nutrition. *Am J Clin Nutr* 2002; **76:** 482–8.

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. A review[1] of clodronate stated that oral doses of 800 to 1600 mg daily were effective in reducing bone turnover in patients with Paget's disease, and that remission after stopping was longer with the higher dose. Duration of therapy also appears to affect response;[1] longer treatment was associated with a longer time to relapse.[2] Short-term intravenous clodronate (300 mg daily for 5 to 10 days) has also been found to reduce biochemical markers of bone turnover, and sustain remission for up to 1 year.[1,3]

Denosumab *(USAN, rINN)*

AMG-162; Dénosumab; Denosumabum.

Деносумаб

CAS — 615258-40-7.

Profile

Denosumab is a human monoclonal antibody that specifically targets the receptor activator of nuclear factor-kappa B ligand (RANKL), a mediator of the resorptive phase of bone remodelling. Denosumab is under investigation for various conditions, including osteoporosis, treatment-induced bone loss, rheumatoid arthritis, bone metastases, and multiple myeloma.

NOTE. Other etidronic acid sodium salts are designated as etidronate monosodium, etidronate trisodium, and etidronate tetrasodium. The name etidronate sodium is used only in *Martindale* where the salt cannot be identified more precisely.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Etidronate Disodium). A white or yellowish, hygroscopic powder. Freely soluble in water; practically insoluble in alcohol and in acetone. A 1% solution in water has a pH of 4.2 to 5.2. Store in airtight containers.

USP 31 (Etidronate Disodium). A white powder that may contain lumps. Freely soluble in water; practically insoluble in alcohol. Store in airtight containers. pH of a 1% solution in water is between 4.2 and 5.2.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. Unlike the newer bisphosphonates etidronate produces marked impairment of bone mineralisation at high therapeutic doses. An increase in bone pain may occur in patients with Paget's disease. Impairment of bone mineralisation may result in osteomalacia, and fractures have been reported. If a fracture occurs etidronate should be stopped until healing is complete. Hyperphosphataemia may occur, usually at high doses, but generally resolves 2 to 4 weeks after the end of therapy. There have been reports of paraesthesias, peripheral neuropathy, and confusion. Burning of the tongue, alopecia, erythema multiforme, and exacerbation of asthma have occurred rarely. Transient loss or alteration of taste has been reported mainly during and after intravenous infusion.

Effects on the blood. For a report of pancytopenia caused by etidronate therapy, see Effects on the Skin, below.

Effects on the ears. Ototoxicity, manifest as tinnitus and hearing loss, has been reported[1] in 2 patients given etidronate for osteoporosis; both patients had pre-existing otosclerosis and the authors recommended that those with ear pathology be monitored audiometrically when given bisphosphonates.

1. Yeşil S, *et al.* Further hearing loss during osteoporosis treatment with etidronate. *Postgrad Med J* 1998; **74:** 363–4.

Effects on the eyes. For reports of ocular effects associated with the bisphosphonates, including etidronate, see under Bisphosphonates, p.1090.

Effects on the gastrointestinal tract. Oral etidronate was not associated with an increased incidence of upper gastrointestinal problems in a retrospective cohort study.[1] There was also no evidence of an increased incidence of gastrointestinal effects when given with NSAIDs or corticosteroids. Similarly, another large cohort study found no increased risk of peptic ulcer disease associated with the use of cyclical etidronate.[2] However, oesophageal ulceration has been reported with daily etidronate;[3,4] in one case possibly associated with incorrect use,[3] and in another, complicated by prior use of diclofenac, and a history of gastro-oesophageal reflux disease.[4]

1. van Staa T, *et al.* Upper gastrointestinal adverse events and cyclical etidronate. *Am J Med* 1997; **103:** 462–7.
2. Burger H, *et al.* Cyclical etidronate use is not associated with symptoms of peptic ulcer disease. *Eur J Clin Pharmacol* 2000; **56:** 319–22.
3. Macedo G, *et al.* Ulcerative esophagitis caused by etidronate. *Gastrointest Endosc* 2001; **53:** 250–1.
4. Maroy B. Ulcère géant de l'œsophage probablement dû à la prise d'étidronate. *Gastroenterol Clin Biol* 2001; **25:** 917–18.

Effects on the kidneys. Bisphosphonates are excreted by the kidneys, thus caution is advised in patients with renal impairment. When given by intravenous infusion for the treatment of hypercalcaemia of malignancy they have been reported to affect renal function adversely; hypercalcaemia or malignancy may also have contributed. For reports of renal failure associated with etidronate see under Bisphosphonates, p.1091.

Effects on mental state. Sensory hallucinations and confusion were reported in an elderly woman given daily etidronate for a week. Symptoms resolved on stopping the drug and recurred on rechallenge.[1] Mood disturbances, lack of concentration, and memory impairment were also reported in 3 patients receiving longer-term cyclical treatment; symptoms again diminished on stopping etidronate and reappeared after rechallenge.[2]

1. Burnet SP, Petrie JP. 'Wake up and smell the roses'—a drug reaction to etidronate. *Aust N Z J Med* 1999; **29:** 93.
2. Wolffenbuttel BHR, van der Klauw MM. Psychische bijwerkingen van behandeling met bisfosfonaten. *Ned Tijdschr Geneeskd* 2003; **147:** 35–7.

Effects on the respiratory system. For a report of bronchospasm induced by etidronate in an aspirin-sensitive asthmatic, see p.1091. For a report of fatal cardiorespiratory failure secondary to acute respiratory distress syndrome caused by etidronate, see Effects on the Skin, below.

Effects on the skin. A 47-year old woman with a history of auto-immune rheumatic disease developed toxic epidermal necrolysis, pancytopenia, and acute respiratory distress syndrome 7 days after starting etidronate for osteoporosis; she died of cardiorespiratory failure, secondary to the acute respiratory distress syndrome, despite aggressive supportive measures.[1]

1. Coakley G, Isenberg DA. Toxic epidermal necrolysis, pancytopenia and adult respiratory syndrome. *Br J Rheumatol* 1995; **34:** 798.

Hypersensitivity. Allergic reactions to bisphosphonates do occur but appear to be rare (see p.1091).

Interactions

As for the bisphosphonates in general, p.1091.

Anti-inflammatory drugs. For a lack of apparent interaction between cyclical etidronate and corticosteroids or NSAIDs see under Effects on the Gastrointestinal Tract, above.

Pharmacokinetics

After oral doses of etidronate, absorption is variable and appears to be dose dependent. At usual doses about 1 to 6% of a dose is absorbed. Absorption is reduced by food, especially by products containing calcium or other polyvalent cations. Etidronate is rapidly cleared from the blood and has been reported to have a plasma half-life of 1 to 6 hours. It is not metabolised. About 50% is excreted in the urine within 24 hours, the remainder being sequestered to bone and slowly eliminated. The half-life of etidronate in bone exceeds 90 days. Unabsorbed etidronate appears in the faeces.

Uses and Administration

Etidronate is a bisphosphonate with general properties similar to those of the other bisphosphonates (p.1091). It inhibits the growth and dissolution of hydroxyapatite crystals in bone and may also directly impair osteoclast activity. It diminishes bone resorption and thus reduces bone turnover.

Etidronate is used as an adjunct in the treatment of severe hypercalcaemia, especially when associated with malignancy. It is also given in bone disorders in which excessive bone resorption is a problem, such as Paget's disease of bone and osteoporosis. In addition, it may be used for the prevention and treatment of ectopic (heterotopic) ossification. A chelate of etidronate with radioactive technetium-99m (p.2055) is used diagnostically as a bone scanning agent and a similar compound with rhenium-186 for the palliation of bone metastases in prostate cancer (see below).

Etidronate is given as the disodium salt, by intravenous infusion over at least 2 hours, or orally, usually as a single daily dose. Food should be avoided for 2 hours before and after oral doses.

In the treatment of **Paget's disease**, etidronate disodium is given orally in a usual initial dose of 5 mg/kg daily for not more than 6 months. Doses above 10 mg/kg daily should be reserved for severe disease and should not be given for more than 3 months at a time. The maximum dose is 20 mg/kg daily. The response to etidronate may be slow in onset and may continue for several months after stopping therapy. Therefore, further treatment should only be given after a drug-free interval of at least 3 months and after evidence of relapse; it should not be given for longer than the initial treatment.

In the treatment of **hypercalcaemia of malignancy** the recommended dose of etidronate disodium by slow intravenous infusion is 7.5 mg/kg daily for 3 successive days, although infusions may be continued for up to 7 days if necessary. This daily dose should be diluted in at least 250 mL of sodium chloride 0.9% and infused over at least 2 hours. There should be at least a 7-day interval between courses of treatment. Once serum-calcium concentrations have been reduced to an acceptable level, maintenance therapy with oral etidronate disodium 20 mg/kg daily for 30 days may be started on the day after the last intravenous dose; treatment may be extended to a maximum of 90 days.

For the prevention and treatment of **ectopic ossification** complicating hip replacement etidronate disodium has been given orally in a dose of 20 mg/kg daily for 1 month before and 3 months after the operation. For ectopic ossification due to spinal cord injury it has been given in a dose of 20 mg/kg daily for 2 weeks followed by 10 mg/kg daily for 10 weeks.

For the treatment of **osteoporosis**, the prevention of bone loss in postmenopausal women, and the prevention and treatment of corticosteroid-induced osteoporosis, etidronate is given in an intermittent or cyclical regimen with a calcium salt; oral etidronate disodium 400 mg is given daily for 14 days followed by the equivalent of 500 mg of elemental calcium orally for 76 days. Treatment has continued for 3 years in most patients; a small number of patients have been successfully treated for up to 7 years. The optimum duration of treatment has not been established.

Administration in renal impairment. Some manufacturers have recommended that etidronate disodium should not be given *intravenously* to patients with serum-creatinine concentrations greater than 50 mg/litre, and that doses may need to be reduced in those with concentrations between 25 and 49 mg/litre. Reduced *oral* doses are similarly recommended in mild renal impairment, and avoidance in moderate to severe impairment.

Ectopic ossification. Bisphosphonates that inhibit bone mineralisation such as etidronate have been used to prevent ectopic ossification (p.100). Some studies, using higher and more prolonged dosage (20 mg/kg daily by mouth for 6 months) than is generally recommended for treatment after spinal cord injury, have suggested that this may improve effectiveness.[1,2] Etidronate has also been used to treat calciphylaxis and vascular and soft-tissue calcification associated with haemodialysis.[3-5]

5. Mori H, *et al.* Etidronate for the treatment of progressive tumoral calcinosis in hemodialysis patients. *Intern Med* 2007; **46:** 1485–6.

Hypercalcaemia. Bisphosphonates (including etidronate although other bisphosphonates may be more suitable) are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated.

There are reports of response[1-3] to etidronate 5 mg/kg twice daily by mouth in the treatment of hypercalcaemia associated with subcutaneous fat necrosis of the newborn refractory to standard treatment.

Malignant neoplasms of the bone. Bisphosphonates are of benefit in some patients with metastatic bone disease (p.660). Etidronate, labelled with rhenium-186 or its isotope rhenium-188, is used for the palliation of painful bone metastases of prostate,[1,2] breast,[3,4] lung,[4,5] and various other cancers.[4]

Osteoporosis. Bisphosphonates are used in the prevention and treatment of osteoporosis (p.1084). Etidronate is used in a cyclical regimen for both the treatment and prevention of **postmenopausal** osteoporosis. It increases bone mineral density (BMD), largely in the lumbar spine and femoral neck, and reduces the risk of vertebral fractures,[1,2] but not non-vertebral fractures.[2] Additive effects on BMD have been found when etidronate was used with oestrogen.[1] Etidronate also prevents bone loss and maintains or increases BMD in **corticosteroid-induced** osteoporosis,[1,3] and has shown some benefit in reducing bone loss after organ transplantation.[1] In an uncontrolled study[4] in **men** with idiopathic vertebral osteoporosis, cyclical etidronate increased BMD at the lumbar spine.

4. Anderson FH, *et al.* Effect of intermittent cyclical disodium etidronate therapy on bone mineral density in men with vertebral fractures. *Age Ageing* 1997; **26:** 359–65.

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. Initial experience was with etidronate, but bisphosphonates that have less effect on bone mineralisation may be preferred. In studies, alendronate[1] and risedronate[2] were found to be more effective than etidronate.

Gallium Nitrate *(USAN)*

Galio, nitrato de; NSC-15200; WR-135675.

$Ga(NO_3)_3,9H_2O = 417.9.$

CAS — 13494-90-1 (anhydrous gallium nitrate); 135886-70-3 (gallium nitrate nonahydrate).

Adverse Effects, Treatment, and Precautions

Gallium nitrate may produce serious nephrotoxicity, especially when given as a brief intravenous infusion; continuous infusion, with adequate hydration, may reduce the incidence of renal damage. Serum creatinine should be monitored during therapy and treatment stopped if it exceeds 25 mg/litre. Gallium nitrate should be given with great care and in reduced doses, if at all, to patients with existing renal impairment.

Gastrointestinal disturbances, rashes, metallic taste, visual and auditory disturbances, anaemia, hypophosphataemia, and hypocalcaemia have also been reported.

Effects on the nervous system. Although it has been suggested, given the chemical similarity of gallium to aluminium, that repeated doses, particularly in the presence of renal impairment, might lead to severe neurotoxicity,[1] studies in *rats* do not provide any evidence of central neurological abnormalities.[2]

1. Altmann P, Cunningham J. Hazards of gallium for the treatment of Paget's disease of bone. *Lancet* 1990; **335:** 477.
2. Matkovic V, *et al.* Hazards of gallium for Paget's disease of bone. *Lancet* 1990; **335:** 1099. Correction. *ibid.*; 1352.

Uses and Administration

Gallium nitrate is an inorganic metallic salt with hypocalcaemic properties. It acts to decrease bone resorption by osteoclasts, with a lesser and probably indirect increase in bone formation, and a consequent decline in serum calcium.

Gallium nitrate is used in the treatment of hypercalcaemia associated with malignant neoplasms. It has been investigated in other disorders associated with abnormally enhanced bone turnover, such as Paget's disease of bone, and is under investigation in refractory non-Hodgkin's lymphoma. For the treatment of hypercalcaemia of malignancy doses of 100 to 200 mg/m^2 may be given daily for up to 5 days, diluted in 1 litre of sodium chloride 0.9% or glucose 5% and infused intravenously over 24 hours. Treatment may be repeated after 2 to 4 weeks, if necessary. Adequate hydration before and during treatment is essential: a urinary output of at least 2 litres daily should be maintained, and renal function should be regularly monitored.

Hypercalcaemia. Gallium nitrate is used in the treatment of hypercalcaemia of malignancy (p.1083). It appears to be effective in patients with solid tumours and increased levels of parathyroid-related protein.[1,2]

1. Chitambar CR. Gallium nitrate revisited. *Semin Oncol* 2003; **30** (suppl): 1–4.
2. Leyland-Jones B. Treatment of cancer-related hypercalcemia: the role of gallium nitrate. *Semin Oncol* 2003; **30** (suppl); 13–19.

Paget's disease of bone. Beneficial results[1] were reported when gallium nitrate was given subcutaneously in doses of 250 or 500 micrograms/kg daily for 14 days to patients with advanced Paget's disease of bone (p.1086). In this pilot multicentre study 14 days of gallium nitrate injections were followed by 4 weeks off medication and the cycle repeated once.

ATC — M05BA06.
ATC Vet — QM05BA06.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. Gastrointestinal symptoms such as abdominal pain, dyspepsia, and nausea are the most frequent adverse effects with oral ibandronate. Severe oesophageal reactions such as oesophagitis, and ulceration have occurred; patients should be advised to stop taking the tablets and seek medical attention if they develop symptoms such as new or worsening dysphagia, pain on swallowing, retrosternal pain, or heartburn. Gastric ulceration has been reported. To minimise the risk of oesophageal reactions, precautions similar to those for alendronate (see p.1088) should be observed. Anaemia and bronchospasm have occurred rarely, as has taste disturbance, paraesthesia, and uraemia. Serum calcium, magnesium, and phosphate should be monitored. Hypocalcaemia should be corrected before starting ibandronate therapy; adequate intake of calcium and vitamin D is important. Transient fever after parenteral use is common. Flu-like symptoms have been reported after both parenteral and intermittent oral use, typically after the first dose.

Effects on the musculoskeletal system. Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including ibandronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

Interactions

As for the bisphosphonates in general, p.1091.

Pharmacokinetics

Like other bisphosphonates, ibandronate is poorly absorbed after oral doses; absolute bioavailability is less than 1%. Absorption is decreased by food, especially by products containing calcium or other polyvalent cations. Bioavailability is reduced by about 90% when given with food, by about 30% when given half an hour before food, and by about 75% when given

2 hours after food. About half of the absorbed portion is sequestered to bone; the remainder is excreted in urine. Plasma protein binding is about 87%. Bisphosphonates do not appear to be metabolised, and the unabsorbed fraction of ibandronate is excreted unchanged in the faeces.

◊ References.

1. Bergner R, *et al.* Renal safety and pharmacokinetics of ibandronate in multiple myeloma patients with or without impaired renal function. *J Clin Pharmacol* 2007; **47:** 942–50.

Uses and Administration

Ibandronate is an aminobisphosphonate (p.1089) that is a potent inhibitor of bone resorption. It is used as the sodium salt in hypercalcaemia of malignancy, for the prevention of fracture and bone complications in patients with breast cancer and bone metastases, and for the treatment and prevention of postmenopausal osteoporosis.

Ibandronate sodium is given by intravenous infusion or orally, the dose being expressed in terms of ibandronic acid; ibandronate sodium 1.13 mg is equivalent to about 1 mg of ibandronic acid. Specific instructions for oral use (see Precautions in Alendronate, p.1088) should be followed to minimise adverse effects and permit adequate absorption.

For **hypercalcaemia of malignancy**, a single intravenous dose of the equivalent of 2 to 4 mg ibandronic acid is given, up to a maximum of 6 mg; it is diluted in 500 mL of sodium chloride 0.9% or glucose 5%, and infused over 2 hours.

For the prevention of skeletal events in patients with breast cancer and **bone metastases**, the equivalent of 6 mg ibandronic acid is given intravenously, diluted in 100 mL of sodium chloride 0.9% or glucose 5%, and infused over at least 15 minutes. The dose is repeated every 3 to 4 weeks. Alternatively, ibandronic acid 50 mg daily may be given orally.

For the prevention and treatment of postmenopausal **osteoporosis**, ibandronate is given orally in a usual dose equivalent to 150 mg of ibandronic acid once monthly on the same date each month; alternatively, 2.5 mg daily by mouth may be given. If the once-monthly dose is missed, and the next scheduled dose is more than 7 days away, the dose should be taken the next morning, and the patient should then return to the original schedule. However, if the next dose is less than 7 days away, then the patient should wait until that next scheduled dose; 2 tablets must not be taken within the same week. Alternatively, treatment may be given intravenously, in a dose equivalent to 3 mg of ibandronic acid once every 3 months; the injection is given over 15 to 30 seconds. If the dose is missed, the injection should be given as soon as possible; the next injection should then be rescheduled 3 months from this injection, as it should not be given more frequently than once every 3 months.

Administration in renal impairment. UK and US licensed product information for ibandronate states that the dose should be adjusted on the basis of creatinine clearance (CC).

When used for the prevention of skeletal events in patients with breast cancer and **bone metastases**, the following *oral* doses are recommended:

- mild or moderate renal impairment (CC equal to or greater than 30 mL/minute): no adjustment necessary
- CC below 30 mL/minute: 50 mg once weekly

Since a 15-minute infusion time has not been studied in cancer patients with a CC less than 50 mL/minute, the following *intravenous* doses are recommended, to be given every 3 to 4 weeks in a solution of sodium chloride 0.9% or glucose 5%:

- CC equal to or greater than 50 mL/minute: no adjustment necessary
- CC less than 50 mL/minute, but equal to or greater than 30 mL/minute: 6 mg in 500 mL of infusion solution, infused over 1 hour
- CC less than 30 mL/minute: 2 mg in 500 mL of infusion solution, infused over 1 hour

In patients with **osteoporosis**, the following recommendations are given, for *oral* or *intravenous* use:

- mild or moderate renal impairment (CC equal to or greater than 30 mL/minute): no adjustment necessary
- CC below 30 mL/minute: not recommended

Hypercalcaemia. Bisphosphonates are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated. In a dose-response study,[1] 2 mg of ibandronate was found to be significantly less effective than 4 or 6 mg in correcting hypercalcaemia, and response was better in those patients with breast cancer or haematological tumours. In comparison to pamidronate,[2] ibandronate was reported to be more effective in those patients with higher initial baseline serum calcium; duration of response was also longer with ibandronate. In a series of case reports, intravenous ibandronate rapidly corrected hypercalcaemia and restored renal function in multiple myeloma patients. The authors suggested that, although unlicensed for this use, ibandronate should be considered in this patient population.[3]

Malignant neoplasms of the bone. Bisphosphonates are of benefit in some patients with metastatic bone disease (p.660) not only to manage bone pain and hypercalcaemia, but to reduce skeletal complications such as fractures. Ibandronate is licensed for such use in many countries. In patients with bone metastases from breast cancer, both oral[1] and intravenous[2] ibandronate reduced the skeletal morbidity period rate (the number of 12-week periods with new bone complications). A pilot study[3] in 18 patients with skeletal metastases from various tumours, and with bone pain insufficiently controlled with opioid analgesics, found short-term intensive intravenous ibandronate (4 mg for 4 consecutive days) to significantly reduce bone pain scores; this analgesic effect was obtained within 7 days, and sustained for a further 5 weeks. A review[4] concluded that once-monthly intravenous dosing could aid compliance, since it can be given simultaneously with cancer therapy; the absence of any apparent renal toxicity associated with ibandronate was a further advantage in its use in cancer patients.

Whether bisphosphonates can prevent the development of new skeletal metastases is unclear.

Osteoporosis. Bisphosphonates are used for the prevention and treatment of osteoporosis (p.1084). In the treatment of **postmenopausal** osteoporosis, *oral* ibandronate in intermittent regimens of 20 mg every alternate day,[1] or 20 mg weekly[2] has been found to have equivalent effects on bone mineral density (BMD) to 2.5 mg daily. Intermittent oral ibandronate (20 mg every alternate day for 12 doses every 3 months) was also as effective as the lower daily dose in reducing the incidence of osteoporotic fractures in postmenopausal women.[3] In the prevention of postmenopausal bone osteoporosis, both 2.5 mg daily[4] and 20 mg weekly[5] prevented bone loss at the spine and hip. A large study comparing three different monthly regimens with the 2.5 mg daily regimen found them to be of similar efficacy in terms of improvement in lumbar BMD after 1 year; 150 mg given once monthly was considered to be superior to the low-dose daily regimen.[6] A review[7] concluded that this unique once-monthly regime could benefit patients by improving compliance.

Intravenous ibandronate 2 mg given every 3 months has also proven effective in increasing BMD in the treatment[8] and prevention[9] of postmenopausal osteoporosis. A large, randomised, double-blind study compared 2 intravenous regimens (2 mg every 2 months and 3 mg every 3 months) with oral ibandronate 2.5 mg daily in postmenopausal women with osteoporosis. After 1 year, both intravenous regimens increased lumbar BMD scores significantly more than the oral regimen. Similar results were obtained for proximal femoral BMD scores, except that for femoral neck BMD, the 2-monthly regimen and daily oral regimen were not significantly different.[10] After 2 years, these results were reported to have been maintained.[11] In **corticosteroid-induced** osteoporosis, intravenous ibandronate 2 mg every 3 months was better than daily oral alfacalcidol at reducing vertebral fractures.[12,13] Intravenous ibandronate has also shown to be of benefit in reducing bone loss after kidney **transplantation**.[14] A pilot study[15] of intermittent ibandronate given intravenously to **men** with severe osteoporosis significantly increased BMD at the lumbar spine, trochanter, and femoral neck.

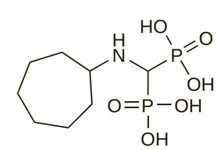
Incadronate

Incadronic Acid *(rINN)*

Acide Incadronique; Ácido incadrónico; Acidum Incadronicum; Cimadronic Acid; YM-175. [(Cycloheptylamino)methylene]diphosphonic acid.

Инкадроновая Кислота

$C_8H_{19}NO_6P_2$ = 287.2.
CAS — 124351-85-5.



Incadronate Disodium

Disodium Incadronate *(rINNM)*; Incadronas Dinatricum; Incadronate Disodique; Incadronato disódico. Disodium [(cycloheptylamino)methylene]diphosphonate.

Динатрий Инкадронат

$C_8H_{17}NNa_2O_6P_2$ = 331.2.
CAS — 138330-18-4.

Profile

Incadronate is an aminobisphosphonate (p.1089) that is a potent inhibitor of bone resorption. It is given by intravenous infusion as incadronate disodium for hypercalcaemia of malignancy in a dose of 10 mg over 2 to 4 hours; if necessary this dose may be repeated at intervals of no less than 1 week. Hypocalcaemia and hypotension may occur. Incadronate is under investigation for the treatment of bone metastases in patients with breast cancer.

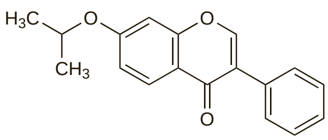
ATC Vet — QM05BX01.



Profile

Ipriflavone is a synthetic isoflavonoid that inhibits resorption of bone and is available in some countries for the treatment of osteoporosis (p.1084). It is given orally in a dose of 200 mg three times daily.

Osteoporosis. Despite an earlier favourable report,[1] a prospective randomised controlled study in postmenopausal women with low bone mass failed to show prevention of bone loss or improvements in markers of bone metabolism with ipriflavone.[2] There was also a significant incidence of lymphopenia with the drug.

Medronate Disodium *(USAN, pINNM)*

Disodium Medronate *(BANM)*; Disodium Methylene Diphosphonate; MDP; Medronas Dinatricum; Médronate Disodique; Medronato disódico. Disodium dihydrogen methylenediphosphonate.

Динатрий Медронат

$CH_4Na_2O_6P_2$ = 220.0.
CAS — 25681-89-4.

Profile

Medronate is a bisphosphonate with general properties similar to those of the other bisphosphonates (p.1089). It has a strong affinity for bone. Complexes of medronate disodium and stannous chloride or fluoride, or medronic acid, stannous chloride dihydrate, and ascorbic acid, are labelled with radioactive technetium-99m (p.2055) and used diagnostically as bone scanning agents; they are given intravenously.

Hypersensitivity. For reference to a severe allergic reaction attributed to the medronate component of a radiopharmaceutical, see under Adverse Effects and Precautions of Bisphosphonates, p.1091.

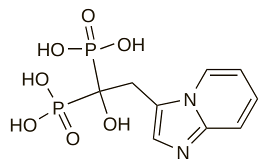
Minodronate

Minodronic Acid *(rINN)*

Acide Minodronique; Ácido minodrónico; Acidum minodronicum; YH-529; YM-529. (1-Hydroxy-2-imidazo[1,2-*a*]pyridin-3-ylethylidene)diphosphonic acid.

Минодроновая Кислота

$C_9H_{12}N_2O_7P_2$ = 322.1.
CAS — 127657-42-5.



Profile

Minodronate is a bisphosphonate under investigation for osteoporosis, multiple myeloma, and bone metastases.

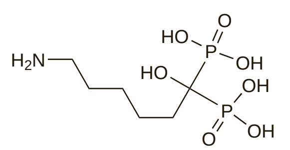
Neridronate

Neridronic Acid *(rINN)*

Acide Néridronique; Ácido neridrónico; Acidum neridronicum; AHDP; AHHexBP; Aminohexane Diphosphonate. (6-Amino-1-hydroxyhexylidene)diphosphonic acid.

Нéридроновая Кислота

$C_6H_{17}NO_7P_2$ = 277.1.
CAS — 79778-41-9.



Neridronate Sodium *(rINNM)*

Natrii Neridronas; Néridronate de Sodium; Neridronato sódico.

Натрий Неридронат

Profile

Neridronate is an aminobisphosphonate with similar properties to those of the bisphosphonates in general (p.1089). It inhibits bone resorption and is given intravenously as the sodium salt in the management of osteogenesis imperfecta (p.1083); it has been used in the treatment of malignant hypercalcaemia (p.1083) and diseases associated with excessive bone turnover such as Paget's disease of bone (p.1086) and osteoporosis (p.1084).

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Nerixia.

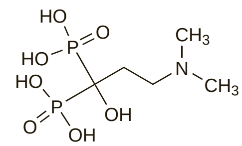
Olpadronate

Olpadronic Acid *(rINN)*

Acide Olpadronique; Ácido olpadrónico; Acidum olpadronicum; Alpudronic Acid. [3-(Dimethylamino)-1-hydroxypropylidene]diphosphonic acid.

Олпадроновая Кислота

$C_5H_{15}NO_7P_2$ = 263.1.
CAS — 63132-39-8.



Olpadronate Disodium

IG-8801; Sodium Olpadronate.

$C_5H_{13}NNa_2O_7P_2$ = 307.1.
CAS — 121368-58-9.

Profile

Olpadronate is an aminobisphosphonate with similar properties to those of the bisphosphonates in general (p.1089). It has been investigated for the treatment of Paget's disease of bone and osteogenesis imperfecta.

Pamidronate Disodium *(USAN, rINNM)*

Aminohydroxypropylidenebisphosphonate Disodium; CGP-23339A; CGP-23339AE; Dinatrii pamidronas pentahydricus; Dinatriumpamidronaattipentahydraatti; Dinatrium-pamidronát pentahydrát; Disodium Aminohydroxypropylidenediphosphonate; Disodium Pamidronate *(BANM)*; Disodu pamidronian pięciowodny; Disodyum Pamidronat; Pamidronaattidinatrium; Pamidronas Dinatricum; Pamidronatdinatrium; Pamidronatdinatriumpentahydrat; Pamidronate Disodique; Pamidronate disodique pentahydraté; Pamidronato disódico; Pamidronatum Dinatricum. Disodium 3-amino-1-hydroxypropylidenebisphosphonate pentahydrate.

Динатрий Памидронат

$C_3H_9NNa_2O_7P_2,5H_2O$ = 369.1.
CAS — 109552-15-0 (pamidronate disodium pentahydrate); 57248-88-1 (anhydrous pamidronate disodium).
ATC — M05BA03.
ATC Vet — QM05BA03.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Pamidronate Disodium Pentahydrate). A white or almost white, crystalline powder. Soluble in water; practically insoluble in dichloromethane. It is sparingly soluble in dilute mineral acids and dissolves in dilute alkaline solutions. A 1.0% solution in water has a pH of 7.8 to 8.8.

USP 31 (Pamidronate Disodium). A white crystalline powder. Soluble in water and in 2N sodium hydroxide; sparingly soluble 0.1N acetic acid and in 0.1N hydrochloric acid; practically insoluble in organic solvents. pH of a 1% solution in water is between 7.8 and 8.8. Store in airtight containers at a temperature not exceeding 30°.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089.

Fever and flu-like symptoms (sometimes accompanied by malaise, rigors, fatigue, and flushes) are common during intravenous infusion of pamidronate but generally resolve spontaneously. Pamidronate should not be given by bolus injection, as severe local reactions and thrombophlebitis have occurred. CNS effects include agitation, confusion, dizziness, lethargy, insomnia, and somnolence. There have been isolated cases of seizures, and visual hallucinations. In addition to hypocalcaemia and hypophosphataemia, which are common, hypomagnesaemia or hypokalaemia may occur, and rarely, hypernatraemia, or hyperkalaemia. Both hypotension and hypertension have been reported. Anaemia, thrombocytopenia, and lymphocytopenia may occur. Bronchospasm and interstitial pneumonitis have occurred rarely.

Pamidronate should be used with caution in those with cardiac disease, because of the potential for fluid overload, and in those who have had thyroid surgery, because of the increased risk of hypocalcaemia due to relative hypoparathyroidism. Serum electrolytes, calcium and phosphate should be monitored during therapy, along with renal function. Patients should be warned against driving or operating machinery after treatment if somnolence or dizziness occur.

Effects on the ears. Ototoxicity, manifest as tinnitus and sudden hearing loss, has been reported[1] in 2 patients given both intravenous and oral pamidronate for pre-existing otosclerosis.[1] A patient given 5 pamidronate infusions for Paget's disease developed tinnitus, vertigo, and hearing loss; the latter two symptoms resolved over 9 months, but tinnitus persisted.[2]

1. Boumans LJJM, Poublon RML. The detrimental effect of aminohydroxypropylidene bisphosphonate (APD) in otospongiosis. *Eur Arch Otorhinolaryngol* 1991; **248:** 218–21.
2. Reid IR, *et al.* Ototoxicity associated with intravenous bisphosphonate administration. *Calcif Tissue Int* 1995; **56:** 584–5.

Effect on electrolytes. Pamidronate has precipitated severe hypocalcaemia, resulting in tetany and paraesthesia, in 2 patients. In each case, other conditions interfered with the expected compensatory physiological response to the hypocalcaemia.[1]

1. Peter R, *et al.* Severe hypocalcaemia after being given intravenous bisphosphonate. *BMJ* 2004; **328:** 335–6.

Effects on the eyes. For reports of ocular effects with the bisphosphonates, including pamidronate, see under Bisphosphonates, p.1090.

Effects on the gastrointestinal tract. The tolerability of pamidronate given *orally* may depend to some extent on the particular formulation. Gastrointestinal disturbances (in 21.8%) and haematological abnormalities (in 9.4%) were the main adverse effects associated with oral pamidronate in an open study of elderly patients.[1] Oesophagitis, noted earlier[2] in 4 of 49 patients given a different formulation, was not reported in this study.[1]

1. Spivacow FR, *et al.* Tolerability of oral pamidronate in elderly patients with osteoporosis and other metabolic bone diseases. *Curr Ther Res* 1996; **57:** 123–30.
2. Lufkin EG, *et al.* Pamidronate: an unrecognised problem in gastrointestinal tolerability. *Osteoporosis Int* 1994; **4:** 320–2.

Effects on the kidneys. Like other bisphosphonates (see p.1091), pamidronate may cause adverse renal effects. UK licensed product information notes that there have been isolated cases of haematuria, acute renal failure, and deterioration of pre-existing renal disease. Renal function should be monitored during long-term pamidronate therapy, especially in patients with pre-existing renal disease or a predisposition to renal impairment. Longer infusion times may reduce the risk of renal toxicity, and various infusion rates have been recommended, see Uses and Administration, below.

Effects on mental state. Palpitations, followed by visual hallucinations, suicidal ideation, and clinical depression were reported in an elderly man after a single infusion of pamidronate for Paget's disease; he had no previous psychiatric history. Treatment with thioridazine reduced the frequency and effect of the hallucinations.[1]

1. Foley-Nolan D, *et al.* Pamidronate associated hallucinations. *Ann Rheum Dis* 1992; **51:** 927–8.

Effects on the musculoskeletal system. Although pamidronate appears to be a less potent inhibitor of bone mineralisation than etidronate, mineralisation defects have been reported in patients with Paget's disease of bone receiving pamidronate.[1] The resultant osteomalacia was not associated with any adverse clinical effects. Pamidronate-induced osteopetrosis has also been reported.[2] Acute pseudogout arthritis in a woman treated with pamidronate for acute hypercalcaemia was possibly due to deposition of calcium in the joints.[3] Severe bone pain occurred in more patients than expected when pamidronate was used for treatment of low bone density in cystic fibrosis;[4] an increase in proinflammatory cytokines was postulated as a mechanism for this effect.[5]

Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including pamidronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

5. Teramoto S, *et al.* Increased cytokines and pamidronate-induced bone pain in adults with cystic fibrosis. *Lancet* 1999; **353:** 750.

Hypersensitivity. Allergic reactions to bisphosphonates are rare. Rash and pruritus occasionally follow pamidronate infusion. Mild skin rashes have also been reported in some patients taking oral pamidronate (see also under Bisphosphonates, p.1091).

Pregnancy. Bisphosphonates cross the placenta in animals and humans. These drugs also persist in mineralised bone for many years. Thus, in theory, even if use were to be avoided during pregnancy, the fetus might still be exposed to bisphosphonates from prior therapy released from the maternal skeleton. Furthermore, suppressed bone turnover caused by residual bisphosphonate might cause maternal complications during pregnancy.[1] However, no adverse effects were seen during pregnancy in 2 women with osteogenesis imperfecta given intravenous pamidronate before conception. One infant had transient asymptomatic hypocalcaemia, and one had bilateral talipes equinovarus (a congenital deformity in which the foot turns downwards and inwards). No other skeletal abnormalities were noted. The authors advised monitoring of neonatal calcium concentrations in infants born to mothers treated with pamidronate.[1] In another report of 3 women given long-term pamidronate before conception, 4 healthy infants were born with no evidence of biochemical or skeletal abnormalities.[2]

Interactions

As for the bisphosphonates in general, p.1091.

Pharmacokinetics

Plasma concentrations of pamidronate rise rapidly after the start of an intravenous infusion; the apparent plasma half-life is 0.8 hours. Plasma protein binding is about 54%. Pamidronate is not metabolised, and about 20 to 55% of the dose is excreted in the urine unchanged within 72 hours; the remainder is mainly sequestered to bone and only very slowly eliminated. Renal clearance is slower in patients with severe renal impairment and infusion rates may need to be reduced (see below).

Like all bisphosphonates, oral pamidronate is poorly absorbed from the gastrointestinal tract; bioavailability is about 1 to 3%.

Uses and Administration

Pamidronate is an aminobisphosphonate with general properties similar to those of the other bisphosphonates (p.1091). It inhibits bone resorption, but appears to have less effect on bone mineralisation than etidronate at comparable doses.

Pamidronate is used as an adjunct in the treatment of severe hypercalcaemia, especially when associated with malignancy. It is also used in the treatment of osteolytic lesions and bone pain in multiple myeloma or bone metastases associated with breast cancer. It may also be of benefit in bone disorders associated with excessive bone resorption, including Paget's disease of bone.

Pamidronate disodium is given by slow intravenous infusion. UK licensed product information recommends infusion at a rate not exceeding 60 mg/hour (or not exceeding 20 mg/hour in patients with established or suspected renal impairment) and at a concentration not exceeding 60 mg per 250 mL of infusion solution (sodium chloride 0.9% or glucose 5%). In the USA, the recommended concentration of infusion and rate vary depending on the indication.

In **hypercalcaemia of malignancy** pamidronate disodium is given by slow intravenous infusion in a total dose of 15 to 90 mg according to the initial plasma-calcium concentration. In the UK, the total dose is given as a single infusion or in divided doses over 2 to 4 days. In the USA, the total dose is given as a single infusion, doses of 60 mg to 90 mg being given over 2 to 24 hours. Plasma-calcium concentrations generally start declining 24 to 48 hours after a dose of pamidronate with normalisation within 3 to 7 days. Treatment may be repeated if normocalcaemia is not achieved within this time or if hypercalcaemia recurs.

In patients with **osteolytic lesions and bone pain** of multiple myeloma or bone metastases associated with breast cancer, pamidronate disodium may be given in doses of 90 mg by intravenous infusion every 3 to 4 weeks.

In the treatment of **Paget's disease** the dosage regimen in the UK is 30 mg by slow infusion once a week for 6 weeks (total dose 180 mg), or 30 mg in the first week then 60 mg every other week for 6 weeks (total dose 210 mg). These courses may be repeated every 6 months, and the total dose increased if necessary up to

The symbol † denotes a preparation no longer actively marketed

a maximum of 360 mg. Alternatively, the dose used in the USA is 30 mg by infusion over 4 hours, repeated on consecutive days to a total dose of 90 mg. This course is repeated when clinically indicated.

Pamidronate has also been given orally.

Administration in renal impairment. Pharmacokinetic studies suggest that no dosage reduction of pamidronate disodium is required in patients with any degree of renal impairment.[1] However, UK product information currently recommends that the rate of infusion be reduced to a maximum of 20 mg/hour for patients with established or suspected renal impairment; use in those with severe renal impairment (creatinine clearance less than 30 mL/minute) is not advised as clinical experience is limited.

1. Berenson JR, *et al.* Pharmacokinetics of pamidronate disodium in patients with cancer with normal or impaired renal function. *J Clin Pharmacol* 1997; **37:** 285–90.

Complex regional pain syndrome. Osteoporosis is one of the features of complex regional pain syndrome (p.6). Bisphosphonates may be of benefit in controlling associated pain in some patients. In small studies, intravenous pamidronate 30 mg daily for 3 days, or at 1 mg/kg daily for 1 or 3 days,[1] or 60 mg daily for 3 days,[2] significantly improved pain and range of movement in cases refractory to previous treatment.

Hypercalcaemia. Bisphosphonates, of which pamidronate is one of the most effective, are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated.

Malignant neoplasms of the bone. Bisphosphonates are of benefit in some patients with metastatic bone disease (p.660) not only to manage bone pain and hypercalcaemia, but to reduce skeletal complications such as fractures. Pamidronate is licensed for such use in many countries. A literature review[1] of phase II and III studies concluded that pamidronate was effective in the treatment of pain and skeletal complications from metastatic disease, particularly in patients with breast cancer or multiple myeloma, but that its efficacy in those with other neoplasms needed confirmation. A long-term follow-up[2] of 2 randomised trials of pamidronate in women with breast cancer confirmed its efficacy over placebo. However, a pooled analysis[3] of its use for palliation of bone pain in men with metastatic prostate cancer found no treatment benefit with pamidronate over placebo. Whether bisphosphonates can prevent the development of new skeletal metastases is unclear.

Osteogenesis imperfecta. Pamidronate has produced benefit in patients with osteogenesis imperfecta (p.1083). Although the dosage and timing varied between centres and age groups, all patients were given cyclical intravenous pamidronate;[1-5] bone mineral density increased, fracture incidence decreased, and patients reported improvements in mobility, pain and chronic fatigue. Treated infants achieved motor milestones earlier than untreated controls; vertebral height was also improved.[5] While bone size and density also increased in patients given pamidronate, especially in those with larger baseline deficits in bone mass,[6] serum calcium decreased markedly, and bone turnover was suppressed;[7] clinical problems were not evident if calcium intake was sufficient, but consequences of a chronically low bone turnover are unknown. A study in young patients found that bone metabolism is still suppressed, and that bone mass gains continue, for 2 years after stopping therapy.[8]

Osteoporosis. Bisphosphonates are used in the prevention and treatment of osteoporosis (p.1084). A placebo-controlled trial of oral pamidronate 150 mg daily found it to be effective in increasing bone mineral density (BMD) of the lumbar spine and femoral neck in both **men** and **women**.[1] Intravenous pamidronate at 30 mg every 3 months, or 60 mg every 6 months, also increased BMD in the lumbar spine, femoral neck, and trochanter in an observational, retrospective study.[2] Single intravenous infusions of pamidronate given every 3 months have also been reported to increase BMD and reduce fracture rates in **children** with osteoporosis;[3,4] annual doses were in the region of 4 mg/kg.

An open study[5] in men with prostate cancer (but no bone metastases) and receiving leuprolide, found that addition of pamidronate 60 mg intravenously every 12 weeks prevented **therapy-induced** bone loss in the hip and lumbar spine. Acute bone loss from the femur and pelvis after hip arthroplasty was also reduced by a single infusion of 90 mg pamidronate in a small prospective study.[6] Similarly, in premenopausal women with chemotherapy-induced bone loss, pamidronate 60 mg intravenously every 3 months prevented bone loss at the spine and hip compared with placebo.[7]

In a small study[8] of patients receiving **corticosteroids**, pamidronate given intravenously either as a single infusion of 90 mg, or as 90 mg followed by 30 mg every 3 months for 1 year, significantly increased BMD at the lumbar spine, femoral neck, and total hip. In lymphoma patients receiving corticosteroids as part of chemotherapy regimens, pamidronate 30 mg intravenously every 3 months reduced bone loss when compared with placebo.[9] Pamidronate has shown beneficial increases in or preservation of BMD in patients after heart,[10,11] liver,[11] lung,[12] or stem cell[13] transplantation.

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. Pamidronate was initially used orally for Paget's disease, but intravenous therapy has been preferred because of a lower incidence of adverse effects.[1,2] With the usual total dose of 180 mg, remission is considered likely in most patients with mild to moderate disease, but unlikely if disease is severe.[2] However, higher doses (about 340 mg) were found to be effective in those with very active disease, and also associated with a longer remission.[1] In a 2-year study[3] of 3 different doses, pamidronate increased bone mineral density in pagetic bone of the lumbar spine, femoral neck, and total hip, but lacked this effect on non-pagetic bone in the same areas; loss of density was apparent in non-pagetic forearm bone in the group given the highest dose (240 mg). Patients with co-existent osteoarthritis or arthropathy responded less well to pamidronate in terms of pain perception, than those patients without joint disease.[4] While hearing loss may or may not improve with pamidronate,[5,6] there has been a report of successful treatment of optic neuropathy due to Paget's disease with pamidronate and dexamethasone.[7] Bisphosphonates have also been given in other bone diseases with a similar pathology, particularly increased osteoclastic resorption. For example, pamidronate has had beneficial effects in patients with fibrous dysplasia of bone, a rare congenital disease leading to osteolytic lesions.[8-10]

Rheumatoid arthritis and spondyloarthropathies. Intravenous[1] and oral[2] use of pamidronate has reportedly produced some modification of disease in a few patients with rheumatoid arthritis (p.11). Continuous oral pamidronate therapy was shown to be effective in preserving and increasing bone mass in a 3-year randomised controlled trial involving 105 patients with rheumatoid arthritis.[3] In contrast, a small controlled study[4] in 26 patients found no significant effect on rheumatoid arthritis disease activity with intravenous pamidronate. There are reports of an analgesic response to pamidronate in patients with acute rheumatic pain of various aetiologies, including arthritis and ankylosing spondylitis, and a trial[5] in patients with ankylosing spondylitis found a dose-dependent therapeutic effect with pamidronate.[6] Use of intravenous pamidronate and methylprednisolone has also been investigated as part of the management of patients with NSAID-unresponsive ankylosing spondylitis.[7]

Parathyroid Hormone *(BAN, USAN, rINN)*

1-84 Parathormone; ALX1-11 (human recombinant parathyroid hormone); Hormona paratiroidea; Hormone Parathyroïde; Hormonum Parathyroidum; Parathormone; Parathyrin; Parathyroid hormone (1-84); PTH; PTH (1-84).

Паратироид Гормон

CAS — 9002-64-6; 68893-82-3 (human parathyroid hormone); 345663-45-8 (human recombinant parathyroid hormone).
ATC — H05AA03.
ATC Vet — QH05AA03.

Adverse Effects, Treatment, and Precautions

Transient hypercalcaemia and hypercalciuria are very common with parathyroid hormone treatment; persistent hypercalcaemia may necessitate dose reduction or withdrawal of therapy (see Uses and Administration, below). Patients should be monitored at months 1, 3, and 6 for elevated concentrations of serum or urinary calcium; monitoring beyond 6 months is not considered necessary for those whose serum calcium is within normal limits at 6 months. On injection, serum calcium concentrations reach a maximum after 6 to 8 hours, returning to baseline after 20 to 24 hours; blood samples for monitoring should thus be taken at least 20 hours after the most recent dose. Gastrointestinal disturbances, especially nausea, also occur commonly, as do headache, dizziness, fatigue, palpitations, muscle cramps, extremity or back pain, and injection site erythema. Hyperuricaemia has also been reported.

Pharmacokinetics

Subcutaneous parathyroid hormone produces peak plasma concentrations 1 to 2 hours after injection. The average half-life is about 1.5 hours and the absolute bioavailability is about 55%. Parathyroid hormone is removed from the blood by a receptor-mediated process in the liver and broken down into smaller peptide fragments, which either undergo further degradation within the cell or are released back into the blood and renally cleared.

Uses and Administration

Parathyroid hormone is a single-chain polypeptide isolated from the parathyroid glands. It contains 84 amino acids and in man the first (N-terminal) 34 appear to be responsible for the hormonal activity. The amino-acid sequence varies according to the source.

Endogenous parathyroid hormone is involved in the maintenance of plasma-calcium concentrations through its actions on bone, kidney, and indirectly on the gastrointestinal tract (see also under Parathyroid Disorders, p.1087).

Exogenous parathyroid hormone was formerly used in acute hypoparathyroidism with tetany. It has also been used in the differential diagnosis of hypoparathyroidism and pseudohypoparathyroidism. A human recombinant form is under investigation for the treatment of hypoparathyroidism.

The human recombinant form is used for the treatment of osteoporosis in postmenopausal women at high risk of fractures. The recommended dose is 100 micrograms once daily, given by subcutaneous injection into the abdomen; treatment may be continued for up to 24 months. Supplemental calcium and vitamin D may be needed if dietary intake is inadequate. However, if serum calcium becomes persistently raised, and there is no underlying disease, calcium and vitamin D should be withdrawn, and parathyroid hormone dosing changed to 100 micrograms on every other day. If elevated concentrations persist, parathyroid hormone therapy should be stopped until values return to normal.

Synthetic preparations of the first 34 amino acids of human and bovine parathyroid hormones are now used for diagnostic purposes, and for the treatment of osteoporosis (see Teriparatide, p.1105).

Administration in renal or hepatic impairment. UK licensed product information states that no dose adjustment is necessary for parathyroid hormone when it is used in patients with mild to moderate renal or hepatic impairment, defined as those with a creatinine clearance of 30 to 80 mL/minute, and a total score of 7 to 9 on the Child-Pugh scale, respectively. Use in severe renal or hepatic impairment is not recommended due to lack of data.

Plicamycin *(BAN, USAN, rINN)*

A-2371; Aureolic Acid; Mithramycin; Mithramycinum; Mitramycin; Mitramysiini; NSC-24559; PA-144; Plicamicina; Plicamycine; Plicamycinum.

Пликамицин

$C_{52}H_{76}O_{24}$ = 1085.1.
CAS — 18378-89-7.
ATC — L01DC02.
ATC Vet — QL01DC02.

Description. Plicamycin is an antineoplastic antibiotic produced by the growth of *Streptomyces argillaceus*, *S. plicatus* and *S. tanashiensis.*

Pharmacopoeias. In *US.*

USP 31 (Plicamycin). A yellow, odourless, hygroscopic, crystalline powder, with a potency of not less than 900 micrograms/mg, calculated on the dry basis. It loses not more than 8% of its weight when dried. Slightly soluble in water and in methyl alcohol; very slightly soluble in alcohol; freely soluble in ethyl acetate. A 0.05% solution in water has a pH of 4.5 to 5.5. Store at 2° to 8° in airtight containers. Protect from light.

Profile

Plicamycin is a highly toxic antibiotic with antineoplastic and hypocalcaemic properties. It may act by complexing with DNA in the presence of divalent cations and inhibiting synthesis of ribonucleic acid. Lowering of serum calcium concentrations has been suggested to result from antagonism of the effects of vitamin D and parathyroid hormone on osteoclasts.

Plicamycin has been used in the symptomatic management of hypercalcaemia and hypercalciuria associated with malignancy if it cannot be managed by other means (see below). It has also been used in the treatment of malignant neoplasms of the testis not susceptible to surgery or radiotherapy; however, other agents are preferred (p.673).

The major adverse effect of plicamycin is a dose-related bleeding syndrome, manifest initially as epistaxis, which may progress to haematemesis and potentially fatal haemorrhage. Severe thrombocytopenia may also occur due to bone-marrow depression. Gastrointestinal effects are common and other adverse effects include fever, malaise, drowsiness, lethargy and weakness, headache, depression, skin rashes, facial flushing, and reduced serum concentrations of calcium, phosphorus, and potassium. There may also be reversible impairment of renal and hepatic function.

Extravasation of plicamycin solutions may cause local irritation, cellulitis, and phlebitis.

Hypercalcaemia. Where treatment is required for hypercalcaemia it is aimed at increasing urinary excretion of calcium and maintaining adequate hydration. Drugs that inhibit bone resorption may also be used if hypercalcaemia is severe, particularly when it is associated with malignancy (see p.1083). Plicamycin is highly toxic, and the bisphosphonates and calcitonins are generally preferred; however, it has been given in a dose of 25 micrograms/kg intravenously over 4 to 6 hours.[1,2] Although a single dose might be sufficient to normalise the serum calcium concentration, the dose can be repeated several times at intervals of 24 to 72 hours.

2. Hall TG, Schaiff RAB. Update on the medical treatment of hypercalcemia of malignancy. *Clin Pharm* 1993; **12:** 117–25.

Paget's disease of bone. Plicamycin has been used as a second- or third-line drug in the therapy of Paget's disease of bone (p.1086), reserved for patients refractory to other treatment. Nonetheless, occasional successes are reported: one patient with refractory Paget's disease had apparent cure of her symptoms after treatment with plicamycin 25 micrograms/kg daily for 15 doses, followed by 1500 micrograms weekly for about 2 months and every 2 weeks for 6 weeks.[1] She had remained asymptomatic for 18 years after treatment. However, similar regimens have been used in other patients without this degree of success.[1] Another patient, who was refractory to calcitonin and pamidronate therapy, showed a considerable improvement in pain relief and biochemical parameters when treated with 30 micrograms/kg plicamycin daily for 3 days.[2]

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. The most frequent adverse effects during risedronate therapy are arthralgia and gastrointestinal disturbances. To minimise the risk of gastrointestinal effects precautions similar to those for alendronate should be observed (see p.1088), although UK licensed product information allows for the tablets to be taken other than on rising (but not at bedtime or within 2 hours of food or drink). Hypocalcaemia should be corrected before beginning risedronate therapy.

Effects on the eyes. For reports of ocular effects with the bisphosphonates, including risedronate, see under Bisphosphonates, p.1090.

Effects on the gastrointestinal tract. Although, like other oral bisphosphonates, it is recommended that risedronate be taken with care (see above) to avoid gastrointestinal effects, pooled analysis of 9 studies involving 10 068 patients receiving risedronate 5 mg daily indicated that the drug was not associated with an increased frequency of upper gastrointestinal effects, even among patients at increased risk due to active gastrointestinal disease or treatment with aspirin or NSAIDs as well.[1] However, it was noted that comprehensive postmarketing data would be required to see how these results would be reflected in clinical practice. Studies in women previously intolerant to alendronate found that risedronate 5 mg daily[2] and 30 mg once weekly[3] were well tolerated.

In 2 large trials, male and female patients with mild to moderate osteoarthritis of the knee were given risedronate 5 mg once daily, 15 mg once daily, 35 mg once weekly, 50 mg once weekly, or placebo. Patients were allowed continued use of aspirin or NSAIDs. Again, pooled analysis found no increased frequency of upper gastrointestinal adverse events in those given risedronate, even in those patients considered at increased risk for such events.[4]

1. Taggart H, *et al.* Upper gastrointestinal tract safety of risedronate: a pooled analysis of 9 clinical trials. *Mayo Clin Proc* 2002; **77:** 262–70. Correction. *ibid.*; 601.
2. Adachi JD, *et al.* Tolerability of risedronate in postmenopausal women intolerant of alendronate. *Aging (Milano)* 2001; **13:** 347–54.
3. Delaney MF, *et al.* Bone density changes with once weekly risedronate in postmenopausal women. *J Clin Densitom* 2003; **6:** 45–50.
4. Adami S, *et al.* Upper gastrointestinal tract safety of daily oral risedronate in patients taking NSAIDs: a randomized, double-blind, placebo-controlled trial. *Mayo Clin Proc* 2005; **80:** 1278–85.

Effects on the musculoskeletal system. From the initial marketing of risedronate until June 2003, the FDA had received 6 reports of severe bone, joint, or muscle pain. It was suggested that pain might tend to be under-reported since it is subjective, and might be attributed to underlying osteoporosis.[1]

Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including risedronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

1. Wysowski DK, Chang JT. Alendronate and risedronate: reports of severe bone, joint, and muscle pain. *Arch Intern Med* 2005; **165:** 346–7.

Effects on the respiratory system. For a report of bronchiolitis obliterans organising pneumonia induced by risedronate, see p.1091.

Hypersensitivity. Allergic reactions to bisphosphonates are rare, see p.1091. Angioedema, generalised rashes, and bullous skin reactions, some severe, have been reported with risedronate.

Interactions

As for the bisphosphonates in general, p.1091.

Pharmacokinetics

Like other bisphosphonates, risedronate is poorly absorbed orally. Absorption is reduced by food, especially by products containing calcium or other polyvalent cations. The mean bioavailability is 0.63% in the fasting state, and is reduced by 30% when given 1 hour before breakfast, and by 55% when given half an hour before breakfast. Plasma protein binding is about 24%. Risedronate is not metabolised. About half of the absorbed portion is excreted in the urine within 24 hours; the remainder is sequestered to bone for a prolonged period. Unabsorbed drug is eliminated unchanged in the faeces.

Absorption. Absorption of a single dose of risedronate was comparable when given 0.5 to 1 hour before breakfast or 2 hours after an evening meal in a study in healthy subjects.[1] The pharmacokinetics of risedronate are dose-proportional after a single oral dose.[2]

1. Mitchell DY, *et al.* The effect of dosing regimen on the pharmacokinetics of risedronate. *Br J Clin Pharmacol* 1999; **48:** 536–42.
2. Mitchell DY, *et al.* Dose-proportional pharmacokinetics of risedronate on single-dose oral administration to healthy volunteers. *J Clin Pharmacol* 2000; **40:** 258–65.

Uses and Administration

Risedronate is an aminobisphosphonate with similar properties to those of the bisphosphonates in general (p.1091). It inhibits bone resorption and is used either alone or with calcium, or with calcium and vitamin D for the prevention and treatment of postmenopausal osteoporosis. It is also used for the treatment of osteoporosis in men. Risedronate is also used for prevention and treatment of corticosteroid-induced osteoporosis, and for the treatment of Paget's disease of bone.

Risedronate is given orally as the sodium salt. The specific instructions given in Adverse Effects and Precautions, above should be followed to minimise gastrointestinal adverse effects and permit adequate absorption. The recommended dosage for **Paget's disease** of bone is 30 mg of risedronate sodium once daily for 2 months. Treatment may be repeated once if necessary after an interval of a further 2 months. The recommended dosage for the treatment or prevention of postmenopausal or corticosteroid-induced **osteoporosis** is 5 mg daily. Alternatively, for postmenopausal osteoporosis, 35 mg may be taken once weekly, 75 mg may be taken on 2 consecutive days of each month, or 150 mg may be taken once a month. For men with osteoporosis, the recommended dose is 35 mg once weekly.

4. White NJ, Perry CM. Risedronate once a week. *Treat Endocrinol* 2003; **2:** 415–20.

Administration. A procedure for the extemporaneous preparation of an oral solution from risedronate tablets has been proposed,[1] for use in patients who cannot swallow whole tablets or require feeding tubes.

1. Dansereau RJ, Crail DJ. Extemporaneous procedures for dissolving risedronate tablets for oral administration and for feeding tubes. *Ann Pharmacother* 2005; **39:** 63–7.

Administration in renal impairment. Renal clearance of risedronate significantly correlated to renal function in a pharmacokinetic study,[1] although the authors concluded that generally no dosage adjustment appears necessary for patients with mild to moderate renal impairment (creatinine clearance (CC) greater than 20 mL/minute). Licensed product information states that no dosage adjustment is necessary when CC is greater than 30 mL/minute; however, use of risedronate is contra-indicated in patients with severe renal impairment (CC less than 30 mL/minute), due to a lack of clinical data.

1. Mitchell DY, *et al.* Effect of renal function on risedronate pharmacokinetics after a single oral dose. *Br J Clin Pharmacol* 2000; **49:** 215–22.

Osteoporosis. Bisphosphonates are used for the prevention and treatment of osteoporosis (p.1084). Risedronate improves bone mineral density (BMD) and reduces the risk of both vertebral and non-vertebral fractures in **postmenopausal** osteoporosis;[1-4] effects are maintained for at least 5 years.[5] In **corticosteroid-induced** osteoporosis, risedronate increases BMD at the lumbar spine, femoral neck, and trochanter.[3,6] Risedronate is also used to treat **men** with osteoporosis. In a controlled study in elderly men after a stroke, those given risedronate had increased BMD and a decreased risk of hip fracture.[7] In a prospective controlled study, 12 months of daily risedronate significantly increased BMD at the lumbar spine, femoral neck, and hip, and significantly reduced the incidence of new vertebral fractures in men with primary or secondary osteoporosis.[8]

A once-monthly regimen of risedronate was found to be similar in efficacy and safety to the once-daily regimen.[9]

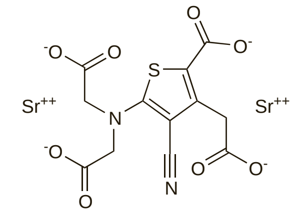
Strontium Ranelate *(rINNM)*

FK-481; Ranelate de Strontium; Ranelato de estroncio; S-12911; Strontii Ranelas. 2-(2-Carboxy-4-cyano-5-[*N*,*N*-di(carboxymethyl)amino]thiophen-3-yl) acetic acid distrontium salt.

Стронций Ранелат

$C_{12}H_6N_2O_8SSr_2$ = 513.5.
CAS — 135459-87-9.
ATC — M05BX03.
ATC Vet — QM05BX03.



Adverse Effects and Precautions

Common adverse effects of strontium ranelate include gastrointestinal disturbances, headache, dermatitis, and eczema. Disturbances in consciousness, memory loss, and seizures may occur. Treatment with strontium ranelate has been associated with an increased incidence in venous thromboembolism including pulmonary embolism, and should be given with caution to those patients considered at risk or with a history of thromboembolic disorders. Transient reversible increases in creatine kinase activity have been reported. Hypersensitivity reactions, including rash, pruritus, urticaria, angioedema, and Stevens-Johnson syndrome have occurred. Drug rash with eosinophilia and systemic symptoms (DRESS), sometimes fatal, has also been reported. Strontium may interfere with certain methods used for the determination of serum and urinary calcium.

Strontium ranelate should not be given with food or antacids—see Interactions, below.

Hypersensitivity. As of November 2007, the EMEA had received reports of 16 cases of drug rash with eosinophilia and systemic symptoms (DRESS), a serious and life-threatening condition, in patients treated with strontium ranelate. Two fatalities were reported. Reactions appeared within 3 to 6 weeks of starting therapy, with skin rash, accompanied by fever, swollen glands, eosinophilia, and effects on the liver, kidneys, and lungs. Patients are advised to stop treatment with strontium ranelate if a rash occurs and to seek medical advice; treatment should not be restarted.[1] Similar advice, and a reminder that the drug should also be used with caution in patients with risk factors for venous thromboembolism, was issued in June 2008 by the Australian regulatory authorities; although there had been no fatalities, they had seen 16 reports of rash, one accompanied by fever and one by eosinophilia.[2]

1. EMEA. EMEA recommends changes in the product information for Protelos/Osseor due to the risk of severe hypersensitivity reactions (issued 16th November 2007). Available at: http://www.emea.europa.eu/humandocs/PDFs/EPAR/protelos/PressRelease_Protelos_41745807en.pdf (accessed 21/01/08)
2. Adverse Drug Reactions Advisory Committee (ADRAC). Severe skin reactions and venous thromboembolism with strontium ranelate (Protos). *Aust Adverse Drug React Bull* 2008; **27:** 10. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0806.pdf (accessed 17/07/08)

Interactions

Food, milk, and calcium-containing compounds may reduce the bioavailability of strontium ranelate; antacids containing aluminium or magnesium may reduce its absorption. Such products should be given at least 2 hours apart from, and, in the case of antacids, preferably after, strontium ranelate. Because of possible complex formation, strontium ranelate should not be given with oral tetracyclines or quinolones.

Pharmacokinetics

Strontium ranelate has an absolute bioavailability of about 25% after an oral dose; calcium or food reduces the bioavailability by about 60 to 70%. Peak plasma concentrations are achieved 3 to 5 hours after an oral dose. Plasma protein binding is low. Strontium ranelate has a high affinity for bone tissue. It is not metabolised, and has a half-life of about 60 hours. Excretion occurs via the kidneys and gastrointestinal tract.

Uses and Administration

Strontium ranelate is claimed to stimulate bone formation as well as reduce bone resorption. It is given orally in the treatment of postmenopausal osteoporosis to reduce the risk of vertebral and hip fractures. The recommended dose is 2 g daily by mouth, given preferably at night and at least 2 hours after food.

Administration in renal impairment. Strontium excretion occurs via the kidneys and clearance decreases as creatinine clearance (CC) decreases. UK licensed product information states that no dosage adjustment of strontium ranelate is required in patients with mild to moderate renal impairment (CC 30 to 70 mL/minute). However, it is not recommended for those with severe renal impairment (CC below 30 mL/minute) because of a lack of pharmacokinetic data in these patients; continuation of treatment in patients developing severe renal impairment should be considered on an individual basis.

Osteoporosis. Strontium ranelate, given orally with calcium and vitamin D supplements, has been found to reduce the risk of vertebral[1] and non-vertebral[2] fractures in postmenopausal women with osteoporosis. A pooled analysis of data from these 2 studies concluded that strontium ranelate reduced both vertebral and non-vertebral fractures in patients aged 80 years or older.[3] Protection against fractures was detected within 12 months, and sustained throughout 3 years of treatment. Hip fractures were also reduced over 3 years, but this did not reach statistical significance; the authors concluded that the analysis may not have been sufficiently powered in this respect. A systematic review[4] concluded that while strontium ranelate reduces vertebral fractures, there is less of a reduction with non-vertebral fractures, and the effect on hip fracture remains unclear. Some have cautioned about the interpretation of bone mineral density (BMD) changes with strontium ranelate, since stronger X-ray attenuation by strontium compared with calcium must be corrected for to avoid overestimating the effect. However, increases in BMD could be useful clinically in gauging long-term compliance.[5]

A review[6] of the place of strontium ranelate in therapy considered that although it might be an alternative in patients who could not tolerate a bisphosphonate there was no convincing published evidence to support claims that it stimulated bone formation as well as reducing resorption. Further reviews[4,7] concluded that additional research to confirm its mechanism of action is required and that long-term fracture data are needed, along with comparative trials evaluating the efficacy of strontium ranelate relative to other therapies such as bisphosphonates.

Teriparatide *(USAN, rINN)*

(1-34) Human parathormone; (1-34) Human parathyroid hormone; 1-34 Parathormone (human); hPTH 1-34; Human parathormone (1-34); Human parathyroid hormone (1-34); Human PTH (1-34); LY-333334; Parathyroid hormone peptide (1-34); Teriparatid; Teriparatida; Tériparatide; Teriparatidum.

Терипаратид

$C_{181}H_{291}N_{55}O_{51}S_2$.
CAS — 52232-67-4.
ATC — H05AA02.
ATC Vet — QH05AA02.

Teriparatide Acetate *(USAN, rINNM)*

Acetato de teriparatida; Tériparatide, Acétate de; Teriparatidi Acetas.

Терипаратида Ацетат

$C_{181}H_{291}N_{55}O_{51}S_2,xH_2O,yC_2H_4O_2$.
CAS — 99294-94-7 (teriparatide acetate).
ATC — H05AA02.
ATC Vet — QH05AA02.

Adverse Effects and Precautions

Gastrointestinal disturbances, pain in the limb of injection, headache, and dizziness are the most common adverse effects in patients treated with subcutaneous teriparatide. Dizziness, vertigo, and syncope may be associated with transient orthostatic hypotension in some patients, particularly when beginning treatment. Those so affected should not drive or operate potentially hazardous machinery. Asthenia, arthralgia, and rhinitis may occur. Angina pectoris, depression, dyspnoea, leg cramps, pneumonia, urinary disorders, and sciatica have also been reported. A metallic taste, tingling of the extremities, and pain at the site of injection have occasionally been associated with the intravenous infusion of teriparatide acetate. It is a peptide and the possibility of systemic hypersensitivity reactions should be borne in mind. Hypercalcaemia may develop with teriparatide or the acetate and it is therefore contra-indicated in patients with pre-existing hypercalcaemia.

Teriparatide is contra-indicated in patients with severe renal impairment and should be used with caution with those with moderate impairment.

There have been reports of osteosarcoma in *rats* given teriparatide and patients who may be at increased risk, including those with a history of skeletal metastases or previous radiotherapy to the skeleton, should not receive it. It is also contra-indicated in those with metabolic bone disease including Paget's disease and hyperparathyroidism, or unexplained elevations of serum alkaline phosphatase. Use in children or those with open epiphyses is also contra-indicated. In the UK treatment is also limited to a maximum of 18 months.

Pharmacokinetics

Teriparatide is extensively absorbed after subcutaneous injection; peak plasma concentrations are reached after about 30 minutes. Absolute bioavailability is reported to be about 95%. The serum half-life is 5 minutes after intravenous use, and approximately 1 hour after subcutaneous injection (reflecting time needed for absorption from the injection site). No studies have been done on the metabolism or excretion of teriparatide; parathyroid hormone is believed to be enzymatically metabolised in the liver and excreted by the kidneys.

Uses and Administration

Teriparatide is a synthetic polypeptide that consists of the 1-34 amino-acid biologically active N-terminal region of human parathyroid hormone (p.1103). It is used in the treatment of established postmenopausal osteoporosis, especially in those with a high fracture risk, and in men with primary or hypogonadal osteoporosis who are at increased risk of fracture. The usual dose is 20 micrograms subcutaneously daily into the thigh or abdominal wall. Treatment is limited to a maximum of 18 months in the UK, although it has been used for up to 2 years in the USA. Teriparatide acetate has been given by intravenous infusion in the differential diagnosis of hypoparathyroidism and pseudohypoparathyroidism.

Hypoparathyroidism. Hypoparathyroidism is characterised by a deficiency in endogenous parathyroid hormone, whereas pseudohypoparathyroidism is characterised by resistance to the effects of parathyroid hormone (see p.1087). Teriparatide acetate is used *diagnostically* to distinguish between these 2 conditions.[1] A synthetic 1-38 fragment of human parathyroid hormone (hPTH 1-38) has been used similarly.[2] Teriparatide has also been used to *treat* hypoparathyroidism.[3-5]

5. Winer KK, *et al.* Long-term treatment of hypoparathyroidism: a randomized controlled study comparing parathyroid hormone-(1-34) versus calcitriol and calcium. *J Clin Endocrinol Metab* 2003; **88:** 4214–20.

Osteoporosis. Parathyroid hormone is capable of stimulating both formation and resorption of bone. Continuous infusion of teriparatide leads to a persistent elevation of parathyroid hormone and greater bone resorption by stimulating osteoclasts, with a net decrease in bone volume, and resultant hypercalcaemia; in contrast, daily (intermittent) injections increase bone volume by increasing osteoblastic proliferation.[1-3] Teriparatide appears to have less effect on cortical than trabecular bone,[3] suggesting that, although it may be helpful in preventing vertebral fractures, its impact on fractures of the proximal femur may be more limited. However, while treatment with teriparatide substantially increases lumbar spine bone mineral density (BMD), beneficial increases are also seen at the hip,[1] and in a pivotal study (the Fracture Prevention Trial)[4] in **postmenopausal** women with osteoporosis (p.1084), it decreased the risk of both vertebral and non-vertebral fracture. In a follow-up study, the reduction in vertebral fracture risk in patients treated with teriparatide for a mean of 19 months persisted for at least an additional 18 months after daily treatment was stopped.[5] Teriparatide appears to improve bone geometry, with no detrimental effect on cortical bone.[6] In the UK, NICE recommends teriparatide as an option for the secondary prevention of osteoporotic fragility fractures in women aged 65 years and older who have had an unsatisfactory response to bisphosphonates, or who are intolerant to bisphosphonates, and who have an extremely low BMD (4 standard deviations or more below the mean) or a very low BMD (3 standard deviations or more) plus one or more additional risk factors.[7] It has been pointed out that evidence of reduction in teriparatide's effect with current or recent alendronate therapy (see below) might make its use as a second-line agent problematic.[8]

Data on combination therapy are limited, but some studies suggest that teriparatide with HRT is more effective than HRT alone.[9] The effect of teriparatide with the antiresorptive bisphosphonates has yet to be determined.[2,6,9,10] Although there is some suggestion that teriparatide still increases bone formation after treatment with alendronate,[9] a study in men found that, when given together, alendronate impaired the anabolic effects of teriparatide.[11] For this reason, some consider that teriparatide be started immediately after stopping bisphosphonates.[10] It has been suggested that the degree of suppression of bone turnover before treatment may dictate the response to teriparatide.[6] A study of daily or cyclical teriparatide in women with osteoporosis found that although the teriparatide-induced increase in BMD may be slightly lower in women who had previously taken alendronate than in those who had never received it, the increase in spinal BMD was still impressive. Intermittent cyclical treatment with teriparatide was found to have similar effects on BMD to those induced by daily dosage.[12]

In postmenopausal women with osteoporosis taking HRT and **corticosteroids**,[13] the addition of teriparatide significantly increased BMD of the lumbar spine; modest changes in hip bone mass were not significant.

In **men** with osteoporosis, teriparatide increased BMD in the lumbar spine and at the femoral neck;[9] risk of fracture was also reduced.[1]

Tiludronate

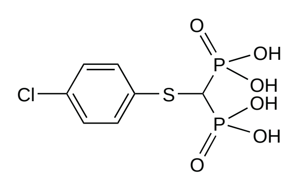
ATC — M05BA05.
ATC Vet — QM05BA05.

Tiludronic Acid *(BAN, rINN)*

Acide Tiludronique; Ácido tiludrónico; Acidum Tiludronicum; ME-3737; SR-41319; Tiludronihappo; Tiludronik Asit; Tiludronsyra. {[(*p*-Chlorophenyl)thio]methylene}diphosphonic acid.

Тилудроновая Кислота

$C_7H_9ClO_6P_2S = 318.6$.
CAS — 89987-06-4.
ATC — M05BA05.
ATC Vet — QM05BA05.



Tiludronate Disodium *(USAN)*

Tiludronate Sodium *(BANM, rINNM)*; Disodium Tiludronate; Natrii Tiludronas; Sodium Tiludronate; SR-41319B; Tiludronate de Sodium; Tiludronato sódico. Disodium dihydrogen {[(*p*-chlorophenyl)thio]methylene}diphosphonate hemihydrate.

Натрий Тилудронат

$C_7H_7ClNa_2O_6P_2S,\frac{1}{2}H_2O$ = 371.6.

CAS — 149845-07-8 (anhydrous disodium tiludronate); 155453-10-4 (tiludronate disodium hemihydrate).

ATC — M05BA05.

ATC Vet — QM05BA05.

Adverse Effects, Treatment, and Precautions

As for the bisphosphonates in general, p.1089. Asthenia and dizziness have been reported rarely.

Effects on the kidneys. Renal failure has been associated with the aminobisphosphonates, including tiludronate, see under Bisphosphonates, p.1091.

Effects on the skin. As with other bisphosphonates, tiludronate has been associated with rash and pruritus. For reference to a case of massive epidermal necrosis possibly associated with tiludronate, see Hypersensitivity, under Bisphosphonates, p.1091.

Interactions

As for the bisphosphonates in general, p.1091. Indometacin may increase the bioavailability of tiludronate two to fourfold; diclofenac does not appear to have this effect. Aspirin may decrease the bioavailability of tiludronate by 50%.

Pharmacokinetics

Like other bisphosphonates tiludronate is poorly absorbed after oral doses. Absorption is reduced by food, especially by products containing calcium or other polyvalent cations. The oral bioavailability of tiludronate is about 6% in the fasting state, and is reduced by about 90% when given within 2 hours of food. Plasma protein binding is about 90%, mostly to albumin. Tiludronate is not metabolised. About half of the absorbed portion is excreted in the urine; the remainder is sequestered to bone for a prolonged period.

Uses and Administration

Tiludronate is a bisphosphonate with similar properties to those of the bisphosphonates in general (p.1091). It inhibits bone resorption and is used for Paget's disease of bone.

It is given orally as tiludronate disodium, but doses are expressed in terms of the equivalent amount of tiludronic acid; 117 mg of tiludronate disodium is equivalent to about 100 mg of tiludronic acid. To ensure adequate absorption doses should be taken with plenty of water (at least 200 mL), at least 2 hours before or after meals. In Paget's disease of bone the usual dose is 400 mg once daily for 3 months, and this may be repeated if necessary after an interval of at least 3 to 6 months.

Tiludronate has been tried in postmenopausal osteoporosis, but results were disappointing.

Zoledronate

ATC — M05BA08.

ATC Vet — QM05BA08.

Zoledronic Acid *(BAN, USAN, rINN)*

Acide Zolédronique; Ácido zoledrónico; Acidum Zoledronicum; CGP-42446; Tsoledronihappo; Zoledronik Asit; Zoledronsyra. (1-Hydroxy-2-imidazol-1-ylethylidene)diphosphonic acid.

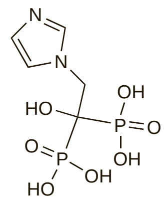
Золедроновая Кислота

$C_5H_{10}N_2O_7P_2$ = 272.1.

CAS — 118072-93-8 (anhydrous zoledronic acid); 165800-06-6 (zoledronic acid monohydrate).

ATC — M05BA08.

ATC Vet — QM05BA08.



Zoledronate Disodium *(BANM, USAN, rINNM)*

CGP-42446A; ZOL-446; Zoledronas Dinatricum; Zolédronate Disodique; Zoledronato disódico. Disodium dihydrogen (1-hydroxy-2-imidazol-1-ylethylidene)diphosphonate tetrahydrate.

Динатрий Золедронат

$C_5H_8N_2Na_2O_7P_2,4H_2O$ = 388.1.

CAS — 165800-07-7.

ATC — M05BA08.

ATC Vet — QM05BA08.

Zoledronate Trisodium *(BANM, USAN, rINNM)*

CGP-42446B; Zoledronas Trinatricum; Zolédronate Trisodique; Zoledronato trisódico. Trisodium hydrogen (1-hydroxy-2-imidazol-1-ylethylidene)diphosphonate hydrate (5:2).

Тринатрий Золедронат

$C_5H_7N_2Na_3O_7P_2,2\frac{1}{2}H_2O$ = 383.1.

CAS — 165800-08-8.

ATC — M05BA08.

ATC Vet — QM05BA08.

Adverse Effects and Precautions

As for Pamidronate, p.1101. It is important to ensure adequate hydration before and after doses of zoledronic acid as dehydration predisposes to deterioration in renal function.

Effect on electrolytes. Zoledronate has more potent effects on calcium than some of the other bisphosphonates, and has precipitated severe hypocalcaemia, resulting in tetany and paraesthesia, in some patients.[1,2] In most cases, pre-existing conditions interfered with the expected compensatory physiological response to the hypocalcaemia.[1] Vitamin D deficiency should be treated before starting zoledronate.[1,2]

2. Breen TL, Shane E. Prolonged hypocalcemia after treatment with zoledronic acid in a patient with prostate cancer and vitamin D deficiency. *J Clin Oncol* 2004; **22:** 1531–2.

Effects on the eyes. For reports of ocular effects with bisphosphonates, including zoledronate, see p.1090.

Effects on the heart. For a report of a possible association between zoledronate and serious atrial fibrillation, see Effects on the Heart, under Bisphosphonates, p.1090.

Effects on the kidneys. Renal failure has been associated with the aminobisphosphonates, see under Bisphosphonates, p.1091. Doses may need adjusting in some patients with renal impairment (see Administration in Renal Impairment, below).

Effects on the musculoskeletal system. Osteonecrosis of the jaw has been reported after the use of bisphosphonates, including zoledronate (see Effects on the Musculoskeletal System, under Adverse Effects of Bisphosphonates, p.1091).

Interactions

As for the bisphosphonates in general, p.1091.

Pharmacokinetics

Plasma concentrations of zoledronate rise rapidly after the start of an intravenous infusion. Plasma protein binding is low; it has been variously reported as 22 or 56%. Zoledronate is not metabolised, and about 23 to 55% of the dose is excreted in the urine unchanged within 24 hours; the remainder is mainly sequestered to bone and only very slowly eliminated. Renal clearance is slower in patients with severe renal impairment (see Administration in Renal Impairment, below).

Uses and Administration

Zoledronate is an aminobisphosphonate (p.1089) that is a potent inhibitor of bone resorption. Zoledronic acid is given as an intravenous infusion over not less than 15 minutes.

It is used for **hypercalcaemia of malignancy**, in a single dose of 4 mg, diluted with 100 mL of sodium chloride 0.9% or glucose 5%. The treatment may be repeated if necessary after at least 7 days, at a dose of 4 mg. Individual doses should not exceed 4 mg, as there is an increased risk of adverse renal effects, including renal failure.

Zoledronic acid is given for the prevention of skeletal events in patients with advanced **bone malignancies** (p.660) at a dose of 4 mg, diluted as above, every 3 to 4 weeks.

For the treatment of **Paget's disease** of bone, zoledronic acid is given as a single intravenous infusion of 5 mg.

Zoledronic acid is also used for the treatment of **osteoporosis** in postmenopausal women; the recommended dose is a single intravenous infusion of 5 mg given once a year.

Administration in renal impairment. Despite the fact that renal clearance of zoledronic acid correlates to renal function, a pharmacokinetic study[1] concluded that no dosage adjustment appeared necessary in patients with mild to moderate renal impairment (creatinine clearance 50 to 80 mL/minute, and 10 to 50 mL/minute, respectively).

Licensed product information also states that no adjustment is necessary in mild to moderate renal impairment for patients with *hypercalcaemia of malignancy*, but defines this degree of impairment in terms of serum creatinine less than 400 micromoles/litre or less than 4.5 mg per 100 mL.

However, for patients with *advanced bone malignancies*, the intravenous dose of zoledronic acid should be adjusted on the basis of creatinine clearance (CC) as follows:

- CC greater than 60 mL/minute: 4 mg (no adjustment necessary)
- CC 50 to 60 mL/minute: 3.5 mg
- CC 40 to 49 mL/minute: 3.3 mg
- CC 30 to 39 mL/minute: 3 mg
- CC below 30 mL/minute: treatment not recommended

Serum creatinine should be measured before each dose and treatment withheld if renal function has deteriorated. Renal deterioration is defined as an increase of 44 micromoles/litre or 0.5 mg per 100 mL for those patients with normal baseline creatinine, and an increase of 88 micromoles/litre or 1 mg per 100 mL for those with abnormal baseline creatinine. Treatment may be restarted at the dose used before treatment interruption once the creatinine returns to within 10% of the baseline value.

For patients with *Paget's disease* or *osteoporosis*, UK licensed product information states that no dose adjustment is considered necessary for those with CC of 40 mL/minute or more; due to a lack of clinical data, treatment is not recommended for those with CC of less than 40 mL/minute.

Hypercalcaemia. Bisphosphonates are the preferred drugs for treating hypercalcaemia of malignancy (p.1083) once the patient has been adequately rehydrated. Zoledronate has been shown to have a faster onset, higher response rate, and longer duration of action than pamidronate.[1] It also has a shorter infusion time than pamidronate,[1] and some consider it the treatment of choice for hypercalcaemia of malignancy.[2-4] However, zoledronate has caused severe hypocalcaemia in some patients, see Effects on Electrolytes, above.

Malignant neoplasms of the bone. Bisphosphonates are of benefit in some patients with metastatic bone disease (p.660) not only to manage bone pain and hypercalcaemia, but to reduce skeletal complications such as fractures. Zoledronate is licensed for such use in many countries.[1]

In the treatment of skeletal complications from bone metastases secondary to multiple myeloma or breast cancer, zoledronate was more effective than pamidronate in reducing the risk of complications from breast cancer; it was of similar efficacy in those with multiple myeloma.[2] In a placebo-controlled study in patients with prostate cancer,[3] zoledronate reduced the number of skeletal-related events, and increased the median time to events. In patients with bone metastases arising from lung cancer and other solid tumours (excluding breast or prostate cancer), zoledronate reduced skeletal morbidity; the primary end-point, which excluded hypercalcaemia as a skeletal-related event, did not reach statistical significance.[4] However, the authors noted that the patient groups had a shorter-than-expected survival-time. A longer term follow-up of this study[5] confirmed a sustained reduction in risk of developing skeletal events with zoledronate. Whether bisphosphonates can prevent the development of new skeletal metastases is unclear.

Osteoporosis. Bisphosphonates are used for the prevention and treatment of osteoporosis (p.1084). Five different dosage regimens of zoledronate all increased bone mineral density (BMD) in **postmenopausal** women when given intermittently over the course of 1 year in a placebo-controlled study.[1] Compared with placebo, a once-yearly infusion of zoledronate over a 3-year period significantly reduced the risk of vertebral, hip, and other fractures in postmenopausal women with osteoporosis.[2] BMD was also significantly increased. Adverse events were similar in both groups, including renal function changes; however, serious atrial fibrillation occurred more frequently in the zoledronate group (see Effects on the Heart, under Bisphosphonates, p.1090). Once-yearly infusion of zoledronate beginning within 90 days after surgical repair of a low-trauma hip fracture was associated with a reduction in the rate of new vertebral and nonvertebral fractures, although the reduction in the risk of new hip fractures was non-significant.[3]

Preliminary results from a study evaluating zoledronate for the prevention of cancer **treatment-induced** bone loss, in postmenopausal women with early breast cancer treated with letrozole, suggest that adding zoledronate to the regimen from the start is more effective than delaying treatment until there is evidence of bone loss.[4] In a small study,[5] zoledronate also improved the calcium content of cancellous bone, maintained femoral neck BMD, and increased lumbar spine BMD after kidney transplantation. In a similar study of liver transplant recipients, zoledronate also had favourable effects on BMD. This effect tended to diminish at 12 months when compared with placebo; the authors considered this to be due to improved general health, mobility, muscle mass, and nutrition as a consequence of improved liver function.[6]

Paget's disease of bone. Bisphosphonates may be indicated for patients with Paget's disease of bone (p.1086) if bone pain is persistent, or to prevent further progression of the disease. Zoledronate is highly effective in Paget's disease. Single infusions of up to 400 micrograms have been shown to inhibit bone resorption in patients with active Paget's disease.[1,2] In a patient[3] with disease refractory to other bisphosphonates, a single infusion of 4 mg improved symptoms and improved biochemical markers of disease activity. A placebo-controlled study compared a single infusion of 5 mg zoledronic acid with a 60-day course of oral risedronate 30 mg daily. Patients receiving zoledronic acid had significantly more rapid and marked reduction in serum alkaline phosphatase concentrations, higher response rates, and shorter median times to response than those on risedronate. During an open extension study, patients on risedronate had a significantly larger loss of therapeutic response than those given zoledronic acid.[4] A review[5] concluded that zoledronic acid was an important first-line treatment for Paget's disease.

Bronchodilators and Anti-asthma Drugs

This chapter includes many of those drugs used for their bronchodilator or anti-inflammatory properties in the management of reversible airways obstruction, such as asthma and chronic obstructive pulmonary disease.

The main bronchodilators discussed in this chapter are the sympathomimetic beta agonists (stimulants of beta-adrenoceptors), and the xanthines (mainly theophylline). The antimuscarinic bronchodilators ipratropium, oxitropium, and tiotropium are also included. The major class of anti-inflammatory drugs, the corticosteroids, are discussed separately, on p.1490; other drugs considered to act on the processes of airway inflammation and which are included in this section include sodium cromoglicate and its analogues, and the various drugs that act on leukotriene synthesis and receptor binding, on platelet-activating factor (PAF), or on other aspects of the inflammatory cascade.

Anti-asthma Drug Groups

Antimuscarinics. The parasympathetic nervous system plays a role in the regulation of bronchomotor tone, and antimuscarinic drugs have bronchodilator properties. The quaternary ammonium compounds ipratropium bromide, oxitropium bromide, and tiotropium bromide are the main antimuscarinic (anticholinergic) bronchodilators in current use; as well as reduced CNS effects they have less effect on mucociliary clearance than drugs such as atropine, which can produce accumulation of viscid lower airway secretions and a risk of mucus plugging in these patients. An antimuscarinic may be the bronchodilator of choice in the management of chronic obstructive pulmonary disease. In patients with asthma they are usually reserved for use in life-threatening acute asthma exacerbations.

Described in this chapter are

Ipratropium, p.1124	Tiotropium, p.1148
Oxitropium, p.1129	

Beta agonists. The sympathetic nervous system plays a role in the regulation of bronchomotor tone and beta$_2$-adrenoceptors in bronchial smooth muscle produce bronchodilatation when stimulated. Short-acting selective agonists of beta$_2$-adrenoceptors (beta$_2$ agonists; beta$_2$ stimulants), of which salbutamol is the paradigmatic example, are therefore first-line drugs for the relief of asthma symptoms. They are also widely used in the management of chronic obstructive pulmonary disease, although antimuscarinic bronchodilators may be preferred or used in addition. Long-acting beta$_2$ agonists are used in asthma in patients also requiring anti-inflammatory therapy.

Described in this chapter are

Arformoterol, p.1115	Orciprenaline, p.1129
Bambuterol, p.1115	Pirbuterol, p.1130
Bitolterol, p.1116	Procaterol, p.1130
Clenbuterol, p.1120	Reproterol, p.1131
Fenoterol, p.1121	Salbutamol, p.1131
Formoterol, p.1122	Salmeterol, p.1135
Hexoprenaline, p.1123	Terbutaline, p.1138
Indacaterol, p.1123	Tretoquinol, p.1149
Isoetarine, p.1125	Tulobuterol, p.1150
Levosalbutamol, p.1125	

Corticosteroids. Corticosteroids are widely used for their anti-inflammatory (glucocorticoid) properties in the management of asthma, and may be beneficial in some patients with chronic obstructive pulmonary disease. Because of the potential adverse effects associated with prolonged systemic corticosteroid therapy, inhalation of corticosteroids with reduced systemic activity is preferred; oral corticosteroids are generally only used in short courses, and at relatively low doses, to gain control of the disease. The actions and uses of the corticosteroids are discussed in much greater detail in the section beginning on p.1490.

Leukotriene inhibitors and antagonists. Leukotrienes appear to play an important role in the inflammatory process of asthma, and some drugs may modify or inhibit this action. Leukotriene synthesis may be prevented by blockade of the enzyme 5-lipoxygenase with inhibitors such as zileuton. Alternatively, leukotriene receptor antagonists such as zafirlukast may be used to block specific receptors (usually those of leukotriene D$_4$) and prevent their activation. These anti-leukotriene drugs have a role in the prophylactic management of asthma as an alternative when inhaled corticosteroids cannot be used in mild asthma, and as add-on therapy in more severe asthma.

Described in this chapter are

Amlexanox, p.1115	Pranlukast, p.1130
Ibudilast, p.1123	Tipelukast, p.1149
Montelukast, p.1126	Zafirlukast, p.1150
Pemirolast,p.1129	Zileuton, p.1151

Mast cell stabilisers. The role of the mast cell in starting an inflammatory cascade has long been recognised as important, and the best established of the mast cell stabilisers are sodium cromoglicate and nedocromil sodium. These compounds inhibit mast cell degranulation in response to antigens or other stimuli, and hence prevent the release of histamine, leukotrienes, and other inflammatory mediators. They are usually well tolerated and guidelines for the treatment of asthma mention their use for prophylactic therapy as an alternative, or a supplement, to corticosteroids, particularly in children. However, it is generally considered that the corticosteroids are more effective.

Described in this chapter are

Amlexanox, p.1115	Repirinast, p.1131
Nedocromil, p.1127	Sodium Cromoglicate, p.1136
Pemirolast, p.1129	Tranilast, p.1149

Xanthines. Xanthines are drugs with complex actions that include, in varying degrees, relaxation of bronchial smooth muscle and relief of bronchospasm, stimulant effects on respiration, and anti-inflammatory effects. Theophylline and its derivatives have long been used for their bronchodilator properties in the management of asthma and chronic obstructive pulmonary disease, but the narrow therapeutic range and the propensity for interactions with other drugs make theophylline a difficult drug to use, and it tends to be reserved for combination therapy in patients who cannot be managed with other bronchodilators (such as the beta$_2$ agonists) plus inhaled corticosteroids.

Described in this chapter are

Acefylline piperazine, p.1114	Doxofylline, p.1120
Ambroxol acefyllinate, p.1114	Etamiphylline Camsilate, p.1120
Aminophylline, p.1114	Etofylline, p.1121
Bamifylline, p.1116	Heptaminol Acefyllinate, p.1123
Bufylline, p.1116	Proxyphylline, p.1130
Caffeine, p.1116	Theobromine, p.1140
Choline Theophyllinate, p.1119	Theophylline, p.1140
Diprophylline, p.1120	

Management of Reversible Airways Obstruction

Asthma

Asthma is a chronic inflammatory disease in which the patient has episodes of reversible airways obstruction due to bronchial hyperresponsiveness. It is a common disorder, the prevalence of which has increased sharply over the last 40 years, particularly in children, with prevalence greater than 30% in some areas. More than 10% of the population in developed countries are affected. Rates are increasing in developing countries as they become more westernised,[1] and global differences in prevalence appear to be lessening.[2] It has been suggested that asthma is probably not one illness, but a collection of different phenotypes which meet the criteria for clinical diagnosis of asthma.[3,4] Although there is no clear definition of the asthma phenotype, 3 categories have been suggested: clinical phenotypes such as severity-defined or defined by age at onset, trigger-related phenotypes such as allergy- or aspirin-induced asthma, and inflammatory phenotypes such as eosinophilic asthma.[4] Current guidelines classify by severity according to the clinical features present before treatment.[5-7] Asthma may be described as extrinsic when it is associated with exposure to a specific allergen such as pollen or house-dust mite, or to a non-specific stimulus such as a chemical irritant or exercise. It may be described as intrinsic when no external precipitating factor is identifiable.

The aetiology of asthma is poorly understood, but both genetic and environmental factors are believed to contribute to development and progression of the disease.[1,8,9] Resistance to airflow in asthma is increased by a number of abnormalities, including contraction of the airway smooth muscle, the presence of excessive secretions within the airway lumen, and inflammatory cell infiltration. The inflammation in chronic asthma causes remodelling, found as shedding and thickening of the airway epithelium, and hypertrophy and hyperplasia of smooth muscle.[8,9] Airway remodelling or thickening may be important in more severe disease and can result in relatively irreversible narrowing of the airways.[7]

The principal symptoms of asthma are wheezing, dyspnoea (breathlessness), chest tightness, and cough, and these symptoms tend to be variable, intermittent, worse at night or early morning, and provoked by particular triggers. In an acute attack, the respiratory rate is rapid and tachycardia is common.[5-7] The peak expiratory flow (PEF) and forced expiratory volume in the first second (FEV$_1$) are decreased in asthma, and in a severe asthmatic attack the PEF is generally less than 50% of predicted values. Life-threatening features include exhaustion, cyanosis, bradycardia, hypotension, confusion, and coma.[5-7]

Management of asthma. As asthma is a chronic disease, management involves prophylactic measures to reduce inflammation and airway resistance and to maintain airflow, as well as specific regimens for the treatment of acute attacks. **Measurements** of lung function play an important part in determining treatment and patients are encouraged to monitor their own disease by using a simple peak flow meter to measure PEF and adjust their therapy accordingly.[5-7] Spirometry is used to measure airflow limitation and reversibility in hospitals and surgeries.[5-7] Use of exhaled nitric oxide has been investigated to monitor disease control with corticosteroids;[10] however, an asthma treatment strategy using exhaled nitric oxide did not result in a large reduction in exacerbations or less use of inhaled corticosteroids.[11]

Drug therapy is preferably given by **inhalation** to deliver the drugs directly to the desired site of action. This produces higher local concentrations and permits smaller doses than would be required orally, with a consequent reduction in adverse effects. Systematic reviews[12-14] have found that hand-held inhaler devices including pressurised metered-dose inhalers (MDIs), dry powder inhalers, and breath actuated pressurised MDIs, are generally equally effective for the delivery of short-acting beta$_2$ agonists and corticosteroids in stable asthma. Choice of inhaler should be individualised, especially in children, taking into account ease of use, safety, and convenience.[6,7,14] Differences in drug delivery exist between inhaler devices and this should be considered when substituting one device for another.[7]

Spacer devices can be fitted to some MDIs to act as reservoirs for the drug to make it easier for the patient to inhale each dose correctly. Use of MDIs with spacer devices produce outcomes which are at least equivalent to nebuliser therapy.[14,15] Nebulisers tend to be reserved for patients who are unable or unwilling to use these devices, although the choice of spacer and method of use may substantially affect drug delivery.[5,16] A large volume spacer device is recommended for the inhalation of high doses of corticosteroids to reduce oropharyngeal deposition and systemic absorption.[5,7] Specially adapted or modified inhalation devices, as well as spacer devices, are also available to enable children to achieve a correct technique when using inhaled drug therapy, but alternative routes of delivery such as oral dosage or nebulisation may be necessary for some infants and small children.[16] Frequent intermittent or continuous nebulisation of short-acting beta$_2$ agonists are both effective in patients with severe bronchoconstriction.[14]

The standard **drugs** used in the management of asthma are the beta$_2$ agonists and corticosteroids.[5-7]

Beta$_2$ agonists relax the bronchial smooth muscle to produce bronchodilatation by selectively stimulating beta$_2$-adrenergic receptors. Short-acting selective beta$_2$ agonists such as salbutamol or terbutaline are the initial drugs of choice for use as required to relieve acute bronchospasm; if inhaled, they can have an almost immediate bronchodilating effect. Regular use of beta$_2$ agonists is mainly restricted to long-acting beta$_2$ agonists such as salmeterol xinafoate in patients also requiring anti-inflammatory prophylactic treatment; a short-acting beta$_2$ agonist should still be used as required.[5-7]

Corticosteroids are the most effective preventer therapy available for the management of asthma.[17] They are used for their anti-inflammatory properties and to reduce bronchial hyperresponsiveness; they must be taken regularly to achieve maximum benefit. Corticosteroid therapy is recommended both for acute attacks and chronic asthma prophylaxis. Meta-analysis suggests that systemic corticosteroids speed the resolution of exacerbations and reduce the rate of relapse.[18,19] It has also been suggested that inhaled corticosteroids may be of benefit in acute asthma if multiple doses are inhaled at intervals of less than 30 minutes, over a 90 to 120 minute period.[20] In chronic asthma, regular inhaled corticosteroids are one of the cornerstones of management. Combining inhaled corticosteroids with long-acting beta$_2$ agonists may have synergistic benefits;[17,21,22] such a combination is more effective than combining inhaled corticosteroids with anti-leukotriene drugs.[23] The use of an inhaled corticosteroid, budesonide, and a rapid and long-acting beta$_2$ agonist, formoterol, in a combined inhaler as both regular maintenance therapy and as a reliever when required, has been studied. Giving additional corticosteroid with each reliever inhalation in response to symptoms could be expected to provide improved control of airway inflammation,[24] and reductions in the rate of exacerbations have been reported[25,26] with relatively lower doses of inhaled corticosteroid in patients with uncontrolled persistent asthma, compared with more conventional treatment regimens using a $beta_2$ agonist as a reliever. While the place of budesonide/formoterol maintenance and reliever therapy in the management of asthma is not yet clearly defined,[24] some guidelines[6,7] include this regimen (referred to by the manufacturer, *AstraZeneca*, as Symbicort® Maintenance and Reliever Therapy, or SMART®) as an option for adults at Step 3 (see below).

Exercise-induced bronchoconstriction is also reduced in both adults and children by regular use of inhaled corticosteroids.[27]

Various studies have examined the role that inhaled corticosteroids might play in modifying the development of asthma in symptomatic children.[28-30] Although the short-term therapeutic efficacy varied between studies, possibly due to the differing lengths of treatment and study populations used, in all 3 studies the long-term clinical and functional outcomes did not differ in children treated with inhaled corticosteroids compared with placebo.

Xanthines such as aminophylline or theophylline may be given for their bronchodilating properties although there is evidence that the long-acting $beta_2$ agonist salmeterol produces a greater improvement in lung function, reduces the need for rescue short-acting $beta_2$ agonists, and has fewer adverse effects compared with theophylline.[31] There is disagreement about adding xanthine treatment to $beta_2$ agonists for the management of acute severe asthma (see below).

Inhaled *antimuscarinics* such as ipratropium bromide or oxitropium bromide, used with $beta_2$ agonists, are given in acute asthma; a systematic review[32] found that inhaled multiple doses of antimuscarinic reduced hospital admissions and improved lung function tests compared with $beta_2$ agonists alone.

Cromoglicate or nedocromil may be used as an alternative to corticosteroids for the prophylaxis of less severe asthma or combined with other therapy. *Anti-leukotrienes* such as the leukotriene receptor antagonist zafirlukast and the leukotriene inhibitor zileuton are another alternative or adjunct to inhaled corticosteroids. When used with inhaled corticosteroids, anti-leukotrienes bring modest improvements in lung function compared with inhaled corticosteroids alone.[33] They may also be useful in exercise-induced bronchoconstriction in some patients.[5-7] The anti-IgE monoclonal antibody *omalizumab*[17,34] is available for use in selected patients with allergen-induced asthma. A systematic review of omalizumab,[35] as adjunctive therapy to corticosteroids, found that treatment led to a reduction, and in some cases, withdrawal of regular inhaled corticosteroid, as well as a reduction in asthma exacerbations; longer term evaluation of adverse effects, direct comparison with inhaled corticosteroids, and assessment in children is needed.

CHRONIC ASTHMA

Advice for patients with chronic asthma includes avoidance of smoking, of allergens such as pollen, and of bronchoconstricting drugs such as beta blockers. Patients who have had asthma induced by aspirin and NSAIDs should also avoid these drugs. Skin testing to determine allergen sensitivity may be advisable.[5-7] US guidelines[5] suggest consideration of immunotherapy to desensitise patients with poorly controlled disease unavoidably exposed to a precipitating allergen. Although there is increasing evidence of benefit from such treatment[36] the size of the benefit overall remains somewhat uncertain, and the potential adverse effects make it controversial (see under Allergen Immunotherapy, p.2251). UK guidelines[6] consider that although there is evidence of benefit from immunotherapy when compared with placebo, comparative studies with other asthma treatments are needed.

Gastro-oesophageal reflux has been suggested as another exacerbating factor;[37] symptoms of gastro-oesophageal reflux disease are about one and a half times more common among individuals with asthma than the general population,[38] although the exact nature of the association remains unclear. A 2003 systematic review of acid suppressive therapy concluded that it did not benefit asthma in most patients;[39] more recent studies on the subject support this view,[40,41] although one did note reduced exacerbations and an improvement in the asthma quality of life in patients given lansoprazole compared with placebo.[41]

Guidelines for drug therapy of chronic asthma have been issued in many countries including Australia,[42] Canada,[43,44] and the UK,[6] and the USA,[5] and by the Global Initiative for Asthma (GINA),[7] and are broadly similar, providing a stepwise approach. Guidelines specifically for the management of childhood asthma have recently been issued by The European Pediatric Asthma Group.[45] Initial control is achieved with the early use of anti-inflammatory drugs at doses most appropriate for the severity of disease. In mild to moderate asthma, starting inhaled corticosteroids at very high doses and stepping down confers no benefit,[46,47] and relatively low initial doses are recommended.[5-7]

Guidelines vary slightly in their definition of low, moderate and high inhaled **corticosteroid doses**—for the definitions of these terms in UK, US, and global asthma guidelines see Asthma, under Choice of Corticosteroid, p.1499.

In adults and older children

The ***UK*** recommendations for adults and children over 5 years of age with chronic asthma are as follows:

- Step 1; mild intermittent asthma

  Patients requiring only occasional relief from symptoms may be adequately managed with an inhaled short-acting $beta_2$ agonist such as salbutamol or terbutaline taken when needed.

- Step 2; regular preventer therapy

  Regular inhaled corticosteroids may be added at an appropriate starting dose for the severity of the disease, if symptoms are present or an inhaled $beta_2$agonist is required three times a week or more, or if symptoms wake the patient from sleep one night a week. Patients who have had an exacerbation of asthma requiring oral corticosteroids in the last 2 years should also be considered for regular inhaled corticosteroids. *Alternatives* are cromoglicate or nedocromil, leukotriene receptor antagonists, or modified-release oral theophylline, but these are less effective.

- Step 3; initial add-on therapy

  If adequate control is not achieved, the preferred treatment is to supplement low-dose inhaled corticosteroids with a long-acting inhaled $beta_2$ agonist such as salmeterol xinafoate. If there is only suboptimal response, the long-acting $beta_2$ agonist is continued and inhaled corticosteroid increased to a moderate dose. If there is no response to a long-acting $beta_2$ agonist, it should be stopped and inhaled corticosteroid increased to a moderate dose; if control is still inadequate addition of either a leukotriene receptor antagonist or modified-release oral theophylline should be considered.

- Step 4; persistent poor control

  For patients with persistent poor control of asthma despite use of inhaled moderate-dose corticosteroids and an additional drug (usually a long-acting inhaled $beta_2$ agonist), increasing the inhaled corticosteroid to a high dose should be considered. Patients over 12 years of age may alternatively benefit from addition of either a leukotriene receptor antagonist, modified-release oral theophylline, or an oral modified-release $beta_2$ agonist. If a trial of a particular treatment option is ineffective, the drug is stopped (or in the case of an increased dose of inhaled corticosteroid, reduced).

- Step 5; continuous or frequent use of oral corticosteroids

  If further control is needed, then an oral corticosteroid such as prednisolone may also be given in single daily doses at the lowest dose providing adequate control. High-dose inhaled corticosteroids should also be maintained. Other treatments may be considered to minimise the use of corticosteroid tablets, such as a 6 week trial of treatment with long-acting $beta_2$ agonists, leukotriene receptor antagonists, or theophylline. If a trial of a particular treatment option is not effective, the drug is stopped. When other treatments have proved unsuccessful in patients over 12 years of age, a 3 month trial of immunomodulators such as methotrexate, ciclosporin, and gold may be considered for their anti-inflammatory, immunosuppressant, and corticosteroid-sparing properties: their use must be balanced against their potentially serious adverse effects. Referral for specialist care is advised for all patients at this step.

The ***US*** recommendations for chronic asthma management in adults and children over 5 years are:

- Step 1

  A short-acting inhaled $beta_2$ agonist is recommended, taken as required to relieve symptoms.

- Step 2

  As in UK guidelines, if regular controller therapy is needed, then a low-dose inhaled corticosteroid is the preferred treatment. Other alternatives include cromoglicate, nedocromil, a leukotriene receptor antagonist, and theophylline.

- Step 3

  The preferred treatment for patients over 12 years who are not controlled with low-dose inhaled corticosteroids, is either addition of a long-acting inhaled $beta_2$ agonist or increasing the inhaled corticosteroid to a moderate dose. In children aged 5 to 12 years either a leukotriene receptor antagonist or modified-release oral theophylline are equally acceptable treatment options in place of a long-acting inhaled $beta_2$ agonist; however, they are secondary options for patients 12 years and over long with the leukotriene inhibitor zileuton.

- Step 4

  An increase in the inhaled corticosteroid to a moderate dose is recommended in patients not controlled by Step 3. A long-acting inhaled $beta_2$ agonist is the preferred addition to this; alternatives include either a leukotriene receptor antagonist or modified-release theophylline, or in patients 12 years and over, the leukotriene inhibitor zileuton.

- Step 5

  High-dose inhaled corticosteroid in addition to a long-acting inhaled $beta_2$ agonist is the preferred treatment for patients on Step 5. Alternatively, children aged 5 to 11 years may benefit from either a leukotriene receptor antagonist or modified-release theophylline in place of a long-acting inhaled $beta_2$ agonist. Omalizumab may be considered for patients 12 years and over who have allergies.

- Step 6

  As in Step 5 of the UK guidelines above, an oral corticosteroid may be added to the inhaled high-dose corticosteroid and long-acting $beta_2$ agonist. Alternatively, children aged 5 to 11 years may benefit from either a leukotriene receptor antagonist or modified-release theophylline in place of a long-acting $beta_2$ agonist. Omalizumab may be considered for patients 12 years and over who have allergies.

Consultation with an asthma specialist is recommended from Step 4.

Global guidelines for the management of asthma in adults and children aged over 5 years recommend:

- Step 1, as for UK guidelines, a short-acting inhaled $beta_2$ agonist is the recommended reliever treatment. An inhaled antimuscarinic such as ipratropium, a short-acting oral $beta_2$ agonist, or immediate-release theophylline may be considered as alternatives.

- Step 2; reliever medication plus single controller

  Similar to UK guidelines, but an anti-leukotriene is the only alternative recommended to the preferred treatment with a low-dose inhaled corticosteroid.

- Step 3; reliever medication plus one or two controllers

  A low-dose inhaled corticosteroid with a long-acting inhaled $beta_2$ agonist (the preferred option in adolescents and adults), or else increasing the inhaled corticosteroid to a moderate (the preferred option in children over 5 years) or high dose should be considered. Alternative treatment options for all ages are a combination of low-dose inhaled corticosteroid with either an anti-leukotriene or modified-release theophylline.

- Step 4; reliever medication plus two or more controllers

  The preferred treatment at Step 4 is to combine a moderate or high dose of an inhaled corticosteroid with a long-acting inhaled $beta_2$ agonist. Addition of either an anti-leukotriene or modified-release theophylline may also provide benefit. High-dose inhaled corticosteroids should be reserved for patients who are not controlled by moderate doses combined with a long-acting inhaled $beta_2$ agonist and/or an additional controller; they are recommended only on a trial basis for 3 to 6 months.

- Step 5

  As in Step 5 of UK guidelines and Step 6 of US guidelines, an oral corticosteroid may be considered in addition to another controller medication. Omalizumab is an option for patients with allergic asthma who remain uncontrolled on combinations of other controllers including a high dose of inhaled or oral corticosteroids.

Referral to an asthma specialist is recommended from Step 4.

A short 'rescue' course of oral prednisolone 30 to 60 mg daily may also be needed at any time and at any step for an acute exacerbation.

In children under 5 years of age

Recommendations for the management of chronic asthma in children under 5 years of age have also been issued in the UK[6] and USA.[5] There is limited information available for this age group, however, and some recommendations are based on extrapolations from studies in older children and adults. These guidelines also provide a stepwise approach to management. UK recommendations for management of chronic asthma in children under 5 years of age are as follows:

- Step 1; mild intermittent asthma

  Inhaled short-acting $beta_2$ agonist as required.
- Step 2; regular preventer therapy

  A low-dose inhaled corticosteroid may be added if control is poor. If a corticosteroid cannot be used, an alternative to be considered is a leukotriene receptor antagonist.
- Step 3; initial add-on therapy

  In children aged 2 to 5 years, addition of a leukotriene receptor antagonist may be considered if control is poor in those already taking inhaled corticosteroids. In those taking a leukotriene receptor antagonist alone, addition of a low-dose inhaled corticosteroid should be reconsidered. Children under 2 years and those who have persistent poor control on Step 3, may be referred to a respiratory paediatrician (Step 4).

The US makes the following recommendations for the management of chronic asthma in children under 5 years of age:

- Step 1, as for UK guidelines above.
- Step 2

  As in UK guidelines, addition of a low-dose inhaled corticosteroid is recommended. Alternative, but less preferable, treatments include the leukotriene receptor antagonist montelukast, and cromoglicate.
- Step 3

  An increase in the inhaled corticosteroid to moderate-dose should be considered.
- Step 4

  In addition to moderate-dose inhaled corticosteroid, consider either a long-acting inhaled $beta_2$ agonist or montelukast.
- Step 5

  The inhaled corticosteroid is increased to high-dose, in addition to either a long-acting $beta_2$ agonist or montelukast.
- Step 6

  In patients who remain uncontrolled, an oral corticosteroid may be added.

Consultation with an asthma specialist is recommended from step 4 onwards.

As in adults and older children, a short course of oral prednisolone (1 to 2 mg/kg daily) may be needed for acute exacerbations of asthma.

For all ages, treatment should be regularly **reviewed** and **reduced** in a stepwise manner if asthma is well controlled. Patients should be maintained on the lowest possible dose of inhaled corticosteroid; a reduction in dose every 3 months should be considered, decreasing the dose by about 25 to 50% each time.

ACUTE SEVERE ASTHMA

An acute attack of severe asthma (status asthmaticus) is potentially life-threatening and treatment should be instituted as soon as possible. UK guidelines[6] provide guidance on the assessment and initial treatment of exacerbations of asthma in general practice and in the accident and emergency department. Patients with any features of a life-threatening attack, or a severe attack persisting after initial treatment with high-dose short-acting $beta_2$ agonist and an oral corticosteroid, require admission to hospital.

In adults.

Guidelines suggest the following regimen for the hospital management of adults:[6]

- Initially, oxygen should be given at the highest concentration available (40 to 60%) with a high flow rate.
- High doses of inhaled short-acting $beta_2$ agonists (salbutamol 5 mg or terbutaline 10 mg) and antimuscarinic (ipratropium bromide 500 micrograms) should be given via a nebuliser with oxygen, or compressed air if oxygen is not available; if neither of these is available, multiple actuations of a MDI into a large volume spacer device may be used.
- High doses of systemic corticosteroids are also required: for example, prednisolone 40 to 50 mg by mouth or hydrocortisone 100 mg intravenously, or both.
- A single intravenous dose of magnesium sulfate (1.2 to 2 g infused over 20 minutes) may be considered at this stage if life-threatening features are still present. The role of magnesium sulfate has not been fully established, however, and results of clinical studies have been conflicting. A meta-analysis concluded that its routine use was not justified, but that it appears to be safe and beneficial in some patients with severe exacerbations.[48]
- Subsequently, oxygen therapy should be continued as should corticosteroid treatment (oral prednisolone 40 to 50 mg daily or hydrocortisone 100 mg every 6 hours intravenously).
- Nebulised $beta_2$ agonists and ipratropium bromide may be given every 4 to 6 hours. If the patient's condition has not improved after 15 to 30 minutes, the nebulised $beta_2$ agonist should be given more frequently (up to every 15 minutes, or in a continuous regimen such as salbutamol 10 mg hourly).
- If progress is still unsatisfactory, then an infusion of aminophylline (5 mg/kg over 20 minutes then 500 to 700 micrograms/kg per hour, monitoring blood concentrations if continued for more than 24 hours; the loading dose should not be given to patients already on maintenance oral therapy), or a parenteral $beta_2$ agonist may be considered, although there is limited evidence to support the routine use of either of these drugs.
- Patients who deteriorate further with drowsiness, unconsciousness, or respiratory arrest need transferral to an intensive care unit and intermittent positive-pressure ventilation.

Once lung function is stabilised the patient can be discharged taking inhaled corticosteroids and bronchodilators, and a short course of oral corticosteroid, which has been shown to reduce the chance of relapse and use of short-acting $beta_2$ agonists.[49]

In children.

UK guidelines suggest the following regimen for **children aged 2 years and over**:

- Severe acute attacks in children are initially treated with oxygen given via either a face mask or nasal cannula. High-dose short-acting $beta_2$ agonists are also given, either via a nebuliser (salbutamol 2.5 mg or terbutaline 5 mg in children aged 2 to 5 years; up to 5 mg of salbutamol and up to 10 mg of terbutaline may be given in children over 5 years) using oxygen as the driving gas, or as multiple actuations of a MDI into a large volume spacer device.[6] There is some evidence that in children with acute asthma, use of spacers rather than nebulisers improves oxygenation, and reduces adverse effects and time spent in the emergency department.[15]
- A systemic corticosteroid at a high dose is also required, either oral prednisolone (20 mg daily in children aged 2 to 5 years, and 30 to 40 mg daily in those over 5 years of age: children already receiving maintenance oral corticosteroids should receive 2 mg/kg up to a maximum of 60 mg daily), or intravenous hydrocortisone (4 mg/kg every 4 hours in more severely affected children).
- If life-threatening features are present, or response to $beta_2$ agonists is poor, nebulised ipratropium bromide (250 micrograms) may be added. Bronchodilators may be repeated every 20 to 30 minutes.
- If no improvement is seen, transferral to a paediatric intensive care unit is recommended. Further treatment options to consider are intravenous salbutamol (15 micrograms/kg over 10 minutes followed by an infusion of 1 to 5 micrograms/kg per minute of a 200 microgram/mL solution); intravenous aminophylline (5 mg/kg over 20 minutes then 1 mg/kg per hour; the loading dose should not be given in children already receiving oral theophylline); and, for children over 5 years of age, a single intravenous dose of magnesium sulfate (40 mg/kg to a maximum of 2 g over 20 minutes).

Subsequent management follows a similar routine to that in adults.

For **children under 2 years of age** with acute asthma UK guidelines recommend beginning with oxygen and a trial of short-acting $beta_2$ agonist given by multiple actuations of an MDI into a large volume spacer, and repeated every 1 to 4 hours if responding. If a poor response is seen, nebulised ipratropium is added, and a short course of a high-dose oral corticosteroid (prednisolone 10 mg daily for up to 3 days) may be considered.

Global guidelines for acute severe asthma are similar to those in the UK; however, US guidelines for acute severe asthma in adults and children are slightly different.[5] Although subcutaneous adrenaline or terbutaline has been used in the management of acute severe asthma in the USA, the guidelines suggest that the parenteral use of $beta_2$ agonists is of unproven value. Moreover, in contrast to the UK the intravenous use of xanthines is not recommended. In compiling the UK guidelines the British Thoracic Society has taken the view that although most patients on maximal doses of nebulised $beta_2$ agonists and corticosteroids derive no additional benefit from intravenous aminophylline, some could obtain additional bronchodilatation; intravenous aminophylline was therefore recommended for patients with life-threatening unresponsive acute asthma attacks;[6] some evidence in children,[50] although not in adults,[51] supports this. In contrast, the most recent US guidelines issued by the National Asthma Education and Prevention Program do not recommend the use of xanthines as they are considered to offer no benefit over the optimal use of inhaled short-acting $beta_2$ agonists and increases the frequency of adverse effects.[5] In consequence, in the US guidelines, adult patients whose asthma cannot be managed with oxygen, inhaled short-acting $beta_2$ agonists and antimuscarinics, and systemic corticosteroids may be considered for treatment with intravenous magnesium sulfate or nebulisation with a mixture of helium and oxygen (heliox) in order to avoid intubation and mechanical ventilation. UK guidelines consider there is no evidence to support the use of heliox; a meta-analysis[52] concluded that the existing evidence on heliox failed to show a clear benefit, and although lung function might be improved in the most severe acute asthma patients, the number and size of studies available for analysis was small and the quality variable.

OTHER ASPECTS OF ASTHMA MANAGEMENT

Other therapeutic approaches for the management of asthma are currently under investigation. Ultra-long-acting $beta_2$ agonists under development such as carmoterol, GSK-159797 (TD-3327), and indacaterol are suitable for once daily use, leading to increased convenience for patients.[53] Carbamazepine has shown potential as a treatment for asthma in addition to regular asthma therapy;[54] improved lung function and fewer exacerbations have been reported. The recombinant human B-type natriuretic peptide (BNP), nesiritide, has been reported to be an effective bronchodilator when given intravenously;[55] its clinical role, if any, remains to be determined. As well as their established antibacterial effect, it has been suggested that macrolides also have immunomodulatory effects that could be useful in the management of respiratory diseases. However, a systematic review[1] found insufficient evidence to support or refute the use of macrolides in chronic asthma although some clinical data indicated a positive effect; routine use was not recommended and further studies were warranted. Ketolides also appear to have immunomodulatory effects: a 10-day course of oral telithromycin started with standard treatment for acute asthma in adults was reported to improve asthma symptoms, regardless of infection with *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*) or *Mycoplasma pneumoniae*.[56] The mechanism of this effect is unclear, however, and further studies are needed.[57]

Interestingly, furosemide given by inhalation has been found to protect against bronchoconstriction induced by exercise[58] and external stimuli,[59,60] but was not effective in improving bronchial hyperresponsiveness in a 4-week study,[61] and provided no additional benefit when added to salbutamol for the treatment of acute asthma in a small study in children.[62] Any clinical application has yet to be determined.[63] There has been some interest in heparin given by inhalation,[63-65] and nebulised lidocaine may be of some benefit;[63,66,67] intravenous lidocaine or oral mexiletine have been shown to block reflex bronchoconstriction.[68] Inhaled magnesium sulfate may also be of some adjunctive benefit to $beta_2$ agonists in the management of acute episodes.[69]

There is increasing study of the cellular mechanisms of inflammation in asthma and ways of controlling them.[70] Phosphodiesterase type-4 is an enzyme that hydrolyses cyclic adenosine monophosphate (cyclic AMP), stimulating the release of acute inflammatory mediators and immune responses; it is found in airways smooth muscle, pulmonary nerves, and inflammatory and immune cells relevant to the pathogenesis of asthma. Phosphodiesterase type-4 inhibitors such as cilomilast and roflumilast are under investigation for their anti-inflammatory and bronchodilator activity.[70,71] The thromboxane A_2 antagonist, seratrodast, is being tried for its effects on pulmonary function and mucus secretion. Asthma-relevant cytokines or chemokines have been targeted in a number of ways. Interleukin-4 (IL-4) stimulates a range of inflammatory processes in asthma, and soluble recombinant interleukin-4 receptor (IL-4R; rhuIL-4R) is being investigated[72,73] as an antagonist to bind and neutralise interleukin-4. Investigation into the recombinant human IL-4 variant, pitrakinra, is showing promising results in late phase asthmatic responses to allergen challenge.[74] The anti-CD25 interleukin-2 antagonist daclizumab has also been investigated with some reported benefit. An anti-interleukin-5 antibody, mepolizumab, has also been investigated;[70,73] although reductions in airway and bone-marrow eosinophils were observed, no clinical benefits were noted. Cytokines which have a potential anti-inflammatory effect are interleukin-10,[70] interleukin-12, and interferon gamma.[70,73] TNF-α may also play a role in severe asthma. The anti-TNF antibody infliximab, and the TNF receptor blocker etanercept have been shown to be effective in other inflammatory diseases.[70] Small studies using parenteral etanercept have shown some benefit on lung function and symptoms;[75,76] promising results have also been reported with intravenous infliximab.[77]

The effects of diet and dietary supplements on asthma have also been of interest. Modification of dietary fatty acids in the first 5 years of life,[78] did not reduce the risk of asthma or allergic disease in children considered to be at high risk for developing asthma. Dietary ascorbic acid supplementation has been investigated in a small group of adult patients with asthma and exercise-induced bronchoconstriction;[79] an improvement in post-exercise lung function and symptoms were noted compared with placebo. Maternal diet during pregnancy has also been examined; Vitamin D deficiency has been suggested as playing a possible role in immune-mediated disorders such as asthma.[80]

Exercise-induced asthma. For most patients exercise-induced asthma is an expression of poorly controlled asthma and regular treatment with inhaled corticosteroids should be reviewed.[6] Immediately before exercise, short-acting beta_2 agonists are the drugs of choice.[6,7] If exercise is a specific problem in patients taking inhaled corticosteroids, consideration may be given to leukotriene receptor antagonists, long-acting beta_2 agonists (although some tolerance may occur), cromoglicate, oral beta_2 agonists or theophylline.[6]

Pregnancy. It is particularly important that asthma should be well controlled during pregnancy; where this is achieved asthma has no important effects on pregnancy, labour, or the fetus.[5-7,81-84]

Inhalation has particular advantages as a means of giving drugs during pregnancy because the therapeutic action can be achieved without the need for plasma drug concentrations liable to have a pharmacological effect on the fetus. Systemic treatment should not be withheld if indicated, although there is insufficient information to support the use of anti-leukotrienes, except as continued treatment in women who were taking these before pregnancy for asthma not controlled by other medications.[6,82,83]

Severe exacerbations can have an adverse effect on pregnancy and should be treated promptly with conventional therapy, including oral or parenteral corticosteroids, oxygen, and nebulisation of a beta_2 agonist.[6,83] Prednisolone is a suitable corticosteroid for oral use since very little of the drug reaches the fetus.[82]

Occupational asthma. More than 10% of adult-onset asthma cases can be attributed to occupational exposure to pulmonary irritants.[85] Reduction or avoidance of exposure to the trigger is ideally an important component of management.[6,7,85] Symptoms may still persist; however, the prognosis for workers with occupational asthma is worse for those who remain exposed for more than one year after symptoms develop, compared with those removed earlier.[6]

Rhinitis and asthma. There is a significant association between allergic rhinitis and asthma.[7,86] It has been proposed that they are both manifestations of a single inflammatory process within the respiratory tract.[87] Asthma outcomes may be improved by following a combined therapeutic approach to comorbid allergic rhinitis and asthma.[86] Intranasal corticosteroids, an effective treatment for allergic rhinitis, have produced conflicting results in studies which assessed their effects on asthma symptoms.[86] Leukotriene receptor antagonists have produced benefits for patients with both allergic rhinitis and asthma and the anti-IgE antibody omalizumab may have a role in more severe cases.[86,88]

Chronic obstructive pulmonary disease

Chronic obstructive pulmonary disease (COPD, chronic obstructive lung disease, chronic obstructive airways disease) is a common disorder characterised by airflow obstruction which is more or less continuous and not fully reversible, unlike asthma. The airflow limitation is usually progressive and is associated with chronic inflammation which is mainly caused by cigarette smoking;[1,2] passive smoking exposure[3] genetic factors, infections, environmental pollution, and occupational dust and chemical exposure[4] may also have an aetiological role. Symptoms of COPD include chronic and progressive dyspnoea, wheeze, frequent respiratory-tract infections, cough, and sputum production.[1,2] COPD may affect central or proximal airways, peripheral airways, lung parenchyma, and pulmonary vasculature to varying degrees in individuals with the disease[1,5]

- **Central airways.** Hypertrophy of the mucous glands and an increase in the number of goblet cells within the bronchial mucosa leads to an increase in mucus production (*chronic bronchitis*). Patients suffer from a chronic productive cough with excessive sputum production, and have been described as 'blue bloaters'. Airway wall changes include squamous metaplasia of the airway epithelium, loss of cilia and ciliary dysfunction, and increased smooth muscle and connective tissue.
- **Peripheral airways.** *Bronchiolitis* is present in the small airways. Goblet cell hyperplasia, squamous cell metaplasia, inflammatory cell infiltration, and fibrosis are all seen, leading to irreversible narrowing of the airways.
- **Lung parenchyma.** *Emphysema* occurs in the lung parenchyma in COPD. An abnormal permanent enlargement of air spaces distal to the terminal bronchioles is accompanied by destruction of the alveolar wall without obvious fibrosis. There is excessive airway collapse upon expiration and irreversible airways obstruction. Dyspnoea is a prominent symptom; a marked loss of weight may also be noted. Patients may hyperventilate to maintain oxygen levels in the blood and have been called 'pink puffers' in contrast to the 'blue bloaters' of the classic bronchitic presentation. Emphysema can sometimes be caused by a hereditary deficiency of alpha$_1$-proteinase inhibitor (alpha$_1$ antitrypsin), see p.2253. Microscopic lesions can progress to form bullae, which are defined as an emphysematous space greater than 1 cm in diameter.
- **Pulmonary vasculature.** Initially these changes are characterised by thickening of the vessel wall and endothelial dysfunction. These are followed by increased vascular smooth muscle and inflammatory cell infiltration. In advanced stages of the disease there is collagen deposition and emphysematous destruction of the capillary bed.
- **Extrapulmonary changes.** Patients with severe COPD with hypoxaemia and hypercapnia can develop *cor pulmonale* (heart disease secondary to disease of the lungs and respiratory system) marked by pulmonary hypertension, right ventricular hypertrophy, and right heart failure.[5,6] COPD is also associated with systemic inflammation and skeletal muscle wasting.[5]

Management of COPD. Although there is less consensus than for asthma, guidelines for the treatment of COPD have been issued in a number of countries,[1,2,5,7-9] and some clinicians have developed clinical algorithms for management.[10] The most important therapeutic intervention is encouraging those patients who smoke to stop; this is the only intervention clearly shown to reduce disease progression.[1,11] Psychological support and adjunctive drug therapy may be required (see Smoking Cessation, p.2354). Prevention of respiratory infection should be considered; influenza vaccination is recommended[1,2,5,7,8] and can reduce serious illness and death in patients with COPD by about 50%.[1,5,7,8] Compared with influenza vaccination, there is less well-defined benefit from pneumococcal vaccination in patients with COPD.[7,8] It is generally recommended however,[1,2,7] and a study found most benefit in younger patients and those with more severe disease.[12]

Drug treatment is primarily symptomatic and palliative using bronchodilators, corticosteroids, and oxygen therapy.

First-line drug therapy for the treatment of COPD consists of bronchodilators to alleviate bronchospasm and any reversible component of the airways obstruction. Either an inhaled short-acting *antimuscarinic*, such as ipratropium bromide, or a short-acting *beta$_2$ agonist*, is suggested as the initial bronchodilator.[1,2,7] Short-acting beta$_2$ agonists, have a more rapid action, but there is some suggestion that short-acting antimuscarinics have a more prolonged effect.[7] Nevertheless, patients vary in their responsiveness and a beta$_2$ agonist should be tried in those who do not respond well to an antimuscarinic, and vice versa.[1] In mild disease inhaled bronchodilators can be used on an as-needed basis.[1,2,7,8] In moderate and more severe disease, therapeutic options include the regular use of these bronchodilators either alone[7] or in combination,[1,2,7,8] or the addition of long-acting bronchodilators such as the beta$_2$ agonists salmeterol and formoterol or the antimuscarinic tiotropium.[1,2,5,8] A review[13] of the role of long-acting bronchodilators in COPD found that they effectively improved lung function; however, they differed in their effects on other outcomes. Only tiotropium had consistent superiority to the short-acting bronchodilator ipratropium. A reduction in COPD exacerbations and related hospitalisations and improved symptoms and quality of life have been reported in two systematic reviews[14,15] of tiotropium compared with either placebo or ipratropium; improvements in lung function compared with either placebo, ipratropium, or a long-acting beta$_2$ agonist were also noted. A treatment algorithm for the introduction of long-acting bronchodilators has been proposed.[13] Regular treatment with long-acting bronchodilators is more effective and convenient than with shorter acting drugs.[1,2,7] Combining bronchodilators with different mechanisms and durations of action may increase the degree of bronchodilatation while avoiding the need for high doses and the associated adverse effects.[1,2] Ipratropium given with salmeterol has been associated with beneficial effects on quality of life and lung function compared with salmeterol alone.[16] Beneficial effects on lung function have also been reported with tiotropium plus formoterol compared with either treatment alone.[17,18] A *xanthine* such as an oral modified-release preparation of theophylline may also be considered, usually where short and long-acting bronchodilators are ineffective, or in patients unable to use inhaled therapy, as there is an increased risk of adverse effects and drug interactions as well as a need for monitoring.[1,2,7,8,19] Low-dose theophylline has been reported to reduce exacerbations in patients with COPD but does not increase post-bronchodilator lung function;[1] it may have positive cardiac inotropic effects which could be of value in cor pulmonale, see under Chronic Obstructive Pulmonary Disease, p.1148.

Guidelines recommend regular treatment with an *inhaled corticosteroid* combined with a long-acting beta$_2$ agonist for symptomatic patients with moderate to severe COPD and repeated exacerbations;[1,2,5] inhaled corticosteroids have been reported to reduce the rate of exacerbations.[20-22] Whether inhaled corticosteroids improve the long-term outcomes of COPD is less clear. There has been some suggestion that inhaled corticosteroids reduce mortality,[23,24] although a subsequent systematic review[22] did not find any significant effect. The effect, if any, that inhaled corticosteroids have on the rate of decline in lung function seen in COPD patients has also been studied. A pooled analysis[25] found that, although small but significant improvements in FEV$_1$ were recorded in the first 6 months of treatment with inhaled corticosteroid compared with placebo (particularly in ex-smokers and women), the rate of decline was not affected after the first 6 months. A systematic review[22] came to similar conclusions regarding lung function decline, but reported a slowing in the rate of decline in quality of life.

Although some guidelines[7] still recommend that patients requiring frequent bronchodilator therapy should receive a trial of oral prednisolone to assess whether inhaled corticosteroids are indicated, a large study[26] found that the response to a trial of oral prednisolone was unrelated to the change in FEV$_1$ and health status over the next 3 years of treatment with either inhaled fluticasone or placebo. A subsequent systematic review[22] also found that bronchodilator reversibility and bronchial hyper-responsiveness did not predict response to inhaled corticosteroids. Other guidelines[1,2] have therefore concluded that a short course of oral corticosteroid is a poor predictor of long-term response to inhaled therapy, and do not recommend this assessment.

Combined therapy with an inhaled corticosteroid and a long-acting beta$_2$ agonist is recommended for patients with more severe disease;[1,2,5,8] combination treatment should be stopped if there is no benefit after 4 weeks.[2] A study[27] designed to assess the effect of a combination inhaler containing an inhaled corticosteroid (fluticasone) and the long-acting beta$_2$ agonist salmeterol on survival in COPD patients did not show a significant reduction in all-cause mortality, but benefits were seen in the rate of exacerbations, lung function, and health status compared with placebo. Unexpectedly, the study investigators also reported a higher probability of pneumonia being reported as an adverse effect amongst patients given medications containing fluticasone. A later case-control study[28] examining the association between inhaled corticosteroids and pneumonia, also found an excess risk in patients with COPD which increased with higher doses of inhaled corticosteroids. Neither of these studies was able to confirm the diagnosis of pneumonia radiographically. Subsequent meta-analyses compared combined inhaled corticosteroid and long-acting beta$_2$ agonist in one inhaler with either placebo,[29] long-acting beta$_2$ agonist,[30] or inhaled corticosteroid.[31] Combination therapy led to a significant reduction in exacerbation rates compared with placebo, long-acting beta$_2$ agonist, and inhaled corticosteroid. All-cause mortality was reduced with combination therapy compared with either placebo or inhaled corticosteroid, but no impact was seen in comparison with long-acting beta$_2$ agonists. Again, the increased incidence of pneumonia in the inhaled corticosteroid groups was a cause of concern. Recently the UK MHRA has warned[32] of the need to be vigilant for the development of pneumonia and other infections in those with COPD who are receiving inhaled corticosteroids as the symptoms of infection often overlap with those of exacerbation of COPD; the use of corticosteroids should be reconsidered if such infections develop.

Long-term maintenance use of *oral* corticosteroids is not generally recommended,[1,2,5,7,8] although they have a place in the short-term management of exacerbations (see below), and withdrawal after an exacerbation may be difficult in some patients with advanced disease.[2]

In patients with severe COPD and persistent hypoxaemia, supplemental *oxygen* provided on an almost continuous long-term basis at home has been found to improve survival and alleviate complications such as cor pulmonale, polycythaemia and neuropsychological impairment.[33,34] Guidelines recommend starting oxygen therapy in patients whose resting PaO_2 is less than 55 mmHg (about 7.3 kPa), or whose arterial-oxygen saturation is less than about 88%.[1,2,5,7,8] It may also be considered when PaO_2 is between 55 and 60 mmHg (7.3 to 8 kPa) or arterial-oxygen saturation is less than 90%, or if there is evidence of polycythaemia, pulmonary hypertension, or right heart failure.[1,2,5,7,8] Nocturnal oxygen therapy may benefit some patients who suffer from nocturnal hypoxaemia,[2,5,7] but not all guidelines recommend it, as evidence for clinical benefits and improvement in survival is lacking.[5,8] Evidence of benefit from short-term, 'as-needed' oxygen inhalation after exertion is also lacking,[35] although a review of studies using ambulatory oxygen during an exercise test reported an improvement in exercise performance versus placebo;[36] selected patients might gain some benefits.[2,37]

A meta-analysis[38] of the use of *mucolytics* suggested a small reduction in exacerbations and in the total number of days of disability; benefit may be greater in patients with frequent or prolonged exacerbations. Although most guidelines do not recommend widespread use,[1,2,7] patients with chronic productive cough may be considered for treatment.[1,2] Patients who are not prescribed inhaled corticosteroids may also gain some benefit.[38] Improved pulmonary function has been reported in patients given aerosolised surfactant.[39]

There is some evidence that treatment with *cardiovascular drugs* can produce improvements in some pulmonary measures. Cohort and case control studies have reported a reduced COPD and pneumonia/influenza mortality risk in association with the use of statins.[40] Another case control study[41] also reported a reduction in pulmonary as well as cardiovascular outcomes with statins, ACE inhibitors, and angiotensin II receptor inhibitors, the largest benefits occurring with the combination of statins and either ACE inhibitors or angiotensin II receptor inhibitors. This combination was associated with a reduction in COPD hospitalisations, total mortality in both high- and low-risk groups, and myocardial infarction in the high-risk group.

A systematic review[42] to assess the effects of cardioselective beta blockers on respiratory function of patients with COPD found no adverse effects on lung function or respiratory symptoms compared with placebo, and concluded that they should not be routinely withheld from patients with COPD and cor pulmonale. Additionally, a retrospective study[43] noted a reduced mortality associated with beta blocker use in patients hospitalised for acute exacerbations of COPD.

Surgery may be used in selected patients with end-stage disease who remain symptomatic despite optimal medical treatment. Bullectomy may be used to remove a large bulla that does not contribute to gas exchange.[1,2,5,7,8,44] Lung transplantation (p.1815) may be used in very advanced COPD,[1,2,5,7,8] particularly in patients with idiopathic emphysema or $alpha_1$ antitrypsin deficiency.[44] In severe COPD with hyperinflation and obvious target areas, lung volume reduction surgery may be considered; it may be a better option than medical therapy to reduce mortality in patients with predominantly upper-lobe emphysema and low exercise capacity.[1,2,5,7,8,45]

Much *investigational therapy* has focussed, with variable results, on three key processes in COPD: oxidative tissue damage, protease-mediated tissue destruction, and leucocyte-driven chronic inflammation.[46,47] Oxidative stress has been targeted with antoxidants, particularly acetylcysteine.[1,48] Various mediators of the inflammatory processes have also been targeted, for example, inhibitors of interleukin-8[48,49] and phosphodiesterase type 4.[48,50,51] Other therapies which have been considered include inhibitors of cell signalling, TNF, and adhesion molecules and chemokines.[48] Retinoids have been studied in emphysema for potential positive effects on lung repair.[52] An inhaled formulation of trospium chloride is under development for the treatment of COPD. There is also evidence that oral therapy with polyunsaturated fatty acids (including omega-3 and omega-6 fatty acids) may improve exercise capacity.[53] As well as their established antibacterial effect, it has been suggested that macrolides also have immunomodulatory effects that could be useful in the management of respiratory diseases; however, their role in COPD remains to be determined.

Exacerbations. Patients with COPD frequently suffer acute exacerbations of their symptoms, and may require hospitalisation. They are triggered mainly by respiratory viruses and bacteria, which infect the lower airway and increase inflammation.[54] Treatment options include maximal bronchodilators, antibacterials, systemic corticosteroids, and oxygen as necessary, with appropriate management of any associated cardiovascular disorder.[1,2,5,7,8,55]

For *bronchodilator* therapy a short-acting $beta_2$ agonist may be combined with a short-acting antimuscarinic such as ipratropium,[1,5,7,8] although evidence for the effectiveness of this combination is lacking.[56] Some guidelines[1,2] further advocate use of a xanthine such as intravenous theophylline in unresponsive patients, although evidence of a clear benefit with systemic xanthines is inconsistent.[57]

Systemic *corticosteroids* are beneficial in acute exacerbations of COPD.[1,2,5,7,8] Studies[58,59] of severe acute exacerbation requiring hospitalisation have found systemic corticosteroids to improve lung function and reduce the length of hospital stay, and a later meta-analysis confirmed that early treatment with oral or parenteral corticosteroids reduced treatment failure and the need for additional treatment, although it was also associated with an increased risk of adverse effects.[60] Some consider that the most effective dose and duration of treatment is yet to be established,[60,61] although one study[58] found that a 2-week course was as effective as a longer course of 8 weeks. Guidelines suggest oral doses of prednisolone 30 to 50 mg daily, or equivalent, for 7 to 14 days.[1,2,5,7,8] There is also no evidence of long-term benefit.[58,59] Nebulised budesonide may be an alternative to oral corticosteroids in the treatment of non-acidotic exacerbations.[1]

The use of *antibacterials* for acute exacerbations has long been controversial. Meta-analysis[62] has suggested a decrease in mortality, treatment failure, and sputum purulence compared with placebo in moderately to severely ill patients, although the analysis included only a small number of studies, with important differences in design (see also Bronchitis, p.165). Guidelines recommend their use on an empirical basis where signs of infection are present[1,2,5,7,8] but do not support prophylactic antibacterial cover for those with recurrent acute exacerbations.[1,2,5,7] Short courses of antibacterial therapy (5 days or less) are as effective as longer courses in mild to moderate exacerbations.[63]

Oxygen therapy is required in patients with hypoxia; the goal is to maintain oxygen saturation above 90% but prevent increasing CO_2 retention.[1,2,5,7] The initial concentration of oxygen to give in COPD exacerbations is controversial. During the transfer to hospital, UK guidelines[2] recommend starting at 40% and titrating upwards if the oxygen saturation falls below 90% and downwards if the patient becomes drowsy or if the saturation exceeds 93 to 94%. Special care is needed for patients with known type II respiratory failure, especially if they require a long ambulance journey or receive oxygen at home for a prolonged period before an ambulance arrives, as uncontrolled oxygen therapy can result in suppression of respiratory drive, carbon dioxide narcosis, and respiratory arrest. In hospital, arterial blood gases should be used to guide treatment. Other guidelines[7] consider that lower initial oxygen concentrations of 24 to 28% are usually sufficient. A 2006 systematic review[64] found a lack of evidence on the safest way to provide initial oxygen treatment in COPD exacerbations.

Respiratory stimulants such as doxapram[65] are of limited use but may be considered when non-invasive ventilation is unavailable or inappropriate.[1,2]

Despite intensive therapy, some patients progress to respiratory muscle fatigue and require ventilatory support.

Acefylline Piperazine *(BAN, rINN)*

Acefilina piperazina; Acéfylline Pipérazine; Acefyllinum Piperazinum; Acepifylline; Piperazine Theophylline Ethanoate. Piperazine bis(theophyllin-7-ylacetate) (1:1).

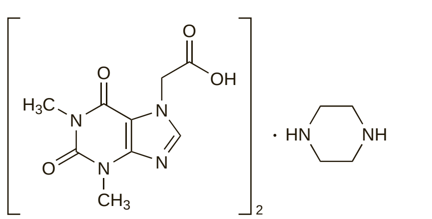
Ацефиллин Пиперазин

$(C_9H_{10}N_4O_4)_2,C_4H_{10}N_2 = 562.5.$

CAS — 18833-13-1; 18428-63-2.

ATC — R03DA09.

ATC Vet — QR03DA09.



Profile

Acefylline piperazine is a derivative of theophylline (p.1140) that has been used for its bronchodilator effects. It is not converted to theophylline in the body.

Preparations

Proprietary Preparations (details are given in Part 3)
India: Etophylate†; ***Indon.:*** Etaphylline.

Multi-ingredient: ***India:*** Cadiphylate.

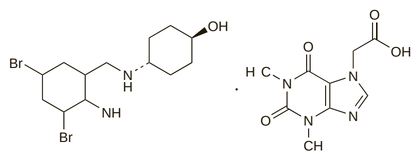
Ambroxol Acefyllinate *(BANM, rINNM)*

Acebrofylline; Acebrophylline; Acefilinato de ambroxol; Ambroxol Acéfylline; Ambroxoli Acefyllinas.

Амброксола Ацефиллинат

$C_{13}H_{18}Br_2N_2O,C_9H_{10}N_4O_4 = 616.3.$

CAS — 96989-76-3.



Profile

Ambroxol acefyllinate is a xanthine derivative that is used as a bronchodilator. It is given in an oral dose of 100 mg twice daily. For doses in children see below.

Administration in children. Ambroxol acefyllinate can be used as a bronchodilator in children. Children from 1 to 6 years of age may be given an oral dose of 25 mg twice daily, and children from 6 to 12 years, 50 mg twice daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Dogistin†; Mucomex†; ***Braz.:*** Brismucol; Brondilat; Bronfilil; Cebronfilina; Expecdilat; Filinar; Teomuc; ***Ital.:*** Ambromucil; Broncomnes; Surfolase; ***Mex.:*** Brismucol; ***Port.:*** Surfolase†; Tusolven†; ***Venez.:*** Brixilon; Bronilis.

Aminophylline *(BAN, pINN)*

Aminofilin; Aminofilina; Aminofylin; Aminofylliini; Aminofyllin; Aminophyllinum; Euphyllinum; Metaphyllin; Teofilinas-etilendiaminas; Teofillinetiléndiamin; Teofylliinietyleenidiamiini; Teofyllinetylendiamin; Theophyllaminum; Theophylline and Ethylenediamine; Theophylline Ethylenediamine Compound; Théophylline-éthylènediamine; Theophyllinum et ethylenediaminum. A mixture of theophylline and ethylenediamine (2:1), its composition approximately corresponding to the formula below.

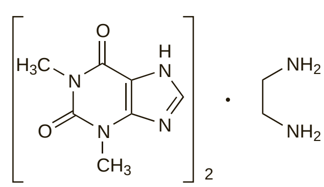
Аминофиллин

$(C_7H_8N_4O_2)_2,C_2H_4(NH_2)_2 = 420.4.$

CAS — 317-34-0 (anhydrous aminophylline).

ATC — R03DA05.

ATC Vet — QR03DA05.



Pharmacopoeias. In *Eur.* (see p.vii), *Int., US,* and *Viet.* Some pharmacopoeias include anhydrous and hydrated aminophylline in one monograph. Some pharmacopoeias do not specify the hydration state.

Ph. Eur. 6.2 (Theophylline-ethylenediamine; Aminophylline BP 2008). It contains 84.0 to 87.4% of anhydrous theophylline and 13.5 to 15.0% of anhydrous ethylenediamine. A white or slightly yellowish powder, sometimes granular. Freely soluble in water (the solution becomes cloudy through absorption of carbon dioxide); practically insoluble in dehydrated alcohol. Store in airtight containers. Protect from light.

USP 31 (Aminophylline). It is anhydrous or contains not more than two molecules of water of hydration. It contains not less than 84.0 and not more than 87.4% of anhydrous theophylline. It consists of white or slightly yellowish granules or powder, having a slight ammoniacal odour. Upon exposure to air it gradually loses ethylenediamine and absorbs carbon dioxide with the liberation of theophylline. One g dissolves in 25 mL of water to give a clear solution; 1 g dissolved in 5 mL of water crystallises upon standing, but redissolves when a small amount of ethylenediamine is added; insoluble in alcohol and in ether. Its solutions are alkaline to litmus. Store in airtight containers.

Aminophylline Hydrate *(BANM, pINNM)*

Aminofilina dwuwodna; Aminofilina hidratada; Aminofylin hydratovaný; Aminophylline, Hydrate d'; Aminophyllini Hydratum; Aminophyllinum Dihydricum; Aminophyllinum Hydricum; Teofylliinietyleenidiamiinihydraatti; Teofyllinetylendiaminhydrat; Théophylline-éthylènediamine hydratée; Theophyllinum et ethylenediaminum hydricum.

Аминофиллина Гидрат

$(C_7H_8N_4O_2)_2,C_2H_4(NH_2)_2,2H_2O = 456.5.$

CAS — 49746-06-7 (aminophylline dihydrate).

ATC — R03DA05.

ATC Vet — QR03DA05.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn, US,* and *Viet.* Some pharmacopoeias include anhydrous and hydrated aminophylline in one monograph. Some pharmacopoeias do not specify the hydration state.

Ph. Eur. 6.2 (Theophylline-ethylenediamine Hydrate; Aminophylline Hydrate BP 2008). It contains 84.0 to 87.4% of anhydrous theophylline and 13.5 to 15.0% of anhydrous ethylenediamine. A white or slightly yellowish powder, sometimes granular. Freely soluble in water (the solution becomes cloudy through absorption of carbon dioxide); practically insoluble in dehydrated alcohol. Store in well-filled airtight containers. Protect from light.

USP 31 (Aminophylline). It is anhydrous or contains not more than two molecules of water of hydration. It contains not less than 84.0 and not more than 87.4% of anhydrous theophylline. It consists of white or slightly yellowish granules or powder, having a slight ammoniacal odour. Upon exposure to air it gradually loses ethylenediamine and absorbs carbon dioxide with the liberation of theophylline. One g dissolves in 25 mL of water to give a clear solution; 1 g dissolved in 5 mL of water crystallises upon standing, but redissolves when a small amount of ethylenediamine is added; insoluble in alcohol and in ether. Its solutions are alkaline to litmus. Store in airtight containers.

Incompatibility. Aminophylline solutions should not be allowed to come into contact with metals.

Solutions of aminophylline are alkaline and if the pH falls below 8, crystals of theophylline will deposit.[1] Drugs known to be unstable in alkaline solutions, or that would lower the pH below the critical value, should not be mixed with aminophylline.

1. Edward M. pH—an important factor in the compatibility of additives in intravenous therapy. *Am J Hosp Pharm* 1967; **24:** 440–9.

Adverse Effects, Treatment, and Precautions

As for Theophylline, p.1140. Hypersensitivity has been associated with the ethylenediamine content.

Porphyria. Aminophylline is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Interactions

As for Theophylline, p.1142.

Pharmacokinetics

Aminophylline, a complex of theophylline with ethylenediamine, readily liberates theophylline in the body. The pharmacokinetics of theophylline are discussed on p.1145.

◊ Studies in healthy subjects suggested that ethylenediamine does not affect the pharmacokinetics of theophylline after oral or intravenous dosage.[1,2]

1. Aslaksen A, *et al.* Comparative pharmacokinetics of theophylline and aminophylline in man. *Br J Clin Pharmacol* 1981; **11:** 269–73.
2. Caldwell J, *et al.* Theophylline pharmacokinetics after intravenous infusion with ethylenediamine or sodium glycinate. *Br J Clin Pharmacol* 1986; **22:** 351–5.

Uses and Administration

Aminophylline has the actions and uses of theophylline (see p.1146) and is used similarly as a bronchodilator in the management of asthma (p.1108) and chronic obstructive pulmonary disease (p.1112). Aminophylline is also used to relieve neonatal apnoea (p.1118). It was formerly used as an adjunct in the treatment of heart failure, and may occasionally have a role in patients with this condition who are also suffering from obstructive airways disease. Aminophylline is usually preferred to theophylline when greater solubility in water is required, particularly in intravenous formulations.

Aminophylline may be given in the anhydrous form or as the hydrate, and doses may be expressed as either; aminophylline hydrate 1.09 mg is equivalent to about

1 mg of aminophylline. The USP 31 specifies that aminophylline preparations should be labelled with respect to their anhydrous *theophylline* content. As the pharmacokinetics of theophylline are affected by a number of factors including age, smoking, disease, diet, and drug interactions, the dose of aminophylline must be carefully individualised and serum-theophylline concentrations monitored (see Uses and Administration of Theophylline, p.1146).

In the management of **acute severe bronchospasm**, aminophylline may be given intravenously by slow injection or infusion. To reduce adverse effects, intravenous aminophylline should not be given at a rate greater than 25 mg/minute. In adults who have not been taking aminophylline, theophylline, or other xanthine-containing medication, a loading dose of 5 mg/kg ideal (lean) body-weight or 250 to 500 mg of aminophylline may be given intravenously over 20 to 30 minutes by slow injection or infusion, followed by a maintenance infusion dose of 500 micrograms/kg per hour. Older patients and those with cor pulmonale, heart failure, or liver disease may require lower maintenance doses; smokers often need higher maintenance doses. A loading dose may not be considered necessary unless the patient's condition is deteriorating.

Intravenous aminophylline is best avoided in patients already taking theophylline, aminophylline, or other xanthine-containing medication but, if considered necessary, the serum-theophylline concentration should first be assessed and the initial loading dose should be calculated on the basis that each 600 micrograms/kg of aminophylline (equivalent to 500 micrograms/kg theophylline) will increase serum-theophylline concentration by 1 microgram/mL.

In the management of **chronic bronchospasm** aminophylline may be given orally as modified-release preparations; a usual dose is aminophylline hydrate 225 to 450 mg twice daily. Therapy should start with the lower dose and be increased as appropriate. Retitration of the dosage is required if the patient is changed from one modified-release preparation to another as the bioavailability of modified-release aminophylline preparations may vary.

For doses of aminophylline used in children, see Administration in Children, below.

Intramuscular injection of aminophylline causes intense local pain and is not recommended.

Aminophylline has also been used as the hydrochloride.

Administration. RECTAL ADMINISTRATION. Absorption from aminophylline suppositories is erratic and this dose form has been associated with toxicity, hence the warnings that suppositories should not be used, especially in children. In the UK suppositories are no longer readily available and one hospital wishing to use the rectal route for apnoea in premature infants (see Neonatal Apnoea, p.1118) achieved therapeutic plasma-theophylline concentrations with a specially formulated rectal gel.[1]

1. Cooney S, *et al*. Rectal aminophylline gel in treatment of apnoea in premature newborn babies. *Lancet* 1991; **337:** 1351.

Administration in children. Aminophylline may be given intravenously, by slow injection or infusion, to manage **acute severe bronchospasm** in children. Doses should be calculated using ideal or lean body-weight. In children who have not been taking aminophylline, theophylline or other xanthine-containing medicine, UK licensed product information recommends a loading dose of 5 mg/kg given by slow injection or infusion over 20 to 30 minutes. Initial maintenance dose ranges are:

- 6 months up to 10 years of age: 1 mg/kg per hour
- 10 to 16 years of age: 800 micrograms/kg per hour

Although unlicensed in the UK for use in children under 6 months, the *BNFC* allows a dose of 1 mg/kg per hour from 1 month of age. Children aged from 16 years and above may be given adult doses, see Uses and Administration, above. Serum-theophylline concentrations should be used to guide further dose adjustments.

Children who are already receiving theophylline, aminophylline or other xanthine-containing medicines, should not normally receive intravenous aminophylline unless serum-theophylline concentration is available to guide dosage. Loading doses are based on the expectation that each 500 micrograms/kg lean body-weight of theophylline will result in a 1-microgram/mL increase in serum-theophylline concentration.

Oral modified-release preparations are given to children with a body-weight over 40 kg in the long-term management of **chronic bronchospasm**. An initial dose of 225 mg twice daily may be given if the child has not previously received xanthine preparations, increased after 1 week to 450 mg twice daily according to serum-theophylline concentrations. Different modified-release preparations are not considered interchangeable.

Aminophylline may also be used in the management of **neonatal apnoea** (see p.1118). Although the injection is unlicensed in the UK in children under 6 months of age, the *BNFC* recommends an initial dose of 6 mg/kg by intravenous injection over 20 minutes. This is followed by 2.5 mg/kg every 12 hours, increased if necessary to 3.5 mg/kg every 12 hours. The plasma theophylline concentration for optimum response in neonatal apnoea is 8 to 12 mg/litre. For further information on the dosage of theophylline itself in neonates, see Administration in Infants, p.1147.

Erectile dysfunction. For reference to the use of a cream containing aminophylline, isosorbide dinitrate, and codergocrine mesilate in the treatment of erectile dysfunction, see under Glyceryl Trinitrate, p.1298.

Methotrexate neurotoxicity. For reference to the use of aminophylline or theophylline to relieve the acute neurotoxicity of methotrexate, see Other Drugs, under Treatment of Adverse Effects, p.747.

Motor neurone disease. A study[1] in 25 patients with amyotrophic lateral sclerosis (see p.2380) found that aminophylline improved the endurance of respiratory muscles and increased the handgrip strength of skeletal muscles; it may have some potential therapeutic benefit in such patients.

1. Berto MC, *et al*. Acute action of aminophylline in patients with amyotrophic lateral sclerosis. *Acta Neurol Scand* 2007; **115:** 301–5.

Reduction of body fat. Cosmetic aminophylline cream has been promoted for its supposed ability to remove fat ('cellulite') from the thighs.[1] Concern has been raised about the potential for topical sensitisation.[2]

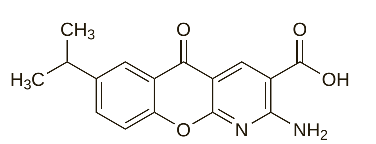
Amlexanox *(BAN, USAN, rINN)*

AA-673; Amlexanoxo; Amlexanoxum; Amoxanox; CHX-3673. 2-Amino-7-isopropyl-5-oxo-5*H*-[1]benzopyrano[2,3-*b*]pyridine-3-carboxylic acid.

Амлексанокс

$C_{16}H_{14}N_2O_4$ = 298.3.
CAS — 68302-57-8.
ATC — A01AD07; R03DX01.
ATC Vet — QA01AD07; QR03DX01.



Profile

Amlexanox has a stabilising action on mast cells resembling that of sodium cromoglicate (p.1136) and also acts as a leukotriene inhibitor. It is given orally in the management of asthma (p.1108) and for allergic rhinitis (p.565); a dose of 25 or 50 mg three times daily has been suggested. Amlexanox is also given as a metered-dose nasal spray for allergic rhinitis.

Amlexanox is also applied as a 5% oral paste four times daily in the management of aphthous ulcers (see Mouth Ulceration, p.1700). A 2-mg biodegradable oral disc designed to deliver amlexanox locally is also available.

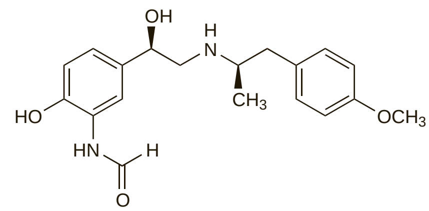
Arformoterol Tartrate *(USAN, rINNM)* ⊗

Arformotérol, Tartrate d'; Arformoteroli Tartras; *R,R*-Formoterol Tartrate; Tartrato de arformoterol. (-)-*N*-[2-Hydroxy-5-((1*R*)-1-hydroxy-2-{[(1*R*)-2-(4-methoxyphenyl)-1-methylethyl]amino}ethyl)phenyl]formamide hydrogen (2*R*,3*R*)-2,3-dihydroxybutanedioate.

Арформотерола Тартрат

$C_{19}H_{24}N_2O_4,C_4H_6O_6$ = 494.5.
CAS — 67346-49-0 (arformoterol); 200815-49-2 (arformoterol tartrate).



(arformoterol)

Profile

Arformoterol is the *R,R*-enantiomer of the beta$_2$-adrenoceptor agonist formoterol (p.1122) and has similar properties. Arformoterol is a long-acting selective beta$_2$ agonist which is used as a bronchodilator in the management of chronic obstructive pulmonary disease (p.1112). It is given as the tartrate, but doses are described in terms of the base; 22 micrograms of arformoterol tartrate is equivalent to about 15 micrograms of arformoterol. Given as a nebulised solution, a usual inhaled dose of arformoterol is 15 micrograms given every 12 hours.

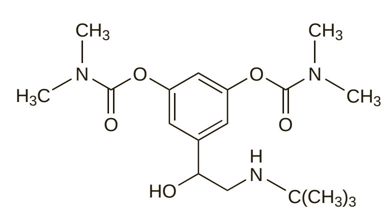
Бамбутерола Гидрохлорид

$C_{18}H_{29}N_3O_5,HCl$ = 403.9.
CAS — 81732-65-2 (bambuterol); 81732-46-9 (bambuterol monohydrochloride).
ATC — R03CC12.
ATC Vet — QR03CC12.



(bambuterol)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Bambuterol Hydrochloride). A white or almost white crystalline powder. It exhibits polymorphism. Freely soluble in water; soluble in alcohol.

Adverse Effects and Precautions

As for Salbutamol, p.1131. Bambuterol is not recommended for patients with severe hepatic impairment as its metabolism would be unpredictable. The dose of bambuterol should be reduced in renal impairment (see below). It is unsuitable for the relief of acute bronchospasm or in patients with unstable respiratory disease.

Effects on the heart. A prescription event monitoring study found an excess risk of non-fatal heart failure in elderly patients receiving bambuterol, particularly in the first month of treatment.[1] See also under Salbutamol, p.1131.

1. Martin RM, *et al.* Risk of non-fatal cardiac failure and ischaemic heart disease with long acting β agonists. *Thorax* 1998; **53:** 558–62.

Interactions

As for Salbutamol, p.1132. Bambuterol inhibits plasma cholinesterases and can prolong the action of drugs such as suxamethonium (see Sympathomimetics, under Suxamethonium, p.1912) that are inactivated by these enzymes.

Pharmacokinetics

Nearly 20% of a dose of bambuterol is absorbed from the gastrointestinal tract after oral doses. It is slowly metabolised in the body to its active metabolite, terbutaline; peak terbutaline concentrations are reported to occur about 4 to 7 hours after a dose of bambuterol as tablets. The slow rate at which metabolism occurs determines the prolonged duration of action of bambuterol of at least 24 hours. Hydrolysis of bambuterol is catalysed by plasma cholinesterase; however, bambuterol also inhibits plasma cholinesterase and therefore partly inhibits its own metabolism. For the metabolism and excretion of terbutaline, see p.1139.

5. Rosenborg J, *et al.* Pharmacokinetics of bambuterol during oral administration of plain tablets and solution to healthy adults. *Br J Clin Pharmacol* 2000; **49:** 199–206.

Uses and Administration

Bambuterol is an inactive prodrug of terbutaline (p.1138), a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on beta$_2$ receptors (a beta$_2$ agonist). It has similar actions to those of salbutamol (p.1133) except that it has a more prolonged duration of action (at least 24 hours). Bambuterol hydrochloride is used as a long-acting bronchodilator for persistent reversible airways obstruction in conditions such as asthma (p.1108). The usual dose is 10 to 20 mg orally once daily at bedtime. Doses may need to be reduced in renal impairment (see below).

Administration in renal impairment. Licensed product information recommends that the initial dose of bambuterol hydrochloride should be halved in patients with renal impairment (glomerular filtration rate less than 50 mL/minute). Further doses should be adjusted according to response.

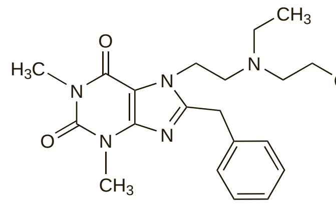
Бамифиллина Гидрохлорид

$C_{20}H_{27}N_5O_3,HCl = 421.9.$

CAS — 2016-63-9 (bamifylline); 20684-06-4 (bamifylline hydrochloride).

ATC — R03DA08.

ATC Vet — QR03DA08.



(bamifylline)

Profile

Bamifylline hydrochloride is a theophylline derivative (p.1140) that is used for its bronchodilator properties in reversible airways obstruction. It is not converted to theophylline in the body. It is given in usual oral doses of 600 or 900 mg daily in 2 or 3 divided doses. It is also given rectally as suppositories, and by slow intravenous infusion.

Bitolterol Mesilate *(BANM, rINNM)* ⊗

Bitoltérol, Mésilate de; Bitolterol Mesylate *(USAN)*; Bitolteroli Mesilas; Mesilato de bitolterol; Win-32784. 4-[2-(*tert*-Butylamino)-1-hydroxyethyl]-*o*-phenylene di-*p*-toluate methanesulphonate.

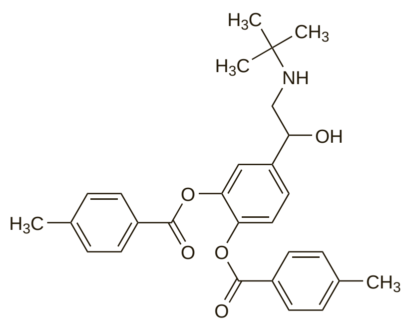
Битолтерола Мезилат

$C_{28}H_{31}NO_5,CH_4O_3S = 557.7.$

CAS — 30392-40-6 (bitolterol); 30392-41-7 (bitolterol mesilate).

ATC — R03AC17.

ATC Vet — QR03AC17.



(bitolterol)

Profile

Bitolterol is an inactive prodrug that is hydrolysed in the body to colterol, a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on beta$_2$ receptors (a beta$_2$ agonist). It has similar properties to those of salbutamol (p.1131).

It has been used as a bronchodilator in the management of diseases with reversible airways obstruction such as asthma (p.1108) or in some patients with chronic obstructive pulmonary disease (p.1112); inhalation results in the rapid onset of bronchodilatation (2 to 4 minutes) with a duration of action of 5 or more hours.

Bitolterol has been given by inhalation via a metered-dose aerosol supplying 370 micrograms of bitolterol mesilate per inhalation. For the *relief* of bronchospasm the usual adult dose is 2 inhalations (740 micrograms) followed by a third inhalation (370 micrograms) if required. For the *prevention* of bronchospasm the usual adult dose is 2 inhalations (740 micrograms) every 8 hours. Maximum doses have been stated to be 3 inhalations (1110 micrograms) every 6 hours or 2 inhalations (740 micrograms) every 4 hours. In patients with asthma, as-required beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, bitolterol indicates deterioration of asthma control and the need for review of therapy.

Alternatively, a 0.2% inhalation solution of bitolterol mesilate has been given by nebulisation. Using *continuous flow* nebulisation, the usual adult dose is from 1.5 to 3.5 mg three or four times daily as required, to a maximum daily dose of 14 mg. Using *intermittent flow* nebulisation, the usual adult dose is 0.5 to 2 mg three or four times daily as required, up to a maximum daily dose of 8 mg. In all cases dosage intervals should be greater than or equal to 4 hours.

Preparations

Proprietary Preparations (details are given in Part 3)

USA: Tornalate.

Bufylline *(BAN)*

Ambuphylline *(USAN)*; Bufilina; Theophylline-aminoisobutanol. 2-Amino-2-methylpropan-1-ol theophyllinate.

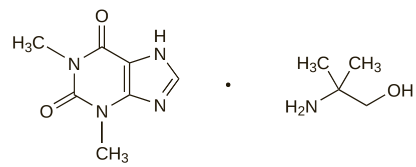
Буфиллин

$C_{11}H_{19}N_5O_3 = 269.3.$

CAS — 5634-34-4.

ATC — R03DA10.

ATC Vet — QR03DA10.



Profile

Bufylline is a theophylline derivative (p.1140) that has been used for its bronchodilator effects as an ingredient of preparations promoted for coughs and other respiratory-tract disorders. The ethiodide has also been used.

Preparations

Proprietary Preparations (details are given in Part 3)

Breast feeding. Studies examining the transfer of caffeine into breast milk after oral doses of 35 to 336 mg of caffeine have recorded peak maternal plasma concentrations of 2.4 to 4.7 micrograms/mL, peak maternal saliva concentrations of 1.2 to 9.2 micrograms/mL, and peak breast-milk concentrations of 1.4 to 7.2 micrograms/mL. At these concentrations in breast milk, the calculated daily caffeine ingestion by breast-fed infants ranged from 1.3 to 3.1 mg, which was not thought to present a hazard, although irritability and a poor sleeping pattern have been reported.[1-4]

The American Academy of Pediatrics[5] states that caffeine is excreted slowly by the infant and may be associated with irritability and poor sleeping pattern when ingested by breast-feeding mothers. However, no effects occur with moderate intake of caffeinated beverages (2 to 3 cups daily) and caffeine is usually compatible with breast feeding.

Effects on the cardiovascular system. An increased caffeine intake has been associated with an increase in daytime blood pressure.[1] The study, in 82 healthy, normotensive adolescents, suggested that caffeine consumption may be a factor contributing to essential hypertension in young people.

High dose caffeine (25 mg/kg) used as a loading dose in the prevention and treatment of neonatal apnoea (see p.1118) resulted in a marked reduction of cerebral and intestinal blood flow velocity in preterm infants;[2] no changes were noted in left ventricular output, blood pressure, or heart rate. The authors attributed the effect on blood flow velocity to vasoconstriction, and suggested a smaller caffeine loading dose, repeated several hours later. A later study, also in preterm infants, which examined the effect of a divided loading dose of caffeine (12.5 mg/kg repeated after 4 hours), found that cerebral blood flow velocity was decreased after the second dose; intestinal blood flow velocity and left ventricular output remained unchanged.[3] The authors concluded that the 20% reduction in cerebral blood flow velocity observed was probably not meaningful for infants with adequate cerebral oxygen supply; however, an infant's ability to respond to hypoxaemia by vasodilatation may be compromised.

For a discussion of the effects of caffeine-containing beverages on cardiovascular risk factors, see p.2415.

1. Regestein QR. Pathologic sleepiness induced by caffeine. *Am J Med* 1989; **87:** 586–8.

Headache. Headache is a recognised symptom of caffeine withdrawal and even subjects who drink moderate amounts of coffee can develop headaches lasting 1 to 6 days when switched to a decaffeinated brand.[1] It has also been suggested that postoperative headache could be attributed to caffeine withdrawal as fasting patients are required to abstain from drinking tea or coffee before surgical procedures. Several studies[2-4] have found a positive association between postoperative headache and daily caffeine consumption, although there have also been negative findings.[5] A prospective study suggested that a prophylactic intravenous dose of caffeine on the day of surgery reduced the likelihood of postoperative headache in patients at risk of caffeine withdrawal.[6]

In a case-control study,[7] investigating the possible association of dietary and medicinal caffeine use with chronic daily headache (CDH), caffeine was found to be a modest risk factor for CDH onset, regardless of headache type. Patients suffering from CDH were more likely overall to have been high caffeine consumers before the onset of CDH; no association was found with current caffeine consumption.

Pregnancy. In the USA, the FDA has advised pregnant women to limit their intake of caffeine and caffeine-containing beverages to a minimum, but this recommendation was based largely on *animal* studies and the effect of caffeine on the human fetus and fetal loss during pregnancy is controversial.[1] Although some studies found no evidence that moderate caffeine use increased the risk of spontaneous abortion,[2,3] others have reported conflicting results.[4,5] There is some evidence for an effect on fetal growth, but again it is not clear that this applies generally: a prospective population-based study in the UK found that a decreased birth-weight with increased caffeine intake was only significant in smokers.[6] The authors of this study concurred that a reduction in caffeine intake during pregnancy would be prudent, together with stopping smoking. An association between high maternal caffeine intake during pregnancy and an increased risk of the sudden infant death syndrome has also been reported,[7] although another study found no such association.[8]

Interactions

Like theophylline (see p.1142) caffeine undergoes extensive metabolism by hepatic microsomal cytochrome P450 isoenzyme CYP1A2, and is subject to numerous interactions with other drugs and substances which enhance or reduce its metabolic clearance.

◊ Reviews.

1. Carrillo JA, Benitez J. Clinically significant pharmacokinetic interactions between dietary caffeine and medications. *Clin Pharmacokinet* 2000; **39:** 127–53.

Alcohol. In a study of 8 healthy subjects given an oral dose of alcohol of 2.2 mL/kg, caffeine 150 mg by mouth did not antagonise the central effects of alcohol and, instead, a synergistic interaction occurred which further increased reaction time. The common practice of drinking coffee after drinking alcohol in order to sober up is not supported by these results.[1] Another study[2] found that some antagonism of the central effects of alcohol was produced by caffeine, although there was no reversal of subjective sensations of drunkenness; however the dose of caffeine in this study (400 mg) was considerably higher.

2. Azcona O, *et al.* Evaluation of the central effects of alcohol and caffeine interaction. *Br J Clin Pharmacol* 1995; **40:** 393–400.

Antiarrhythmics. In 7 healthy subjects and 5 patients with cardiac arrhythmias, *mexiletine* in a single dose of 200 mg and a dose of 600 mg daily respectively, reduced the elimination of caffeine by 30 to 50%.[1] *Lidocaine*, *flecainide*, and *tocainide* had no effect on caffeine elimination in healthy subjects.[1]

1. Joeres R, Richter E. Mexiletine and caffeine elimination. *N Engl J Med* 1987; **317:** 117.

Antibacterials. Caffeine elimination half-life has been reported to be increased and clearance decreased when given with *ciprofloxacin*,[1-3] *enoxacin*,[2,3] and *pipemidic acid*,[2,3] whereas *lomefloxacin*,[4] *norfloxacin*,[2,3] and *ofloxacin*[2,3] had little or no effect on these parameters. Enoxacin had the greatest inhibitory effect on caffeine clearance.[2,3]

2. Harder S, *et al.* Ciprofloxacin-caffeine: a drug interaction established using in vivo and in vitro investigations. *Am J Med* 1989; **87** (suppl 5A): 89–91S.
3. Barnett G, *et al.* Pharmacokinetic determination of relative potency of quinolone inhibition of caffeine disposition. *Eur J Clin Pharmacol* 1990; **39:** 63–9.
4. Healy DP, *et al.* Lack of interaction between lomefloxacin and caffeine in normal volunteers. *Antimicrob Agents Chemother* 1991; **35:** 660–4.

Antidepressants. Fluvoxamine has been reported to significantly reduce the clearance and prolong the elimination half-life of caffeine.[1] The clinical importance of this interaction, attributed to inhibition of cytochrome P450 isoenzyme CYP1A2 by fluvoxamine, remains to be established.

1. Culm-Merdek KE, *et al.* Fluvoxamine impairs single-dose caffeine clearance without altering caffeine pharmacodynamics. *Br J Clin Pharmacol* 2005; **60:** 486–93.

Antiepileptics. The mean clearance of caffeine was increased and its half-life decreased in epileptic patients taking *phenytoin* compared with healthy controls, resulting in lower plasma-caffeine concentrations. Treatment with *carbamazepine* or *valproic acid* had no effect on the pharmacokinetics of caffeine.[1]

1. Wietholtz H, *et al.* Effects of phenytoin, carbamazepine, and valproic acid on caffeine metabolism. *Eur J Clin Pharmacol* 1989; **36:** 401–6.

Antifungals. In a single-dose study in healthy subjects, *terbinafine* 500 mg by mouth decreased the clearance and increased the elimination half-life of caffeine 3 mg/kg given intravenously. *Ketoconazole* 400 mg by mouth did not prolong the elimination of caffeine to a significant extent.[1]

1. Wahlländer A, Paumgartner G. Effect of ketoconazole and terbinafine on the pharmacokinetics of caffeine in healthy volunteers. *Eur J Clin Pharmacol* 1989; **37:** 279–83.

Antigout drugs. In a study in 2 healthy subjects, the plasma half-life of caffeine was essentially unchanged by 7 days of treatment with *allopurinol* 300 mg or 600 mg daily by mouth. However, allopurinol caused a specific, dose-dependent inhibition of the conversion of 1-methylxanthine to 1-methyluric acid.[1]

1. Grant DM, *et al.* Effect of allopurinol on caffeine disposition in man. *Br J Clin Pharmacol* 1986; **21:** 454–8.

Gastrointestinal drugs. *Cimetidine* 1 g daily by mouth reduced the systemic clearance of caffeine and prolonged its elimination half-life in 5 healthy subjects. Although the steady-state plasma-caffeine concentration would increase by about 70%, it was thought unlikely that this would produce adverse clinical effects.[1] However, in contrast a study in 11 children given cimetidine in doses of 11 to 36 mg/kg daily for gastritis found no evidence that it altered the metabolism of a dose of ^{13}C-labelled caffeine.[2]

2. Parker AC, *et al.* Lack of inhibitory effect of cimetidine on caffeine metabolism in children using the caffeine breath test. *Br J Clin Pharmacol* 1997; **43:** 467–70.

Lithium. For mention of the effect of caffeine on serum-lithium concentrations, see Xanthines, p.405.

Methoxsalen. Single oral doses of 1.2 mg/kg methoxsalen have reduced the clearance of caffeine in patients with psoriasis,[1,2] consistent with a cytochrome P450 isoenzyme CYP1A2-dependent inhibition of caffeine demethylation.[2]

2. Bendriss EK, *et al.* Inhibition of caffeine metabolism by 5-methoxypsoralen in patients with psoriasis. *Br J Clin Pharmacol* 1996; **41:** 421–4.

Sex hormones. The clearance of caffeine has been reported to be reduced and its elimination half-life increased in women taking *oral contraceptives*.[1-3] This interaction was thought to be due to impairment of hepatic metabolism of caffeine by sex hormones and could result in increased accumulation of caffeine. Similar results have been reported[4] in a study of postmenopausal women given oestrogens for *hormone replacement therapy* and caffeine.

4. Pollock BG, *et al.* Inhibition of caffeine metabolism by estrogen replacement therapy in postmenopausal women. *J Clin Pharmacol* 1999; **39:** 936–40.

Sympathomimetics. Use of caffeine 400 mg with *phenylpropanolamine* 75 mg, both given orally as modified-release preparations, produced greater plasma-caffeine concentrations in healthy subjects than caffeine alone. Greater increases in blood pressure and more reports of physical adverse effects occurred after the combination than after either drug alone.[1]

Giving caffeine with *ephedrine* has been reported to produce significant cardiovascular, metabolic, and hormonal responses, including increased systolic blood pressure and heart rate, and raised fasting glucose and insulin.[2] These enhanced effects appear to be the result of a pharmacodynamic rather than a pharmacokinetic interaction, and led to the issue of a warning by Health Canada in 2006 not to use weight loss products containing both caffeine and ephedrine, since the combination had caused reported adverse effects ranging from dizziness, tremors, headaches, and irregularities in heart rate to seizures, psychosis, heart attacks, and stroke.[3] Those particularly at risk include individuals suffering from ischaemic heart disease, hypertension, and diabetes.[2,3]

2. Haller CA, *et al.* Enhanced stimulant and metabolic effects of combined ephedrine and caffeine. *Clin Pharmacol Ther* 2004; **75:** 259–73.
3. Health Canada. Health Canada advises consumers not to use weight loss products containing ephedrine and caffeine (issued 23rd May 2006). Available at: http://www.hc-sc.gc.ca/ahc-asc/media/advisories-avis/_2006/2006_33-eng.php (accessed 09/07/08)

Theophylline. For the effect of caffeine on the metabolism and elimination of theophylline, see p.1144.

Pharmacokinetics

Caffeine is absorbed readily after oral doses and is widely distributed throughout the body. It is also absorbed through the skin. Absorption when given rectally by suppository may be slow and erratic. Absorption after intramuscular injection may be slower than after oral doses. Caffeine passes readily into the CNS and into saliva; low concentrations are also present in breast milk. Caffeine crosses the placenta.

In adults, caffeine is metabolised almost completely in the liver via oxidation, demethylation, and acetylation, and is excreted in the urine as 1-methyluric acid, 1-methylxanthine, 7-methylxanthine, 1,7-dimethylxanthine (paraxanthine), 5-acetylamino-6-formylamino-3-methyluracil (AFMU), and other metabolites with only about 1% unchanged. Hepatic cytochrome P450 isoenzyme CYP1A2 is involved in caffeine enzymatic metabolism. Neonates have a greatly reduced capacity to metabolise caffeine, due to their immature hepatic enzyme systems, and it is largely excreted unchanged in the urine. By 9 months of age, urinary excretion is similar to that seen in adults. Elimination half-lives are about 3 to 7 hours in adults but may be about 3 to 4 days in neonates.

Metabolism and excretion. The metabolism of caffeine has been shown to be dose dependent[1,2] with clearance decreasing as the dose is increased suggesting saturable metabolism. Four- to fivefold differences in plasma half-lives of caffeine are common among healthy people. The plasma half-life of caffeine is decreased by smoking[3] and by exercise,[4] and is increased by liver disease such as cirrhosis and viral hepatitis,[3,5] and in pregnancy.[3] The plasma half-life of caffeine is not affected by old age[6] or obesity.[7] Drug interactions also affect the pharmacokinetics of caffeine (see above).

Uses and Administration

Caffeine is a methylxanthine that, like theophylline (p.1146), inhibits the enzyme phosphodiesterase and has an antagonistic effect at central adenosine receptors. It is a stimulant of the CNS, particularly the higher centres, and it can produce a condition of wakefulness and increased mental activity. It may also stimulate the respiratory centre, increasing the rate and depth of respiration. Its bronchodilating properties are weaker than those of theophylline. Caffeine facilitates the performance of muscular work and increases the total work that can be performed by a muscle. The diuretic action of caffeine is weaker than that of theophylline.

Caffeine is used as a mild CNS stimulant in usual oral doses of 50 to 100 mg, although doses of up to 200 mg may be used. Doses should not be taken more often than every 3 hours. It is also frequently included in oral analgesic preparations with aspirin, paracetamol, or codeine in unit doses of about 15 to 65 mg but its clinical benefit is debated (see Pain, below). Caffeine is sometimes given with ergotamine in preparations for the treatment of migraine, usually in unit doses of 100 mg. Caffeine citrate has been used similarly. For details of doses in children, see Administration in Children, below.

Caffeine and sodium benzoate and caffeine and sodium salicylate are readily soluble in water and have been used when caffeine is to be given by injection.

Beverages of coffee, tea, and cola provide active doses of caffeine (see p.2415).

Administration in children. Caffeine is used in the short-term treatment of neonatal apnoea of prematurity (below). An initial loading dose of caffeine citrate is 20 mg/kg (equivalent to 10 mg/kg caffeine), followed by a maintenance dose of caffeine citrate 5 mg/kg daily. These doses may be given either orally or by intravenous infusion. Serum concentrations of caffeine should be measured before starting treatment in infants who have already been treated with theophylline (which is metabolised to caffeine in infants) or whose mothers consumed caffeine before delivery; serious toxicity has been associated with serum concentrations greater than 50 micrograms/mL.

Asthma. Caffeine's bronchodilating activity is about 40% that of theophylline[1] and oral doses of 5 or 10 mg/kg have been shown to produce an effect.[2,3] Because of its weak action other xanthines are generally recommended in asthma (p.1108), but it may need to be avoided before tests of lung function.[4]

Dementia. A cohort study in 7017 patients aged 65 years and over examined the association between caffeine intake, cognitive decline, and incident dementia.[1] Caffeine consumption itself was found to be significantly associated with a wide range of variables also associated with cognitive decline, such as age, gender, depressive symptoms, and cardiovascular disease. Although no relationship was found between baseline caffeine intake and incident dementia in a 4-year follow-up period, caffeine consumption appeared to reduce cognitive decline in women without dementia. The authors concluded that further studies are required to ascertain whether caffeine may be of value in prolonging the period of mild cognitive impairment in women before a diagnosis of dementia.

Diabetes mellitus. A single dose of caffeine 250 mg proved beneficial in augmenting warning symptoms and physiological responses to experimentally-induced hypoglycaemia in diabetic patients,[1] and was suggested as a potentially useful adjunct for diabetics who have difficulty in recognising the onset of hypoglycaemia (see Diabetic Emergencies, p.435). In a subsequent placebo-controlled crossover study oral caffeine 200 mg twice daily appeared to enhance the intensity of hypoglycaemic warning symptoms in patients with type 1 diabetes on a low-caffeine diet.[2] A later study[3] reported an association between caffeine and a reduction in the frequency of nocturnal hypoglycaemia in patients with type 1 diabetes, which the authors suggested may explain the increase in warning symptoms and hormonal responses previously reported in daytime hypoglycaemia. Caffeine has also been seen to impair postprandial glucose metabolism in patients with type 2 diabetes,[4] raising concern about the potential hazards of caffeine in these patients for whom decreases in insulin sensitivity might increase average glucose levels and the risk of diabetic complications.

Diagnosis and testing. Caffeine excretion assessed by measuring its urinary metabolites or by the exhalation of labelled CO_2 in breath after doses of ^{13}C- or ^{14}C-labelled caffeine has been used to develop liver function tests and to determine the activity of specific enzymes such as xanthine oxidase, P450 cytochromes, and polymorphic *N*-acetyltransferase.[1]

Caffeine given orally has been used to assess acetylator status by determining the metabolic ratio of the metabolites 5-acetylamino-6-formylamino-1-methyluracil (AFMU) to 1-methylxanthine in urine,[2] but some have questioned its value.[3]

Caffeine has also been investigated in the diagnosis of susceptibility to malignant hyperthermia.[4] Intramuscular injection induced a temporary hypermetabolic reaction in subjects susceptible to malignant hyperthermia, but not in non-susceptible subjects or healthy controls. The authors suggested that monitoring of carbon dioxide, produced by hypermetabolism, might offer a minimally invasive test for such susceptibility.

ECT. In patients whose seizure duration is declining despite maximal ECT stimulation, pretreatment with high-dose intravenous caffeine increases seizure duration without affecting seizure threshold. Theophylline has been used similarly, see p.1142.

Neonatal apnoea. Apnoea of infancy has been defined as cessation of breathing either lasting 20 seconds or more or associated with bradycardia, cyanosis, pallor, and marked hypotonia, for which no specific cause can be identified.[1] Premature infants (less than 37 weeks of gestation) can exhibit periodic breathing with pathological apnoea (apnoea of prematurity); this usually resolves as the infant approaches term and the neurological systems controlling ventilation mature.[1,2]

The management of neonatal apnoea for which no underlying disorder can be found may involve supportive measures such as cardiorespiratory monitoring;[1] continuous positive airways pressure and drug therapy may be required.[3]

The methylxanthines, aminophylline, theophylline, and caffeine, reduce the frequency of apnoea and the need for mechanical ventilation in preterm infants during the first seven days of therapy.[4] In preterm infants given intermittent positive airway pressure, prophylactic methylxanthine treatment increases the chances of successful extubation within one week.[5] There is evidence to suggest that this benefit might be more helpful in infants of extremely low birth-weight extubated in the first week. High doses of caffeine, 20 mg/kg daily, have been used around the time of extubation in neonates born at less than 30 weeks of gestation. Short term benefits were noted,[6] and no evidence of harm in the first year of life. Caffeine has also been reported to reduce the incidence of bronchopulmonary dysplasia in infants with very low birth-weight,[3] so that positive airways pressure could be stopped earlier in infants given caffeine compared with those given placebo. A later evaluation of these infants found that caffeine therapy improved the rate of survival without neurodevelopmental disability at 18 to 21 months.[7] The incidence of cerebral palsy and cognitive delay were also reduced. Earlier stopping of positive airway pressure in the infants assigned to caffeine explained almost half of the beneficial long-term effect of caffeine, but further studies are required to ascertain other potential mechanisms of action. Caffeine has a wider therapeutic index, fewer peripheral adverse effects than theophylline, and a longer half-life enabling once-daily dosage, and is therefore preferred.[4,8] Caffeine is given as the citrate salt. It is well absorbed when given orally; intravenous treatment is rarely necessary. For details of doses, see Administration in Children, above. The *BNFC* considers appropriate serum concentrations in neonatal apnoea to be 8 to 12 micrograms/mL for theophylline and 10 to 20 micrograms/mL for caffeine. Higher caffeine concentrations of 25 to 35 micrograms/mL may sometimes be required. Previous treatment with theophylline, infants born to mothers who consumed caffeine before delivery, infants showing signs of toxicity, or infants who require higher doses will require monitoring of plasma caffeine concentrations; however, routine monitoring of plasma concentrations is not always considered necessary.[9] During the first year of life, the elimination half-life of both caffeine and theophylline decreases significantly as the infant matures; regular monitoring of serum concentrations and constant dosage adjustments are therefore required if therapy is prolonged.[1]

For details of the adverse effects on the cardiovascular system associated with caffeine during treatment of neonatal apnoea, see Effects on the Cardiovascular System, above.

Use of doxapram may be considered for apnoea that does not respond to xanthine therapy.[1,2,10] It is reported to be similar in effect to the methylxanthines, and may also be of benefit as an addition to xanthine therapy.[11,12] Doxapram is poorly absorbed orally and adverse effects such as hypertension, CNS stimulation, and heart block have been reported.[13]

Obesity. A 1999 review[1] of non-prescription weight loss supplements concluded that controlled studies have not shown fat loss in overweight individuals using caffeine without an energy-restricted diet. A later study[2] examined a herbal combination product, containing amongst its active ingredients caffeine (from kola nut) and ephedrine (from ephedra), in the treatment of overweight and obesity without other lifestyle modifications. Some beneficial effects on body-weight were reported after 12 weeks of treatment compared with placebo; however, although no serious adverse effects were seen in the healthy subjects enrolled in this study, the herbal product used contained relatively low amounts of active ingredients compared with preparations used in other similar studies. The FDA has since banned the sale of dietary supplements containing ephedra as they present an unreasonable risk to health (see Ephedra, p.1558), and concerns have been raised about potential additive stimulant effects of preparations containing both caffeine and ephedrine, see Sympathomimetics under Interactions, above.

Orthostatic hypotension. Caffeine has been of benefit in the treatment of orthostatic hypotension (p.1530) due to autonomic failure in some patients, especially for postprandial hypotension.[1-3] However, efficacy has only been shown in mild cases and it is usually ineffective in severe cases.[4]

Pain. Caffeine has been widely used in analgesic preparations to enhance the effects of both non-opioid and opioid analgesics but is of debatable benefit (see under Choice of Analgesic, p.2). Some investigators have failed to show that caffeine offers any benefit[1,2] but others have shown that the adjuvant use of caffeine can increase analgesic activity.[3-8] A meta-analysis of 10 studies comparing paracetamol plus caffeine with paracetamol alone in women with postpartum uterine cramp found any benefit of the combination to be minimal.[9] A literature review[10] concluded that there was some evidence that caffeine may be useful as an analgesic adjuvant in relieving headache, but that the dose may need to be at least 65 mg and that these higher doses increase the risk of nervousness and dizziness. Evidence for the effects of caffeine in other types of pain, such as postpartum, postoperative, dental, rheumatic, and cancer pain, was inconclusive.

In the UK it is generally recommended that caffeine-containing analgesic preparations should not be used not only because of doubts about caffeine enhancing the analgesic effect but because it can add to gastrointestinal adverse effects and in large doses can itself cause headache.

Whether caffeine enhances the gastrointestinal absorption of ergotamine in preparations for the relief of migraine is not clear.

POST-DURAL PUNCTURE HEADACHE. Intravenous caffeine sodium benzoate may relieve post-dural puncture headache (p.1851) that persists despite conservative therapy.

Psoriasis. The efficacy of a 10% formulation of topical caffeine in the treatment of psoriasis has been investigated in a group of 39 patients with stable plaque psoriasis.[1] Improvements were seen at each 2-week follow-up stage, but the difference only became significant after 8 weeks. The only adverse effect noted during the study was mild itching, reported by 2 of the caffeine recipients.

Choline Theophyllinate *(BAN, rINN)*

Choline, Théophyllinate de; Cholini Theophyllinas; Koliiniteofyllinaatti; Kolinteofyllinat; Oxtriphylline; Teofilinato de colina; Theophylline Cholinate.

Холина Теофиллинат

$C_{12}H_{21}N_5O_3$ = 283.3.
CAS — 4499-40-5.
ATC — R03DA02.
ATC Vet — QR03DA02.

Pharmacopoeias. In *Br., Chin.,* and *US.*

BP 2008 (Choline Theophyllinate). A white crystalline powder, odourless or with a faint amine-like odour. It contains between 41.9% and 43.6% of choline and between 61.7% and 65.5% of theophylline, each calculated with reference to the dried substance. Very soluble in water; soluble in alcohol; very slightly soluble in chloroform and in ether. Store at a temperature not exceeding 25°. Protect from light.

USP 31 (Oxtriphylline). A white crystalline powder, having an amine-like odour. It contains not less than 61.7% and not more than 65.5% of anhydrous theophylline. Soluble 1 in 1 of water; freely soluble in alcohol; very slightly soluble in chloroform. A 1% solution in water has a pH of about 10.3. Store in airtight containers.

Profile

Choline theophyllinate is a theophylline salt that liberates theophylline (p.1140) in the body; choline theophyllinate 1.57 mg is equivalent in theophylline content to about 1 mg of anhydrous theophylline. It is used as a bronchodilator for reversible airways obstruction. The usual oral maintenance dose for adults is 800 mg daily, in 4 divided doses. The daily dose should be adjusted according to clinical response and serum-theophylline concentrations (see Uses and Administration of Theophylline, p.1146). For details of doses in children see Administration in children, below.

Administration in children. Choline theophyllinate can be given to children in oral doses of 10 to 20 mg/kg daily, in 3 or 4 divided doses.

Preparations

BP 2008: Choline Theophyllinate Tablets;
USP 31: Oxtriphylline Delayed-release Tablets; Oxtriphylline Extended-release Tablets; Oxtriphylline Oral Solution; Oxtriphylline Tablets.

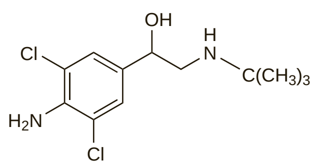
Кленбутерола Гидрохлорид

$C_{12}H_{18}Cl_2N_2O,HCl$ = 313.7.

CAS — 37148-27-9 (clenbuterol); 21898-19-1 (clenbuterol hydrochloride).

ATC — R03AC14; R03CC13.

ATC Vet — QR03AC14; QR03CC13.



(clenbuterol)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of clenbuterol:

Angel Dust;
Clen.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Clenbuterol Hydrochloride). A white or almost white crystalline powder. Soluble in water and in alcohol; slightly soluble in acetone. A 5% solution in water has a pH of 5.0 to 7.0.

Profile

Clenbuterol hydrochloride is a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131). It is used as a bronchodilator in the management of reversible airways obstruction, as in asthma (p.1108) and in certain patients with chronic obstructive pulmonary disease (p.1112). A usual oral dose is 20 micrograms twice daily; doses of up to 40 micrograms twice daily have occasionally been given. Clenbuterol hydrochloride has also been given by inhalation. In patients with asthma, as-required beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, clenbuterol indicates deterioration of asthma control and the need for review of therapy.

Abuse. Clenbuterol has been used illicitly in animal feeds in an attempt to promote weight gain and to increase muscle to lipid mass. Adverse effects typical of sympathomimetic activity have been attributed to such misuse both in farmers perpetrating such acts[1] and in innocent persons consuming meat products from affected animals.[2-5] Clenbuterol has been abused by sportsmen for its anabolic effects,[6] although it is doubtful as to whether it enhances performance.[7] Myocardial infarction was described in an otherwise healthy 17-year-old bodybuilder after abuse of clenbuterol.[8] Coronary artery spasm and/or temporary thrombosis were suggested as possible explanations for this adverse effect. Contamination of illicit heroin with clenbuterol has also been reported.[9]

Urinary incontinence. A systematic review of the use of adrenergic agonists, including clenbuterol, in urinary incontinence, found that there was weak evidence to suggest that their use was better than placebo.[1] Although only minor adverse effects were reported, the authors noted that there was still potential for rare but serious adverse effects reported elsewhere in the literature.

Diprophylline *(BAN, rINN)*

Dihydroxypropyltheophyllinum; Diprofilina; Diprofilinas; Diprofillin; Diprofylin; Diprofylliini; Diprofyllin; Diprophyllinum; Dyphylline; Glyphyllinum; Hyphylline. 7-(2,3-Dihydroxypropyl)-1,3-dimethylxanthine; 7-(2,3-Dihydroxypropyl)theophylline.

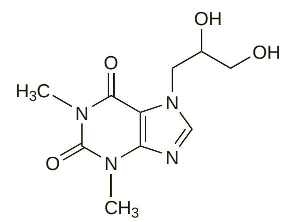
Дипрофиллин

$C_{10}H_{14}N_4O_4$ = 254.2.

CAS — 479-18-5.

ATC — R03DA01.

ATC Vet — QR03DA01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Diprophylline). A white or almost white, crystalline powder. Freely soluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Dyphylline). A white, odourless, amorphous or crystalline solid. Freely soluble in water; sparingly soluble in alcohol and in chloroform; practically insoluble in ether. A 1% solution in water has a pH of 5.0 to 7.5. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Theophylline, p.1140. Diprophylline is primarily excreted unchanged in the urine and should therefore be used with caution in patients with renal impairment; dose adjustments may be required. However, unlike theophylline, plasma concentrations of diprophylline are not greatly affected by changes in liver function or hepatic enzyme activity such as those produced by smoking or age.

Breast feeding. In a study of 20 women given diprophylline by intramuscular injection,[1] diprophylline was found to concentrate in breast milk, with a milk to serum concentration ratio of about 2. However, it was felt that the quantity of diprophylline a breast-fed infant would ingest was unlikely to produce any pharmacological action unless the child was very sensitive. The American Academy of Pediatrics[2] also considers that the use of diprophylline is usually compatible with breast feeding.

1. Jarboe CH, *et al.* Dyphylline elimination kinetics in lactating women: blood to milk transfer. *J Clin Pharmacol* 1981; **21:** 405–10.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 19/03/08)

Interactions

Since diprophylline does not undergo metabolism by hepatic microsomal cytochrome P450 it does not exhibit the numerous interactions seen with theophylline (p.1142). However, the possibility of synergistic effects should be borne in mind if it is prescribed with other xanthines.

Probenecid. Probenecid has been reported to decrease the clearance of diprophylline thus prolonging its half-life.[1-3]

1. May DC, Jarboe CH. Inhibition of clearance of dyphylline by probenecid. *N Engl J Med* 1981; **304:** 791.
2. May DC, Jarboe CH. Effect of probenecid on dyphylline elimination. *Clin Pharmacol Ther* 1983; **33:** 822–5.
3. Acara M, *et al.* Probenecid inhibition of the renal excretion of dyphylline in chicken, rat and man. *J Pharm Pharmacol* 1987; **39:** 526–30.

Pharmacokinetics

Diprophylline is rapidly absorbed from the gastrointestinal tract and from the site of intramuscular injections. Diprophylline is not converted to theophylline in the body. It is largely excreted unchanged in the urine with an elimination half-life of about 2 hours. Diprophylline is distributed into breast milk.

Uses and Administration

Diprophylline is a theophylline derivative which is used similarly to theophylline (p.1146) as a bronchodilator in reversible airways obstruction.

The usual oral dose of diprophylline is up to 15 mg/kg every 6 hours. It has also been given intramuscularly. Diprophylline is also an ingredient of preparations that have been promoted for coughs.

Action. Improvements in measurements of lung function after diprophylline in oral doses of 15 and 20 mg/kg were only one-third to one-half those obtained after oral theophylline 6 mg/kg.[1]

1. Furukawa CT, *et al.* Diphylline versus theophylline: a double-blind comparative evaluation. *J Clin Pharmacol* 1983; **23:** 414–18.

Preparations

USP 31: Dyphylline and Guaifenesin Elixir; Dyphylline and Guaifenesin Tablets; Dyphylline Elixir; Dyphylline Injection; Dyphylline Tablets.

Adverse Effects and Precautions

As for Salbutamol, p.1131.

Increased mortality. Since the introduction of metered-dose aerosols of beta agonists there have been two reported epidemics of increased morbidity and mortality in asthmatic patients associated with their use. The first occurred in the 1960s and was linked with the use of high-dose isoprenaline inhalers.[1] The use of isoprenaline was subsequently largely stopped in favour of more selective beta$_2$ agonists.

The second epidemic occurred in New Zealand in the late 1970s and 1980s and was associated with the use of fenoterol.[1-5] When use of fenoterol fell in New Zealand, so too did the asthma mortality rate.[5] Heavy or regular use of fenoterol was implicated.[6,7] Fenoterol was also implicated in increased asthma morbidity and mortality in a study in Canada,[7] as was salbutamol, and results from Japan also suggested a relation between asthma deaths and excessive use of beta agonists, particularly fenoterol.[8] However, an analysis of the New Zealand deaths could not identify such a risk with beta agonists other than fenoterol.[5]

There is still debate about this second epidemic. The individual case control studies, including the one from Canada,[7] showed an increased morbidity and mortality in patients taking fenoterol, but a meta-analysis of the accumulated data to 1992 suggested that the increase in mortality in the patients taking beta$_2$ agonists was slight and only significant when they were given by nebulisation.[9] Also a working party of the UK CSM considered[10] that a causal link between asthma mortality and beta-agonist use could neither be confirmed nor refuted.

Not surprisingly there are different views on the cause of the increased asthma mortality. The cardiotoxicity of the beta agonist might have to be considered, although evidence for such an effect is felt by some to be slight.[11] The severity of the asthma might have been a factor in two different ways. One hypothesis is that patients used more fenoterol because they had severe asthma and were already at increased risk of dying.[12] Another proposes that heavy beta-agonist use led to an increase in asthma severity[13] which could be explained by a down regulation of beta receptors.[14]

This may appear to be only of historical interest since mortality rates have fallen and current recommendations for the use of short-acting beta$_2$ agonists, which are generally more selective than fenoterol, are for them to be taken as required rather than on a regular basis; indeed increasing use of such drugs is seen as an indication to amend the treatment schedule. Moreover, the dose of fenoterol has been reduced in recent years. However, controversy over regular use of short-acting beta$_2$ agonists continues to be fed by conflicting studies of their benefit. More recently 2 further observational studies have reported an association between use of short-acting beta$_2$ agonists and adverse effects on mortality.[15,16] A cohort study,[15] designed to evaluate the effect of respiratory medications on asthma death, found an association between the excessive use of short-acting beta$_2$ agonists and an increased risk of asthma death; no additional risk was found with fenoterol beyond the risk associated with beta$_2$ agonists as a class. It was unknown whether excessive use was a symptom or a cause of worsening asthma. A case-control study[16] similarly found a modestly increased risk of mortality associated with use of short-acting beta$_2$ agonists in the previous 1 to 5 years. However, the study had insufficient power to come to any conclusions regarding the effects of fenoterol, which was rarely prescribed alone, and concluded that evidence for a direct adverse effect of beta$_2$ agonists was inconclusive; other explanations might include lack of more appropriate asthma care, more severe disease or increasing severity of disease, or a tendency for patients whose disease was not responding to receive a wider range of treatments.

For discussion of similar concerns about the use of *long-acting* beta$_2$ agonists in asthma, see Salmeterol, p.1135.

Pulmonary oedema. Pulmonary oedema has occurred in women given beta agonists, including fenoterol,[1] for premature labour. The risk factors, the most important of which is fluid overload, are discussed under Precautions for Salbutamol, on p.1132.

1. Hawker F. Pulmonary oedema associated with β -sympathomimetic treatment of premature labour. *Anaesth Intensive Care* 1984; **12:** 143–51.

Interactions

As for Salbutamol, p.1132.

Pharmacokinetics

Fenoterol is incompletely absorbed from the gastrointestinal tract and is also subject to extensive first-pass metabolism by sulfate conjugation. It is excreted in the urine and bile almost entirely as the inactive sulfate conjugate. Fenoterol is distributed into breast milk.

Uses and Administration

Fenoterol is a direct-acting sympathomimetic with beta-adrenoceptor stimulant activity largely selective for beta$_2$ receptors (a beta$_2$ agonist). It has actions and uses similar to those of salbutamol (p.1133) and is used as a bronchodilator in the management of reversible airways obstruction, as occurs in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). On inhalation, fenoterol acts rapidly (5 minutes) and has a duration of action of about 6 to 8 hours.

In the management of **reversible airways obstruction,** fenoterol hydrobromide may be given from a *metered-dose aerosol* in a dose of 1 or 2 inhalations of 100 micrograms up to 3 or 4 times daily, to a maximum of 800 micrograms daily. Current asthma guidelines recommend that inhaled short-acting beta$_2$ agonists such as fenoterol be used on an 'as-required', not regular, basis. In those patients requiring more than occasional use of fenoterol, anti-inflammatory therapy is also needed. An increased requirement for, or decreased duration of effect of, fenoterol indicates deterioration of asthma control and the need for increased anti-inflammatory therapy.

Fenoterol hydrobromide may be given as a *nebulised solution*; the usual dose for inhalation by this route is 0.5 to 1 mg. In more refractory cases up to 2.5 mg may be given. Treatment may be repeated every 6 hours as required.

Fenoterol hydrobromide may also be given *orally* for the relief of bronchospasm at a dose of 2.5 to 5 mg three times daily.

For doses in children, see Administration in Children, below.

Fenoterol hydrobromide has also been used similarly to salbutamol, in the management of **premature labour** (see p.2003). A suggested dose, by intravenous infusion, has been 1 to 3 micrograms/minute, up to a maximum of 5 micrograms/minute, followed by oral doses of 5 mg every 3 to 6 hours.

Administration in children. In some countries fenoterol has been given via a metered-dose inhaler to children over 6 years of age, at the same doses used in adults (see Uses and Administration, above).

Fenoterol hydrobromide is also given orally to children for the relief of bronchospasm in the following doses:

- children aged 1 to 3 years, 1.25 mg three times daily
- children aged 4 to 10 years, 2.5 mg three times daily
- children aged over 10 years, as for adults (see Uses and Administration, above)

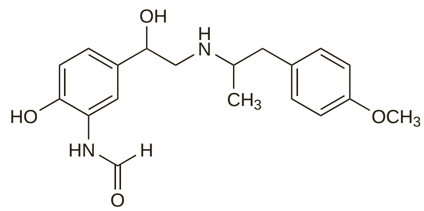
ATC — R03AC13.

ATC Vet — QR03AC13.



(formoterol)

Pharmacopoeias. In *Jpn. Eur.* (see p.vii) includes the dihydrate.

Ph. Eur. 6.2 (Formoterol Fumarate Dihydrate; Formoteroli Fumaras Dihydricus). A white or almost white or slightly yellow powder. Slightly soluble in water and in isopropyl alcohol; practically insoluble in acetonitrile; soluble in methyl alcohol. A 0.1% solution in water has a pH of 5.5 to 6.5. Protect from light.

Adverse Effects and Precautions

As for Salbutamol, p.1131. Inhalation of formoterol may be associated with paradoxical bronchospasm, and high doses have been associated with an increase in severe exacerbations of asthma. It should not be used in patients who are not also receiving an inhaled corticosteroid.

Long-acting $beta_2$ agonists such as formoterol are not appropriate for the treatment of acute bronchospasm.

Conjunctival irritation and eyelid oedema have been reported in isolated cases.

Asthma. A review of 3 controlled studies comparing inhaled formoterol with placebo, concluded that regular use of high-dose formoterol (48 micrograms daily) may be associated with more frequent serious asthma exacerbations.[1] The concomitant use of inhaled corticosteroids was allowed but not mandatory, and was not reported in the review, which led to debate on whether the results of the study would be applicable when current prescribing guidelines for asthma were followed.[2,3]

In contrast to this, a subsequent study,[4] designed to test the hypothesis of a dose-related increase in serious asthma exacerbations with formoterol therapy, did not show any increase in serious asthma exacerbations between different formoterol doses and placebo. Again, inhaled corticosteroid use was allowed but not mandatory, with 62.4% of patients reported as receiving regular anti-inflammatory therapy.

A systematic review[5] firmly concluded that the addition of a long-acting $beta_2$ agonist (such as formoterol) to low or high doses of inhaled corticosteroids reduced the risk of asthma exacerbations compared with ongoing treatment with similar doses of inhaled corticosteroids alone. The addition of a long-acting $beta_2$ agonist reduced by 19% the relative risk and by 5% the absolute risk of patients requiring systemic corticosteroids for an asthma exacerbation, over 4 to 54 weeks.

For discussion of serious adverse effects associated with long-acting $beta_2$ agonists in asthma, see Increased Mortality, under Salmeterol p.1135.

Effects on skeletal muscle. Myalgia and muscle weakness associated with elevated creatine kinase has been reported during formoterol therapy.[1] Subsequent muscle biopsy suggested mitochondrial dysfunction. No inflammatory changes were seen and symptoms resolved on withdrawal of formoterol.

1. Kiernan MC, *et al.* Mitochondrial dysfunction and rod-like lesions associated with administration of β2 adrenoceptor agonist formoterol. *Neuromuscul Disord* 2004; **14:** 375–7.

Tolerance. Regular use of formoterol produced bronchodilator desensitisation,[1-3] and tachyphylaxis to bronchoprotection against methacholine, effects that have been noted with other long-acting $beta_2$ agonists (see Salmeterol, p.1135) and short-acting $beta_2$ agonists (see Salbutamol, p.1132).

Interactions

As for Salbutamol, p.1132.

Pharmacokinetics

Inhaled formoterol is rapidly absorbed. It is largely metabolised by glucuronidation and *O*-demethylation, with about 10% being excreted in the urine as unchanged drug. The mean terminal elimination half-life after inhalation is estimated to be 10 hours.

Stereoselectivity. Formoterol occurs as a racemic mixture, of which arformoterol (p.1115) is the *R,R*-enantiomer. Only the *R,R*-enantiomer is active.[1,2] It has been suggested that stereoselective metabolism and excretion may account for the individual variation in duration of effect seen with formoterol, although the exact mechanism remains unclear.[1,3]

3. Zhang M, *et al.* Stereoselective urinary excretion of formoterol and its glucuronide conjugate in human. *Br J Clin Pharmacol* 2002; **54:** 246–50.

Uses and Administration

Formoterol is a direct-acting sympathomimetic with mainly beta-adrenoceptor stimulant activity specific to $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1133), but like salmeterol (p.1135) it has a prolonged duration of action of up to 12 hours; it is therefore not considered suitable for the symptomatic relief of acute attacks of bronchospasm. It is used when the regular use of a long-acting $beta_2$ agonist is needed for management of reversible airways obstruction, as in chronic asthma (p.1108) or in some patients with chronic obstructive pulmonary disease (p.1112).

Formoterol is given by inhalation as the fumarate but how the dose is expressed may depend on the formulation.

- A usual dose is 12 micrograms of formoterol fumarate twice daily from inhalational capsules, increased to 24 micrograms twice daily if necessary in severe disease.
- Metered doses from a dry powder inhaler may be expressed as the amount delivered *into* the mouthpiece (multiples of 6 micrograms per inhalation) or the amount delivered *from* the mouthpiece (corresponding to multiples of 4.5 micrograms per inhalation). Usual doses, expressed as the amount delivered *into* the mouthpiece, are 6 or 12 micrograms once or twice daily, increased if necessary in severe disease to 24 micrograms twice daily.
- Metered doses from an aerosol inhaler may also be expressed as the amount delivered *into* the mouthpiece (12 micrograms per inhalation) or the amount delivered *from* the mouthpiece (corresponding to 10.1 micrograms per inhalation). Usual doses are 1 or 2 inhalations twice daily.

Treatment should be reassessed if this proves inadequate; in the UK, some preparations are licensed for additional short-term symptom relief, but such use is contrary to current asthma guidelines (see p.1108).

Formoterol fumarate may also be inhaled via a nebuliser in a dose of 20 micrograms twice daily. Oral doses of 80 micrograms have been given twice daily in adults.

For doses of formoterol fumarate used in children, see Administration in Children, below.

◊ Reviews.

3. Sovani MP, *et al.* A benefit-risk assessment of inhaled long-acting β -agonists in the management of obstructive pulmonary disease. *Drug Safety* 2004; **27:** 689–715.

Administration in children. Doses of formoterol fumarate inhaled from inhalational capsules in children aged 5 years or older are the same as those for adults, see Uses and Administration, above.

Formoterol fumarate may be given by metered-dose dry powder inhaler to children 6 years of age and over. The usual dose, expressed as the amount delivered *into* the mouthpiece, is 6 to 12 micrograms once or twice daily. Occasionally up to 48 micrograms daily may be required (maximum single dose should not exceed 12 micrograms).

In some countries, such as Japan, formoterol fumarate has been given orally to children from the age of 6 months at a dose of 4 micrograms/kg daily, in 2 or 3 divided doses.

Asthma. Formoterol is a long-acting beta$_2$ agonist (duration of action about 12 hours). Guidelines on the management of asthma, see p.1108, generally recommend that the use of long-acting beta$_2$ agonists be reserved for patients with chronic asthma who have already progressed to inhaled corticosteroids; it is not a substitute for corticosteroids. The exact dose of inhaled corticosteroid at which to add additional therapy, such as a long-acting beta$_2$ agonist, has yet to be determined. There is some evidence to suggest that, apart from in severe exacerbations, adding a long-acting beta$_2$ agonist to standard dose inhaled corticosteroid therapy may be more effective than increasing the dose of corticosteroid, or than combining a corticosteroid and an anti-leukotriene drug. Combinations of formoterol with an inhaled corticosteroid, used as both maintenance and reliever therapy, have also been studied. Results are seemingly encouraging, although what role such combinations should play in therapy is not yet clearly defined. Some asthma guidelines include this regimen as an option for adults at treatment step 3, see p.1108. Formoterol may also be useful in controlling persistent nocturnal asthma or preventing exercise-induced attacks. There is some evidence that after prolonged use, protection against bronchoconstriction is reduced (see Tolerance, above), and high-dose therapy may be associated with an increased rate of severe exacerbations (see Asthma under Adverse Effects and Precautions, above).

$C_{22}H_{32}N_2O_6,H_2SO_4$ = 518.6.
CAS — 32266-10-7.
ATC — R03AC06; R03CC05.
ATC Vet — QR03AC06; QR03CC05.

Profile

Hexoprenaline is a direct-acting sympathomimetic with mainly beta-adrenergic activity selective to beta$_2$ receptors (a beta$_2$ agonist). It has properties similar to those of salbutamol (p.1131) and has been used as a bronchodilator in the treatment of reversible airways obstruction as occurs with asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). It has sometimes been used similarly to salbutamol in the management of premature labour (p.2003).

Hexoprenaline is usually given as the hydrochloride or sulfate.

For the relief of **bronchoconstriction**, a typical adult oral dose of the salts has been 0.5 to 1 mg three times daily. By inhalation, hexoprenaline sulfate has been given by aerosol inhaler in doses of 100 to 200 micrograms up to 6 times daily, and the hydrochloride has been given by nebulisation in doses of 250 to 500 micrograms every 4 to 6 hours to a maximum of 3 mg daily. In patients with asthma, as-required beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, hexoprenaline indicates deterioration of asthma control and the need for review of therapy.

In the management of **premature labour** an intravenous infusion of hexoprenaline sulfate, diluted in glucose 5% or sodium chloride 0.9%, can be given at an initial rate of about 300 nanograms/minute. Infusion may be preceded by slow intravenous injection of 10 micrograms as a loading dose over 5 to 10 minutes. A prolonged infusion of 75 nanograms/minute has been used when there is no cervical change. Therapy may be changed from intravenous to oral once suppression of labour has been achieved for at least 24 hours.

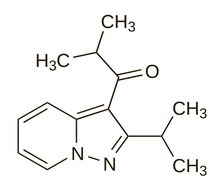
$C_{14}H_{18}N_2O$ = 230.3.
CAS — 50847-11-5.
ATC — R03DC04.
ATC Vet — QR03DC04.



Profile

Ibudilast is an orally active leukotriene antagonist (p.1108), phosphodiesterase inhibitor, and platelet-activating factor antagonist. It is given orally in the management of asthma (p.1108) in a dose of 10 mg twice daily.

Ibudilast is also promoted for the management of dizziness secondary to impaired cerebral circulation following cerebral infarction, in doses of 10 mg three times daily.

Ibudilast is also under investigation for the treatment of multiple sclerosis and for chronic neuropathic pain.

Adverse Effects and Precautions

Ipratropium and other inhaled antimuscarinic bronchodilators commonly cause dry mouth and constipation, and rarely, urinary retention. They should be used with care in prostatic hyperplasia. Acute angle-closure glaucoma has been reported; the mist or solution should not be allowed to enter the eyes, particularly in patients susceptible to glaucoma. As with other bronchodilators, paradoxical bronchospasm has occurred. Tachycardia, palpitations, and arrhythmias have been reported with ipratropium. Hypersensitivity reactions, including urticaria, angioedema, rash, and anaphylaxis have occurred rarely. Nausea and vomiting, dyspepsia, headaches, and dizziness have also been reported.

Intranasal ipratropium has been associated with nasal dryness, irritation, and epistaxis.

For details of the adverse effects of, and precautions for, antimuscarinics in general, see Atropine, p.1219.

Buccal ulceration. A report[1] of inflammation and ulceration of the buccal mucosa associated with the use of an ipratropium bromide inhaler.

1. Spencer PA. Buccal ulceration with ipratropium bromide. *BMJ* 1986; **292:** 380.

Effects on the eyes. Ocular complications have been reported with the use of aerosolised ipratropium. A patient with a history of glaucoma developed angle-closure glaucoma after use of ipratropium from a metered dose inhaler (MDI) with nebulised salbutamol.[1] Pupillary dilatation[2] and blurred vision[3] have been reported in association with ipratropium given through a spacer device in patients also given salbutamol therapy, and a 4-year-old child who attempted to self-administer an ipratropium MDI developed anisocoria (unequal dilatation of the pupils) and ataxia.[4] Angle-closure glaucoma,[5-7] pupillary dilatation,[7-10] and anisocoria[11,12] have been reported in patients given *nebulised* ipratropium, usually with salbutamol, through a poorly fitting face mask. The antimuscarinic effects of ipratropium can lead to impaired drainage of aqueous humour in the eyes of patients predisposed to angle-closure glaucoma; use with salbutamol may intensify this problem by increasing the production of aqueous humour.[6] Studies[13,14] suggest that patients with a history of angle-closure glaucoma might be at an increased risk of developing glaucoma when nebulised ipratropium and salbutamol are used together.

14. Kalra L, Bone MF. The effect of nebulized bronchodilator therapy on intraocular pressures in patients with glaucoma. *Chest* 1988; **93:** 739–41.

Effects on the gastrointestinal tract. Paralytic ileus developed shortly after starting ipratropium therapy in 2 patients, apparently due to the inadvertent swallowing of the drug during inhalation.[1,2] Both patients also had other predisposing factors for paralytic ileus (cystic fibrosis,[1] spastic diplegia[2]).

1. Mulherin D, FitzGerald MX. Meconium ileus equivalent in association with nebulised ipratropium bromide in cystic fibrosis. *Lancet* 1990; **355:** 552.
2. Markus HS. Paralytic ileus associated with ipratropium. *Lancet* 1990; **355:** 1224.

Effects on the respiratory tract. Antimuscarinics typically inhibit mucociliary clearance and inhibit secretions of the nose, mouth, pharynx, and bronchi. However, inhaled ipratropium bromide has virtually no effect on sputum viscosity or volume and, in contrast to atropine, it does not affect mucociliary function in the respiratory tract.[1,2]

1. Gross NJ. Ipratropium bromide. *N Engl J Med* 1988; **319:** 486–94.
2. Mann KV, *et al.* Use of ipratropium bromide in obstructive lung disease. *Clin Pharm* 1988; **7:** 670–80.

BRONCHOSPASM. Paradoxical bronchoconstriction occurring after the use of ipratropium was reported in 3 patients.[1] A further report[2] of paradoxical bronchoconstriction after nebulised salbutamol and ipratropium suggested that this adverse effect might have been caused by benzalkonium chloride present in the nebuliser solutions. Nebuliser solutions of ipratropium in some countries contain benzalkonium chloride as a preservative. Solutions available in the UK are preservative-free but licensed product information still recommends that the first doses of ipratropium nebuliser solution should be inhaled under medical supervision.

2. Pras E, *et al.* Urinary retention associated with ipratropium bromide. *DICP Ann Pharmacother* 1991; **25:** 939–40.

Increased mortality. A case-control study found an unexpected association between death from asthma and treatment with ipratropium, which was not explained by co-morbidity due to chronic obstructive airways disease.[1] A retrospective cohort study[2] of elderly patients found no increase in all-cause mortality associated with the use of ipratropium for chronic obstructive pulmonary disease (COPD). In patients with asthma there was a slight increase in the risk of death, but this may have been due to the confounding effect of disease severity. A later longitudinal cohort study of 1100 patients with obstructive lung disease found an increased risk of premature death associated with ipratropium in both asthma and COPD patients.[3] After adjusting for confounding factors such as forced expiratory volume, smoking status, BMI, and presence of cor pulmonale, ipratropium was associated with a mortality risk ratio (RR) of 2.4 in asthmatic patients and 1.6 in COPD patients. Again, residual confounding by disease severity could not be ruled out.

Interactions

For interactions associated with antimuscarinics in general, see Atropine, p.1220. However, these interactions are not usually seen with antimuscarinics, such as ipratropium, given by inhalation.

Salbutamol. For reference to nebulised salbutamol exacerbating the adverse effects of nebulised ipratropium in patients predisposed to angle-closure glaucoma, see under Effects on the Eyes, above.

Pharmacokinetics

After inhalation, around 10 to 30% of a dose is deposited in the lungs where it exerts its therapeutic effect. Only a small amount of ipratropium reaches the systemic circulation. The majority of a dose is swallowed but is poorly absorbed from the gastrointestinal tract. Ipratropium and its metabolites are eliminated in the urine and faeces.

◊ References.

Uses and Administration

Ipratropium bromide is a quaternary ammonium antimuscarinic (p.1108). It is used by inhalation as a bronchodilator in the treatment of reversible airways obstruction, as in asthma and chronic obstructive pulmonary disease (see below).

In the UK the dose of ipratropium bromide from the metered-dose aerosol is expressed in terms of the amount of drug released from the valve into the mouthpiece (20 micrograms) whereas in the USA it is expressed in terms of the dose emitted from the mouthpiece (17 micrograms, equivalent to 21 micrograms released from the valve); recommended doses may therefore appear lower in the USA. For **reversible airways obstruction**, the usual UK dose from a metered-dose aerosol is 1 or 2 inhalations (20 or 40 micrograms) three or four times daily; single doses of up to 4 inhalations may be required. Comparable doses are used in the USA, but it is recommended that the daily dose should not exceed 12 inhalations.

Dry powder inhalation capsules are also available; the usual dose is 40 micrograms three or four times daily, to a maximum of 320 micrograms daily.

Ipratropium bromide may be given by inhalation as a nebulised solution in doses of 250 to 500 micrograms up to 4 times daily.

Ipratropium bromide, given intranasally, is also used in the management of rhinorrhoea associated with **rhinitis**. A dose of 42 micrograms is given into each nostril by metered-dose nasal spray 2 or 3 times daily. US licensing also permits higher doses of 84 micrograms into each nostril 3 or 4 times daily, for up to 4 days when rhinorrhoea is associated with the common cold; doses of 84 micrograms may be given into each nostril 4 times daily, for up to 3 weeks when rhinorrhoea is associated with seasonal allergic rhinitis.

For details of doses in children, see Administration in Children, below.

Administration in children. Children may be given ipratropium bromide via a metered dose aerosol in the treatment of **reversible airways obstruction**. UK licensed product information recommends doses by age as follows:

- under 6 years: 1 inhalation of 20 micrograms three times daily
- 6 to 12 years: 1 or 2 inhalations of 20 micrograms three times daily
- 12 years and over: adult doses, see above

Dry powder inhalation capsules are also available, and are licensed for use in children from 12 years of age using the adult dose, see above.

Ipratropium bromide may also be given by inhalation as a nebulised solution. UK licensed product information recommends the following doses:

- under 6 years, for the treatment of acute asthma only: 125 to 250 micrograms, given no more often than every 6 hours up to a total daily dose of 1 mg
- 6 to 12 years, for the treatment of acute or chronic asthma: 250 micrograms, repeated if necessary up to a total daily dose of 1 mg
- 12 years and over: adult doses, see above.

Ipratropium bromide is used in the management of rhinorrhoea associated with **rhinitis**. A dose of 42 micrograms may be given into both nostrils two or three times daily. In the UK this dose may be given to children from 12 years of age, but in the USA this dose is licensed in children from 6 years of age.

US licensing also permits higher doses for up to 4 days when rhinorrhoea is associated with the common cold:

- 5 to 11 years: 84 micrograms into each nostril three times daily
- 12 years and over: adult doses, see above

Higher doses are also permitted in the USA for up to 3 weeks when rhinorrhoea is associated with seasonal allergic rhinitis. Children 5 years of age and over may be given the same dose as adults, see above.

Asthma. Ipratropium bromide is currently recommended as an adjunct to beta$_2$ agonists in the management of acute severe asthma, see p.1108. Antimuscarinic drugs, mainly ipratropium but also including oxitropium (p.1129), glycopyrronium and atropine, have been reviewed in the treatment of both acute and chronic asthma. A systematic review and meta-analysis[1] of the effectiveness of antimuscarinics in the treatment of acute asthma in children and adults, found they produced significant reductions in hospital admissions. Combined treatment with an inhaled beta$_2$ agonist also produced a significant increase in respiratory function.

Systematic reviews of antimuscarinic drugs have concluded that there is currently insufficient evidence to justify their routine use in adults[2] or children[3] with chronic asthma.

1. Rodrigo GJ, Castro-Rodriguez JA. Anticholinergics in the treatment of children and adults with acute asthma: a systematic review with meta-analysis. *Thorax* 2005; **60:** 740–6.

3. McDonald NJ, *et al.* Anticholinergic therapy for chronic asthma in children over 2 years of age. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2003 (accessed 18/02/08).

Chronic obstructive pulmonary disease. Inhaled antimuscarinics, such as ipratropium bromide, are currently recommended as bronchodilators in chronic obstructive pulmonary disease (COPD) guidelines, see p.1112. A systematic review compared regular treatment with ipratropium (given for at least 4 weeks) with treatment using regular short-acting beta$_2$ agonists in stable COPD;[1] it found small benefits on lung function outcomes and quality of life with ipratropium compared with a short-acting beta$_2$ agonist; a reduction in the requirements for oral corticosteroids was also seen. Combination therapy with ipratropium and a short-acting beta$_2$ agonist was associated with some clinically meaningful lung function outcomes compared with the beta$_2$ agonist alone, but these were not reflected in subjective improvements or symptom scores.

A systematic review comparing ipratropium with a long-acting beta$_2$ agonist in stable COPD,[2] found that salmeterol had more effect than ipratropium on lung function, but no major differences were seen between symptom responses to ipratropium and salmeterol. Combination treatment with these two drugs was better than salmeterol alone in terms of quality of life.

Rhinitis. Ipratropium bromide is used intranasally for the treatment of rhinorrhoea in allergic and non-allergic rhinitis (p.565). It has also relieved rhinorrhoea and sneezing associated with the common cold.

USP 31 (Isoetharine Mesylate). White or practically white, odourless, crystals. Freely soluble in water; soluble in alcohol; practically insoluble in acetone and in ether. A 1% solution in water has a pH of 4.5 to 5.5. Store in airtight containers.

Profile

Isoetarine is a sympathomimetic with mainly beta-adrenergic activity. It has actions similar to those of salbutamol (p.1131) but is less selective for beta$_2$ adrenoceptors. Isoetarine has been used as a bronchodilator in the management of reversible airways obstruction.

Isoetarine is given by inhalation, as a nebulised solution of the hydrochloride in strengths up to 0.25%; a 1% solution can be given by a hand nebuliser.

Preparations

USP 31: Isoetharine Inhalation Solution; Isoetharine Mesylate Inhalation Aerosol.

Adverse Effects and Precautions

As for Salbutamol, p.1131.

Incidence of adverse effects. Some studies have reported that beta-adrenergic adverse effects (e.g. nervousness and increased heart rate) are less frequent with inhaled levosalbutamol than with racemic salbutamol.[1-3] Despite preliminary evidence that the increased airway hyperresponsiveness occasionally seen with long-term racemic salbutamol (see Tolerance, p.1132) may be due to the *S*(+)-enantiomer, and therefore might not occur with levosalbutamol,[4] a small study was unable to find any favourable protective effect.[5]

5. Sjöswärd KN, *et al.* Single-isomer R-salbutamol is not superior to racemate regarding protection for bronchial hyperresponsiveness. *Respir Med* 2004; **98:** 990–9.

Interactions

As for Salbutamol, p.1132.

Pharmacokinetics

There is some systemic absorption of inhaled levosalbutamol. After a single dose levosalbutamol has a half-life of 3.3 hours. For details of the metabolism and excretion of salbutamol enantiomers, see Stereoselectivity, under Salbutamol p.1133.

Metabolism. There is evidence that levosalbutamol is metabolised faster than *S*(+)-salbutamol.

Uses and Administration

Levosalbutamol, the *R*(−)-enantiomer of salbutamol (p.1131), may be used as an alternative to racemic salbutamol for the management of asthma (p.1108). It is given as the hydrochloride, sulfate, or tartrate but doses are usually expressed in terms of the base; 1.15 mg of levosalbutamol hydrochloride, 2.4 mg of levosalbutamol sulfate, and 2.63 mg of levosalbutamol tartrate are equivalent to about 1 mg of levosalbutamol. For the relief of acute bronchospasm, 1 or 2 inhalations of the equivalent of 45 micrograms of levosalbutamol can be given from a metered-dose aerosol, repeated every 4 to 6 hours as required.

Levosalbutamol may also be inhaled via a nebuliser; usual doses equivalent to levosalbutamol 630 micrograms are inhaled three times daily, increased if necessary to 1.25 mg three times daily. For children's doses, see Administration in Children below. In patients with asthma, as-required beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, levosalbutamol indicates deterioration of asthma control and the need for review of therapy.

Levosalbutamol is also under investigation in a topical formulation for the treatment of cutaneous lupus erythematosus.

◊ General reviews.

5. Kelly HW. Levalbuterol for asthma: a better treatment? *Curr Allergy Asthma Rep* 2007; **7:** 310–14.

Action. *In vitro*, levosalbutamol had slightly higher affinity than racemic salbutamol for beta$_1$ and beta$_2$ adrenoceptors.[1] The *S*(+)-enantiomer had low affinity for these receptors. All 3 were mildly selective for beta$_2$ adrenoceptors.

1. Penn RB, *et al.* Comparison of R-, S-, and RS-albuterol interaction with human β - and β -adrenergic receptors. *Clin Rev Allergy Immunol* 1996; **14:** 37–45.

Administration in children. Children aged 4 years and older may be given levosalbutamol via a metered-dose aerosol at the same dose as that used for adults, see Uses and Administration, above.

Children aged from 6 to 11 years of age may be given levosalbutamol via a nebuliser in doses from 310 to 630 micrograms three times daily.

Asthma. Controlled studies comparing levosalbutamol with racemic salbutamol for the treatment of asthma have produced variable results. Levosalbutamol provided greater bronchodilatation than the equivalent amount of the racemate in some studies.[1,2] A decrease in hospital admissions and an increase in patient-discharge rates have also been reported.[3-5] Two controlled studies comparing levosalbutamol with racemic salbutamol in children with acute asthma failed to show any clinical benefit over the racemate.[6,7] A review concluded that, although current studies did not provide evidence of a substantial advantage for levosalbutamol over racemic salbutamol, the data were insufficient to determine whether subsets of the patient population might benefit from single isomer therapy.[8]

Adverse Effects and Precautions

As for Zafirlukast, p.1150.

◊ Suspected adverse effects reported to the UK CSM after the launch of montelukast included oedema, agitation and restlessness, allergy (including anaphylaxis, angioedema, and urticaria), chest pain, tremor, dry mouth, vertigo, and arthralgia.[1] Further suspected adverse effects included nightmares, sedation, palpitations, and increased sweating.[2] In March 2008 the FDA announced[3] that it was investigating a possible association between the use of montelukast and behaviour/mood changes, suicidality, and suicide. Other postmarketing adverse events that had been incorporated into the US licensed product information in the previous year had included: tremor, depression, suicidality, and anxiousness.

Churg-Strauss syndrome. Churg-Strauss syndrome has been reported with the use of montelukast.[1-5] Relapse has occurred in a patient with Churg-Strauss syndrome who was in complete remission when montelukast therapy was started.[5] For discussion of the unresolved role of leukotriene antagonists in this disorder and precautions to be observed, see under Zafirlukast, p.1150.

5. Solans R, *et al.* Montelukast and Churg-Strauss syndrome. *Thorax* 2002; **57:** 183–5.

Hepatic impairment. Although there is evidence of effects on the liver in patients receiving montelukast, and although it is largely eliminated by hepatic metabolism, montelukast (unlike zafirlukast) is not considered by UK licensed product information to be contra-indicated in hepatic impairment, and no dose adjustment is considered necessary in mild to moderate hepatic impairment.

Interactions

Licensed product information recommends caution when potent inducers of the cytochrome P450 isoenzyme CYP3A4 such as phenytoin, phenobarbital, or rifampicin are given with montelukast.

Corticosteroids. For a report of peripheral oedema in a patient given montelukast and *prednisone*, see Leukotriene Antagonists, p.1495.

Phenobarbital. Peak serum concentrations after a single dose of montelukast 10 mg were reduced by 20% in 14 healthy subjects who took phenobarbital 100 mg daily for 14 days, and area under the serum concentration-time curve was reduced by 38%. However, it was not thought that montelukast doses would need adjustment if given with phenobarbital.[1]

1. Holland S, *et al.* Metabolism of montelukast (M) is increased by multiple doses of phenobarbital (P). *Clin Pharmacol Ther* 1998; **63:** 231.

Pharmacokinetics

Peak plasma concentrations of montelukast are achieved in 3 to 4 hours after oral doses. The mean oral bioavailability is 64%. Montelukast is more than 99% bound to plasma proteins. It is extensively metabolised in the liver by cytochrome P450 isoenzymes CYP3A4, CYP2A6, and CYP2C9, and is excreted principally in the faeces via the bile.

Uses and Administration

Montelukast is a selective leukotriene receptor antagonist with actions and uses similar to those of zafirlukast (p.1150) although it is reported to have a longer duration of action. It is used as the sodium salt, but doses are expressed in terms of the base; montelukast sodium 10.38 mg is equivalent to about 10 mg of montelukast.

In the management of chronic asthma (see below), allergic rhinitis (see below), and as prophylaxis for exercise-induced asthma, montelukast sodium is given in doses equivalent to 10 mg of montelukast once daily in the evening. It should not be used to treat an acute asthma attack.

For details of doses in children, see below.

Administration in children. Montelukast sodium is available as oral granules and chewable tablets for use in children. Oral granules are suitable for infants as they may be given directly into the mouth or mixed with a small amount of soft food. UK licensed oral doses for the management of chronic asthma and as prophylaxis for exercise-induced asthma, expressed as montelukast, are as follows:

- 6 months to 5 years, 4 mg daily taken in the evening
- 6 to 14 years, 5 mg daily taken in the evening
- 15 years and over, use the adult dose, see above

In the USA these doses are licensed from 1 year of age in asthma and from 15 years in exercise-induced asthma. Montelukast is also licensed for use in allergic rhinitis (p.565) in the USA. The above doses can be given from 2 years of age in seasonal allergic rhinitis and from 6 months of age in perennial allergic rhinitis.

Asthma. Use of montelukast in asthma has been reviewed,[1-3] (further general references for leukotriene antagonists can be found under Zafirlukast, p.1151). Montelukast produced modest improvements compared with placebo in chronic asthma and exercise-induced asthma in both adults[4,5] and children.[6-8] In a systematic review[9] of studies in adults and children comparing leukotriene receptor antagonists with inhaled corticosteroids for mild to moderate asthma, in which more than half of the studies used montelukast, leukotriene antagonists were found to be less effective in maintaining asthma control. A more recent study in children came to a similar conclusion,[10] but another 12-month study in children with mild persistent asthma, reported that montelukast was not inferior to an inhaled corticosteroid (fluticasone);[11] similar numbers of days without rescue medication, the primary outcome in this study, were reported with both treatments. However, some of the conclusions drawn from the latter study have been questioned[12] since patients who received inhaled fluticasone achieved better secondary outcomes such as fewer asthma attacks and less requirement for systemic corticosteroids.

Addition of montelukast to an inhaled corticosteroid has significantly improved asthma control in adults[13] and children[14,15] with mild to moderate asthma. Significant improvements in quality of life have also been reported,[16] in association with a fall in the levels of exhaled inflammatory mediators leading the authors of this study to conclude that leukotriene receptor antagonists may provide a complementary effect to inhaled corticosteroids when suppression of inflammation is incomplete. Another study[17] has reported that the use of montelukast did permit reduction in the dose of inhaled corticosteroid; adding montelukast to an inhaled corticosteroid (budesonide) may be as effective as doubling the dose of the corticosteroid.[18]

There is some evidence that montelukast may be more effective than inhaled salmeterol for the chronic treatment of exercise-induced asthma,[19,20] and although a later study[21] found similar effects on lung function with the two drugs, a more favourable effect was seen on gas exchange during moderate exercise with the use of montelukast.

An intravenous form of montelukast is under investigation for the treatment of severe acute asthma.[22,23]

Bronchiolitis. Bronchiolitis due to RSV infection is often followed by post-bronchiolitic reactive airways disease, characterised by asthma-like wheeze and other symptoms. In a pilot study,[1] montelukast 5 mg orally daily was given for 4 weeks to infants who had been admitted for moderate to severe bronchiolitis. Symptom-free days and nights were increased, daytime cough was reduced, and exacerbations were delayed compared with placebo. The benefit of montelukast over placebo was only apparent after the first 2 weeks of treatment. Although the safety and efficacy of such treatment remains to be properly established,[2] there is some interest in whether montelukast can prevent or modify more persistent asthma that has been associated with RSV.

Cystic fibrosis. A small study in children with cystic fibrosis (p.166) found that montelukast reduced eosinophilic inflammation.[1] A later study,[2] reported improved lung function and a reduction in coughing and wheezing, and concluded that montelukast may have measurable anti-inflammatory activity in patients with cystic fibrosis. In a small group of adult patients with cystic fibrosis[3] montelukast improved symptoms, in particular exercise tolerance and peak expiratory flow rates. The patients who benefited the most had positive *Aspergillus* serology, and the authors suggested that colonisation of the airways in cystic fibrosis by *Aspergillus* stimulates T helper cell inflammation and leukotriene synthesis. A review of leukotriene receptor antagonists in cystic fibrosis[4] concluded that clinical benefit seemed likely in a subset of patients with cystic fibrosis who experience bronchial hyperresponsiveness similar to that seen in asthma.

A study into the pharmacokinetics of montelukast in cystic fibrosis[5] found that the dose of montelukast and the dosing interval do not need to be modified if the goal of therapy is to achieve similar serum concentrations as for asthma treatment; however the effectiveness of these concentrations for the inflammatory lung disease of patients with cystic fibrosis was unknown.

Eczema. Despite early indications from some small clinical studies and case reports[1-3] that montelukast might be of benefit in eczema (p.1579) larger, more recent studies have failed to show any improvement compared with placebo.[4,5]

4. Veien NK, *et al.* Montelukast treatment of moderate to severe atopic dermatitis in adults: a randomized, double-blind, placebo-controlled trial. *J Am Acad Dermatol* 2005; **53:** 147–9.
5. Friedmann PS, *et al.* A double-blind, placebo-controlled trial of montelukast in adult atopic eczema. *Clin Exp Allergy* 2007; **37:** 1536–40.

Gastrointestinal disorders. Benefit has been reported[1] with the use of montelukast in patients with eosinophilic oesophagitis, a rare condition involving eosinophilic infiltration of the oesophagus with intermittent painful dysphagia. A systematic review with recommendations for the diagnosis and treatment of eosinophilic oesophagitis[2] concluded that although leukotriene receptor antagonists had been shown to induce symptomatic relief at high doses, no significant improvements in histology were noted and their use for the treatment of eosinophilic oesophagitis is not supported by the current literature.

1. Attwood SEA, *et al.* Eosinophilic oesophagitis: a novel treatment using montelukast. *Gut* 2003; **52:** 181–5.
2. Furuta GT, *et al.* American Gastroenterological Association; North American Society of Pediatric Gastroenterology, Hepatology, and Nutrition. Eosinophilic esophagitis in children and adults: a systematic review and consensus recommendations for diagnosis and treatment. *Gastroenterology* 2007; **133:** 1342–63. Also available at: http://download.journals.elsevierhealth.com/pdfs/journals/0016-5085/PIIS0016508507014746.pdf (accessed 14/04/08)

Graft-versus-host disease. A pilot study in refractory, chronic graft-versus-host disease (GVHD) after allogeneic haematopoietic stem cell transplantation (p.1811),[1] saw an improvement in 15 of 19 patients after montelukast was added to their standard immunosuppressive regimens; in 4 patients signs of chronic GVHD were resolved, 2 showed significant improvement, and 9 showed moderate improvement.

1. Or R, *et al.* Sparing effect by montelukast treatment for chronic graft versus host disease: a pilot study. *Transplantation* 2007; **83:** 577–81.

Mastocytosis. Montelukast has been tried, with some success, in the treatment of systemic mastocytosis (p.1138) in an infant.[1]

1. Tolar J, *et al.* Leukotriene-receptor inhibition for the treatment of systemic mastocytosis. *N Engl J Med* 2004; **350:** 735–6.

Rhinitis. Montelukast is used in allergic rhinitis (p.565), where large placebo-controlled studies have shown it to relieve symptoms in both seasonal allergic rhinitis,[1,2] and perennial allergic rhinitis.[3] However, a meta-analysis[4] of leukotriene antagonists (mainly montelukast) for management of allergic rhinitis concluded that while leukotriene antagonists were modestly more effective than placebo and of similar efficacy to antihistamines, in reducing nasal symptoms and improving rhinoconjunctivitis, they were less effective than corticosteroids even when used with antihistamines. A later systematic review[5] commented that some studies in allergic rhinitis using a combination of montelukast and an antihistamine had produced results comparable with intranasal corticosteroids. Also, in patients with both allergic rhinitis and asthma, montelukast had resulted in significant improvements in both when compared with placebo.

5. Nayak A, Langdon RB. Montelukast in the treatment of allergic rhinitis: an evidence-based review. *Drugs* 2007; **67:** 887–901.

Sleep-disordered breathing. Montelukast with an intranasal corticosteroid has been reported to be beneficial in a small study in children with residual sleep-disordered breathing after tonsillectomy and adenoidectomy.[1]

1. Kheirandish L, *et al.* Intranasal steroids and oral leukotriene modifier therapy in residual sleep-disordered breathing after tonsillectomy and adenoidectomy in children. *Pediatrics* 2006; **117:** e61–e66.

Urticaria. Montelukast has been investigated in the treatment of urticaria (p.1584) with variable results.[1] However, urticaria has also been described as a suspected adverse effect of montelukast therapy (see above).

Montelukast has been reported to be more effective than placebo when used with the antihistamine desloratadine in the treatment of delayed pressure urticaria.[2]

Nedocromil Sodium *(BANM, USAN, rINNM)*

FPL-59002 (nedocromil); FPL-59002KC (nedocromil calcium); FPL-59002KP (nedocromil sodium); Natrii Nedocromilum; Nédocromil Sodique; Nedocromilo sódico; Nedocromilum Natricum; Nedokromiilinatrium; Nedokromil Sodyum; Nedokromilnatrium. Disodium 9-ethyl-6,9-dihydro-4,6-dioxo-10-propyl-4*H*-pyrano[3,2-g]quinoline-2,8-dicarboxylate.

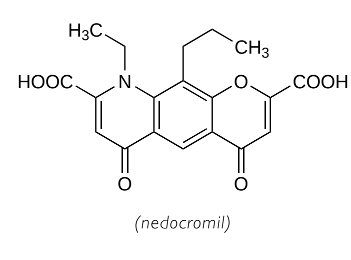
Натрий Недокромил

$C_{19}H_{15}NNa_2O_7 = 415.3.$

CAS — 69049-73-6 (nedocromil); 69049-74-7 (nedocromil sodium); 101626-68-0 (nedocromil calcium).

ATC — R01AC07; R03BC03; S01GX04.

ATC Vet — QR01AC07; QR03BC03; QS01GX04.



(nedocromil)

NOTE. Nedocromil Calcium is also *USAN*.

Adverse Effects and Precautions

Inhaled nedocromil sodium may cause headache, gastrointestinal disturbances (nausea, vomiting, dyspepsia, and abdominal discomfort). An unusual or unpleasant taste is reported rarely. Paradoxical bronchospasm may occur. Eye drops may cause transient burning and stinging.

It should not be used for the treatment of acute asthma attacks. The general cautions described under sodium cromoglicate (see p.1136) also apply.

Incidence of adverse effects. A review[1] of nedocromil sodium noted that adverse effects were infrequent, mild, and short-lived. The most common effect appeared to be an unpleasant or bitter taste, which was experienced by 12 to 13% of patients, although less than 1% of patients stopped treatment because of it. Other adverse effects included cough (in 7%), headache (6%), sore throat (5.7%), nausea (4%), and vomiting (1.7%).

1. Brogden RN, Sorkin EM. Nedocromil sodium: an updated review of its pharmacological properties and therapeutic efficacy in asthma. *Drugs* 1993; **45:** 693–715.

Pharmacokinetics

Nedocromil sodium is poorly absorbed from the gastrointestinal tract; about 10% of the inhaled dose is absorbed from the lungs. Absorption is also poor after topical ophthalmic use, and occurs mainly through the nasal mucosa. Nedocromil sodium is excreted unchanged in the urine and faeces. The half-life is stated to range from about 1 to 3.3 hours.

◊ The extent of absorption or bioavailability of nedocromil sodium after inhalation in healthy subjects was 7 to 9% of the dose, including 2 to 3% oral absorption and 5 to 6% absorption from the respiratory tract.[1] After inhalation of nedocromil sodium 4 mg the mean peak plasma concentration was 3.3 nanograms/mL in healthy subjects and 2.8 nanograms/mL in asthmatic patients, with peak values being reached at about 20 and 40 minutes respectively. The mean total urinary excretion 24 hours after a single dose was 5.4% of the dose in healthy subjects and 2.3% in asthmatics.

1. Neale MG, *et al.* The pharmacokinetics of nedocromil sodium, a new drug for the treatment of reversible obstructive airways disease, in human volunteers and patients with reversible obstructive airways disease. *Br J Clin Pharmacol* 1987; **24:** 493–501.

Uses and Administration

Nedocromil sodium has a stabilising action on mast cells resembling that of sodium cromoglicate (p.1137) and is used similarly in the management of chronic asthma. It should not be used to treat an acute attack of asthma.

For **asthma**, nedocromil sodium is inhaled from a metered-dose aerosol. The usual dose for adults and children from 6 years of age is 4 mg inhaled four times daily which may be decreased to 4 mg twice daily after control of symptoms is achieved. Clinical improvement may not be obtained for 1 week or longer after beginning therapy.

Nedocromil sodium is also used topically in the treatment of **allergic conjunctivitis** and allergic **rhinitis**. For seasonal and perennial allergic conjunctivitis it is given as a 2% solution, instilled into each eye twice daily. This may be increased to 4 times daily if necessary, which is the usual dose in vernal keratoconjunctivitis. In seasonal allergic conjunctivitis, treatment is usually given for no more than 12 weeks. In allergic rhinitis nedocromil sodium is used as a 1% nasal spray: one spray is given into each nostril 4 times daily. For details of doses in children, see Administration in Children, below.

◊ General references.

2. Parish RC, Miller LJ. Nedocromil sodium. *Ann Pharmacother* 1993; **27:** 599–606.

Administration in children. Nedocromil sodium is given by metered-dose aerosol inhalation for the treatment of asthma in children from 6 years of age at the adult dose, see above. Although unlicensed in the UK for younger children, the *BNFC* recommends the same dose from 5 years of age.

Similarly, for the topical treatment of seasonal allergic conjunctivitis and vernal keratoconjunctivitis, the adult dose may be given to children from 6 years of age, see above. Treatment of perennial allergic conjunctivitis with nedocromil sodium is not licensed in children in the UK, but the *BNFC* recommends adult doses from 6 years of age.

Asthma. Nedocromil sodium is generally considered to be an alternative to sodium cromoglicate in the management of asthma (p.1108). Nedocromil has been shown to improve symptoms and reduce bronchodilator intake in adults[1] and children[2] with chronic asthma. However, a systematic review[3] of nedocromil for chronic asthma in children subsequently found that although a number of small studies have shown that nedocromil improves airflow limitation, reduces symptoms, and reduces bronchial hyperresponsiveness, this has not been confirmed in a larger long-term study of children with milder asthma. Its place in relation to other asthma therapies for children is also unclear. It may be used before exercise to reduce exercise-induced bronchoconstriction,[4] and appears to be as effective as sodium cromoglicate for this indication.[5]

5. Kelly K, *et al.* Nedocromil sodium versus sodium cromoglycate for preventing exercise-induced bronchoconstriction in asthmatics. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2000 (accessed 14/04/08).

Cough. For references indicating a positive response to sodium cromoglicate but not to nedocromil sodium in the management of cough induced by ACE inhibitor therapy, see Cough, p.1137.

Rhinitis and conjunctivitis. Nedocromil has been used in the management of allergic rhinitis (p.565) and conjunctivitis (p.564). In the management of seasonal allergic rhinitis, there is some evidence that prophylactic mometasone furoate (p.1539) reduces symptoms more effectively than nedocromil.[1] In vernal keratoconjunctivitis (see p.1138) nedocromil may be more effective than cromoglicate, but is less effective than fluorometholone.[2]

Omalizumab *(BAN, USAN, rINN)*

CGP-51901; E-25; IGE-025; Olizumab; Omalizumabum; rhuMAb-E25. Immunoglobulin G, anti-(human immunoglobulin E Fc region)(human-mouse monoclonal E25 clone pSVIE26 γ-chain), disulfide with human-mouse monoclonal E25 clone pSVIE26 κ-chain, dimer.

Омализумаб

CAS — 242138-07-4.

ATC — R03DX05.

ATC Vet — QR03DX05.

Adverse Effects and Precautions

Injection site reactions are common with the use of omalizumab. Other adverse effects that have been reported include generalised pain, fatigue, arthralgia, dizziness, earache, gastrointestinal disturbances, headache, and alopecia. An increased incidence of parasitic infection has been reported in patients at high risk for helminthic infections. Viral infections, upper respiratory-tract infections, sinusitis, pharyngitis, and flu-like illness can also occur. Churg-Strauss syndrome has also been reported. Hypersensitivity reactions such as urticaria, dermatitis, and pruritus can occur. Rarely, systemic reactions, including potentially life-threatening anaphylaxis, have occurred. Anaphylactic reactions may occur up to 4 days after a dose, and as early as the first dose or more than 1 year after beginning regular treatment.

Severe thrombocytopenia has been reported with use of omalizumab.

Licensed product information notes an increased incidence of malignancies in patients given omalizumab.

Omalizumab should not be used for the treatment of acute asthma attacks, and inhaled corticosteroids should not be abruptly withdrawn on starting omalizumab therapy.

Pharmacokinetics

Omalizumab is absorbed after subcutaneous injection with a bioavailability of about 62%, reaching peak serum concentrations after 7 to 8 days. It is removed by IgG and IgE clearance processes in the liver, with a serum elimination half-life of about 26 days. During treatment with omalizumab, the serum concentration of free IgE decreases but that of total IgE increases because the omalizumab-IgE complex has a slower elimination rate than free IgE.

◊ References.

1. Hayashi N, *et al.* A mechanism-based binding model for the population pharmacokinetics and pharmacodynamics of omalizumab. *Br J Clin Pharmacol* 2007; **63:** 548–61.

Uses and Administration

Omalizumab is a recombinant humanised monoclonal antibody that selectively binds to IgE. It inhibits the binding of IgE on the surface of mast cells and basophils, thus reducing the release of mediators of the allergic response. Omalizumab is used in the prophylactic management of moderate to severe, persistent allergic asthma (p.1108). The dose depends on the patient's weight and pre-treatment serum-IgE concentrations; regimens range from 75 to 300 mg every 4 weeks to 225 to 375 mg every 2 weeks. Omalizumab is given by subcutaneous injection, and not more than 150 mg should be given at one injection site. Total IgE concentrations rise during treatment (see Pharmacokinetics, above), remaining elevated for up to 1 year after withdrawal, and cannot be used to determine continued dosage. Dose determination after treatment interruptions lasting up to 1 year should be based on pre-treatment serum-IgE concentrations.

Omalizumab is under investigation in the prophylactic management of seasonal allergic rhinitis.

Aspergillosis. Successful treatment of allergic bronchopulmonary aspergillosis with omalizumab has been reported in children with cystic fibrosis.[1,2] In one such report,[1] repeated improvement in symptoms and normalisation in lung function within 2 to 4 hours of giving omalizumab led to complete withdrawal of corticosteroid treatment in a 12 year old girl. Others[2] have reported similar benefits.

Asthma. Current guidelines recommend omalizumab as an option for the treatment of severe persistent allergic (IgE mediated) asthma as an add-on therapy to optimised standard therapy in adults (see Asthma, p.1108). It has been shown to reduce exacerbations and corticosteroid requirement compared with placebo in adults with moderate-to-severe allergic asthma.[1] It also reduced exacerbation rates in patients with inadequately controlled, severe persistent asthma,[2] and is considered to be an effective therapy in difficult-to-treat, high-risk adult patients.[3,4]

A systematic review[5] of omalizumab therapy for chronic asthma found that omalizumab was more effective than placebo at reducing exacerbations and improving quality of life. Although omalizumab had an *inhaled*-corticosteroid-sparing effect, the clinical significance of the magnitude of reduction remains open to interpretation, and other factors such as cost-effectiveness and comparative efficacy compared to other add-on therapy should be considered. In patients on *oral* corticosteroids, no significant impact was seen on either exacerbations or oral corticosteroid dose.

Omalizumab has been investigated in the treatment of childhood asthma with encouraging results.[6,7]

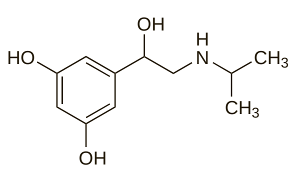
$(C_{11}H_{17}NO_3)_2,H_2SO_4$ = 520.6.

CAS — 586-06-1 (orciprenaline); 5874-97-5 (orciprenaline sulfate).

ATC — R03AB03; R03CB03.

ATC Vet — QR03AB03; QR03CB03.



(orciprenaline)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Orciprenaline Sulphate). A white, slightly hygroscopic, crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane. A 10% solution in water has a pH of 4.0 to 5.5. Store in airtight containers. Protect from light.

USP 31 (Metaproterenol Sulfate). A white to off-white crystalline powder. Freely soluble in water. A 10% solution in water has a pH of 4.0 to 5.5. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for Salbutamol, p.1131. Adverse effects are more common because of the non-selective beta agonist effect of orciprenaline. For the adverse effects and precautions pertaining to non-selective beta agonists see under Sympathomimetics, p.1407.

Interactions

As for Salbutamol, p.1132.

Pharmacokinetics

After oral doses orciprenaline is absorbed from the gastrointestinal tract and undergoes extensive first-pass metabolism in the liver; about 40% of an oral dose is reported to reach the circulation unchanged. It is excreted in the urine primarily as metabolites.

Uses and Administration

Orciprenaline sulfate is a direct-acting sympathomimetic with mainly beta-adrenoceptor stimulant activity. It has actions and uses similar to those of salbutamol (p.1133) but is less selective for beta$_2$ receptors.

Orciprenaline sulfate is used as a bronchodilator in the management of reversible airways obstruction, as in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). However, more selective beta$_2$ agonists such as salbutamol or terbutaline are now preferred. On inhalation, the onset of action is usually within 30 minutes and can last from 1 to 5 hours.

A typical adult dose for the relief of acute **bronchospasm** has been 1 or 2 inhalations of orciprenaline sulfate 750 micrograms from a metered-dose aerosol, repeated as needed up to a maximum of 12 inhalations (9 mg) in 24 hours. In patients with asthma, 'as-required' beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, orciprenaline indicates deterioration of asthma control and the need for review of therapy.

Orciprenaline sulfate has also been inhaled in 5% solution from a hand nebuliser, the usual adult dose being 10 inhalations. If the solution is used with any other nebulising device such as an intermittent positive-pressure breathing (IPPB) apparatus the adult dose is 0.2 to 0.3 mL of a 5% solution diluted up to about 2.5 mL with physiological saline (i.e. dilution to a 0.4 to 0.6% solution) given not more often than every 4 hours. Unit-dose vials containing a prediluted solution of orciprenaline sulfate 0.4 and 0.6% are also available for nebulisation by an IPPB device.

In the chronic management of reversible airways obstruction, orciprenaline sulfate has been given orally in a usual adult dose of 20 mg three or four times daily.

Orciprenaline sulfate has also been used similarly to isoprenaline (see p.1317) for its cardiovascular effects in the treatment of **bradycardia** of various types, notably in AV heart block and sinus bradycardia. In such cases oral doses of up to 240 mg daily in divided doses, or 250 to 500 micrograms by slow intravenous injection have been given; orciprenaline sulfate may also be given by intravenous infusion, or intramuscular or subcutaneous injection. For doses of orciprenaline used in children, see Administration in Children, below.

Administration in children. Although more selective beta agonists are generally preferred, in some countries orciprenaline sulfate is licensed for use in children via a metered-dose inhaler in similar doses to adults; in the USA, use is not recommended under 12 years of age. A metered-dose inhaler was formerly available in the UK and licensed doses in children were:

- under 6 years of age: 1 inhalation of 750 micrograms as necessary; doses should not be repeated within 30 minutes. A maximum of 4 inhalations in 24 hours was suggested
- 6 to 12 years of age: 1 or 2 inhalations of 750 micrograms as necessary; doses should not be repeated within 30 minutes. A maximum of 8 inhalations in 24 hours was suggested

In patients with asthma, 'as-required' beta agonist therapy is preferable to regular use, and chronic oral treatment with orciprenaline would generally be regarded as inappropriate in children. Nonetheless, a syrup is licensed for such use in the UK, licensed oral doses in children being:

- up to 1 year: 5 mg three times daily, increased if necessary to a maximum of 10 mg three times daily
- 1 to 3 years: 5 mg four times daily, increased if necessary to a maximum of 10 mg four times daily
- 3 to 12 years: 10 mg four times daily, increased if necessary to a maximum of 20 mg three times daily
- over 12 years: as for adults (see above)

Preparations

BP 2008: Orciprenaline Tablets;

Oxitropium Bromide *(BAN, rINN)*

Ba-253; Bromuro de oxitropio; Oksitropiumbromidi; Oxitropii bromidum; Oxitropium, bromure d'; Oxitropiumbromid. 6,7-Epoxy-8-ethyl-3-[(*S*)-tropoyloxy]tropanium bromide; (3*s*,6*R*,7*S*,8*r*)-8-Ethyl-3-[(*S*)-tropoyloxy]-6,7-epoxytropanium bromide.

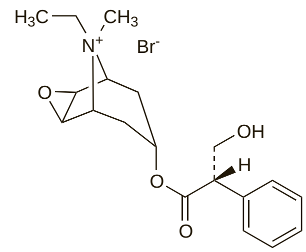
Окситропия Бромид

$C_{19}H_{26}BrNO_4$ = 412.3.

CAS — 30286-75-0.

ATC — R03BB02.

ATC Vet — QR03BB02.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Oxitropium Bromide). A white or almost white, crystalline powder. It exhibits polymorphism. Very soluble in water; sparingly soluble in alcohol; freely soluble in methyl alcohol; practically insoluble in dichloromethane.

Profile

Oxitropium bromide is a quaternary ammonium antimuscarinic with actions similar to those of ipratropium bromide (p.1124), to which it is structurally related. It is used as a bronchodilator in the treatment of reversible airways obstruction, as in asthma (p.1108) and chronic obstructive pulmonary disease (p.1112). Doses of 100 or 200 micrograms by inhalation from a metered-dose aerosol have been given 2 or 3 times daily. Oxitropium bromide may also be given as a nebulised solution in doses of 1.5 mg inhaled 2 or 3 times daily. *Animal* studies have shown reproductive toxicity with high doses of oxitropium, hence the recommendation that it should not be used during pregnancy.

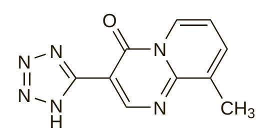
Pemirolast Potassium *(USAN, rINNM)*

BL-5617; BMY-26517; Kalii Pemirolastum; Pemirolast potásico; Pémirolast Potassique. Potassium 9-methyl-3-(1*H*-tetrazol-5-yl)-4*H*-pyrido[1,2-*a*]pyrimidin-4-one.

Калия Пемироласт

$C_{10}H_7KN_6O$ = 266.3.

CAS — 69372-19-6 (pemirolast); 100299-08-9 (pemirolast potassium).



(pemirolast)

Profile

Pemirolast potassium has mast cell stabilising properties like sodium cromoglicate (p.1136) and may also be a leukotriene inhibitor. It has been used in the treatment of chronic asthma (p.1108) and in the prophylaxis of allergic rhinitis (p.565) and conjunctivitis (p.564). Pemirolast potassium has no bronchodilator properties and should not be used for the treatment of acute asthma attacks.

For asthma, the usual dose is 10 mg orally twice daily after food. For allergic rhinitis the dose is halved. Pemirolast potassium 0.1% eye drops are instilled 4 times daily in the prophylactic management of allergic conjunctivitis. For details of doses in children, see below.

Pemirolast has also been investigated for the prevention of restenosis after coronary artery stent placement.

8. Yahata H, *et al.* Prophylactic effect of pemirolast, an antiallergic agent, against hypersensitivity reactions to paclitaxel in patients with ovarian cancer. *Int J Cancer* 2006; **118:** 2636–8.

Administration in children. Pemirolast potassium may be used in the management of asthma in children in the following oral doses:

- 1 to 4 years: 2.5 mg twice daily after food
- 5 to 10 years: 5 mg twice daily after food
- 11 years and above: use adult doses, see above

For allergic rhinitis, the above doses are halved.

Pemirolast potassium 0.1% eye drops can be used four times daily in children over 3 years with allergic conjunctivitis.

Пирбутерола Гидрохлорид

$C_{12}H_{20}N_2O_3,2HCl$ = 313.2.
CAS — 38029-10-6.
ATC — R03AC08; R03CC07.
ATC Vet — QR03AC08; QR03CC07.

Profile

Pirbuterol is a direct-acting sympathomimetic with mainly beta-adrenoceptor stimulant activity and a selective action on $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131).

Pirbuterol is used for its bronchodilating properties. It is given as the acetate in the management of reversible airways obstruction, as in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). On inhalation, pirbuterol exerts an effect within 10 minutes, which is reported to last at least 5 hours.

Pirbuterol is given by inhalation as the acetate but doses are expressed in terms of the base: pirbuterol acetate 250 micrograms is equivalent to about 200 micrograms of pirbuterol. It is given via a metered-dose aerosol in a usual dose equivalent to pirbuterol 200 to 400 micrograms (1 to 2 inhalations) as required but not more often than every four hours. A total daily dose of 2.4 mg (12 inhalations) should not be exceeded. In patients with asthma, 'as-required' beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, pirbuterol indicates deterioration of asthma control and the need for review of therapy.

Pirbuterol has also been given orally as the hydrochloride.

Profile

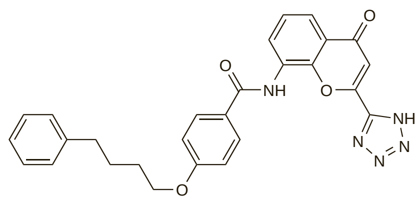
Pitrakinra is a dual interleukin-4 and -13 receptor antagonist that is under investigation in the treatment of asthma.

Pranlukast *(BAN, rINN)*

ONO-1078; Pranlukastum. *N*-[4-Oxo-2-(1*H*-tetrazol-5-yl)-4*H*-1-benzopyran-8-yl]-*p*-(4-phenylbutoxy)benzamide.

Пранлукаст

$C_{27}H_{23}N_5O_4$ = 481.5.
CAS — 103177-37-3.
ATC — R03DC02.
ATC Vet — QR03DC02.



Profile

Pranlukast is a selective antagonist of the leukotriene C_4, D_4, and E_4 receptors with similar properties to zafirlukast (p.1150). It is used in the management of asthma (p.1108) and allergic rhinitis (p.565), at a usual oral dose of pranlukast hydrate 225 mg twice daily. For details of doses in children, see below.

◊ References.

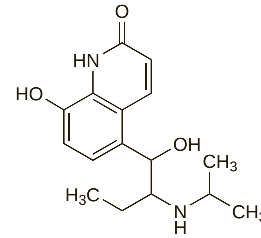
(±)-*erythro*-8-Hydroxy-5-(1-hydroxy-2-isopropylaminobutyl)quinolin-2(1*H*)-one hydrochloride; (±)-8-Hydroxy-5-[(1*R**,2*S**)-1-hydroxy-2-isopropylaminobutyl]-2-quinolone hydrochloride.

Прокатерола Гидрохлорид

$C_{16}H_{22}N_2O_3,HCl$ = 326.8.
CAS — 72332-33-3 (procaterol); 59828-07-8 (procaterol hydrochloride).
ATC — R03AC16; R03CC08.
ATC Vet — QR03AC16; QR03CC08.



(procaterol)

NOTE. Commercial procaterol hydrochloride is the hemihydrate ($C_{16}H_{22}N_2O_3,HCl,½H_2O$ = 335.8).

Pharmacopoeias. *Chin.* and *Jpn* include the hemihydrate.

Profile

Procaterol hydrochloride is a direct-acting sympathomimetic with mainly beta-adrenoceptor stimulant activity selective to $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131) and it is used as a bronchodilator in the management of reversible airways obstruction, as in asthma (p.1108) or in some patients with chronic obstructive pulmonary disease (p.1112). On inhalation it produces an effect within 5 minutes and the effect can last up to 8 hours.

To relieve acute bronchospasm, a usual dose of 20 micrograms of procaterol hydrochloride is given by inhalation from a metered-dose aerosol or dry powder inhaler up to 4 times daily. In patients with asthma, 'as-required' beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, procaterol indicates deterioration of asthma control and the need for review of therapy. An inhalation solution containing 100 micrograms/mL has been given via a nebuliser in usual doses of 30 to 50 micrograms. Procaterol hydrochloride can also be given orally in doses of 50 micrograms once or twice daily.

Reproterol Hydrochloride *(BANM, USAN, rINNM)* ⊗

D-1959 (reproterol); Hidrocloruro de reproterol; Réprotérol, Chlorhydrate de; Reproteroli Hydrochloridum; W-2946M. 7-{3-[(3,5,β-Trihydroxyphenethyl)amino]propyl}theophylline hydrochloride.

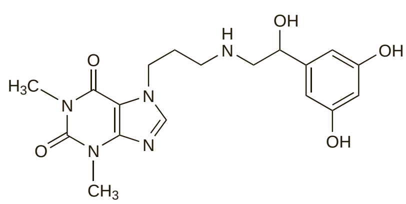
Репротерола Гидрохлорид

$C_{18}H_{23}N_5O_5,HCl$ = 425.9.

CAS — 54063-54-6 (reproterol); 13055-82-8 (reproterol hydrochloride).

ATC — R03AC15; R03CC14.

ATC Vet — QR03AC15; QR03CC14.



(reproterol)

Profile

Reproterol is a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131).

Reproterol hydrochloride is used as a bronchodilator in the management of reversible airways obstruction, as in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112).

For the relief of acute attacks of bronchospasm the usual dose of reproterol hydrochloride is 1 or 2 inhalations of 500 micrograms from a metered-dose aerosol repeated every 3 to 6 hours as required. Reproterol is often used with sodium cromoglicate in combined preparations. In patients with asthma, 'as-required' beta agonist therapy is preferable to regular use. An increased need for, or decreased duration of effect of, reproterol indicates deterioration of asthma control and the need for review of therapy. It has also been given orally: adult doses are 10 to 20 mg three times daily. A slow intravenous injection of 90 micrograms, repeated after 10 minutes if necessary, has been used in the treatment of status asthmaticus.

For doses of reproterol used in children, see Administration in Children, below.

Administration in children. Reproterol hydrochloride has been given via a metered-dose aerosol to relieve bronchospasm in children from 6 years of age at the same dose used in adults (see Uses and Administration, above). Reproterol is often used with sodium cromoglicate in combined preparations.

Reproterol hydrochloride has also been given orally to children from 6 years of age at a dose of 10 mg three times daily.

USP 31 (Albuterol Sulfate). A white or practically white powder. Freely soluble in water; slightly soluble in alcohol, in chloroform, and in ether. Protect from light.

Stability. For mention of the stability of a 1:1 mixture of salbutamol and ipratropium nebuliser solutions, see under Ipratropium, p.1124.

Adverse Effects

As for Sympathomimetics, p.1407. Salbutamol has mainly beta-agonist effects and, like other beta agonists, may cause fine tremor of skeletal muscle (particularly the hands), palpitations, tachycardia, nervous tension, headaches, peripheral vasodilatation, and rarely muscle cramps. Inhalation causes fewer adverse effects than systemic dosage, and the more selective $beta_2$ agonists cause fewer adverse effects than less selective beta agonists. Potentially serious hypokalaemia has been reported after large doses. Myocardial ischaemia has also been reported. Hypersensitivity reactions have occurred, including paradoxical bronchospasm, angioedema, urticaria, hypotension, and collapse.

The high doses of salbutamol used intravenously to delay premature labour have additionally been associated with nausea and vomiting, and with severe adverse cardiac and metabolic effects and pulmonary oedema.

Effects on the CNS. Visual hallucinations lasting for an hour have been reported[1] after use of nebulised salbutamol in an elderly patient. At the time of the report the manufacturers were aware of 3 cases of hallucinations in children given oral salbutamol but no such reaction had been previously reported in adults given recommended doses.

Hyperactivity and restlessness have been reported with the use of salbutamol; however, a small placebo-controlled study of 19 children,[2] failed to show a statistically significant difference in activity levels after a nebulised dose of salbutamol.

1. Khanna PB, Davies R. Hallucinations associated with the administration of salbutamol via a nebuliser. *BMJ* 1986; **292:** 1430.
2. Hadjikoumi I, *et al.* Bronchodilator therapy and hyperactivity in preschool children. *Arch Dis Child* 2002; **86:** 202–4. Also available at: http://adc.bmj.com/cgi/reprint/86/3/202 (accessed 15/01/08)

Effects on electrolytes and metabolism. Salbutamol, in common with other $beta_2$-agonists, may cause *hypokalaemia* and *hyperglycaemia*. These effects are related to the dose and route of salbutamol used; hypokalaemia is more common after parenteral and nebulised use. Hypokalaemia may be potentiated by therapy with corticosteroids, diuretics, or xanthines, and by hypoxia; potassium concentrations should therefore be monitored in severe asthma.

Effects on the eyes. It has been suggested that salbutamol and to a greater extent ritodrine may contribute to retinopathy in the premature infant when used for premature labour.[1]

A case of acute angle-closure glaucoma was attributed to dilatation of the pupil by stimulation of the sympathetic nervous system secondary to local absorption of nebulised salbutamol in the eye; the patient also had other risk factors for developing glaucoma.[2] For reports of glaucoma precipitated by the combined use of ipratropium bromide and salbutamol via a nebuliser, see Ipratropium Bromide, p.1124.

Effects on the heart. The main adverse cardiac effect of salbutamol is tachycardia due to increased sympathetic effects on the cardiovascular system. Such tachycardia is dose dependent and is more common after systemic than inhaled therapy. A meta-analysis[1] of randomised, placebo-controlled studies in patients with asthma or chronic obstructive pulmonary disease (COPD) confirmed that single doses of $beta_2$ agonists can cause an increase in heart rate and a reduction in potassium concentrations (see also Effects on Electrolytes and Metabolism, above). The longer-term effects of beta$_2$ agonists on the cardiovascular system were also assessed and an increased risk of adverse cardiovascular events due to sinus tachycardia was found. There was also a trend towards an increase in major adverse events including ventricular tachycardia, atrial fibrillation, syncope, heart failure, myocardial infarction, cardiac arrest, and sudden death. Myocardial ischaemia has been reported in association with salbutamol when used to delay premature labour.[2] Eleven of 17 reports were considered serious, including one fatality. Most of these reports involved the use of parenteral formulations; none involved the use of inhaled salbutamol formulations for the relief of bronchospasm. However, there is some evidence that high doses of inhaled salbutamol can decrease coronary flow reserve, and might exacerbate ischaemia in patients with coronary artery disease.[3] Case-control studies[4,5] have also suggested that the use of inhaled beta$_2$ agonists is associated with an increased risk of myocardial infarction, and another case-control study[6] found an increased risk of cardiac arrest in patients with asthma being treated with inhaled short-acting beta$_2$ agonists, but not in those with COPD. In contrast, however, a cohort study[7] of patients with COPD found no increase in the risk of myocardial infarction associated with the use of beta$_2$ agonists given by inhalation, nebulisation, or mouth. Case-control and cohort studies have also suggested that patients with pre-existing heart failure may be at increased risk of hospitalisation from arrhythmias[8] or exacerbation of heart failure[9,10] with the use of beta$_2$ agonists.

A causal relationship cannot necessarily be established from these case-control and cohort studies, however, because of confounding factors such as co-morbidity, and because the extent of beta$_2$ agonist use could only be estimated from prescription record systems.

Effects on the respiratory system. Paradoxical bronchoconstriction has occasionally been reported after bronchodilating therapy. With nebuliser solutions, it has been suggested that the preservatives present could be responsible (see also under Ipratropium, p.1124), or that the pH may contribute if non-neutral. In addition, regular use of beta$_2$ agonists such as salbutamol (as opposed to use on an as-needed basis) has been shown to increase airway hyperresponsiveness to various stimuli and to lead to the possible development of tolerance to the bronchoprotective effect (see below).

The increased risk of pulmonary oedema associated with salbutamol is mentioned under Pulmonary Oedema, below.

Increased mortality. The increased incidence of morbidity and mortality that occurred in asthmatic patients mainly involved fenoterol, but salbutamol has been implicated. The debate on the relevance of beta agonist therapy to this increased morbidity and mortality is discussed under Fenoterol on p.1121.

Overdosage. Reports of overdosage with salbutamol[1-6] have generally only described the features that may be expected with beta$_2$ agonists such as tachycardia, CNS stimulation, tremor, hypokalaemia, and hyperglycaemia. Symptomatic treatment of the adverse effects has proved successful although it is unlikely to be required after repeated inhalation. Activated charcoal may be considered after oral overdose in patients who have taken a potentially toxic amount and present within 1 hour. The plasma-potassium concentration and pulse rate have been found to correlate with the plasma concentration of salbutamol.[7]

Pregnancy. Most adverse effects associated with salbutamol in pregnancy relate to the cardiovascular and metabolic effects of the very high doses given by intravenous infusion in attempts to delay premature labour (see also under Pulmonary Oedema, below). Maternal effects include myocardial ischaemia,[1,2] unifocal ventricular ectopics associated with the hypokalaemic response to intravenous salbutamol,[3] and heart failure in a hypertensive woman.[4] Similarly, serious fetal and neonatal cardiovascular complications have also been associated with tocolytic salbutamol.[5]

Metabolic acidosis after salbutamol infusions in diabetic women has also been reported.[6,7]

Pulmonary oedema. Pulmonary oedema has occurred in women given beta$_2$ agonists, including salbutamol,[1-4] for premature labour. The risk factors, the most important of which is fluid overload, are discussed under Precautions, below.

Tolerance. Some studies suggest that regular inhalation of a short-acting beta$_2$ agonist, although it continues to produce bronchodilatation, increases airway hyperresponsiveness and may reduce the protective effect against bronchoconstriction provoked by stimuli such as bradykinin, methacholine, or allergen.[1-6] Such tolerance is considered another argument against regular use of short-acting drugs.[1] Reduced bronchoprotective effects have also been demonstrated with long-acting beta$_2$ agonists (see Salmeterol, p.1135).

It has been suggested that reduced benefit with salbutamol may be due to the *S*(+)-enantiomer,[7,8] which unlike the *R*(−)-enantiomer (levosalbutamol, p.1125) does not possess bronchodilating activity. Stereoselective metabolism (see under Pharmacokinetics, below) means that regular use of the racemate could lead to accumulation of the *S*-enantiomer, which provides a possible mechanism for the effect. Genetic polymorphism of the beta$_2$-adrenoceptor has also been proposed as another possible mechanism.[9,10]

Precautions

Salbutamol and other beta agonists should be given with caution in hyperthyroidism, myocardial insufficiency, arrhythmias, susceptibility to QT-interval prolongation, hypertension, and diabetes mellitus (especially on intravenous use—blood glucose should be monitored since ketoacidosis has been reported).

In *severe asthma* particular caution is also required to avoid inducing hypokalaemia as this effect may be potentiated by hypoxia or by the effect of other anti-asthma drugs on potassium (see Interactions, below); plasma-potassium concentrations should be monitored.

Beta$_2$ agonists such as salbutamol are not appropriate for use alone in the treatment of more than mild asthma (see Asthma, p.1108). Increasing need for, or decreased duration of effect of, inhaled salbutamol and other short-acting beta$_2$ agonists indicates deterioration of asthma control and the likely requirement for increased anti-inflammatory therapy.

In *women being treated for premature labour* the risk of pulmonary oedema means that the patient's state of hydration and cardiac and respiratory function should be monitored very carefully; the volume of infusion fluid should be kept to the minimum (normally using glucose 5% as the diluent), and beta$_2$-agonist therapy should be stopped immediately and diuretic therapy started if signs of pulmonary oedema develop. Other risk factors for pulmonary oedema include multiple pregnancy and heart disease. Ischaemic heart disease or significant risk factors for ischaemic heart disease are specific contra-indications; where heart disease is suspected assessment by a physician experienced in cardiology is needed. Eclampsia and severe pre-eclampsia are also contra-indications, with special care needed in mild to moderate pre-eclampsia. Other contra-indications include intra-uterine infection, intra-uterine fetal death, antepartum haemorrhage (which requires immediate delivery), placenta praevia, and cord compression; beta$_2$ agonists should not be used for threatened miscarriage. See also Uses and Administration, below.

For details of the precautions to be observed with sympathomimetics in general, see p.1407.

Abuse. Salbutamol inhalers have been subject to abuse, particularly by children and young adults.[1-5] This has occurred in both asthmatic and non-asthmatic individuals and has been thought to be for the effect of sympathetic stimulation and for the effect of the fluorocarbon propellants. The introduction of fluorocarbon-free inhalers should reduce the latter motivation, although not the former.

Interactions

Use of salbutamol and other beta$_2$ agonists with corticosteroids, diuretics, or xanthines increases the risk of hypokalaemia, and monitoring of potassium concentrations is recommended in severe asthma, where such combination therapy is common (see also Effects on Electrolytes and Metabolism, above). For an outline of interactions associated with sympathomimetics in general, see p.1407.

Beta$_2$ agonists. Patients receiving *salmeterol* may require salbutamol to control an acute attack of bronchospasm. One study indicated that the effects might be additive,[1] but another showed that patients receiving salmeterol had reduced sensitivity to salbutamol and might need higher doses of the latter for acute relief.[2] However, a study in asthmatics admitted to a hospital emergency department with acute exacerbations of their illness, found that previous salmeterol therapy did not reduce the effectiveness of standard doses of salbutamol.[3] Others have also noted attenuation of the bronchoprotective effects of a beta$_2$ agonist (in this case, *fenoterol*) by salmeterol.[4]

2. Grove A, Lipworth BJ. Bronchodilator subsensitivity to salbutamol after twice daily salmeterol in asthmatic patients. *Lancet* 1995; **346:** 201–6.
3. Korosec M, *et al.* Salmeterol does not compromise the bronchodilator response to albuterol during acute episodes of asthma. *Am J Med* 1999; **107:** 209–13.
4. van Veen A, *et al.* Regular use of long-acting β -adrenoceptor agonists attenuates the bronchoprotective efficacy of short-acting β -adrenoceptor agonists in asthma. *Br J Clin Pharmacol* 2000; **50:** 499P.

Beta blockers. Non-cardioselective beta blockers oppose the bronchodilator effects of beta-agonist bronchodilators and are contra-indicated in asthmatic patients as they may cause serious bronchoconstriction, even if given as eye drops. No adverse interaction normally occurs between beta-agonist bronchodilators and cardioselective beta blockers; however, bronchospasm can sometimes occur in asthmatic patients, particularly if high doses are used. In a case-control study in postoperative coronary artery bypass graft patients, use of sotalol with salbutamol led to an increased risk for postoperative atrial fibrillation.[1]

1. Vader C, *et al.* Interaction between sotalol and albuterol after CABG: influence on postoperative arrhythmias and length of stay at an intensive care unit. *Br J Clin Pharmacol* 2002; **53:** 555P–556P.

Cardiac glycosides. Hypokalaemia produced by beta$_2$ agonists may result in an increased susceptibility to digitalis-induced arrhythmias although salbutamol intravenously and by mouth can also decrease serum concentrations of *digoxin* (see Beta$_2$ Agonists, p.1262).

Corticosteroids. Corticosteroids and beta$_2$ agonists may both produce falls in plasma potassium concentrations; there is evidence that such falls can be exacerbated by use together.[1] The possibility of enhanced hyperglycaemic effects from such a combination should also be borne in mind.

It has been suggested that in acute severe asthma, corticosteroids may modify beta receptors, reversing the beta receptor desensitisation and downregulation caused by beta$_2$ agonists and enhancing the bronchodilator response.[2] In chronic asthma there is little evidence to support this theory; however, combination therapy with corticosteroids and beta$_2$ agonists has been found to have beneficial effects on asthma control; the exact mechanism for this remains unclear.

2. Taylor DR, Hancox RJ. Interactions between corticosteroids and β agonists. *Thorax* 2000; **55:** 595–602.

Diuretics. Hypokalaemia is known to be a possible adverse effect during treatment with beta$_2$ agonists such as salbutamol or terbutaline, and this may be enhanced if diuretics are also given;[1,2] in addition the arrhythmogenic potential of this interaction may be clinically important in patients with ischaemic heart disease.[1]

1. Lipworth BJ, *et al.* Prior treatment with diuretic augments the hypokalemic and electrocardiographic effects of inhaled albuterol. *Am J Med* 1989; **86:** 653–7.
2. Newnham DM, *et al.* The effects of frusemide and triamterene on the hypokalaemic and electrocardiographic responses to inhaled terbutaline. *Br J Clin Pharmacol* 1991; **32:** 630–2.

Neuromuscular blockers. Salbutamol given intravenously has been reported to enhance the neuromuscular blockade produced by *pancuronium* and by *vecuronium* (see Sympathomimetics, p.1905).

Xanthines. An enhanced hypokalaemic effect may occur when salbutamol is given with *theophylline*.[1,2] See also under Terbutaline, p.1139 and Sympathomimetics, under Theophylline, p.1145 for the potentiation of other effects.

2. Kolski GB, *et al.* Hypokalemia and respiratory arrest in an infant with status asthmaticus. *J Pediatr* 1988; **112:** 304–7.

Pharmacokinetics

Salbutamol is readily absorbed from the gastrointestinal tract. When given by inhalation, 10 to 20% of the dose reaches the lower airways. The remainder is retained in the delivery system or is swallowed and absorbed from the gut.

Salbutamol is subject to first-pass metabolism in the liver and possibly in the gut wall but does not appear to be metabolised in the lung; the main metabolite is the inactive sulfate conjugate.

Salbutamol is rapidly excreted, mainly in the urine, as metabolites and unchanged drug; a smaller proportion is excreted in the faeces.

The plasma half-life of salbutamol has been estimated to range from 4 to 6 hours.

Stereoselectivity. The *R*(–)-enantiomer of salbutamol (levosalbutamol—p.1125) is preferentially metabolised and is therefore cleared from the body more rapidly than the *S*(+)-enantiomer, which lacks bronchodilator activity but may be implicated in some of the adverse effects of salbutamol (see Tolerance, under Adverse Effects, above).

Uses and Administration

Salbutamol is a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on beta$_2$ receptors (a beta$_2$ agonist—p.1108). This results in its bronchodilating action being more prominent than its effect on the heart.

Salbutamol and salbutamol sulfate are used as bronchodilators in the management of reversible airways obstruction, as in asthma and in some patients with chronic obstructive pulmonary disease. Salbutamol also decreases uterine contractility and may be given as the sulfate to arrest premature labour (p.2003).

Inhalation results in the rapid onset (within 5 minutes) of bronchodilatation, which lasts for about 3 to 6 hours. After oral doses, the onset of action is within 30 minutes, with a peak effect between 2 to 3 hours after the dose, and a duration of action of up to 6 hours; modified-release preparations that have a longer duration of action are available.

Salbutamol is used as the base or sulfate in aerosol inhalers and as the sulfate in other preparations. The dosage is expressed in terms of salbutamol base; salbutamol sulfate 1.2 mg is equivalent to about 1 mg of salbutamol.

For the relief of **acute bronchospasm**, 1 or 2 inhalations of salbutamol 100 micrograms may be given from a conventional *metered-dose aerosol* as required, up to 4 times daily. Two inhalations may also be given just before exertion for the prophylaxis of exercise-induced bronchospasm. (In the USA these inhalations may be expressed as supplying 100 micrograms, the amount delivered *into* the mouthpiece, or 90 micrograms, the amount delivered *from* the mouthpiece.) Current asthma guidelines (see p.1108) recommend that inhaled short-acting beta$_2$ agonists such as salbutamol be used on an as-required, not regular, basis. In those patients requiring more than occasional use of salbutamol, anti-inflammatory therapy is also needed. An increased requirement for, or decreased duration of effect of, salbutamol indicates deterioration of asthma control and the need for increased anti-inflammatory therapy. Salbutamol sulfate is now available in chlorofluorocarbon (CFC)-free aerosols. Doses for these aerosols (expressed in terms of salbutamol) are the same as for conventional aerosols.

Salbutamol may also be inhaled as the sulfate from dry powder *inhalation capsules* or *discs*, particularly by patients who experience difficulty in using aerosol formulations. Owing to differences in the relative bioavailability to the lungs between these dry powder systems and the inhalation aerosol a 200-microgram dose (expressed in terms of salbutamol) from an inhalation capsule or disc is about equivalent in activity to a 100-microgram dose from a conventional aerosol; usual recommended doses are 200 or 400 micrograms up to four times daily.

When inhalation is ineffective, *oral* salbutamol may be given in a dose of 2 to 4 mg three or four times daily as the sulfate; some patients may require doses of up to 8 mg three or four times daily, but such increased doses are unlikely to be tolerated or to provide much extra benefit. Elderly patients should be given the lower doses initially. Modified-release preparations are also available; a usual adult dose is 8 mg twice daily.

In more severe or unresponsive bronchospasm salbutamol sulfate may be given intermittently via a *nebuliser* in adults and children. Licensed doses are 2.5 to 5 mg of salbutamol repeated up to 4 times daily; continuous use is also possible, usually at a rate of 1 to 2 mg/hour. However, guidelines allow for more frequent use or continuous use at a higher rate in acute severe asthma (see under Asthma, p.1108). Single-dose units of 0.1% or 0.2%, or a concentrated solution of salbutamol 0.5%, are available for nebulisation. Continuous use is usually as a 0.005 to 0.01% solution in sodium chloride 0.9%. Patients with acute severe asthma may require supplemental oxygen.

In acute severe asthma where delivery via nebuliser is not available, 4 to 6 inhalations of salbutamol 100 micrograms from a metered-dose inhaler may be given at intervals of 10 to 20 minutes via a large volume spacer.

In the management of a severe attack of bronchospasm a slow *intravenous injection* of salbutamol 250 micrograms as a solution containing 50 micrograms/mL as the sulfate may be required; alternatively salbutamol may be given by intravenous infusion of a solution containing 5 mg in 500 mL (10 micrograms/mL) at a usual rate of 3 to 20 micrograms/minute according to the patient's need; higher dosages have been used in patients with respiratory failure.

Salbutamol sulfate can also be given for bronchospasm by *subcutaneous* or *intramuscular* injection in doses of salbutamol 500 micrograms every 4 hours as required.

For the arrest of uncomplicated **premature labour** between 24 and 33 weeks of gestation salbutamol sulfate is given by *intravenous infusion*, preferably with the aid of a syringe pump at a concentration of 200 micrograms/mL of salbutamol in glucose 5%. If no syringe pump is available then the infusion should be with a more dilute solution of 20 micrograms/mL in glucose 5%. The same dose is used as with the syringe pump. The recommended initial rate of infusion is 10 micrograms/minute increased at intervals of 10 minutes until there is a response; the rate is then increased slowly until contractions cease. The usual effective dose is 10 to 45 micrograms/minute. The infusion should be maintained at the rate at which contractions cease for 1 hour, then reduced by decrements of 50% at intervals of 6 hours. Prolonged therapy should be avoided as the risks to the mother (see Precautions, above) increase after 48 hours, and there is a lack of evidence of benefit from further treatment.

The maternal pulse should be monitored throughout the infusion and the infusion rate adjusted to avoid a maternal heart rate of more than 140 beats/minute. A close watch should also be kept on the patient's state of hydration since fluid overload is considered to be a key risk factor for pulmonary oedema.

Salbutamol may subsequently be given *orally* in a dose of 4 mg three or four times daily but such usage is not recommended by the *BNF*, given the problems with prolonged therapy already mentioned.

For doses of salbutamol used in children, see Administration in Children below.

Administration. Beta$_2$ agonists are used extensively in the management of reversible airways obstruction. A common, effective, and convenient method of dosage is by a pressurised aerosol inhaler. With this route relief is provided rapidly and fewer systemic adverse effects are likely to occur than with oral use. It is important that patients using conventional inhalers employ the correct technique, which involves coordinating actuation of the aerosol with inhalation; if patients have difficulty with this, alternatives are available. Spacer devices may be used with inhalers. These are added on to the inhaler and reduce the velocity of the aerosol; also more propellant may evaporate before inhalation allowing a greater proportion of the drug to reach the lungs, and coordination of actuation of the aerosol and inhalation is less important. Breath-actuated aerosol inhalers and dry powder inhalers are also available and are actuated by the patient's inspiration and thus avoid entirely the need for coordination of actuation and inhalation; however, inhalation of the dry powder has occasionally caused irritation of the throat or coughing.

The oral route can be used although generally a form of inhaled therapy as described above is preferable. Formulations intended for oral use are commercially available, including modified-release formulations. Nebulisation is an alternative method of delivery and this may be used in the management of severe acute attacks as may parenteral therapy.

Chlorofluorocarbon (CFC) propellants in pressurised aerosol inhalers are being replaced by hydrofluoroalkane (HFA) propellants. Conventional and breath-actuated HFA preparations are available. HFA aerosols may feel and taste different to CFC aerosols.

Administration in children. For the treatment of reversible airways obstruction, including nocturnal asthma, and prevention of exercise-induced **bronchospasm** in children, the *BNFC* suggests the following doses:

by aerosol inhalation

- 1 month to 18 years of age, 100 or 200 micrograms (1 or 2 inhalations) up to four times daily, for occasional use only

by inhalation of dry powder from inhalation capsules or discs

- 5 to 12 years of age, 200 micrograms up to four times daily, for occasional use only
- over 12 years of age, doses as for adults, see Uses and Administration, above

Inhaled therapy is generally considered first-line treatment, but oral therapy may be necessary if an inhaler device cannot be used. In the UK salbutamol syrup is licensed for children from 2 years of age and modified-release oral preparations from 3 years of age.

by mouth using an immediate-release preparation

- 1 month to 2 years of age, 100 micrograms/kg (up to a maximum dose of 2 mg) three or four times daily
- 2 to 6 years of age, 1 to 2 mg three or four times daily
- 6 to 12 years of age, 2 mg three or four times daily
- over 12 years of age, doses as for adults, see Uses and Administration, above

by mouth using a modified-release preparation

- 3 to 12 years of age, 4 mg twice daily
- over 12 years of age, as for adults, see above

In the management of acute mild to moderate **exacerbations** of asthma, salbutamol may be given using a metered-dose aerosol inhaler via a spacer device. For children of all ages, 1 inhalation (100 micrograms) may be given every 15 to 30 seconds up to a maximum of 10 inhalations. The dose may be repeated after 20 to 30 minutes if required. In more severe exacerbations, salbutamol can be given intermittently via a nebuliser. A dose of 2.5 mg, which can be increased to 5 mg in children over 5 years of age, can be repeated every 20 to 30 minutes if necessary. Immediate transfer to hospital and inhalation of oxygen is also required. Children under 18 months of age often respond poorly to bronchodilators; nebulised beta$_2$ agonists have been associated with mild paradoxical bronchospasm and transient worsening of oxygen saturation.

Although parenteral salbutamol is not licensed in the UK for use in children, the *BNFC* recommends the following doses in the management of **acute severe** or life-threatening acute asthma:

by intravenous injection over 5 minutes

- 1 month to 2 years of age, 5 micrograms/kg as a single dose
- 2 to 18 years of age, 15 micrograms/kg (to a maximum of 250 micrograms) as a single dose

by continuous intravenous infusion

- 1 month to 18 years of age, 60 to 300 micrograms/kg per hour, adjusted according to response and heart rate. Doses above 120 micrograms/kg per hour require close monitoring

Salbutamol can be used to treat severe **hyperkalaemia** in children (see Hyperkalaemia below). The *BNFC* recommends:

by intravenous injection over 5 minutes

- children of all ages, 4 micrograms/kg as a single dose; repeated if necessary

by inhalation of nebulised solution (although intravenous injection is preferred)

- children of all ages, 2.5 or 5 mg as a single dose; repeated if necessary

Asthma. Short-acting beta$_2$ agonists such as salbutamol are used for short-term relief in all patients with symptomatic asthma (p.1108). High doses are used in acute asthma, but current recommendations for chronic asthma are for low doses to be inhaled as required rather than regularly. When patients with mild asthma find that symptomatic relief is needed more than 2 or 3 times a week, then that should be a sign for additional treatment with anti-inflammatory drugs. Increasing need for, or decreased effect of, short-acting beta$_2$ agonists indicates deteriorating asthma and the requirement for stepping up therapy. In one placebo-controlled study,[1] patients with stable asthma receiving regular high doses of a short-acting inhaled beta$_2$ agonist were able to reduce the dose considerably with no change in asthma control, lending further support to the recommendation for 'as-required' rather than regular use of these drugs. The discussion under Fenoterol on p.1121 on the increased mortality that has been observed in asthma patients and the connection with asthma therapy includes a view that regular use might have contributed to the increased mortality. However, a systematic review[2] of studies of short-acting beta$_2$ agonists, most of which used salbutamol, found no clear clinical advantage or detriment from regular use compared with taking them as required.

Bronchiolitis. Acute bronchiolitis (inflammation of the bronchioles associated with viral respiratory-tract infection, usually due to RSV—see p.860) is a poorly defined respiratory condition seen in infants and young children. The diagnostic criteria, and the usual management, vary considerably from country to country. Beta$_2$ agonists such as salbutamol are widely prescribed in the USA, but not in the UK, and attempts to establish their benefits have produced conflicting results.[1] Modest benefit (but no difference in hospital admission rate) has been reported from a meta-analysis of bronchodilator therapy in general,[2] but a meta-analysis of beta$_2$-agonist therapy in bronchiolitis did not show it to be effective.[3] Some comparative studies have suggested that nebulised adrenaline is more effective than salbutamol.[4,5] However, one study in hospitalised children found no benefit from nebulised salbutamol in terms of improved oxygenation or length of hospital stay,[6] and another[7] found no difference in efficacy between nebulised adrenaline, salbutamol, and sodium chloride 0.9%.

The use of oral salbutamol in infants with acute viral bronchiolitis has been found to be no more effective than placebo and so is not recommended.[8]

Chronic obstructive pulmonary disease. Salbutamol and other beta$_2$ agonist bronchodilators form part of the first-line treatment of chronic obstructive pulmonary disease (p.1112).

Cough. For studies of inhaled salbutamol in the treatment of cough, see under Beclometasone, p.1518.

Hyperkalaemia. Salbutamol can lower plasma-potassium concentrations by promoting intracellular uptake,[1,2] and this effect has been used in treating mild hyperkalaemia (p.1669) associated with chronic disorders such as renal failure[3,4] and hyperkalaemic periodic paralysis.[5] However, such use is controversial: the effects of salbutamol may be inconsistent[6] and some clinicians prefer to avoid the use of beta$_2$ agonists because of fears that large doses may induce cardiac arrhythmias.[7]

Salbutamol has been used to lower plasma-potassium concentrations in children[8] and premature neonates[9] with some success. For doses of salbutamol used to treat severe hyperkalaemia in children, see Administration in Children above.

Lymphangioleiomyomatosis. Inhaled beta$_2$ agonists are often helpful in treating the reversible component of airway obstruction in women with pulmonary lymphangioleiomyomatosis, and a trial of treatment is warranted.[1,2] For mention of the use of medroxyprogesterone in this rare disease, see Respiratory Disorders, p.2114.

Muscular dystrophies. There is some evidence that beta$_2$ agonists affect muscle strength and have an anabolic effect. Salbutamol has therefore been investigated in a small number of patients in the management of muscular dystrophies (p.1507). Oral doses of modified-release salbutamol up to 12 mg daily have been used in boys aged between 5 and 11 years with Duchenne or Becker muscular dystrophies,[1,2] and doses of 8 or 16 mg twice daily have been given to adults with facioscapulohumeral dystrophy.[3,4] Although some improvements in muscle strength and muscle mass have been reported, not all muscle groups respond and the long-term effects of treatment are not known.

4. van der Kooi EL, *et al.* Strength training and albuterol in facioscapulohumeral muscular dystrophy. *Neurology* 2004; **63:** 702–8.

Premature labour. Beta$_2$ agonists such as salbutamol have been used as tocolytics in the management of premature labour (p.2003), and can postpone labour for a few days, but the risk of adverse cardiovascular and metabolic events including pulmonary oedema (see above) means that great care and appropriate monitoring of the patient's heart rate and state of hydration are needed.

Proctalgia fugax. Inhalation of salbutamol from a metered-dose inhaler at the beginning of an attack has been shown to reduce the duration of pain in patients with proctalgia fugax.[1]

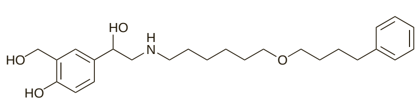
ATC Vet — QR03AC12.



(salmeterol)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Salmeterol Xinafoate). A white or almost white powder. Practically insoluble in water; slightly soluble in dehydrated alcohol; soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

As for Salbutamol, p.1131. Inhalation of salmeterol may be associated with paradoxical bronchospasm, and it should not be used in patients who are not also receiving an inhaled corticosteroid.

Salmeterol is not appropriate for the treatment of acute bronchospasm or for patients whose asthma is deteriorating.

Effects on the cardiovascular system. A pooled analysis[1] of safety data from 7 studies of salmeterol in chronic obstructive pulmonary disease found no evidence of an increased risk of cardiovascular adverse effects. The duration of these studies had ranged from 12 weeks to 1 year.

1. Ferguson GT, *et al.* Cardiovascular safety of salmeterol in COPD. *Chest* 2003; **123:** 1817–24.

Effects on the respiratory system. Transient paradoxical bronchoconstriction with breathlessness, wheeze, or cough has been reported in 6 asthmatic patients after inhalation of salmeterol from a metered-dose aerosol but not after inhalation of the dry powder formulation by diskhaler.[1] The fluorocarbon propellants in the metered-dose aerosol were suspected as the irritants causing bronchoconstriction.

1. Wilkinson JRW, *et al.* Paradoxical bronchoconstriction in asthmatic patients after salmeterol by metered dose inhaler. *BMJ* 1992; **305:** 931–2.

Effects on the skin. Urticarial rash associated with inhaled salmeterol, of which the propellant was not the cause, has been reported. Although many urticarial reactions and a variety of rashes had been attributed to beta-agonist therapy their reproducibility had not always been documented.[1]

1. Hatton MQF, *et al.* Salmeterol rash. *Lancet* 1991; **337:** 1169–70.

Increased mortality. Interim results from a large controlled study (SMART)[1] designed to evaluate the safety of salmeterol compared with placebo, found a small but statistically significant increase in respiratory-related and asthma-related deaths or life-threatening episodes in the total population receiving salmeterol compared with placebo. This imbalance occurred mainly in the African-American subpopulation, and combined with difficulties in enrolment, led to early termination of the study. Various factors may have influenced the differences in outcomes seen with salmeterol; greater disease severity was noted at baseline in the African-American subgroup compared to Caucasian subjects, and nearly half of all participants were not receiving inhaled corticosteroids.

A subsequent meta-analysis[2] of 19 placebo-controlled studies of patients with asthma who were taking the long-acting $beta_2$ agonists salmeterol or formoterol (see p.1122), reported an increased risk of hospitalisation for an asthma exacerbation, life-threatening asthma attacks, and asthma-related deaths compared with placebo. A sub-group analysis that examined studies in which more than 75% of patients were also receiving inhaled corticosteroids also found an increased risk of hospital admission. The applicability of this review to therapy as recommended by current guidelines has been questioned,[3] as many of the studies included in the primary analysis did not require inhaled corticosteroids to be used, and studies which compared different asthma maintenance regimens were excluded because they were not placebo-controlled. Concomitant asthma treatments and adherence to treatment,[4,5] differences in baseline disease severity,[1,4] racial or genetic factors,[1] polymorphism,[6] tolerance,[6,7] and masking of underlying airway inflammation by long-acting $beta_2$ agonists[6] have all been proposed as possible explanations for the increased risk of adverse outcomes reported with long-acting $beta_2$ agonists.

In contrast to the above studies, a case-control study[8] that included 532 patients under age 65 who had died from asthma, matched with 532 controls with a hospital admission for asthma, found no evidence of adverse effects on mortality with medium to long-term use of inhaled long-acting $beta_2$ agonists. An earlier observational cohort study also found no evidence that salmeterol contributed to deaths reported from asthma.[9]

Current guidelines advocate use of a long-acting $beta_2$ agonist in addition to inhaled corticosteroids, and not as monotherapy, see Management of Asthma, p.1108

A recent review[10] by the UK MHRA concluded that:

- epidemiological data indicated that since the introduction of long-acting beta-agonists there had been a reduction in asthma-related hospitalisations in adolescents and a decrease in asthma related-mortality in all ages.
- data from controlled clinical study did not reflect the safety concern from postmarketing studies, possibly due to more consistent use of corticosteroids in controlled settings
- the data supported the use of long-acting beta-agonists with inhaled corticosteroids consistent with the UK guidelines on the management of asthma and that to aid compliance in the concomitant use of a corticosteroid, a combination inhaler should be used when appropriate

Tolerance. As with short-acting $beta_2$ agonists (see Salbutamol, p.1132), there is evidence that regular use of long-acting $beta_2$ agonists such as salmeterol produces tachyphylaxis to their protective effect against bronchoconstriction, as provoked by stimuli such as allergen, methacholine, or exercise.[1-4] The authors of a study of the long-term effect of salmeterol on exercise-induced asthma concluded that the decreased bronchoprotective effect over time was due to a decrease in duration of action (to less than 9 hours) rather than tachyphylaxis,[5] but this interpretation was criticised.[6,7]

There is also some evidence to suggest that symptomatic relief by short-acting $beta_2$ agonists is significantly reduced by regular use of long-acting $beta_2$ agonists.[8,9] Receptor downregulation, induced by regular use of a long-acting $beta_2$ agonist, has been suggested as the mechanism for this reduction in response and may lead to patients requiring higher doses of $beta_2$ agonists to attain relief from an acute asthma attack.[9,10] One study suggested that the greater tachyphylaxis to short-acting $beta_2$ agonists seen with salmeterol compared with formoterol might represent the expression of partial antagonism by salmeterol at $beta_2$ receptors.[8] Whatever the mechanism, the reduced bronchoprotective effect is perhaps more of a concern with long-acting $beta_2$ agonists, since, unlike the short-acting $beta_2$ agonists, their use on a regular basis is recommended.[11] See also $Beta_2$ Agonists, under Interactions of Salbutamol, p.1132.

Interactions

As for Salbutamol, p.1132.

◊ For a study suggesting a decreased effect of salbutamol in patients receiving salmeterol, as well as a report of additive effects, see $Beta_2$ Agonists under Interactions of Salbutamol, p.1132.

Pharmacokinetics

Plasma concentrations of salmeterol are negligible after inhalation of therapeutic doses.

◊ Reviews.

1. Cazzola M, *et al.* Clinical pharmacokinetics of salmeterol. *Clin Pharmacokinet* 2002; **41:** 19–30.

Uses and Administration

Salmeterol is a direct-acting sympathomimetic with beta-adrenoceptor stimulant activity and a selective action on $beta_2$ receptors (a $beta_2$ agonist). When given by inhalation, salmeterol acts as a bronchodilator. The onset of action is about 10 to 20 minutes but the full effect may not be apparent until after several doses. Unlike short-acting $beta_2$ agonists (see Salbutamol, p.1133), salmeterol is therefore not suitable for the symptomatic relief of an acute attack of bronchospasm. However, it is long-acting with a duration of action of about 12 hours and is indicated where the regular use of a long-acting $beta_2$ agonist is required for persistent reversible airways obstruction, as in chronic asthma or in some patients with chronic obstructive pulmonary disease. It may be useful in protecting against nocturnal and exercise-induced asthma attacks. Short-acting beta$_2$ agonists (on an as-required basis) and regular anti-inflammatory therapy should continue to be used.

Salmeterol is used in the form of the xinafoate; doses are expressed in terms of the equivalent amount of salmeterol; salmeterol xinafoate 1.45 micrograms is equivalent to about 1 microgram of salmeterol.

The usual dose is 50 micrograms of salmeterol twice daily from a metered-dose aerosol or dry powder inhaler; if necessary, up to 100 micrograms may be inhaled twice daily. For doses of salmeterol used in children, see Administration in Children, below.

Administration in children. For persistent reversible airways obstruction which requires regular bronchodilatation, including nocturnal asthma and prevention of exercise-induced asthma, children aged 4 to 12 years may be given 50 micrograms of salmeterol twice daily by inhalation.

Asthma. Salmeterol is a long-acting beta$_2$ agonist (duration of action about 12 hours). Guidelines on the management of asthma, see p.1108, generally recommend that salmeterol should be reserved for use in patients with chronic asthma who have already progressed to inhaled corticosteroids; it is not a substitute for corticosteroids. Evidence suggests that, apart from in severe exacerbations, adding a long-acting beta$_2$ agonist to standard dose inhaled corticosteroid therapy may be more effective than increasing the dose of corticosteroid, or than combining a corticosteroid and an anti-leukotriene drug. Salmeterol may also be useful in controlling persistent nocturnal asthma or preventing exercise-induced attacks. There is some evidence that after prolonged use, duration of protection against exercise-induced bronchoconstriction is reduced (see Tolerance, above).

Chronic obstructive pulmonary disease. Short-acting beta$_2$ agonists are used as bronchodilators in patients with chronic obstructive pulmonary disease (see p.1112), although there is some evidence to suggest that an antimuscarinic might be preferable. Guidelines indicate that long-acting beta$_2$ agonists such as salmeterol may be used for maintenance therapy in moderate and more severe disease. Improvement in lung function and symptoms has been seen in such patients after regular treatment with inhaled salmeterol;[1-3] a reduction in exacerbations has also been seen.[4] Additional benefit has been reported from the use of salmeterol with inhaled corticosteroids.[5-7]

Seratrodast *(USAN, rINN)*

A-73001; AA-2414; Abbott-73001; ABT-001; Sératrodast; Seratrodastum. (±)-2,4,5-Trimethyl-3,6-dioxo-ζ-phenyl-1,4-cyclohexadiene-1-heptanoic acid.

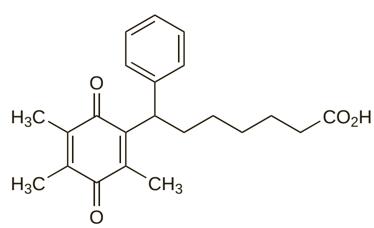
Сератродаст

$C_{22}H_{26}O_4$ = 354.4.

CAS — 112665-43-7; 103186-19-2.

ATC — R03DX06.

ATC Vet — QR03DX06.



Profile

Seratrodast is a thromboxane A_2 antagonist that is reported to reduce airway hyperresponsiveness. It is given orally in the prophylactic management of asthma (p.1108), in single doses of 80 mg in the evening after food.

Adverse effects include gastrointestinal disturbances, drowsiness, headache, palpitations, and hepatitis. Hepatic function should be monitored and the drug should be withdrawn if hypersensitivity reactions such as rashes and pruritus occur, or if there is elevation of liver enzyme values. Seratrodast should be used with care in patients with pre-existing hepatic impairment. It is not suitable for the treatment of an acute asthmatic attack.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*
Ph. Eur. 6.2 (Sodium Cromoglicate). A white or almost white, hygroscopic, crystalline powder. Soluble in water; practically insoluble in alcohol. Store in airtight containers. Protect from light.
USP 31 (Cromolyn Sodium). A white, odourless, hygroscopic, crystalline powder. Soluble in water; insoluble in alcohol and in chloroform. Store in airtight containers.

Adverse Effects

Inhalation of sodium cromoglicate may cause transient bronchospasm, wheezing, cough, nasal congestion, and irritation of the throat. Nausea, headache, dizziness, an unpleasant taste, and joint pain and swelling have been reported. Other reactions include aggravation of existing asthma, urticaria, rashes, pulmonary infiltrates with eosinophilia, dysuria, and urinary frequency. Severe reactions such as marked bronchospasm, laryngeal oedema, angioedema, and anaphylaxis have been reported rarely.

Intranasal use of sodium cromoglicate may cause transient irritation of the nasal mucosa, sneezing, and occasionally epistaxis. Nausea, skin rashes, and joint pains have occurred when it is taken orally. Transient burning and stinging have occasionally been reported after use of sodium cromoglicate eye drops.

Formulation. Some of the adverse effects reported with sodium cromoglicate may be due to its formulation: there is a view that some of the irritant effects reported on inhalation may be due to the use of dry powder inhalers. It has also been suggested that in some patients receiving sodium cromoglicate via a nebuliser, hypotonicity of the nebuliser solution may induce bronchospasm,[1] although others consider this debatable.[2] Nausea, bloating, abdominal cramps, and flatulence developed in a 24-year-old lactase-deficient woman 2 hours after the use of sodium cromoglicate (*Intal*) inhalation capsules via a turbo-haler for exercise-induced asthma.[3] These symptoms recurred on rechallenge and were attributed to ingestion of lactose contained within the capsules.

Precautions

Sodium cromoglicate has no role in the treatment of acute asthmatic attacks. Withdrawal of sodium cromoglicate may lead to recurrence of the symptoms of asthma. Should withdrawal be necessary it has been suggested that the dose be reduced gradually over a period of one week; patients in whom sodium cromoglicate therapy has permitted a reduction of corticosteroid dosage may require restoration of full corticosteroid cover.

Systemic corticosteroid therapy that has been reduced or stopped in asthmatic patients may need to be reinstated if symptoms increase, during periods of stress such as infection, illness, trauma, or severe antigen challenge, or where airways obstruction impairs inhalation of sodium cromoglicate.

Pharmacokinetics

Sodium cromoglicate is poorly absorbed from the gastrointestinal tract, with a reported bioavailability of only 1%. It has been reported that on inhalation as a fine powder only about 8% of a dose is deposited in the lungs from where it is rapidly absorbed and excreted unchanged in the urine and bile. Less than 7% of an intranasal dose appears to be absorbed. The majority of an inhaled or an intranasal dose is swallowed and excreted unchanged via the gastrointestinal tract. About 0.03% of an ophthalmic dose is reported to be absorbed. The terminal elimination half-life has been reported to be about 20 minutes after intravenous dosage, but the elimination half-life after oral doses or inhalation is about 80 minutes.

◊ A study[1] in patients with exercise-induced asthma concluded that the plasma concentration of cromoglicate was almost certainly not related directly to its protective effect, although another study in asthmatic children given sodium cromoglicate by dry-powder inhalation, found both blood concentration and clinical response to be correlated with inhalation technique.[2]

1. Patel KR, *et al.* Plasma concentrations of sodium cromoglycate given by nebulisation and metered dose inhalers in patients with exercise-induced asthma: relationship to protective effect. *Br J Clin Pharmacol* 1986; **21:** 231–3.
2. Yahav Y, *et al.* Sodium cromoglycate in asthma: correlation between response and serum concentrations. *Arch Dis Child* 1988; **63:** 592–7.

Uses and Administration

Sodium cromoglicate is used for the prevention of allergic reactions. Although its precise mode of action remains uncertain, it is believed to act primarily by preventing release of mediators of inflammation from sensitised mast cells through stabilisation of mast-cell membranes. It has no direct antihistamine or anti-inflammatory action.

Sodium cromoglicate can prevent the asthmatic response to a variety of allergic and non-allergic stimuli. It is used in the management of chronic asthma that cannot be managed with inhaled $beta_2$ agonists alone; it is not used for acute attacks of asthma.

Sodium cromoglicate is also used in the prophylaxis and treatment of seasonal and perennial allergic rhinitis and allergic conditions of the eye including acute and chronic allergic conjunctivitis and vernal keratoconjunctivitis. It has been given orally, with dietary restriction, for the prevention of food allergies, and is also used in the treatment of mastocytosis.

It is important that the regular use of sodium cromoglicate is maintained, both in the prophylactic control of asthma and in the management of other allergic conditions. Beneficial effects may take several weeks to become established.

In the prophylaxis of **asthma**, sodium cromoglicate is given by inhalation either as a dry powder, or as a nebulised solution, or from a metered-dose aerosol. The usual dose as dry powder or nebulised solution is 20 mg by inhalation 4 times daily increased, if necessary, to 6 or 8 times daily. Once the asthma has been stabilised it may be possible to reduce the dosage. In different countries, sodium cromoglicate is available in different strengths of metered-dose aerosol. Using a metered-dose aerosol providing 5 mg per inhalation, the usual dose is 10 mg four times daily, increased to 6 to 8 times daily if necessary; it may be possible to reduce the dosage to 5 mg four times daily once the asthma has been stabilised. Additional doses as the aerosol or dry powder may be taken before exercise. Metered-dose aerosols providing 1 mg per inhalation are also available. The usual dose is 2 mg four times daily, which can be doubled if necessary. The adequacy of the lower dosage has been questioned (see under Administration, below).

Inhalation of sodium cromoglicate may cause bronchospasm; separate inhalation of a $beta_2$ agonist such as salbutamol a few minutes beforehand should prevent this. Use of a combination product containing a $beta_2$ agonist is not recommended as this is liable to be used inappropriately for relief of bronchospasm rather than for its prophylactic effect.

For the prophylaxis of **allergic rhinitis**, a 2 or 4% sodium cromoglicate solution can be given as a spray into both nostrils. The 2% spray contains about 2.5 mg per actuation and is given 4 to 6 times daily, and the 4% spray contains about 5 mg per actuation and is given 2 to 4 times daily. Prophylactic treatment for seasonal allergic rhinitis should begin 2 to 3 weeks before exposure to the offending allergen and should continue throughout the season. In **allergic conjunctivitis** and **vernal keratoconjunctivitis**, sodium cromoglicate is used as drops of 2 or 4%, applied 4 to 6 times daily.

In **food allergy** and in **mastocytosis**, sodium cromoglicate may be given in oral doses of 200 mg four times daily before meals. If satisfactory control is not achieved within 2 to 3 weeks the dosage may be doubled, but should not exceed 40 mg/kg daily; a reduction in dosage may be possible once symptoms have been controlled.

For details of doses in children, see Administration in Children below.

Action. Sodium cromoglicate has a range of actions at cellular level that may be important for its protective effect in asthma. It is known as a mast cell stabiliser that inhibits the release of histamine and other inflammatory mediators from sensitised mast cells. Other reported actions include a direct effect on airway nerves[1,2] and antagonism[3] of substance P, which ties up with its inhibition of the effects of platelet activating factor (PAF).[4,5]

There have been a few reports[6-8] of sodium cromoglicate producing bronchodilatation. However, in practice other drugs with accepted bronchodilating activity are used for this effect in asthma treatment schedules, see p.1108.

Administration. The effectiveness of sodium cromoglicate 2 mg four times daily by metered-dose aerosol inhaler has been reported by controlled studies in adults and children with asthma.[1-5] However, although sodium cromoglicate 2 mg by inhalation from a metered-dose aerosol was reported[6] to be as effective as 20 mg inhaled as powder, the tenfold difference in dosage has been questioned,[7] and others have reported contrary results.[8,9] It has been suggested that an aerosol supplying 5 mg per metered dose (see Uses and Administration, above) would be preferable.[10] In a comparison of single-dose pretreatment from metered-dose inhalers, sodium cromoglicate 10 mg (2 × 5 mg puffs) was as effective as beclometasone dipropionate 200 micrograms in inhibiting bronchial responsiveness to histamine.[11]

Care is required if inhaled sodium cromoglicate is given via a spacer device; evidence suggests that these may greatly influence the amount of drug delivered, reducing it to one-third of the dose delivered by inhaler actuation in some cases.[12]

Administration in children. Children may be given sodium cromoglicate for prophylactic management of asthma and allergic rhinitis, and in the prophylaxis and treatment of acute and chronic allergic conjunctivitis and vernal keratoconjunctivitis, using adult doses, see Uses and Administration, above. Different countries may have different licensed lower age limits and some inhalation dosage forms are unsuitable in very young children.

In food allergy and in mastocytosis, sodium cromoglicate may be given orally to children from 2 years of age. A dose of 100 mg is given four times daily before meals. If satisfactory control is not achieved within 2 to 3 weeks the dosage may be doubled but should not exceed 40 mg/kg daily; a reduction in dosage may be possible once symptoms have been controlled. For food allergy, adult doses may be given to children from 14 years of age, and from 13 years for mastocytosis, see above.

Asthma. Sodium cromoglicate is used as a prophylactic agent in the management of chronic asthma (p.1108), but in practice inhaled corticosteroids are preferred if regular prophylactic treatment is indicated, i.e. if the condition cannot be managed with occasional use of an inhaled short-acting $beta_2$ agonist alone. Even in children, in whom cromoglicate has tended to be more widely used, inhaled corticosteroids are considered first-line preventers. A systematic review[1] comparing sodium cromoglicate with inhaled corticosteroids found that inhaled corticosteroids were superior in terms of asthma control and lung function for both children and adults with chronic asthma. However, guidelines still specify the use of cromoglicate or nedocromil as a valid alternative to inhaled corticosteroids in some circumstances.

Response to treatment with nebulised sodium cromoglicate was found to be age-related in a study of children under 2 years of age with recurrent or persistent wheezy bronchitis and a history of allergic symptoms.[2] It was effective in children of 12 to 24 months of age but not in those below 12 months. Similarly, nebulised sodium cromoglicate was no more effective than placebo in the treatment of a group of 31 infants with persistent wheezing aged under 1 year,[3] and long-term inhalation therapy was ineffective in children aged 1 to 4 years.[4]

Cogan's syndrome. Sodium cromoglicate eye drops improved blurred vision in a patient who had had Cogan's syndrome (p.1502) for 18 years.[1] Sodium cromoglicate capsules [by mouth] also reduced the frequency of fever attacks in this patient.

1. Carter F, Nabarro J. Cromoglycate for Cogan's syndrome. *Lancet* 1987; **i:** 858.

Cough. Sodium cromoglicate has been used with modest success by aerosol inhalation to suppress the cough associated with ACE inhibitor therapy (p.1194) in some patients.[1,2] However, inhalation of nedocromil sodium was not helpful in the treatment of ACE inhibitor induced cough in 6 diabetic patients.[3] A systematic review[4] considered that there was no good evidence to support the use of inhaled cromoglicate or nedocromil in the treatment of non-specific cough in children.

4. Chang A, *et al.* Inhaled cromones for prolonged non-specific cough in children. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2004 (accessed 14/04/08).

Eczema. Application of a 4% sodium cromoglicate lotion was found to be of benefit in improving symptoms and reducing topical corticosteroid use in a study[1] in children with moderately severe atopic dermatitis (p.1579).

1. Stainer R, *et al.* Efficacy and acceptability of a new topical skin lotion of sodium cromoglicate (Altoderm) in atopic dermatitis in children aged 2–12 years: a double-blind, randomized, placebo-controlled trial. *Br J Dermatol* 2005; **152:** 334–41.

Food allergy. Oral sodium cromoglicate has been used in the prophylaxis of food allergy reactions (p.564). However, efficacy has not been unequivocally established.

Mastocytosis. Mastocytosis is a rare condition characterised by abnormal proliferation of mast cells and their accumulation in body tissues.[1-3] Signs and symptoms of the disease result from the spontaneous or induced release of mast cell mediators. Mastocytosis occurs in cutaneous or systemic forms, which are further subdivided based on clinical presentation and prognosis. Clinical algorithms and recommendations for diagnosis, treatment, and response criteria have been developed.[4]

- *Cutaneous mastocytosis* most often manifests as urticaria pigmentosa (disseminated red-brown macules, papules, or plaques); other symptoms include flushing, pruritus, urticaria, blistering, and dermatographism. Mastocytomas may occur as brownish solitary or multiple nodular accumulations of mast cells. In children with cutaneous mastocytosis, symptoms will resolve in about half by adolescence.
- *Systemic mastocytosis* can involve diverse organs and tissues including the bones, liver, spleen, lymph nodes, haematopoietic system, gastrointestinal tract, and also the skin. General symptoms include fatigue, weight loss, fever, and sweats. Gastrointestinal complaints such as abdominal pain and diarrhoea are common, and some patients may experience malabsorption, steatorrhoea, or peptic ulcer disease. Bone marrow involvement may result in bone pain, osteoporosis, fractures, bone marrow fibrosis, and myeloproliferative and myelodysplastic diseases. Other systemic effects include lymphadenopathy, hepatosplenomegaly, headache and other neuropsychiatric symptoms, syncope, and anaphylactoid reactions.

Avoidance of trigger factors is an important measure in the management of mastocytosis. Such factors include exposure to extremes of cold or heat (hot bath or sunbathing), emotional stress, mechanical irritation (vigorous towel rubbing, massage), infections, alcohol, some drugs (e.g. aspirin, NSAIDs, opioid analgesics, sympathomimetics, polymyxin B, dextran, radiographic dyes), and animal venoms.[1,2,5]

Treatment is aimed at relieving symptoms and does not alter the course of the disease.[1,2,4-6] H_1-antagonist antihistamines such as hydroxyzine and cyproheptadine are used to provide relief of flushing, pruritus, urticaria, blistering, and abdominal pain. Patients at risk of anaphylactoid reactions should carry adrenaline for self-injection, and those who have repeated reactions should be given prophylactic antihistamines. H_2-antagonist antihistamines such as cimetidine, and proton pump inhibitors such as omeprazole, are used to manage gastrointestinal symptoms, particularly gastritis and peptic ulcer disease. Bisphosphonates may be helpful for osteopenia and bone pain. Sodium cromoglicate is given to manage abdominal pain, nausea, and diarrhoea. It may also provide some relief of headache, neuropsychiatric symptoms, and skin symptoms in some patients. Photochemotherapy using an oral psoralen with ultraviolet A irradiation (PUVA—see p.1606) has been used to reduce cutaneous manifestations of mastocytosis, but urticaria pigmentosa usually recurs within several weeks. Topical PUVA appears to be ineffective. Mastocytomas that cause symptoms may be treated with local PUVA or potent topical corticosteroids. Although surgical removal may be considered, the majority of mastocytomas will involute spontaneously.

Other treatments have also been tried in the treatment of small numbers of patients with aggressive systemic mastocytosis. Mixed results have been reported with the use of interferon alfa.[1] There is a report of ciclosporin with methylprednisolone being used successfully.[4] Imatinib has been used successfully in systemic mastocytosis with associated eosinophilia and with a mutation of the platelet-derived growth factor receptor-α gene on chromosome 4q12.[6] Beneficial responses to cladribine have also occurred in a small number of patients with systemic disease.[6,7]

Rhinitis and conjunctivitis. Many drugs, including sodium cromoglicate, are used in the management of allergic rhinitis (p.565) and conjunctivitis (p.564). There is some evidence that nedocromil[1] or lodoxamide[2] may be more effective than cromoglicate in the management of vernal keratoconjunctivitis.

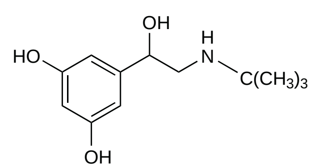
CAS — 23031-25-6 (terbutaline); 23031-32-5 (terbutaline sulfate).

ATC — R03AC03; R03CC03.

ATC Vet — QR03AC03; QR03CC03.



(terbutaline)

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Terbutaline Sulphate). A white or almost white crystalline powder. It exhibits polymorphism. Freely soluble in water; slightly soluble in alcohol.

USP 31 (Terbutaline Sulfate). A white to grey-white crystalline powder; odourless or has a faint odour of acetic acid. Soluble in water and in 0.1N hydrochloric acid; insoluble in chloroform; slightly soluble in methyl alcohol. Store at 15° to 30°. Protect from light.

Adverse Effects and Precautions

As for Salbutamol, p.1131.

Overdosage. An overdose of terbutaline due to transcutaneous absorption has been reported after inappropriate topical application to skin infected with tinea.[1] Transcutaneous absorption should be considered especially when children with facial eczema or dermatitis are given terbutaline via a nebuliser and mask.

For general effects of $beta_2$ agonists after overdose, see Salbutamol p.1132.

1. Ingrams GJ, Morgan FB. Transcutaneous overdose of terbutaline. *BMJ* 1993; **307:** 484.

Pulmonary oedema. Pulmonary oedema has occurred in women given $beta_2$ agonists, including terbutaline, for premature labour.[1] The risk factors, the most important of which is fluid overload, are discussed under Precautions for Salbutamol, p.1132.

1. Perry KG, *et al.* Incidence of adverse cardiopulmonary effects with low-dose continuous terbutaline infusion. *Am J Obstet Gynecol* 1995; **173:** 1273–7.

Tolerance. As with other $beta_2$ agonists (see p.1132) there is some evidence[1] that tolerance may develop to terbutaline when it is used regularly.

1. Hancox RJ, *et al.* Tolerance to beta-agonists during acute bronchoconstriction. *Eur Respir J* 1999; **14:** 283–7.

Tooth erosion. The pH of some inhaled powder formulations of terbutaline, as well as of some corticosteroids, was found to be below 5.5, and it was suggested that this might contribute to the dissolution of enamel surfaces of teeth.[1] A later cohort study found no association between asthma and tooth erosion; however only about 10% of the medication prescribed for asthma in the cohort had a pH lower than 5.5.[2]

1. O'Sullivan EA, Curzon MEJ. Drug treatments for asthma may cause erosive tooth damage. *BMJ* 1998; **317:** 820.
2. Dugmore CR, Rock WP. Asthma and tooth erosion: is there an association? *Int J Paediatr Dent* 2003; **13:** 417–24.

Interactions

As for Salbutamol, p.1132.

Xanthines. The metabolic and cardiovascular responses to terbutaline infusion were significantly enhanced by *theophylline* in a study in 7 healthy subjects; in particular the fall in serum potassium was greater when both drugs were given.[1] Careful monitoring of serum potassium is recommended in severe asthma where theophylline and beta$_2$-agonists may be given together.

Terbutaline conversely has an effect on theophylline. Terbutaline can reduce serum-theophylline concentrations by increasing its systemic clearance. This may, or may not, have clinical implications, as improved clinical scores have still occurred with combined therapy despite the theophylline concentration being lower than when used alone; if respiratory symptoms persist, an increase in dosage may be contemplated while monitoring theophylline adverse effects and concentration.[2]

1. Smith SR, Kendall MJ. Potentiation of the adverse effects of intravenous terbutaline by oral theophylline. *Br J Clin Pharmacol* 1986; **21:** 451–3.
2. Garty M, *et al.* Increased theophylline clearance in asthmatic patients due to terbutaline. *Eur J Clin Pharmacol* 1989; **36:** 25–8.

Pharmacokinetics

On inhalation of terbutaline, less than 10% of the drug is absorbed from the airways. The remainder is swallowed where it is variably absorbed from the gastrointestinal tract. Fasting bioavailability after oral doses is reported to be about 14 to 15% and is reduced by food. Terbutaline undergoes extensive first-pass metabolism by sulfate (and some glucuronide) conjugation in the liver and the gut wall. It is excreted in the urine and faeces partly as the inactive sulfate conjugate and partly as unchanged terbutaline, the ratio depending upon the route by which it is given. The terminal half-life after single and multiple dosing is reported to be between 16 and 20 hours. There is some placental transfer. Trace amounts are distributed into breast milk.

Stereoselectivity. Terbutaline, like many other sympathomimetics, exists in two stereoisometric forms but only the (−)-enantiomer of terbutaline is pharmacologically active. Pharmacokinetic studies have been conducted on the two enantiomers and on the racemate.

The oral bioavailability of (−)-terbutaline was 14.8%, which was similar to that of the racemate; the bioavailability of (+)-terbutaline was much lower at 7.5%. The difference in bioavailability between the two enantiomers was mainly due to a difference in absorption (about 75% and 50% respectively) although a small difference in subsequent first-pass metabolism also occurred, with the (+)-isomer undergoing slightly more metabolism. It appeared that the (+)-isomer governed the elimination behaviour, both first-pass metabolism and renal clearance, of the racemate whereas the (−)-isomer determined the absorption.[1]

Other studies have also shown stereoselective sulfate conjugation of terbutaline with sulfation of the (+)-enantiomer being double that of the (−)-enantiomer.[2] The primary site of terbutaline sulfation for both enantiomers appears to be in the gut and is significantly correlated with the activity of catechol sulfotransferase.[3]

Uses and Administration

Terbutaline sulfate is a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on beta$_2$ receptors (a beta$_2$ agonist). It has actions and uses similar to those of salbutamol (p.1133).

Terbutaline is given as the sulfate for its bronchodilating properties in reversible airways obstruction, as occurs in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). It also decreases uterine contractility and may be used to arrest premature labour (p.2003).

On inhalation, the bronchodilating effect of terbutaline usually begins within 5 minutes and lasts for up to 6 hours. The onset of action after oral doses is 30 to 45 minutes and its duration is up to 8 hours; the maximum effect occurs 1 to 4 hours after the dose.

Current asthma guidelines (see p.1108) recommend that inhaled short-acting beta$_2$ agonists such as terbutaline be used on an 'as-required', not regular, basis. In those patients requiring more than occasional use of terbutaline, anti-inflammatory therapy is also needed. An increased requirement for, or decreased duration of effect of, terbutaline indicates deterioration of asthma control and the need for increased anti-inflammatory therapy.

- To relieve **acute bronchospasm** the usual dose is 1 or 2 inhalations of terbutaline sulfate 250 micrograms as required from a *metered-dose aerosol* every 4 to 6 hours, to a maximum of 8 inhalations in 24 hours.
- A breath-actuated metered-dose *powder inhaler* containing terbutaline sulfate is also available; one inhalation of 500 micrograms is taken when required up to a maximum of 6 inhalations in 24 hours.
- When inhalation is ineffective, terbutaline sulfate may be given *orally*; the usual initial dose is 2.5 or 3 mg three times daily increased up to 5 mg three times daily as necessary. Modified-release tablets are also available; the usual adult dose is 7.5 mg twice daily.
- Severe or unresponsive bronchospasm may require the use of terbutaline sulfate intermittently via a *nebuliser.* A usual dose is 5 to 10 mg inhaled 2 to 4 times daily. Single-dose units or a suitable dilution of a concentrated solution containing terbutaline sulfate 1% are used for this purpose.

Guidelines also allow for beta$_2$ agonists to be given more frequently or by continuous dosage at a higher rate in acute severe asthma (see under Asthma, p.1108).

- In the treatment of severe forms of bronchospasm, terbutaline sulfate may be given by subcutaneous, intramuscular, or slow intravenous *injection*; a dose of 250 to 500 micrograms may be given up to 4 times daily. Terbutaline sulfate may also be given by *intravenous infusion*, as a solution containing 3 to 5 micrograms/mL at a rate of 0.5 to 1 mL/minute.

Terbutaline sulfate is also used to arrest uncomplicated **premature labour** between 24 and 33 weeks of gestation. It is given by *intravenous infusion* in glucose 5%, preferably by syringe pump when the concentration is 100 micrograms/mL. If no syringe pump is available then the concentration of the infusion should be 10 micrograms/mL. The recommended initial rate of infusion is 5 micrograms/minute increased by 2.5 micrograms/minute at intervals of 20 minutes until contractions stop. Usually, a rate of up to 10 micrograms/minute is sufficient; rates in excess of 20 micrograms/minute should not be used and if that maximum rate does not delay labour then the infusion should be stopped. The maternal pulse should be monitored throughout the infusion which should be adjusted to avoid a maternal heart rate of more than 135 beats/minute. A close watch should also be kept on the patient's state of hydration since fluid overload is considered to be a key risk factor for pulmonary oedema. Once contractions have ceased, the infusion should be given for 1 hour, then the dose may be decreased by 2.5 micrograms/minute at 20-minute intervals to the lowest maintenance dose that produces continued suppression of contractions. After a further 12 hours, *oral* maintenance therapy with 5 mg three times daily may be started. However, such usage is not recommended by the *BNF* as the risks to the mother (see Precautions under Salbutamol, p.1132) increase after 48 hours, and furthermore there is a lack of evidence of benefit from further treatment. *Subcutaneous* doses of 250 micrograms four times daily have been given for a few days before oral treatment was commenced.

For terbutaline sulfate doses used for bronchospasm in children, see Administration in Children, below.

Terbutaline in a bioadhesive vaginal gel is under investigation for the treatment of infertility linked to endometriosis.

Administration in children. To relieve **acute bronchospasm** in children, the *BNFC* recommends a dose of 500 micrograms of terbutaline sulfate, inhaled via a metered-dose *powder inhaler*, up to four times daily in children aged 5 years and over. *Oral* doses, although not recommended and unlicensed in the UK for children under 7 years of age, may be given in doses ranging from:

- 1 month to 7 years of age, 75 micrograms/kg (maximum dose 2.5 mg) three times daily
- 7 to 15 years of age, 2.5 mg two or three times daily
- over 15 years of age, as for adults (see Uses and Administration, above)

Severe or unresponsive bronchospasm may require the use of terbutaline sulfate inhaled via a *nebuliser*. UK licensed product information gives doses based on weight and age:

- under 3 years of age, average body-weight 10 kg, 2 mg given 2 to 4 times daily
- 3 to 5 years of age, average body-weight 15 kg, 3 mg given 2 to 4 times daily
- 6 to 7 years of age, average body-weight 20 kg, 4 mg given 2 to 4 times daily
- 8 years of age and over, body-weight greater than 25 kg, 5 mg given 2 to 4 times daily

In the treatment of severe forms of bronchospasm, terbutaline sulfate may be given by subcutaneous or slow intravenous *injection*; in children 2 years of age and over, the *BNFC* recommends a dose of 10 micrograms/kg given every 6 hours as required. A maximum single dose of 300 micrograms is recommended in children from 2 to 15 years of age, and in children over 15 years a maximum single dose of 500 micrograms is recommended.

Terbutaline sulfate may also be given by *intravenous infusion*; the *BNFC* recommends an initial dose of 2 to 4 micrograms/kg, then 1 to 10 micrograms/kg per hour according to response and heart rate. Although the injection is unlicensed in the UK for children under 2 years of age, the *BNFC* allows this dose for children from 1 month of age.

Cardiac disorders. A case report on the use of oral terbutaline for chronotropic support, in the setting of acute rejection after heart transplantation, found it to be effective and without any significant adverse effects.[1]

1. Coons JC, *et al.* Terbutaline for chronotropic support in heart transplantation. *Ann Pharmacother* 2004; **38:** 586–9.

Hypoglycaemia. Giving terbutaline 5 mg orally at night reduced the risk of nocturnal hypoglycaemia in a study in patients with type 1 diabetes.[1] A later study[2] reproduced these results in 21 patients with type 1 diabetes; however, hyperglycaemia was seen the next morning.

2. Raju B, *et al.* Nocturnal hypoglycaemia in type 1 diabetes: an assessment of preventive bedtime treatments. *J Clin Endocrinol Metab* 2006; **91:** 2087–92.

Systemic capillary leak syndrome. Systemic capillary leak syndrome is a rare disorder marked by shifts of plasma from the intravascular to the extracellular space, and is often fatal. Acute attacks are treated with intravenous fluid resuscitation, but there is some anecdotal evidence that treatment with terbutaline combined with aminophylline or theophylline, both orally, may be useful in preventing further attacks.[1-3] Infusion of epoprostenol has also been used in acute management.[4]

4. Fellows IW, *et al.* Epoprostenol in systemic capillary leak syndrome. *Lancet* 1988; **ii:** 1143.

Urticaria. Patients with various types of urticaria unresponsive to conventional therapy with antihistamines (see p.1584) have obtained benefit from treatment with a combination of terbutaline and ketotifen; the urticarias have included chronic idiopathic urticaria,[1] dermographism,[1] and cold urticaria.[1,2] Terbutaline on its own was relatively ineffective and the mechanism of the combination was believed to be due to a stabilising effect on mast cells.[1]

Treatment of cold urticaria with a combination of terbutaline and aminophylline has also been studied.[3] The effectiveness of this combined therapy was reported to vary considerably between patients, but complete remission of the urticarial response was eventually seen in 37 of the 42 patients. Treatment was stopped in 3 patients in the first week due to cardiac adverse effects.

Theobromine *(BAN)*

Santheose; Teobromiini; Teobromin; Teobromina; Teobrominas; Theobromin; Théobromine; Theobrominum. 3,7-Dihydro-3,7-dimethylpurine-2,6(1*H*)-dione; 3,7-Dimethylxanthine.

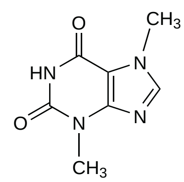
Теобромин

$C_7H_8N_4O_2$ = 180.2.

CAS — 83-67-0.

ATC — C03BD01; R03DA07.

ATC Vet — QC03BD01; QR03DA07.



Pharmacopoeias. In *Eur.* (see p.vii)

Ph. Eur. 6.2 (Theobromine). A white or almost white powder. Very slightly soluble in water and in dehydrated alcohol; slightly soluble in ammonia. It dissolves in dilute solutions of alkali hydroxides and in mineral acids.

Profile

Theobromine has the general properties of the other xanthines (see Theophylline, p.1140). It has a weaker activity than theophylline or caffeine and has practically no stimulant effect on the CNS. Large doses can cause nausea and vomiting. Theobromine has been used for its bronchodilating properties and in the treatment of cardiovascular disorders. Theobromine and calcium salicylate (theosalicin), theobromine and sodium acetate, and theobromine and sodium salicylate (themisalum, theobromsal) have all been used similarly to theobromine.

Theobromine is the chief xanthine in the beverage cocoa (p.2415). It is also present in chocolate and in small amounts in tea. Theobroma oil may contain up to 2% theobromine.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Austria:*** Asthma-Hilfe; ***Braz.:*** Urodonal†.

Theophylline *(BAN)*

Anhydrous Theophylline; Teofilin; Teofilina; Teofilinas; Teofillin; Teofillina; Teofylliini; Teofyllin; Theofylin; Théophylline; Theophyllinum. 3,7-Dihydro-1,3-dimethylpurine-2,6(1*H*)-dione; 1,3-Dimethylxanthine.

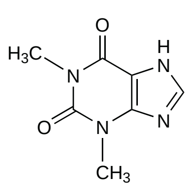
Теофиллин

$C_7H_8N_4O_2$ = 180.2.

CAS — 58-55-9.

ATC — R03DA04.

ATC Vet — QR03DA04.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn, US,* and *Viet.* Some pharmacopoeias include anhydrous and hydrated theophylline in one monograph.

Ph. Eur. 6.2 (Theophylline). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol. It dissolves in solutions of alkali hydroxides, in ammonia, and in mineral acids.

USP 31 (Theophylline). It contains one molecule of water of hydration or is anhydrous. It is a white, odourless, crystalline powder. Slightly soluble in water, more soluble in hot water; sparingly soluble in alcohol, in chloroform, and in ether; freely soluble in solutions of alkali hydroxides and in ammonia.

Theophylline Hydrate *(BANM)*

Teofilina monohidrato; Teofilinas monohidratas; Teofylliinimonohydraatti; Teofyllinmonohydrat; Theofylin monohydrát; Theophylline Monohydrate; Théophylline monohydratée; Theophyllinum monohydricum.

Теофиллина Гидрат

$C_7H_8N_4O_2,H_2O$ = 198.2.

CAS — 5967-84-0.

ATC — R03DA04.

ATC Vet — QR03DA04.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *US,* and *Viet.* Some pharmacopoeias include anhydrous and hydrated theophylline in one monograph.

Ph. Eur. 6.2 (Theophylline Monohydrate; Theophylline Hydrate BP 2008). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol. It dissolves in solutions of alkali hydroxides, in ammonia, and in mineral acids.

USP 31 (Theophylline). It contains one molecule of water of hydration or is anhydrous. It is a white, odourless, crystalline powder. Slightly soluble in water, more soluble in hot water; sparingly soluble in alcohol, in chloroform, and in ether; freely soluble in solutions of alkali hydroxides and in ammonia.

Stability. Alcohol-free theophylline liquid repackaged in clear or amber polypropylene oral syringes could be stored at room temperature under continuous fluorescent lighting for at least 180 days without significant change in the concentration of theophylline.[1] However, it was recommended that solutions be protected from light because of the potential for discoloration.

Extemporaneous oral preparations of theophylline 5 mg/mL in commercial suspension vehicles were found[2] to be stable for up to 90 days in amber plastic bottles stored at 23° to 25°.

2. Johnson CE, *et al.* Stability of anhydrous theophylline in extemporaneously prepared alcohol-free oral suspensions. *Am J Health-Syst Pharm* 2005; **62:** 2518–20.

Adverse Effects

The adverse effects commonly encountered with theophylline and xanthine derivatives irrespective of the route, are gastrointestinal irritation and stimulation of the CNS. Serum concentrations of theophylline greater than 20 micrograms/mL (110 micromol/litre) are associated with an increased risk of adverse effects (but see below).

Theophylline may cause nausea, vomiting, abdominal pain, diarrhoea, and other gastrointestinal disturbances, insomnia, headache, anxiety, irritability, restlessness, tremor, and palpitations. Overdosage may also lead to agitation, diuresis and repeated vomiting (sometimes haematemesis) and consequent dehydration, cardiac arrhythmias including tachycardia, hypotension, electrolyte disturbances including profound hypokalaemia, hyperglycaemia, hypomagnesaemia, metabolic acidosis, rhabdomyolysis, convulsions, and death. Severe toxicity may not be preceded by milder symptoms. Convulsions, cardiac arrhythmias, severe hypotension, or cardiac arrest may follow rapid intravenous injection, and fatalities have been reported. The drug is too irritant for intramuscular use. Proctitis may follow repeated use of suppositories.

◊ Adverse effects are uncommon at serum-theophylline concentrations of 5 to 10 micrograms/mL but become more frequent at 15 micrograms/mL or above, and are greatly increased in frequency and severity at concentrations greater than 20 micrograms/mL.[1-3] The severity of toxicity is generally correlated with age, underlying disease, and serum-theophylline concentration, but a distinction has been made between acute and chronic theophylline intoxication; symptoms appear to occur at a lower theophylline concentration in chronic toxicity than after acute ingestion of large amounts.[1,2,4,5] Young infants and the elderly (over 60 years) appear to be at particular risk from chronic intoxication with theophylline.[6,7] Older patients with chronic intoxication may be at greater risk of major toxic effects, such as arrhythmias, seizures, and death, than those with acute intoxication.[5]

Common clinical manifestations of theophylline toxicity after overdosage of aminophylline or theophylline include nausea, vomiting, diarrhoea, agitation, tremor, hypertonicity, hyperventilation, supraventricular and ventricular arrhythmias, hypotension, and seizures. Metabolic disturbances such as hypokalaemia, hyperglycaemia, hypophosphataemia, hypercalcaemia, metabolic acidosis, and respiratory alkalosis often occur.[1-3] Other toxic effects reported include dementia,[8] toxic psychosis,[9] symptoms of acute pancreatitis,[10] rhabdomyolysis[11-13] with associated renal failure,[11] and acute compartment syndrome.[14]

Serious toxic symptoms may not be preceded by minor symptoms. In acute intoxication with sustained-release preparations the onset of major toxic symptoms may be delayed for up to 24 hours[1] and prolonged monitoring of such patients is required. Patients have recovered despite serum-theophylline concentrations in excess of 200 micrograms/mL[12,14] but fatalities have occurred with much lower serum concentrations.[10,15,16] Mortality in severe poisoning may be as high as 10%.

Effects on carbohydrate metabolism. Hyperglycaemia is frequent in theophylline intoxication, and is thought to be secondary to theophylline-induced adrenal catecholamine release.[1,2] Whether the effects on blood glucose are significant at more modest serum concentrations of theophylline is unclear, although in 29 preterm infants, mean plasma-glucose concentrations were significantly higher after treatment with intravenous aminophylline and oral theophylline than in those not treated. Two of 15 treated infants developed clinically significant hyperglycaemia and glycosuria. It was recommended that plasma-glucose concentrations be monitored in preterm infants receiving theophylline.[3]

3. Srinivasan G, *et al.* Plasma glucose changes in preterm infants during oral theophylline therapy. *J Pediatr* 1983; **103:** 473–6.

Effects on electrolytes. Hypokalaemia is a common metabolic disturbance in theophylline intoxication, but it has also been reported[1] in patients with plasma-theophylline concentrations within the therapeutic range. It is considered to be secondary to theophylline-induced adrenal catecholamine release, with cellular influx of potassium ions.[2] It is recommended[1] that plasma-potassium is monitored during intravenous theophylline therapy particularly if other drugs predisposing to hypokalaemia are also given (see also Interactions, below). Hypophosphataemia[1,3] and hyponatraemia[1] can also occur at therapeutic plasma-theophylline concentrations. Hypomagnesaemia[4] and hypercalcaemia[5] have occurred in theophylline overdose.

Effects on the heart. *ARRHYTHMIAS.* Theophylline or aminophylline can precipitate sinus tachycardia and supraventricular and ventricular premature contractions at therapeutic serum-theophylline concentrations[1] and in overdose.[2,3] Multifocal atrial tachycardia has also been associated with both theophylline overdose[2] and serum-theophylline concentrations within the generally accepted therapeutic range of 10 to 20 micrograms/mL.[4] Use of theophylline with oral beta-adrenoceptor stimulants is associated with a significant increase in the mean heart rate.[5,6]

Effects on the kidneys. For a report of rhabdomyolysis-induced acute renal failure occurring after aminophylline overdose, see the general discussion on toxicity, above.

Effects on mental function. As mentioned in the general discussion on toxicityabove, theophylline toxicity has been associated with reports of dementia and toxic psychosis, as well as the more common adverse effects of anxiety and restlessness.

LEARNING AND BEHAVIOUR PROBLEMS. Several small studies[1-3] have suggested that theophylline may be associated with learning and behaviour problems in children, especially those with a low IQ. However, the FDA has concluded[4] that such studies provide insufficient evidence to support an adverse effect of theophylline on learning behaviour or school performance. Other studies have found no marked behavioural adverse effects that could be attributed to theophylline.[5,6] Additionally, academic achievement generally appeared to be unaffected by either asthma or by treatment with appropriate doses of theophylline.[7]

Effects on the nervous system. *CONVULSIONS.* The risk of convulsions with acute theophylline toxicity is low at serum theophylline concentrations less than 60 micrograms/mL;[1] seizures are most likely in patients with peak concentrations above 100 micrograms/mL.[2] However, the risk of seizures is much greater after chronic overdosage;[1,2] seizure activity has been reported at serum concentrations just above or even within the therapeutic range.[3] Elderly patients or those with previous brain injury or neurological disease may be at increased risk,[2-4] although some have questioned the association.[1] The outcome of seizures appears to be variable: death and severe neurological deficit have occurred,[2,3] but other series have recorded recovery without serious morbidity.[4]

Effects on the skin. For reports of cutaneous reactions to theophylline and aminophylline, see under Hypersensitivity, below.

Effects on the urinary tract. Although diuresis is more commonly seen, urinary retention has been reported in male patients during therapy with aminophylline[1] or theophylline.[2]

1. Owens GR, Tannenbaum R. Theophylline-induced urinary retention. *Ann Intern Med* 1981; **94:** 212–13.
2. Prakash M, Washburne JD. Theophylline and urinary retention. *Ann Intern Med* 1981; **94:** 823.

Hypersensitivity. Hypersensitivity reactions have been reported after oral or intravenous doses of aminophylline. Reactions include erythematous rash with pruritus,[1,2] erythroderma,[2] and exfoliative dermatitis.[3] Aminophylline can produce both type I (immediate) and type IV (delayed) hypersensitivity reactions, the latter being due to the ethylenediamine component and can be confirmed by skin patch tests.[1-3] If hypersensitivity to ethylenediamine is confirmed it is recommended that aminophylline is avoided and treatment continued with theophylline or another theophylline salt.[1,3,4] Hypersensitivity reactions to theophylline have been reported rarely but type I reactions have occurred.[4] An erythematous, maculopapular rash has been reported[5] during treatment with a modified-release theophylline preparation, which did not occur when another modified-release theophylline product was given.

5. Mendel S, *et al.* Dermatologic reaction to a sustained-release theophylline product. *Clin Pharm* 1985; **4:** 334–5.

Hyperuricaemia. In a study of 112 asthmatic patients receiving modified-release theophylline 200 to 400 mg 12-hourly, there was a significant correlation of serum-uric acid concentrations and serum-theophylline concentrations.[1] Gout has been reported in a woman receiving theophylline and aminophylline;[2] her serum-uric acid concentration was increased while receiving the xanthines, but subsequently fell when they were stopped, and rose again when treatment was resumed.

2. Toda K, *et al.* Gout due to xanthine derivatives. *Br J Rheumatol* 1997; **36:** 1131–2.

Necrotising enterocolitis. Although there have been reports of neonatal necrotising enterocolitis associated with oral theophylline or aminophylline,[1,2] a study of 275 infants concluded that theophylline did not significantly contribute to its development.[3] It has been suggested that the high osmolality of liquid feeds and drugs including oral theophylline preparations may be involved in the aetiology of necrotising enterocolitis.[4]

4. Watkinson M, *et al.* Hyperosmolar preparations for neonates. *Pharm J* 1987; **241:** 488.

Withdrawal syndromes. Episodes of apnoea beginning 28 hours after birth and increasing in frequency and severity over the next 4 days occurred in a neonate whose mother had taken aminophylline and theophylline throughout pregnancy. Measurement of serum-theophylline concentration showed the increasing apnoea coincided with falling theophylline concentration. The infant's apnoea resolved on giving theophylline; treatment was stopped after 4 months.[1]

Worsening asthma control may occur when theophylline is withdrawn; there is some evidence of a rebound deterioration in lung function due to the development of tolerance.[2]

2. Bennett JA, *et al.* The airway effects of stopping regular oral theophylline in patients with asthma. *Br J Clin Pharmacol* 1998; **45:** 402–4.

Treatment of Adverse Effects

After theophylline or aminophylline overdosage, elimination may be enhanced by repeated oral doses of activated charcoal regardless of the route of overdose (see below). An osmotic laxative may also be considered. Treatment is symptomatic and supportive; ECG monitoring is recommended. Serum-theophylline concentrations should be monitored and if modified-release preparations have been taken monitoring should be prolonged. Metabolic abnormalities, particularly hypokalaemia, should be corrected; hypokalaemia may be so severe as to require intravenous infusion of potassium. In the non-asthmatic patient severe tachycardia, hypokalaemia, and hyperglycaemia may be reversed by a non-selective beta blocker (see also below). Patients with asthma or chronic obstructive pulmonary disease (COPD) who, after correction of hypokalaemia, have severe tachycardia, may be treated with intravenous verapamil. Alternatively direct current (DC) cardioversion may be considered. Ventricular arrhythmias causing haemodynamic compromise should also be treated with DC cardioversion. Isolated convulsions may be controlled by intravenous diazepam or a barbiturate; phenytoin may be less effective. In the most refractory cases general anaesthesia, and neuromuscular blockade, with ventilation, may be required.

Charcoal haemoperfusion or haemodialysis may be required.

Activated charcoal. Multiple-dose oral activated charcoal is considered the cornerstone of treatment for theophylline and xanthine poisoning. It reduces the absorption of oral theophylline, and also enhances the elimination of theophylline from the body even after absorption or intravenous doses of xanthine. Aggressive antiemetic therapy may be required to allow use and retention of activated charcoal, since theophylline toxicity causes protracted vomiting. A cathartic such as sorbitol may be given with the activated charcoal to aid elimination of theophylline, but can cause fluid and electrolyte disturbances. For oral theophylline overdose the use of gastric lavage before oral activated charcoal may not be better than activated charcoal alone.

Beta blockers. Infusion of propranolol after theophylline overdose in 2 patients was associated with improvement in hyperglycaemia, hypokalaemia, tachycardia, and hypotension. Beta-adrenergic blockade may therefore be of benefit in the management of the metabolic changes of theophylline poisoning, especially in the non-asthmatic patient.[1,2] However, in asthmatic patients, beta blockers should be reserved for those with severe hypokalaemia or cardiac arrhythmias when mechanical ventilation is available as beta blockers can cause bronchoconstriction.[1,2] Propranolol reduces the clearance of theophylline (see under Interactions, below) and it has been suggested that a non-interacting beta blocker may be more appropriate.[3] Esmolol has been used successfully to manage cardiovascular symptoms of overdosage.[4]

Endoscopy. Absorption is delayed after overdosage with modified-release oral preparations of aminophylline or theophylline and may be further prolonged by the formation of tablet aggregates, or bezoars, in the stomach.[1-3] Of 11 patients admitted with overdosage, one vomited a bezoar, 2 had bezoars removed at gastroscopy, and in one a bezoar was found at necropsy.[3] If bezoar formation occurs gastric lavage and activated charcoal will have little if any effect and the patient may appear to stabilise before experiencing increasing serum-theophylline concentration and clinical deterioration;[1,2] fatalities have been reported.[1] Endoscopy should be considered in cases of modified-release theophylline overdosage in which clinical signs and serial concentration measurements suggest continuing drug absorption.[2]

Haemodialysis and haemoperfusion. Extracorporeal theophylline removal techniques after overdosage of aminophylline or theophylline have been reviewed.[1] Neither peritoneal dialysis nor exchange transfusion produced a significant increase in the total body clearance of theophylline, whereas haemodialysis could be expected to double clearance, and haemoperfusion results in four- to sixfold increases in clearance. Charcoal haemoperfusion should be considered if the plasma-theophylline concentration exceeds 100 micrograms/mL in an acute intoxication, or 60 micrograms/mL in chronic overdose (40 micrograms/mL if there is significant respiratory or heart failure, or liver disease) though plasma concentrations alone should not determine its use (see under Adverse Effects, above). If there is intractable vomiting, arrhythmias, or seizures charcoal haemoperfusion should be started without delay. In most patients a 4-hour haemoperfusion allows significant clinical improvement, but treatment should continue until plasma concentrations are below 15 micrograms/mL. Plasma concentrations should be followed at least every 4 hours for the first 12 hours post-perfusion, as rebound increases have been noted on terminating perfusion.

Haemodialysis may rarely be an alternative if haemoperfusion is not available, or in series with haemoperfusion if significant rhabdomyolysis is present. There has been a case report[2] of continuous venovenous haemofiltration used to treat severe theophylline toxicity.

Precautions

Theophylline or aminophylline should be given with caution to patients with peptic ulceration, porphyria, hyperthyroidism, hypertension, cardiac arrhythmias or other cardiovascular disease, or epilepsy, as these conditions may be exacerbated. They should also be given with caution to patients with heart failure, hepatic dysfunction, acute febrile illness, and to neonates and the elderly, since in all of these circumstances theophylline clearance may be decreased, resulting in increases in serum-theophylline concentrations and serum half-life. Conversely, smoking and alcohol consumption increase theophylline clearance. Many drugs interact with theophylline; for details see Interactions, below.

Intravenous injections of theophylline or aminophylline must be given very slowly to prevent dangerous CNS and cardiovascular adverse effects resulting from the direct stimulant effect.

Dosage requirements of theophylline vary widely between subjects; in view of the many factors affecting theophylline pharmacokinetics, serum concentration monitoring is necessary to ensure concentrations are within the therapeutic range.

Patients should not be transferred from one modified-release theophylline or aminophylline preparation to another without clinical assessment and the measurement of serum-theophylline concentrations because of bioavailability differences.

Acute febrile illness. A reduction in theophylline clearance has been noted in patients presenting with acute respiratory illness[1] and appears to be associated with the severity of the underlying pulmonary disease and the rate of change in the patient's condition.[2] Caution has been advised in giving theophylline to patients with chronic obstructive pulmonary disease with acute exacerbations, since these patients appear most likely to exhibit altered theophylline metabolism.[2]

Similarly, a decrease in theophylline clearance and an increase in the incidence of adverse effects has been reported during acute viral infections such as influenza in children receiving theophylline therapy for chronic asthma.[3,4] Another study in asthmatic children found that acute febrile illness accompanied by increased C-Reactive Protein (CRP) level may affect theophylline metabolism.[5] The authors postulated that cytokines released in the process of acute illness were responsible. Influenza vaccination has also been reported to reduce theophylline clearance (see under Interactions, below). The mechanism by which theophylline metabolism is reduced in these patients may be related to increased interferon production during the acute febrile response. A dosage reduction of one half has been recommended[6] in children receiving chronic theophylline therapy who are febrile for more than 24 hours. Further dose adjustments should be based on serum-theophylline concentrations until the patients have recovered from their acute illness and are restabilised on their usual dosage. However, conflicting results have been reported and in one controlled study RSV infection was found to have no significant effect on theophylline disposition in children.[7]

Age. For the effects of age on the metabolism and excretion of theophylline see under Pharmacokinetics, below. Dosage regimens for infants are discussed under Administration in Infants, in Uses and Administration, below.

Breast feeding. From one study of 3 women it was estimated that less than 1% of the total theophylline eliminated was found in breast milk.[1] Another study of 5 women estimated that a breast-fed infant would receive less than 10% of the maternal dose of theophylline.[2] These amounts were considered unlikely to cause toxicity, but it has been reported that irritability in one infant seemed to occur on the intermittent days when the mother took aminophylline. The American Academy of Pediatrics[3] states that theophylline is usually compatible with breast feeding, although it noted that irritability has been reported in infants whose mothers were receiving theophylline.

ECT. Patients receiving theophylline are at risk of prolonged seizures during ECT, and status epilepticus has been reported.[1,2] The ability of theophylline to prolong seizures has led to it being used as an adjunct in ECT.[3] Caffeine has been used similarly, see p.1118.

3. Leentjens AFG, *et al.* Facilitation of ECT by intravenous administration of theophylline. *Convuls Ther* 1996; **12:** 232–7.

Porphyria. Theophylline has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. It has been recommended[1] that serum-theophylline concentrations are measured at monthly intervals throughout pregnancy and 1 and 4 weeks after delivery since the pharmacokinetics of theophylline may be altered. An increase in the volume of distribution of theophylline, a decrease in plasma-protein binding, and a continuing decrease in clearance throughout pregnancy have been noted in some patients, especially during the later part of pregnancy,[2-4] but other studies have noted an increase in theophylline clearance during pregnancy.[1,5] Some studies have found that after delivery there is a return of clearance values to those existing before pregnancy,[2] while others have not.[4]

In a study of 12 neonates whose mothers received various theophylline preparations throughout their pregnancies[6] maternal, cord, and neonatal heelstick theophylline concentrations ranged from 2.3 to 19.6 micrograms/mL. Transient jitteriness was seen in 2 neonates and tachycardia in one, at cord theophylline concentrations of 11.7 to 17 micrograms/mL. There were no instances of vomiting, seizure, arrhythmias, diarrhoea, or feeding disturbances, which had been reported previously.

Renal impairment. Theophylline is eliminated mainly by hepatic metabolism and usual doses of aminophylline or theophylline can be given to patients with renal impairment. In patients undergoing haemodialysis the clearance of theophylline is increased and its elimination half-life reduced; mean values of 84.8 and 83 mL/minute and 2.5 and 2.3 hours respectively have been reported.[1,2] Haemodialysis removes up to 40% of a dose of theophylline.[1] Peritoneal dialysis has little effect on the pharmacokinetics of theophylline removing about 3.2% of a dose.[1]

2. Anderson JR, *et al.* Effects of hemodialysis on theophylline kinetics. *J Clin Pharmacol* 1983; **23:** 428–32.

Smoking. Certain components of tobacco smoke, notably aromatic hydrocarbons, induce hepatic drug-metabolising enzymes and cigarette smoking has been reported[1-3] to increase theophylline clearance and shorten its elimination half-life. The effect of smoking may override factors that tend to decrease theophylline clearance, such as old age.[4] The duration of enzyme induction after stopping smoking is uncertain; theophylline clearance decreased by 38% after one week of abstinence from smoking in one study,[5] while others have found changes in clearance persisting for at least 3 months.[1] Tobacco chewing has also been reported to increase theophylline clearance,[6] but nicotine chewing gum appears to have no effect.[5]

Interactions

The toxic effects of theophylline, aminophylline, and other xanthines are additive. Use with other xanthine medications should therefore be avoided; if intravenous aminophylline is to be given for acute bronchospasm in patients who have been taking maintenance theophylline therapy, serum-theophylline concentrations should be measured first and the initial dose reduced as appropriate (see Uses and Administration, below).

Theophylline clearance may be reduced by interaction with other drugs including allopurinol, some antiarrhythmics, cimetidine, disulfiram, fluvoxamine, interferon alfa, macrolide antibacterials and quinolones, oral contraceptives, tiabendazole, and viloxazine, and the dose of theophylline may need to be reduced. Phenytoin and some other antiepileptics, ritonavir, rifampicin, and sulfinpyrazone may increase theophylline clearance, and require an increase in dose or dosing frequency of theophylline.

Xanthines can potentiate hypokalaemia caused by hypoxia or associated with the use of beta$_2$-adrenoceptor stimulants (beta$_2$ agonists), corticosteroids, and diuretics. There is a risk of synergistic toxicity if theophylline is given with halothane or ketamine, and it may antagonise the effects of adenosine and of competitive neuromuscular blockers; lithium elimination may be enhanced with a consequent loss of effect. The interaction between theophylline and beta blockers is complex (see below) but use together tends to be avoided on pharmacological grounds since beta blockers produce bronchospasm.

◊ Theophylline is metabolised by several hepatic cytochrome P450 isoenzymes, of which the most important seems to be CYP1A2.[1] Numerous drugs affect the metabolic clearance of theophylline and aminophylline,[2] but the variability in theophylline pharmacokinetics makes the clinical significance of these interactions difficult to predict. Giving theophylline with drugs that inhibit its metabolism should be avoided but, if unavoidable, the dose of theophylline should be halved.[3] There is some evidence to suggest that less of a dose reduction is required in the presence of severe liver dysfunction,[4] aside from that already required by impaired hepatic metabolism, see Administration in Hepatic Impairment, below. Subsequent doses should be adjusted based on serum-theophylline monitoring.[3] Even when introducing medication for which no interaction is suspected, a check on the serum-theophylline concentration within 24 hours of beginning the new drug has been advised.[3]

Theophylline reduces liver plasma flow[5] and may therefore prolong the half-life and increase steady-state levels of hepatically eliminated drugs but it is claimed to have no effect on antipyrine clearance.[6]

Antiarrhythmics. An increase in serum-theophylline concentration from 93.2 to 194.2 micromol/litre with symptoms of tachycardia, nervousness, and tremors occurred in a patient 9 days after starting *amiodarone* therapy.[1] Elevated theophylline concentrations and/or decreased clearance have also been reported following addition of *mexiletine* to theophylline therapy.[2-6] Amiodarone and mexiletine probably interact with theophylline through inhibition of its hepatic metabolism. *Tocainide* has also been found to impair theophylline metabolism resulting in a reduction in theophylline clearance but the effect was substantially smaller than that of mexiletine.[7] In one patient stabilised on theophylline therapy, an increase in the plasma-theophylline concentration with subsequent toxicity was noted after starting treatment with *propafenone*.[8] See also under Calcium-channel Blockers, below.

8. Lee BL, Dohrmann ML. Theophylline toxicity after propafenone treatment: evidence for drug interaction. *Clin Pharmacol Ther* 1992; **51:** 353–5.

Antibacterials. ***IMIPENEM.*** Seizures have been reported in 3 patients receiving theophylline who were given imipenem,[1] although serum concentrations of theophylline were not affected.

1. Semel JD, Allen N. Seizures in patients simultaneously receiving theophylline and imipenem or ciprofloxacin or metronidazole. *South Med J* 1991; **84:** 465–8.

ISONIAZID. Isoniazid inhibits oxidative enzymes in the liver and has been found to impair the elimination of theophylline. Both clearance and volume of distribution of theophylline were reduced with an increase in serum-theophylline concentrations in healthy subjects after 14 days of pretreatment with isoniazid[1] and theophylline toxicity has been reported[2] in a patient one month after adding theophylline to isoniazid therapy.

2. Torrent J, *et al.* Theophylline-isoniazid interaction. *DICP Ann Pharmacother* 1989; **23:** 143–5.

MACROLIDES. There are conflicting reports of the effect of *erythromycin* on the pharmacokinetics of theophylline. Significant decreases in the clearance of theophylline and prolonged elimination half-life have been reported[1-3] but other studies have found no interaction.[4,5] It has also been noted that the serum concentrations and bioavailability of erythromycin may be reduced by theophylline[6,7] (see also p.271). The clearance of theophylline is also markedly decreased by *troleandomycin*,[8-10] but there have been reports that for clinical purposes the pharmacokinetics of theophylline do not seem to be significantly altered by *dirithromycin*,[11-13] *josamycin*,[9,14] *midecamycin*,[10,15,16] *rokitamycin*,[17] *roxithromycin*,[18] or *spiramycin*.[19] *Clarithromycin* also seems unlikely to have a significant effect in most patients, but in a few theophylline dosage may need to be adjusted.[20,21] In one case report, serum-theophylline concentrations fell over a few days after the withdrawal of *azithromycin*.[22]

QUINOLONES. The fluoroquinolone antibacterials vary in their propensity to interact with theophylline. *Enoxacin* shows the most marked interaction and has been reported[1] to cause serious nausea and vomiting, tachycardia, and headaches, associated with unexpectedly high plasma-theophylline concentrations in patients with respiratory-tract infections. Studies,[2-5] mainly in healthy subjects, have found that enoxacin decreases theophylline clearance by up to 74%[3] with an increase in the elimination half-life and serum-theophylline concentration.

Ciprofloxacin[2,6-8] and *pefloxacin*[2] interact with theophylline to a lesser extent than enoxacin, decreasing theophylline clearance by about 30%. Eight clinically important interactions between ciprofloxacin and theophylline had been reported to the UK CSM[9] including 1 death. A ciprofloxacin-induced seizure has been reported[10] which may have been due to the combined inhibitory effects of the 2 drugs on GABA binding. It has been recommended that ciprofloxacin should not be used in patients treated with theophylline.[9]

Norfloxacin[4,11-13] and *ofloxacin*[4,11,14] have been reported to have minor effects on the pharmacokinetics of theophylline. Although their effects were usually considered not to be clinically significant, the US FDA had received 9 reports of theophylline toxicity associated with use with norfloxacin, including 1 death.[15] *Fleroxacin*,[16] *flumequine*,[17] *lomefloxacin*,[8,18,19] *moxifloxacin*,[20] and *rufloxacin*[21] have been reported to have no significant effect on the pharmacokinetics of theophylline in small studies in healthy subjects.

The mechanism of interaction involves a reduction in the metabolic clearance of theophylline due to inhibition of hepatic microsomal enzymes. However, the exact mechanism is unknown and it is difficult to predict which patients will be at risk. Extreme caution should be used when giving quinolones with theophylline, particularly in the elderly[15] and it may be advisable to use a non-interacting fluoroquinolone, although theophylline concentrations should still be monitored.

Of the non-fluorinated quinolones, *nalidixic acid*[2] has been reported not to affect theophylline clearance whereas *pipemidic acid* has markedly inhibited theophylline clearance.[19]

RIFAMPICIN. Rifampicin induces hepatic oxidative enzymes and a dose of 600 mg daily by mouth for 6 to 14 days has been shown to increase mean plasma-theophylline clearance by 25 to 82% due to enhancement of hepatic theophylline metabolism. This increase in clearance is sufficient to require dosage adjustment in some patients,[1-4] including children.[5]

TETRACYCLINES. *Tetracycline* weakly inhibited theophylline clearance after 5 days of therapy in 5 non-smoking adults with chronic obstructive airways disease[1] and theophylline toxicity has been reported[2] in a patient given a 10-day course of tetracycline during theophylline therapy. *Doxycycline* has been reported not to have any significant effect on theophylline pharmacokinetics in healthy subjects.[3]

Antidepressants. Significantly reduced clearance and increased plasma concentrations of theophylline have been reported when given with *viloxazine*.[1,2] The dosage of theophylline should be decreased and its plasma concentrations monitored when viloxazine is also prescribed.[2] The interaction probably involves competition between the two drugs for hepatic microsomal enzymes.

Fluvoxamine has also been associated with a significant reduction in theophylline clearance[3,4] and theophylline toxicity has been described in patients when fluvoxamine was added to their therapy.[5,6] This interaction which is due to potent liver enzyme inhibition[7] has been the subject of a warning by the UK CSM[8] in which they issued the standard advice of avoiding the two drugs if at all possible and, where they could not be avoided, of giving half the dose of theophylline and monitoring plasma concentrations. A small study evaluating the effect of liver cirrhosis on the interaction between fluvoxamine and theophylline observed a decrease in fluvoxamine-induced inhibition of theophylline clearance as the severity of liver cirrhosis increased.[4] The authors suggest that theophylline may require less of a dose reduction in the presence of severe liver dysfunction, aside from that already required by impaired hepatic metabolism, see Administration in Hepatic Impairment, below.

St John's wort may have decreased theophylline concentrations and increased the theophylline dosage requirement in one case report.[9] However, a study[10] in 12 healthy subjects found that 15 days of treatment with St John's wort did not significantly change theophylline pharmacokinetics.

For a mention of the effect of theophylline on the renal clearance of *lithium*, see Xanthines, under Interactions of Lithium, p.405.

Antiepileptics. *Phenytoin* markedly decreases the elimination half-life and increases the clearance of theophylline, probably due to hepatic enzyme induction, at therapeutic serum-phenytoin concentrations,[1-3] at subtherapeutic phenytoin concentrations,[2,4] and even in heavy smokers.[2] A preliminary report suggested that the serum concentration of phenytoin may be decreased simultaneously,[5] perhaps due to enzyme induction by theophylline[5] or reduced phenytoin absorption.[6] The interaction has been reported to occur within 5 to 14 days of taking phenytoin and theophylline, and theophylline clearance has increased by up to 350%, and reductions in serum half-life have ranged from 25 to 70% of initial values.[3,4]

Carbamazepine has also been seen to increase theophylline elimination. In one patient, theophylline serum half-life was decreased by about 24 to 60%, and clearance was increased by about 35 to 100% when carbamazepine was given.[2] In an 11-year-old girl theophylline-serum half-life was almost halved with loss of asthma control after 3 weeks of concurrent carbamazepine therapy.[7] In turn, theophylline has been reported to reduce serum concentrations of carbamazepine—see p.475.

Although *phenobarbital* was not found to have a significant effect on the pharmacokinetics of a single dose of theophylline given intravenously,[8] enhanced theophylline clearance has been seen in patients after longer periods of treatment with phenobarbital.[9,10] The magnitude of the changes in theophylline elimination appears to be smaller with phenobarbital than phenytoin. *Pentobarbital* in high doses has also been reported to increase theophylline metabolism.[11] A more recent study[12] has also shown that therapeutic doses of pentobarbital (100 mg daily) increase plasma clearance of theophylline by a mean of 40%, although this was subject to marked interindividual variations. Renal clearance was not affected, suggesting hepatic enzyme induction as the probable mechanism.

Antifungals. There have been reports that *ketoconazole* does not appear significantly to alter the pharmacokinetics of theophylline.[1,2] The manufacturer of *fluconazole* has, however, stated that plasma clearance of theophylline may be decreased by fluconazole. A 16% reduction in theophylline clearance has been reported[3] after oral fluconazole but fluconazole was considered to have only a minor inhibitory effect on theophylline metabolism and theophylline disposition was not significantly affected. Theophylline metabolism has been inhibited to a similar degree by *terbinafine*.[4]

4. Trépanier EF, *et al.* Effect of terbinafine on theophylline pharmacokinetics in healthy volunteers. *Antimicrob Agents Chemother* 1998; **42:** 695–7.

Antigout drugs. *Allopurinol* 300 mg by mouth daily for 7 days was found to have no effect on the pharmacokinetics of theophylline after a single intravenous dose of aminophylline[1,2] or after oral theophylline given to steady state.[1] However, oral allopurinol 600 mg daily for 28 days has been found to inhibit the metabolism of theophylline,[3] increasing the mean half-life by 25% after 14 days and 29% after 28 days and there has been a report of allopurinol increasing peak plasma-theophylline concentrations by 38% in one patient within 2 days of use together.[4]

Probenecid has been reported[5] to have no effect on the hepatic metabolism or total body clearance of theophylline in a single-dose study in healthy subjects.

Sulfinpyrazone 800 mg daily for 7 days increased the total plasma clearance of theophylline by 22% in healthy subjects due to selective induction of certain cytochrome P450 isoenzymes.[6]

Antineoplastics. There has been a report of increased clearance of theophylline in 3 patients given *aminoglutethimide*.[1]

The clearance of theophylline (given as theophylline, aminophylline, or choline theophyllinate) was reported to decrease by an average of 19% in 8 patients with severe corticosteroid-dependent asthma given low-dose weekly intramuscular injections of *methotrexate*.[2] A high degree of interpatient variability was seen. Three patients reported nausea; one of whom required a decrease in theophylline dose. The authors reported that the most likely explanation for the change in theophylline clearance was inhibition of microsomal enzyme activity.

For reference to a possible interaction between theophylline and *lomustine*, see Lomustine, p.741.

1. Lønning PE, *et al.* Effect of aminoglutethimide on antipyrine, theophylline, and digitoxin disposition in breast cancer. *Clin Pharmacol Ther* 1984; **36:** 796–802.
2. Glynn-Barnhart AM, *et al.* Effect of low-dose methotrexate on the disposition of glucocorticoids and theophylline. *J Allergy Clin Immunol* 1991; **88:** 180–6.

Antivirals. A single injection of recombinant human *interferon alfa* reduced theophylline clearance by 33 to 81% in 8 of 9 subjects, resulting in a 1.5- to sixfold increase in the theophylline elimination half-life.[1] Injection of interferon alfa once daily for 3 days in 11 healthy subjects also reduced theophylline clearance and increased elimination half-life,[2] but the magnitude of the changes were of a similar order to normal intra-individual variation and the interaction was considered of minor clinical significance.

Licensed product information for *ritonavir* states that it substantially increases the clearance of theophylline; theophylline dosage may need to be increased to maintain efficacy.

There is evidence[3] that *aciclovir* inhibits theophylline metabolism, resulting in accumulation.

3. Maeda Y, *et al.* Inhibition of theophylline metabolism by aciclovir. *Biol Pharm Bull* 1996; **19:** 1591–5.

Benzodiazepines. For reference to the antagonism of benzodiazepine sedation by aminophylline, see Xanthines, under Interactions of Diazepam, p.992.

Beta blockers. *Propranolol* reduced theophylline clearance by 36% in healthy subjects given aminophylline intravenously. *Metoprolol* did not reduce clearance in the group as a whole, but a reduction was noted in some smokers whose theophylline clearance was initially high.[1] Propranolol is thought to exert a dose-dependent selective inhibitory effect on the separate cytochrome P450 isoenzymes involved in theophylline demethylation and 8-hydroxylation.[2] The less lipophilic beta blockers *atenolol*[3,4] and *nadolol*[4] had no significant effect on the pharmacokinetics of theophylline.

In general, however, beta blockers should be avoided in patients taking theophylline as they can dangerously exacerbate bronchospasm in patients with a history of asthma or chronic obstructive pulmonary disease.

Caffeine. Abstention from dietary methylxanthines by healthy subjects has resulted in faster elimination of theophylline.[1] While the addition of extra caffeine to the diet has been reported not to alter theophylline disposition,[2] some studies in healthy subjects have indicated that the ingestion of moderate amounts of caffeine (120 to 900 mg daily), which could be consumed by drinking several cups of coffee daily, can have a pronounced influence on the pharmacokinetics of theophylline.[3,4] In these latter studies the mean theophylline clearance was reduced by 23 and 29% with a corresponding increase in the elimination half-lives.

Calcium-channel blockers. *Verapamil* has been reported[1] to decrease the clearance of theophylline by a mean of 14% in healthy subjects and although this was not considered to be clinically significant, symptoms of theophylline toxicity, associated with near doubling of the serum-theophylline concentration have occurred in a 76-year-old woman taking theophylline after 6 days of therapy with verapamil.[2] Studies in healthy subjects and asthmatic patients have produced conflicting results of the effect of *nifedipine* on the pharmacokinetics of theophylline. Reduced clearance[1] and an increase in the volume of distribution[3,4] of theophylline have been reported and both decreased[4] and increased[5] serum-theophylline concentrations; theophylline toxicity has been reported.[6,7] However, most studies have concluded that the effects of nifedipine are unlikely to be of clinical importance.[1,4,5,8]

Serum concentrations of theophylline have been reported to be increased by *diltiazem*[5] and reduced by *felodipine*;[9] neither of these effects were considered to be clinically significant.

Cannabis. A search of the literature[1] revealed 2 studies, both published in the 1970s, that showed that marijuana smoking increased the clearance of theophylline.

1. Brown D. Influence on theophylline clearance. *Pharm J* 1994; **253:** 595.

Corticosteroids. In 3 patients with acute severe asthma given aminophylline intravenously, serum-theophylline concentrations rose rapidly from the therapeutic range to between 40 and 50 micrograms/mL when *hydrocortisone* was given intravenously.[1] In studies in healthy subjects, no significant changes in serum-theophylline concentrations were noted when hydrocortisone, *methylprednisolone*,[2] or *prednisone*[3] were given, although there was a trend towards increased theophylline clearance during corticosteroid therapy.[2,3] In preterm neonates, exposure to *betamethasone in utero* stimulated the hepatic metabolism of theophylline,[4,5] but did not affect dosage requirements.

The possibility that adverse effects such as hypokalaemia may be potentiated by use of theophylline with corticosteroids should be borne in mind.

5. Baird-Lambert J, *et al.* Theophylline metabolism in preterm neonates during the first weeks of life. *Dev Pharmacol Ther* 1984; **7:** 239–44.

Disulfiram. In a study involving 20 recovering alcoholic patients, disulfiram decreased the plasma clearance and prolonged the elimination half-life of theophylline in a dose-dependent manner.[1] It was concluded that disulfiram exerts a dose-dependent inhibitory effect on the hepatic metabolism of theophylline and that, in order to minimise the risk of toxicity, the dosage of theophylline may need to be reduced by up to 50% if given together.

1. Loi C-M, *et al.* Dose-dependent inhibition of theophylline metabolism by disulfiram in recovering alcoholics. *Clin Pharmacol Ther* 1989; **45:** 476–86.

Diuretics. Although increased mean serum-theophylline concentrations were noted in 10 patients given continuous intravenous aminophylline infusions after intravenous injection of *furosemide*,[1] in 8 patients with chronic stable asthma, mean peak serum-theophylline concentrations were reduced from 12.14 micrograms/mL with placebo to 7.16 micrograms/mL when furosemide was given. Reduced concentrations were noted for up to 6 hours after furosemide.[2] Decreased theophylline concentrations were also noted in 4 neonates receiving oral or intravenous theophylline when given furosemide.[3] Serum-theophylline concentrations returned to normal when furosemide and theophylline were given more than 2 hours apart.

The possibility that adverse effects such as hypokalaemia may be potentiated if theophylline is given with diuretics should be borne in mind.

Gastrointestinal drugs. Oral *antacids* do not appear to affect the total absorption of theophylline from the gut.[1-5] However, some studies have shown a reduction in the rate of absorption from both immediate-[1] and modified-release theophylline preparations[2] after antacids. Also an increase in peak serum-theophylline concentrations has been noted with certain modified-release formulations.[3]

Cimetidine inhibits the oxidative metabolism of theophylline reducing its clearance by 20 to 35% and prolonging its serum half-life;[6-8] toxic effects have been reported.[6] It has been recommended that the dose of aminophylline should be reduced by about one-third if given with cimetidine.[6] This inhibition of theophylline metabolism may be enhanced by liver disease,[9] but there is wide interindividual variation. The reduction in clearance may be greater in smokers.[10] Studies have suggested that *ranitidine* does not significantly inhibit theophylline metabolism,[11-14] even at very high doses.[15] However, there have been occasional reports of theophylline toxicity after use with ranitidine.[16-18] *Famotidine*[19] has also been reported to not alter theophylline disposition but one small study found a significant decrease in theophylline clearance in some patients with chronic obstructive pulmonary disease.[20]

Omeprazole, lansoprazole, and *pantoprazole* generally have insignificant or no effect on theophylline clearance.[21,22] In CYP2C19 poor metabolisers there may be an increase in omeprazole concentrations and subsequent induction of CYP1A, a major enzyme of theophylline metabolism. A pharmacokinetic study[23] of this induction in 5 poor metabolisers given omeprazole did find a trend towards an increase in theophylline clearance.

General anaesthetics. There have been several reports[1,2] of increased cardiotoxicity when patients taking theophylline were anaesthetised with *halothane.* There was also an early report of seizures and tachycardia attributed to an interaction between theophylline and *ketamine.*[3]

3. Hirschman CA, *et al.* Ketamine-aminophylline-induced decrease in seizure threshold. *Anesthesiology* 1982; **56:** 464–7.

Leukotriene inhibitors and antagonists. *Zileuton* prolongs the half-life and reduces the clearance of theophylline;[1] dosage of theophylline should be reduced to avoid toxicity when both drugs are given together, and plasma-theophylline concentrations should be monitored. Use of *zafirlukast* with theophylline decreased zafirlukast plasma concentrations but had no effect on theophylline plasma concentrations in clinical trials. However, toxic serum-theophylline concentrations occurred in one patient when zafirlukast was added to therapy, and recurred on rechallenge.[2] A dose of *montelukast* 10 mg daily did not affect the pharmacokinetics of theophylline, but doses of 200 mg and 600 mg daily reduced the maximum plasma concentration, area under the concentration-time curve, and elimination half-life of theophylline.[3]

Methoxsalen. In a single-dose pharmacokinetic study in 3 healthy subjects, the rate of elimination of theophylline was decreased after a single oral dose of methoxsalen, while urinary excretion of unchanged theophylline increased.[1] Methoxsalen probably inhibits the metabolism of cytochrome P450 isoenzyme CYP1A2,[2] and it has been suggested that theophylline dose reductions are likely to be required when used with systemic methoxsalen but seem unlikely to be necessary with topical PUVA therapy.

1. Apseloff G, *et al.* Inhibition and induction of theophylline metabolism by 8-methoxypsoralen: in vivo study in rats and humans. *Drug Metab Dispos* 1990; **18:** 298–303.

Neuromuscular blockers. For reference to resistance to neuromuscular block with pancuronium in patients receiving aminophylline, see Xanthines, p.1905.

Oral contraceptives. Oral contraceptives have been reported to decrease the clearance of theophylline by about 30%, and serum concentrations may be increased,[1-3] due to the inhibitory effects of oral contraceptives on hepatic P450 isoenzymes.

3. Roberts RK, *et al.* Oral contraceptive steroids impair the elimination of theophylline. *J Lab Clin Med* 1983; **101:** 821–5.

Sympathomimetics. The effect of beta-adrenoceptor agonists on the pharmacokinetics of theophylline is unclear. Whereas some studies have found that *orciprenaline*[1] or *terbutaline*[2] had no effect on theophylline disposition, others have shown an increase in theophylline clearance after *isoprenaline*[3,4] or *terbutaline.*[5,6]

Use of theophylline with beta-adrenoceptor agonists can potentiate adverse effects including hypokalaemia,[7,8] hyperglycaemia,[7] tachycardia,[7,8] hypertension,[7] and tremor.[9] Of 9 patients reported to the UK CSM with hypokalaemia during such combined therapy, 4 had clinical sequelae of cardiorespiratory arrest, intestinal pseudo-obstruction, or confusion. Monitoring of serum-potassium concentrations was recommended in patients with severe asthma given both beta-adrenoceptor agonists and xanthine derivatives.[10]

The possibility of an interaction with *phenylpropanolamine* should also be borne in mind, as it has been shown to reduce the clearance of theophylline significantly.[11]

2. Lew G, *et al.* Theophylline-thiabendazole drug interaction. *Clin Pharm* 1989; **8:** 225–7.

Ticlopidine. Theophylline elimination half-life was increased and plasma clearance was decreased in 10 healthy subjects after the use of ticlopidine 500 mg daily by mouth for 10 days.[1]

1. Colli A, *et al.* Ticlopidine-theophylline interaction. *Clin Pharmacol Ther* 1987; **41:** 358–62.

Vaccines. Transient inhibition of the hepatic metabolism of theophylline, possibly secondary to interferon production, resulting in increased theophylline serum half-life and concentration has been reported after BCG vaccination[1] and influenza vaccination.[2,3] Other studies have not been able to confirm the interaction with influenza vaccine.[4-7] The differing findings are probably due to differences in vaccine; modern purified subvirion vaccines which do not induce interferon production do not appear to alter theophylline metabolism.[8,9]

Pharmacokinetics

Theophylline is rapidly and completely absorbed from liquid preparations, capsules, and uncoated tablets; the rate, but not the extent, of absorption is decreased by food, and food may also affect theophylline clearance. Peak serum-theophylline concentrations occur 1 to 2 hours after ingestion of liquid preparations, capsules, and uncoated tablets. Modified-release preparations exhibit considerable variability in their absorption characteristics and in the effect of food. They are generally not considered to be interchangeable; if a patient needs to be transferred from one such preparation to another then the dose should be retitrated. Rectal absorption is rapid from enemas, but may be slow and erratic from suppositories. Absorption after intramuscular injection is slow and incomplete.

Theophylline is about 40 to 60% bound to plasma proteins, but in neonates, or adults with liver disease, binding is reduced. Optimum therapeutic serum concentrations for bronchodilatation are generally considered to range from 10 to 20 micrograms/mL (55 to 110 micromol/litre) although some consider a lower range appropriate (see Therapeutic Drug Monitoring, below).

Theophylline is metabolised in the liver to 1,3-dimethyluric acid, 1-methyluric acid (via the intermediate 1-methylxanthine), and 3-methylxanthine. Demethylation to 3-methylxanthine (and possibly to 1-methylxanthine) is catalysed by the cytochrome P450 isoenzyme CYP1A2; hydroxylation to 1, 3-dimethyluric acid is catalysed by CYP2E1 and CYP3A3. Both the demethylation and hydroxylation pathways of theophylline metabolism are capacity-limited, resulting in non-linear elimination. The metabolites are excreted in the urine. In adults, about 10% of a dose of theophylline is excreted unchanged in the urine, but in neonates around 50% is excreted unchanged, and a large proportion is excreted as caffeine. Considerable interindividual differences in the rate of hepatic metabolism of theophylline result in large variations in clearance, serum concentrations, and half-lives. Hepatic metabolism is further affected by factors such as age, smoking, disease, diet, and drug interactions. The serum half-life of theophylline in an otherwise healthy, non-smoking asthmatic adult is 7 to 9 hours, in children 3 to 5 hours, in cigarette smokers 4 to 5 hours, in neonates and premature infants 20 to 30 hours, and in elderly non-smokers 10 hours. The serum half-life of theophylline may be increased in patients with heart failure or liver disease. Steady state is usually achieved within 48 hours with a consistent dosing schedule.

Theophylline crosses the placenta; it is also distributed into breast milk.

Absorption. *FOOD.* Food has substantial but variable effects on the absorption of theophylline from modified-release formulations but it is difficult to predict whether a particular formulation will be affected.[1] Some formulations are not affected by the presence of food but for others increases or decreases in the rate and/or extent of absorption have been reported. The composition and fluid content of the food appears to be important and a rapid release of theophylline ('dose-dumping') has occurred with some formulations after a meal, especially one with a high fat content.

A diet high in protein and low in carbohydrate has been reported to increase theophylline clearance, and a low-protein, high-carbohydrate diet to decrease theophylline clearance.[2-6] The consumption of methylxanthines, particularly caffeine, in the diet may decrease theophylline clearance (see Caffeine, under Interactions, above).

Metabolism and excretion. *AGE.* From about 1 year of age until adolescence, children have a rapid theophylline clearance.[1] Premature infants and those under 1 year of age have a slower clearance[2,3] due to immature metabolic pathways.[3-5] In neonates the capacity of hepatic cytochrome P450 enzymes is much reduced compared with older children and adults, and *N*-demethylation and oxidation reactions play a minor role in the metabolism of theophylline.[4-6] Neonates are, however, capable of methylating theophylline at the N7 position to form caffeine, which is present at about one-third the concentration of theophylline at steady state.[5,6] The proportion of theophylline excreted unchanged is also increased in premature neonates and decreases with age as hepatic enzyme systems develop.[6] More rapid clearance on the first day of life in premature neonates has been reported.[7]

Some studies have found a progressive decline in clearance throughout adult years[8] whereas others have not.[9] Similarly, some studies have noted a decreased clearance in the elderly[10,11] but others have found no significant change.[12,13]

ELIMINATION KINETICS. There is evidence that the elimination of theophylline is dose-dependent and that at high serum concentrations, a small change in dose of a theophylline preparation could cause a disproportionate increase in serum-theophylline concentration, due to a reduction in clearance.[1-3] However, it is not clear that this effect is clinically significant when serum-theophylline concentrations are within the therapeutic range.[4-8] It has also been suggested that repeated oral dosing of theophylline might result in a decrease of clearance compared with pre-treatment values.[9]

GENDER. A higher theophylline clearance and shorter elimination half-life has been reported in healthy premenopausal women than in healthy men, probably due to sex-related differences in hepatic metabolism.[1] Changes in the pharmacokinetics of theophylline in women have also been reported according to the stage of the menstrual cycle;[2,3] another study[4] found no changes.

Pregnancy and breast feeding. For mention of the pharmacokinetics of theophylline during pregnancy and breast feeding, see under Precautions, above.

Protein binding. Albumin is the major plasma binding protein for theophylline, binding is pH-dependent, and the percentage of theophylline bound at physiological pH is reported to range from about 35 to 45%.[1,2] Some studies have found the plasma protein binding of theophylline to be concentration dependent,[3] but others have not confirmed this.[1,4] Protein binding has been reported to be slightly but significantly higher in patients with bronchial asthma than in healthy controls.[5] Reduced protein binding occurs in patients with hypoalbuminaemia;[6,7] it has also been found in obese subjects[8] (possibly due to elevated concentrations of free fatty acids, which can displace theophylline from binding sites).

Therapeutic drug monitoring. Dosage requirements of theophylline preparations vary widely between subjects and even vary with time in individuals, since serum-theophylline concentrations are influenced by factors including disease states, other drugs, diet, smoking, and age. Serious toxicity is related to serum concentration and may not be preceded by minor symptoms. For these reasons it is recommended that serum-theophylline concentrations should be monitored.

The generally accepted optimal serum concentration is between 10 and 20 micrograms/mL,[1-4] but this should be regarded as a guide and not a rigid barrier and clinical decisions should never be based solely on the serum concentration.[1] The therapeutic range in the treatment of neonatal apnoea is usually considered to be 5 to 15 micrograms/mL although some babies may respond at lower concentrations.[5] Some now consider that this is a more appropriate range in asthma (except perhaps acute severe asthma).[6] It has been suggested that pulmonary function tests provide a better guide in long-term therapy with theophylline.[7]

Serum-theophylline concentrations were originally measured by spectrophotometry but this is subject to considerable interference from other drugs. High performance liquid chromatography is now the method of choice when extreme accuracy is important and the enzyme multiplied immunoassay technique (EMIT) has become popular because of its rapidity and adaptability to processing large batches.[2] Devices are also available that provide serum-theophylline measurements within several minutes using monoclonal antibody technology.[2,8]

The use of salivary concentrations for monitoring theophylline dosage requirements has been tried, because it is noninvasive, but poor correlations between salivary- and serum-theophylline concentrations mean it has not gained general usage.

Uses and Administration

Theophylline is a xanthine (p.1108) and relaxes bronchial smooth muscle, relieves bronchospasm, and has a stimulant effect on respiration. It stimulates the myocardium and CNS, decreases peripheral resistance and venous pressure, and causes diuresis. It is still not clear how theophylline exerts these effects. Inhibition of phosphodiesterase with a resulting increase in intracellular cyclic adenosine monophosphate (cyclic AMP) occurs, and may play a role. Other proposed mechanisms of action include adenosine receptor antagonism, prostaglandin antagonism, and effects on intracellular calcium. In addition, theophylline may also have an anti-inflammatory effect.

Theophylline is used as a bronchodilator in the management of reversible airways obstruction, such as in asthma. Although selective $beta_2$ adrenoceptor stimulants ($beta_2$ agonists) such as salbutamol are generally the preferred bronchodilators for initial treatment, theophylline is commonly used as an adjunct to $beta_2$ agonist and corticosteroid therapy in patients requiring an additional bronchodilating effect. Some patients with chronic obstructive pulmonary disease also have a beneficial response to theophylline therapy. Theophylline is also used to relieve apnoea in neonates. It was formerly used as an adjunct in the treatment of heart failure, and may occasionally have a role in patients with this condition who are also suffering from obstructive airways disease.

Theophylline may be given in the anhydrous form or as the hydrate. Doses of theophylline are usually expressed as anhydrous theophylline; theophylline hydrate 1.1 mg is equivalent to about 1 mg of theophylline.

The pharmacokinetics of theophylline may be altered by factors including age, smoking, disease, diet, and drug interactions (see above under Precautions, Interactions, and Pharmacokinetics). Theophylline doses should therefore be adjusted for each individual patient according to clinical response, adverse effects, and serum-theophylline concentrations.

- Optimum **therapeutic serum concentrations** of theophylline are traditionally considered to range from 10 to 20 micrograms/mL (55 to 110 micromoles/litre) and toxic effects are more common above 20 micrograms/mL. A range of 5 to 15 micrograms/mL may be effective, and associated with fewer adverse effects.

For long-term use, once a maintenance dose has been established, monitoring of serum-theophylline concentrations at 6- to 12-monthly intervals has been recommended.

In the management of **acute severe bronchospasm**, theophylline may be given by *intravenous infusion* where available, though usually aminophylline is preferred (see p.1114). (Anhydrous theophylline 1 mg is equivalent to about 1.18 mg anhydrous aminophylline or 1.28 mg aminophylline hydrate.)

- In patients who have not received theophylline, aminophylline, or other xanthine-containing medications in the previous 24 hours, a suggested loading dose of 4 to 5 mg/kg may be given by intravenous infusion over 20 to 30 minutes followed by a suggested maintenance dose of 400 to 600 micrograms/kg per hour. Lower doses should be used in the elderly and those with cor pulmonale, heart failure, or liver disease; smokers may require a higher maintenance dose. Dosage should be calculated in terms of lean or ideal body-weight.
- Intravenous theophylline therapy is best avoided in patients already taking theophylline, aminophylline, or other xanthine-containing medication but, if considered necessary, serum-theophylline concentrations should be measured to determine a loading dose. Loading doses are based on the expectation that each 500 micrograms of theophylline/kg of lean body-weight will result in an increase of serum-theophylline concentration of 1 microgram/mL.

In the treatment of **acute bronchospasm** that has not required intravenous therapy, theophylline has been given *orally* in conventional dosage forms; modified-release preparations are not suitable.

- In adults not currently taking theophylline or xanthine-containing products a suggested loading dose is 5 mg/kg, to produce an average peak serum concentration of 10 micrograms/mL. Doses should again be reduced in the elderly and those with cor pulmonale, heart failure, or liver disease; smokers may require a higher maintenance dose.

In the long-term management of **chronic bronchospasm**, theophylline may be given orally in doses ranging from 300 to 1000 mg daily in divided doses as conventional tablets, capsules, liquid preparations, or modified-release preparations. For conventional dosage forms the divided doses are generally given every 6 to 8 hours. However, modified-release preparations are more commonly used as they reduce adverse effects and the need for frequent dosing, especially in patients with a rapid theophylline clearance.

- A usual dose of modified-release theophylline is 175 to 500 mg every 12 hours, though the bioavailability of different modified-release theophylline preparations may not be comparable and retitration of dosage is required if the patient is changed from one modified-release preparation to another. Larger doses may be given in either the evening or the morning to achieve optimum therapeutic effect when symptoms are most severe. Modified-release preparations which are given once daily are also available; usual doses are 400 or 600 mg daily.
- Initially, low doses of theophylline should be given and they should be gradually adjusted according to clinical response and serum-theophylline measurements. In the USA a preferred approach to initial dosage titration in adults may be to begin with 300 mg daily, in divided doses, for 3 days; if well tolerated, the total daily dose is increased to 400 mg for 3 days, and then, if tolerated and required, to 600 mg. For doses of theophylline used in children, see Administration in Children, below.

Intramuscular injection and dosage by suppository are not recommended due to severe local irritation and slow unreliable absorption.

Theophylline is an ingredient of some preparations promoted for coughs.

There are topical cosmetic preparations containing theophylline derivatives, particularly aminophylline, that have been promoted for the local reduction of body fat (p.1115).

Theophylline monoethanolamine (theophylline olamine), theophylline calcium salicylate, theophylline and sodium acetate (theophylline sodium acetate), theophylline sodium glycinate (theophylline sodium aminoacetate), theophylline calcium glycinate, and theophylline glycinate have all been used similarly to theophylline.

Administration. Various methods have been proposed for estimating theophylline pharmacokinetic parameters to enable optimisation of initial dosage but none should be substituted for the subsequent determination of serum-theophylline concentrations and clearance at steady state.[1-3]

It was noted in 1997 that dosage requirements for theophylline had declined relative to those of historical controls, apparently due to a downward shift in theophylline clearance in the US population (perhaps due to environmental changes, such as a decrease in exposure to tobacco smoke).[4] It was suggested that earlier dosage guidelines for theophylline needed to be revised in the light of these data, so that the initial oral dose did not exceed 300 mg daily—for an approach to initial dosage titration consonant with this view, see Uses and Administration, above.

Administration in children. In the management of **acute severe bronchospasm** in children, theophylline may be given by *intravenous infusion* where available, although aminophylline is preferred (see p.1115). In children who have not had theophylline, aminophylline or other xanthine-containing medicine in the previous 24 hours, a suggested loading dose of 4 to 5 mg/kg may be given by intravenous infusion over 20 to 30 minutes. Initial maintenance doses are designed to achieve a serum-theophylline concentration of 10 micrograms/mL. The following doses, based on lean or ideal body-weight, have been suggested:

- 1 to 9 years of age, 0.8 to 1 mg/kg per hour
- 9 to 12 years of age, 0.7 to 0.77 mg/kg per hour

Serum-theophylline concentrations should be used to guide further dose adjustments. See Administration in Infants, below for doses used in children under 1 year of age. Children 12 years of age and over can receive similar doses to adults, see Uses and Administration, above.

If intravenous theophylline therapy is considered necessary in children who are already being given theophylline, aminophylline or other xanthine-containing medicine, serum-theophylline concentrations should be measured to determine a loading dose. Loading doses are based on the expectation that each 500 micrograms of theophylline/kg of lean body-weight will result in a 1-microgram/mL increase in serum-theophylline concentration.

In the treatment of **acute bronchospasm** that has not required intravenous therapy, theophylline has been given *orally* using immediate-release preparations to children aged 1 year old and above, using doses similar to those used in adults, see Uses and Administration, above. For doses used in children under 1 year of age, see Administration in Infants, below.

Oral modified-release preparations of theophylline are given to children from 6 months of age in the long-term management of **chronic bronchospasm**. Dose and dosage frequency depend on the preparation being used, and licensed product information should be consulted; different formulations are not considered interchangeable.

ADMINISTRATION IN INFANTS. Theophylline clearance is reduced in premature neonates and infants under 1 year of age due to an immature hepatic microsomal enzyme system (see under Metabolism and Excretion in Pharmacokinetics, above). Postconceptional age may have a slight influence on theophylline clearance but postnatal age is thought to be more significant.[1]

Theophylline dosage guidelines for infants under 1 year of age were issued by the FDA[2] in 1985, but a number of clinicians considered that higher doses might be necessary.[1,3,4] Subsequent guidelines for *oral* theophylline,[5] issued in 1995, suggested a modified regimen: premature infants should be given initial doses of 1 mg/kg every 12 hours if less than 24 days postnatal age, or 1.5 mg/kg every 12 hours if more than 24 days; in full-term infants up to 1 year of age initial daily dosage (to be given in 3 or 4 divided doses) could be calculated on the basis of the equation:

$$\text{Daily dose (mg/kg)} = (0.2 \times \text{age in weeks}) + 5.0$$

Subsequent dosage should be adjusted based on steady-state serum-theophylline concentrations, which might take as long as 5 days to be achieved in premature neonates if a loading dose is not used.[5] The recommended serum concentrations were 5 to 10 micrograms/mL in neonates and 10 to 15 micrograms/mL in older infants. If a loading dose is considered necessary, 5 mg/kg (or 1 mg/kg for each 2 micrograms/mL increase in serum-theophylline concentration in those already being given theophylline) has been suggested.

Other equations and models of population pharmacokinetics have been proposed for the calculation of appropriate theophylline doses in neonates.[6-8]

Theophylline may be given by *intravenous infusion*, where available, in the management of **acute severe bronchospasm** in infants, although aminophylline is preferred (see p.1115). In infants who have not had theophylline, aminophylline or other xanthine-containing medicine in the previous 24 hours, a suggested loading dose of 4 to 5 mg/kg may be given by intravenous infusion over 20 to 30 minutes. In neonates the following initial maintenance doses have been suggested by the *American Hospital Formulary Service* to achieve a serum-theophylline concentration of 7.5 micrograms/mL :

- neonate, postnatal age 24 days or less, 1 mg/kg every 12 hours
- neonate, postnatal age over 24 days, 1.5 mg/kg every 12 hours

To achieve a serum-theophylline concentration of 10 micrograms/mL the following initial maintenance doses have been suggested by the *Canadian Pharmacists Association*:

- neonate, 170 micrograms/kg per hour
- 6 weeks to 6 months of age, 430 micrograms/kg per hour
- 6 months to 1 year of age, 500 to 600 micrograms/kg per hour

Serum-theophylline concentrations should be used to guide further dose adjustments.

Theophylline may be given prophylactically to reduce some of the adverse renal consequences of perinatal asphyxia (see below).

Theophylline has been used in **neonatal apnoea**, although caffeine is preferred. See Neonatal Apnoea, under Caffeine p.1118.

Administration in hepatic impairment. Theophylline clearance is reduced by 50% or more in patients with hepatic insufficiency such as cirrhosis, acute hepatitis, or cholestasis. Careful attention to dose reduction and frequent monitoring of serum-theophylline concentrations are required.

Asthma. Theophylline and its derivatives may be used in the treatment of chronic asthma (p.1108) as an adjunct to beta$_2$ agonists and corticosteroid therapy when an additional bronchodilator is indicated. Modified-release preparations can be useful in the control of nocturnal asthma.

Evidence suggests[1,2] that adding low-dose oral theophylline to inhaled corticosteroids is as effective as increasing the dose of corticosteroid in patients with moderate asthma and persistent symptoms. A systematic review[3] of studies that compared theophylline with long-acting beta$_2$ agonists found that they were both effective for control of nocturnal asthma, but that long-acting beta$_2$ agonists may be more effective in reducing asthma symptoms, including night waking and the need for rescue medication, and are associated with fewer adverse effects.

The use of xanthines in acute asthma attacks is more controversial. UK guidelines permit the use of intravenous aminophylline in patients with severe or life-threatening acute asthma unresponsive to maximal doses of bronchodilators and oral corticosteroids, (a point supported in children[4] but not in adults[5] by systematic review) whereas US guidelines do not consider xanthines have any benefit over the optimal use of beta agonists and consequently do not recommend their use (see p.1108).

Cardiac arrhythmias. Theophylline has been tried in various bradyarrhythmias, usually when other treatment has failed or is contra-indicated.[1-6] It appears to be of little value in bradyasystolic cardiac arrest.[7,8]

Cheyne-Stokes respiration. Oral theophylline considerably reduced Cheyne-Stokes respiration (periodic breathing) and episodes of central apnoea in 2 studies in patients with stable heart failure and left ventricular systolic dysfunction.[1,2] This was associated with an improvement in arterial-oxygen saturation during sleep. One study[1] observed no significant change in cardiac function, although pulmonary function did improve. Theophylline was also effective in a patient with Cheyne-Stokes respiration possibly related to diabetic autonomic neuropathy[3] (the use of the term Cheyne-Stokes respiration to describe this patient's respiratory disorder has been questioned[4,5]).

Chronic obstructive pulmonary disease. In the treatment of chronic obstructive pulmonary disease (p.1112), the bronchodilators of first choice are usually either an antimuscarinic such as ipratropium bromide, or a beta$_2$ agonist such as salbutamol, given by inhalation. However the addition of an oral xanthine such as theophylline may be of value in some patients to maximise respiratory function and for its positive cardiac inotropic effects.

A systematic review[1] of studies comparing oral theophylline with placebo in patients with moderate to severe chronic obstructive pulmonary disease (COPD), found that theophylline treatment improved lung function, ventilatory capacity, and arterial blood gas tensions. A decrease in thoracic gas entrapment and hyperinflation, and an increase in respiratory muscle function and diaphragmatic strength could be responsible for the improvement in symptoms. Improvements in arterial blood gas tensions may result from an increased tidal volume caused by either a direct positive inotropic effect on the respiratory muscles, or a central stimulatory action, or both. The authors concluded that theophylline produced an improvement in lung function similar to that reported for long acting beta$_2$ agonists in COPD patients, and that with close monitoring beneficial effects may be obtained from theophylline therapy in those patients who remain symptomatic from COPD despite first-line bronchodilator therapy. Theophylline has been reported to exert an inhibitory effect on airway inflammation in COPD, particularly at plasma concentrations below 10 micrograms/mL.[2] It has also been suggested that low-dose theophylline may restore corticosteroid responsiveness in COPD patients, but further research is required to assess its role.

Contrast nephropathy. For mention of theophylline as a potential protectant against kidney damage induced by iodinated contrast media, see Effects on the Kidneys, under Amidotrizoic Acid, p.1476.

ECT. For mention of the use of theophylline as an adjunct to electroconvulsive therapy, see under Precautions, above.

Erythrocytosis. When pharmacological treatment is required for secondary erythrocytosis (p.1198), current UK guidelines[1,2] recommend an ACE inhibitor or an angiotensin II receptor antagonist as the usual drugs of first choice. Although theophylline appears to be less effective than an ACE inhibitor in post-transplantation erythrocytosis[3] an oral daily dose of 8 mg/kg has produced beneficial effects.[4,5] Theophylline may be of use given either alone or with an ACE inhibitor in those who fail to respond to first-line therapy. Theophylline treatment may also reduce erythrocytosis associated with chronic obstructive pulmonary disease.[6]

Methotrexate neurotoxicity. For reference to the use of aminophylline or theophylline to relieve the acute neurotoxicity of methotrexate, see Other Drugs, under Treatment of Adverse Effects, p.747.

Perinatal asphyxia. Perinatal asphyxia frequently results in damage to the kidneys;[1] vasomotor nephropathy or acute renal failure may develop as a result of decreased perfusion to the kidneys.[2] Theophylline has been studied for the prevention of renal dysfunction associated with perinatal asphyxia in both term and preterm neonates.[1-3] Beneficial effects have been observed after early use of intravenous theophylline, including significant decreases in serum creatinine[1-3] and urinary β2-microglobulin (an indicator of tubular performance),[1,3] and a significant increase in creatinine clearance.[1-3] A single dose of 8 mg/kg theophylline, by slow intravenous injection in the first hour of life, was given to neonates at term.[1,3] Lower doses were used for preterm neonates; 1 mg/kg daily for 3 consecutive days.[2]

Tiotropium Bromide *(BAN, rINN)*

Ba-679; Ba-679BR; Bromuro de tiotropio; Tiotropii bromidum; Tiotropium, bromure de; Tiotropyum Bromür: 6β,7β-Epoxy-3β-hydroxy-8-methyl-1α*H*,5α*H*-tropanium bromide di-2-thienylglycolate.

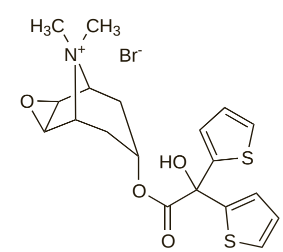
Тиотропия Бромид

$C_{19}H_{22}BrNO_4S_2$ = 472.4.

CAS — 186691-13-4 (tiotropium); 139404-48-1 (anhydrous tiotropium bromide or tiotropium bromide hydrate); 136310-93-5 (anhydrous tiotropium bromide); 411207-31-3 (tiotropium bromide monohydrate).

ATC — R03BB04.

ATC Vet — QR03BB04.



Adverse Effects and Precautions

As for Ipratropium Bromide (p.1124).

Pharyngitis, sinusitis, rhinitis, and epistaxis have also been reported after inhalation.

Patients with moderate to severe renal impairment (creatinine clearance 50 mL/minute or less) should be closely monitored as tiotropium bromide is mainly excreted by the kidneys.

Effects on the cerebrovascular system. In March 2008 the FDA reported[1] that the manufacturer of tiotropium bromide (*Boehringer Ingelheim*) had informed them that they had identified a possible increased risk of stroke in patients taking tiotropium bromide. From pooled analysis of 29 clinical studies in patients with chronic obstructive pulmonary disease preliminary estimates of the risk of stroke were 8 per 1000 patients treated for one year with tiotropium compared with 6 per 1000 patients given placebo for one year. The FDA had not yet confirmed the analyses and urged caution in interpreting these preliminary results.

1. FDA. Early communication about ongoing safety review of tiotropium (marketed as Spiriva HandiHaler) (issued 18th March 2008). Available at: http://www.fda.gov/cder/drug/early_comm/tiotropium.htm (accessed 22/05/08)

Effects on the skin. Subacute cutaneous lupus erythematosus has been reported in a patient inhaling tiotropium.[1] Skin lesions developed one week after introduction of the drug, resolved when the drug was stopped, and recurred on rechallenge.

Inhaled tiotropium has also been associated with a photosensitive lichenoid eruption in another patient,[2] 22 months after starting treatment. The lesions resolved when the drug was stopped; patch testing however, gave a negative result. Rechallenge was not attempted.

Interactions

For interactions associated with antimuscarinics in general, see Atropine, p.1220. However, these interactions are not usually seen with antimuscarinics, such as tiotropium, given by inhalation.

Pharmacokinetics

After inhalation, some tiotropium bromide is absorbed from the lung, with the majority deposited in the gastrointestinal tract. In healthy subjects a systemic bioavailability of about 20% is reported after dry powder inhalation, and about 33% after inhalation of the solution. Tiotropium is about 72% bound to plasma proteins. It is excreted largely unchanged in the urine, although it may undergo some metabolism by non-enzymatic cleavage and by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4. The terminal elimination half-life is between 5 and 6 days.

Uses and Administration

Tiotropium bromide is a quaternary ammonium antimuscarinic that is structurally related to ipratropium but has a prolonged bronchodilator action. It is used similarly to ipratropium (p.1124) in the maintenance treatment of reversible airways obstruction, as in chronic obstructive pulmonary disease (below); tiotropium is not suitable for the initial treatment of acute bronchospasm. Tiotropium bromide can be given as inhalation powder in capsules containing 22.5 micrograms of tiotropium bromide monohydrate, equivalent to 18 micrograms of tiotropium, and supplying 10 micrograms of tiotropium from the mouthpiece of the inhaler device. The contents of one capsule are inhaled daily, at the same time each day.

Tiotropium bromide can also be given as inhalation solution via a metered-dose inhaler. Each metered dose contains 3.124 micrograms of tiotropium bromide monohydrate equivalent to 2.5 micrograms of tiotropium. Two doses of 2.5 micrograms are inhaled daily, at the same time each day.

Chronic obstructive pulmonary disease. In chronic obstructive pulmonary disease (COPD; p.1112) tiotropium bromide has been shown to be effective at improving dyspnoea,[1-3] health-related quality of life,[1,3] symptom-limited exercise tolerance,[2] lung function measurements,[3] and reducing exacerbations[1,3,4] compared with placebo.

Tiotropium has also been found to be more effective than ipratropium at improving dyspnoea, health-related quality of life,[5] and lung function,[5,6] and reducing exacerbations;[5] consideration of tiotropium as first-line maintenance treatment in COPD has been suggested.

Similarly, tiotropium has produced better bronchodilatation, reduced dyspnoea, and improved health-related quality of life scores compared with salmeterol.[7]

Combining tiotropium therapy with an inhaled corticosteroid and a long-acting $beta_2$ agonist did not statistically influence rates of COPD exacerbations but did improve lung function, quality of life, and hospitalisation rates in patients with moderate to severe COPD.[8]

A systematic review[9] and a meta-analysis[10] confirmed that tiotropium reduces exacerbations and related hospitalisations, improves quality of life and symptoms in stable COPD. Tiotropium may also have slowed the decline in forced expiratory volume (FEV) seen in COPD; however, the authors concluded that further studies are required to evaluate the effect of tiotropium on FEV and to clarify its role in relation to long-acting $beta_2$ agonists.

The role of tiotropium in the management of COPD has been extensively reviewed.[11-14]

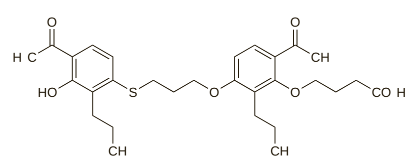
Tipelukast *(USAN, rINN)*

KCA-757; MN-001; Tipélukast; Tipelukastum. 4-(6-Acetyl-3-{3-[(4-acetyl-3-hydroxy-2-propylphenyl)sulfanyl]propoxy}-2-propylphenoxy)butanoic acid.

Типелукаст

$C_{29}H_{38}O_7S$ = 530.7.
CAS — 125961-82-2.



Profile

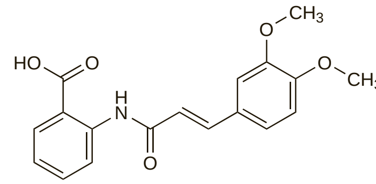
Tipelukast is a leukotriene receptor antagonist (p.1108), a phosphodiesterase inhibitor, and 5-lipoxygenase inhibitor that is under investigation for the treatment of asthma.

Tranilast *(USAN, rINN)*

MK-341; N-5′; Tranilastum. *N*-(3,4-Dimethoxycinnamoyl)anthranilic acid.

Траниласт

$C_{18}H_{17}NO_5$ = 327.3.
CAS — 53902-12-8.



Adverse Effects and Precautions

Adverse effects reported with tranilast have included gastrointestinal disturbances, headache, drowsiness or insomnia, dizziness, malaise, and skin rashes and generalised pruritus. Rarely, liver function disturbance or jaundice, renal dysfunction, cystitis-like symptoms, anaemia, leucopenia, thrombocytopenia, palpitations, oedema, facial flushing, and stomatitis may occur. Tranilast should be used with caution in patients with impaired hepatic or renal function. Haematological monitoring is recommended.

Irritation and blepharitis have been reported after topical application to the eye.

Licensed product information advises against the use of tranilast in pregnancy because of teratogenicity in *animal* studies.

Tranilast should not be used for the treatment of acute asthma attacks. The general cautions described under sodium cromoglicate (p.1136) also apply.

Uses and Administration

Tranilast has a stabilising action on mast cells resembling that of sodium cromoglicate (p.1137). It is also stated to inhibit collagen synthesis in fibroblasts. It is used in the prophylactic management of asthma (p.1108) and in allergic rhinitis (p.565), conjunctivitis (p.564), and eczema (p.1579). It is also used in the management of keloids and hypertrophic scarring. The usual oral adult dose is 100 mg three times daily. For details of doses in children, see below. Eye drops containing tranilast 0.5% are used four times daily for allergic conjunctivitis.

Tranilast has been investigated for the prevention of restenosis after coronary artery revascularisation procedures but was found to be ineffective.

Administration in children. Tranilast is given to children for the prophylactic management of asthma, in allergic rhinitis and eczema, and in the management of keloids and hypertrophic scars. An oral daily dose of 5 mg/kg, given in 3 divided doses, may be used.

Sarcoidosis. For a mention of possible benefit from tranilast in cutaneous sarcoidosis, see p.1512.

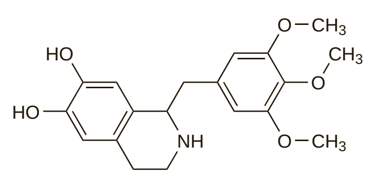
Третохинола Гидрохлорид

$C_{19}H_{23}NO_5,HCl,H_2O$ = 399.9.
CAS — 30418-38-3 (tretoquinol); 18559-59-6 (anhydrous tretoquinol hydrochloride).
ATC — R03AC09; R03CC09.
ATC Vet — QR03AC09; QR03CC09.



(tretoquinol)

Pharmacopoeias. In *Jpn.*

Profile

Tretoquinol is a direct-acting sympathomimetic reported to have a selective action on $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131). It is given as the hydrochloride for its bronchodilating properties in the management of reversible airways obstruction, as in asthma (p.1108) or in some patients with chronic obstructive pulmonary disease (p.1112).

Preparations

Proprietary Preparations (details are given in Part 3)
Indon.: Inolin; ***Jpn:*** Inolin†.

Tulobuterol Hydrochloride *(BANM, rINNM)* ⊗

C-78; Hidrocloruro de tulobuterol; HN-078 (tulobuterol); Tulobutérol, Chlorhydrate de; Tulobuterolhydroklorid; Tulobuteroli Hydrochloridum; Tulobuterolihydrokloridi. 2-*tert*-Butylamino-1-*o*-chlorophenylethanol hydrochloride.

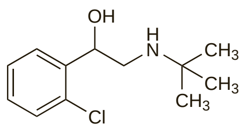
Тулобутерола Гидрохлорид

$C_{12}H_{18}ClNO,HCl$ = 264.2.

CAS — 41570-61-0 (tulobuterol); 56776-01-3 (tulobuterol hydrochloride).

ATC — R03AC11; R03CC11.

ATC Vet — QR03AC11; QR03CC11.



(tulobuterol)

Pharmacopoeias. In *Jpn.*

Profile

Tulobuterol is a direct-acting sympathomimetic with mainly beta-adrenergic activity and a selective action on $beta_2$ receptors (a $beta_2$ agonist). It has properties similar to those of salbutamol (p.1131).

Tulobuterol is used as a bronchodilator in the management of reversible airways obstruction, as in asthma (p.1108) and in some patients with chronic obstructive pulmonary disease (p.1112). It is given orally as the hydrochloride. The initial oral dose in adults is 1 or 2 mg of tulobuterol hydrochloride twice daily, which can be increased to 3 mg twice daily if necessary. An increased need for, or decreased duration of effect of, tulobuterol indicates deterioration of asthma control and the need for review of therapy. Tulobuterol has also been given as the base by inhalation from a metered-dose inhaler. A transdermal formulation of tulobuterol base is also available; a dose of 2 mg daily is used together with anti-inflammatory therapy.

For doses of tulobuterol used in children aged 14 years and under, see Administration in Children, below.

Administration in children. Tulobuterol hydrochloride has been used to treat bronchospasm in children in the following *oral* doses:

- 1 to 6 years of age, 0.25 to 0.5 mg twice daily
- 6 to 10 years of age, 0.5 to 1 mg twice daily
- 10 to 14 years of age, 1 to 1.5 mg twice daily

In some countries, children 12 years of age and over may be given the adult dose of tulobuterol, see above.

Transdermal delivery of tulobuterol is also used in children, in the following doses:

- 6 months to 3 years of age, 0.5 mg once daily
- 3 to 9 years of age, 1 mg once daily
- 9 years of age and older, as for adults (see above)

Zafirlukast *(BAN, USAN, rINN)*

ICI-204219; Tsafirlukasti; Zafirlukastum. Cyclopentyl 3-{2-methoxy-4-[(o-tolylsulfonyl)carbamoyl]benzyl}-1-methylindole-5-carbamate.

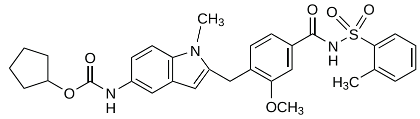
Зафирлукаст

$C_{31}H_{33}N_3O_6S$ = 575.7.

CAS — 107753-78-6.

ATC — R03DC01.

ATC Vet — QR03DC01.



Adverse Effects and Precautions

Headache, an increased incidence of respiratory-tract infection (in the elderly), and gastrointestinal disturbances have been reported with zafirlukast and other leukotriene antagonists. Other adverse effects have included generalised and abdominal pain, arthralgia, myalgia, fever, malaise, insomnia, and dizziness. Elevations in liver enzyme values have occurred, and rarely, symptomatic hepatitis or hyperbilirubinaemia (see also below); fatalities have occurred. Hypersensitivity reactions, including rashes, pruritus, urticaria, and angioedema, have been reported. There have also been rare reports of agranulocytosis, bleeding, bruising and oedema. There have been a few reports of systemic eosinophilia consistent with Churg-Strauss syndrome in patients receiving zafirlukast (see below); treatment should be withdrawn in these patients.

Zafirlukast and other leukotriene antagonists should not be used for the treatment of acute asthma attacks. Zafirlukast is contra-indicated in patients with hepatic impairment or cirrhosis.

Incidence of adverse effects. An observational study[1] of 7976 patients prescribed zafirlukast found it to be generally well tolerated. Similarly to UK licensed product information, the most frequently reported adverse effects (1 to 2% of patients) were headache, rash, abdominal pain, malaise, and gastrointestinal disturbances such as nausea, diarrhoea, and dyspepsia. Dizziness and palpitations were more common in the first month of treatment. An increased incidence of depression was also noted.

1. Twaites BR, *et al.* Safety of zafirlukast: results of a postmarketing surveillance study on 7976 patients in England. *Drug Safety* 2007; **30:** 419–29.

Churg-Strauss syndrome. Pulmonary infiltrates and eosinophilia, resembling the Churg-Strauss syndrome, with dilated cardiomyopathy, were reported after withdrawal of corticosteroid therapy in 8 patients taking zafirlukast.[1] Symptoms responded to withdrawal of zafirlukast and treatment with corticosteroids, with or without cyclophosphamide. It has been suggested that the patients' original asthmatic symptoms had been part of an unrecognised vasculitic syndrome that was unmasked by stopping corticosteroids.[2,3] However, others have reported Churg-Strauss syndrome associated with zafirlukast in those not receiving corticosteroids,[4,5] although these cases were not inconsistent with the view that treatment with leukotriene antagonists was coincidental.[6] It has also been noted that leukotriene receptor antagonists tend to be prescribed for patients with more severe asthma, which may be a precursor to the development of Churg-Strauss syndrome.[3] In addition, eosinophilic syndromes have been reported for other anti-asthma drugs including inhaled fluticasone and sodium cromoglicate, evidence supporting a non-drug-related aetiology.[6] However, the number of reports with zafirlukast and the other leukotriene antagonists, montelukast (see p.1126) and pranlukast,[7] means that a particular class-effect cannot be ruled out.[3,8] It has been suggested that patients should be monitored carefully (e.g. by measuring erythrocyte sedimentation rate, C reactive protein, and eosinophil counts) if the introduction of an anti-asthma drug such as a leukotriene antagonist permits the reduction of oral corticosteroid dosage.[9] In addition, in patients with asthma and features of multisystem disease, the possibility of underlying Churg-Strauss syndrome (p.1501) may be worth considering.

Effects on the liver. Severe hepatotoxicity has been associated with zafirlukast.[1-4] The Canadian manufacturer reported[4] in April 2004 that from worldwide postmarketing surveillance of zafirlukast there had been 46 reports of hepatitis, 14 of hepatic failure, 3 of which progressed to fulminant hepatitis, and 59 reports of other clinically significant hepatic dysfunction; 7 fatalities had occurred. In most, but not all, cases symptoms had abated and liver enzymes had returned to normal after stopping zafirlukast. It was important that prescribers, patients and/or their carers were alert to the signs and symptoms of hepatotoxicity. Licensed product information for zafirlukast advises stopping treatment if hepatotoxicity is suspected, and performing liver function tests;

Lupus. Zafirlukast was thought to be responsible for the development of lupus in a 9-year-old girl.[1]

1. Finkel TH, *et al.* Drug-induced lupus in a child after treatment with zafirlukast (Accolate). *J Allergy Clin Immunol* 1999; **103:** 533–4.

Renal impairment. The UK licensed product information states that zafirlukast should be used with caution in patients with moderate or severe renal impairment because of limited experience in this group. However, the US product information mentions no such caution, and states that the pharmacokinetics of zafirlukast in patients with renal impairment do not appear to differ from those in patients with normal renal function. Only about 10% of a dose is reported to be excreted in the urine.

Interactions

Zafirlukast is metabolised by hepatic cytochrome P450, specifically the CYP2C9 isoenzyme, and has been shown to inhibit the activity of isoenzymes CYP2C9 and CYP3A4. Therefore, use with other drugs that are metabolised by these hepatic enzymes may result in increases in plasma concentrations, and possibly, adverse effects. Patients receiving warfarin may develop prolongation of the prothrombin time and anticoagulant dosage should be adjusted accordingly. Erythromycin, terfenadine, and theophylline may reduce plasma concentrations of zafirlukast; zafirlukast has rarely been reported to increase plasma-theophylline concentrations. Increased plasma concentrations of zafirlukast have been seen when given with high doses of aspirin.

Pharmacokinetics

Peak plasma concentrations of zafirlukast occur about 3 hours after oral doses. The absolute bioavailability is uncertain, but taking it with food reduces both the rate and extent of absorption, decreasing bioavailability by about 40%. Zafirlukast is about 99% bound to plasma proteins. It is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP2C9, and excreted principally in faeces, as unchanged drug and metabolites. About 10% of a dose is excreted in urine as metabolites. The terminal elimination half-life of zafirlukast is about 10 hours. Studies in *animals* suggest that small amounts cross the placenta; it is also distributed into breast milk.

◊ Reviews.

1. Dekhuijzen PNR, Koopmans PP. Pharmacokinetic profile of zafirlukast. *Clin Pharmacokinet* 2002; **41:** 105–14.

Uses and Administration

Zafirlukast is a selective and competitive antagonist of the leukotriene C_4, D_4, and E_4 receptors (p.1108), stimulation of which by circulating leukotrienes is thought to play a role in the pathogenesis of asthma. The drug suppresses both early and late bronchoconstrictor responses to inhaled antigens or irritants, but is not suitable for the management of acute attacks of asthma.

Zafirlukast is used in the management of chronic asthma (see below). It is given orally in doses of 20 mg twice daily, taken at least 1 hour before or 2 hours after meals. For details of doses in children, see below.

Administration in children. In the management of chronic asthma, US licensed product information recommends a zafirlukast dose of 10 mg twice daily orally in children aged from 5 to 11 years. Children 12 years of age and over may be given the adult dose, see above. In the UK, zafirlukast is unlicensed in children under 12 years of age.

Asthma. Zafirlukast produces modest improvement in mild-to-moderate asthma,[1,2] which was of a similar order to that seen with inhaled sodium cromoglicate in one study,[3] but less than that of inhaled salmeterol in another.[4] It has also been found to be less effective than inhaled fluticasone in persistent asthma.[5-7] Guidelines for the management of asthma (p.1108) permit the use of zafirlukast as an alternative to inhaled corticosteroids in patients with mild persistent asthma, who cannot be managed with inhaled $beta_2$ agonists on an as-needed basis alone. It can also be considered for use in moderate or severe persistent asthma, usually added to standard therapy of inhaled corticosteroids and long-acting inhaled $beta_2$ agonists. Combination of anti-leukotriene drugs with inhaled corticosteroids alone seems, however, to be less effective than a combination of the latter with long-acting inhaled $beta_2$ agonists. In a study in patients presenting to the emergency room with acute severe asthma, adding zafirlukast to standard therapy in hospital and for 28 days after discharge was associated with a reduced rate of relapse, and a reduction in the need for extended care.[8]

Rhinitis. Although it was reported to improve symptoms of seasonal allergic rhinitis (p.565) in one study,[1] zafirlukast 20 mg twice daily was not effective when compared with placebo and intranasal beclometasone in another.[2] Some benefits have been reported in perennial allergic rhinitis, in particular an improvement in nasal obstruction.[3,4] A review of the role of leukotrienes in allergic rhinitis concluded that leukotriene receptor antagonists have modest efficacy given alone but can be usefully added to other treatments.[5]

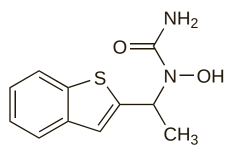
Zileuton *(BAN, USAN, rINN)*

A-64077; Abbott-64077; Zileutón; Zileutonum. (±)-1-(1-Benzo[*b*]thien-2-ylethyl)-*N*-hydroxyurea.

Зилейтон

$C_{11}H_{12}N_2O_2S$ = 236.3.

CAS — 111406-87-2.



Pharmacopoeias. In *US.*

USP 31 (Zileuton). A white to off-white powder. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

The most commonly reported adverse effects associated with zileuton treatment are headache, pain including pharyngolaryngeal pain, gastrointestinal disturbances, myalgia, and sinusitis. Hypersensitivity, urticaria, rash, and leucopenia have been reported in a few patients. Zileuton has also been associated with raised liver enzyme values and severe hepatic injury.

Zileuton is not suitable for the treatment of acute asthma attacks.

Effects on the liver. Cases of severe hepatotoxicity including fatalities, jaundice, hyperbilirubinaemia, and raised liver enzymes have been reported in patients taking zileuton. US licensed product information therefore contraindicates the use of zileuton in patients with active liver disease or liver transaminase elevations greater than or equal to three times the upper limit of normal. Caution is required in patients with a history of liver disease or who consume substantial quantities of alcohol. Alanine aminotransferase (ALT) is considered the most sensitive indicator of liver injury due to zileuton. Most rises in ALT concentrations occurred in the first 3 months of zileuton therapy,[1] and monitoring is therefore recommended before starting zileuton therapy, once a month for the first 3 months of therapy, every 2 to 3 months for the remainder of the first year of therapy, and periodically thereafter.

1. Watkins PB, *et al.* Clinical pattern of zileuton-associated liver injury: results of a 12-month study in patients with chronic asthma. *Drug Safety* 2007; **30:** 805–15.

Interactions

Zileuton has been reported to impair the metabolism of some drugs metabolised via hepatic cytochrome P450 enzymes, including propranolol, terfenadine, theophylline, and warfarin.

Pharmacokinetics

Zileuton is reported to be well absorbed from the gastrointestinal tract after oral dosage, with peak plasma concentrations of immediate-release preparations occurring within about 2 hours of a dose. It is about 93% bound to plasma proteins. It is extensively metabolised in the liver by the cytochrome P450 isoenzymes CYP1A2, CYP2C9, and CYP3A4, and excreted in the urine, largely as glucuronide metabolites. The elimination half-life is reported to be about 2.5 hours for the immediate-release preparation and about 3 hours for the controlled-release preparation.

7. Dubé LM, *et al.* Zileuton, a leukotriene synthesis inhibitor in the management of chronic asthma: clinical pharmacokinetics and safety. *Clin Rev Allergy Immunol* 1999; **17:** 213–21.

Uses and Administration

Zileuton is an orally active 5-lipoxygenase inhibitor and therefore inhibits leukotriene formation (p.1108). It is used in the management of chronic asthma (see below) but has no bronchodilator properties and is not suitable for the management of acute attacks. Zileuton is given in oral doses of 600 mg 4 times daily as an immediate-release preparation. A controlled-release formulation of zileuton is also available; the usual oral dose is 1.2 g twice daily.

It has also been tried in other disorders including arthritis, allergic rhinitis, and inflammatory bowel disease.

Asthma. Zileuton has been found to be of some benefit in asthma, including that provoked by cold air, exercise, and NSAIDs. US guidelines for the management of asthma (p.1108) permit its use in addition to inhaled corticosteroid therapy in moderate persistent asthma. Combination of anti-leukotriene drugs with inhaled corticosteroids alone seems however to be less effective than a combination of the latter with long-acting inhaled $beta_2$ agonists. Due to a lack of data on efficacy and the need for liver function monitoring, zileuton is also considered a less desirable treatment option for addition to inhaled corticosteroids than the leukotriene receptor antagonists.

An intravenous form of zileuton is under investigation for use in asthma.

Inflammatory bowel disease. Despite initial hopes that inhibition of lipoxygenase might prove of benefit in patients with ulcerative colitis,[1] a study in those with mild or moderately active relapsing disease found that the symptomatic benefits of zileuton were confined to those not already receiving sulfasalazine.[2] A subsequent study showed zileuton was not significantly better than placebo in maintaining remission.[3] For a discussion of inflammatory bowel disease and its management, see p.1697.

This chapter describes drugs used principally in the management of cardiovascular disorders, as well as the choice of treatment for a particular disorder. Blood products, plasma expanders, and haemostatics, which also have a role in cardiovascular disease, are described elsewhere (p.1042).

The Circulatory System

The cardiovascular system consists of the heart and two vascular systems, the pulmonary and systemic circulations. The **heart** (below) pumps blood from the right ventricle through the **pulmonary circulation**, in which gas exchange occurs, and the oxygenated blood then returns to the left side of the heart, where the left ventricle pumps it to the **systemic circulation** which delivers blood to individual organs. Arteries supply blood at high pressure whereas arterioles are smaller vessels with muscular walls which allow direct control of flow through the capillary beds. Capillaries have thin walls, comprising a single layer of endothelial cells, which allow exchange of substances such as nutrients, hormones, and waste products between blood and tissues. Veins return blood from the capillary beds to the heart, and contain about 70% of the circulating blood volume.

Cardiac output is the product of heart rate and stroke volume; typically, in a 70-kg adult, these might be around 70 beats per minute, and 70 mL respectively, giving an output of around 5 litres per minute. Stroke volume in turn is dependent on **preload** (the ventricular volume at the end of diastole, when the ventricle relaxes and fills), **afterload** (the resistance to ventricular ejection, or systemic vascular resistance, determined mainly by the diameter of the arterioles), and **contractility**, or the strength of contraction of the heart muscle, which is influenced by the sympathetic nervous system but also by many other factors, including drugs, acid-base balance, and myocardial oxygen supply. In a healthy individual, cardiac output should adjust to match metabolic demand.

Blood pressure and flow is controlled by complex neurohormonal systems, involving the autonomic nervous system and peptides and regulators released by the kidneys and the circulatory system itself, such as the renin-angiotensin system and the natriuretic peptides. Substances such as nitric oxide and prostacyclin, produced by the endothelium of the vascular system, play an important role in controlling local blood flow.

All these systems can be manipulated by pharmacological therapy with the various drug groups (see below) used in the treatment of cardiovascular disorders (p.1156).

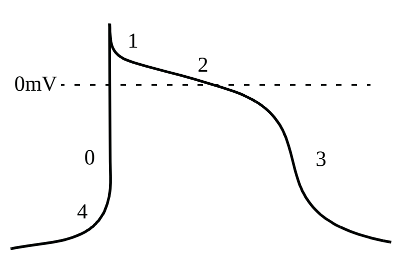
The Heart

The heart acts as a pump, maintaining circulation of blood around the body. It does this by coordinated contraction and relaxation of the cardiac muscle (myocardium). In a normal cardiac cycle the atria contract first (atrial systole), forcing blood into the ventricles, which then contract (ventricular systole), pumping blood out into the blood vessels; atria and ventricles then both relax (diastole), allowing the atria to refill before the cycle begins again. Each cycle corresponds to a heart beat and in a healthy 70-kg person at rest cycles occur regularly at a rate of 70 to 75 beats/minute, although the exact rate varies more widely than this depending on circumstances.

The contraction of myocardial cells is controlled by electrical changes across the cell membrane, which can be represented by the *action potential*. The action potential in cardiac cells has 5 phases, although the exact pattern depends on the type of cell. A typical ventricular action potential is shown in Figure 1 (below).

- phase 0 is the depolarisation phase when there is rapid influx of sodium ions (lasting a few milliseconds) and the cell contracts
- in phase 1, there is a transient rapid efflux of potassium ions and the cell begins to repolarise
- a slow influx of calcium ions then occurs which balances the potassium efflux leading to a plateau stage (phase 2) and maintenance of contraction
- this is followed by an increase in potassium efflux, while calcium influx stops, and repolarisation (phase 3) occurs
- the cell then relaxes and finally returns to the resting membrane potential (phase 4), and ion pumps return the balance of sodium and potassium to the baseline state

Figure 1. The action potential.

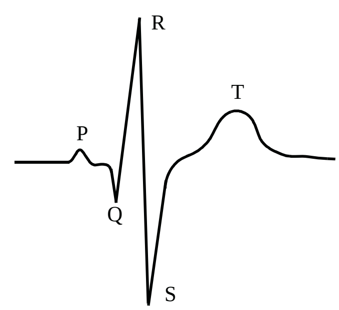


The depolarisation of one cell triggers action potentials in adjacent cells, allowing the electrical impulse to spread rapidly across the myocardium so that in a healthy heart all of the cells contract at the same time in a coordinated fashion.

Certain cells within the heart undergo spontaneous depolarisation during phase 4 and the initial depolarisation depends mainly on calcium ion influx rather than sodium ions. These *pacemaker cells* are able to initiate impulses. Although a number of cells have this property, impulses are normally generated in the *sino-atrial* (SA) or *sinus node*; the resulting heart rhythm is known as *sinus rhythm*, and has been defined as a sinus node rate of 60 to 100 beats/minute. Impulses generated in the SA node spread across the atria, causing them to contract, but normally only pass to the ventricles through the specialised conducting cells of the atrioventricular (AV) node. From the AV node, the impulse passes through the bundle of His and down the Purkinje fibres to the ventricles, which then contract. The delay caused by this selective conduction through the AV node means that the atria contract before the ventricles and ensures the forward movement of the blood.

The movement of electrical impulses can be recorded as an electrocardiogram (ECG). The ECG corresponds to the phases of the action potential in different parts of the heart and depends on the position of the recording leads; a typical ECG trace is shown in Figure 2, below. The P wave corresponds to atrial depolarisation, while the QRS complex corresponds to ventricular depolarisation; the PR interval corresponds to the delay between atrial and ventricular depolarisation. Phases 0 and 1 of the ventricular action potential produce the R and S waves, and phase 2 corresponds to the ST interval. The T wave represents ventricular repolarisation (phase 3).

Figure 2. A normal ECG trace.



Cardiovascular Drug Groups

Although very diverse, cardiovascular drugs can be broadly classified according to their pharmacological action. Basic details of the major groups follow, together with lists of the drugs described in this chapter.

ACE inhibitors

The main uses of ACE (angiotensin-converting enzyme) inhibitors are in the management of heart failure, hypertension, and myocardial infarction. Their actions and uses are discussed in more detail on p.1193.

Described in this chapter are
- Alacepril, p.1206
- Benazepril, p.1223
- Captopril, p.1239
- Cilazapril, p.1244
- Delapril, p.1256
- Enalapril, p.1276
- Enalaprilat, p.1276
- Fosinopril, p.1291
- Imidapril, p.1313
- Lisinopril, p.1325
- Moexipril, p.1343
- Perindopril, p.1368
- Quinapril, p.1382
- Ramipril, p.1385
- Spirapril, p.1399
- Temocapril, p.1409
- Teprotide, p.1410
- Trandolapril, p.1416
- Zofenopril, p.1434

Adrenergic neurone blockers

Adrenergic neurone blockers are used in hypertension although they have largely been superseded by other drugs less likely to cause orthostatic hypotension. They have also been used in open-angle glaucoma.

Adrenergic neurone blockers act by selectively inhibiting transmission in postganglionic adrenergic nerves. They are believed to act mainly by preventing the release of noradrenaline at nerve endings; they cause the depletion of noradrenaline stores in peripheral sympathetic nerve terminals. They do not prevent the secretion of catecholamines by the adrenal medulla.

Described in this chapter are

Debrisoquine, p.1256	Guanadrel, p.1300
Guabenxan, p.1299	Guanethidine, p.1300

Alpha blockers

Alpha blockers are used mainly in the management of hypertension and to relieve urinary obstruction in benign prostatic hyperplasia.

Alpha blockers are also known as alpha-adrenergic antagonists or alpha-adrenergic receptor antagonists. Some have particular affinities for one of the subtypes of the alpha adrenoceptor. Drugs such as indoramin or prazosin are much more potent in blocking $alpha_1$ than $alpha_2$ adrenoceptors and are often termed selective $alpha_1$ blockers. Blockade of $alpha_1$ adrenoceptors inhibits the vasoconstriction induced by endogenous catecholamines. Both arteriolar and venous vasodilatation may occur resulting in a fall in blood pressure because of decreased peripheral resistance. Blockade of $alpha_2$ adrenoceptors with a selective drug such as yohimbine (p.2200) can conversely lead to a rise in blood pressure. With phenoxybenzamine and phentolamine, which broadly have similar affinities for both the $alpha_1$ and $alpha_2$ subtypes of receptor, any increase in blood pressure due to $alpha_2$ blockade is prevented by the inhibition of vasoconstriction caused by $alpha_1$ blockade. Alpha blockers also act at alpha adrenoceptors in nonvascular smooth muscle, for example in the bladder where alpha blockade produces decreased resistance to urinary outflow; alpha blockers used mainly for urinary disorders are discussed under Urological Drugs, p.2178. Most alpha blockers are reversible or 'competitive' inhibitors of alpha adrenoceptors; phenoxybenzamine is an irreversible or 'non-competitive' alpha blocker and is particularly useful in phaeochromocytoma.

Angiotensin II receptor antagonists

Angiotensin II receptor antagonists (angiotensin II receptor blockers) are used in the management of hypertension; they may have a particular role in patients who develop cough with ACE inhibitors. Some are also used in diabetic nephropathy and in the management of heart failure. They act mainly by selective blockade of AT_1 receptors thus reducing the pressor effects of angiotensin II.

Antiarrhythmics

Antiarrhythmics (formerly described as cardiac depressants) are a diverse group of drugs that affect the conduction of electrical impulses within the heart (see p.1152). Many of them, such as beta blockers (p.1225), digoxin (p.1259), lidocaine (p.1862), magnesium (p.1678), and phenytoin (p.495) have important actions in addition to their antiarrhythmic properties and thus, have a wide range of other clinical applications.

The most widely used **classification** of antiarrhythmics is that proposed by Vaughan Williams (later modified by Harrison) and is based largely on their *in-vitro* electrophysiological effects. There are 4 main classes:

◊ **Class I** includes drugs that block the fast inward sodium channels and therefore interfere with depolarisation (phase 0 of the action potential); these drugs have been called membrane-stabilising drugs and have both antiarrhythmic and local anaesthetic properties. They have different properties depending on their affinity for different states of the sodium channel (open, closed, or inactivated) and can be further subdivided depending on additional characteristics.

Class Ia drugs slow the rate of change of the depolarisation phase of the action potential, although less so than class Ic drugs. They also prolong the repolarisation phase (phase 3), possibly by an effect on potassium channels. They prolong the PR, QRS, and QT intervals on the ECG.

Described in this chapter are

Ajmaline, p.1206	Pirmenol, p.1373
Disopyramide, p.1269	Procainamide, p.1377
Hydroquinidine, p.1312	Quinidine, p.1383

◊ *Class Ib* drugs have little effect on the rate of change of the depolarisation phase of the action potential in normal cells, but have a more selective effect in ischaemic or diseased tissue; they are also more effective if external potassium concentrations are high. They shorten the repolarisation phase, shorten the QT interval, and elevate the fibrillation threshold. The local anaesthetic lidocaine has class Ib properties.

Described in this chapter are

Aprindine, p.1216	Tocainide, p.1414
Mexiletine, p.1339	

◊ *Class Ic* drugs markedly slow the rate of change of the depolarisation phase of the action potential, but have little effect on the repolarisation phase. They prolong the PR and QRS intervals.

Described in this chapter are

Ethacizine, p.1283	Pilsicainide, p.1371
Flecainide, p.1288	Propafenone, p.1379

◊ **Class II** drugs are characterised by beta-blocking activity; they reduce both heart rate and myocardial contractility, and also slow conduction of impulses through the myocardial conducting system. They reduce the rate of spontaneous depolarisation in cells with pacemaker activity but have little effect on the action potential in most myocardial cells.

Described in this chapter are

Beta blockers (but sotalol has mainly class III activity), p.1225	Bretylium, p.1236

◊ **Class III** drugs slow the repolarisation phase (phase 3) and prolong the action potential duration and the QT interval. Various mechanisms may be involved, but most class III drugs act by potassium channel blockade.

Described in this chapter are

Amiodarone, p.1210	Dofetilide, p.1272
Azimilide, p.1222	Ibutilide, p.1312
Bretylium, p.1236	Nifekalant, p.1357
Cibenzoline, p.1244	Sotalol, p.1398

◊ **Class IV** drugs are calcium-channel blockers (p.1154) that act by blocking the slow inward calcium current and particularly affect the pacemaker cells where calcium influx is relatively more important. However, differences in tissue specificity mean that not all calcium-channel blockers have antiarrhythmic properties.

Described in this chapter are

Cibenzoline, p.1244	Verapamil, p.1421
Diltiazem, p.1265	

◊ A major limitation of the Vaughan Williams classification is that many antiarrhythmics have multiple actions, and may not fit neatly into a single class. Some are assigned to several classes, while others are included in one class although they also have characteristics of another. Bretylium is included in both class II and class III, whereas propafenone is usually considered a class Ic drug despite possessing beta-blocking properties. Beta blockers are traditionally described as class II, although some also have class I actions, while sotalol, despite sharing the properties of beta blockers, has mainly class III activity and is usually described as a class III drug. Drugs such as adenosine and digoxin do not fit into the Vaughan Williams classification at all.

Another problem with the Vaughan Williams classification is that the electrophysiological effects of antiarrhythmics are not clearly related to their effectiveness in treating a particular arrhythmia in an individual patient. Alternative classification systems have therefore been suggested, for example based on the cardiac tissue that the drug affects. Thus drugs that act on the sino-atrial node include beta blockers, class IV antiarrhythmics, and cardiac glycosides such as digoxin; class I and class III antiarrhythmics act on the ventricles; and drugs acting on atrial arrhythmias include class Ia, Ic, and III antiarrhythmics and beta blockers. Class Ia and III antiarrhythmics act on accessory pathways and drugs acting on the AV node include class Ic and IV antiarrhythmics, beta blockers, and cardiac glycosides. A simplification of this scheme is to classify drugs into those that act on both ventricular and supraventricular arrhythmias such as amiodarone, beta blockers, disopyramide, procainamide, and quinidine, those that act mainly on ventricular arrhythmias such as lidocaine, mexiletine, and phenytoin, and those that act mainly on supraventricular arrhythmias such as verapamil. The Sicilian Gambit is another approach based on the mechanisms by which arrhythmias are generated and the ways that drugs could influence them.

Anticoagulants

Anticoagulants are used in the treatment and prophylaxis of thromboembolic disorders. They may be divided into direct anticoagulants such as the heparins, low-molecular-weight heparins, heparinoids, and direct thrombin inhibitors, and indirect anticoagulants such as the coumarin and indanedione derivatives.

◊ **Direct anticoagulants**

Heparin inhibits clotting of blood *in vitro* and *in vivo* by enhancing the action of antithrombin III. Antithrombin III, which is present in plasma, inhibits the activity of activated clotting factors including thrombin (factor IIa) and activated factor X (factor Xa). With normal therapeutic doses heparin has an inhibitory effect on both thrombin and factor Xa. The low doses that are given subcutaneously for the prophylaxis of thromboembolism have a selective effect on antithrombin III's inhibition of factor Xa. Very high doses are reported to reduce the activity of antithrombin III. Heparin also has some effect on platelet function, inhibits the formation of a stable fibrin clot, and has an antilipidaemic effect.

Low-molecular-weight heparins are salts of fragments of heparin produced by chemical or enzymatic depolymerisation of the heparin molecule. Commercially available low-molecular-weight heparins differ in their method of production, molecular-weight range, and degree of sulfation. Like heparin, these compounds enhance the action of antithrombin III but they are characterised by a higher ratio of anti-factor Xa to anti-factor IIa (antithrombin activity) than heparin. Although the possibility that such selective factor-Xa inhibition would result in antithrombotic activity without anticoagulant, and hence haemorrhagic, effects has not been confirmed by clinical experience, they have more predictable effects and require less monitoring than heparin. Low-molecular-weight heparins also have less effect on platelet aggregation than heparin.

Fondaparinux and idraparinux are synthetic polysaccharides that act as direct inhibitors of factor Xa. Rivaroxaban, an oral factor Xa inhibitor, is under investigation.

Described in this chapter are

Bemiparin, p.1223	Nadroparin, p.1346
Certoparin, p.1242	Parnaparin, p.1366
Dalteparin, p.1255	Reviparin, p.1388
Enoxaparin, p.1277	Rivaroxaban, p.1389
Fondaparinux, p.1291	Tinzaparin, p.1413
Heparin, p.1301	
Idraparinux, p.1312	

◊ The *direct thrombin inhibitors* bind to the active thrombin site and inhibit both free and clot-bound thrombin. Most are recombinant forms or synthetic analogues of hirudin and need to be given parenterally, but oral thrombin inhibitors have been developed. Dabigatran, given orally as the prodrug dabigatran etexilate, is used in the prophylaxis of venous thromboembolism. Ximelagatran, another synthetic small molecule with oral activity, was withdrawn from the market due to toxicity (as was melagatran, the parenteral form).

◊ The term *heparinoid* includes heparin derivatives and has also been used more loosely to include naturally occurring and synthetic highly sulfated polysaccharides of similar structure, such as danaparoid and dermatan sulfate. Some compounds have been described in many ways; some of the terms used include sulfated glucosaminoglycans, glycosaminoglycan polysulfate compounds, or sulfated mucopolysaccharides.

Described in this chapter are

Danaparoid, p.1255	Sodium Apolate, p.1397
Dermatan Sulfate, p.1256	Suleparoid, p.1406
Pentosan Polysulfate Sodium, p.1367	Sulodexide, p.1406

◊ **Indirect anticoagulants**

Indirect anticoagulants act by depressing the hepatic vitamin K-dependent synthesis of coagulation factors II (prothrombin), VII, IX, and X, and of the anticoagulant protein C and its cofactor protein S. Warfarin, a coumarin, is the main drug used; other coumarins (although not all coumarins have anticoagulant activity) and indanediones such as phenindione are also available. Since they act indirectly, they have no effect on existing clots. Also as the coagulation factors involved have half-lives ranging from 6 to 60 hours, several hours are required before an effect is observed. A therapeutic effect is usually apparent by 24 hours, but the peak effect may not be achieved until 2 or 3 days after a dose; the overall effect may last for 5 days.

Described in this chapter are

Acenocoumarol, p.1201	Fluindione, p.1290
Anisindione, p.1216	Phenindione, p.1369
Dicoumarol, p.1258	Phenprocoumon, p.1370
Ethyl Biscoumacetate, p.1284	Tioclomarol, p.1413
	Warfarin, p.1425

Antiplatelet drugs

Platelet aggregation is important in haemostasis (p.1045) and is also involved in thrombus formation, particularly in the arterial circulation. Antiplatelet drugs reduce platelet aggregation and are used to prevent further thromboembolic events in patients who have suffered myocardial infarction, ischaemic stroke or transient ischaemic attacks, or unstable angina, and for primary prevention of a thromboembolic event in patients at risk. Some are also used for the prevention of reocclusion or restenosis following angioplasty and bypass procedures.

Antiplatelet drugs act through a wide range of mechanisms. Aspirin (p.20) is the most widely used and studied; it acts by irreversibly inhibiting platelet cyclo-oxygenase and thus preventing synthesis of thromboxane A_2. Reversible cyclo-oxygenase inhibitors such as indobufen are also available, and thromboxane synthase inhibitors and thromboxane receptor antagonists have also been used.

Drugs that interfere with adenosine metabolism have an antiplatelet effect and those used include some prostaglandins, which act by increasing platelet cyclic adenosine monophosphate levels; the thienopyridines clopidogrel and ticlopidine, which interfere with adenosine diphosphate mediated platelet activation; and the adenosine reuptake inhibitor dipyridamole.

Thrombin inhibitors such as heparin and the hirudins have antiplatelet and anticoagulant effects. Glycoprotein IIb/IIIa-receptor antagonists, such as abciximab, eptifibatide, and tirofiban, interfere with the final step in platelet aggregation and are used in unstable angina and as adjuncts in reperfusion and revascularisation procedures.

Beta blockers

Beta blockers are competitive antagonists at beta-adrenergic receptor sites and are used in the management of cardiovascular disorders such as hypertension, angina pectoris, cardiac arrhythmias, myocardial infarction, and heart failure. They are also given to control symptoms of sympathetic overactivity in alcohol withdrawal, anxiety states, hyperthyroidism, and tremor and in the prophylaxis of migraine and of bleeding associated with portal hypertension. Their actions and uses are discussed in more detail on p.1225.

Beta blockers used mainly as eye drops to reduce raised intra-ocular pressure in glaucoma and ocular hypertension are discussed under Miotics, Mydriatics, and Antiglaucoma Drugs, p.1873.

Calcium-channel blockers

The main use of calcium-channel blockers is in the management of angina pectoris and hypertension; some are also used in cardiac arrhythmias.

Calcium-channel blockers, (calcium antagonists, calcium-entry blockers, or slow-channel blockers) inhibit the cellular influx of calcium that is responsible for maintenance of the plateau phase of the action potential. Thus calcium-channel blockers primarily affect tissues in which depolarisation is dependent upon calcium rather than sodium influx, such as vascular smooth muscle, myocardial cells, and cells within the sino-atrial (SA) and atrioventricular (AV) nodes. The main actions of the calcium-channel blockers include dilatation of coronary and peripheral arteries and arterioles with little or no effect on venous tone, a negative inotropic action, reduction of heart rate, and slowing of AV conduction. However, the effects of individual drugs, and therefore their uses, are modified by their selectivity of action at different tissue sites and by baroreceptor reflexes.

Traditionally, calcium-channel blockers have been classified according to their chemical structure; other methods of classification relate to the subtypes of calcium channels which they block, and their effects on heart rate. There are three major groups that are highly specific blockers of calcium channels.

Dihydropyridine calcium-channel blockers (such as nifedipine) act on slow, L-type channels. They have a greater selectivity for vascular smooth muscle than for myocardium and therefore their main effect is vasodilatation. They are non-rate-limiting, with little or no action at the SA or AV nodes, and negative inotropic activity is rarely seen at therapeutic doses. They are used for their antihypertensive and anti-anginal properties. Some dihydropyridine derivatives, for example nimodipine, cross the blood-brain barrier and are used in cerebral ischaemia.

Benzothiazepine calcium-channel blockers (such as diltiazem) and **phenylalkylamine** calcium-channel blockers (such as verapamil) also act on L-type channels but they have less selective vasodilator activity than dihydropyridine derivatives. They are classed as rate-limiting and have a direct effect on myocardium, causing depression of SA and AV nodal conduction. They are used for their antiarrhythmic, anti-anginal, and antihypertensive properties.

Drugs acting principally on the fast T-type calcium channels have also been investigated. Mibefradil, a benzimidazolyl-substituted tetraline derivative, is an example of this class. It is rate-limiting, and causes coronary and peripheral vasodilatation. However, it is no longer used clinically due to serious interactions with a wide range of drugs.

For further discussion of the actions and uses of the three main groups of calcium-channel blockers, see Nifedipine, p.1350, Diltiazem, p.1265, and Verapamil, p.1421, respectively.

Cardiac inotropes

Positive cardiac inotropes increase the force of contraction of the myocardium and are therefore used in the management of acute and chronic heart failure. Some inotropes also increase or decrease the heart rate (positive or negative chronotropes), provide vasodilatation (inodilators), or improve myocardial relaxation (positive lusitropes), and these additional properties influence the choice of drug in specific situations. Drugs that are used mainly for their inotropic effects include the cardiac glycosides and phosphodiesterase inhibitors; sympathomimetics have a role as inotropes but also have other important uses.

◊ **Cardiac glycosides**, such as digoxin, possess positive inotropic activity, which is mediated by inhibition of sodium-potassium adenosine triphosphatase (Na/K-ATPase). They also reduce conductivity in the heart, particularly through the atrioventricular node, and therefore have a negative chronotropic effect. The cardiac glycosides have very similar pharmacological effects but differ considerably in their speed of onset and duration of action. They are used to slow the heart rate in supraventricular arrhythmias, especially atrial fibrillation, and are also given in chronic heart failure.

Centrally acting antihypertensives

Centrally acting antihypertensives include $alpha_2$-adrenoceptor agonists such as clonidine and methyldopa. Stimulation of $alpha_2$ adrenoceptors in the CNS results in a reduction in sympathetic tone and a fall in blood pressure. Heart rate is also reduced. They are used in the management of hypertension, although other drugs with fewer adverse effects are generally preferred. Apraclonidine (p.1877) and brimonidine (p.1878) are alpha$_2$-adrenoceptor agonists that are used in the management of glaucoma.

Described in this chapter are

Clonidine, p.1247	Methyldopa, p.1334
Guanabenz, p.1299	Moxonidine, p.1345
Guanfacine, p.1301	Rilmenidine, p.1388

Diuretics

Diuretics promote the excretion of water and electrolytes by the kidneys. They are used in the treatment of heart failure or in hepatic, renal, or pulmonary disease when salt and water retention has resulted in oedema or ascites. Diuretics are also used, either alone, or in association with other drugs, in the treatment of hypertension, although the mechanism for their antihypertensive effect is poorly understood.

The principal groups of diuretics are as follows.

◊ **Carbonic anhydrase inhibitors** such as acetazolamide (p.1875) are weak diuretics and are used mainly to reduce intra-ocular pressure in glaucoma. They are described under Miotics, Mydriatics, and Antiglaucoma Drugs, p.1873.

◊ **'Loop'** or **'high-ceiling' diuretics** produce an intense, dose-dependent diuresis of relatively short duration.

Described in this chapter are

Azosemide, p.1222	Furosemide, p.1292
Bumetanide, p.1237	Piretanide, p.1372
Etacrynic Acid, p.1283	Torasemide, p.1415
Etozolin, p.1284	

◊ **Osmotic diuretics** raise the osmolality of plasma and renal tubular fluid. They are used to reduce or prevent cerebral oedema, to reduce raised intra-ocular pressure, and in acute renal failure.

Described in this chapter are

Isosorbide, p.1317	Mannitol, p.1330

◊ **Potassium-sparing diuretics** have a relatively weak diuretic effect and are normally used in conjunction with thiazide or loop diuretics. Canrenone, eplerenone, potassium canrenoate, and spironolactone are aldosterone antagonists and are particularly used in conditions where aldosterone contributes to the pathophysiology.

Described in this chapter are

Amiloride, p.1209	Spironolactone, p.1400
Canrenone, p.1239	Triamterene, p.1417
Eplerenone, p.1279	
Potassium Canrenoate, p.1374	

◊ **Thiazides** (benzothiadiazines), such as bendroflumethiazide and hydrochlorothiazide, and certain other compounds, such as metolazone, with structural similarities to the thiazides, inhibit sodium and chloride reabsorption in the kidney tubules and produce a corresponding increase in potassium excretion.

Described in this chapter are

Altizide, p.1209	Hydroflumethiazide, p.1311
Bemetizide, p.1223	Indapamide, p.1314
Bendroflumethiazide, p.1224	Mebutizide, p.1331
Benzthiazide, p.1225	Mefruside, p.1332
Butizide, p.1238	Methyclothiazide, p.1334
Chlorothiazide, p.1243	Meticrane, p.1336
Chlortalidone, p.1243	Metipamide, p.1336
Clopamide, p.1250	Metolazone, p.1337
Cyclopenthiazide, p.1254	Polythiazide, p.1373
Cyclothiazide, p.1254	Quinethazone, p.1383
Epitizide, p.1279	Teclothiazide, p.1409
Hydrochlorothiazide, p.1307	Trichlormethiazide, p.1418
	Tripamide, p.1419
	Xipamide, p.1434

Endothelin receptor antagonists

Endothelin receptor antagonists act by blocking the effects of endothelin, a potent vasoconstrictor. Bosentan blocks both the endothelin ET$_A$ and ET$_B$ receptors, whereas ambrisentan and sitaxentan are selective for ET$_A$. They are used in the management of pulmonary hypertension. Tezosentan, which blocks both ET$_A$ and ET$_B$, has been investigated in heart failure.

Described in this chapter are

Ambrisentan, p.1209	Sitaxentan, p.1396
Bosentan, p.1235	Tezosentan, p.1411

1. Attinà T, *et al*. Endothelin antagonism in pulmonary hypertension, heart failure, and beyond. *Heart* 2005; **91:** 825–31.

Ganglion blockers

Ganglion blockers are nicotinic antagonists that inhibit the transmission of nerve impulses in both sympathetic and parasympathetic ganglia. Their antihypertensive action is due to sympathetic blockade, which produces peripheral vasodilatation; there is also a direct vasodilator effect on peripheral blood vessels.

Described in this chapter are

Azamethonium, p.1222	Trimetaphan, p.1419
Mecamylamine, p.1331	

Lipid regulating drugs

Lipid regulating drugs are used to modify blood lipid concentrations in the management of hyperlipidaemias and for the reduction of cardiovascular risk. The principal groups of lipid regulating drugs are the statins, fibrates, bile-acid binding resins, nicotinates, and omega-3 triglycerides; ezetimibe, an inhibitor of intestinal cholesterol absorption, is also used.

◊ The **statins** are inhibitors of 3-hydroxy-3-methylglutaryl-coenzyme A (HMG-CoA) reductase, the rate-determining enzyme for cholesterol synthesis. They reduce cholesterol by stimulating an increase in low-density-lipoprotein (LDL)-receptors on hepatocyte membranes, thereby increasing the clearance of LDL from the circulation. Their main effect is to reduce LDL-cholesterol, but they may also reduce triglycerides to a modest extent and increase high-density-lipoprotein (HDL)-cholesterol. They are generally considered to be the most effective lipid lowering drugs.

Described in this chapter are

Atorvastatin, p.1218	Pitavastatin, p.1373
Fluvastatin, p.1290	Pravastatin, p.1374
Lovastatin, p.1328	Rosuvastatin, p.1389
Mevastatin, p.1339	Simvastatin, p.1390

◊ The **fibrates** include derivatives of fibric acid and related compounds. They are activators of peroxisome proliferator-activated receptor (PPAR)-α and inhibit the synthesis of cholesterol and bile acids, and enhance the secretion of cholesterol in bile. Their main effect is to reduce triglycerides by reducing the concentration of very-low-density lipoproteins (VLDL); they also increase HDL-cholesterol and have variable effects on LDL-cholesterol. They are used mainly in patients with hypertriglyceridaemia.

Described in this chapter are

Bezafibrate, p.1232	Fenofibrate, p.1286
Ciprofibrate, p.1246	Gemfibrozil, p.1295
Clinofibrate, p.1246	Pirifibrate, p.1372
Clofibrate, p.1246	
Etofylline Clofibrate, p.1284	

◊ **Bile-acid binding resins** (bile-acid sequestrants) lower cholesterol by combining with bile acids in the gastrointestinal tract and preventing their reabsorption. This leads to an increased oxidation of cholesterol to replace the lost bile acids, and an increase in LDL-receptor synthesis on hepatocytes, resulting primarily in a reduction of LDL-cholesterol.

Described in this chapter are

Colesevelam, p.1252	Colestyramine, p.1252
Colestilan, p.1252	Colextran, p.1254
Colestipol, p.1252	

◊ **Nicotinates** include nicotinic acid (p.1957) and its derivatives. Nicotinic acid is a member of the vitamin B group and, in high doses, has beneficial effects on blood lipids; it reduces triglycerides and increases HDL-cholesterol, and may also modestly reduce LDL-cholesterol. Nicotinates are mainly used in hypertriglyceridaemia. Compounds derived from both nicotinic acid and clofibrate (nicotinate-fibrate derivatives) are also used.

Described in this chapter are

Acipimox, p.1201	Niceritrol, p.1348
Binifibrate, p.1234	Tocoferil Nicotinate, p.1415
Etofibrate, p.1284	

◊ **Omega-3 fatty acids** are long-chain polyunsaturated fatty acids that primarily reduce triglycerides.

Described in this chapter are

Omega-3 Fatty Acids, p.1362

Nitrates

Nitrates are peripheral and coronary vasodilators used in the management of angina pectoris, heart failure, and myocardial infarction. Some of them may also be used to control blood pressure during surgery. Nitrates are believed to exert their vasodilator effect through release of nitric oxide (p.1358), which causes stimulation of guanylate cyclase in the vascular smooth muscle cells; this results in an increase in cyclic guanosine monophosphate. This nucleotide induces relaxation, probably by lowering the free calcium concentration in the cytosol. Nitrates are thus termed nitrovasodilators. In their action on vascular muscle, venous dilatation predominates over dilatation of the arterioles. Venous dilatation decreases venous return as a result of venous pooling, and lowers left ventricular diastolic volume and pressure (termed a reduction in preload). The smaller or less important dilatation of arterioles reduces both peripheral vascular resistance and left ventricular pressure at systole (termed a reduction in afterload). The consequent effect is a reduction in the primary determinants of myocardial oxygen demand. The effect on preload is not shared by beta blockers or calcium-channel blockers. Nitrates also have a coronary vasodilator effect which improves regional coronary blood flow to ischaemic areas resulting in improved oxygen supply to the myocardium.

Described in this chapter are

Eritrityl Tetranitrate, p.1282	Linsidomine, p.1325
Glyceryl Trinitrate, p.1296	Molsidomine, p.1343
Isosorbide Dinitrate, p.1317	Pentaerithrityl Tetranitrate, p.1366
Isosorbide Mononitrate, p.1318	Propatylnitrate, p.1380
	Sodium Nitroprusside, p.1397
	Tenitramine, p.1410

Potassium-channel openers

Potassium-channel openers (potassium-channel activators) have been used in the management of hypertension; nicorandil is used in angina pectoris. They have a direct relaxant effect on smooth muscle. They act at potassium channels to allow cellular efflux of potassium which hyperpolarises the cell membrane and leads to a reduction in intracellular calcium. The reduction in intracellular calcium produces relaxation of smooth muscle. Activation of potassium channels in blood vessels produces vasodilatation. Potassium-channel openers may also have potential use in other conditions caused by smooth muscle contraction, for example asthma and urinary incontinence.

Described in this chapter are

Nicorandil, p.1349	Pinacidil, p.1371

Prostaglandins

Prostaglandins (p.2374) are endogenous substances with a wide range of actions. Epoprostenol (the synthetic form of prostacyclin or prostaglandin I$_2$) and its analogues have vasodilator and antiplatelet properties and are used in pulmonary hypertension and peripheral vascular disease, and to prevent clotting of blood in extracorporeal circuits. Limaprost, an analogue of alprostadil (prostaglandin E$_1$), has similar properties and is used in peripheral vascular disease.

Described in this chapter are

Beraprost, p.1225	Limaprost, p.1325
Epoprostenol, p.1279	Treprostinil, p.1417
Iloprost, p.1313	

Sympathomimetics

Sympathomimetics produce either direct or indirect stimulation of adrenergic receptors and have various effects depending on the specific receptors involved. Their actions and uses are described in more detail on p.1407. In cardiovascular disorders, they are mainly used for their alpha$_1$ and beta$_1$ properties to provide haemodynamic support in the management of acute heart failure and shock.

Sympathomimetics with primarily non-cardiovascular uses include alpha agonists, such as phenylephrine (p.1568), pseudoephedrine (p.1571), and naphazoline (p.1565), which are used to produce vasoconstriction of the nasal mucosa for the symptomatic relief of nasal congestion. Apraclonidine (p.1877) and brimonidine (p.1878) are examples of sympathomimetics with alpha$_2$-agonist properties that are used to lower intra-ocular pressure and treat glaucoma. Beta$_2$ agonists are used as bronchodilators and in premature labour and are described under Bronchodilators and Anti-asthma Drugs, p.1108.

Described in this chapter are

Adrenaline, p.1203	Mephentermine, p.1332
Amezinium, p.1209	Metaraminol, p.1333
Arbutamine, p.1216	Methoxamine, p.1333
Denopamine, p.1256	Midodrine, p.1341
Dimetofrine, p.1268	Noradrenaline, p.1360
Dobutamine, p.1271	Norfenefrine, p.1361
Docarpamine, p.1272	Octodrine, p.1361
Dopamine, p.1273	Oxedrine, p.1364
Dopexamine, p.1274	Oxilofrine, p.1364
Etilefrine, p.1284	Pholedrine, p.1371
Ibopamine, p.1312	Prenalterol, p.1377
Isoprenaline, p.1316	Xamoterol, p.1433

Thrombolytics

Thrombolytics are used in the treatment of thromboembolic disorders such as myocardial infarction, peripheral arterial thromboembolism, and venous thromboembolism (deep-vein thrombosis and pulmonary embolism), and some may be used in ischaemic stroke. They are also used to clear blocked cannulas and shunts.

Thrombolytics activate plasminogen to form plasmin, a proteolytic enzyme that degrades fibrin and thus produces dissolution of clots. Some thrombolytics, such as alteplase, act only on fibrin-bound plasminogen and have little effect on circulating, unbound plasminogen; these thrombolytics are termed fibrin-specific agents. Thrombolytics, such as streptokinase, that affect circulating, unbound as well as fibrin-bound plasminogen are termed fibrin-nonspecific agents. Although it has been suggested that the degree of fibrin specificity should influence the risk of haemorrhage, the clinical significance of this has not been established (see Haemorrhage under Adverse Effects of Streptokinase, p.1403).

Vasodilators

Vasodilator is a broad term applied to drugs that produce dilatation of blood vessels. The main groups of drugs producing vasodilatation are ACE inhibitors (p.1193), nitrates (above), and direct-acting vasodilators.

◊ **Direct-acting vasodilators** act predominantly on the arterioles reducing peripheral resistance and producing a fall in blood pressure. Their main use is in hypertension, although other drugs are generally preferred. Some of them are used in hypertensive crises.

Described in this chapter are

Cadralazine, p.1238	Hydralazine, p.1305
Diazoxide, p.1257	Minoxidil, p.1342
Dihydralazine, p.1264	Todralazine, p.1415
Endralazine, p.1277	Tolazoline, p.1415

◊ **Other vasodilators** may be used for ischaemic heart disease.

Described in this chapter are

Carbocromen, p.1241	Fendiline, p.1286
Cinepazet, p.1246	Hexobendine, p.1305
Cloridarol, p.1251	Oxyfedrine, p.1365
Dilazep, p.1265	Trapidil, p.1416
Etafenone, p.1283	Trimetazidine, p.1419

◊ Vasodilators are also used for cerebral and peripheral vascular disorders. Some of these are now thought to improve microcirculatory flow disturbances by altering the rheological properties of blood or tissue metabolism, and this may be more important than their vasodilator effects.

Management of Cardiovascular Disorders

Management of the main cardiovascular disorders is discussed below. These overviews focus on pharmacological therapy, but other options are also mentioned where they form an important part of treatment.

Advanced cardiac life support

Cardiac arrest is the cessation of effective cardiac mechanical activity and is usually a result of ischaemic heart disease in adults and respiratory or circulatory failure in children. It may be associated with four arrhythmias, namely **ventricular fibrillation, pulseless ventricular tachycardia, asystole**, and **electromechanical dissociation (pulseless electrical activity)**. Ventricular fibrillation is the commonest in adults and asystole in children. In ventricular fibrillation and pulseless ventricular tachycardia there is chaotic electrical and mechanical activity; in asystole a total absence of both activities; and in electromechanical dissociation an absence of mechanical activity, or undetectable activity, in the presence of some electrical activity.

Cardiac arrest is an emergency situation[1,2] and should be treated with full life support measures.

International recommendations[3] for advanced life support and the immediate period of cardiac arrest have been published, developed by the International Liaison Committee on Resuscitation. American,[4] European,[5] and UK[6] guidelines have also been published; these are based on the international recommendations and, apart from some differences in detail, are broadly similar.

In order to maintain cardiorespiratory function, **basic life support** (cardiopulmonary resuscitation; CPR) consisting of chest compression and ventilation (mouth-to-mouth/mask or mouth-to-nose) should be started immediately and continued during the resuscitation attempt. **Subsequent procedures** will depend to some extent on the type of arrhythmia present. For the commonest, ventricular fibrillation, rapid *defibrillation* is of paramount importance and should not be delayed by other necessary measures such as giving oxygen, intubation, and providing intravenous access. Defibrillation is intended to produce momentary asystole and allow the natural pacemakers to resume normal activity. *Adrenaline* is given principally to increase the efficacy of basic life support rather than as an adjunct to defibrillation although evidence that it improves survival is limited; through its alpha agonist effects it increases myocardial and cerebral blood flow. A dose of 1 mg of adrenaline is regarded as the 'standard' intravenous dose for adults. A higher dose of 5 mg has been used in some clinical trials, but there is no evidence that this dose is associated with an improvement in overall survival rate and it is not generally recommended. For children, the usual initial dose is 10 micrograms/kg; as in adults, higher doses have been used subsequently but again there is no evidence that this is beneficial.[7] *Vasopressin* has been tried as an alternative although it has not been shown to be superior to adrenaline.[8] In the case of asystole, atropine may be given to block excess vagal tone. *Amiodarone* may be considered for ventricular tachycardia or fibrillation; *lidocaine* may be used if amiodarone is not available. A study[9] comparing lidocaine with amiodarone for shock-resistant ventricular fibrillation found that survival to hospital admission was higher in those given amiodarone. Survival to discharge was not increased, however, but the study was not powered to assess this outcome. *Other drugs* that may be given for specific indications during resuscitation attempts include buffering agents such as intravenous sodium bicarbonate for acidosis, calcium, magnesium, or potassium salts for known deficiencies, and aminophylline for refractory bradycardia. Therapeutic *hypothermia* may be beneficial in patients who remain unconscious after resuscitation, and cooling to 32° to 34° has been recommended[3-6] in unconscious adults whose initial rhythm was ventricular fibrillation. Specific guidelines for the different types of arrhythmia are as follows.

Ventricular fibrillation and **pulseless ventricular tachycardia** are treated in the same way. The guidelines for **adults** emphasise that the first defibrillating shock must be given as quickly as possible, although a short period of CPR may be appropriate first if the arrest was not witnessed. In cases of witnessed cardiac arrest a precordial thump, which sometimes aborts the arrhythmia if given within 30 seconds of the loss of cardiac output, may be given before attaching the monitor/defibrillator, but the attachment of the defibrillator must not be delayed. Although a strategy of three initial shocks has been the standard, it is now recommended that a single shock is given, since this appears to be as effective as three shocks while minimising the interruption to chest compressions. Monophasic or biphasic shocks may be given, depending on the equipment available. For monophasic devices, the recommended energy for all shocks is 360J. For biphasic devices the optimum energy varies; in the UK and Europe an initial shock of 150-200J is recommended, with subsequent shocks of 150-360J, but in other countries devices using lower energies may be available.

After the initial shock, CPR should be immediately resumed for 2 minutes before reassessing the rhythm; a further shock should then be given if indicated, followed by immediate resumption of CPR, and this cycle of assessment, shock, and CPR should be continued throughout resuscitation. At the same time, drug therapy may be started. In the UK and Europe, adrenaline 1 mg intravenously is recommended before the third shock, repeated every 3 to 5 minutes (roughly every 2 cycles) while resuscitation continues; in the USA, adrenaline may be started before the second or third shock. If the intravenous route is not available, the same dose may be given by intraosseous injection. Endotracheal dosage is a further alternative; doses 2 to 3 times greater than those given intravenously are suggested, although studies investigating this route have had mixed results.[10,11] A single dose of vasopressin (as argipressin) 40 units intravenously may be given instead of the first or second dose of adrenaline,[4] but this is not universally recommended.[5,6] Amiodarone may be given before the fourth shock (before the third or fourth shock in the USA); lidocaine is an alternative if amiodarone is not available. Other drugs (such as those described above) may be used as appropriate. Cycles of CPR, shocks, and adrenaline should continue for as long as defibrillation is indicated. The total number of cycles is a matter of judgement but a resuscitation attempt may reasonably last for anything from 10 minutes to 1 hour.

Ventricular fibrillation in **children** is unusual; the basic management is the same as in adults, but the energies used for defibrillation and the doses of drugs used are different and a precordial thump is not generally given. The dose of adrenaline is 10 micrograms/kg by intravenous or intraosseous injection. A higher dose of 100 micrograms/kg has been used for the second and subsequent doses but is no longer recommended.[3-6] The endotracheal route is an alternative, but only if intravenous or intraosseous access cannot be obtained; the suggested endotracheal dose is 100 micrograms/kg.

In survivors of ventricular fibrillation and pulseless ventricular tachycardia in whom it is considered there is a high risk of **recurrence**, implantable cardioverter defibrillators may be used. Drug therapy may also be used prophylactically (see Ventricular Tachycardia under Cardiac Arrhythmias, p.1160).

Asystole and **electromechanical dissociation** have a much less favourable prognosis than ventricular fibrillation or pulseless ventricular tachycardia, although there are certain causes such as hypovolaemia, hypoxia, pneumothorax, pulmonary embolism, drug overdose, hypothermia, and electrolyte imbalances that may respond to treatment and these should be considered and the appropriate therapy given promptly once resuscitation has been started. As described above, a precordial thump may be appropriate if the cardiac arrest is witnessed. Once ventricular fibrillation or tachycardia is positively excluded, CPR should begin immediately and adrenaline 1 mg should be given by intravenous or intraosseous injection every 3 to 5 minutes; in the USA, a single dose of vasopressin may be given instead of either the first or second dose of adrenaline if the patient is in asystole.[4] For asystole a single dose of atropine 3 mg intravenously is also given to block vagal activity;[5,6] in the American guidelines[4] atropine is recommended in repeated doses of 1 mg to a total maximum dose of 3 mg. Other drugs (such as buffering agents) may be considered. Cardiac pacing may be started once there is evidence of electrical activity. Resuscitation should generally continue for at least 20 to 30 minutes from the time of collapse; it is not usually prolonged as recovery rarely occurs after 15 to 20 minutes of asystole if there has been no response.

For **children** with asystole or electromechanical dissociation, the initial dose of adrenaline recommended is 10 micrograms/kg given by intravenous or intraosseous injection; as for ventricular fibrillation, higher doses have been used subsequently but are not generally recommended. Alternatively, adrenaline may be given by the endotracheal route in doses of 100 micrograms/kg. Atropine is not generally used and a precordial thump is not recommended.

Angina pectoris

Angina pectoris is a syndrome that arises from an inadequate myocardial oxygen supply (myocardial ischaemia) and is part of the spectrum of coronary or ischaemic heart disease. Myocardial oxygen supply depends upon coronary blood flow, which normally increases to meet increased oxygen demands. Ischaemia occurs when blood flow either cannot be increased, or is reduced; this may be due to a fixed obstruction in the coronary arteries, vasoconstriction, thrombus formation, or platelet aggregation. The main symptom is transient precordial discomfort ranging from a mild ache to severe pain. Some patients may also experience dyspnoea, nausea, sweating, and left arm discomfort.

Three main types of angina have been described: stable angina; unstable angina; and Prinzmetal's angina. Although these are discrete groups, stable angina may become unstable, and Prinzmetal's angina may co-exist with stable or unstable angina.

Stable angina (effort angina) is usually brought on by exertion and relieved by rest. It is often called chronic stable angina and as the name implies the frequency, intensity, and duration of the attacks are stable. The main underlying disorder is coronary atherosclerosis causing a fixed obstruction in one or more coronary arteries. While the restricted coronary blood flow is still adequate for oxygenation of the unstressed heart, it is not capable of being increased to meet the increase in myocardial oxygen demand that may occur during exercise, cold exposure, emotional stress, or after eating.

Unstable angina and the related condition **non-ST elevation myocardial infarction** are acute coronary syndromes intermediate between stable angina pectoris and acute myocardial infarction. There are 3 main presentations:

- angina that presents from the beginning as severe and frequent attacks
- an increase in the frequency, intensity, and/or duration of previously stable angina, often with diminishing responsiveness to sublingual nitrates (crescendo angina)
- recurring or prolonged angina at rest

As in stable angina, the underlying disorder is usually coronary atherosclerosis, but the decreased coronary artery blood flow is usually caused by disruption of an atherosclerotic plaque, which leads to platelet adhesion and aggregation, thrombus formation, and vasoconstriction. This may result in partial occlusion of one or more coronary arteries, and the coronary blood flow can be so restricted that it does not meet the oxygenation demands of the unstressed heart. However, in unstable angina the ischaemia is not severe enough to cause myocardial damage, whereas in non-ST elevation myocardial infarction some degree of myocardial necrosis occurs, although to a lesser extent than in acute myocardial infarction. Patients with the different acute coronary syndromes may present similarly and definitive diagnosis is only possible retrospectively once the results of biochemical measurements such as cardiac troponins or cardiac enzymes are available or the ECG shows evidence of new Q waves. However, patients without ST-elevation on the presenting ECG rarely develop Q waves and are managed as for unstable angina; those with ST-elevation should be treated as for acute myocardial infarction (p.1175). Patients with unstable angina are at an increased risk of sudden death or progression to myocardial infarction, and those with rest pain are at the greatest risk.

Prinzmetal's angina (variant angina) is a rare form of angina caused by coronary vasospasm, although it is often associated with atherosclerosis. It occurs spontaneously at rest and with greater frequency during the night or early hours of the morning. It is associated with transient ST-segment elevation and carries a risk of progression to myocardial infarction. Prolonged vasospasm may also lead to ventricular arrhythmias, heart block, or death.

Patients who have **angina with normal coronary arteries** as shown by angiography may have microvascular dysfunction or altered cardiac pain perception. Prognosis is generally better than in other forms of angina although quality of life may be significantly impaired.[1,2]

In addition to the types of angina described above periods of **silent myocardial ischaemia** (asymptomatic transient myocardial ischaemia) in which there is no anginal pain have been identified during ECG monitoring. In some patients all ischaemic episodes are asymptomatic. However, asymptomatic ischaemic episodes also occur in patients with angina and seem to be more common than symptomatic episodes. It is not clear why some episodes of ischaemia are symptomatic while others are not.

Treatment depends on the type of angina and involves symptomatic management of acute anginal pain, antithrombotic therapy to prevent progression to myocardial infarction, and long-term management both to prevent angina attacks and to reduce the risk of other cardiovascular events. Anti-anginal treatment is used in both stable and unstable angina and is described in more detail below; it includes drug therapy (nitrates, beta blockers, calcium-channel blockers, and potassium-channel openers), and non-pharmacological interventions. Antithrombotics are used in unstable angina and include anticoagulants and antiplatelet drugs (see Treatment of Unstable Angina, below). Long-term measures to reduce cardiovascular risk are important in all patients, even when symptoms are controlled, and include antiplatelet therapy (which should be given to all patients unless contra-indicated), lipid lowering therapy, and lifestyle changes; these interventions are discussed in more detail under Cardiovascular Risk Reduction, p.1164. Patients with ischaemic heart disease who undergo non-cardiac surgery are at risk of complications resulting from perioperative myocardial ischaemia.

Anti-anginal drugs act in a variety of ways. Glyceryl trinitrate and other organic *nitrates* have a vasodilator effect with venodilatation predominating over dilatation of the arterioles. Dilatation of veins decreases venous return as a result of venous pooling and lowers left ventricular diastolic volume and pressure (together termed a reduction in preload). The smaller or less important dilatation of arterioles reduces both peripheral vascular resistance and left ventricular pressure at systole (termed a reduction in afterload). The consequence of these effects is a reduction in myocardial oxygen demand. Also the vasodilator effect improves regional coronary blood flow to ischaemic areas, and alleviates coronary spasm. *Beta blockers* cause a slowing of the heart rate and reduction in contractility and therefore reduce myocardial oxygen demand. *Calcium-channel blockers* reduce the work of the heart by dilating peripheral arteries, and diltiazem and verapamil also slow the heart rate. Calcium-channel blockers also act on the coronary circulation preventing spasm. *Potassium-channel openers* act as coronary vasodilators, while nicorandil also has a nitrate component that may contribute to its effect.

The main ***non-pharmacological treatments*** used are *percutaneous coronary interventions* (PCI), such as balloon angioplasty and stenting, and bypass surgery. Balloon angioplasty is a catheter-based technique that mechanically dilates the occluded artery; coronary stents are used to prevent recoil and to reduce the incidence of restenosis. Nitrates and calcium-channel blockers may be given to alleviate coronary spasm due to the procedure. Coronary artery *bypass surgery* uses a vein or artery graft to bypass the occlusion. Both PCI and bypass surgery abolish or reduce episodes of angina in most patients but symptoms commonly recur over a period of time due to restenosis. Adjunctive therapy is therefore needed both to prevent short-term thromboembolic complications and long-term reocclusion (see Reperfusion and Revascularisation Procedures, p.1181). Other non-pharmacological methods that have been tried in refractory angina include enhanced external counterpulsation, transmyocardial revascularisation, and spinal cord stimulation;[3,4] gene- and stem cell-based therapies are also under investigation.[4]

Treatment of stable angina. Management of the patient with stable angina[4-10] mainly involves the use of anti-anginal drugs, antiplatelet therapy, and measures to reduce cardiovascular risk. Any contributory conditions, such as anaemia, should be identified and treated.

Treatment of *infrequent* angina episodes (less than about 2 attacks per week) usually consists of glyceryl trinitrate given when required, generally sublingually; alternatively, a buccal tablet or spray formulation may be used. Isosorbide dinitrate, in the form of sublingual tablets or spray, may be used, although it has a slower onset of action than glyceryl trinitrate. Glyceryl trinitrate in sublingual or buccal forms may also be used before an activity or circumstance that might precipitate an attack.

When episodes occur *more frequently*, sublingual glyceryl trinitrate, at least on its own, may no longer be appropriate, and regular symptomatic treatment has to be considered. Choice depends upon patient characteristics and any concurrent medical conditions.

- Beta blockers are the mainstay of therapy. They are generally considered to be first-line treatment if sublingual glyceryl trinitrate is not adequate since they provide effective symptom control and have also been shown to reduce mortality in certain patients with high cardiovascular risk.[5,6,9] The different beta blockers have similar efficacy in terms of symptom control, but those with $beta_1$-selectivity may be preferred;[9] beta blockers with intrinsic sympathomimetic activity may be less effective for secondary prevention after myocardial infarction and are not recommended.[11]
- Calcium-channel blockers appear to have similar efficacy to beta blockers in terms of symptom control and cardiovascular outcomes[12] and long-acting calcium-channel blockers may be used as alternative first-line therapy,[5,9] particularly in patients unable to tolerate beta blockers. Both dihydropyridines (such as nifedipine) and rate-limiting calcium-channel blockers (diltiazem and verapamil) may be used, with choice depending on individual patient characteristics and adverse effects. Short-acting preparations of nifedipine have been associated with increased mortality and are not recommended (see under Adverse Effects of Nifedipine, p.1350).
- Regular nitrate therapy is a further alternative, and includes modified-release forms of glyceryl trinitrate, for example transdermal patches, and the long-acting nitrates such as isosorbide dinitrate or isosorbide mononitrate; it may be particularly suitable in patients with left ventricular dysfunction. Diminished effectiveness or tolerance occurs, particularly with nitrate preparations that produce sustained plasma concentrations, and dosage regimens including a nitrate-free period should be used (see Nitrate Tolerance, p.1297).
- Nicorandil, which is both a potassium-channel opener and a nitrate, is another alternative that can be used for monotherapy.[6,9] Ivabradine, a selective sinus node I_f inhibitor, may be used in patients with normal sinus rhythm, who have a contra-indication or intolerance for beta blockers. Other drugs that are sometimes used include trimetazidine, which has anti-ischaemic effects through a metabolic action and may be of benefit in refractory angina, and the nitrovasodilator molsidomine. Several other vasodilators have also been used (see p.1156) but no longer have an established role.

Where optimal therapy with a single drug fails to control symptoms, *combination therapy* may be used. There is additional benefit from nitrates with beta blockers, since nitrates can moderate the excessive effects that beta blockers may have in increasing left ventricular diastolic volume and pressure and in inducing bradycardia. Calcium-channel blockers may also be used with nitrates; the use of verapamil or diltiazem with a nitrate may be preferrable to nifedipine (or other dihydropyridine derivative) with nitrates as both nifedipine and nitrates cause reflex tachycardia, hypotension, and headaches. Use of beta blockers with calcium-channel blockers may also be of benefit,[13] although adverse effects can be a problem. Combined therapy with beta blockers and dihydropyridines or diltiazem improves exercise tolerance, but caution is needed with dihydropyridines in patients with heart failure (although amlodipine and felodipine appear to be safe) and with diltiazem in patients with conduction disorders. Verapamil should generally be avoided with beta blockers as the risk of conduction disorders is particularly high (see p.1422).

Nicorandil may also be given with other anti-anginals. Ranolazine, which has metabolic effects, is another drug that may be used as an adjunct to standard therapy, although its role is not yet established.

Triple therapy using a nitrate, a beta blocker, and a calcium-channel blocker may sometimes be used although it is likely to be associated with more adverse effects.

If medical treatment does not control the angina the patient should be investigated to determine suitability for *revascularisation*.[9,14] The choice between PCI and coronary artery bypass surgery in patients with coronary artery disease is not entirely clear, and a systematic review[15] found that both procedures had similar effects on mortality, but the need for further revascularisation procedures was lower with bypass surgery. In general, PCI is preferred in patients with single-vessel disease, whereas bypass surgery is usual in patients with triple-vessel disease, disease of the left main coronary artery, or impaired left ventricular function.[16,17] PCI has also been used in patients whose angina is controlled with medical therapy, but its role is not clear. Although symptom control and quality of life may be higher with PCI than medical therapy,[18,19] a meta analysis[20] found no evidence that it improved mortality or reduced the incidence of major cardiovascular events.

Treatment of unstable angina. Unstable angina and non-ST segment elevation myocardial infarction are managed similarly,[21-28] and are generally regarded as an emergency. Patients with a change in the pattern of previously stable angina or with recurring or prolonged angina at rest should therefore be hospitalised and rapidly assessed. Presenting symptoms are similar for all the acute coronary syndromes and a resting ECG should be obtained as a priority. This allows identification of patients with ST elevation, who require treatment for acute myocardial infarction (p.1175), and also allows initial risk stratification. In patients without ST elevation, the immediate priority is to control symptoms and reduce ischaemia; at the same time, the risk of progression to acute myocardial infarction should be assessed, and subsequent treatment planned as appropriate. *Initial treatment* involves antiplatelet drugs, anticoagulants, nitrates, beta blockers, and possibly calcium-channel blockers; additional antiplatelet therapy and urgent revascularisation may then be considered. Once the patient has been stabilised, underlying risk factors should be identified and treated, and long-term anti-anginal therapy may be given.

- Aspirin is routinely included in the initial treatment. It inhibits platelet aggregation and substantially reduces the incidence of myocardial infarction and death, although it has not been shown to reduce the number of ischaemic episodes or to relieve pain during the acute phase.
- Clopidogrel or ticlopidine may be alternatives if aspirin is not tolerated, although clopidogrel has fewer adverse effects and is generally preferred. Dual antiplatelet therapy with clopidogrel and aspirin, both started immediately, may provide additional benefit[29] and has been recommended.[21,23,28]
- Anticoagulants are generally given in addition to aspirin to reduce thrombin generation and fibrin formation, although the optimum choice is unclear.[21]

  Both unfractionated heparin[30,31] and low-molecular-weight heparin[31] reduce the number of ischaemic episodes and major cardiovascular events during the acute phase, and also longer term. There is some evidence that low-molecular-weight heparins may be more effective than unfractionated heparin.[32-34] They may also be easier to use since low-molecular-weight heparins are given subcutaneously, whereas unfractionated heparin is generally given by continuous infusion for at least 48 hours,[22] although it may also be effective subcutaneously.[35] Reactivation of unstable angina may occur when treatment with either unfractionated[36] or low-molecular-weight heparin[37] is stopped; it is less likely in patients who are also taking aspirin,[36] and the risk may be reduced if treatment is stopped gradually. Guidelines[21,23,28] therefore allow the use of either unfractionated or low-molecular-weight heparin; unfractionated heparin may be preferred in patients undergoing bypass surgery[21] but either is suitable for PCI.[38]

  The pentasaccharide fondaparinux may be an alternative; it is at least as effective as enoxaparin[39] and may be the preferred option in patients for whom urgent PCI is not planned;[23] however, the incidence of catheter thrombosis was increased with fondaparinux in patients undergoing PCI[40] and unfractionated heparin should be given at the time of the procedure if PCI is performed.[21,23] For patients in whom early PCI is planned, the direct thrombin inhibitor bivalirudin is another alternative; a study[41,42] in patients scheduled for PCI found that bivalirudin was as effective as heparin (unfractionated or low-molecular-weight) and the risk of bleeding was reduced.
- Nitrates are widely used although evidence from controlled studies is limited.[21,23] The initial treatment may be given intravenously to produce a fast response and to provide better dose control than can be achieved with other routes. Glyceryl trinitrate or isosorbide dinitrate are used. Generally, the intravenous route is only used during the acute phase, and once the patient is stabilised the infusion is withdrawn, usually within about 48 hours. Sublingual glyceryl trinitrate may be tried initially in patients with less severe symptoms.
- Treatment with a beta blocker is started during the acute phase to reduce myocardial oxygen demand. Oral treatment is usually preferred,[21,23] although the intravenous route may be used initially if required. Beta blockers with intrinsic sympathomimetic activity do not reduce resting heart rate and are not recommended.[11,21,22]
- Calcium-channel blockers may be added to therapy although they are generally reserved for patients with angina refractory to treatment with the above drugs, or in whom beta blockers are contra-indicated. However, calcium-channel blockers are the drugs of choice if the angina has a vasospastic aetiology, for example in Prinzmetal's angina. The choice of calcium-channel blocker is described under the treatment of stable angina above.
- Thrombolytics have been tried in unstable angina but do not improve outcome and are associated with an excess of bleeding complications; thrombolytic therapy is therefore not recommended in patients with unstable angina.[21,22]

Once the initial therapy has been started patients at high or intermediate risk of progression to acute myocardial infarction, including those with recurrent ischaemia and those with raised cardiac troponins, should be assessed for *additional treatment*. Patients may be assigned to either an invasive or a conservative strategy. For those in whom an invasive strategy is chosen, early angiography is performed, with urgent revascularisation if appropriate. For those assigned to a conservative strategy and in patients at lower risk, angiography and revascularisation are only performed if medical therapy fails to control symptoms or if indicated by stress testing. Choice between the two remains controversial. Meta-analyses[43-45] have suggested that an invasive strategy is associated with a reduction in recurrent angina; there may also be a reduction in myocardial infarction and mortality in the longer term, although a later review[46] was unable to confirm this. Most benefit appears to be in higher risk patients, and a conservative strategy may be appropriate in those at lower risk.

- Additional antiplatelet therapy with glycoprotein IIb/IIIa inhibitors may have a role in patients treated invasively or conservatively.[47] Benefit has been established in patients undergoing PCI (see Reperfusion and Revascularisation Procedures, p.1181), but results in patients treated medically have been less consistent. A meta-analysis[48] of studies of glycoprotein IIb/IIIa inhibitors in unstable angina or non-ST elevation myocardial infarction found that they reduced the risk of death or myocardial infarction in patients who were not scheduled for early revascularisation, particularly in those at high risk of progression, such as those with raised troponins. However, many of the patients included in the analysis did receive revascularisation and the use of glycoprotein IIb/IIIa inhibitors in patients not undergoing intervention remains questionable.[21] Whether all the glycoprotein IIb/IIIa inhibitors are effective is also unclear. For patients not undergoing PCI, individual studies have reported beneficial results with tirofiban and aspirin, alone[49] or in combination with heparin therapy,[50] and with eptifibatide[51] in addition to standard therapy, but not with abciximab[52] in addition to aspirin and heparin. The benefit of treatment with glycoprotein IIb/IIIa inhibitors in patients already taking aspirin and clopidogrel is also not yet established.[53,54]
- The use of statins early after admission for acute coronary syndromes has been recommended,[23] although meta-analyses have come to differing conclusions regarding their benefit. One analysis[55] found early use of statins had no effect on outcomes at 1 or 4 months after the initial event, but another[56] reported a reduction in cardiovascular events with statin therapy for 6 months or longer; benefit may be increased with high-dose regimens.[57]

After discharge, patients should continue to take aspirin and a beta blocker; clopidogrel should also continue to be added to aspirin for up to 9 to 12 months.[21,23,58] Statins should also be continued, and other measures to reduce cardiovascular risk should be adopted. Anti-ischaemic drugs should be given as required; some patients are given a long-acting nitrate for long-term prophylaxis, although nitrates have not been shown to protect against subsequent cardiovascular events. Long-term oral anticoagulation has been used but is not routine therapy, and studies of warfarin with aspirin have given mixed results.[59,60] Prolonged use of low-molecular-weight heparins has been investigated,[61,62] but benefit has not been confirmed.

Treatment of Prinzmetal's angina. This should be treated like unstable angina with the addition of a calcium-channel blocker; the selection of an appropriate calcium-channel blocker is described above under the treatment of stable angina. Once stabilised, maintenance should include a nitrate, or calcium-channel blocker, or both to protect against further spasm. Surgery may be considered in some patients.

Treatment of angina with normal coronary arteries. Symptomatic treatment with standard anti-anginal drugs is the mainstay in patients with angina but no evidence of coronary artery disease, although response varies. Beta blockers appear to be the most effective treatment and are usually considered first-line.[1,2]

Treatment of silent myocardial ischaemia. Silent myocardial ischaemia has been recognised as a potential risk factor for future cardiovascular morbidity and mortality and research has been undertaken to assess whether suppressing such episodes can improve long-term outcome. Although many of the therapies used in angina reduce the incidence of silent ischaemia it is not yet clear whether complete suppression of ischaemia affects prognosis.[63,64] Other studies have suggested that periods of ischaemia may protect the heart during subsequent myocardial infarction, although the clinical relevance of this is unclear.[65,66]

Ascites

Ascites is the accumulation of fluid within the peritoneal cavity. Although it is not strictly a cardiovascular disorder, treatment depends mainly on cardiovascular drugs. Alcoholic hepatic cirrhosis is probably the commonest underlying cause in the western world; others include malignant neoplasms, heart failure, and tuberculosis. The following discussion is restricted mainly to **cirrhotic ascites**.

The mechanism of ascites formation in hepatic cirrhosis has been explained by various hypotheses. Whatever the mechanism, ascites formation is linked to renal sodium and water retention partly as a result of increased circulating renin and aldosterone concentrations. Portal hypertension and hypoalbuminaemia may be contributory factors. More details may be found in reviews of the pathophysiology of ascites formation.[1-3]

Small amounts of ascitic fluid may go undetected but as it accumulates abdominal distension becomes apparent, and there is a feeling of discomfort. There may be respiratory distress and cardiac dysfunction in severe cases. Peripheral oedema may, or may not, be present. Renal dysfunction may progress to severe impairment (the hepatorenal syndrome). Patients are at risk of primary (spontaneous) bacterial peritonitis (p.184).

Management[1-10] depends on the severity of ascites but the mainstays are dietary sodium restriction and diuretic treatment. In mild to moderate ascites, sodium restriction alone may sometimes be effective but most patients also require diuretics. Bed rest has been advocated but is no longer generally recommended.[10] Response is monitored by measuring the daily reduction in body-weight. The diuretic of choice is the aldosterone antagonist spironolactone, with the addition of a loop diuretic such as furosemide if necessary. Amiloride or another potassium-sparing diuretic may be used as an alternative to spironolactone if adverse effects are a problem. Spironolactone together with furosemide from the outset has also been used; benefit has also been suggested with combined furosemide and albumin in selected patients.[11] In tense or refractory ascites, large-volume or total paracentesis (removal of ascitic fluid by drainage) is often used initially; patients may then be maintained on diuretics or repeated paracentesis may be used. Plasma volume replacement with albumin or dextrans after paracentesis is usual, particularly if large volumes are removed. Where ascites remains refractory or repeated paracentesis is not tolerated various shunting procedures have been tried, although their role is not established. In severe cases liver transplantation may be necessary.

In **malignant ascites** (ascites due to malignant neoplasms; see Malignant Effusions, p.659), paracentesis is often necessary but spironolactone may be of benefit in some patients.

Atherosclerosis

Atherosclerosis is a pathological condition affecting medium and large arteries in which lipid-rich lesions (atheromas) develop in the intimal lining, leading to arterial dysfunction, obstruction of blood flow, and ischaemia. **Ischaemic heart disease** (coronary heart or coronary artery disease), which includes angina pectoris (p.1157) and myocardial infarction (p.1175), is the most common manifestation of atherosclerosis and in most industrialised countries ischaemic heart disease is a leading cause of death. Atherosclerosis of peripheral or cerebral arteries leads to peripheral vascular disease (p.1178) or ischaemic stroke (p.1185). Atherosclerotic diseases are thus a major cause of mortality and morbidity and the prevention and treatment of atherosclerosis has an important role in the management of these diseases.

Atherosclerosis is a progressive condition and various stages of atheroma development are recognised.[1-3] Early lesions include fatty streaks, which develop from infancy and are composed of lipid-filled macrophages (foam cells). These progress to fibrous plaques, which consist of a core of lipid and lipid-rich macrophages surrounded by a connective-tissue matrix. Plaques may undergo calcification and may become sufficiently large to obstruct the lumen of the artery. However, acute occlusion more commonly occurs as a result of thrombosis at the site of a plaque, due to endothelial denudation or disruption of the plaque (plaque rupture or fissuring) with exposure of the thrombogenic core. Endothelial dysfunction is an important underlying factor, promoting both the development of atheromas (atherogenesis) and subsequent thrombosis.[4,5]

Although symptoms depend on the site of obstruction, atherosclerosis is essentially a generalised condition and patients with peripheral vascular disease, for example, are also likely to develop, or to have evidence of, ischaemic heart disease.

The management of atherosclerotic diseases involves treatment of the clinical manifestations (as discussed under the specific diseases) and measures to reduce the risk of cardiovascular events occurring (see Cardiovascular Risk Reduction, p.1164). Some of the measures used to reduce risk, such as lipid regulating drugs or antihypertensives, may also reduce the progression of atherosclerosis. Other approaches have been targeted more directly at the atherosclerotic process, and some of these are discussed below.

Oxidation of low-density lipoprotein (LDL) is thought to be a crucial step in atherogenesis[6-8] and a number of studies have investigated the use of dietary antoxidants such as vitamins E and C and betacarotene (see Prophylaxis of Ischaemic Heart Disease, p.1926). Although some studies have found a reduction in the progression of atherosclerosis, others have not confirmed this finding, and several large studies have failed to find any effect on the risk of clinical events. Polyphenol compounds found in various foods, including red wine, have also received much attention for their possible role in the prevention of atherosclerosis.

Hyperhomocysteinaemia has been suggested as a risk factor for atherosclerosis, although its importance is not clear.[9] Interventions to reduce homocysteine, such as the use of folic acid or vitamin B supplements (see Cardiovascular Disease, p.1941), have been tried. Some effects on endothelial function have been noted, but there is as yet no evidence that clinical events are reduced.

Inflammation appears to have an important role in the development and progression of atherosclerosis, and in acute events due to plaque instability.[10,11] Various studies have shown an association between C-reactive protein, a marker of inflammation, and cardiovascular events, although its precise role is unclear.[9] Statins, which lower blood lipids and have an established role in reducing clinical events, have also been shown to reduce the progression of atherosclerosis,[5] possibly through an effect on inflammation, and high doses may induce regression.[12] Other non-lipid effects such as improvement of endothelial dysfunction, or an effect on thrombosis, have also been suggested.

Another possible cause of inflammation that has been investigated is infection,[13] and serological and pathological studies have found an association with a number of organisms. The evidence appears to be strongest for *Chlamydophila pneumoniae* (*Chlamydia pneumoniae*), although its precise role in the development or progression of atherosclerosis is unclear.[14] Treatment with antibacterials has been tried in patients with atherosclerotic disorders but any benefit has not yet been confirmed;[13,14] meta-analyses[15,16] of trials using antichlamydial drugs in patients with ischaemic heart disease have found no evidence that they reduced either mortality or further cardiovascular events. Some antibacterials may also have a direct anti-inflammatory action that could contribute to their effects.[14]

Chelation therapy with disodium edetate has been tried, as calcium deposition has been proposed as another factor in the development of atherosclerosis; however, the benefits remain to be established (see Atherosclerosis under Sodium Edetate, p.1464).

Women have a lower risk of atherosclerotic disease than men of a comparable age, although the difference narrows with increasing age postmenopausally, and the use of HRT has therefore been investigated. HRT lowers lipid concentrations and some angiographic or ultrasound studies have shown beneficial effects on the progress of atherosclerosis, although others have failed to confirm these findings. However, controlled studies do not support a role for HRT in the prevention of cardiovascular disease in postmenopausal women (see Effects on the Cardiovascular System, p.2073).

Therapeutic angiogenesis (the development and growth of blood vessels) is also under investigation to improve perfusion in atherosclerotic diseases. Preliminary studies of growth factor proteins, such as vascular endothelial growth factor (VEGF) and fibroblast growth factor (FGF), and gene therapy to stimulate VEGF production, have shown promise.[17,18] The use of stem cells is also being investigated.[19] However, since neovascularisation of the vessel wall and plaque angiogenesis may play a role in atherosclerosis, anti-angiogenic therapy may also have potential.[20]

Cardiac arrhythmias

Cardiac arrhythmias are disorders of the rhythm of the heart (p.1152) that may affect its ability to maintain blood circulation. They can be asymptomatic and in some cases benign, but often cause symptoms and may lead to syncope and sudden death; thromboembolic disorders associated with atrial arrhythmias are a common cause of stroke.

Definitions. A *cardiac arrhythmia* can be defined as any abnormality of rate, regularity, or site of origin of the cardiac impulse or as a disturbance in conduction that causes an abnormal sequence of activation. Arrhythmias may therefore occur due to disorders of the SA node, affecting initiation of impulses; disorders of the AV node and conducting system, affecting spread of the impulse to the ventricles; or abnormal conduction through other myocardial cells such as accessory pathways. Impulses may be generated outside the SA node (*ectopic pacemakers*), particularly in the AV node or the His-Purkinje system. The normal rate of impulse generation by these ectopic pacemakers is less than that of the SA node and therefore they do not usually trigger the heart beat, although they may become dominant in some situations. Since the action potential depends on the movement of ions across cell membranes, electrolyte disorders may be an important cause of arrhythmias; congenital disorders affecting the ion channels (channelopathies) are also increasingly being recognised as a cause.

Arrhythmias may be classified as bradyarrhythmias (slow) or tachyarrhythmias (fast), depending on the heart rate, and as supraventricular (atrial or AV junctional) or ventricular, depending on their presumed site of origin. They may also be divided on the basis of the underlying mechanism into those associated with abnormal automaticity, re-entry, or triggered activity (see Tachyarrhythmias, below). Symptoms depend on the arrhythmia but may include fatigue, dyspnoea, dizziness, and syncope; sudden death may occur. *Palpitations*, an unacceptable awareness of the beating heart, may occur normally in circumstances such as emotion, exercise, or stress but can occur in association with arrhythmias.

Bradyarrhythmias are commonly caused by sinus node dysfunction (sick sinus syndrome), which either depresses impulse generation or disturbs the conduction of impulses from the sinus node to the atria.[1] In some patients periods of bradycardia and tachycardia alternate (bradycardia-tachycardia syndrome), making management difficult. *Heart block* (AV block) is another cause of bradycardia, and involves disturbance of conduction of the atrial impulse to the ventricles. First-degree block, in which the impulse is delayed, is usually asymptomatic but may progress to second- or third-degree block, with intermittent (second-degree) or complete (third-degree) failure of atrial impulses to reach the ventricles. This usually causes bradycardia since the intrinsic rate of ventricular contraction is slower than that of the atria, but in AV dissociation ventricular activity is faster than, and independent of, the atrial activity.

Tachyarrhythmias may arise in either the atria or the ventricles. The precise mechanism is often unclear, but for many of the clinically important tachyarrhythmias it involves *re-entry*. Impulses normally spread in a single direction and die out once ventricular contraction occurs, but in re-entry the impulse continues to propagate in a cyclical manner, reactivating the heart. Abnormal automaticity and triggered activity are alternative mechanisms that may be involved.

Ectopic beats, *extrasystoles*, or *premature contractions* can arise in either the atria or the ventricles and, although their precise meaning and definition differs, for practical purposes they can be considered equivalent. Generally, they cause few or no symptoms and usually have no prognostic value although some patients suffer distressing symptoms or palpitations.

Diagnosis. The precise identification of an arrhythmia is not always easy, but is important for correct management since inappropriate use of antiarrhythmics may be not only ineffective but actively harmful. Clinical symptoms may be useful, but the mainstay of diagnosis is the electrocardiogram (ECG), which records the electrical rhythm of the heart. A typical normal ECG trace is shown in Figure 2, p.1152. Many arrhythmias have distinctive ECG patterns, but this is not always the case; an arrhythmia with a narrow QRS complex is always supraventricular in origin whereas a broad QRS complex can indicate either a supraventricular or ventricular origin. Other specialised tests and features relevant to the individual arrhythmias may aid diagnosis.

Management. Treatment of arrhythmias may be indicated to relieve symptoms and/or to improve survival and may involve antiarrhythmic drugs (see p.1153 for an explanation of the classification of antiarrhythmics), electrical cardioversion, or cardiac pacing; surgical or catheter ablation of arrhythmic pathways also has an increasingly important role. Drug therapy is mainly used for tachyarrhythmias and these are the focus of the following discussion. For **bradyarrhythmias**, cardiac pacing is the treatment of choice,[1-3] although atropine[2] or sympathomimetics have been used.

Atrial fibrillation is a supraventricular tachyarrhythmia with an underlying mechanism of re-entry. It is the commonest arrhythmia encountered clinically, and has been the subject of reviews[4-11] and guidelines.[12-14] Atrial fibrillation is usually associated with disorders that predispose the atria to re-entry, although it is now recognised that the arrhythmia may start from an ectopic focus, often in the pulmonary vein. The main underlying cardiovascular disorders are ischaemic or hypertensive heart disease and heart failure, and the incidence increases markedly with age. Rheumatic heart disease is also an important cause, although this is now less common in developed countries. Other causes include hyperthyroidism and acute alcohol intoxication. Atrial fibrillation is also relatively common after cardiothoracic surgery, although this is usually self-limiting. In some patients there is no obvious cause ('lone' atrial fibrillation).

Atrial fibrillation is characterised by an irregular and very rapid atrial rate (usually more than 300 beats/minute) and, although the AV node is incapable of conducting all the impulses adequately, the increased ventricular response results in a rapid and totally irregular ventricular rate. Atrial fibrillation has been classified in several ways, but patients with 2 or more episodes are generally considered to have recurrent atrial fibrillation; this may be classed as paroxysmal (intermittent) if the arrhythmia terminates spontaneously, or persistent (chronic) if it is sustained. Persistent atrial fibrillation that does not respond to cardioversion or where cardioversion is not attempted is classed as permanent.

Although atrial fibrillation can cause distressing symptoms such as severe palpitations and exercise intolerance it is not usually immediately life-threatening; however, it does result in long-term morbidity and mortality. The increased rate may lead to tachycardia-induced cardiomyopathy, while left atrial dilatation and reduced cardiac output lead to stasis of blood in the left atrium, which can result in thrombus formation and subsequent systemic embolisation, notably ischaemic stroke. Thromboembolic events are relatively rare in lone atrial fibrillation but the risk is very much increased if other cardiovascular disease is present, especially rheumatic heart disease.

Management of atrial fibrillation aims to control symptoms and prevent long-term morbidity and mortality, including thromboembolic complications. The available approaches are to restore and maintain sinus rhythm (*rhythm control*), or to control the ventricular rate while allowing atrial fibrillation to continue (*rate control*). Use of anticoagulation depends on the risk of thromboembolic events but may be required with either strategy.

- Rate control may be used for both acute management of symptoms and maintenance therapy and generally involves drugs that act on the AV node to slow conduction.[15] Digoxin has traditionally been used, but has a slow onset of action and is not effective during exercise and is no longer considered first-line in most patients. Beta blockers or rate-limiting calcium-channel blockers such as diltiazem or verapamil are usually the preferred treatment; they provide effective rate control, including during exercise, and may be given intravenously when acute control is needed. Digoxin may be used in sedentary patients, and is also useful in patients with heart failure; it is often given with beta blockers or calcium-channel blockers since many patients require more than one drug to maintain an adequate rate. Amiodarone, which has rate-limiting properties as well as an antifibrillatory effect, may be used if symptoms are not controlled with digoxin and beta blockers or calcium-channel blockers; catheter ablation of AV conduction pathways followed by permanent pacing may be necessary in patients intolerant or unresponsive to drug therapy.
- In a rhythm control approach, restoration of sinus rhythm (cardioversion) may be achieved either by synchronised direct current or by drugs, but both methods must be preceded by anticoagulation unless fibrillation is of recent onset (less than 24 hours). Both methods are effective and choice depends on the duration of atrial fibrillation, availability, and preference; direct current cardioversion restores sinus rhythm more rapidly and is more effective than pharmacological cardioversion if atrial fibrillation is not of recent onset but has the disadvantage that it needs to be performed under sedation or general anaesthesia. Various drugs have been used but evidence of efficacy is limited in some cases[13,14,16] and adverse effects may be a problem. Flecainide and propafenone are most widely recommended as first-line;[12-14] ibutilide and dofetilide are alternatives.[12,14] Amiodarone may also be used;[12-14] it has a slower onset but is equally effective[17] and is particularly useful in patients with structural heart disease.[13] Evidence is more limited for quinidine, procainamide, disopyramide, and sotalol. Adjunctive pharmacological therapy may be started before electrical cardioversion to increase the success of the procedure and to reduce the risk of early recurrence;[13,14] drugs used include amiodarone, flecainide, ibutilide, propafenone, and sotalol.

  Once sinus rhythm has been achieved, long-term maintenance drug therapy needs to be considered since relapse is common. Patients with a first episode of atrial fibrillation are rarely started on maintenance therapy, particularly if a reversible cause has been identified and can be treated.[13,14] However, patients who have troublesome symptoms due to paroxysmal or recurrent atrial fibrillation are usually given long-term antiarrhythmics. Drugs used are similar to those used for cardioversion, and again there is limited evidence to guide choice.[18] Beta blockers may be tried initially,[13] particularly in patients with lone atrial fibrillation,[14] and they have the advantage of providing rate control if relapse occurs, but flecainide, propafenone, or sotalol are often required. Amiodarone and dofetilide may also be used; amiodarone may be more effective than other antiarrhythmics[19] but its use is limited by long-term adverse effects and it is generally only recommended in resistant cases or in patients with heart failure who are unsuitable for alternative therapy. Catheter ablation procedures (for example, isolation of the pulmonary veins[20]) are an alternative to drugs, and surgery or implantable defibrillators may be used in selected cases. Patients with infrequent episodes of paroxysmal atrial fibrillation and good response to drugs may be prescribed single doses of flecainide or propafenone for outpatient use ('pill-in-the-pocket') if symptoms recur.[13,14,21]

The choice between rate and rhythm control has been debated. Rhythm control has theoretical advantages since restoration of sinus rhythm should both alleviate symptoms and reduce thromboembolic risk. However, the adverse effects and limited efficacy of antiarrhythmic drugs in preventing relapse may limit any benefit. A review[22] and meta-analyses[23,24] of studies comparing rate control with rhythm control found little difference between the two strategies in terms of symptom control or clinical events, and choice therefore depends on patient characteristics and preference.[12-14,25] For elderly patients with minimal symptoms rate control is generally the preferred option, whereas younger patients or those who remain symptomatic despite rate control should be considered for rhythm control.

Prophylaxis of atrial fibrillation may have a role in some situations. Although atrial fibrillation after cardiothoracic surgery is usually self-limiting, it may be associated with increased morbidity and mortality, and prophylaxis should be considered. Beta blockers, amiodarone, and sotalol are effective,[13,14,26,27] and some benefit has also been reported with magnesium[28,29] and corticosteroids.[30] Use of statins[31] or omega-3 fatty acids[32] has also been investigated. For non-surgical patients, there is some evidence of a lower incidence of atrial fibrillation in patients taking drugs affecting the renin-angiotensin system,[33] but the benefit of prophylactic use requires confirmation in controlled studies.

Prevention of thromboembolic events, particularly ischaemic stroke, is a major aspect of atrial fibrillation management and has been the subject of several reviews[34-38] as well as being addressed in the general reviews and guidelines quoted above. Patients are at risk both during cardioversion procedures and long-term, and should be given appropriate antithrombotic therapy. If atrial fibrillation has been present for 48 hours or more it is generally recognised that there is a potential risk of causing systemic embolisation once sinus rhythm is restored. In unstable patients who require immediate cardioversion, intravenous heparin should be given. In more stable patients cardioversion should be delayed until the patient has received adequate anticoagulation with warfarin for 3 to 4 weeks, but if more rapid cardioversion is preferred, intravenous heparin may be started, followed by transoesophageal echocardiography to exclude the presence of thrombi. Control of the ventricular rate as outlined above should be undertaken while the patient is waiting for cardioversion, and oral anticoagulants are usually continued for at least 4 weeks after a successful procedure.[39] There is some evidence[40] that subcutaneous low-molecular weight heparin may be an alternative to intravenous heparin followed by oral anticoagulants when transoesophageal echocardiography is used.

Long-term prophylaxis is indicated in selected patients. The risk of stroke is increased about 17 times in atrial fibrillation associated with rheumatic heart disease and the benefits of long-term prophylaxis with warfarin are well-established. For non-rheumatic heart disease the risk is less, but is still increased by about fivefold and affects many more patients; however, the use of warfarin is more controversial. Meta-analyses have clearly shown that warfarin is effective in the primary[41,42] and secondary[41,43] prevention of stroke in patients with non-rheumatic atrial fibrillation, and cohort studies[44,45] have reported similar findings. Oral anticoagulants are therefore recommended in all patients with atrial fibrillation and a history of stroke or transient ischaemic attack,[13,14,39,46] but for primary prevention the relative risks and benefits are less clear and the decision to treat depends on individual patient factors. Oral anticoagulants are recommended for all patients at high risk of thromboembolism, including older patients and those with ischaemic or hypertensive heart disease, heart failure, hyperthyroidism, or history or evidence of thromboembolism.[39,46] In some patients, alternative strategies may be appropriate. Antiplatelet therapy is widely used and there is good evidence that aspirin reduces the risk of stroke.[47,48] However, antiplatelets are generally considered less effective than warfarin for both primary[41] and secondary prevention,[41,49] and are usually only recommended where the risk of stroke is outweighed by the risk of haemorrhage, or in those who are unwilling or unable to take anticoagulants. Use of low-dose warfarin with aspirin has been shown[50,51] to be less effective than adjusted-dose warfarin and is not recommended, although a study[52] using triflusal and moderate-dose phenprocoumon reported beneficial effects. A study[53] using clopidogrel in addition to aspirin found that the combination was less effective than warfarin.

Atrial flutter is an arrhythmia somewhat similar in nature to atrial fibrillation and has been discussed in reviews[54] and guidelines.[55] Like atrial fibrillation it is characterised by a rapid (about 300 beats/minute) atrial rate, although the atrial rhythm is more regular and organised, and by a corresponding increase in the ventricular rate. It is far less common than atrial fibrillation, to which it often degenerates if left untreated; it may revert to normal sinus rhythm in some cases. Unlike atrial fibrillation, atrial flutter has not been considered to carry an increased risk of thromboembolic episodes, but several studies have suggested this may not be the case.[56-58] Anticoagulation may therefore have a role in patients with recurrent or chronic atrial flutter,[39,54,55] and has been recommended prior to cardioversion.[39,55] Management strategies for atrial flutter are broadly similar to those outlined above for atrial fibrillation, namely controlling the increased ventricular response rate and cardioversion. However, in general terms drug therapy for either of these interventions is less successful in flutter than in fibrillation. Cardioversion with drug therapy has a relatively low success rate and cardiac pacing is usually used, which often results in a self-terminating atrial fibrillation. Synchronised direct current cardioversion may be used to restore sinus rhythm if pacing fails. Radiofrequency ablation may also be used,[55] and may be the treatment of choice if long-term therapy is required.[54]

Other atrial arrhythmias include **atrial premature beats** and various types of **atrial tachycardia**. Premature beats are usually asymptomatic but if symptoms are severe (the awareness of a pause between normal beats) beta blockers may be used.[59] Atrial tachycardia may also be treated with beta blockers or rate-limiting calcium-channel blockers,[55,60,61] but if it is due to digoxin toxicity, withdrawal of digoxin may be all that is required.[55]

Paroxysmal supraventricular tachycardia is a re-entry arrhythmia. The term paroxysmal atrial tachycardia was formerly used, but became obsolete when it was realised that many such arrhythmias arise in the atrioventricular junction rather than in atrial muscle. The re-entry circuit can be either due to an accessory pathway between the atria and ventricles (atrioventricular reciprocating tachycardia; AVRT) or re-entry can occur at the site of the node itself (atrioventricular nodal reciprocating tachycardia; AVNRT). It is a relatively common arrhythmia occurring in otherwise healthy individuals. It may resolve spontaneously, or reflex vagal stimulation by respiratory manoeuvres, prompt squatting, or pressure over one carotid sinus may restore normal sinus rhythm. If symptoms associated with the rapid heart rate are severe, treatment will be needed. For termination of paroxysmal supraventricular tachycardia adenosine given intravenously is often the drug of choice;[55,59,60,62,63] intravenous verapamil or diltiazem, or intravenous beta blockers, are alternatives. If there is no response, or in patients with a wide QRS complex and unclear diagnosis, propafenone, flecainide, procainamide, sotalol, amiodarone, or ibutilide may be used.[55,59,60,63] Direct current cardioversion may be necessary in some cases, particularly in those who are unstable. Long-term maintenance therapy to prevent recurrence is required in some patients, but there is limited evidence to guide choice of therapy.[55] For many patients radiofrequency catheter ablation is the preferred treatment, particularly in those with AVRT and an accessory pathway. Alternatively, pharmacological therapy may be used. Drugs that block AV conduction are first-line and include beta blockers, rate-limiting calcium-channel blockers, and digoxin. Flecainide and propafenone, class Ic drugs that act on atrial refractoriness, may be used if first-line drugs are ineffective; amiodarone is generally preferred if patients have structural heart disease. Other drugs that may be used include sotalol, quinidine, procainamide, and dofetilide.

Wolff-Parkinson-White syndrome[64] is a congenital abnormality characterised by an accessory atrioventricular conduction pathway known as a Kent bundle that leads to ventricular pre-excitation. Although many patients remain asymptomatic, there is an increased risk of atrial fibrillation or paroxysmal supraventricular tachycardia with a danger of degeneration into ventricular fibrillation, particularly if AV-blocking drugs are used. Antiarrhythmics should be used with great caution in such patients, and catheter ablation of the accessory pathway is the treatment of choice.[55,63]

Supraventricular tachycardia can occur rarely *in utero* and is associated with hydrops fetalis and perinatal mortality and morbidity. Treatment is with antiarrhythmic drugs such as digoxin, flecainide, sotalol, or amiodarone given to the mother (transplacental therapy).[61,65,66] In resistant cases direct intraperitoneal or intravascular dosage to the fetus may be necessary.

Ventricular tachycardia[67-70] is usually a re-entry arrhythmia and is often associated with underlying cardiovascular disease such as myocardial infarction or cardiomyopathies. It may also be caused by drugs that prolong the QT interval, or by digoxin toxicity. Congenital channelopathies such as Brugada syndrome[71] and long QT syndrome may cause ventricular arrhythmias in patients with structurally normal hearts. The heart rate is about 120 to 250 beats/minute and the tachycardia, which arises in the ventricles below the AV node, can be paroxysmal, consisting of short self-terminating episodes, or can be sustained (lasting 30 seconds or longer). Ventricular tachycardia can be asymptomatic (if the episodes are non-sustained) or cause minimal symptoms such as palpitations, but is potentially a serious condition which may lead to reduced cardiac output, shock, and progression to **ventricular fibrillation** and cardiac arrest. It is one of the most common causes of sudden unexplained cardiac death.[72] The ECG trace of ventricular tachycardia may be confused with that of supraventricular tachycardia but since the treatments differ markedly, every effort should be made to obtain the correct diagnosis; if the diagnosis is unclear the patient should be treated for ventricular tachycardia.[2,55]

The *initial treatment* of ventricular tachycardia depends largely on the haemodynamic status of the patient. Unstable patients with ventricular fibrillation or pulseless ventricular tachycardia, and patients with irregular sustained ventricular tachycardia, should be given defibrillation, as outlined under Advanced Cardiac Life Support (p.1156). More stable patients with regular monomorphic ventricular tachycardia may be treated with intravenous antiarrhythmics or by sedation and direct current cardioversion; pacing may be effective in some patients. Amiodarone is widely recommended;[2,73,74] procainamide is an alternative[2,73] and may be preferred if a rapid effect is required.[74] Sotalol may also be used, and lidocaine (which was previously the drug of choice) may have a role in some patients, although it is generally less effective. Other alternatives that are available in some countries include ajmaline, flecainide, and propafenone. In some patients with non-sustained ventricular tachycardia, beta blockers may be effective; catheter ablation may have a role if termination of the arrhythmia is not urgent.[74]

After restoration of normal sinus rhythm *maintenance therapy* needs to be considered. Long-term treatment is generally not warranted in low risk patients such as those who have experienced asymptomatic non-sustained ventricular tachycardia, but patients with severe symptoms or those at high risk of sudden cardiac death, such as survivors of ventricular fibrillation and pulseless ventricular tachycardia, require treatment. Although antiarrhythmic drugs have been used, studies have shown that implantable cardioverter defibrillators reduce mortality more effectively, and these are now recommended for most patients.[74-76] Beta blockers are also effective and may be used,[74] but there is little evidence to support the use of other drugs, even when electrophysiological testing is used, and this is no longer generally recommended. Sotalol, or amiodarone with a beta blocker, may have a role if implantable cardioverter defibrillators are considered inappropriate, or to prevent frequent device activation in patients with implantable cardioverter defibrillators and recurrent arrhythmias.[74,77] There is also some evidence that drugs that are beneficial for cardiovascular risk reduction may reduce the risk of ventricular arrhythmias, including ACE inhibitors and omega-3 fatty acids, but their role is not yet established.[74]

Myocardial infarction is a particular risk factor for ventricular arrhythmias and prophylactic treatment has therefore been tried. Arrhythmias are particularly common early after acute myocardial infarction and lidocaine has been used prophylactically; however, there is little evidence of benefit and routine use is no longer recommended.[78,79] Implantable cardioverter defibrillators may be used for primary prevention of sudden cardiac death in patients with evidence of sustained ventricular tachycardia more than 48 hours after acute myocardial infarction, particularly in patients who also have heart failure; beta blockers,[80,81] amiodarone,[82] or sotalol, may also be considered. Patients with asymptomatic ventricular arrhythmias may also be at increased risk of sudden death but use of antiarrhythmic drugs increases mortality[80,81,83] and is not advised.

Primary prophylaxis may also have a role in other cardiac disorders that are known to cause ventricular arrhythmias and sudden cardiac death, including heart failure, cardiomyopathies, and Brugada syndrome or similar congenital disorders. Implantable cardioverter defibrillators are recommended in high risk patients; beta blockers and amiodarone may have a role in specific cases.[74]

QT prolongation and drug-induced arrhythmias. Antiarrhythmic drugs also have proarrhythmic properties and may exacerbate or induce arrhythmias of all kinds, and non-cardiac drugs may also have proarrhythmic effects. *Torsade de pointes* is a particularly serious ventricular arrhythmia that is often drug-induced. It is associated with prolongation of the QT interval (prolongation of ventricular repolarisation), which allows afterdepolarisations to trigger a re-entry tachycardia; this is often non-sustained, but may persist for long enough to cause syncope or it may even progress to ventricular fibrillation. Drugs that cause QT prolongation include antiarrhythmics and several non-cardiac drugs[84-89] including phenothiazines, tricyclic antidepressants, antihistamines such as astemizole and terfenadine, antibacterials such as erythromycin, the antimalarial halofantrine, and the lipid lowering drug probucol. Patients with congenital channelopathies may also have QT prolongation and develop torsade de pointes, often in response to stress- or exercise-induced tachycardia; other causes include electrolyte disorders and bradycardia. If torsade de pointes is drug-induced, withdrawal and subsequent avoidance of the offending drug is mandatory. Initial therapy is usually with intravenous magnesium, to correct any contributory magnesium deficiency, with temporary pacing of the atria or ventricles and correction of any other electrolyte disorders as appropriate. Isoprenaline has been given cautiously to increase the heart rate and shorten the QT interval, until pacing is instituted. Congenital long QT syndromes are usually treated with beta blockers and/or pacing.[84,85]

Cardiomyopathies

Cardiomyopathy is a term used to describe diseases of the heart muscle associated with cardiac dysfunction. Although formerly used to describe conditions with an unknown cause (idiopathic), increased awareness of disease mechanisms and genetic factors has broadened the definition. Cardiomyopathies may develop as a consequence of other cardiovascular or systemic disorders, such as systemic or pulmonary hypertension, ischaemic heart disease, valvular heart disease, congenital abnormalities, metabolic disorders, inflammatory or infectious diseases, and drug-induced conditions. Primary cardiomyopathies (those affecting only or predominantly the heart muscle) have usually been divided into 3 distinct types namely dilated cardiomyopathy, hypertrophic cardiomyopathy, and restrictive cardiomyopathy; the dilated and hypertrophic forms are the two major types. Other forms identified more recently, such as arrhythmogenic right ventricular cardiomyopathy, do not fit readily into this classification and differentiation based on genetic or non-genetic origin may now be preferred.[1] The management of the individual forms has been reviewed.[2-15]

In **dilated cardiomyopathy** (previously known as congestive cardiomyopathy) the main finding is systolic dysfunction with dilated and poorly contracting ventricles and a low cardiac output. The right, left, or both ventricles may be affected. Although there may be some ventricular hypertrophy, because of the dilatation there is no overall increase in the thickness of the ventricle walls. Dilated cardiomyopathy may be asymptomatic for some time but the initial manifestations are commonly those of heart failure; chest pain, systemic and pulmonary embolism, and arrhythmias may also occur. Management should generally follow the conventional strategies for heart failure (see p.1165), including ACE inhibitors, diuretics, and beta blockers. Early studies[16-18] with beta blockers in patients with dilated cardiomyopathy found significant improvements in cardiac function and symptoms, together with prevention of clinical deterioration, but failed to show a significant effect on overall mortality. However, a further trial evaluating carvedilol therapy in patients with heart failure, including patients with dilated cardiomyopathy, was terminated early because mortality was significantly reduced in the carvedilol groups[19] and the CIBIS-II trial[20] using bisoprolol was also terminated early because of favourable results. A further long-term study[21] using metoprolol has also reported a significantly higher survival rate in those taking metoprolol for up to 7 years. Although calcium-channel blockers are not usually used in heart failure, symptomatic improvement has also been reported with the calcium-channel blocker diltiazem.[22]

Patients with dilated cardiomyopathy may be at particular risk for systemic or pulmonary thromboembolism, due to blood stasis in the poorly contracting ventricle. Chronic oral anticoagulation has therefore been suggested, although current recommendations generally limit its use to those with atrial fibrillation, previous systemic embolism, or severe left ventricular dysfunction.[2,23] Arrhythmias should be treated as appropriate (see Cardiac Arrhythmias, p.1160); amiodarone may be particularly suitable as it has no negative inotropic effect. Low-dose amiodarone has been tried in patients at high risk of sudden death, but its role has not yet been confirmed.[2,8]

Surgical treatments that restore ventricular shape and function have been tried but cardiac transplantation remains the main method of improving survival in these patients. Other therapies that have been tried include growth hormone, levothyroxine, pentoxifylline, levocarnitine, and immunosuppressants for presumed myocarditis.

In **hypertrophic cardiomyopathy** (previously known as obstructive cardiomyopathy) there is, as the name implies, ventricular hypertrophy but the ventricles are not dilated. This leads to diastolic dysfunction since diastolic filling is impaired by the stiff hypertrophied ventricular walls. It is an inherited condition occurring as an autosomal dominant trait and can occur at any age although presentation during the second decade of life is common. Patients may be asymptomatic or may experience chest pain, syncope, dyspnoea, or arrhythmias. Sudden death associated with emotional stress or exercise is not an uncommon finding and patients should avoid intense exercise. However, overall life expectancy is similar to that of the general population and many patients have little or no disability and do not require treatment.[5,11]

Patients should be investigated for the presence of any arrhythmias and treated appropriately (see Cardiac Arrhythmias, p.1160) although this may not necessarily prevent sudden death. Atrial fibrillation is particularly important and is probably most effectively treated with amiodarone.[4,5,11-13] Anticoagulation should be considered in all patients with sustained atrial fibrillation.[4,5,11-13]

Beta blockers may be used for control of symptoms. They curtail emotion- or exercise-induced tachycardia. Anginal pain is also reduced and syncopal attacks may be prevented. Calcium-channel blockers (usually verapamil) also improve symptoms and exercise tolerance and may be considered in those who continue to have disabling symptoms or who are unable to tolerate beta blockers; however, verapamil may have adverse effects in patients with outflow obstruction and it should be used with caution in such patients.[9-13] In a crossover study,[24] exercise capacity was not improved by either verapamil or nadolol, although most patients preferred one or other of the drugs rather than placebo and quality of life did appear to be improved by verapamil. Other drugs that may provide symptomatic relief include disopyramide, which is used for its negative inotropic effect and is often given with beta blockers. Diuretics may be needed for congestive symptoms but may also reduce cardiac output. Surgery or septal ablation to reduce outflow obstruction may be of benefit in some patients whose symptoms are resistant to drug therapy.[4,5,9-13]

The risk of sudden death is difficult to assess, particularly in asymptomatic patients. Neither beta blockers nor verapamil, as used for possible symptomatic relief, prevent ventricular arrhythmias. However, there is some evidence[25] that high-dose therapy with beta blockers may improve survival in children with hypertrophic cardiomyopathy. Low-dose amiodarone may have a role in high risk patients, but adverse effects may limit its use;[9,11] implantable cardioverter-defibrillators are also used in some patients.[11-13,26]

In **restrictive cardiomyopathy** the filling of the ventricles is impaired, often due to endomyocardial fibrosis, resulting in mostly diastolic dysfunction. Diuretics may improve congestive symptoms but should be used cautiously as they may decrease cardiac output. Arrhythmias should be treated if they are symptomatic and anticoagulation is advised, particularly in patients with atrial fibrillation, valvular disorders, or a low cardiac output.[6]

Management of **arrhythmogenic right ventricular cardiomyopathy** may involve implantation of a defibrillator, the use of antiarrhythmic drugs (notably sotalol), or catheter ablation.[27-30]

Cardiovascular risk reduction

Atherosclerotic cardiovascular disease includes ischaemic (coronary) heart disease (myocardial infarction and angina pectoris), ischaemic stroke, and peripheral vascular disease. Ischaemic heart disease, in particular, is a major cause of mortality in developed countries, and cardiovascular disease overall is associated with considerable morbidity. The benefits of a number of interventions are well established in patients at high risk of cardiovascular disease, and identification and treatment of such people is therefore an important healthcare strategy.[1-6]

Overall cardiovascular risk depends on a number of factors. Those who are at the highest risk are those with manifestations of atherosclerosis, particularly those who have already had a cardiovascular event such as a myocardial infarction or ischaemic stroke, but also those with symptoms of angina or peripheral vascular disease. The major modifiable risk factors identified through epidemiological studies are tobacco smoking, raised blood pressure, and raised blood-lipid concentrations;[7,8] other established risk factors include age, sex, left ventricular hypertrophy, and family history. Diabetics are also at considerable risk of ischaemic heart disease, even when treated, and aggressive therapy to reduce risk may be appropriate. Obesity, lack of exercise, abnormal blood clotting profile, and hyperhomocysteinaemia have also been associated with increased risk, although their relevance is less established;[9] psychosocial factors may also be involved.[10] Patients with abdominal obesity, hypertension, dyslipidaemia, and glucose intolerance are considered to have the **metabolic syndrome**, and are at increased risk of both cardiovascular disease and diabetes mellitus.[11-13]

The aim of cardiovascular risk reduction is to prevent clinical events occurring by abolishing or reducing any modifiable risk factors that are present. This requires both individual intervention, to identify and treat those at high risk, and also a population approach based on general health promotion and education to reduce the overall levels of risk factors in the general populace. Guidelines[1,3-6] have been published for identification and management at the individual level, including specific guidelines for women[14] and the elderly.[15] Since atheroma development may begin in childhood, approaches to risk reduction should also be considered from an early age,[16] especially in those at high risk.[17]

Lifestyle and dietary modifications are the mainstay of risk reduction, particularly at a population level, and include advice not to smoke, avoidance of obesity, increased exercise, moderation of alcohol intake, and a diet that is low in saturated fat and high in fruit, vegetables, and fish.[1,3-6,18-21] In unselected populations, these efforts probably produce only modest changes in risk factors,[22,23] and while the incidence of ischaemic heart disease is falling in many populations, the WHO MONICA project (Monitoring the Trends and Determinants in Cardiovascular Diseases) found only a weak association between changes in classic risk factors and changes in event rates.[24] In individuals with established modifiable risk factors, drug treatment may also be required. Smoking cessation should be encouraged in all smokers, and specific strategies are discussed on p.2354. Influenza vaccination may reduce the risk of cardiovascular events and has been recommended.[25] Treatment of hypertension and hyperlipidaemias depends on their severity and the patient's overall risk and is discussed under the individual diseases (see p.1171 and p.1169, respectively). Assessment of risk is a complex procedure and risk and treatment tables are available to aid decisions about when to start therapy in patients without established cardiovascular disease.[3,4] Guidelines differ as to the level of risk at which treatment should start; this is a matter of judgement and may depend on economic factors and the balance between benefit and risk of adverse effects in otherwise healthy people. Tight control of blood glucose is important in diabetic patients (see Diabetic Complications, p.433). Other interventions that may be of benefit in some individuals include antiplatelet therapy, reduction of lipids in those with normal lipid concentrations, and ACE inhibitors.

Antiplatelet therapy has been investigated for primary and secondary prevention of various cardiovascular disorders. Numerous studies[26] have established that antiplatelet therapy reduces the risk of subsequent cardiovascular events but that the risk of bleeding is increased, and absolute benefit therefore depends on the individual level of risk. In patients with a previous vascular event, the use of antiplatelet drugs for secondary prevention is well established.[3-6] Aspirin, given in the acute phase and continued long-term, reduces the risk of re-infarction and death after myocardial infarction and should be given indefinitely.[26] Long-term prophylaxis with aspirin also reduces the risk of future serious vascular events, including stroke, in patients who have suffered an ischaemic stroke or transient ischaemic attack,[26-28] regardless of age.[29] A number of studies also support the benefits of antiplatelet drugs for primary prevention of cardiovascular events in individuals at high risk. Aspirin may reduce the risk of first myocardial infarction in patients with stable chronic angina.[30] The Thrombosis Prevention Trial[31] in males at high risk of developing occlusive vascular disease and the Hypertension Optimal Treatment (HOT) trial[32] in hypertensive patients have, more recently, confirmed that aspirin reduces the incidence of myocardial infarction in these at-risk groups, although both studies reported little or no effect on the overall incidence of stroke. The Primary Prevention Project,[33] a study in patients with at least one major risk factor, showed a reduction in cardiovascular mortality and in a composite of cardiovascular events including death, myocardial infarction, and stroke.

Primary prevention in healthy individuals is more controversial, and studies have produced conflicting results. A study in healthy male physicians in the UK[34] found no reduction in the incidence of fatal and non-fatal myocardial infarction in those who had taken aspirin, while a similar study in the US[35] showed a reduction in subjects 50 years of age or older; both showed a slight non-significant increase in the number of disabling strokes which, in the US study, were attributed to cerebral haemorrhage. In women, a large observational study in healthy US nurses[36] indicated that aspirin might reduce the risk of first myocardial infarction, but a randomised trial[37] found no effect on either myocardial infarction or death, although the incidence of stroke was reduced. Meta-analyses[26,38,39] have generally concluded that for most healthy individuals, aspirin therapy is inappropriate.

Aspirin has been the most widely studied antiplatelet drug and appears to be effective over a range of doses (see p.24); however, some patients are resistant to its effects and remain at high risk for cardiovascular events.[40] Other drugs may be used in those intolerant of aspirin, and combination therapy may also be considered. In the CAPRIE study,[41] clopidogrel was shown to be at least as effective as aspirin in reducing cardiovascular events, including myocardial infarction and stroke, in individuals at high risk. In patients with ischaemic stroke, dipyridamole, given alone or with aspirin, is effective for secondary prevention,[42] but use of clopidogrel with aspirin increases the risk of bleeding without reducing the risk of ischaemic events.[43] Clopidogrel with aspirin is of benefit in patients with acute coronary syndromes, but in patients with high cardiovascular risk who do not present acutely the increased bleeding risk appears to outweigh any benefit.[44] ***Oral anticoagulants*** may be more effective than antiplatelet therapy but the risk of bleeding is increased,[31,45] and they are generally only recommended in patients unable to take antiplatelet drugs or in whom they are ineffective. Addition of antiplatelet drugs in patients taking oral anticoagulants for other indications only appears to be beneficial in those with mechanical heart valves.[46]

Lipid lowering therapy has an established role in cardiovascular risk reduction, and the benefits of statins, in particular, have been demonstrated in a wide range of patients. Meta-analyses[47-52] have shown that statins improve outcomes when used for primary or secondary prevention, and that this includes patients with raised or average cholesterol concentrations, women, and older individuals. The absolute benefit depends on the patient's initial cardiovascular risk and the degree of cholesterol reduction achieved,[51] and increased benefit has been reported[53-55] with the use of intensive lipid lowering regimens. Although most recent studies have used statins, fibrates[56] and other lipid lowering drugs may also be effective; beneficial effects for secondary prevention of ischaemic heart disease have been reported for gemfibrozil[57] in men whose primary lipid abnormality was a low HDL-cholesterol level, and for omega-3 marine triglycerides[58] in a Mediterranean population.

There has been concern that there might be an association between low cholesterol concentrations and increased morbidity and mortality from non-cardiac causes including haemorrhagic stroke, cancer, accidents and suicide, and chronic respiratory, liver, and bowel disease.[59-64] Although controlled studies suggest that the risk of haemorrhagic stroke may be increased,[65] meta-analyses have shown that statin therapy reduces both cardiovascular and all-cause mortality,[47,50,51] and that there is no significant increase in non-illness mortality.[66]

The use of ***ACE inhibitors*** has mainly been investigated in individuals with established cardiovascular disease. Studies[67,68] in patients with heart failure suggested that ACE inhibitors also reduced the risk of myocardial infarction, while in the HOPE study,[69] treatment with ramipril significantly reduced the rate of death, myocardial infarction, and stroke in patients at high risk for cardiovascular disease. A reduction in cardiovascular events was also found[70] in patients with stable ischaemic heart disease given perindopril, but not in a trial using trandolapril;[71] the authors suggested that patients in the trandolapril trial may have been at lower risk due to intensive treatment of other risk factors.

The main benefit seen with ACE inhibitors is due to the reduction in blood pressure they cause, but blockade of the renin-angiotensin system may also have other beneficial effects.[72] A study[73] using perindopril, alone or with a diuretic, found that the risk of recurrent stroke was reduced in patients with a history of stroke or transient ischaemic attack, irrespective of whether they had normal or raised blood pressure at study entry. However, a study[74] using enalapril in patients with ischaemic heart disease and normal blood pressure found no significant effect on cardiovascular events and no benefit when compared with amlodipine. ***Angiotensin II receptor antagonists*** have been tried as an alternative to ACE inhibitors; a study[75] comparing losartan with a beta blocker in hypertensive patients with left ventricular hypertrophy found that there was a greater reduction in cardiovascular events with losartan despite a similar effect on blood pressure.

Women have a lower risk of atherosclerotic disease than men of a comparable age, although the difference narrows with increasing age postmenopausally, and the use of ***HRT*** has therefore been investigated. Some epidemiological studies have suggested that HRT lowers the risk of cardiovascular events, although other studies have produced conflicting results (see p.2076). However, randomised trials have failed to confirm a beneficial effect on clinical events[76,77] and HRT is no longer recommended[14] for either the primary or secondary prevention of cardiovascular disease in women.

Specific interventions to reduce the progression of atherosclerosis are discussed on p.1159.

Cerebrovascular disease

The term 'cerebrovascular disease' may cover disorders of the cerebral circulation such as ischaemic stroke and subarachnoid haemorrhage (see Stroke, p.1185), but is often used to cover the rather vague concept of cerebrovascular insufficiency.

At one time it was believed that the dementia associated with Alzheimer's disease (p.362) was due to cerebrovascular insufficiency and many drugs with vasodilator activity have been tried, but overall there is little convincing evidence of benefit.[1] Ergot derivatives such as codergocrine mesilate and nicergoline have been commonly used; however, any effectiveness is now attributed to their action as metabolic enhancers or nootropic drugs rather than to vasodilatation and their place in therapy has still to be established. The calcium-channel blocker nimodipine has shown benefit in some patients with dementia. Other vasodilators used have included buflomedil, cyclandelate, isoxsuprine, naftidrofuryl, pentoxifylline, and propentofylline.

Heart failure

Heart failure is a clinical diagnosis made in a patient with a known or suspected cardiac disorder who presents with dyspnoea, fatigue, and oedema (peripheral and/or pulmonary). It may be graded as mild, moderate, or severe depending upon whether symptoms such as dyspnoea and fatigue appear on ordinary physical exertion, on little exertion, or at rest, respectively. Another grading system (that of the New York Heart Association) has four grades (NYHA grades I, II, III, IV), again partly classified on appearance of symptoms in relation to exertion (with grade IV representing the most severe form). The discussion that follows focuses on the chronic form of heart failure; acute heart failure, which may result in cardiogenic shock, is covered under Shock, p.1183.

Heart failure is a common condition[1] and is a consequence of abnormalities in cardiac structure or function. It may result from disorders or diseases of the heart muscle, injury, or cardiovascular stress such as hypertension or valve disorders. Myocardial infarction is one of the leading causes of heart failure, and chronic myocardial ischaemia may also be a contributing factor. Cardiomyopathies, cor pulmonale, infections causing myocardial damage, and cardiotoxicity arising from alcoholism or induced by drugs may also lead to heart failure. The increased demands put on the heart by chronic severe anaemia or hyperthyroidism can also be precipitating factors.

Traditionally, heart failure has been thought of in purely haemodynamic terms, as a condition in which the heart is unable to provide an adequate blood flow to meet the metabolic demands of the body. However, it is now appreciated that compensatory neurohormonal mechanisms play just as important a role in its development.[2-4] Echocardiography, the most useful investigative procedure in patients with heart failure, assesses haemodynamic factors; it allows assessment of ventricular function and ejection fraction, enables structural changes to be observed, and rapidly identifies patients with potentially correctable abnormalities such as valvular disease. Measurement of blood concentrations of brain natriuretic peptide has been suggested as another useful investigation;[5-8] this relates to the neurohormonal mechanisms involved.

Echocardiography may identify dysfunction of either the right or left ventricle (right- or left-sided heart failure), although dysfunction of both ventricles is likely to be present to some extent. In most patients, the predominant finding is that of a dilated and poorly contracting left ventricle, with a reduction in both ventricular ejection fraction and cardiac output. This represents left ventricular systolic dysfunction, and is particularly common in patients with heart failure after myocardial infarction. Patients with symptoms of heart failure but a preserved left ventricular ejection fraction are often described as having diastolic dysfunction or isolated left ventricular diastolic dysfunction;[9-11] cardiac output is usually normal in such patients, but fails to increase in response to exercise. Diastolic dysfunction is more common in the elderly and also occurs in some cardiomyopathies (see p.1163); many patients have both diastolic and systolic dysfunction. Asymptomatic left ventricular dysfunction has been found in some patients, especially those in the early postmyocardial infarction period, and although these patients are not strictly defined as having heart failure, treatment may be given to prevent the development of full symptomatic disease.

Neurohormonal disturbances both result from, and contribute to, the deterioration in ventricular function.[3,4] Myocardial injury or impairment leads to an inability of the ventricles to empty adequately during systole. The resulting ventricular dilatation increases wall tension and initially leads to an increase in contraction while the decrease in cardiac output and blood pressure results in activation of the sympathetic nervous system, leading to an increase in the force and frequency of contraction. Reduced blood flow to the kidney also leads to activation of the renin-angiotensin-aldosterone system, resulting in vasoconstriction and fluid retention. At the same time, an increase in wall stress also occurs in the atria, leading to secretion of atrial natriuretic peptide; this inhibits the release of noradrenaline but also has direct vasodilator and natriuretic actions that lower the haemodynamic load on the heart. Thus, in the short term, compensation for myocardial injury can occur and cardiac output may be maintained. In the long term, these compensatory haemodynamic and neurohormonal mechanisms become ineffective. Ventricular dilatation progresses, the sympathetic nervous system and renin-angiotensin system are persistently activated, ventricular hypertrophy occurs, and ventricular function deteriorates progressively.

Management. Heart failure is a progressively disabling condition associated with considerable morbidity and mortality. Management is aimed therefore not only at providing symptomatic relief, but also at improving prognosis, in terms of both progression and mortality. Reviews[6,12-18] and guidelines[5,7,8] about management have been published; these are generally specific to heart failure due to left ventricular systolic dysfunction. The management of patients with preserved left ventricular ejection fraction, or diastolic dysfunction, is less clear.[8-11,19] In theory, this should differ from systolic dysfunction, but few trials have specifically studied such patients. While many of the early drug trials were based on a clinical diagnosis of heart failure and may have included patients with diastolic dysfunction, therapy for such patients is not established and the following discussion is specific for patients with systolic dysfunction unless stated otherwise.

Treatment involves non-pharmacological and pharmacological interventions. Any underlying cause or exacerbating factors should be corrected, and several general measures may be beneficial. Weight reduction should be attempted in the overweight and moderate salt restriction may be undertaken. In acute heart failure bed rest may become necessary, but in controlled chronic heart failure exercise should be encouraged and specific exercise programmes may be of benefit.[5,8,20,21] Immunisation with influenza and pneumococcal vaccines is advised.[5,7,8,19] Anaemia may be both a cause and a consequence of heart failure and should be treated appropriately (see p.1042). Drug therapy of heart failure is based on the use of diuretics, ACE inhibitors or angiotensin II receptor antagonists, and beta blockers; aldosterone antagonists, cardiac glycosides, and vasodilators may also be used. Surgical interventions and implantable devices may have a role in selected patients.

Diuretics have been the mainstay in the treatment of heart failure, and continue to have an important role. They provide very effective symptomatic control in patients with peripheral or pulmonary oedema and rapidly relieve dyspnoea. If symptoms of fluid retention are only mild, a *thiazide diuretic*, such as *bendroflumethiazide* or *hydrochlorothiazide*, may be adequate. However, in most cases, especially in moderate or severe fluid retention, a *loop diuretic* such as *furosemide* will be necessary. Combination treatment with diuretics that behave synergistically by acting at different sites (the principle of sequential nephron blockade) may be needed in some patients, especially when there is diuretic resistance.[22] A loop diuretic with either a thiazide or *metolazone* is often used,[5,7,19] but severe fluid and electrolyte disturbances may occur, particularly with metolazone; loop diuretics with potassium-sparing diuretics have also been used[7] but should be reserved for patients with hypokalaemia. *Spironolactone* is an aldosterone antagonist and has diuretic and possibly additional effects, as discussed below.

However, diuretics are not a sufficient treatment on their own as clinical stability tends to deteriorate over time. In addition, although a meta-analysis[23] has suggested that diuretics have beneficial effects on symptoms and mortality, there have been no long-term trials assessing the effect of diuretics on prognosis, and drugs that have been shown to have a mortality benefit are also required.

At all stages of chronic heart failure, ***ACE inhibitors*** given orally produce additional clinical benefit to that seen with diuretics. They relieve symptoms such as dyspnoea and improve exercise tolerance. Studies have also shown that ACE inhibitors improve survival and reduce the progression of mild or moderate heart failure to more severe stages.[24] ACE inhibitors may also be beneficial in asymptomatic left ventricular dysfunction.[25] The Studies of Left Ventricular Dysfunction (SOLVD)[26] trials indicated that ACE inhibitors, in this case enalapril, might protect against myocardial infarction, unstable angina, and cardiac death in patients with either symptomatic or asymptomatic heart failure. ACE inhibitors are therefore now recommended[7,8,19] in all patients with symptomatic heart failure due to left ventricular systolic dysfunction, including those whose symptoms are controlled with diuretic therapy. Some guidelines[7,8,19] recommend that ACE inhibitors should be given to all patients with significantly reduced left ventricular ejection fraction, whether or not they have symptoms. Where tolerated, doses should be titrated to those found to be effective in randomised trials, rather than according to symptomatic response.

ACE inhibitors have also been given to patients shortly after suffering myocardial infarction (p.1175) but before the development of symptomatic heart failure and appear to be beneficial. However, it is not yet clear which patients should be given such therapy or when it should be started.

The precise mode of action of ACE inhibitors in heart failure is not completely understood but appears to be a result of both haemodynamic and neurohormonal mechanisms. They are vasodilators and cause both arteriolar and venous dilatation, mainly through reduction of angiotensin II formation. They also attenuate the ventricular dilatation and prevent the ventricular remodelling that develops after a myocardial injury. It has also been suggested that they may protect against the development of arrhythmias,[27] although this has not been confirmed.[28]

Angiotensin II receptor antagonists have been investigated both as alternatives to ACE inhibitors, and also with ACE inhibitors to provide more complete blockade of the renin-angiotensin system. Although an early study[29] suggested that *losartan* improved mortality compared with enalapril, this was not confirmed in the larger ELITE II study,[30] although losartan was found to be better tolerated. Studies with losartan[31] and *valsartan*[32] in patients with heart failure after myocardial infarction also failed to show superiority over ACE inhibitors. However, there were generally fewer adverse effects with angiotensin II receptor antagonists, and a further study[33] found that *candesartan* was of benefit in patients who could not take ACE inhibitors. Guidelines therefore continue to recommend ACE inhibitors as first-line therapy, with angiotensin II receptor antagonists as an alternative, particularly in those unable to tolerate ACE inhibitors.

Dual inhibition of the renin-angiotensin system using ACE inhibitors and angiotensin II receptor antagonists together may be of benefit; both candesartan[34] and valsartan[35] have been shown to reduce hospitalisation for heart failure when added to ACE inhibitors, although the effects on mortality are unclear. Although one study[35] suggested detrimental effects in patients who were also taking beta blockers, this has not been confirmed. Use of ACE inhibitors and angiotensin II receptor antagonists together may therefore be considered in patients who remain symptomatic despite standard therapy, including patients receiving beta blockers.[7,8,19]

Beta blockers have negative inotropic properties and have generally been contra-indicated in patients with heart failure. However, persistent activation of the sympathetic nervous system is associated with disease progression and the benefit of beta blockers in the long-term management of heart failure is now established.[36-39] It is not clear whether all beta blockers are equally effective.[40] *Bisoprolol*, *carvedilol*, and *metoprolol* have shown positive effects on mortality and morbidity in patients with varying degrees of heart failure and are acceptable therapy, although a meta-analysis[41] in patients with mild to moderate heart failure has suggested that vasodilating beta blockers such as carvedilol have a greater effect on overall mortality than those that do not produce vasodilatation. A large study[42] comparing carvedilol with metoprolol also found a greater mortality reduction with carvedilol, although the equivalence of the doses used in the study has been questioned.[43] Another beta blocker with vasodilator properties, *nebivolol*, has shown benefit in elderly patients with heart failure.[44] The role of beta blockers in severe heart failure is less established; a study with *bucindolol*[45] was stopped early because no mortality benefit was found, although carvedilol was found to reduce mortality in a similar study.[46] Beta blockers are now recommended[5,7,8,19] in all patients with clinically stable heart failure due to left ventricular systolic dysfunction and should be given with ACE inhibitors and diuretics. They must be introduced cautiously since symptoms may initially worsen, but if tolerated the doses should then be titrated to those found to be effective in randomised trials. Beta blockers also appear to be of value in heart failure due to idiopathic dilated cardiomyopathy (see Cardiomyopathies, p.1163) and possibly in isolated diastolic dysfunction.

Although the precise neurohormonal mechanisms leading to the development of heart failure are still not clear, there is evidence that raised levels of aldosterone may contribute to the pathophysiology.[47] ACE inhibitor therapy suppresses aldosterone production but this effect is not complete and ***aldosterone antagonists*** have therefore been studied in combination with ACE inhibitors. In patients with severe heart failure, addition of low-dose *spironolactone* to ACE inhibitors and loop diuretics reduced the risk of death or hospitalisation.[48] Another aldosterone antagonist, *eplerenone*, has shown benefit[49] in patients with heart failure after myocardial infarction. Guidelines[7,8,19] therefore recommend that aldosterone antagonists may be added to standard therapy in patients with severe heart failure, and in patients with heart failure after myocardial infarction. In patients with less severe heart failure, their role remains to be established, although a small study[50] has suggested that spironolactone may be of benefit. However, adverse effects may limit use, and all patients taking spironolactone with ACE inhibitors must have their plasma-potassium concentrations closely monitored.

Cardiac glycosides such as *digoxin* or *digitoxin* have an extremely long history in the management of heart failure. They are positive inotropes and increase the contractility of the heart thereby increasing cardiac output. Additional effects in heart failure appear to be due to neuroendocrine suppression such as inhibition of the sympathetic nervous system and indirect arterial vasodilatation.

The benefit of cardiac glycosides in heart failure accompanied by atrial fibrillation is not disputed although beta blockers are generally preferred. However, their role in patients with sinus rhythm has been debated. There is evidence that withdrawal of digoxin from patients taking diuretics (the PROVED trial)[51] or ACE inhibitors (the RADIANCE study)[52] carries a considerable risk of clinical deterioration, and patients stable on such combinations should therefore be continued on them. However, the large DIG study[53] found that, while addition of digoxin to diuretics and ACE inhibitors improved symptoms, there was no effect on mortality, and a systematic review[54] came to a similar conclusion. The role of digoxin therefore appears to be limited, although it may be used in patients who remain symptomatic despite ACE inhibitor, diuretic, and beta-blocker therapy.[5,7,8,19]

Various ***vasodilators*** have been studied in heart failure. There appears to be no specific role for direct-acting vasodilators, but some benefit has been reported with a combination of *isosorbide dinitrate* and *hydralazine*. The rationale for using them together has been that nitrates produce a predominantly venous dilatation whereas hydralazine produces arterial vasodilatation, although other mechanisms may also be involved. Used together, they alleviate peripheral vasoconstriction and produce symptomatic control, including a benefit on exercise tolerance, but are of somewhat limited efficacy in long-term control. A modest improvement in long-term survival has been noted but this effect is less than that seen with ACE inhibitors. Subgroup analysis suggested that the effect might be greater in black patients, and a later study[55] in black patients found that addition of isosorbide dinitrate and hydralazine to standard therapy improved both morbidity and mortality. Use of isosorbide dinitrate with hydralazine may be considered in patients with left ventricular dysfunction who are unable to tolerate ACE inhibitors or angiotensin II receptor antagonists;[8] they may also be used as adjuncts in patients who remain symptomatic despite therapy with ACE inhibitors, diuretics, beta blockers, and digoxin.

Calcium-channel blockers, like beta blockers, have generally been contra-indicated in heart failure because of their negative inotropic activity. Despite this, their use as adjuncts has been investigated but studies have failed to show any additional benefit in patients given standard therapy for heart failure. However, in both the PRAISE study[56] (using *amlodipine*) and the V-HeFT III study[57] (using *felodipine*), no adverse effect on morbidity or mortality was found. Amlodipine or felodipine might therefore be suitable as a treatment for angina or hypertension in patients with heart failure, although experience is limited with felodipine in severe heart failure.

Phosphodiesterase inhibitors act as both positive inotropes and vasodilators, a combination of mechanisms that appears particularly attractive in heart failure. Short-term use improves haemodynamic variables, and intravenous *amrinone* or *milrinone* may have a role in patients with severe heart failure unresponsive to other treatment. However, studies with long-term oral phosphodiesterase inhibitors have generally been disappointing. A systematic review[58] found that treatment with oral phosphodiesterase inhibitors was associated with a significant increase in mortality in patients with heart failure, and their use is not therefore recommended.

Antiarrhythmics are not routinely used in heart failure since many have a negative inotropic effect. However, sudden deaths in patients with severe heart failure have been attributed to ventricular arrhythmias,[59] and antiarrhythmics such as *amiodarone*, which is not a negative inotrope, have therefore been tried. A meta-analysis[60] of 5 studies involving 1452 patients with symptomatic compensated heart failure indicated that amiodarone reduced the rate of arrhythmic or sudden death in high-risk patients and that this resulted in an overall reduction in mortality, but a later study[61] in mild to moderate heart failure found no survival benefit. Adverse effects may also limit the use of amiodarone, and it is currently only recommended in patients who also have symptomatic arrhythmias. Implantable devices may be an alternative. A reduction in mortality has been shown[61] with use of implantable cardioverter-defibrillators. Resynchronisation therapy using biventricular pacemakers improves symptoms and reduces mortality from progressive heart failure, although a meta-analysis[62] found that the effect on overall mortality was not significant. Both implantable cardioverter-defibrillators and resynchronisation therapy may therefore be considered in selected patients,[5,7,8,19] and there is evidence that they may be used safely together.[63]

The risk of thromboembolism is increased in heart failure, but the role of routine ***antithrombotic*** therapy is unclear.[64] Anticoagulants should be given to patients who have additional indications, such as atrial fibrillation. The use of *aspirin* in heart failure has been controversial, since there has been some suggestion that it might reduce the benefit of ACE inhibitors. However, such an effect has not been confirmed and guidelines[5,7] therefore recommend that aspirin should be given to heart failure patients with appropriate indications, such as atherosclerosis.

Miscellaneous drugs targeting a number of mechanisms have been tried in heart failure, but in most cases results have been disappointing, and toxicity and increased mortality have also been seen. *Flosequinan*, an arterial and venous vasodilator, and *epoprostenol*, a prostaglandin that causes vasodilatation, have both been associated with increased mortality. Oral sympathomimetic inotropes including *xamoterol*, a partial β_1-adrenoceptor agonist, and *ibopamine*, an oral dopamine agonist, have similarly produced negative effects. Increased mortality has also been reported with long-term intermittent *dobutamine* infusions, although a small study[65] suggested that survival might be increased if patients were also given amiodarone. *Moxonidine*, a centrally-acting antihypertensive, has also been associated with increased mortality. *Endothelin antagonists* such as *bosentan* appear to be ineffective.[66] Disappointing results have also been reported[67] with *tumour necrosis factor antagonists* such as *etanercept* and *infliximab*, and there have been reports[68] of exacerbation of heart failure in some patients.

Other approaches that have been tried include inhibition of neutral endopeptidase, the enzyme that inactivates atrial natriuretic peptide, with drugs such as *candoxatril*. *Omapatrilat*, a dual inhibitor of endopeptidase and angiotensin-converting enzyme, has shown some benefit,[69] but adverse effects may limit its use. *Vasopressin antagonists*, such as *conivaptan* and *tolvaptan*, are also under investigation. Positive haemodynamic effects have been reported with *growth hormone*, although further studies are needed.[70] There is also some evidence that *statins* may be of benefit.[71,72]

Many patients with chronic heart failure have exacerbations of their condition (**decompensated heart failure**) requiring hospitalisation.[73,74] Guidelines for treatment are limited.[75,76] Patients with peripheral or pulmonary oedema due to fluid overload may need intravenous diuretics. Intravenous vasodilators reduce cardiac filling pressure and increase cardiac output and may be needed if symptoms are severe or there is an inadequate response to diuretics. Intravenous nitrates are often used; *nesiritide*, a natriuretic peptide with vasodilator properties, is an alternative, although its effects on mortality are controversial.[77] If cardiac output is low, intravenous inotropes, such as dobutamine or milrinone, may be required. *Levosimendan*, a calcium-sensitiser with both vasodilator and inotropic actions, may also be used. Patients who cannot be weaned from intravenous inotropes may require long-term continuous infusions, either as palliative therapy or as a bridge to transplantation, but regular intermittent infusions may increase mortality and are not generally recommended.[19]

Some patients with **refractory heart failure** may be suitable for ***surgical*** management. Heart transplantation is the optimum surgical therapy but availability is limited and various alternatives have been tried.[78] Left ventricular assist devices may be useful as a bridge to recovery or transplantation, but are not yet established for long-term use. Revascularisation or mitral valve repair may have a role in selected patients, but procedures to augment the heart muscle or reduce ventricular dilatation are not generally recommended since there is limited evidence to support their use.[7]

High-altitude disorders

Rapid ascent (ascent without time to acclimatise) to high altitudes may produce a spectrum of illness (altitude illness) ranging from the usually benign acute mountain sickness to life-threatening pulmonary oedema and cerebral oedema. Factors influencing the development of altitude illness include rate of ascent, altitude attained, sleeping altitude, and length of stay at altitude. Individual susceptibility is also an important factor. Symptoms of altitude sickness are common at altitudes above 2500 metres (8125 feet), although susceptible individuals may be affected at altitudes as low as 2000 metres (6500 feet).[1-3] Reported incidences at higher altitudes vary, but in general symptoms occur in about 50% of people ascending rapidly to altitudes of over 4000 metres (13 000 feet) and in about 75% of people at 4500 metres (14 625 feet); they are severe (pulmonary oedema or cerebral oedema) in about 4%.

Symptoms of **acute mountain sickness** include headache, which is worse in the supine position, nausea, vomiting, anorexia, lethargy, insomnia, and dizziness. These may develop during ascent, but characteristically occur 6 to 48 hours after arrival at altitude. They are usually short-lived and resolve after a few days at altitude. In a very few people symptoms persist for longer. Chronic mountain sickness, characterised by persistent severe hypoxia and polycythaemia, may develop during prolonged residence at high altitude. The discussion that follows is limited to management of the acute forms. A small proportion of people with acute mountain sickness suddenly deteriorate and develop pulmonary oedema or cerebral oedema, both of which may be life-threatening. Occasionally, pulmonary or cerebral oedema develops without symptoms of acute mountain sickness. Symptoms of **pulmonary oedema** include rapid onset of breathlessness and tachypnoea at rest, and a dry cough which may develop into haemoptysis. Symptoms of **cerebral oedema** include increasing headache, ataxia, mental disturbances, drowsiness and eventually coma. Pulmonary and cerebral oedema frequently occur together.

The **pathogenesis** of altitude illness is not fully understood, and it is not known whether the mechanisms of acute mountain sickness and pulmonary or cerebral oedema differ in nature or merely degree. Hypoxia, a result of the reduced partial pressure of oxygen at high altitudes, is considered the primary stimulus in the development of altitude illness.[1-4] When ascent to high altitudes occurs gradually, the bicarbonate concentration and the pH of extracellular fluid fall progressively. The falling pH increases the sensitivity of chemoreceptors to hypoxia and so permits greater ventilation, thus allowing acclimatisation. Rapid ascent to high altitudes does not allow time for these changes to occur and although the hypoxia stimulates hyperventilation, it produces a respiratory alkalosis which limits the ventilatory response to hypoxia. The hypoxaemia produced leads to neurohumoral and haemodynamic changes that ultimately result in the symptoms of altitude illness.[1] Symptoms are often worse at night when ventilation is reduced leading to a worsening of the hypoxaemia.

Prophylaxis. Altitude illness may be avoided by ascending to high altitudes slowly and thereby allowing time for acclimatisation. This may be achieved by spending several days at 1500 to 3000 metres and avoiding strenuous physical activity, thus allowing the body to adapt to the reduced oxygen pressure and to ascend above 3000 metres without sickness. Acclimatisation may also be achieved when going above 3000 metres by increasing the sleeping altitude by no more than 300 to 600 metres a day and by adding a rest day for every 1000 metres climbed;[1,2,4] slower rates of ascent than this have also been advised.

However, when time for acclimatisation is limited or when abrupt arrival at high altitude (for instance by air) cannot be avoided, drug prophylaxis may be considered. Prophylaxis should also be considered for those individuals who have developed symptoms on ascending to high altitudes on previous occasions.

Acetazolamide is the most frequently used drug[1-4] and has been shown[5,6] to effectively reduce the frequency of symptoms, although the optimum dose is not clear. It produces a mild metabolic acidosis which has the effect of stimulating chemoreceptors to produce an increase in the rate of respiration and tidal volume, and it therefore accelerates the process of acclimatisation. Although acetazolamide has diuretic actions it does not prevent fluid retention or prevent or protect against pulmonary or cerebral oedema. It improves sleep hypoxaemia and quality of sleep, reduces proteinuria, improves exercise performance, and reduces loss of muscle mass, probably by improving oxygen supply to the tissues.[7] Acetazolamide should be taken on the day of ascent or 1 or 2 days before ascent to altitudes above 3000 metres, and continued for several days at the higher altitudes.[1,4] However, there has been concern that the use of acetazolamide to prevent symptoms of acute mountain sickness may encourage too rapid an ascent and perhaps increase the risk of developing pulmonary or cerebral oedema.[7]

Dexamethasone has also been shown[5] to be effective in the prevention of acute mountain sickness. The rationale for its use is to control the mild cerebral oedema thought to contribute to the symptoms of acute mountain sickness, although it has also been shown to prevent the development of pulmonary oedema.[8] However, as the adverse effects associated with dexamethasone are more severe than those associated with acetazolamide, it is not considered suitable for routine prophylaxis; it may have a role if acetazolamide is unavailable or contra-indicated.[1,2,4] If it is used, dexamethasone should be started a few hours before ascent;[4] adverse effects may be fewer if the dose is tapered before stopping.[5]

Nifedipine has been shown to lower pulmonary artery pressure and to protect against pulmonary oedema in people susceptible to the development of pulmonary symptoms at altitude[9] but is not usually recommended for prophylaxis due to the risk of adverse effects.

Other drugs that have shown some benefit in small studies include *spironolactone*,[5] *sildenafil*,[10,11] and sumatriptan.[12] *Ginkgo biloba* has also been used, but a randomised trial[6] found no benefit. A study[13] with inhaled *salmeterol* suggested that it reduced the risk of pulmonary oedema in people considered to be at high risk, while tadalafil reduced the risk of pulmonary oedema but did not prevent acute mountain sickness.[8] *Aspirin* was reported[14] to reduce the incidence of headache in a small study in people with a history of headache at high altitude.

Treatment. Once symptoms of altitude illness develop the course of action should be determined by the severity and nature of the symptoms.

When symptoms are ***mild*** and are not suggestive of pulmonary or cerebral oedema, rest and mild analgesics for headache are usually all that is required; symptoms resolve within a few days and further ascent is possible.[1,2,4] *Acetazolamide* may have some benefit in relieving symptoms[1-3,15] although studies have been small. If mild symptoms of pulmonary oedema are present, such as dyspnoea and cough, rest with supplementary oxygen and further oxygen at night may resolve the symptoms and allow further ascent; however signs and symptoms at altitude may be confusing and it is always safest to descend. The use of hypnotics at altitude is not generally advised since there is a risk that respiratory depression may further reduce oxygen saturation. However, a small study[16] using the short-acting benzodiazepine *temazepam* reported that sleep quality was improved without an alteration in mean oxygen saturation.

When symptoms are ***moderate to severe***, and are progressing or suggestive of cerebral oedema, immediate descent is necessary.[1-4] Descending by as little as 400 to 500 metres is beneficial. Various drugs and therapies have been given to alleviate symptoms and to facilitate descent and should also be used when immediate descent is not possible. For example, *dexamethasone* can reduce the symptoms of acute mountain sickness and might be used in emergencies.[17,18] Portable hyperbaric chambers are available[19] and provide rapid but short-term improvement. They may be useful in combination with dexamethasone, which has a more sustained effect.[20]

If pulmonary oedema is present, oxygen, which relieves hypoxia and reduces pulmonary hypertension, should be given;[1-4] *nifedipine*, which suppresses the exaggerated hypoxic pulmonary vasoconstrictor response seen in people with pulmonary oedema, has provided benefit.[21] Positive-pressure expiration may also be useful;[2] it has the effect of increasing oxygen saturation and partial pressure of carbon dioxide at altitude. Inhalation of nitric oxide has also been reported to improve oxygenation but use may not be feasible at altitude.[22]

People with cerebral oedema should be given *dexamethasone* and oxygen therapy.[3]

Hyperlipidaemias

Hyperlipidaemia results from a disorder in the synthesis and degradation of plasma lipoproteins. Although the main concern has generally been the overall elevation of plasma lipids (hyperlipidaemia), it is now increasingly recognised that the balance of lipids in the plasma is also important, and the term dyslipidaemia is often used. Dyslipidaemias have genetic and other causes, and are often associated with a high-fat diet. Although patients with hyperlipidaemia may have symptoms that require treatment, the major concern is their increased risk of ischaemic heart disease.

The **lipids** that are of relevance in hyperlipidaemias are cholesterol, an essential component of cell membranes and a precursor of steroid hormone synthesis, and triglyceride, an important energy source. They are transported in the blood as lipoproteins.

Lipoproteins are complex particles[1,2] comprising a hydrophilic coat of phospholipids, free cholesterol, and specific polypeptides termed apolipoproteins (apoproteins) around a core of varying proportions of triglyceride and cholesterol (present as cholesteryl ester). The lipoproteins are characterised by their density, which in general increases as they are metabolised and the proportion of cholesteryl ester to triglyceride increases. Table 1, below, lists the principal lipoproteins and their associated lipids. The lowest density lipoproteins are the **chylomicrons** which transport triglyceride derived from dietary fat, and the **VLDL** (very low-density lipoproteins; pre-β lipoproteins) which transport endogenous triglyceride mainly synthesised in the liver, to peripheral tissues. The triglyceride is hydrolysed in the peripheral tissues by lipoprotein lipase, which is activated by apolipoprotein CII present in the lipoproteins. Both chylomicrons and VLDL are progressively depleted of triglyceride, yielding increasingly dense lipoprotein particles termed 'remnant' particles. Chylomicron remnants are cleared rapidly from plasma by the liver where they are metabolised, releasing free cholesterol. VLDL remnants, which include **IDL** (intermediate-density lipoproteins; broad β-lipoproteins), may also be cleared by the liver or converted to **LDL** (low-density lipoprotein; β-lipoprotein). **HDL** (high-density lipoproteins; α-lipoproteins) are synthesised in the liver and small intestine and have a role in the transport of cholesterol from the peripheral tissues back to the liver, where it is either utilised or excreted in the bile as bile acids and unesterified cholesterol. The majority is reabsorbed from the intestines and a small proportion is excreted in the faeces.

Defining hyperlipidaemia is difficult due to the marked variation in lipid concentrations between different populations. Apparently 'normal' lipid concentrations may still be associated with a significant risk of cardiovascular disease, and this may depend on which lipids are affected. Epidemiological data show a progressive and continuous relationship between plasma-cholesterol concentrations and mortality from ischaemic heart disease. The Framingham Study[3] found a 9% increase in death from cardiovascular disease for each 10 mg/dL (0.26 mmol/litre) rise in total plasma-cholesterol concentration. Plasma-cholesterol concentrations of 5.2 mmol/litre (200 mg/dL) or less are associated with a low risk of ischaemic heart disease. The increased risk is due mainly to raised LDL-cholesterol. In contrast, HDL-cholesterol is inversely associated with ischaemic heart disease. Low plasma concentrations of HDL-cholesterol (below 1 mmol/litre or 40 mg/dL) are generally associated with increased risk of ischaemic heart disease, whereas high concentrations are protective.[4] There also appears to be an association between plasma-triglyceride concentrations and risk of ischaemic heart disease.[5] Some triglyceride-rich lipoproteins such as chylomicron remnant particles and IDL are atherogenic and the risk of heart disease increases as triglyceride concentrations increase in patients who also have high total cholesterol and low HDL-cholesterol concentrations. Hypertriglyceridaemia alone (greater than 2.3 mmol/litre or 200 mg/dL) may be an independent risk factor for ischaemic heart disease, but any clinical benefit from intervention to lower triglyceride levels is yet to be established.[6] However, the absolute risk for any individual also depends on other cardiovascular risk factors, including smoking and hypertension, and treatment decisions should in general be based on assessment of overall risk (see Cardiovascular Risk Reduction, p.1164).

Hyperlipidaemias may result from a number of underlying defects and various methods have been used for classification.[7] A simple system is to divide them on the basis of whether raised serum cholesterol (hypercholesterolaemia), triglyceride (hypertriglyceridaemia), or both (mixed or combined hyperlipidaemia) is the predominant abnormality. Alternatively, the Frederickson/WHO method (see Table 2, below) describes them in terms of the lipoprotein abnormality (hyperlipoproteinaemia), although this is less useful clinically. Within these systems, primary hyperlipidaemias are those with an underlying genetic defect, whereas secondary hyperlipidaemias are caused by another disease state or by drug therapy. Primary and secondary causes of hyperlipidaemia may co-exist.

Primary hyperlipidaemias (see Table 3, p.1170) may be monogenic, relating to a single genetic defect, but much more commonly they are due to the interaction of a number of genes with dietary and other factors (polygenic). Individuals with common, polygenic (multifactorial) hypercholesterolaemia tend to have only mild or moderate elevations of plasma-cholesterol, whereas those with monogenic hyperlipidaemias tend to have much higher plasma-lipid concentrations.

Secondary hyperlipidaemias may have various causes. Diseases producing hypertriglyceridaemia include diabetes mellitus, chronic renal failure, and bulimia. Hypercholesterolaemia can occur in hypothyroidism, nephrotic syndrome, biliary obstruction, and anorexia nervosa. Drugs that may produce hypertriglyceridaemia and/or hypercholesterolaemia include thiazide diuretics (in high doses), beta blockers, corticosteroids, and antivirals in patients with HIV infection. Excessive alcohol intake may produce elevated plasma-triglyceride concentrations.

The degree of hyperlipidaemia seen in patients with either primary or secondary hyperlipidaemia is influenced by various factors, including, importantly, diet. A diet rich in saturated fat and cholesterol and poor in fibre can produce hypercholesterolaemia. Obesity further predisposes to hyperlipidaemia. Other factors that may influence lipid concentrations include pregnancy, lack of exercise, and smoking. After myocardial infarction cholesterol levels may be temporarily reduced for several weeks; therefore, to measure the patient's usual level of cholesterol, blood samples should be taken within a few hours of the infarction.

The majority of people with hyperlipidaemia have plasma-lipid concentrations that are only mildly or moderately elevated, and they exhibit no **clinical symptoms**. At the other end of the spectrum, severe hypercholesterolaemia can cause tendon, tuberous, or planar xanthomas, xanthelasma, and arcus corneae; it is also associated with an increased risk of ischaemic stroke. Severe hypertriglyceridaemia can cause acute severe abdominal pain due to pancreatitis; hepatic and splenic enlargement, eruptive xanthomas, and lipaemia retinalis may also occur. However, the main concern in patients with hyperlipidaemias is the increased risk of ischaemic heart disease. In patients with very severe hypercholesterolaemia, such as familial hypercholesterolaemia, this may occur at a very young age; in those with the heterozygous form onset of heart disease during their 20s or 30s is not unusual, and in the rarer homozygous form ischaemic heart disease may develop by the age of 10.

Treatment of hyperlipidaemias. In patients with clinical symptoms, treatment is indicated to promote the regression or non-progression of disfiguring xanthomas, or to prevent attacks of acute pancreatitis in those with severe hypertriglyceridaemia. The main aim of treatment, however, particularly in patients with only mildly elevated lipids, is to reduce the risk of ischaemic heart disease.[1,8-12]

Since the relationship between plasma-cholesterol concentrations and ischaemic heart disease is continuous, the level at which treatment with lipid regulating drugs should be started has been widely debated. Guidelines recommend that the decision to treat should be based on the overall risk profile of the patient and that other risk factors

Table 1. Principal lipoproteins and associated lipids.

Lipoprotein	Lipid
Chylomicron	Triglyceride
VLDL	Triglyceride
IDL	Cholesterol and triglyceride
LDL	Cholesterol
HDL	Cholesterol

Table 2. Classification of hyperlipoproteinaemias.

		Plasma lipids affected	
WHO classification	Lipoproteins elevated	Cholesterol	Triglyceride
I	Chylomicrons	Normal or elevated	Elevated
IIa	LDL	Elevated	Normal
IIb	LDL and VLDL	Elevated	Elevated
III	VLDL with abnormally high cholesterol content	Elevated	Elevated
IV	VLDL	Normal or elevated	Elevated
V	Chylomicrons and VLDL	Elevated	Elevated

Table 3. Primary hyperlipidaemias.

	Lipoprotein Abnormality (WHO type)	Prevalence	Typical lipid concentrations (mmol/L) Cholesterol	Triglyceride	Risk of IHD	Pancreatitis
Common (polygenic) hypercholesterolaemia	IIa or IIb	Very common	6.5 to 9.0	< 2.3	+	–
Familial hypercholesterolaemia	IIa or IIb	Moderately common	7.5 to 16.0	< 2.3	+++	–
Familial hypertriglyceridaemia	IV or V	Common	6.5 to 12.0	10 to 30	?	++
Familial combined hyperlipidaemia	IIa, IIb, IV, or V	Common	6.5 to 10.0	2.3 to 12.0	++	–
Familial dysbetalipoproteinaemia or remnant hyperlipoproteinaemia	III	Uncommon	9.0 to 14.0	9.0 to 14.0	++	+
Abnormal lipoprotein lipase function	I	Rare	< 6.5	10.0 to 30.0	–	+++

+ = elevated risk; – = no risk; ? = uncertain risk; IHD = ischaemic heart disease

should also be treated (see Cardiovascular Risk Reduction, p.1164). Specifically, British guidelines[13] advise that all high-risk patients should have drug therapy, including patients with established cardiovascular disease, most diabetics, patients with a ratio of total plasma cholesterol to HDL-cholesterol 6.0 or higher, and those with familial dyslipidaemias. In all cases, the target for therapy is total cholesterol below 4.0 mmol/litre and LDL-cholesterol below 2.0 mmol/litre; alternatively, a 25% reduction in total cholesterol and a 30% reduction in LDL-cholesterol should be the target if this results in a lower concentration. European guidelines[14] suggest that diabetics and patients with established cardiovascular disease should have a target of total cholesterol below 4.5 mmol/litre (and below 4.0 mmol/litre if feasible) and LDL-cholesterol below 2.5 mmol/litre (and below 2.0 mmol/litre if feasible); patients with total cholesterol above 8 mmol/litre or LDL-cholesterol above 6 mmol/litre should be treated irrespective of their other risk factors. US guidelines[2,15] suggest that drug treatment should be considered if the LDL-cholesterol level is 190 mg/dL or higher. For patients with 2 or more risk factors, drug therapy should be considered if the LDL-cholesterol is 160 mg/dL or higher, and for those with existing cardiovascular disease, diabetes mellitus, or particularly high risk, drug therapy should be considered if LDL-cholesterol is 130 mg/dL or higher. The US guidelines also give target LDL-cholesterol levels of less than 160 mg/dL, less than 130 mg/dL, and less than 100 mg/dL, respectively, for the three risk groups. However, it has been suggested[16] that treatment may be appropriate in some very high risk patients at LDL-cholesterol concentrations below 100 mg/dL and that a goal of below 70 mg/dL may be reasonable; others consider that there is little good clinical evidence to support such targets.[17] Although low HDL-cholesterol is an additional risk factor, the benefits of raising HDL-cholesterol are not established and no target is therefore specified in the current guidelines.

The main methods of treating hyperlipidaemias are dietary and lifestyle changes and the use of lipid regulating drugs.[2,13-15] Some surgical and other procedures may also be used in familial hypercholesterolaemia (see below).

Dietary therapy should be started in all patients with hyperlipidaemia with the aim of weight reduction in the obese and a reduction in total fat intake. Dietary recommendations[13,15] include a reduction in saturated fatty acids, restriction of *trans* fatty acids, increased consumption of fish or other sources of long-chain n-3 polyunsaturated fatty acids, and increased intake of fruit and vegetables; the intake of cholesterol and n-6 polyunsaturated fatty acids should be restricted. Increased physical exercise is also recommended. Moderation of alcohol intake is advised, particularly in patients with hypertriglyceridaemia, in whom alcohol may precipitate pancreatitis. However, more rigorous diet than that often recommended may be necessary for diet alone to be of much value,[18] and most patients will require drug therapy to achieve target lipid concentrations. Patients at low cardiovascular risk should have a trial of dietary therapy before drugs are started, but in those with established cardiovascular disease or major risk factors drug therapy and dietary changes may be started at the same time.

The principal groups of **lipid regulating drugs** (hypolipidaemic drugs) are the statins, fibric acid derivatives and related compounds, bile-acid binding resins, nicotinic acid and its derivatives, the omega-3 marine triglycerides, and ezetimibe.[1,10-12,19,20] *Statins* (HMG-CoA reductase inhibitors) reduce cholesterol by stimulating an increase in LDL-receptors on hepatocyte membranes, thereby increasing the clearance of LDL from the circulation. Their main effect is to reduce LDL-cholesterol, but they may also reduce triglycerides to a modest extent and increase HDL-cholesterol. They are generally considered to be the most effective lipid lowering drugs. *Fibrates* inhibit the synthesis of cholesterol and bile acids, and enhance the secretion of cholesterol in bile. Their main effect is to reduce triglycerides by reducing the concentration of VLDL; they also increase HDL-cholesterol and have variable effects on LDL-cholesterol. They are used mainly in patients with hypertriglyceridaemia. *Bile-acid binding resins* lower cholesterol by combining with bile acids in the gastrointestinal tract and preventing their reabsorption. This leads to an increased oxidation of cholesterol to replace the lost bile acids, and an increase in LDL-receptor synthesis on hepatocytes, resulting primarily in a reduction of LDL-cholesterol. *Nicotinic acid* inhibits production of VLDL in the liver; it lowers LDL-cholesterol and triglycerides and increases HDL-cholesterol, but adverse effects may limit its use. *Omega-3 fatty acids* primarily reduce triglycerides. *Ezetimibe* is a cholesterol absorption inhibitor and reduces intestinal absorption of both dietary and biliary cholesterol.[21] *Dietary supplements* containing soluble fibre, such as guar gum or ispaghula, or plant stanols or sterols, may also be used to reduce cholesterol absorption; garlic preparations and other supplements have also been used, although their role is not established.[22] *Other drugs* that have been tried include cholesteryl ester transfer protein inhibitors, which increase HDL; however, they have not yet been shown to have clinical benefits,[23] and development of torcetrapib was stopped as it was found to increase mortality. In postmenopausal women, oestrogen therapy reduces lipid concentrations, but the adverse effects may outweigh any benefit (see Effects on the Cardiovascular System, p.2073); soya protein may have a similar effect.

Choice of therapy ideally depends upon the lipid profile of the individual patient since the drug groups differ in their effects on the different lipid components. In practice, most patients have common, polygenic hypercholesterolaemia, and can be treated effectively with statins as first-line therapy. Bile-acid binding resins or nicotinic acid may be alternatives, but are generally less well tolerated. Ezetimibe or fibrates may also be used, but are generally only recommended when patients are unable to take statins.[24,25] Combination therapy may be required in some patients to reach target lipid concentrations, but the risk of adverse effects is increased in patients taking statins and fibrates together (see Effects on Skeletal Muscle under Adverse Effects of Simvastatin, p.1391). In patients with hypertriglyceridaemia, statins or fibrates may be used, although fibrates should only be given first-line in severe, isolated hypertriglyceridaemia;[25] resins should not be used alone since they may increase triglyceride concentrations.

Patients with the less common familial dyslipidaemias[26] generally have higher lipid concentrations and require more intensive therapy. Specific treatment strategies are as follows:

- ***FAMILIAL HYPERCHOLESTEROLAEMIA.*** Patients with familial hypercholesterolaemia usually have very high plasma-cholesterol concentrations, which rarely respond adequately to diet alone and drug therapy is therefore often necessary in this high-risk group. Aggressive therapy may lead to regression of atherosclerotic lesions.[27] The first-line drugs are the statins. In severe cases combination therapy is usually required, such as a statin with a bile-acid binding resin, ezetimibe, or nicotinic acid. A low dose of the bile-acid binding resin may be sufficient. In the homozygous form of familial hypercholesterolaemia there may be a complete lack of functional LDL-receptors and drugs that act by increasing LDL-receptors, such as statins and bile-acid binding resins, may be less effective. However, statins may be useful as adjunctive therapy in those patients who have some LDL-receptor function. In some forms of familial hypercholesterolaemia, and where plasma-cholesterol concentrations are very high, plasma-triglyceride concentrations may also be raised. In these cases a fibric acid derivative or nicotinic acid may be effective, and in more severe cases the combination of a bile-acid binding resin together with a fibric acid derivative or a statin may be used. In patients with the homozygous form liver transplantation is the most definitive treatment. Plasma exchange (weekly or fortnightly) or more selective procedures such as LDL apheresis, including the use of heparin to precipitate LDL (the HELP system—Heparin Extracorporeal LDL Precipitation) may also be used in combination with lipid regulating drugs. Gene therapy is under investigation as a treatment for familial hypercholesterolaemia.
- ***FAMILIAL HYPERTRIGLYCERIDAEMIA.*** In patients with familial hypertriglyceridaemia dietary therapy is generally adequate, but drugs may be required if there is a high risk of acute pancreatitis or if there is a family history of atherosclerosis. The risk of acute pancreatitis is high when plasma-triglyceride concentrations are above 20 mmol/litre. Nicotinic acid or the fibric acid derivatives, particularly gemfibrozil, are generally recommended and may be used in combination in severe cases. Omega-3 marine triglycerides may also be of value. In severe intractable hypertriglyceridaemia, particularly type V hyperlipoproteinaemia, norethisterone has been suggested for women or oxandrolone for men.
- ***FAMILIAL COMBINED HYPERLIPIDAEMIA.*** Drug therapy may be used in patients who do not respond to dietary therapy alone. The choice will depend on the predominant lipid abnormality. A statin is the first choice, particularly in cases where hypercholesterolaemia is predominant. A fibric acid derivative may be used when hypertriglyceridaemia predominates, and nicotinic acid is useful where plasma concentrations of triglyceride and cholesterol are raised to a similar degree. Bile-acid binding resins should not be used alone since they can aggravate hypertriglyceridaemia, but they may be useful with a triglyceride-lowering drug in some patients. Treatment with a combination of drugs that lowers both cholesterol and triglyceride concentrations may be required in some patients especially in those with markedly raised plasma concentrations of triglyceride or cholesterol, as treatment of these patients with drugs effective against only the predominant lipid may produce a rise in the plasma-concentrations of the other lipid. The choice of treatment in these cases is largely empirical as responses are not always predictable in individual patients.
- ***FAMILIAL DYSBETALIPOPROTEINAEMIA*** (remnant hyperlipoproteinaemia; remnant particle disease). In this lipid

disorder the degree of hyperlipidaemia is usually severe and, although it may respond remarkably to dietary therapy, drug treatment is usually necessary. Fibric acid derivatives, statins, or nicotinic acid may be used.

- *ABNORMAL LIPOPROTEIN LIPASE FUNCTION* (chylomicronaemia). Drug therapy is largely ineffective, although fibrates and nicotinic acid may have modest effects. The condition is treated with severe restriction of dietary fat; the diet may be supplemented by medium-chain triglycerides to improve tolerability, but their value is controversial.[8]

Hypertension

Hypertension, particularly essential or primary hypertension, is widespread. Although it is usually asymptomatic, hypertension is a major risk factor for cardiovascular morbidity and mortality, especially that associated with stroke, and control of hypertension is therefore a major aspect of cardiovascular risk reduction. National[1-3] and international[4,5] guidelines on management have been published, but several areas of controversy remain,[6,7] and in many patients hypertension continues to be difficult to treat.[8]

Definitions. The term ***blood pressure*** generally means arterial blood pressure, that is, the pressure of the blood on artery walls. It is usually measured indirectly in the brachial artery just above the elbow using an appropriately calibrated sphygmomanometer[9] and is expressed in mmHg. Two measurements are made:

- *systolic* or maximum blood pressure (achieved during ventricular contraction of the heart)
- *diastolic* or minimum blood pressure (achieved during ventricular dilatation)

Hypertension means a higher than 'normal' blood pressure; it has been defined as the level of blood pressure above which intervention has been shown to reduce the associated cardiovascular risk. Many factors influence blood pressure, resulting in a bell-shaped distribution curve in the general population, and in consequence it is difficult to define an absolute norm.

Classification and subsequent treatment decisions should be based on blood pressure measurements taken on several occasions over a period that varies according to the severity of hypertension. Ambulatory blood pressure monitoring may have advantages in some situations[1,2,5,9,10] and automated devices for home monitoring may also have a role.[1,5,9] However, home and ambulatory blood pressures tend to be lower than those measured in healthcare settings, and different thresholds for normal and abnormal values apply.[1,5,9,10] Guidelines generally use conventional blood pressure measurements to determine treatment decisions since this is the basis of most outcome studies.

Normal adult blood pressure has been arbitrarily defined as a systolic pressure below 130 mmHg together with a diastolic pressure below 85 mmHg (i.e. below 130/85 mmHg), but more recent studies have suggested that optimal blood pressure, in terms of cardiovascular risk, may be lower than this. US guidelines[2] now define normal blood pressure as below 120/80 mmHg, while European[5] and British[1] guidelines classify this as optimal. Blood pressures of 130–139/85–89 mmHg are regarded as high normal[1,5] or are included in the classification of *pre-hypertension*.[2] Although hypertension was formerly defined in terms of diastolic blood pressure alone, it is now recognised that systolic pressure is also important in determining risk, and current guidelines give equal emphasis to both.

Blood pressure above 140 mmHg systolic, and/or 90 mmHg diastolic is generally considered to represent hypertension. Although classifications of *mild*, *moderate*, and *severe hypertension* have been widely used, these terms may be misleading since absolute cardiovascular risk is more important in determining the need for treatment and depends on other factors in addition to blood pressure. Most guidelines[1,4,5] therefore use a grading system to classify hypertension, as follows:

grade 1: 140–159/90–99 mmHg;

grade 2: 160–179/100–109 mmHg;

grade 3: ≥180/≥110 mmHg.

In the US guidelines,[2] stage 1 hypertension corresponds to grade 1, whereas stage 2 includes both grades 2 and 3.

When systolic and diastolic pressure fall into different categories the higher value is used for classification purposes.

The term *malignant* or *accelerated hypertension* has been used for rapidly progressing severe hypertension associated with retinopathy and often renal impairment, but this is now generally considered part of the spectrum of hypertensive crises (see below).

Isolated systolic hypertension occurs mainly in the elderly and has been defined[1,5] as systolic pressure of 140 mmHg or more and diastolic pressure under 90 mmHg.

Origins. In the majority of cases of hypertension the cause is unknown, and such *primary* or *essential* hypertension is probably multifactorial in origin, with genotype, as well as external factors such as diet and body-weight, playing a role.[11,12] Hypertension may also be associated with surgery or pregnancy and is prevalent in diabetics. In a limited number of cases hypertension is *secondary* to some other condition, such as renal disease, Cushing's syndrome, phaeochromocytoma, or the adverse effects of drugs such as oestrogens, and such causes may be suspected particularly in resistant or malignant hypertension.[13] Although treatment of the underlying condition will generally be desirable, the resultant hypertension will not necessarily be abolished by this.

Management of hypertension. Most of what follows relates to primary or essential hypertension in adults. Hypertensive crises, hypertension in children, and hypertension associated with surgery, diabetes, renal disease, or pregnancy are also discussed below under separate headings.

Hypertension may be discovered because of adverse vascular events, especially in the eyes, brain, kidneys, or heart, but is more often asymptomatic and only discovered on routine measurement of blood pressure. Once diagnosed, decisions have to be made about the need for treatment. It is well-established that hypertension is a risk factor for the development of stroke, heart failure, and renal damage, and to a lesser extent ischaemic heart disease, and a reduction in blood pressure is generally beneficial, although mortality remains higher than in non-hypertensives.[14] However, it is important to assess hypertension in the context of overall cardiovascular risk, including the presence of target-organ disease, such as left ventricular hypertrophy or renal disease, associated conditions such as atherosclerosis or diabetes, and other risk factors such as hyperlipidaemia or smoking. Treatment of hypertension may involve both non-pharmacological and pharmacological interventions to reduce blood pressure, as well as assessment and treatment of any other cardiovascular risk factors (see Cardiovascular Risk Reduction, p.1164); any co-existing diseases should also be treated. Differences in the detail of guidelines on the management of hypertension reflect varying judgements on the justification for intervention and the relative risks and benefits of different treatments.

Non-pharmacological treatment. Adopting a healthy lifestyle is beneficial for all individuals, and any patient with raised blood pressure should be encouraged to make lifestyle changes that will reduce their cardiovascular risk. Some of these changes may also reduce blood pressure,[11,15,16] and in those who are at low overall risk no other treatment may be needed; a trial of non-pharmacological treatment is recommended in most patients before starting drug therapy,[1,2,4,5] but should not unnecessarily delay treatment, especially if the patient is at high risk.[1,5] Interventions that have been shown to reduce blood pressure include:

- reduction in excess weight
- reduction in excess alcohol consumption
- reduction in sodium intake
- adequate exercise
- reduced fat intake
- increased fruit and vegetable consumption

Other interventions that have been tried, but with less evidence of benefit, include:

- increased intake of potassium, magnesium, and calcium
- increased polyunsaturated fat intake with reduced saturated fat intake
- relaxation therapies for stress reduction.

These lifestyle changes may also be promoted in the population as a whole, or in individuals most likely to develop hypertension, in strategies for the *primary prevention* of high blood pressure.[17]

Pharmacological treatment. The main decisions in drug treatment relate to the blood pressure at which therapy should be begun, the target blood pressure, and the most appropriate drug regimen to use. Controversies exist in all these areas.

When to intervene with antihypertensive drugs depends on factors including both the measured blood pressure and the overall cardiovascular risk.

- Patients with grade 3 hypertension (180/110 mmHg or higher) should receive prompt drug treatment.[1,2,5]
- In grade 2 hypertension, drug therapy is indicated if blood pressure remains at 160/100 mmHg or higher after a period of lifestyle modification, which varies depending on the overall level of risk;[1,2,5] prompt drug therapy is advised for those at high or very high risk.[5]
- For patients with grade 1 hypertension, the need for treatment is less well established; those with associated risk factors should be given drug therapy if lifestyle modification is inadequate, but some guidelines suggest that antihypertensives are not indicated in those at lower risk,[1] or state that priority should be given to those at highest risk.[4]
- Lower thresholds may apply in patients with renal disease or diabetes (see below), but whether there is any benefit in treating uncomplicated patients with prehypertension is controversial.[18]

For *elderly patients* (over 60 years) there is evidence[19-22] to support the benefit of treating hypertension, including isolated systolic hypertension,[23] and this applies up to at least 80 years of age, suggesting a strict age limit to drug therapy is inappropriate. Guidelines therefore generally recommend that treatment decisions should not be based on age, although slower titration of drugs has been suggested[5] in older patients since they may be more susceptible to adverse effects. In the very old (those over 80 years) the benefit of starting therapy is less clear,[21,23,24] although a study[25] in patients aged 80 years and over found a reduction in mortality; those already being treated should continue.[1,5]

Target blood pressures are also controversial. There has been concern that over-aggressive reduction of diastolic pressure might increase the risk of ischaemic heart disease,[26] although a meta-analysis[27] suggested that any increased mortality at low blood pressures was not linked to antihypertensive therapy but may have been due to poor health as a cause of low blood pressure. The HOT study[28] found that effective control to maintain the diastolic pressure below 90 mmHg (at about 85 mmHg) reduced the rate of cardiovascular events, but lower pressures (of around 70 mmHg) did not provide any further benefit, while a meta-analysis[29] found no evidence of a threshold for treatment benefit down to a blood pressure of at least 115/75 mmHg. Target blood pressures of below 140/90 mmHg[2,5] or below 140/85 mmHg[1] are now recommended; lower targets may be considered if tolerated by the patient, particularly in patients at high risk.[5] A lower target of below 130/80 mmHg has also been suggested for patients with established ischaemic heart disease,[30] and lower targets may also be appropriate in diabetics and patients with renal disease (see below).

The drug regimen may include drugs with differing pharmacological actions; the antihypertensive mechanism is not fully understood in all cases. Historically, thiazide diuretics and beta blockers have been the mainstay of drug therapy for hypertension, but calcium-channel blockers, ACE inhibitors, angiotensin II receptor antagonists, and alpha blockers are now also widely used.

Choice of initial therapy depends on antihypertensive efficacy, safety, and long term effects on morbidity and mortality.[31,32] Studies such as the TOMHS[33] (comparing chlortalidone, acebutolol, amlodipine, enalapril, and doxazosin), and a similar study[34] (comparing hydrochlorothiazide, atenolol, diltiazem, captopril, prazosin, and clonidine), have shown that the main types of antihypertensive drug reduce blood pressure to a similar extent and in a similar proportion of patients, although the response may also depend on individual factors such as age[35] and race.[36,37] Angiotensin II receptor antagonists also effectively reduce blood pressure. However, it is now generally acknowledged that a single drug is unlikely to control blood pressure adequately and most patients will require more than one drug to reach their treatment target. Tolerance of the drug groups is also similar, although there has been concern about the metabolic effects of thiazides and beta blockers. Alpha blockers (specifically doxazosin[38]) have been associated with an increased risk of heart failure, which may limit their use. The safety of short-acting dihydropyridine calcium-channel blockers has also been questioned, and they are no longer generally recommended for hypertension (see Effects on Mortality under Adverse Effects of Nifedipine, p.1350); long-acting dihydropyridines, however, are of established benefit.[39]

All of the main drug groups are therefore established as effective antihypertensives, but their effects on long-term mortality and morbidity have been less clear. The different drug groups have differing effects on several surrogate outcomes, such as left ventricular hypertrophy[40] and endothelial dysfunction,[41] but the clinical significance of this has not been established, although there is some evidence[42] that regression of left ventricular hypertrophy is associated with a reduction in clinical events. Diuretics (particularly thiazides) and beta blockers were the first drugs to demonstrate an effect on mortality in long-term outcome studies and have therefore been preferred for initial therapy. However, long-term studies with other drug groups have now been performed, and have generally shown comparable effects on mortality and morbidity. A meta-analysis[43] concluded that there was little difference in overall cardiovascular outcomes for regimens based on ACE inhibitors, angiotensin II receptor antagonists, calcium-channel blockers, beta blockers, or diuretics, suggesting the major benefit of treatment related to reduction of blood pressure rather than to specific properties of the individual drugs. However, cause-specific outcomes did differ between the drug groups, and some large studies have also questioned the benefit of certain regimens. A study[44] (ALLHAT) comparing treatment based on a diuretic (chlortalidone), an ACE inhibitor (lisinopril), or a calcium-channel blocker (amlodipine), found no differences in all-cause mortality, but another arm of the study based on an alpha blocker (doxazosin) was stopped early due to an excess of heart failure in this group.[38] Another study[45] (ASCOT-BP-LA) was also stopped early when results suggested that a regimen of amlodipine with addition of perindopril if required, prevented major cardiovascular events more effectively than a regimen of atenolol with addition of a thiazide if required. However, blood pressure reductions were greater in patients receiving the amlodipine-based regimen, making the significance of the results unclear. Subsequent meta-analyses[37,46,47] have, however, found that beta blockers may be less effective than the other major groups of antihypertensives, particularly in older patients,[37] and their role in initial therapy has therefore been questioned.

In general, guidelines acknowledge that lowering blood pressure appears to be more important than which drug is chosen for initial therapy, and that most patients will require a combination of drugs, making the initial choice less important. Thiazide diuretics, ACE inhibitors, angiotensin II receptor antagonists, or calcium-channel blockers may all be used, and choice should take into account individual patient characteristics, including age, ethnicity, contra-indications or compelling indications for specific drugs, adverse effects, and relative cost-effectiveness.[1,2,4,5] Strict guidance is therefore not generally given, although for uncomplicated patients US[2] and international[4] guidelines recommend *thiazide diuretics* as first-line, whereas in the UK[3] diuretics or *calcium-channel blockers* are recommended for older patients (55 years or over) and black patients, while in younger, non-black patients *ACE inhibitors* or *angiotensin II receptor antagonists* are preferred. Compelling indications in all the guidelines include the use of ACE inhibitors or angiotensin II receptor blockers in patients with nephropathy, diuretics or calcium-channel blockers in elderly patients, and beta blockers in patients who have had a myocardial infarction. The use of *beta blockers* as initial therapy in patients who have not had a myocardial infarction remains controversial; UK guidelines[3] issued since the publication of ASCOT-BPLA suggest that they should be avoided except in younger patients who are unable to take ACE inhibitors or angiotensin II receptor antagonists and in women of child-bearing potential, whereas more recent European guidelines[5] allow their use in all patients other than those at risk of metabolic effects.

Having decided what drug to use, treatment is started at the lowest recommended dose. If this is ineffective or only partially effective the dose may be increased (except in the case of thiazide diuretics where there is generally no additional benefit, but more adverse effects); alternatively another first-line drug may either be substituted (*sequential therapy*) or added (*combination therapy*). Two-drug combinations will control blood pressure in a higher proportion of patients and may be necessary in most patients to achieve optimal levels, although the effects of the two drugs may not be fully additive. Combination therapy also allows lower doses of the individual drugs to be used with a consequent reduction in adverse effects. Initial treatment with a low-dose combination may be considered in some patients.[2,5] The most effective combinations involve drugs that act on different physiological systems. Appropriate combinations therefore include:

- diuretic plus beta blocker
- diuretic plus ACE inhibitor
- diuretic plus angiotensin II receptor antagonist
- calcium-channel blocker plus ACE inhibitor
- calcium-channel blocker plus angiotensin II receptor antagonist
- calcium-channel blocker (except verapamil) plus beta blocker

Alpha blockers may be used with any of the other classes but are usually reserved for third-line therapy unless specifically indicated for another reason. A 3-drug combination is often required, especially in severe hypertension. In patients who maintain an elevated diastolic blood pressure despite triple therapy the possibility of secondary hypertension should be considered, although factors such as non-compliance, NSAID use, or alcohol abuse may contribute to resistance.[7,8]

Other classes of antihypertensive drugs that are sometimes used include: centrally acting drugs such as clonidine, methyldopa, and the less sedating moxonidine; direct-acting vasodilators such as hydralazine and minoxidil; the aldosterone antagonist, eplerenone; and the renin inhibitor, aliskiren. Older drugs like the adrenergic neurone blocker guanethidine and the rauwolfia alkaloid reserpine are rarely recommended now. Endopeptidase inhibitors and endothelin antagonists are among various drug groups that are under investigation.

Withdrawal of drug treatment. It has been standard teaching that drug treatment for hypertension is continued indefinitely, but there have been some reports of successful withdrawal in selected patients.[48-50] If this is attempted, blood pressure must be closely monitored and lifestyle measures should be continued indefinitely.[3,5]

Hypertension in children. Hypertension is less common in children than in adults but the incidence may be increasing in parallel with an increase in childhood obesity,[51] and guidelines for diagnosis and management have been published.[52] Lifestyle measures are the mainstay of treatment, particularly in children with less severe hypertension and no evidence of target organ damage, since the benefits of treatment and the risks of long-term drug therapy are not established. However, drug treatment may be required in some cases and should generally be based on individual patient characteristics.

Hypertensive crises. Patients with severe hypertension may be divided into those in whom there is evidence of rapid or progressive CNS, cardiovascular, or renal deterioration (hypertensive *emergencies*) and those with no evidence of target-organ damage (urgent hypertensive crises or hypertensive *urgencies*).[2,53-57] In the former case the goal is a reduction in mean arterial blood pressure by 25%, or a fall in diastolic blood pressure to 100 to 110 mmHg, over a period of several minutes to several hours depending on the clinical situation; intravenous therapy is often required although oral therapy may be adequate. In the latter case a drastic reduction in blood pressure is inappropriate and oral therapy is preferred, with the aim of a reduction in blood pressure over several hours to days. In both situations too rapid a reduction of blood pressure may be detrimental and may lead to cerebral infarction and blindness, to deterioration in renal function, and to myocardial ischaemia.

If *oral treatment* can be given and there is no evidence of ongoing target-organ damage, beginning standard antihypertensive therapy is appropriate, although the patient should be closely monitored. Short-acting drugs with a rapid effect are often used, although caution is required since they may lower blood pressure abruptly. Drugs that have been recommended[2,55,56] include the beta blocker labetalol, the centrally acting drug clonidine, the ACE inhibitor captopril, and the alpha blocker prazosin (especially when there are increased circulating catecholamines); calcium-channel blockers such as amlodipine, felodipine, and isradipine may also be suitable.[56] Diuretics may have a role in volume overload but many patients with hypertensive crises are volume depleted and diuretics may therefore be less appropriate in the initial stages. Nifedipine and captopril have been given sublingually for a faster onset, but there appears to be no clearly defined clinical advantage for this route and it is generally considered that nifedipine should not be used.[2,54,56,58]

In the emergency situation, when *parenteral therapy* is required, choice of therapy depends on concomitant clinical conditions.[53,54,56] Sodium nitroprusside given by intravenous infusion, has most often been the drug of choice, but close monitoring is required as toxicity may be a problem.[2,53,55,56] Intravenous labetalol, nicardipine, or fenoldopam are suitable alternatives in most situations. Other drugs that are used in specific indications include glyceryl trinitrate (in patients with coronary ischaemia), phentolamine (in phaeochromocytoma and other states associated with catecholamine excess such as the MAOI-tyramine interaction), enalaprilat (in acute heart failure), esmolol (particularly in aortic dissection or perioperatively), and hydralazine (in eclampsia, but see Hypertension in Pregnancy, below). Trimetaphan[54] and urapidil[56] have also been used.

Hypertensive emergencies in children are managed similarly to those in adults.[52,59,60]

Hypertension during surgery. Giving antihypertensive drugs to patients about to undergo surgery is not only safe but probably best continued up to and including the morning of surgery.[2,61]

Perioperative hypertension may occur as a result of surgery and often needs to be controlled with parenteral antihypertensives since the oral route may not be available. The parenteral drug of choice is often sodium nitroprusside; others include glyceryl trinitrate (especially after coronary artery bypass), labetalol, enalaprilat, esmolol, fenoldopam, and nicardipine; diazoxide, hydralazine, and methyldopa have also been used.[61-63]

Hypertension in diabetic patients. Hypertension is twice as common in diabetic as in nondiabetic subjects, and up to 50% of patients with type 2 diabetes mellitus become hypertensive.[64,65] The reasons proposed for this increased prevalence are controversial, but insulin resistance has been implicated.[66] In addition to being a major risk factor for atherosclerosis in large blood vessels, hypertension in diabetes appears to contribute to small vessel disease and is a risk factor for diabetic nephropathy and possibly for diabetic retinopathy. The UK Prospective Diabetes Study (UKPDS) Group has reported[67] that tight control of blood pressure (with a target of below 150/85 mmHg) reduces the risk of diabetes-related death and diabetic complications, including diabetic retinopathy, in type 2 diabetics.

The threshold for intervention with drug treatment may be lower in diabetic than in non-diabetic hypertensive patients and treatment targets are also lower. An initial target of 140/80 mmHg has been suggested,[1] while a target below 130/80 mmHg may be optimal and is recommended in many guidelines;[1,2,4,5,13,68] the lower target is particularly advised in type 1 diabetics with nephropathy.

All the main groups of antihypertensive drugs can be used in diabetics,[69] and most patients will require at least two drugs to achieve target blood pressure. ACE inhibitors (with angiotensin II receptor antagonists as an alternative) have been particularly recommended, as there is evidence of benefit in preserving renal function in patients with nephropathy. However, a systematic review[70] found limited evidence to support a specific renoprotective action in diabetics, independent of their effect on blood pressure. Diuretics and beta blockers have often been avoided because of their potential adverse effects on glucose and lipid metabolism, but may be used where indicated. In the UKPDS treatment with an ACE inhibitor (captopril) or a beta blocker (atenolol) was equally effective in reducing the risk of diabetic complications, although the ACE inhibitor appeared to be better tolerated.[71] Although there has been concern regarding the safety of calcium-channel blockers, long-acting calcium-channel blockers have been shown to be a suitable choice.[72]

Hypertension and renal disease. Hypertension is closely linked with the kidney—the kidney may have a role in the pathogenesis of hypertension and it may also be a prime target of damage caused by hypertension. Both renal parenchymal disorders and renovascular disorders may be associated with hypertension. In the former, hypertension is often resistant to treatment and a combination of drugs, including vasodilators, may be required. Antihypertensive therapy is also important in these patients since it may slow the decline in renal function in patients with nephropathy.[73] There is some evidence that ACE inhibitors may have a greater protective effect than other antihypertensives,[74,75] although this is not certain,[70] and they have been recommended as the basis of therapy (with angiotensin II receptor antagonists as an alternative), usually with a diuretic.[1,2,5] The effect of blood pressure reduction appears to be related to the degree of proteinuria, and studies have shown that patients with proteinuria higher than 1 g/day benefit from lower blood pressures.[75] Current guidelines[1,2,5] recommend a target blood pressure of below 130/80 mmHg in patients with nephropathy, with a lower target[1] of 125/75 mmHg in those with proteinuria of 1 g/day or over.

Renovascular hypertension has been defined as arterial hypertension resulting from obliteration or compression of one or both renal arteries, the commonest cause being stenosis due to atherosclerosis. Underperfusion of the kidney leads to increased release of renin and a consequent rise in blood pressure. However, the relationship between renovascular hypertension and renal artery stenosis is not clear cut; the two conditions may simply co-exist or hypertension may cause the stenosis rather than the other way round.[76,77]

Renovascular hypertension may be difficult to distinguish clinically, but carries a worse prognosis than essential hypertension, may be less amenable to treatment, carries a higher risk of progression to accelerated or malignant hypertension, and may result in irreversible ischaemic failure of the affected kidney.

Diagnostic methods used to detect renovascular hypertension include imaging studies such as ultrasonography and angiography, and functional tests such as the captopril test (see under ACE inhibitors on p.1198 for further details); renal scintigraphy with and without ACE inhibition is also used.

Although blood pressure in renovascular hypertension can often be controlled by antihypertensive drugs, patients with renal artery stenosis are often treated by angioplasty of the affected artery. There is some evidence that angioplasty lowers blood pressure more effectively than drug therapy, particularly in patients with bilateral stenosis, but the relative effects on other outcomes are less clear.[77,78] Renal function may deteriorate in patients given antihypertensives since blood flow to the kidney is reduced; however, sudden restoration of blood flow by angioplasty may also have deleterious effects. Reduced blood flow is a particular concern with the use of ACE inhibitors or angiotensin II receptor antagonists, since renal perfusion may be dependent on angiotensin II in patients with renal artery stenosis, and renovascular hypertension is often considered a contra-indication to the use of these drugs, particularly in patients with bilateral stenosis or stenosis affecting the only functioning kidney. However, they may be required in patients with resistant hypertension,[79] although they must be used cautiously and in low doses, with careful monitoring of renal function (see Precautions for ACE inhibitors, p.1195).

Hypertension in pregnancy. Hypertension in pregnancy may be life-threatening to both mother and fetus. It may be pre-existing or may develop for the first time during pregnancy. Definitions vary, but hypertension presenting before 20 weeks of gestation generally continues long-term and is considered chronic hypertension. After the twentieth week (gestational hypertension) it may be transient (pregnancy-induced hypertension), chronic, or represent pre-eclampsia. Gestational hypertension is usually defined as a blood pressure of 140/90 mmHg or more on at least two occasions in a previously normotensive woman; it is considered transient hypertension if the blood pressure has returned to normal limits by the twelfth week postpartum. In pre-eclampsia, increased blood pressure occurs with proteinuria; abnormal coagulation, liver dysfunction, and oedema may also be present. Pre-eclampsia may progress to eclampsia, a convulsive phase.

Recommendations about the treatment of ***gestational*** or ***pre-existing hypertension*** during pregnancy have been controversial. Most women with chronic or transient hypertension will have grade 1 or grade 2 hypertension and a low risk of cardiovascular complications during the short period of pregnancy, and the benefits of treatment in such patients are not established. It is usually agreed that blood pressures of 170/110 mmHg or above should be treated as an emergency,[5,80] but recommendations for management of lower blood pressures are less clear. Although treatment of patients with blood pressures of 140/90 mmHg or above has been suggested,[5,80,81] there is little evidence that this improves maternal or neonatal outcomes, although the incidence of severe hypertension is reduced.[82] Some guidelines allow withdrawal of antihypertensives in pregnant women with pre-existing hypertension, with treatment restarted if the blood pressure exceeds specific threshold values.[2,81,83] However, women with mild hypertension are at an increased risk of developing pre-eclampsia, regardless of whether they receive antihypertensives, and should be closely monitored.

For women with *mild to moderate hypertension* in whom the decision is made to give antihypertensives, optimum choice of drug therapy is unclear. Women with pre-existing hypertension usually continue their existing treatment, although ACE inhibitors and angiotensin II receptor antagonists are contra-indicated in pregnancy and should be changed to an alternative. For gestational hypertension, methyldopa or beta blockers have generally been preferred, although there is little evidence that outcomes differ for any of the main drug groups.[82] A systematic review[84] found no evidence of substantive benefits with beta blockers, but another review[82] found that they reduced the risk of severe hypertension more effectively than methyldopa. Methyldopa has the advantage of reassuring long-term safety results in the infant, whereas there have been concerns about fetal growth retardation with beta blockers, particularly with atenolol.[85-87] Nifedipine[81,88] or hydralazine[81] may also be used. Diuretics are not generally recommended for controlling hypertension in pregnancy because of the theoretical risk of exacerbating the volume depletion of pre-eclampsia; however, they appear to be safe in practice and may be used if necessary.[1,83]

For patients with ***pre-eclampsia***[81,89-92] the definitive *treatment* is delivery (although pre-eclampsia may also develop post-partum[92]), but where the maternal condition allows this is usually delayed to allow fetal maturation. Antihypertensive therapy is therefore given to reduce the risk of maternal complications, and prophylactic anticonvulsants, particularly magnesium sulfate, may also be given in those at high risk for eclampsia (see p.470). Evidence to guide choice of antihypertensive in severe hypertension is limited.[93] Oral therapy may be appropriate, in which case methyldopa or beta blockers (preferably labetalol[5,92]) are usually first-line; calcium-channel blockers such as nifedipine are an alternative. However, in acute pre-eclampsia or if delivery is imminent, parenteral antihypertensives are required. Intravenous hydralazine is widely used,[2,92] although there is some evidence that it may be less effective and have more adverse effects than other drugs,[94] and some guidelines recommend that it should be avoided.[5] Intravenous labetalol and oral nifedipine are also used, and sodium nitroprusside may be required in some patients.[2,5] Glyceryl trinitrate may be used if there is pulmonary oedema.[5] Other drugs that have been given include diazoxide and clonidine.

Prevention of pre-eclampsia. It was hoped that prevention of pre-eclampsia might be possible by reducing the local platelet aggregation thought to be responsible for some of its manifestations. Several small studies suggested that low-dose aspirin reduced the risk of pregnancy-induced hypertension and intra-uterine growth retardation in high-risk patients.[95] However, larger studies in women at lower risk generally failed to confirm this benefit[96,97] and in one[97] the risk of placental abruption was higher in those taking aspirin. Findings of the CLASP (Collaborative Low-dose Aspirin Study in Pregnancy) multicentre study[98] involving over 9000 women considered to be at increased risk of pre-eclampsia or intra-uterine growth retardation did not support the routine prophylactic or therapeutic use of antiplatelet therapy in all such women. A further study[99] in high-risk women also failed to show any benefit, although aspirin appeared to be safe for mother and fetus. However, systematic reviews[100,101] have concluded that antiplatelet therapy provides a small to moderate benefit in patients at risk of developing pre-eclampsia, although it is not clear which women are most likely to benefit.[101] Calcium supplementation has also been shown[102] to reduce the risks of pregnancy-induced hypertension and pre-eclampsia, although its role is not yet established. Preliminary evidence suggested that supplementation with vitamins C and E might be beneficial in women at high risk,[103] but further studies[104,105] were unable to confirm this effect.

Hypotension

As discussed under Hypertension (above) many factors influence blood pressure making it difficult to define an absolute norm. The link between chronically raised blood pressure and cardiovascular risk is well established, and definitions of 'normal' blood pressure are based on estimates of this risk. For adults, a systolic pressure below 130 mmHg, with a diastolic pressure below 85 mmHg (i.e. below 130/85 mmHg) has generally been considered as normal, although recent guidelines[1,2] have suggested that a blood pressure below 120/80 mmHg may be more desirable. Exactly how far below these values blood pressure can safely be remains uncertain. Although acute hypotension leads to symptoms such as syncope (fainting) or shock, the consequences of chronically low blood pressure are much less clear. Thus, while there are national and international guidelines relating to the diagnosis and treatment of hypertension, there is no accepted definition for low blood pressure or hypotension.

Despite such shortcomings over definition, the existence of several acute and chronic hypotensive disorders is recognised.

Hypotension can occur after haemorrhage or in other forms of shock and the management of this acute and potentially dangerous form of low blood pressure is usually with volume replacement and vasopressors (see Shock, p.1183); sympathomimetics with vasoconstrictor properties, such as noradrenaline and dopamine, are particularly useful when blood pressure is very low. Another situation in which acute hypotension can develop is during anaesthesia and surgery; spinal or epidural block is associated with a greater risk than many other forms of anaesthesia. Hypotension results from venodilatation and decreased cardiac output due to sympathetic block, and the usual treatment is again with sympathomimetics, particularly ephedrine or phenylephrine (see p.1559).

Recurrent forms of acute hypotension may also occur. These include orthostatic (postural) hypotension and neurally mediated hypotension; both are important causes of syncope.[3,4] Orthostatic hypotension may be due to autonomic failure and loss of the reflex vasoconstriction that usually occurs on rising, or may be related to volume depletion. Drug treatment is usually with fludrocortisone (see p.1530). For neurally mediated hypotension, however, choice of therapy is less clear.[3,5-9]

Neurally mediated hypotension (neurocardiogenic syncope, neurally mediated reflex syncope, vasodepressor syncope, or vasovagal syncope) is a common cause of recurrent lightheadedness (presyncope) and syncope in persons with structurally normal hearts. It is characterised by a paradoxical neurocardiogenic reflex; although the mechanism is not entirely clear, reduced cardiac filling appears to stimulate cardiac receptors that normally respond to hypertension, and there is an inappropriate autonomic response leading to vasodilatation, bradycardia, and hypotension. Diagnostic tests may be required to exclude structural or arrhythmic cardiac disorders as a cause of the syncope, and tilt-testing may be necessary to confirm the diagnosis.[3] Treatment primarily involves reassurance and non-pharmacological measures such as avoidance of triggering factors, an increase in dietary salt and fluid intake, and physical manoeuvres such as crossing the legs or tensing the muscles if presyncope occurs.[3,9] Cardiac pacing may be required in some patients, although there is limited evidence of benefit.[10]

Drug treatment for neurally mediated hypotension is more controversial and there is little evidence that any drugs are effective.[4-6,8,9] Fludrocortisone and beta blockers have been widely used, but controlled studies[11,12] with beta blockers have found no evidence that they are superior to placebo; beta blockers may also lead to an increase in adverse effects.[3,8] Disopyramide has also been used, but is not considered first-line.[8] SSRIs have been effective in some cases.[5-7] Benefit has also been reported with vasoconstrictors, including the alpha agonist midodrine.[5,9,13,14] Antimuscarinics, such as propantheline bromide, have also been tried.[6,8]

One contentious issue has been whether general and nonspecific symptoms of ill health such as mental and physical fatigue, depression, and anxiety could be attributed to a chronically low blood pressure (for example, a systolic pressure below 110 mmHg or diastolic pressure below 60 mmHg).[15] In the UK and the USA such an association has not generally been accepted whereas in some European countries (e.g. Germany) a wide range of preparations, usually containing a sympathomimetic, has been available for treatment. There is some evidence that depression[16-18] and reduced general well-being[19] are associated with low blood pressure, and there may also be a link with cognitive impairment.[20] Studies have also suggested an association between chronic fatigue syndrome and either neurally-mediated[21,22] or orthostatic[23] hypotension. However, any implications for treatment are far from clear.

Kawasaki disease

Cardiac effects including coronary artery abnormalities are the major complications of Kawasaki disease, also known as mucocutaneous lymph node syndrome of childhood. Normal immunoglobulin and aspirin are used in its initial management, and antiplatelet therapy, usually with aspirin, may be continued long term to prevent coronary thrombosis. Further details concerning the overall management of Kawasaki disease are provided under Normal Immunoglobulins, p.2228.

Myocardial infarction

Myocardial infarction is an acute coronary syndrome in which necrosis of the heart muscle occurs as a result of acute ischaemia. In the initial stages, clinical symptoms are similar to those of unstable angina, but necrosis results in irreversible damage to the myocardium and long-term complications. The definition of myocardial infarction has changed considerably as the accuracy of detecting myocardial necrosis has improved. It is now considered that any degree of necrosis associated with clinical ischaemia should be defined as myocardial infarction,[1] since it is associated with a worse prognosis, although this definition includes many cases that would formerly have been classified as unstable angina. However, most evidence for treatment is based on earlier classifications, and in practice the diagnosis of acute myocardial infarction is generally made on clinical grounds, determined by characteristic symptoms, ECG changes (ST-segment elevation or bundle branch block), and changes in biochemical markers. The following discussion relates to the management of acute ST-elevation myocardial infarction (STEMI); the management of other acute coronary syndromes is discussed under Angina Pectoris (p.1157).

Although the incidence may be declining, myocardial infarction remains a leading cause of mortality in western societies. The introduction of aspirin and reperfusion techniques has transformed the management of acute STEMI, but a significant number of sudden deaths occur within the first hour and therefore before treatment can be begun. While new therapies for the management of acute STEMI may further reduce in-hospital mortality, earlier recognition and presentation for treatment is important if survival is to be improved further, and primary prophylaxis in patients at risk or at a population level may also have a role (see Cardiovascular Risk Reduction, p.1164). Patients who survive a myocardial infarction are at high risk for further cardiovascular events and often develop complications such as arrhythmias, left ventricular failure, persistent angina, and venous thromboembolism. Management of acute STEMI therefore involves both early treatment of the acute condition, and long-term therapy in survivors to reduce risk and to treat and prevent complications.

Myocardial ischaemia generally occurs as a result of coronary artery occlusion, usually due to thrombosis at the site of a recently ruptured atheromatous plaque; in a few patients coronary embolism or spasm, arteritis, spontaneous thrombosis, or a sudden severe rise in blood pressure, as in phaeochromocytoma, is responsible. The immediate consequence of coronary occlusion is myocardial ischaemia, which leads to impaired contractility, arrhythmias, and eventually myocardial cell death. The lay term 'heart attack' describes both sudden cardiac death and myocardial infarction. Sudden death is usually due to ventricular fibrillation and most patients who are resuscitated from ventricular fibrillation develop features of myocardial infarction or have coronary artery disease. In many cases myocardial infarction is asymptomatic or 'silent' and is only diagnosed due to characteristic changes on the ECG.[2]

Early management. Guidelines,[3-7] recommendations,[8] and reviews[9-11] emphasise the importance of rapid recognition and treatment of patients with acute STEMI. The initial symptoms are usually chest pain, breathlessness, and sweating. The chest pain is typically severe and resembles that of angina pectoris, being precordial with radiation to the neck, lower jaw, and left arm; chest pain lasting more than 20 minutes is generally considered to indicate myocardial infarction, although this is absent in many patients. Other signs and symptoms include nausea and vomiting, bradycardia, hypotension, and apprehension. The characteristic ECG changes confirm the clinical diagnosis and guide initial treatment; elevation of biochemical markers such as troponins and cardiac enzymes develops later and is useful for confirming the diagnosis and determining prognosis.

Those patients with myocardial infarction who develop ventricular fibrillation very quickly have a high mortality and require rapid provision of life support measures. Ventricular fibrillation is treated by defibrillation followed by adrenaline and possibly antiarrhythmics if defibrillation alone is unsuccessful (see Advanced Cardiac Life Support, p.1156, for further details). Paramedic ambulance teams experienced in defibrillation and programmes aimed at educating the public in the basic techniques of cardiopulmonary resuscitation have an important role. Patients with suspected myocardial infarction should be admitted to hospital and where possible managed in a coronary care unit.

The immediate priority in patients with suspected acute STEMI is to give aspirin (as discussed below), to relieve pain and anxiety, and to confirm the diagnosis so that reperfusion can be achieved as rapidly as possible.

Pain should be relieved with an opioid analgesic, usually diamorphine or morphine given intravenously (see Myocardial Infarction Pain, p.8); an antiemetic such as metoclopramide intravenously may also be necessary. Supplemental oxygen should also be given. An inhaled mixture of nitrous oxide and oxygen (Entonox) has sometimes been used to provide pain relief before arrival in hospital; sublingual glyceryl trinitrate or an alternative fast-acting nitrate may also be given. A benzodiazepine may be useful for ***anxiety***.

Reperfusion. In patients with confirmed STEMI, the value of rapid reperfusion is well established. The extent of myocardial necrosis or recovery depends on the speed and completeness with which coronary blood flow can be restored,[12] and reperfusion should therefore be achieved as rapidly as possible. Two methods are commonly used: pharmacological reperfusion with intravenous thrombolytics, or mechanical reperfusion with percutaneous coronary intervention (PCI). Combination of the two methods has been tried but benefit has not yet been established.

Thrombolytics are given intravenously to break up the thrombus or clot and restore the patency of the coronary artery, thereby limiting infarct size and irreversible damage to the myocardium. Several large studies have established that thrombolytics can preserve left ventricular function and improve short-term and long-term mortality in patients with ECG evidence of ST elevation or new left bundle branch block (for more details see Ischaemic Heart Disease under Uses of Streptokinase, p.1405). The greatest benefit is seen in those given thrombolytics early;[13] mortality is significantly reduced in those receiving treatment within 6 hours of symptom onset, and there is also benefit up to 12 hours. In those presenting later than 12 hours, the benefits are less well established; there has been some evidence of early excess mortality due to cardiac rupture in some patients given late thrombolytics. Evidence of benefit in patients over the age of 75 years is also limited;[13]

there is some evidence of increased short-term mortality, but this may be outweighed by improved longer-term outcomes.[14]

Streptokinase has been the most widely used thrombolytic, although fibrin-specific thrombolytics such as alteplase are increasingly preferred,[7] particularly in patients presenting late after symptom onset.[3] Overall efficacy appears to be similar for all the drugs available and factors such as cost, method of use, and contra-indications help to determine the choice. If streptokinase or anistreplase, so-called antigenic thrombolytics, have been used recently, non-antigenic drugs such as alteplase or urokinase should be given. However, choice of thrombolytic is probably less important than ensuring that one is given as soon as possible; recommendations are for a delay of no more than 90 minutes between calling the medical services and thrombolytic therapy ('call to needle' time),[3] and for no more than 30 minutes between admission to hospital and therapy ('door to needle' time).[3,5] Prehospital thrombolysis is feasible and reduces the time to give a thrombolytic, and short-term mortality.[15] Five-year follow-up of one study[16] has suggested that there is also a beneficial effect on long-term mortality.

Percutaneous coronary interventions include balloon angioplasty, coronary stenting, and similar procedures. They are effective methods for reopening occluded coronary arteries,[17] including in elderly patients,[14] and can be used in acute coronary syndromes (primary PCI) and in stable coronary heart disease. However, specialist facilities are required, and availability may be limited. PCI is also safe and effective in patients in whom thrombolytics have failed to achieve adequate reperfusion (rescue PCI)[18] and appears to be more effective than repeated thrombolytics or conservative therapy.[19] Routine PCI after successful thrombolysis (facilitated PCI) has also been tried but appears to provide no additional benefit and may be detrimental, particularly if a full dose of thrombolytic has been given.[20,21]

Choice of reperfusion strategy is controversial and depends on patient factors and availability.[12,17] PCI is more effective at opening occluded arteries than thrombolysis. Studies have shown that it is associated with lower mortality and re-infarction rates both early and late after STEMI,[22] with benefit maintained up to 5 years,[23] including in patients with cardiogenic shock.[24] However, the advantage of PCI over thrombolysis appears to diminish as the delay to reperfusion increases; although some analyses[25] have found that PCI is superior to thrombolysis irrespective of the time delay, others have suggested[26] that thrombolysis may be preferred if the delay to PCI is 90 minutes or more, although this depends on patient characteristics.[27] Guidelines[3,4,7] therefore recommend that all patients with STEMI presenting within 12 hours should be reperfused. For those with a symptom duration of 3 hours or less, primary PCI is preferred if it can be performed within 90 minutes or the delay to treatment is less than 1 hour longer than for thrombolysis; PCI is also preferred if symptom duration is greater than 3 hours, if the patient has cardiogenic shock or heart failure, or if thrombolytics are contra-indicated. Patients presenting more than 12 hours after symptom onset should generally only receive thrombolysis or PCI if there is evidence of ongoing ischaemia.

The overall effectiveness of reperfusion is limited by persistent coronary occlusion, re-occlusion, and infrequent but serious bleeding complications (including intracranial haemorrhage with thrombolytics), and long-term restenosis after PCI. Antiplatelet and antithrombin drugs are given as **adjuncts** to thrombolytics to improve reperfusion and limit re-occlusion,[28] and have been given in the ambulance as an adjunct to prehospital thrombolysis.[29] Adjunctive therapy is also necessary with PCI to prevent re-occlusion and restenosis but is discussed under Reperfusion and Revascularisation Procedures (p.1181).

Antiplatelet drugs. The value of giving oral aspirin as an antiplatelet drug was shown by the ISIS-2 study,[30] in which aspirin started during the first 24 hours after myocardial infarction reduced mortality and also reduced the incidence of re-infarction and stroke. Use with streptokinase proved to be more effective than either streptokinase or aspirin alone. Aspirin should therefore be taken as soon as possible when myocardial infarction is suspected and the tablet chewed so that some buccal absorption occurs;[4] alternatively, it has been given intravenously..

Additional antiplatelet therapy has been investigated in an attempt to further improve outcomes. There is some evidence that early use of clopidogrel in addition to aspirin and other standard therapies improves short-term outcomes,[31,32] including mortality,[32] and immediate dual antiplatelet therapy with aspirin and clopidogrel is now recommended.[6,7] Glycoprotein IIb/IIIa inhibitors may also add to the effects of aspirin in some patients, and a reduction in mortality has been shown with abciximab in patients receiving primary angioplasty.[33] However, in those given thrombolytics, no mortality benefit has been shown with abciximab,[33,34] although early patency rates may be improved.[35] Similarly disappointing results have been reported with eptifibatide[36] and tirofiban.[37]

Anticoagulants. Heparin was widely used in acute myocardial infarction before thrombolytics were available, but the necessity for adjuvant therapy with heparin in addition to aspirin in patients treated with thrombolytics is not certain. An overview of randomised studies[38] found that in patients receiving aspirin, addition of heparin (either intravenous or subcutaneous) produced a small reduction in mortality but was associated with an excess of major bleeds, while a later meta-analysis[39] found no conclusive benefit with intravenous unfractionated heparin, although most of the studies included were underpowered to show an effect on mortality. In addition, many of the studies supporting the use of thrombolytics included unfractionated heparin, and it continues to be widely used. It has been suggested that heparin may provide benefit by preventing re-occlusion of the artery after thrombolysis, a problem that occurs particularly with fibrin-specific thrombolytics such as alteplase. Heparin, normally given for up to 48 hours, has therefore been suggested when alteplase or similar thrombolytics are used, but may not be necessary with streptokinase;[3,4] however, updated guidelines[6] recommend that anticoagulants should be given irrespective of the thrombolytic used. Low-molecular-weight heparins have also been tried. They appear to be more effective than unfractionated heparin,[39,40] and may therefore be preferred; however, studies have generally compared short-term unfractionated heparin (up to 48 hours) with longer-term low-molecular-weight heparin (4 to 8 days), and any benefit may reflect the longer duration of treatment. Fondaparinux, a direct factor Xa inhibitor, is also effective,[41] and may be used as an alternative.[6,7] Direct thrombin inhibitors have generally proved disappointing (see Ischaemic Heart Disease under Lepirudin, p.1323), although they may have a role in patients with heparin-induced thrombocytopenia.[4] Longer-term use of heparin to prevent systemic embolisation may be considered in patients at risk of developing left ventricular mural thrombosis or in those with complications likely to result in immobility.

Standard early therapy for STEMI therefore consists of antiplatelet drugs, anticoagulants, and immediate pharmacological or mechanical reperfusion. **Other early treatments** that have been tried include beta blockers, nitrates, ACE inhibitors, magnesium, and metabolic support.

Beta blockers. In studies performed before the routine use of thrombolytics, intravenous beta blockers, such as atenolol and metoprolol, given in the early period after myocardial infarction were associated with a reduction in mortality. Contributory mechanisms were considered to be a reduction in size of infarction or number of re-infarctions and an antiarrhythmic effect, although the ISIS-1 study[42] suggested that beta blockers improved early survival by reducing the incidence of cardiac rupture. The role of intravenous beta blockers in the reperfusion era is less clear. A systematic review[43] of randomised studies found that early use of beta blockers provided, at most, a small mortality benefit; most of the studies preceded routine use of reperfusion, although some thrombolytic studies were included. A later randomised study,[44] in which about half of the patients received thrombolytics, found that early intravenous metoprolol followed by oral dosage did not reduce mortality at 28 days; there was a reduction in re-infarction and ventricular fibrillation but this was offset by an increase in deaths due to cardiogenic shock, particularly during the first few days. Current recommendations[6,7] are that intravenous beta blockers should not be used in patients with cardiogenic shock or other contra-indications, and it has been suggested[6] that early use should be reserved for patients with hypertension.

Nitrates. Intravenous nitrates are widely used in acute myocardial infarction, although evidence to support their use in patients undergoing reperfusion is limited. An overview[45] of studies carried out before reperfusion (thrombolysis or PCI) became routine found that the use of intravenous nitrates (glyceryl trinitrate or sodium nitroprusside) within 24 hours of the onset of pain was associated with a reduction in mortality, but whether they are of benefit in addition to reperfusion is not clear. However, they appear to be safe[46] and should therefore be given where clinically indicated for ongoing ischaemic pain.[4,7] Nicorandil, which is both a potassium-channel opener and a nitrate, has also been tried in the early stages of myocardial infarction, but results have been mixed.[47,48]

ACE inhibitors. ACE inhibitors have an established role in the long-term management of patients after myocardial infarction, but their use in the early stages is more controversial (see p.1199). A systematic review[49] of studies of ACE inhibitors started within the first 1 to 2 days after acute myocardial infarction found that 30-day mortality and the incidence of heart failure were reduced in those given ACE inhibitors, although the greatest absolute benefit was seen in high-risk patients such as those who had already developed heart failure. Guidelines[3,4] therefore agree that patients with evidence of heart failure should be given early treatment with ACE inhibitors; routine use in all patients may be considered[4,7] but is less well-established.

Magnesium. Magnesium has an important physiological role in maintaining the ion balance in muscle including the myocardium and it has been suggested that use of magnesium in acute myocardial infarction might protect against both arrhythmias and reperfusion injury. Although early studies reported some benefit, larger studies found no effect on mortality, and a systematic review[50] concluded that it was unlikely that magnesium reduced mortality; ventricular arrhythmias were less frequent, but profound hypotension and bradycardia were increased. Routine use of magnesium is therefore not currently recommended.

Metabolic support. Infusions containing glucose, insulin, and potassium have been used in small numbers of patients with the aim of providing metabolic support in the acute phase of myocardial infarction. A meta-analysis of randomised controlled trials that were performed before the widespread use of thrombolytics found that mortality was reduced in recipients of glucose-insulin-potassium,[51] but large randomised studies[52] in patients undergoing reperfusion have found no overall effect on mortality. Intensive glucose control, including insulin-glucose infusions, is however of benefit in diabetics with acute myocardial infarction (see Myocardial Infarction under Insulin, p.452) and short-term outcomes may also be improved in non-diabetics with hyperglycaemia treated with insulin.[53]

Other early treatments that are being investigated[54] include hypothermia, hyperbaric oxygen, calcium modulation, and complement inhibitors such as pexelizumab. Early use of stem cell infusions[55] or colony-stimulating factors[56] to promote myocardial repair has also been tried, but the optimum approach remains unclear.[57]

Long-term management. Patients who survive the immediate post-infarction period remain at high risk for cardiovascular mortality. The main predictors of poor outcome are the extent of left ventricular dysfunction, residual myocardial ischaemia, and ventricular arrhythmias. Follow-up should include cardiac rehabilitation and the identification and modification of risk factors for ischaemic heart disease (see Cardiovascular Risk Reduction, p.1164). Exercise testing, echocardiography, myocardial imaging techniques, and pharmacological stress testing (see Myocardial Imaging under Dipyridamole, p.1268) can be used after myocardial infarction to help identify those at high risk for recurrent ischaemic events and to select patients needing coronary angiography.[3,4] In patients who develop angina soon after myocardial infarction, exercise testing may be unhelpful and potentially hazardous, although many will need angiography to determine whether angioplasty or bypass surgery is required.

Drug therapy is important in the long-term management of patients after myocardial infarction, both for symptom control and for secondary prevention.[3,4,58,59]

- *Aspirin*, given during the acute phase and then continued for one to two years, has been shown to reduce mortality and re-infarction rates. A meta-analysis[60] confirmed the benefit of prolonged antiplatelet treatment in the secondary prevention of myocardial infarction and patients should receive antiplatelet therapy indefinitely. Clopidogrel appears to be as effective as aspirin[61] and should be considered in patients intolerant of, or with contra-indications to, aspirin. Dual antiplatelet therapy with both aspirin and clopidogrel for 2 to 4 weeks may also be considered after acute STEMI,[6,58] and it may be reasonable to continue for longer.[6]

- Routine use of *oral anticoagulation* after acute myocardial infarction in patients without another indication is not usually recommended, although warfarin may be used in patients unable to take antiplatelet drugs.[58] There is some evidence that medium-intensity warfarin anticoagulation (INR 2.0 to 2.5) given with aspirin may be more effective than aspirin alone,[62] but bleeding is increased and the combination is only generally recommended as an alternative in patients requiring dual antiplatelet therapy who are unable to take clopidogrel.[58]
- Long-term prophylactic treatment with oral *beta blockers* (most studies have used propranolol, metoprolol, or timolol) has reduced mortality and the rate of re-infarction.[43] In patients with no contra-indications to beta-blocker therapy (see Precautions, p.1227) they are usually started before hospital discharge and continued for a minimum of one year; indefinite use has been recommended.[3,4,6,58] A survey of 201 752 patients who had a myocardial infarction found that low-risk patients and those with conditions often considered to be contra-indications also benefited from a beta blocker.[63] There is also clear evidence of benefit in the elderly,[64,65] although beta blockers have often been underused in such patients.
- *Calcium-channel blockers* are not routinely used in the long-term management of myocardial infarction, although in selected patients without heart failure verapamil or diltiazem may be of some benefit if beta blockers are contra-indicated.
- *ACE inhibitors* reduce left ventricular remodelling, a process which sometimes follows myocardial infarction and is a recognised precursor of symptomatic heart failure. Myocardial infarction patients with left ventricular dysfunction benefit from long-term oral ACE inhibitors started early after infarction and continued for at least 4 to 6 weeks.[66,67] Long-term use of ACE inhibitors in patients without left ventricular dysfunction is less established, since less benefit has been found in this group. However, the HOPE study[68] found that treatment with ramipril significantly improved outcome in patients at high risk for cardiovascular disease, including patients with previous myocardial infarction but preserved left ventricular function, and some guidelines[6,58] therefore consider that long-term use of ACE inhibitors is reasonable in all patients after myocardial infarction.
- *Angiotensin II receptor antagonists* may be an alternative; a study[69] comparing valsartan with captopril found that both were equally effective, although another study[70] comparing losartan with captopril suggested that ACE inhibitors should remain first-line.
- *Aldosterone receptor blockade* with a drug such as eplerenone is recommended in patients with evidence of heart failure.[6,7,58]
- *Statins* are effective in the primary and secondary prevention of myocardial infarction in patients with both high and average cholesterol concentrations and their use has been advocated in all patients who have suffered a myocardial infarction (see Cardiovascular Risk Reduction, p.1164).
- *Omega-3 acid ethyl esters* may be considered if dietary intake is inadequate.[58]
- Some patients, for example those with myocardial ischaemia or poor left ventricular function, may require long-term *nitrates*, but there is no evidence to support their routine use in all patients.[3]

Post-infarction problems such as heart failure (left ventricular dysfunction), angina pectoris, and arrhythmias are discussed on p.1165, p.1157, and p.1160, respectively.

Patent ductus arteriosus

The ductus arteriosus is a vascular channel present in the fetal circulation that connects the pulmonary artery and the descending aorta. In some infants the ductus arteriosus fails to close, a condition known as persistent patent ductus arteriosus. Details of its management are given on p.68.

Peripheral arterial thromboembolism

Occlusion of the peripheral arteries may occur due to embolism or thrombosis (see Thromboembolic Disorders, p.1187). Sudden or acute occlusion causes reduction of blood flow to the distal portions of the limb and may lead to critical limb ischaemia. Emergency treatment with surgery or thrombolytic drugs is often required to restore blood flow and preserve the limb.

Acute peripheral arterial thromboembolism produces pain, pallor, and coldness in the affected limb. Numbness and paraesthesia may occur and if the clot is not removed, gangrene develops. Sudden onset is usually due to occlusion by an embolus. The heart is a frequent source of emboli; atrial fibrillation, cardiomyopathy, myocardial infarction, and valvular heart disease are all associated with peripheral arterial embolism. Peripheral arterial thrombosis often has a more gradual onset due to collateral vessels maintaining some perfusion of the limb. Thrombosis is usually the result of thrombus formation at a site of atheroma in an atherosclerotic artery; thus it may occur in patients with chronic occlusive arterial disease (see Peripheral Vascular Disease, p.1178). Thrombosis is now more common than pure embolism although the two may coexist.

Sudden arterial occlusion requires emergency treatment to restore circulation and to avoid gangrene and possible amputation of the limb. Where there is imminent danger to the limb surgery is necessary to rapidly restore blood flow. In patients with **embolism** in otherwise healthy arteries surgical removal of the embolus by catheter (embolectomy) is used and usually results in restoration of blood flow. Sudden arterial occlusion due to **thrombosis** where gangrene is imminent requires emergency bypass surgery to restore blood flow; surgical removal of a thrombus (thrombectomy) is not usually successful as most arterial thromboses are superimposed on atheromatous plaques, particularly in elderly patients, and thrombectomy adds to the intimal damage.

Where the risk from ischaemia is less acute, angiography may be performed to confirm the type of occlusion, and intra-arterial thrombolysis may be used as initial therapy, particularly if the cause is thrombotic.[1-3] This method is particularly useful for occlusion of smaller vessels, distal occlusions in surgically inaccessible small arteries, or in patients too ill to undergo surgery. However, it is a slower method of restoring blood flow and its use in limb-threatening ischaemia is controversial.[4] The TOPAS study[5] reported no significant difference in outcomes in patients with acute arterial occlusion treated initially with thrombolysis or surgery, although the rate of bleeding complications was higher with thrombolysis. It has therefore been suggested that thrombolysis may be appropriate for initial therapy in acute occlusion, providing this will not lead to an unacceptable delay in reperfusion.[6-8] However, others[9] consider that thrombolysis should not be used as first-line therapy due to the lack of significant benefit and the increased risk of bleeding.

Thrombolytics may be given intravenously, but giving low doses of intra-arterial thrombolytics directly into the clot is often preferred. Despite the use of low doses the risk of major haemorrhage is still about 10%. Continuous intra-arterial infusion, pulse infusion, and different thrombolytics (alteplase, streptokinase, or urokinase) are used; the optimal technique and choice of thrombolytic are unclear. Local treatment with low-dose streptokinase or urokinase infused into the clot is successful in about 50 to 80% of patients and recanalisation is sustained for a year in 50%. Thrombolytic therapy is more likely to be successful if it is begun soon after thrombosis occurs. If no lysis has occurred within the first 12 to 24 hours the procedure is unlikely to be successful, but where thrombolysis is occurring infusion has been continued for several days. There is rather less experience with alteplase; it is claimed to produce more rapid thrombolysis than streptokinase although studies have been too small to provide evidence of reduced limb loss or mortality.[1] On completion of thrombolytic therapy angiography should be repeated to identify the underlying abnormalities that caused the original occlusion. The lesions can then be treated by balloon angioplasty or surgical repair, and this should be done as soon as possible to avoid rethrombosis, which occurs in about 10 to 30% of patients.

Intra-arterial thrombolysis may also be used in conjunction with surgical techniques, particularly when surgery fails to restore blood flow due to distal occlusions.[10-13]

Adjunctive treatment with antithrombotics, such as heparin and aspirin, is often given to patients with peripheral arterial thromboembolism to prevent propagation of the clot and also to prevent postoperative thromboembolic complications. However, there is an increased risk of serious bleeding complications if heparin is used with thrombolytic therapy.[5] Glycoprotein IIb/IIIa-receptor antagonists, such as abciximab, have also been tried.[14] Where the occlusion has been due to embolism, the patient should be investigated for a possible source of emboli and long-term oral anticoagulation should be considered to prevent recurrent embolism.

Peripheral vascular disease

The term peripheral vascular disease is often used for atherosclerotic or occlusive arterial disease but in its widest sense covers both arterial and venous disorders and may be due to atherosclerosis, vasospasm, or thromboembolism. Peripheral arterial occlusive disorders are the subject of the following discussion; for reviews of vasospastic arterial disorders see p.1188. Venous disorders are covered under Venous Thromboembolism (p.1189); for chronic venous disease see also Varicose Veins (p.2347) and Wounds and Ulcers (p.1585).

The commonest form of **occlusive arterial disease** is caused by atherosclerosis. It may well be only one manifestation of a generalised atherosclerotic process and sufferers also usually experience, or are at increased risk of, ischaemic heart disease. **Thromboangiitis obliterans** (Buerger's disease)[1] is also an occlusive arterial disease, but, rather than being caused by atherosclerosis, it is a result of inflammatory and proliferative lesions in medium and small arteries and veins of the limbs. The lesions are mainly thrombotic in nature. It progresses more rapidly than atherosclerotic disease; severe ulceration and gangrene, necessitating amputation, may often occur. Sufferers are typically heavy smokers. **Intermittent claudication** is a major feature of occlusive arterial disease of the lower limbs and is characterised by pain that develops during exercise and which usually disappears at rest although it may persist in severe forms of disease. The pain is due to ischaemia (insufficient oxygen supply) resulting from the obstruction or vasoconstriction of peripheral arteries. Ischaemia may also result in trophic changes in the skin. In severe or advanced disease, ulceration of skin and tissues can occur and may even progress to gangrene. Although the cause of arterial obstruction is usually atherosclerosis, ischaemia is commonly precipitated by thrombosis. Smoking causes vasoconstriction and is frequently a contributory factor.

Management. Patients with occlusive arterial disease are at high risk of other cardiovascular events such as myocardial infarction and stroke, and treatment is important both to reduce this risk and to improve symptoms.[2-11] Measures to reduce cardiovascular risk (see p.1164) include general lifestyle changes, antiplatelet therapy, treatment of hypertension and hyperlipidaemia, and smoking cessation. In the case of thromboangiitis obliterans, cessation of smoking is essential to halt progression of the disease. These measures do not generally improve symptoms in those with intermittent claudication, although supervised exercise programmes have been shown[12] to improve walking distance and are recommended,[7] and there is also some evidence[13,14] that lipid lowering therapy may do the same.

Many **drugs** have been used for symptom control in occlusive arterial disease, but studies have often been unsatisfactory and their efficacy and/or overall place in management remains to be firmly established.[15,16]

Vasodilators have been the most commonly used drugs in intermittent claudication, although any purported benefit is probably due to mechanisms other than vasodilatation, such as actions on blood cells or changes in blood rheology. Vasodilators do not preferentially dilate the affected arteries, which may in any case be fully dilated already. Dilatation of arteries supplying non-ischaemic tissues elsewhere in the body may actually divert blood away from the affected ischaemic area—the so-called 'steal' phenomenon; this is a known risk with all vasodilators, but especially with powerful arterial vasodilators such as hydralazine and this type of drug is not suitable for use in peripheral arterial disease. *Cilostazol*, which has antiplatelet and vasodilator effects, has been shown to increase walking distance,[17,18] and has been recommended in patients with disabling claudication.[7,19] *Naftidrofuryl* and *pentoxifylline* have been widely used; they may increase the time and distance walked before the onset of pain, but evidence of benefit is limited.[15,20] Pentoxifylline may be considered[7] as second-line therapy to cilostazol. Other vasodilators that have been promoted for the treatment of intermittent claudication include buflomedil, cinnarizine, cyclandelate, and inositol nicotinate; ketanserin, which inhibits vasoconstriction and also changes indices of blood rheology, has also been used.

Prostaglandins such as *alprostadil* (prostaglandin E_1) and *epoprostenol* (prostacyclin) act as vasodilators and have been used in obstructive arterial disease.[2,3] A beneficial effect on rest pain has been noted and some ulcers have either regressed or healed; in selected patients this form of therapy has avoided the need for amputation. However, their role remains unclear. A systematic review[21] concluded that prostaglandin E_1 and its analogues, given intravenously or intra-arterially, were beneficial, but their use may not be practical in most patients.[7] Oral prostaglandins such as *beraprost* have also been tried but do not appear to be effective and are not recommended.[7,9,19] Topical *dinoprostone* has also been used.

Other drugs that have shown positive results in small studies include arginine,[16] ginkgo biloba,[15] glutathione,[16] levocarnitine,[15,22] policosanol,[16] and sulodexide.[23] Growth factors[24] (given locally) and gene therapy[25] have also been tried.

If intermittent claudication is severe, and does not respond to medical treatment, **non-pharmacological** techniques such as bypass surgery, endarterectomy, percutaneous transluminal angioplasty, or intravascular stenting should be considered.[7,9] After these procedures, treatment to prevent postoperative thrombosis and restenosis may be necessary (see Reperfusion and Revascularisation Procedures, p.1181).

Sudden or **acute arterial occlusion** due to emboli or to thrombosis may occur in 10% of patients with atherosclerotic disease, but is rare in thromboangiitis obliterans. The initial approach has been surgical removal; dissolution of the thrombus using local or systemic thrombolytic therapy may be considered. For further details, see Peripheral Arterial Thromboembolism, p.1178.

Phaeochromocytoma

Phaeochromocytoma is a rare catecholamine-secreting tumour of the adrenal medulla. Patients with phaeochromocytoma are usually hypertensive and suffer headache, palpitations, and excessive sweating; the hypertension may be either episodic or sustained. However, if the tumour is mainly adrenaline-secreting, tachyarrhythmias may be associated with a normal or even decreased arterial pressure and if the tumour secretes mainly noradrenaline, vasoconstriction may lead to contraction of the venous pool and hypovolaemia. If the effects of the release of catecholamines are not controlled a life-threatening crisis ultimately ensues and may range from a shock-like syndrome with multiple organ failure to hypertensive crisis, depending on the predominance of the catecholamine secreted.

For a diagnosis of phaeochromocytoma, history and clinical symptoms are important, but a firm diagnosis requires further investigative techniques. Raised plasma or urinary concentrations of catecholamine metabolites indicate the presence of a tumour; measurement of urinary or plasma concentrations of adrenaline and noradrenaline may be necessary to confirm the diagnosis in some patients. The precise location of the tumour can be established by procedures such as computed tomography, magnetic resonance imaging, or scintigraphy with ^{131}I-iobenguane (^{131}I-*m*-iodobenzylguanidine). Other tests that may be used include use of drugs such as clonidine that suppress catecholamine release in normal patients but not in those with phaeochromocytoma. A glucagon stimulation test may also be used but other provocative tests are generally considered obsolete.

Although surgery to remove the tumour is the ultimate treatment goal, the initial step in management must be the prevention of the pressor and other effects of catecholamines. Alpha blockers, given orally, are the mainstay of therapy; they both reduce the blood pressure and allow the plasma volume to return to normal. Phenoxybenzamine is the alpha blocker of choice since the long-lasting, non-competitive blockade that it produces cannot be overridden by surges of catecholamine release, as may happen with competitive blockers. In patients who are unable to tolerate phenoxybenzamine, a selective alpha$_1$-adrenoceptor blocker such as prazosin may be used; it results in less tachycardia and may be preferable if the tumour is predominantly adrenaline-secreting, but hypotension may be a problem. Phentolamine may be given intravenously in patients with hypertensive crises. The initial dose of alpha blocker should be small and should be increased gradually until all signs of pressor activity are suppressed. Once, but not until, alpha blockade is successfully established, tachycardia can be controlled by the cautious use of a beta blocker. A beta$_1$-selective blocker is preferred so that peripheral beta$_2$-mediated vasodilatation is unaffected. α-Methyltyrosine, which suppresses catecholamine synthesis, may be tried in selected patients such as those resistant to alpha blockade or those in whom the effects of alpha or beta blockade may be undesirable.

Once the pressor effects of catecholamine secretion are controlled, surgery can be undertaken. Drugs used for premedication and anaesthesia should be chosen so as to avoid those which may cause pressor responses or tachycardia and ideally should suppress the adrenergic response to surgical stimuli. This will still not be adequate to prevent catecholamine release when the tumour is handled and potent vasodilators such as sodium nitroprusside or glyceryl trinitrate have been given intravenously to prevent dangerously high arterial pressures; the alpha blocker phentolamine has also been advocated although tachycardia is invariably a problem. Cardioselective beta blockers such as atenolol may be given, often in high dosage, to control tachycardia during surgery.

If it proves impossible to remove all the active tissue of a phaeochromocytoma during surgery, or in patients who are unsuitable for surgery or who have malignant phaeochromocytoma, maintenance therapy with alpha and beta blockade needs to be continued or α-methyltyrosine may be used. Alternatively, ^{131}I-iobenguane has been given in high doses sufficient to cause radionecrosis; antineoplastic therapy has also been used.

Pulmonary hypertension

Pulmonary hypertension is a disorder in which there is an increase in pulmonary vascular resistance, leading to an increase in pulmonary arterial pressure. Mean pulmonary artery pressure in a resting individual at sea level is normally about 15 mmHg; pulmonary hypertension is usually defined as a pressure above 25 mmHg at rest, or above 30 mmHg during exercise. Pressures will be correspondingly higher at higher altitudes.

Pulmonary hypertension has been classified in a number of ways and the terminology used has changed as the underlying pathophysiology has become clearer. The most common classification used has been to divide pulmonary hypertension into primary and secondary forms, depending on the absence or presence of an underlying cause. However, this classification has little meaning in terms of the pathophysiology or treatment and guidelines[1,2] now recommend against the use of these terms. Pulmonary arterial hypertension is the preferred term where the increased pressure is due to a disorder of the pulmonary arteries themselves. This includes both idiopathic and familial forms (previously classified as primary pulmonary hypertension), as well as forms that were previously classified as secondary, including those associated with connective tissue disorders, infections, drugs and toxins, and a number of other disorders. The discussion that follows relates to the management of these forms. Other types are classified into groups covering pulmonary hypertension associated with cardiac, pulmonary, thromboembolic, or other disorders, for which management primarily involves treatment of the underlying disease.

Pulmonary arterial hypertension[3-8] is a progressive disease with a high mortality rate, and patients appear to be prone to sudden death. Idiopathic pulmonary arterial hypertension occurs in patients of all ages and in both sexes but women in the fourth decade of life are those typically seen. A functional classification system similar to the New York Heart Association grades used for heart failure (see p.1165) may be used to indicate severity.[1,2] Initial complaints include dyspnoea on exertion, fatigue, and chest discomfort or pain. In advanced disease, cor pulmonale (an enlargement of the right ventricle due to either dilatation, hypertrophy, or both) occurs and may progress to right-sided heart failure. The pulmonary arteries may also be affected by thromboembolic disease.

The aim of treatment in pulmonary arterial hypertension has generally been to decrease the pulmonary arterial pressure, preferably in conjunction with an increase in cardiac output, and thus improve symptoms. However, more recent therapies also improve survival and reduce the need for transplantation, and this is reflected in current guidelines[1,9,10] for management. Although most studies have been in patients with idiopathic pulmonary arterial hypertension, there is some evidence that patients with pulmonary arterial hypertension associated with other disorders respond similarly,[1,6,10] and they are usually managed in the same way. Improved understanding of the pathophysiology of pulmonary arterial hypertension has also led to the development of new treatments, although evidence of long-term benefit is limited in most cases.

General treatment for pulmonary arterial hypertension[1,9,10] includes measures to prevent hypoxia, since this causes pulmonary vasoconstriction, and treatment of associated right-sided heart failure. Oxygen therapy may be needed in some patients, and anaemia should be avoided. Pneumococcal and influenza vaccines are recommended to reduce the risk of pulmonary infections. *Diuretics* produce symptomatic benefit in patients with fluid retention, and should be given as appropriate. *Digoxin* has been used, although its role is less clearly established unless patients also have atrial fibrillation. Patients with pulmonary arterial hypertension also appear to be at risk of thromboembolic complications, and *oral anticoagulation* has been advised.

Specific therapy has generally been based on the use of vasodilators. Vasoconstriction is believed to play an important role in the pathophysiology of pulmonary arterial hypertension, and many of the vasodilators used in systemic hypertension have therefore been tried.[11] While most reduce pulmonary artery pressure, they also reduce systemic blood pressure,[12] producing undesirable and sometimes intolerable adverse effects, and this limits their use. Those with an established role in pulmonary arterial hypertension are calcium-channel blockers and prostacyclin analogues.

Calcium-channel blockers improve pulmonary haemodynamics, and there is some evidence of a survival benefit; an observational study[13] over a 5-year period found that survival was improved in patients given high doses. However, only a small proportion of patients respond,[14] and adverse effects may be a concern. Guidelines[1,9,10] therefore recommend that an acute response test should be performed in all patients before starting long-term treatment. Although oral calcium-channel blockers have been used for testing, this has been associated with severe adverse effects and it is now recommended that only short-acting vasodilators such as intravenous epoprostenol, intravenous adenosine, or inhaled nitric oxide, should be used. Those who respond may then be started on oral calcium-channel blockers, with the choice usually being nifedipine in patients with relative bradycardia, and diltiazem in those with relative tachycardia. The dose should be increased gradually, as tolerated, and long-term therapy should only be continued in patients with a sustained response.

Prostacyclin is a potent endogenous vasodilator and there is evidence that it may be deficient in patients with pulmonary arterial hypertension. Epoprostenol, a synthetic form of prostacyclin, was originally used in patients with end-stage pulmonary hypertension to sustain them long enough to have a heart-lung transplant. However, some studies have suggested that long-term therapy with epoprostenol may also have a role as an alternative to transplantation. Sustained clinical improvement and improved survival have been reported[15,16] in some patients given long-term intravenous therapy using portable infusion pumps, and guidelines[1,9,10] now recommend that epoprostenol may be used in patients with pulmonary arterial hypertension who do not respond to calcium-channel blockers and who are in functional class III or class IV. Continuous intravenous iloprost, a more stable analogue, has also shown some benefit,[17] and may be an alternative. Another analogue, treprostinil, can be given by continuous subcutaneous infusion[18,19] and may be used, particularly in patients for whom intravenous treatment is not suitable;[10] a small study[20] has reported the safe transfer of patients from epoprostenol to treprostinil therapy. However, severe pain may occur with subcutaneous treprostinil, and it may be given intravenously if required.[10,21] Prostaglandin analogues have also been given by inhalation. Epoprostenol has been used, but iloprost, which has a longer action, is generally preferred;[10,22] treprostinil has also been used.[23] Another analogue, beraprost sodium, has been given orally,[24-26] but is not widely available. Although primarily thought to act as vasodilators, epoprostenol and its analogues also affect vascular remodelling and platelet aggregation and this may contribute to their beneficial effects.

Endothelin receptor antagonists may also be used. Endothelin-1 is a potent endogenous vasoconstrictor and appears to be overproduced in pulmonary arterial hypertension; it also stimulates vascular remodelling and has pro-inflammatory effects. Bosentan, an oral endothelin receptor antagonist, has been shown[27,28] to improve haemodynamics and exercise capacity, and there is some evidence that survival may also be improved.[29] It may be used as an alternative to prostacyclin analogues in patients in functional class III and a small study[30] has suggested that some patients can be safely transferred from prostacyclin analogues to bosentan. However, in unstable functional class IV patients, epoprostenol is usually preferred.[1,10] Studies with sitaxentan[31] and ambrisentan,[32] which are selective for the endothelin ET_A-receptor, have also demonstrated positive results.

Phosphodiesterase inhibitors such as sildenafil have also shown some benefit in pulmonary arterial hypertension,[33,34] and may have a role, particularly in patients who fail to respond to other therapies.[1,10] Another alternative may be to use a combination of treatments, such as a prostacyclin analogue with an endothelin receptor antagonist, but this suggestion is based on limited evidence and is not yet established.[1,6,10] There have been case reports[35-37] suggesting benefit with imatinib, a platelet-derived growth factor antagonist, but controlled studies are needed.

Surgical intervention, and ultimately lung or heart-lung transplantation may be needed in patients who do not respond to vasodilator therapy.[1,9]

Pulmonary hypertension associated with an established cardiopulmonary disorder is much more common than pulmonary arterial hypertension and the clinical manifestations are dominated by those of the underlying condition. Chronic obstructive pulmonary disease is the commonest respiratory cause, but it may also occur in patients with respiratory distress syndromes, sarcoidosis, or cryptogenic fibrosing alveolitis. Pulmonary arterial pressure may also be raised in thromboembolic disease, and in patients with impaired left ventricular function, for example associated with myocardial infarction or mitral valve disease. Management generally involves appropriate treatment of the underlying disorder. Inhaled nitric oxide has been used in patients with acute pulmonary hypertension following cardiac surgery or associated with respiratory distress syndrome.[38] There have also been reports[39] of long-term use in patients with chronic lung disease.

Persistent pulmonary hypertension of the newborn, sometimes also termed persistent fetal circulation, is a form of pulmonary hypertension specifically affecting neonates. It can be primary in nature (that is, idiopathic, affecting infants with an anatomically normal heart and no pulmonary disease) or secondary, being associated with a number of cardiopulmonary conditions including congenital heart disease, diaphragmatic hernia, meconium aspiration, respiratory distress syndrome, or sepsis. The pulmonary hypertension and altered vasoreactivity lead to a right-to-left shunting of blood across the patent ductus arteriosus or foramen ovale and this often results in critical hypoxaemia.

Management generally involves high-frequency oscillatory ventilation (to achieve optimal lung inflation) and, if necessary, extracorporeal membrane oxygenation. Treatment to reduce pulmonary vascular resistance may also be tried. Mechanical hyperventilation has been used to induce alkalosis, since this reduces pulmonary vasoconstriction; intravenous sodium bicarbonate may be an alternative.[40] Inhaled *nitric oxide* which is a potent, selective pulmonary vasodilator, is also widely used.[41] Studies[42-46] have shown that it can cause marked improvement in oxygenation and a reduction in the need for extracorporeal membrane oxygenation, but no effect on mortality has been found. Although there have been concerns that use of inhaled nitric oxide might adversely affect neurodevelopmental outcome more than conventional therapy, this has not been confirmed in infants followed up for up to 2 years.[47,48] Use of inhaled nitric oxide in combination with high-frequency oscillatory ventilation may have additional benefits.[49]

Nitric oxide is not effective in all patients and alternatives may be required.[50,51] Intravenous vasodilators have been used, although, as discussed above, this is generally limited by their systemic effects. *Tolazoline* has been most commonly used, and may be given intravenously or by the endotracheal route. Intravenous *epoprostenol* is also used; it has also been given by inhalation,[52,53] which may reduce systemic effects. *Phosphodiesterase inhibitors* may have a role; dipyridamole has been used, and there have been reports[54,55] of benefit with sildenafil. Other vasodilators that have been tried include intravenous *adenosine*,[56,57] intravenous *magnesium sulfate*,[58-60] and inhaled *sodium nitroprusside*,[61] but none of these has an established role.

Raised intracranial pressure

The intracranial compartment consists of brain parenchyma, vascular tissue, and cerebrospinal fluid (CSF). Since the skull is a rigid structure an increase in the volume of any one of these compartments will raise intracranial pressure. This may be due to the formation of cerebral oedema after head injury or around tumours, mass-lesions such as tumours or haemorrhage, CNS infections, or metabolic disorders. Other mechanisms that can raise intracranial pressure include increased dural sinus venous pressure, increased resistance to CSF outflow, and an increased rate of formation of CSF. In idiopathic intracranial hypertension there is no obvious cause. Raised intracranial pressure (intracranial hypertension) can produce irreversible damage to the CNS and is potentially fatal; herniation of brain tissue can occur and reduced cerebral blood flow can lead to cerebral ischaemia. Symptoms of raised intracranial pressure include headache, which is often worse in the morning and may wake the patient from sleep, vomiting, drowsiness, and visual disturbances; most patients have papilloedema on examination.

There are several ways of reducing raised intracranial pressure, the choice of treatment being determined mainly by the underlying cause.[1-8] Whatever the cause, in acutely raised intracranial pressure the initial aim is to reduce the volume of the intracranial contents as quickly as possible to prevent brain damage. For patients with haematoma or tumours the treatment of choice is often surgery but other methods may be used to control intracranial pressure before surgery.

Intracranial pressure monitoring can be helpful in guiding therapy since reducing the intracranial pressure too far is also deleterious. Patients may be sedated to avoid elevations of intracranial pressure due to unnecessary movement but if this is ineffective the use of neuromuscular blockers such as pancuronium or atracurium with artificial ventilation should be considered. Hyperventilation reduces the intracranial pressure by constricting the cerebral blood vessels and controlled hyperventilation has been used; however, it also reduces cerebral blood flow and routine use is not generally advised.[4,5] Raising the patient's head to promote venous drainage may be helpful. Although restriction of fluid intake has been advised, hypotension reduces cerebral blood flow and should be avoided, and intravenous fluids should therefore be given as required.[4] Removal of CSF through a ventricular catheter may also be effective. Controlled hypothermia has been used, but a review[9] of its use in head injury found no evidence that it improves outcome.

The mainstay of pharmacological treatment for acutely raised intracranial pressure is diuretic therapy, usually with an osmotic diuretic. Mannitol is most often used but urea, glycerol, sorbitol, and hypertonic glucose or sodium chloride solutions have also been given.[3] Osmotic diuretics act by increasing the osmolality of plasma and drawing water out of the tissues, as well as by promoting an osmotic diuresis. They should not be given to patients with intracranial bleeding after head injury since they can exacerbate the bleeding,[6] and should also be avoided in patients who are already dehydrated. *Mannitol* decreases intracranial pressure and increases cerebral blood flow both by an osmotic effect and by decreasing blood viscosity.[4,10] It is widely used to reduce intracranial pressure after severe head injury,[4,5,8] although evidence from randomised studies is limited.[11] It is also used to control intracranial pressure before surgery, and has been suggested for cerebral oedema in hepatic failure.[12] Mannitol has also produced beneficial responses in *children* with raised intracranial pressure from birth asphyxia,[13] diabetic ketoacidosis,[14] or Reye's syndrome.[15,16] The use of osmotic diuretics to reduce intracranial pressure in patients with cerebral malaria is not routinely recommended and is controversial in other CNS infections.

In addition to its ability to lower intracranial pressure *glycerol* is reported to be able to increase blood flow to areas of brain ischaemia. It has been used orally or intravenously in an attempt to reduce cerebral oedema and raised intracranial pressure in a variety of conditions including Reye's syndrome[17] and meningitis;[18] it has been reported to be ineffective in hepatic coma.[19] Some patients have experienced severe adverse effects including haemolysis, haemoglobinuria, and renal failure. Strongly *hyperosmotic glucose* solutions (25 to 50%) have been used to reduce raised intracranial pressure and cerebral oedema caused by delirium or acute alcohol intoxication. *Hypertonic sodium chloride* has been shown to reduce intracranial pressure in several studies. It may have a role in resistant cases,[4,20] and has also been suggested in place of mannitol in acute head injury.[21]

If control is required for more than a few hours, repeated doses or continuous administration of osmotic diuretics may be necessary. Mannitol may accumulate with continuous infusion and repeated bolus doses are generally preferred. Fluid and electrolyte balance and plasma osmolality should be closely monitored.

Loop diuretics such as *furosemide* are also effective and may be used as alternatives to osmotic diuretics, particularly where a sustained effect is required. They may increase the effect of osmotic diuretics and may be used as adjuncts, usually given after the osmotic diuretic. Furosemide decreases cerebral water content and possibly also reduces secretion of CSF. It may be preferred to mannitol in patients undergoing neurosurgery.[22]

Corticosteroids have an accepted and important role in the management of raised intracranial pressure associated with tumour-induced cerebral oedema. They may be used intravenously in high doses to control acutely raised intracranial pressure due to a rapidly expanding tumour. Lower doses are given orally for maintenance or where the onset of cerebral oedema is more insidious. Corticosteroids have also been tried in patients with stroke, but results have been disappointing. Although corticosteroids have been widely used in traumatic head injury, a large randomised trial[23] found that they increased the risk of mortality and they are no longer routinely recommended.[24]

The use of barbiturate-induced coma with intravenous *thiopental* or *pentobarbital* for raised intracranial pressure has been controversial but it may be of benefit in patients refractory to conventional therapies.[4,5] In addition to their effect on intracranial pressure barbiturates may be able to protect the brain from ischaemia. *Trometamol* is reported to lower raised intracranial pressure in patients with head injury; it may do this by causing metabolic acidosis leading to vasoconstriction of cerebral vessels.[3]

Idiopathic intracranial hypertension (pseudotumor cerebri) is a rare disorder of unknown cause in which there is a raised intracranial pressure in the absence of an intracranial mass or obstruction to CSF outflow. Although it was previously known as benign intracranial hypertension, since it is not life-threatening and is usually self-limiting, symptoms may be severe or become chronic, and there is a risk of irreversible visual loss.[25,26] Patients are often obese and tend to be young and female. Drug-induced intracranial hypertension may also occur.

Management of mild symptoms usually involves diuretic treatment with furosemide, a thiazide, or acetazolamide. Analgesics, tricyclic antidepressants, or the antiepileptic topiramate may be used to control headache.[25] Corticosteroids can control acute symptoms but long-term adverse effects limit their use. Repeated lumbar puncture to remove CSF may relieve symptoms and has been used every 2 to 5 days to induce remission. In patients who cannot be controlled medically, surgical methods such as lumboperitoneal shunting may be required. There has been an anecdotal report of beneficial effects with *octreotide* in a few patients.[27]

Acetazolamide has also been tried in the treatment of patients with chronically raised intracranial pressure due to cryptococcal meningitis.[28]

Reperfusion and revascularisation procedures

Ischaemia due to impaired blood flow is a major factor in cardiovascular disorders such as angina pectoris (p.1157), myocardial infarction (p.1175), peripheral vascular disease (p.1178) and ischaemic stroke (p.1185). The underlying cause is usually atherosclerosis (p.1159); this leads to narrowing of arteries with a consequent reduction in blood flow, while rupture of the atherosclerotic plaque may lead to thrombosis and acute occlusion of the artery. Restoration of blood flow is therefore one of the main aims of treatment for atherosclerotic disorders, and may be achieved by pharmacological and non-pharmacological methods. The choice of method depends on the condition being treated and is discussed under the individual diseases. Pharmacological methods such as thrombolysis are usually only used in acute occlusion to break down the blood clot and restore flow. Non-pharmacological methods may be used in acute occlusion or electively in situations where stenosis of the blood vessel restricts but does not totally obstruct flow. The methods used in the coronary circulation include percutaneous coronary interventions (PCI) such as balloon angioplasty and stenting,[1-3] and surgical procedures such as coronary artery bypass grafting (CABG); similar techniques are used for peripheral vascular and cerebrovascular disease. Where non-pharmacological methods are used, adjunctive drug therapy is required to prevent and treat acute and long-term complications, and this is the focus of the following discussion.

Patients undergoing surgery or PCI are at risk of **thrombosis** during and immediately after the procedure due to damage to the arteries at the site of intervention and the use of angioplasty catheters or extracorporeal circulation. Antithrombotic therapy with anticoagulants and antiplatelet drugs therefore has an important role[2-4] at the time of the procedure and may also be needed long-term (see below).

Anticoagulants are used in both surgery and PCI.

- For *surgery* involving cardiopulmonary bypass, high doses of unfractionated heparin are given by intravenous infusion. The dose is usually adjusted according to the activated clotting time (ACT), although monitoring blood-heparin concentrations may be an alternative. A target ACT of 400 to 480 seconds has been suggested,[5] with reversal of anticoagulation at the end of surgery.

Lower doses may be adequate in patients undergoing 'off-pump' or 'beating-heart' surgery (target ACT 250 seconds[5]) and in peripheral bypass surgery, although the optimum degree of anticoagulation is not established.

- Alternatives to heparin have been tried and positive results have been reported with hirudins (bivalirudin[6] and lepirudin[7]) and with the direct thrombin inhibitor argatroban,[8] although they are usually reserved for patients with heparin-induced thrombocytopenia.[5]
- Antifibrinolytics have been given to reduce bleeding complications after surgery, although there is some evidence that use of aprotinin may be detrimental (see Haemorrhagic Disorders under Uses and Administration of Aprotinin, p.1055).
- In *PCI*, unfractionated heparin is generally used since it can be rapidly reversed if emergency surgery is required, but the high doses (target ACT 250 to 350 seconds[2,3]) make bleeding a problem and alternatives have been tried. Lower doses of heparin may be effective and safer, particularly if glycoprotein IIb/IIIa-receptor antagonists are also used, and a target ACT of 200 to 250 seconds has been suggested;[2,3] however, an analysis[9] found no clear relation between heparin dose and outcome.
- Low-molecular-weight heparins have been used, although evidence for their efficacy is limited;[2,3,10,11] a meta-analysis[12] that included mostly non-blinded studies found that low-molecular-weight heparin was as safe and effective as unfractionated heparin, and further studies[13,14] have come to similar conclusions.
- Direct thrombin inhibitors may be another alternative;[2,3,11] bivalirudin appears to be as effective as heparin,[15,16] while a study with desirudin[17] found fewer early ischaemic events but no long term benefit compared with heparin.
- Fondaparinux has also been tried,[18] but the risk of catheter thrombosis may be increased and additional unfractionated heparin is recommended at the time of the procedure.[3,11]

Antiplatelet drugs have an important role in reducing acute thrombotic complications and in long-term treatment.

- In patients undergoing *surgical* bypass, they are not usually started until after the procedure since they increase the risk of bleeding, and patients who are already taking such drugs usually have them withheld for several days before elective surgery.[19] Continuation of antiplatelet therapy pre-operatively increases blood loss and the need for blood products,[20-22] although there is some evidence that use of aspirin pre-operatively may improve outcomes.[23]
- In patients undergoing *PCI*, the use of antiplatelet drugs with anticoagulants during the procedure is of established benefit. Aspirin is considered standard therapy,[2,3,11] and patients who are not already taking aspirin are usually given a loading dose at least 2 hours before the procedure; a thienopyridine such as clopidogrel or ticlopidine may be used in patients unable to tolerate aspirin. However, aspirin does not completely inhibit platelet function and combination therapy and more potent drugs have also been studied.
- Use of clopidogrel with aspirin improves outcomes and is now generally recommended,[2,3,11] although the dose and timing have been debated. Pretreatment with clopidogrel appears to be most effective, but the increased bleeding risk may be of concern if emergency surgery is required. Use of a 300-mg loading dose shortly before the procedure appears to be safe, but efficacy may be reduced if it is given less than 6 hours before the intervention[2,3] and there is some evidence that it needs to be given at least 15 hours before.[24] A higher dose of 600 mg may be effective if given at least 2 hours before PCI[25,26] and has been recommended,[3] particularly in patients with non-ST elevation acute coronary syndromes.[11] However, in patients with stable angina, routine use of a 600-mg loading dose at least 6 hours before angiography was no more effective than a selective strategy in which the same dose was given immediately after angiography only to those patients proceeding to PCI.[27]
- Glycoprotein IIb/IIIa-receptor antagonists such as abciximab, eptifibatide, and tirofiban given intravenously improve outcomes in a variety of patients undergoing PCI,[28] including those with acute coronary syndromes, those undergoing elective PCI, and patients receiving intracoronary stents. However, recommendations for their use vary,[2,3,11,29] and some guidelines consider them unnecessary in low-risk patients unless complications occur. Evidence for tirofiban is limited to patients with acute coronary syndromes, while abciximab is generally preferred in patients undergoing PCI for acute myocardial infarction.

  In most studies glycoprotein IIb/IIIa-receptor antagonists have been given as adjuncts to heparin and aspirin, and their role in patients also taking clopidogrel is less clear; studies in patients undergoing PCI electively[30] or for acute coronary syndromes[31] have found that abciximab adds no further benefit to clopidogrel pretreatment except in patients with raised troponins. There is also some evidence[32] that use of glycoprotein IIb/IIIa-receptor antagonists (in this case eptifibatide) with both clopidogrel and aspirin may make the routine use of heparin unnecessary.

Other acute complications during PCI include vasospasm, reperfusion injury, and arrhythmias; lack of reflow in the target artery ('no-reflow') may result from vasospasm or distal embolisation. Vasodilators such as nitrates or calcium-channel blockers may be given at the start of the procedure to reduce vasospasm;[2] verapamil, adenosine, or sodium nitroprusside may be used to treat no-reflow,[2] but are not recommended for routine prophylaxis.[33] Various drugs have been tried for cardioprotection,[34] and to protect against myocardial reperfusion injury,[35] but none yet has an established role.

Long-term treatment. Patients undergoing surgical or percutaneous revascularisation remain at risk of thrombosis after the procedure as the endothelium heals, and are also at risk of further cardiovascular events due to generalised atherosclerosis. Antithrombotic therapy should therefore be continued long-term, and patients should also be assessed for their overall cardiovascular risk and treated as appropriate (see Cardiovascular Risk Reduction, p.1164).

Anticoagulants are usually only given intravenously at the time of the procedure and oral anticoagulants such as warfarin are not routinely used. They may have a role in addition to aspirin in patients at high risk of graft occlusion after peripheral artery bypass,[36] although a study[37] comparing oral anticoagulants with aspirin found no difference in reocclusion or mortality, whereas bleeding was higher in patients receiving anticoagulants.

Antiplatelet drugs have an established role in reducing major coronary events after surgical and percutaneous revascularisation procedures,[38,39] and may also reduce reocclusion after peripheral percutaneous interventions.[40] Aspirin is recommended indefinitely in all patients.[11,19,36] Clopidogrel may be used as an alternative in patients unable to take aspirin, but may also be given as additional therapy. There is evidence that it reduces major coronary events when given with aspirin after PCI,[41] and long-term use of the combination has been recommended,[3,11,19] especially in patients with coronary stents.

Coronary artery stents[1,42] were initially developed to treat or prevent acute occlusion of the vessel due to elastic recoil after balloon angioplasty, but are now used routinely in most PCI to reduce the risk of restenosis (see below), although their effect on mortality is unclear.[43] Thrombotic occlusion 2 to 14 days after the procedure (subacute stent thrombosis) is a major complication with stent use, and initially led to the use of intensive anticoagulant/antiplatelet regimens.[42] However, with optimal stent deployment and use of heparin during the procedure, oral antiplatelet drugs alone appear to be adequate, and a combination of aspirin with clopidogrel is now recommended. Aspirin should be continued indefinitely, but the optimum duration for clopidogrel therapy is less clear. For patients with bare metal stents, clopidogrel should be given for at least 2 to 4 weeks,[2] and treatment for 12 months has been recommended.[3,19] For patients with drug-eluting stents, the risk of occlusion persists for longer, and the benefit of continuing clopidogrel is better established.[44,45] Combination therapy is therefore recommended for at least 12 months,[3,19,46] and may be continued indefinitely if tolerated.[19] Cilostazol has also been used, both as an alternative to thienopyridines,[47,48] and as part of a triple platelet regimen.[49] Heparin-coated stents may also have a role.[50]

Restenosis is a specific long-term complication of percutaneous procedures.[1,51,52] Several pathological processes are believed to be responsible, including platelet aggregation and thrombus formation, elastic recoil, vascular remodelling, and neointimal hyperplasia. Symptomatic restenosis often requires a repeat revascularisation procedure and increases the risk for clinical events. Stents reduce restenosis by preventing elastic recoil and vascular remodelling, but are associated with a higher risk of neointimal hyperplasia, and in-stent restenosis is a particular problem.[53,54] This has led to the investigation of drugs to prevent restenosis, but results have generally been disappointing. Greater success has been reported with drug-eluting stents, and these are now widely used, as discussed below; however, they are not without complications, and oral therapies continue to be investigated.

Although **systemic therapy** with antiplatelet drugs and anticoagulants reduces the risk of thrombus formation, there is little evidence that they reduce the degree of restenosis; studies with cilostazol have suggested that it may have some effect,[55,56] but this is not yet established. Lipid-regulating drugs are indicated in most PCI patients for cardiovascular risk reduction, but again their effects on restenosis are unclear;[51] there is weak evidence that omega-3 fatty acids[57] reduce restenosis, while mixed results have been reported with statins[58,59] and with probucol.[60,61] Folate therapy (folic acid, vitamin B6, and vitamin B12) has been tried since it reduces plasma-homocysteine concentrations, a risk factor for atherosclerosis and possibly restenosis, but again results have been mixed.[62]

Antiproliferative drugs have been tried, but early positive results have generally not been confirmed in larger studies.[51,63] Sirolimus, which is widely used in drug-eluting stents, has shown benefit[64-66] when given orally. Other drugs for which positive or mixed results have been reported include angiotensin II receptor antagonists,[67,68] calcium-channel blockers,[69,70] corticosteroids,[71] and thiazolidinediones,[72] but none has an established place in therapy.

The disappointing results with systemic drug treatment may relate to the difficulty in achieving adequate concentrations at the target site and **localised methods** of treatment have therefore been tried. Intracoronary radiotherapy (brachytherapy) has reduced the rates of restenosis after angioplasty,[73] and after stenting,[74] but is complex to perform and availability may be limited. *Drug-eluting stents* are now generally the preferred treatment.

These usually consist of metal stents coated with a polymer containing the drug, which is then released over a period of time, and they allow the localised delivery of high doses of drugs to the site of vessel injury. Heparin-coated stents have been used to reduce periprocedural thrombosis and may reduce long-term stenosis,[50] but stents releasing antiproliferative drugs are most widely used. Both sirolimus- and paclitaxel-eluting stents have been shown[75,76] to reduce neointimal proliferation and clinical events, including the need for repeat revascularisation, and they appear to be more effective than intravascular brachytherapy.[77,78] Outcomes may be better with sirolimus than with paclitaxel,[79] but this does not appear to be clinically important.[80,81] Other drugs that are used include sirolimus analogues such as everolimus and zotarolimus, and dexamethasone; lanreotide, and the sirolimus analogues tacrolimus and biolimus A9 are under investigation. Use of a paclitaxel-coated angioplasty balloon has also been tried,[82] and local gene therapy is also under investigation.

Although drug-eluting stents clearly reduce the incidence of restenosis, late stent thrombosis has been reported[83,84] and appears to occur more frequently than with bare-metal stents;[85] possible mechanisms include delayed endothelialisation due to the drug or hypersensitivity reactions possibly related to the polymer coating.[86] However, analyses using different definitions of late thrombosis have suggested[87] that there is no significant difference between the types of stent, and the clinical relevance of any increase in the incidence of late thrombosis remains unclear. The effect of drug-eluting stents on mortality has also been debated; some analyses[88,89] have reported an increased mortality with drug-eluting stents, whereas others[85,90] have found no significant effect. There is some evidence[91,92] that outcomes with drug-eluting stents are worse in high-risk clinical situations, although observational studies[93,94] suggest they are as safe as bare metal stents in such patients, and it appears that late events may be related to duration of antiplatelet therapy.[84] The FDA has stated[46] that the concerns about thrombosis do not outweigh the benefits of drug-eluting stents when used for their approved indications, but that outcomes may not be the same in other patients.

Shock

Shock is a complex clinical syndrome in which there is a failure of the circulatory system to maintain cellular perfusion and function. There are many aetiologies, but the underlying defect is either inadequate venous return to the heart due to an absolute or relative reduction in plasma volume, or failure of the pumping action of the heart. A traditional approach has been to place the cause of shock into one of several basic groups:

- *Hypovolaemic shock* results from fluid loss; cardiac output is reduced due to inadequate filling pressure. Haemorrhagic causes include severe gastrointestinal bleeding and traumatic injury, while non-haemorrhagic causes include severe vomiting and diarrhoea, polyuria, and burns. Hypovolaemia can also be present in other forms of shock; in septic or anaphylactic shock fluid loss from the vasculature may occur due to capillary leakage, while peripheral vasodilatation may lead to relative hypovolaemia

- *Cardiogenic shock* usually results from acute cardiac dysfunction or failure, leading to an inadequate stroke volume and reduced cardiac output. It has a number of causes, but is most often associated with acute myocardial infarction. Other cardiac causes include valvular heart disease, cardiomyopathies, and severe cardiac arrhythmias; episodes of acute heart failure may also occur due to decompensation in patients with chronic heart failure. Shock due to circulatory disorders such as massive pulmonary embolism is also sometimes classified as cardiogenic. Other forms of shock may also have a cardiac component
- *Septic shock* occurs as a complication of infectious disease and is described and defined in more detail under Septicaemia, p.190. Hypotension occurs primarily due to peripheral vasodilatation, but fluid loss and direct effects on the heart may also be involved. Cardiac output may be reduced due to hypovolaemia; however, if circulatory volume is adequate, cardiac output is often high
- *Anaphylactic shock* (p.1205) is the result of a hypersensitivity reaction and is similar haemodynamically to septic shock

In the early stages of shock, compensatory mechanisms are usually sufficient to maintain the blood pressure, but these generally become inadequate and patients in decompensated shock classically present with hypotension, tachycardia, and tachypnoea. The skin is often cold, clammy, and cyanotic, due to compensatory peripheral vasoconstriction, while impaired organ perfusion results in dulled mental alertness, which may progress to stupor or coma; oliguria or anuria, due to impaired renal perfusion, are also frequent. Pulmonary oedema may occur as a result of impaired cardiac output in cardiogenic shock. Complications of shock include disseminated intravascular coagulation due to platelet sludging and microvascular insufficiency, acute respiratory distress syndrome (previously termed 'shock lung') (p.1498), and acute renal failure. The terms multiple organ failure syndrome (MOFS) and multiple organ dysfunction syndrome (MODS) are applied to the consequences of shock where several organs or body systems have become hypoperfused and are unable to maintain their normal function.

Management. The initial aim of treatment in all forms of shock is to restore tissue perfusion by correcting hypovolaemia and hypotension, and restoring cardiac output.[1-6] Hypoxaemia should be avoided and supplemental oxygen or mechanical ventilation may be required. Intravenous opioid analgesics may be needed for pain, and an adequate diuresis should be maintained in order to prevent renal failure; diuretics may also be required if there is pulmonary oedema. Impaired tissue perfusion often leads to lactic acidosis, but the need for specific treatment (see Metabolic Acidosis, p.1667) is unclear; sodium bicarbonate may be given for severe acidosis,[1] although some[4] consider that it should not be used. Other electrolyte abnormalities should be corrected as appropriate.

Hypovolaemia. Restoration of the circulating volume is essential, both to replace lost fluids in hypovolaemia and to maintain cardiac filling pressure in other forms of shock; small volumes may be beneficial in cardiogenic shock, but should be given cautiously to prevent pulmonary oedema. Replacement fluids available include blood products and crystalloid or colloid plasma expanders,[7-9] and the choice depends on the clinical situation. Blood products are expensive and not always available, while the relative merits of crystalloids and colloids continue to be debated.

In haemorrhage, volume expansion to maintain organ perfusion is initially the most important consideration,[10] although in trauma patients the optimum timing and quantity of fluid to give is not clear.[8,9,11] Anaemia is generally better tolerated than hypovolaemia, but where blood loss is extensive (usually considered as 40% or more of the total blood volume), red cell replacement is also required.[10,12] This usually takes the form of packed red cells with plasma expanders, and other plasma components as required. Blood substitutes are also under investigation as an alternative to red cell products, but none yet has an established role.[8,9]

In non-haemorrhagic hypovolaemia, plasma expanders alone are used. Crystalloids (solutions containing solutes such as glucose or sodium chloride that can pass a semipermeable membrane) rapidly expand both the intravascular and extravascular compartments, which could be beneficial since both become depleted in hypovolaemia. However, large volumes may be required and the duration of effect is short as fluid is rapidly redistributed. Hypertonic crystalloid solutions may allow smaller volumes to be used. Colloids (solutions containing large molecules such as albumin, dextrans, gelatins, and etherified starches, which do not pass semipermeable membranes) expand the intravascular space more effectively; they have a longer duration of effect and smaller volumes are required. This may be beneficial since it causes less haemodilution, but the exact significance of this has been questioned; the risk of hypersensitivity reactions, including anaphylaxis, may also be a concern.

Studies comparing the use of crystalloids and colloids in hypovolaemia have generally been of poor quality and the results are difficult to interpret. A systematic review[13] of trials in critically ill patients concluded that there was a small increase in mortality associated with the use of colloids, and that since they were more expensive and of no proven benefit they should not be routinely used. A further review,[14] looking specifically at the use of albumin, also suggested an increased mortality with use of the colloid. Both reviews were severely criticised,[15-17] and the relative benefits of the different types of fluid continue to be debated. A large trial[18] comparing the use of albumin and sodium chloride 0.9% in intensive care patients who required fluid resuscitation found no difference in mortality at 28 days. Updates to both reviews[19,20] to include this study found that there was no evidence of any benefit for colloids compared with crystalloids, and the authors continued to state that colloids should not be routinely used. However, there was no clear difference in mortality between patients given colloids or crystalloids, other than a suggestion[20] that albumin might increase mortality in patients with burns or hypoproteinaemia. In practice, a mixture of colloids and crystalloids tends to be given. Choice of the best crystalloid or colloid to give remains unclear; systematic reviews have found no evidence that one colloid is better than another,[21] or that hypertonic solutions are better than isotonic solutions if crystalloids are used.[22]

Hypotension and low cardiac output. Although correction of hypovolaemia may be sufficient to restore blood pressure, hypotension in shock may be profound (sometimes a systolic pressure of less than 70 mmHg) despite fluid replacement, and additional therapy with inotropes and vasopressors is often needed to improve cardiac output and reverse signs of impaired organ function.[1,4] Sympathomimetics are often used since they may have effects on the heart and the vasculature, but alternative vasoconstrictors and inotropes may also have a role. Choice depends on individual patient characteristics and the type of shock,[23] although this is generally based on theoretical considerations; a systematic review[24] of the use of vasopressors in shock found insufficient evidence to make any recommendations.

In cardiogenic or hypovolaemic shock cardiac output is usually low but peripheral resistance is high and drugs that have predominantly inotropic effects, such as dobutamine or dopamine, are often chosen. Dobutamine causes some peripheral vasodilatation and is useful where hypotension is not significant; dopamine similarly causes peripheral vasodilatation at low doses but at higher doses vasoconstriction occurs. Low-dose dopamine has been widely used as an adjunct to other inotropes since it was thought that the vasodilatation would lead to renal protection, but clinical benefit has not been established and such use is no longer recommended (see Surgery and Intensive Care, p.1274). Phosphodiesterase inhibitors such as amrinone and milrinone can also be considered in low cardiac output states; they have positive inotropic activity and produce peripheral vasodilatation, and may be particularly useful in patients with decompensated chronic heart failure who have been taking beta blockers.[2,4,5] Vasodilators such as intravenous glyceryl trinitrate or sodium nitroprusside may also be beneficial for patients in shock with a low cardiac output but adequate blood pressure, as well as in patients with pulmonary oedema.[1,2,5] They act by reducing cardiac afterload but must be used with care as there is a risk of precipitating hypotension.

In septic or anaphylactic shock, where cardiac output is generally high but peripheral resistance is low, vasoconstrictors such as noradrenaline or dopamine are usually preferred;[1,6] they may be given with more potent inotropes such as dobutamine or adrenaline. Adrenaline has also been given alone although renal artery vasoconstriction may limit its use; it has also been reported to cause lactic acidosis,[25] but a study[26] comparing noradrenaline plus dobutamine with adrenaline alone found no difference in outcomes in patients with septic shock. Vasopressin may be an alternative,[6,27,28] particularly in patients with vasodilatation that is resistant to sympathomimetics, but is not recommended for routine use. It may also be used as an adjunct to sympathomimetics, although no clear benefit has been shown compared with sympathomimetics alone.[29].

The opioid antagonist naloxone may also improve blood pressure in shock,[30] but its role is not established.

Specific therapies are indicated in some types of shock. In cardiogenic shock associated with ***myocardial infarction***,[2,31] specific therapy to restore myocardial perfusion is also required (see p.1175).

In ***septic shock*** appropriate antibacterial therapy should be given as outlined under Septicaemia on p.190. Methods of inhibiting endogenous mediators released in response to sepsis that are thought to be responsible for the haemodynamic effects are also under investigation but clinical benefits have not yet been shown.[3,32] However, improved outcomes have been reported[33,34] with the use of low-dose corticosteroids, and in severe sepsis activated protein C may also be used.[6]

Adrenaline is the cornerstone of management in ***anaphylactic shock*** (see p.1205).

Stroke

Stroke, sometimes called a cerebrovascular accident, is the major consequence of cerebrovascular disease and has been defined as an acute neurological dysfunction of vascular origin with sudden (within seconds) or at least rapid (within hours) occurrence of symptoms and signs corresponding to the involvement of focal areas of the brain. If signs and symptoms persist for more than 24 hours or lead to death the event is termed a completed stroke, whereas if they disappear within a few minutes or hours, or at most within 24 hours, the event is termed a transient ischaemic attack.

Strokes may be ischaemic (infarction-related) or haemorrhagic.[1-4] **Ischaemic stroke** is by far the commonest type and generally results from occlusion of cerebral arteries. This may be caused by local thrombosis at sites of atheroma, but more commonly results from thromboemboli arising from outside the brain and lodging in the cerebral vessels; an example of the latter is cardioembolic infarction associated with atrial fibrillation or acute myocardial infarction. Arterial occlusion results in inadequate cerebral perfusion, which leads to ischaemia and subsequently to stroke. About 20% of patients with acute ischaemic stroke experience worsening of symptoms within a few days of onset. This is termed progressing stroke, stroke-in-evolution, or unstable stroke, and may be due to progression of the thrombosis; haemorrhagic conversion, with bleeding into the infarcted area, may also occur. **Transient ischaemic attacks** are acute episodes of focal neurological deficit or monocular visual loss (amaurosis fugax), mainly due to ischaemia associated with atherothrombosis. There is usually complete clinical recovery but a tendency for recurrence, and patients are also at an increased risk of stroke. **Haemorrhagic stroke** is secondary to subarachnoid or to intracerebral haemorrhage. *Subarachnoid haemorrhage* is bleeding into the fluid-filled subarachnoid space between the brain and the skull, and usually occurs after rupture of an aneurysm; other causes include arteriovenous malformations and hypertensive microaneurysms. *Intracerebral haemorrhage* is bleeding into the parenchyma of the brain, and may result from rupture of arteries damaged by chronic hypertension. Haemorrhage produces a focal haematoma causing a local increase in pressure which may lead to further bleeding and enlargement of the haematoma. The increase in pressure in the area of the haematoma may also produce local ischaemia.

Clinical presentation of stroke can vary enormously in severity and combination of signs and symptoms, and depends on the site and extent of infarction or haemorrhage. Haemorrhagic stroke is typically of sudden onset with severe headaches, vomiting, and rapid deterioration of consciousness – all signs of raised intracranial pressure – but mild to moderate haemorrhage may be difficult to distinguish from infarction on the basis of clinical signs alone. Neurological deficits in all forms of stroke may include impairments to speech, balance, vision, touch sensation, and movement. Recovery is variable and patients have been classed as major or minor stroke (reversible ischaemic neurological deficit) victims according to their degree of recovery at a given time after the stroke.

Accurate diagnosis of the type of stroke is important since management is very different and interventions that are beneficial in infarction may be dangerous in patients with haemorrhage. Although clinical presentation may suggest the type of stroke this is not always reliable and imaging is usually required to distinguish between haemorrhagic and ischaemic stroke. Computed tomography (CT) is the preferred technique, but magnetic resonance imaging may also be used.[5,6] Diagnosis of transient ischaemic attacks usually rests on the patient's history as these short attacks are seldom witnessed by a physician and there are no objective confirmatory tests; however, imaging has an important role in determining aetiology and guiding subsequent management.[7,8]

Management of stroke involves immediate treatment of the acute stroke, treatment and prevention of complications such as swallowing disorders or spasticity, rehabilitation, and long-term treatment for secondary prevention. Where possible, patients should be managed within a stroke unit since this has been shown to improve outcome. Primary prevention may be considered in individuals at risk of ischaemic stroke. This includes those with atrial fibrillation, a major risk factor for stroke (see Cardiac Arrhythmias, p.1160), and those with risk factors for atherosclerosis (see Cardiovascular Risk Reduction p.1164); the role of endarterectomy in individuals with carotid artery stenosis is discussed under Long-term Management, below.

Ischaemic stroke. Reviews[9-14] and guidelines[5,6,15] emphasise that, as in myocardial infarction, early recognition of symptoms and prompt evaluation and treatment of stroke are of vital importance. The aim of treatment is to limit or reverse damage to the brain. Ischaemia deprives the cells of oxygen and glucose, leading to infarction, but this appears to be time-dependent. While some tissue may be irreversibly damaged when the patient presents, there is evidence that surrounding tissue (the 'ischaemic penumbra') may be salvageable. Restoration or improvement of blood flow is therefore a logical means to preserve this tissue; strategies to protect the cells from the consequences of ischaemia are an alternative approach.

Acute management involves general supportive measures, and specific treatments to reverse ischaemia and protect the brain tissue. General supportive measures include ensuring adequate oxygenation and fluid and electrolyte balances, avoiding hypercapnia and hyperglycaemia or hypoglycaemia, abolishing seizures, and treating fever; nutritional status should also be assessed. Control of hypertension is controversial since lowering the blood pressure may reduce cerebral perfusion and worsen ischaemia, and hypertension usually resolves spontaneously without treatment.[16] Antihypertensive therapy may be indicated in specific patients, such as those with severe hypertension or those being considered for thrombolytic therapy.

Specific therapy for ischaemic stroke is limited. As in myocardial infarction, the main cause of ischaemic stroke is thromboembolic occlusion, and use of antithrombotic drugs such as antiplatelets, heparin, and thrombolytics, therefore appears logical. However, evidence of benefit is not as clear as it is in myocardial infarction, and the risks may be greater; the presence of haemorrhage must be excluded and the risk of potentiating spontaneous secondary brain haemorrhage (haemorrhagic transformation) must be borne in mind. Other strategies to improve blood flow or to limit the effects of ischaemia using neuroprotectants have also been tried, but results to date have been disappointing.

Antiplatelet drugs. Aspirin has been evaluated in two large studies—the International Stroke Trial (IST)[17] and the Chinese Acute Stroke Trial (CAST).[18] The combined results of these studies[18] found that aspirin 160 mg[18] or 300 mg[17] daily started within 48 hours of symptom onset produced about 9 fewer deaths or non-fatal strokes per 1000 patients in the first few weeks following ischaemic stroke. Aspirin has therefore been recommended for patients with ischaemic stroke who are not receiving thrombolytic or anticoagulant therapy, and should be started within 48 hours of stroke onset.[5,6,19] Other antiplatelet drugs are under investigation, but do not yet have an established role;[5,6] a study with the glycoprotein IIb/IIIa antagonist abciximab was stopped early due to an increased incidence of bleeding.[20]

Anticoagulants are not routinely recommended in the early management of acute ischaemic stroke,[5] although they may have a role in selected patients.[6] Anticoagulation should prevent further thrombus formation and limit the size of the cerebral infarct; however, any benefit may be offset by an increase in intracranial haemorrhage, and a systematic review[21] has suggested there is no evidence to support routine use. The IST,[17] which evaluated two dosages of heparin (5000 units or 12 500 units subcutaneously twice daily), found no benefit from either regimen and the higher dose particularly was associated with haemorrhagic stroke and bleeding. Another study,[22] comparing the low-molecular-weight heparin tinzaparin with aspirin, similarly found no benefit. It had been suggested that patients with cardioembolic stroke were likely to benefit from heparin therapy,[23] even though there is a special risk of haemorrhagic transformation in these patients, which means that early anticoagulation is often hazardous. However, the IST[17] failed to show any benefit in this group, and a study[24] of low-molecular-weight heparin in patients with acute ischaemic stroke and atrial fibrillation also showed no benefit. No improvement in outcome was reported after 3 months in a study of danaparoid given in acute ischaemic stroke.[25] A study[26] with ancrod found an improvement in outcome when given within 3 hours of stroke onset, but a further study was terminated due to lack of benefit.

The risk of venous thromboembolism (deep-vein thrombosis and pulmonary embolism) is increased after stroke, particularly in immobile patients, and prophylaxis with low-dose subcutaneous heparin or low-molecular-weight heparin may be considered in those at high risk.[6,19]

Thrombolytics. Intravenous thrombolytics increase the risk of cerebral haemorrhage and have therefore generally been contra-indicated in both ischaemic and haemorrhagic stroke. However, there is evidence that use of thrombolytics in ischaemic stroke may be of benefit, despite the increased risk of bleeding, and they may have a role in selected patients,[27-29] particularly if they can be given in the early stages.[30] A study[31] with alteplase given within 3 hours of the onset of stroke (NINDS—National Institute of Neurological Disorders and Stroke rt-PA Stroke Trial) found that clinical outcome was improved, despite an increased incidence of symptomatic intracerebral haemorrhage. Patients treated with alteplase were more likely to have minimal or no disability 3 months after stroke,[31] and this benefit was maintained at 12 months.[32] However, there was no difference in mortality or rate of recurrence of stroke. On the basis of this study, guidelines[5,6,19] now recommend alteplase for selected patients if it can be given within 3 hours of stroke onset, and this appears to be safe in practice.[33,34] Other thrombolytics, such as streptokinase, have generally produced less favourable results, and none of these are currently recommended. The intra-arterial route has also been tried and may be used in selected patients.[5,6,19] Combined use of intravenous and intra-arterial alteplase,[35] as well as use of adjunctive therapies such as therapeutic ultrasound[36] or antithrombotics, are under investigation but do not yet have an established role.[5]

Other approaches that have been tried include various methods to improve cerebral blood flow. Haemodilution with *dextran* or *pentastarch* has generally been disappointing and is not usually recommended.[5,6] Drug-induced hypertension may also increase cerebral blood flow and appears to be safe,[37] but clinical benefit remains to be established.[5] Hypoxia and hypocapnia may cause cerebral vasoconstriction as well as directly contributing to ischaemic injury, and there have been anecdotal reports and small studies reporting benefit with *hyperbaric oxygen therapy*, although a systematic review[38] suggested that clinical benefit was unlikely. Treatment with *corticosteroids* or hyperosmolar diuretics such as *glycerol* or *mannitol* in an attempt to reduce the cerebral oedema has also been disappointing. There may be some benefit with glycerol, but further evidence is needed.[39]

Neuroprotection. Ischaemia leads to a complex series of biochemical changes, the 'ischaemic cascade', resulting eventually in cell necrosis. The process is incompletely understood, but steps include calcium influx and release of neurotransmitters. Drugs acting at different steps in this ischaemic cascade, sometimes termed neuroprotectants, have been tried in acute ischaemic stroke in the hope of limiting the damage caused by ischaemia. Results of studies so far have been largely disappointing, and no drug has yet been found to be effective. However, research continues,[40] with many trials focusing on starting treatment in the first few hours after ischaemic stroke.[41]

Long-term management. Patients who have had an ischaemic stroke or transient ischaemic attack are at risk of further stroke but are also at increased risk of other cardiovascular events, including myocardial infarction and sudden death. Long-term treatment for secondary prevention therefore has an important role.[6,42-46] All patients should be assessed for standard cardiovascular risk factors, particularly hypertension, and these should be treated as appropriate (see Cardiovascular Risk Reduction, p.1164). There is some evidence that reduction of blood pressure and lipids reduces the risk of stroke irrespective of the presence of hypertension or hyperlipidaemia,[44] and the use of ACE inhibitors or angiotensin II receptor antagonists[47] and statins[6] has been recommended. Atrial fibrillation is a specific risk factor for stroke and should also be treated (see Cardiac Arrhythmias, p.1160). Hypercoagulability may increase the risk of stroke and blood screening for polycythaemia, thrombocytosis, and abnormal coagulation function has been recommended. Carotid endarterectomy is of established benefit for secondary prevention in patients with clinically significant carotid stenosis,[6,48] but its role in primary prevention is less clear.[49,50] Antithrombotic therapy may also have a specific role.

Antiplatelet drugs. Long-term prophylaxis with aspirin reduces the risk of future serious vascular events including stroke in patients who have already suffered an ischaemic stroke or transient ischaemic attack,[19,45,46,51] regardless of age.[52] The optimum dose is unclear; medium doses of 75 to 325 mg of aspirin daily have been most widely studied[51] and an analysis of trials using aspirin over a dose range of 50 to 1500 mg daily found no relationship between dose and the reduction in risk of stroke.[53] In patients undergoing carotid endarterectomy the risk of stroke, myocardial infarction, and death over 3 months may be lower for those taking medium dose aspirin compared with higher doses.[54] Dipyridamole is also effective,[55,56] and has been used in patients unable to tolerate aspirin, but it is more effective when given with aspirin[56,57] and combination therapy is now preferred.[6,19,45] Clopidogrel is another alternative,[58] but should not be given with aspirin since any benefit is offset by an increased risk of bleeding.[59] Ticlopidine has also been used, but adverse effects are a problem and a study[60] in black patients found that it was less effective than aspirin.

Anticoagulants. Oral anticoagulants have an established role in patients with cardioembolic stroke, but in patients with non-cardioembolic stroke or with transient ischaemic attacks they have no clear advantage over antiplatelet drugs,[61,62] and some studies[63,64] comparing warfarin with aspirin have been stopped early due to increased bleeding risks with the anticoagulant. Anticoagulants are therefore not generally recommended for secondary prevention in non-cardioembolic stroke[6,45,46] although they have been used in patients with recurrent symptoms despite antiplatelet therapy and may be considered in other selected patients.[6,19,45]

Subarachnoid haemorrhage. Subarachnoid haemorrhage[65-68] is associated with high morbidity and mortality, early deaths being due to damage from initial bleeding, recurrence of bleeding, and infarction. Infarction is often a result of vasospasm which is one of the pathophysiological mechanisms that contributes to stopping the bleeding; clot formation and increasing intracranial pressure are other processes involved. Up to a quarter of patients with subarachnoid haemorrhage develop delayed cerebral ischaemia mainly between days 5 and 14 after the initial bleed, and again vasospasm may be a contributory factor. Early medical treatment aims to prevent delayed cerebral ischaemia, to prevent rebleeding, and to stabilise the patient. Surgical or endovascular interventions to clip or embolise the aneurysm or correct the arteriovenous malformation are then performed to prevent further haemorrhage. Vasospasm and delayed cerebral ischaemia may be prevented by maintaining or slightly increasing plasma volume and blood pressure, and a fluid intake of 2 to 3 litres daily has been recommended.[65] However, there is no good evidence to support routine volume expansion.[69] Oral nimodipine is of benefit[70] and should be started as soon as possible after diagnosis of subarachnoid haemorrhage. Antiplatelet drugs have also been tried and may improve outcomes, but this remains to be confirmed.[71] Established vasospasm may be treated by angioplasty, or intra-arterial vasodilators may be given. There is some evidence of benefit with intra-arterial papaverine,[72] although adverse effects have also been reported;[73] verapamil has also been used.[74] Use of antifibrinolytics such as aminocaproic acid or tranexamic acid to prevent rebleeding is no longer generally recommended.[65] A systematic review[75] found that any benefits were offset by an increase in poor outcomes due to cerebral ischaemia; paradoxically, rebleeding has been noted in patients given high doses of aminocaproic acid after subarachnoid haemorrhage (see Effects on the Blood, under Adverse Effects of Aminocaproic Acid, p.1053). Headache can be managed with analgesics such as paracetamol, dextropropoxyphene, codeine, or tramadol. Localised haematomas may be amenable to surgical evacuation, and intraventricular thrombolytics have also been used.[76]

Intracerebral haemorrhage. Outcome of intracerebral haemorrhage depends on the location and size of the haematoma (determined by computed tomography), on the level of consciousness, and on the progression of neurological signs, and development of increased intracranial pressure.[77-79] Any known cause of bleeding, such as warfarin anticoagulation, should be reversed. Optimum management of blood pressure is uncertain; it should probably be lowered when it is very high (>200 mmHg systolic[80]), but hypoperfusion should be avoided. Short-acting antihypertensives such as labetalol, esmolol, or sodium nitroprusside are generally used,[80] although theoretically nitroprusside may increase intracranial pressure and should be avoided if this is already raised.[79] Surgical drainage of the haematoma may sometimes be possible, but its role is uncertain;[79,80] routine early surgery has not been shown[81] to improve outcome. Instillation of a thrombolytic to improve aspiration of the haematoma has been reported,[82] but benefit has not been established. Raised intracranial pressure should be controlled[80] (see p.1181). Antiepileptic prophylaxis may be necessary in some patients.[80] Use of activated factor VII to reduce the risk of further bleeding provided some benefit,[83] but has not been shown to improve survival or functional outcome.[84] Long-term management of risk factors, particularly hypertension, should be considered for secondary prevention.

Thromboembolic disorders

The term thromboembolic disorder has been applied loosely to cardiovascular disorders associated with thrombus and embolus formation in blood vessels. A **thrombus** is a stationary blood clot composed of fibrin and platelets and other cellular elements. **Thrombosis** is occlusion of a vein or artery by a thrombus. An **embolus** is a fragment of blood clot, atheromatous material, or other foreign matter carried along in the bloodstream. Occlusion of a blood vessel by an embolus is termed **embolism** or **thromboembolism**.

Formation of blood clots in the body is the result of a coagulation cascade (see Haemostasis and Fibrinolysis, p.1045). Under normal circumstances systemic coagulation is prevented by natural antithrombotic systems that limit blood clots to sites of vascular injury. Thromboembolic disorders occur when there is an imbalance between these systems. Three factors are involved, namely damage to the endothelial lining of blood vessels, reduced blood flow, or changes in the coagulation mechanisms of the blood. A further factor that increases the risk of clotting is the presence of an artificial surface in contact with the blood, for example mechanical heart valves, intravascular catheters, or during extracorporeal circulation procedures. Thromboembolism can occur in any part of the circulation, including the heart and the capillaries, but the characteristics of the thrombi, the consequences, and the management of thromboembolism depend to a large extent upon whether the arterial or venous system is involved.

The mainstay of management for thromboembolic disorders is antithrombotic drugs. These act at different points in the coagulation cascade and include anticoagulants and antiplatelet drugs, which are used to limit the extent of thrombosis or thromboembolism and to prevent further thromboembolic events occurring, and thrombolytics, which are used to lyse the clot.

Arterial thromboembolism is almost always a consequence of damage to the endothelium due to atherosclerosis (p.1159); the atheroma may block the blood vessel or, more commonly, occlusion is a result of thrombus formation at a site of a recently ruptured atheromatous plaque. Arterial thrombi contain more platelets than venous thrombi and tend to remain fixed, but emboli may break off and occlude distal vessels. Arterial emboli may also result from thrombosis within the heart, for example due to arrhythmias or valvular heart disorders.

Thrombosis or thromboembolism in the arterial circulation produces ischaemia in the tissues perfused by the artery, which may lead to infarction. It may therefore result in myocardial infarction (p.1175) or unstable angina (p.1157) if it occurs in coronary arteries, stroke (p.1185) if it occurs in cerebral arteries, or critical limb ischaemia if it occurs in peripheral arteries (p.1178).

Venous thromboembolism (p.1189) is usually a consequence of stasis of the blood, but other factors such as local trauma or coagulation activation are also required. Reduced venous blood flow occurs in many conditions, including obesity, heart failure, and during prolonged immobilisation. Abnormal clotting may occur in conditions such as malignancy, pregnancy, and the nephrotic syndrome, or during oestrogen therapy; it may also be due to inherited or acquired clotting disorders or thrombophilias (see below). Surgical operations are particularly associated with venous thromboembolism; trauma activates clotting factors and reduced blood flow may occur during the procedure and recovery period.

Venous thrombi have a 'red tail' of fibrin and red cells that may occlude the vein but which often separates to form an embolus; this is most likely during the early stages when the thrombus is only loosely attached. Thrombosis or thromboembolism in the venous circulation produces oedema or inflammation in the tissue drained by the affected vein. The commonest type of venous thrombosis is deep-vein thrombosis, which is associated especially with immobility and the postoperative period. Pulmonary embolism is the most serious complication of deep-vein thrombosis and occurs when part of the thrombus migrates in the circulation and becomes lodged in the pulmonary artery. Hypercoagulable states may result in deep-vein thrombosis or more generalised clotting in microvessels (microvessel thrombosis), such as thrombotic thrombocytopenic purpura or purpura fulminans (see Thrombotic Microangiopathies, p.1076).

Thrombophilias are acquired or inherited disorders of the clotting system in which the antithrombotic mechanisms are impaired. Inherited deficiencies of antithrombin III, protein C and protein S all predispose to thromboembolism. Resistance to activated protein C has been identified as a major cause of inherited thrombophilia and appears to be due to a mutation in the factor V gene (factor V Leiden). A mutation in the prothrombin (factor II) gene is associated with increased concentrations of prothrombin and risk of thrombosis. Acquired thrombophilias may occur secondary to disorders such as malignancy, infection, or collagen-vascular disorders; in many cases antiphospholipid antibodies (such as lupus anticoagulant) are present. Hyperhomocysteinaemia is another risk factor and may have both inherited and acquired causes.

Inherited thrombophilias generally result in venous thromboembolism; this is often recurrent and may occur in unusual sites or at a young age. They often present when some further risk factor is present, such as pregnancy, use of combined oral contraceptives, or surgery, but the value of screening asymptomatic patients remains unclear. Acquired thrombophilias may lead to arterial or venous thromboembolism.

Patients with thrombophilias who develop thromboembolism should be treated conventionally, with anticoagulants or thrombolytics as appropriate. There continues to be debate regarding the duration of therapy, with some authorities recommending life-long anticoagulant therapy after a single episode and others recommending life-long therapy only in those with recurrent thrombosis. The optimum intensity of long-term anticoagulation in patients with thrombophilia is also debated. If anticoagulation is not continued, thromboprophylaxis should be given during high risk situations. Thromboprophylaxis is probably also necessary during pregnancy, particularly in women with antiphospholipid antibodies who are at risk for recurrent fetal loss (see Systemic Lupus Erythematosus, p.1513), but the risks to the fetus from anticoagulant therapy must also be considered (see Venous Thromboembolism, p.1189). Replacement of antithrombotic factors may have a role in some situations.

Valvular heart disease

Valvular heart disease affects the normal function of the heart and leads to disorders of blood circulation. The principal cause of valvular disease in the developing world is rheumatic heart disease. Other causes are more common in Western countries; they include congenital abnormalities, cardiovascular disorders such as ischaemic heart disease and hypertension, and degenerative disorders. Any of the heart valves may be affected but disorders of the aortic and mitral valves are most significant; more than one valve may be involved in some patients.

The symptoms of valvular heart disease depend upon the valve that is affected, and whether the problem is stenosis or regurgitation. All valve disorders place a haemodynamic burden on the heart and ultimately lead to heart failure. Other consequences include the development of pulmonary hypertension and arrhythmias. Infective endocarditis and thromboembolic disorders, in particular stroke or systemic embolism, are important complications.

The main aims of treatment in patients with valvular heart disease are to reduce symptoms, prevent complications, and reduce mortality.[1-3] Surgical management is usually necessary once symptoms develop and may also be warranted in some patients who are asymptomatic. Medical therapy is generally reserved for pre-operative symptom control and for patients who are unsuitable for surgery.

Medical treatment for **symptomatic patients** is similar to that used in other forms of heart failure (see p.1165). In acute situations sodium nitroprusside and inotropes such as dopamine or dobutamine may be indicated, but for chronic therapy diuretics, digoxin, ACE inhibitors, and beta blockers are used. The choice of drug depends on the valve affected. ACE inhibitors and other vasodilators have generally been avoided in *aortic stenosis* since any reduction in blood pressure cannot be balanced by an increase in cardiac output and there is a theoretical risk of severe hypotension. However, symptomatic improvement has been reported[4] with enalapril in patients with severe aortic stenosis and preserved left ventricular function, although it was not tolerated in those with left ventricular dysfunction, and sodium nitroprusside has been used successfully for acute symptoms.[5] Some guidelines also recommend that beta blockers should be avoided in aortic stenosis.[3] For patients with *aortic regurgitation* who require medical therapy, vasodilators may be of particular value, especially in severe forms.[6] Symptomatic benefit has also been reported[7] with ACE inhibitors in *mitral stenosis*. Arrhythmias should be treated with standard antiarrhythmics (see p.1160).

Drug therapy to prevent the progression of valvular disorders has generally been disappointing. Although similarities have been suggested between aortic stenosis and atherosclerosis, an observational study[8] in asymptomatic patients taking ACE inhibitors for hypertension found no effect on the progression of stenosis, and initial indications of benefit[8] with statins in patients with calcific aortic stenosis were not confirmed in later studies,[9,10] except in a small group of patients with very early disease.[9] The results of an early study[11] indicating that long-term vasodilator therapy with nifedipine improved outcome in asymptomatic patients with severe aortic regurgitation have not been confirmed by a later study of long-term therapy with nifedipine or enalapril.[12] Another study[13] found no benefit with ACE inhibitors in asymptomatic patients with mitral regurgitation.

Surgery is the mainstay of treatment in valvular heart disease and generally involves valve replacement with either bioprosthetic (tissue) or mechanical valves; the latter are longer lasting, but pose a greater risk for thromboembolism. Valve repair may be suitable in some cases, particularly for mitral regurgitation, while balloon valvulotomy may have a role in some patients with stenosis.[2] Valve replacement alleviates symptoms, but patients remain at risk for complications.

In **asymptomatic patients** and in those with **prosthetic valves**, the main aim of therapy is to prevent the complications of bacterial endocarditis and of systemic embolism from thrombus formation within the heart. Antibacterial prophylaxis should be given to patients with valvular heart disease where indicated (see Endocarditis, p.168). Long-term thromboembolism prophylaxis is generally only recommended in patients with another risk factor for embolisation, such as atrial fibrillation, a dilated left atrium, left ventricular dysfunction, a hypercoagulable state, or previous systemic embolism,[2,14,15] and in those with mechanical replacement valves. However, antiplatelet drugs may be considered in other patients.

Long-term treatment with an oral anticoagulant such as warfarin is generally regarded as essential for patients with a *mechanical prosthetic heart valve*,[2,3,15] but the optimum level of anticoagulation is unclear. The risk of thromboembolism depends upon the type and position of the valve and the presence of other risk factors, but must be balanced against bleeding risk. In the UK, specific target INRs are recommended where the valve type and position are known and vary between 2.5 and 3.5 for valves in the aortic position and between 3.0 and 3.5 for valves in the mitral position. If specific information is not available a generic target of 3.0 is recommended for valves in the aortic position and 3.5 for valves in the mitral position.[16] In the USA, the recommended INR range is 2.5 to 3.5, with a lower range of 2.0 to 3.0 suggested as being adequate for most types of valves in the aortic position when there are no other risk factors.[2,15] However, a large study[17] in patients stratified to different target INR ranges found that the risk of moderate to severe thromboembolism and of bleeding complications was comparable for INRs ranging from 2.0 to 4.5; patients had aortic or mitral valve replacement, or both, and all had one particular type of valve. There is evidence that adding an antiplatelet drug (dipyridamole or low-dose aspirin) further reduces the risk of death and thromboembolism although the risk of bleeding is increased.[18] Adjunctive antiplatelet drugs may be considered for patients with additional risk factors such as embolism while on warfarin therapy, or ischaemic heart disease.[2,3,15] Alternatively, or in addition, patients with systemic embolism despite an adequate INR may have their target INR range increased.[15]

For patients with *bioprosthetic heart valves* anticoagulants are recommended for the first 3 months after replacement,[15] although aspirin may be equally effective,[19] and it is often used instead of anticoagulants when only the aortic valve is involved. Longer term oral anticoagulant therapy is generally considered necessary only for patients with additional risk factors (as for asymptomatic patients, above).[2,15] An INR of 2.0 to 3.0 appears adequate for patients with bioprosthetic heart valves. Low-dose aspirin has been recommended[2,15] in patients with bioprosthetic valves who do not require oral anticoagulants, although other guidelines[3] state that there is no evidence to support this.

For patients on long-term anticoagulation, interruption of therapy for surgical procedures or due to bleeding complications exposes patients to the risk of thromboembolism. A study[20] in patients with haemorrhage suggested that it is safe to withhold oral anticoagulants. For patients undergoing surgery, the evidence for either withholding anticoagulants or converting to an alternative form of antithrombotic therapy perioperatively is not conclusive, although recommendations have been made.[2,3] In procedures with a low bleeding risk, anticoagulation can usually be continued. In procedures with a higher bleeding risk, anticoagulants may be withheld if the risk of thromboembolism is low, but otherwise conversion to heparin is recommended. Intravenous unfractionated heparin is preferred;[2,3] low-molecular-weight heparin may be suitable as an alternative, but there have been concerns about its safety and this remains controversial.[21]

The use of anticoagulants is also controversial in patients with infective endocarditis because of the substantial increase in risk of haemorrhage in these patients. Routine anticoagulation is not advised, and patients who are already taking oral anticoagulants should generally stop therapy until it is clear that surgery is not required and the patient is stable.[15]

If obstruction of prosthetic valves by thrombus formation occurs, surgical intervention is usually recommended.[2,3,22] Thrombolytics such as streptokinase or urokinase may be used[15] but are often ineffective and are associated with high risk. They are therefore usually reserved for patients at greatest risk from surgical intervention,[2,3] although a study[23] of patients with left-sided prosthetic valve thrombosis found thrombolytics to be more successful than surgery, especially in the critically ill. Repeated treatments[24] may increase the success rate. Heparin may have a role in non-obstructive thrombosis. Patients who have had a valve thrombosis should have their anticoagulant control optimised;[3] higher target INRs or adjunctive antiplatelet therapy may be considered.[2,15]

The haemodynamic changes that occur during **pregnancy** may complicate the management of women with valvular heart disease.[25-27] In addition, pregnancy is a known risk-factor for thromboembolism and patients with valvular heart disease who become pregnant are therefore at increased risk.[28] However, long-term prophylaxis with an oral anticoagulant such as warfarin presents a problem since warfarin is generally contra-indicated in pregnancy (see Adverse Effects under Warfarin, p.1425). Women with mechanical prosthetic valves must continue anticoagulation but choice of therapy is unclear.[2,29] A systematic review[30] found that continued use of oral anticoagulants increased the risk to the fetus, but that thromboembolic complications were higher with heparin. Most guidelines therefore advise that the choice should be discussed with the patient, balancing the risks for each individual, but specific recommendations vary.[2,3,31] The main risk of embryopathy with warfarin is between weeks 6 and 12 of gestation and heparin therapy is often substituted during this period and also at term (to avoid an anticoagulated neonate). However, satisfactory outcomes have been reported[32] with use of warfarin throughout pregnancy, including the first trimester. The risk of embryopathy appears to be lower with daily warfarin doses of 5 mg or lower, and patients with an adequate INR at this dose may continue warfarin until the 36th week, before switching to heparin.[2,3] If heparin is substituted for warfarin, either during the first trimester or throughout pregnancy, use of an adequate dosage is critical, and strict monitoring is required. Adjusted-dose subcutaneous heparin, with an initial dose of 17 500 to 20 000 units subcutaneously every 12 hours has been suggested;[31] intravenous heparin may be an alternative, but low-dose subcutaneous heparin should not be used as it provides inadequate protection. Low-molecular-weight heparin has also been used, although this is controversial;[2,3,21] if it is used, anti-factor Xa concentrations should be monitored carefully. Low-dose aspirin may be used as an adjunct to subcutaneous heparin or warfarin in women at high risk of thromboembolism.[2,31]

Vasospastic arterial disorders

Raynaud's syndrome is the most important form of vasospastic peripheral arterial disease and forms part of the spectrum of peripheral vascular disease (see p.1178). Vasospastic arterial disorders represent an inappropriate response to temperature, resulting in vasoconstriction and/or vasospasm; Raynaud's syndrome, acrocyanosis, and chilblains are usually induced by cold, whereas erythromelalgia is caused by heat.

In **Raynaud's syndrome**, paroxysmal attacks of pallor and cyanosis, usually of the digits, occur in response to cold, or sometimes emotional stress. Erythema replaces the cyanosis as the attacks resolve. The cause of primary Raynaud's syndrome (Raynaud's disease) is unknown. Features identified include intense vasoconstriction or vasospasm, disturbance of sympathetic nerve supply, changes in circulating catecholamines, enhanced platelet aggregation, red cell deformability, and fibrinolysis. It is probable that not all cases are due to the same mechanism. It has been suggested that the underlying problem may not be an overreaction to the initial cold insult but a defect in the normal ensuing adaptive response. Secondary Raynaud's syndrome (Raynaud's phenomenon) frequently co-exists with arterial occlusive disease such as thromboangiitis obliterans and connective tissue disorders, in particular scleroderma (systemic sclerosis). Trauma and certain drugs, notably beta blockers and ergotamine, may also be responsible for inducing secondary Raynaud's syndrome.

Management. In mild cases of Raynaud's syndrome, where attacks are infrequent and of limited severity, protective measures to keep warm are the mainstay of treatment; this involves wearing appropriate clothing and the use of appliances such as heated gloves. Smoking should be avoided because of the vasoconstriction caused. Any underlying or co-existing disease or cause in secondary Raynaud's syndrome should be treated. Drug therapy is indicated in more severe cases.[1-7] It is directed towards producing vascular smooth muscle relaxation and vasodilatation in order to improve resting blood flow, thereby reducing the extent of tissue ischaemia. Some drugs may also act by modifying platelet aggregation or blood rheology. Numerous drugs have been tried in Raynaud's syndrome, although only a few have an established role.

- *Calcium-channel blockers* have been of benefit and are widely used in Raynaud's syndrome, but it is not entirely clear which of their pharmacological actions is responsible. Dihydropyridines are usually preferred; the most widely used and studied is *nifedipine*.
- *Moxisylyte*, an alpha blocker with vasodilating activity, is also widely employed. Other alpha blockers, for example, phenoxybenzamine and prazosin, as well as reserpine, have been used although in some cases adverse effects have limited their usefulness.
- *Cinnarizine*, *naftidrofuryl*, *pentoxifylline*, and *nicotinic acid derivatives* such as inositol nicotinate have had widespread use in Raynaud's syndrome but evidence of efficacy is lacking. Topical vasodilators, including glyceryl trinitrate, have also been used.
- In severe Raynaud's syndrome complicated by ulceration and gangrene, *prostaglandins* have been promising. *Alprostadil*, *epoprostenol*, and *iloprost* have been given by intravenous infusion. In some cases the beneficial effects have persisted for a few months after treatment and two or three infusions given at intervals over the winter months have prevented the severe complications of Raynaud's suffered in previous years. Oral iloprost has also been reported to reduce the severity of attacks. Prostaglandins applied topically in ulcerative cases include *dinoprostone*.
- Small studies or anecdotal reports have noted variable effects with many *other drugs* including the ACE inhibitors captopril and enalapril, the serotonin reuptake inhibitors fluoxetine and venlafaxine, ketanserin, piracetam, sodium nitroprusside, calcitonin gene-related peptide, and losartan. None of these therapies appears, however, to have an established role. There is also some evidence[8] that phosphodiesterase type-5 inhibitors such as sildenafil may be of benefit.

Acrocyanosis is characterised by a persistent blue discoloration of the skin. There is an abnormal constriction of arterioles, even at normal environmental conditions and this is potentiated by cold. **Chilblains** are an inflammatory condition (perniosis) affecting the extremities and symptoms include erythema, pruritus, and ulceration; they may be acute or chronic. Chilblains are more common in cold damp conditions. Acrocyanosis and chilblains do not generally require specific treatment; smoking cessation, protection from the cold, or symptomatic antipruritic treatment are often sufficient. However, if severe, the drugs described above under Raynaud's syndrome may be considered.

Erythromelalgia (sometimes also called erythermalgia) is a vasospastic condition usually provoked by heat although it may also be drug-induced or secondary to other conditions. It is characterised by painful, red extremities together with a burning sensation and increased skin temperature of the affected area. Thrombocythaemia (p.654) is the most common underlying cause and, indeed, erythromelalgia may be the presenting feature of this disorder; in thrombocythaemia, arteriolar occlusion may occur as a result of platelet aggregation. Small doses of aspirin have produced considerable relief in some patients, presumably by preventing platelet aggregation. Beta blockers may also be of some help, and there are anecdotal reports of benefit with various other drugs.[9] Attacks should be prevented wherever possible by avoiding exposure to heat.

Venous thromboembolism

The term venous thromboembolism embraces both deep-vein thrombosis (DVT) and pulmonary embolism;[1] the two often co-exist and should be considered as a single clinical entity. In DVT a thrombus forms, often in the pockets of valves, and blocks the veins of the lower limbs or main pelvic veins. Pulmonary embolism occurs when the thrombus or part of it migrates in the circulation and blocks the pulmonary artery. About 70% of patients with confirmed pulmonary embolism have thrombosis in their deep leg veins and about 40% of patients with confirmed DVT have silent pulmonary embolism. Proximal DVT is associated with a higher risk of pulmonary embolism than distal DVT.

Venous thromboembolism is a common but underdiagnosed condition and causes considerable morbidity and mortality, especially among hospitalised patients. Various factors underlie the development of thrombosis and there are a number of conditions that predispose patients to venous thromboembolism (see Thromboembolic Disorders, p.1187).

Symptoms of *deep-vein thrombosis* include a tender and swollen calf; increased temperature, cyanosis, and engorgement of the superficial veins of the affected limb; fever; and tachycardia. However, about half of all cases may be symptomless. In the longer term chronic venous insufficiency and venous ulceration often occur (post-phlebitic or post-thrombotic syndrome). As most clinical signs of DVT are non-specific, the diagnosis should always be confirmed before committing a patient to long-term anticoagulation treatment. UK guidelines[2] suggest that assessment of clinical probability and measurement of D-dimer concentrations may be used to exclude the diagnosis in symptomatic outpatients, but diagnostic imaging is recommended for patients with a moderate or high clinical probability or with raised D-dimer concentrations, and also for all patients with a history of venous thromboembolism or who are pregnant. It should be noted that D-dimer assays may be affected by heparin use, and where possible should be done on blood taken before heparin is given.[2] Where imaging is required, noninvasive techniques are usually adequate, although venography may be required in some patients.[3,4] Compression ultrasound is the preferred method; impedance plethysmography may also be used,[3] but is less sensitive. *Pulmonary embolism* may present in a number of ways depending on its extent and duration. Acute massive embolism causes serious haemodynamic disturbance with a sudden reduction in cardiac output and circulatory collapse. The most common form of pulmonary embolism seen, however, is acute minor embolism where the patient may present with pleuritic pain, haemoptysis, dyspnoea, tachycardia, and fever. Diagnosis may involve perfusion/ventilation scans, angiography, or computed tomography (CT); echocardiography may also be used.[5,6]

Prophylaxis of venous thromboembolism. Prophylaxis with anticoagulants aims to prevent DVT and hence pulmonary embolism in patients at risk. Ideally all medical and surgical hospital inpatients should be assessed for risk factors and should be given prophylaxis according to their degree of risk at least until discharge or, for those at higher risk, after discharge; however, considerable underuse has been reported.[7] A prophylactic regimen should be chosen for a particular patient after balancing the degree of risk against the potential complications of prophylaxis. Guidelines have been published in the UK[8-10] and the USA.[11]

Patients can be categorised as being at low, medium, or high risk of venous thromboembolism according to the duration and type of operation in those undergoing surgery, to age, and to the presence of other risk factors such as cancer, heart failure, and lung disease.[10,11] Low-risk patients include young patients undergoing short operative procedures. Older age, operations lasting longer than 30 minutes, and a history of thrombophilia or previous thromboembolism indicate medium risk. Orthopaedic surgery is associated with a high risk of venous thromboembolism in all patients. Other patients at high risk include those with multiple risk factors. Non-surgical patients are also at risk of thromboembolism, particularly if they are immobile, or have major trauma or spinal cord injury. Pregnancy is also a risk factor and is discussed in more detail below.

Methods of prophylaxis may be physical or pharmacological. Physical methods act by increasing venous blood flow and include elevation of the legs, early ambulation, graduated compression stockings, and intermittent pneumatic compression devices. Pharmacological methods generally involve anticoagulation with heparin, low-molecular-weight heparins, or an oral anticoagulant. Other therapies that have been used include antiplatelet drugs, dihydroergotamine, dextrans, heparinoids such as danaparoid, and the direct thrombin inhibitor desirudin. Fondaparinux is a more recently introduced alternative. Ancrod and argatroban have been used in patients who have developed heparin-induced thrombocytopenia or thrombosis.

For low-risk surgical patients measures such as early ambulation and the use of graduated compression stockings are generally considered adequate. Moderate- and high-risk patients require pharmacological methods, although physical methods alone may be used in those who are at high risk from bleeding complications. Physical methods are not suitable in patients with significant peripheral vascular disease. In practice, a combination of mechanical and pharmacological methods is often used, and may give better protection than either method alone.[8,10,11]

For moderate-risk patients, such as those undergoing general surgical procedures lasting more than 30 minutes, low-dose subcutaneous heparin has been the most widely used pharmacological method. Alternatively, subcutaneous low-molecular-weight heparins may be used,[8,9,11] and may be preferred.[9,10] Fondaparinux may also be used.[10,11] High-risk patients may require more aggressive prophylaxis with higher doses of low-molecular-weight heparin; higher doses of unfractionated heparin or oral anticoagulants may also be used.

The use of ***unfractionated heparin*** for surgical thromboembolism prophylaxis is well established. It is usually given subcutaneously in a low dose ('standard heparin prophylaxis'); a typical regimen is 5000 units subcutaneously 2 hours pre-operatively, then every 8 or 12 hours postoperatively for 7 days or until the patient is mobile. In an overview[12] of more than 70 randomised studies in 16 000 patients heparin reduced the risk of subclinical DVT by 67% in general surgery, 68% in orthopaedic surgery, and 75% in urological surgery. There was also a 40% reduction in non-fatal cases of pulmonary embolism, a 64% reduction in fatal cases, and a 47% reduction of all cases. Surgical thromboembolism prophylaxis with heparin also decreased total mortality. Adjusted-dose heparin may be more effective in higher risk patients but the need for laboratory monitoring and the risk of bleeding complications limit its use.

Low-molecular-weight heparins have a number of potential advantages over unfractionated heparin, including less frequent dosage and no need for monitoring, and they are widely used. However, they have not been clearly shown to reduce the risk of bleeding and they may increase the risk of spinal haematoma with spinal or epidural anaesthesia, which may limit their use. Generally, studies have shown low-molecular-weight heparins to be as effective as unfractionated or standard heparin, but meta-analyses have come to differing conclusions regarding superiority.

The evidence suggests that low-molecular-weight heparins are better in orthopaedic surgery,[13-16] particularly with regard to proximal DVT;[15] however a systematic review[17] concluded that, in patients having surgery for hip fracture, there was not enough evidence to say whether either is better, or to confirm protection against pulmonary embolism. In general surgery both types of heparin appear to be of equivalent efficacy, although one analysis[14] reported that low-molecular-weight heparins were superior. A large study[18] showed low-molecular-weight heparins to be as effective as heparin for prophylaxis after major abdominal surgery and to be associated with fewer bleeding complications. UK[9] and US[11] guidelines suggest that, in general surgery, either may be used. Two meta-analyses of 45 studies[19] and 56 studies[20] respectively evaluated the efficacy of several prophylactic methods (such as aspirin, dextran, oral anticoagulants, heparin, heparin with dihydroergotamine, low-molecular-weight heparins, and intermittent pneumatic compression) against DVT after major hip surgery and concluded that low-molecular-weight heparins should be the method of choice. A meta-analysis[21] of low-molecular-weight heparins in major orthopaedic surgery found no evidence that giving the first dose pre- rather than postoperatively was more effective; there were similar risks for major bleeds. Either option is therefore acceptable; first dosage close to the time of surgery may be more effective but has been associated with increased risk of major bleeds. Low-molecular-weight heparins may also be more effective than unfractionated heparin in patients with major trauma.[22]

The optimum *duration of prophylaxis* is unclear.[23] Prophylaxis is usually only continued during hospitalisation but extended prophylaxis may have a role, particularly in high-risk patients after orthopaedic surgery,[8,10,11] or in very high-risk general surgical patients.[8,11] After orthopaedic surgery there is an increased risk for DVT detected by venography up to a month after discharge, which may be reduced by low-molecular-weight heparin.[24,25] However, the clinical significance of this finding has been questioned[26] and a systematic review[27] suggested that the benefit of extended prophylaxis may have been overestimated. A meta-analysis[28] of 2 studies in patients having surgery for cancer also found a reduction in thrombosis when enoxaparin or dalteparin was given for 4 weeks.

Oral anticoagulants have not been so widely used as subcutaneous heparin although US guidelines[11] allow the use of adjusted-dose warfarin to give an international normalised ratio (INR) of 2.0 to 3.0 in patients having hip or knee replacement surgery.

Antiplatelet drugs such as aspirin have been considered less effective antithrombotics than anticoagulants in the venous circulation and to be of limited value in preventing venous thromboembolism. An overview[29] of randomised trials of antiplatelet therapy (mainly aspirin) available up to March 1990 and a more recent placebo-controlled trial[30] of aspirin in patients having hip surgery have suggested that antiplatelet drugs reduce the risk of venous thromboembolism and should thus be considered in high-risk patients. However, both reports have been criticised and, while some guidelines recommend the use of aspirin,[8] others suggest it should not be used alone since other methods are generally more effective.[11] Long-term use of low-dose aspirin appears to have little effect on the incidence of venous thromboembolism.[31]

Direct thrombin inhibitors have been tried.[32] *Desirudin* has been shown to be effective and was reported to be superior to both low-dose subcutaneous heparin and to a low-molecular-weight heparin in patients undergoing hip replacement surgery. *Bivalirudin* has also been tried. *Dabigatran*, an oral direct thrombin inhibitor, is effective[33] and may be used in patients having hip or knee replacement.

The ***direct inhibitor of factor Xa***, *fondaparinux*, a synthetic pentasaccharide, has been reported[34] to be more effective than low-molecular-weight heparin for orthopaedic surgery, and may be used as an alternative,[9-11] although bleeding may be increased. Extended prophylaxis may be of benefit.[35] *Rivaroxaban*, an oral factor Xa inhibitor, has also been tried.[36]

Of the ***other drugs*** tried for surgical thromboembolism prophylaxis, *dihydroergotamine* can reduce venous stasis by vasoconstriction of capacitance vessels and has enhanced postoperative prophylaxis when used with low-dose heparin, but there is a risk of peripheral ischaemia and it is no longer widely used. *Dextrans* (dextran 70 or dextran 40) alone, or with dihydroergotamine, have also been used for prophylaxis, but their use involves the infusion of 500 to 1000 mL of fluid, a procedure which is cumbersome and may interfere with fluid balance.

In non-surgical patients, meta-analyses[37,38] have confirmed that anticoagulant prophylaxis reduces the risk of symptomatic venous thromboembolism, but it is less clear which patients require treatment.[39] Use of low-dose subcutaneous heparin or low-molecular-weight heparin should be considered in patients at high risk;[8,11] low-molecular-weight heparin may be preferred.[9] Patients with cancer are at particular risk;[40] one study[41] showed that very-low-dose warfarin (average daily dose of 2.6 mg) was safe and effective in patients given chemotherapy for metastatic breast cancer. Prophylaxis with low-molecular-weight heparin has been shown to be effective in patients with immobilisation of the leg,[42] and in acutely ill medical patients with risk factors for venous thromboembolism.[43,44] Standard unfractionated heparin prophylaxis, however, had no effect on mortality in patients admitted to hospital with infection.[45] A study[46] in older medical patients found that fondaparinux may be effective. Although some studies[47,48] have shown an increased risk of venous thromboembolism after prolonged travel, the role of prophylaxis is unclear. A systematic review[49] suggested that compression stockings were effective in preventing flight-related venous thromboembolism in low- to high-risk patients; compression stockings and low-dose aspirin may be considered, while low-molecular-weight heparin may be needed in those at high risk.[8] Other guidelines[11,50] make similar recommendations but do not support the use of aspirin.

Treatment of venous thromboembolism. Treatment of *deep-vein thrombosis*[3,51,52] aims to prevent the development of pulmonary embolism, to prevent extension of the thrombus, to reduce the risk of recurrence, and to reduce the long-term complications of chronic venous insufficiency and venous ulceration. Non-pharmacological therapy may include bed rest with the foot of the bed raised, limb exercise, and graduated compression stockings.[53] These measures may be adequate in patients with small thrombi confined to the calf veins, although this is controversial. Heparin and oral anticoagulants are the mainstay of treatment; they prevent further thrombosis while allowing natural thrombolytic mechanisms to act on the existing clot. Anticoagulants may be used with non-pharmacological methods; graduated compression stockings may reduce the risk of post-phlebitic symptoms in patients receiving anticoagulants,[54,55] and are recommended for 2 years.[56] Thrombolytics or surgical thrombectomy may sometimes have a role.[57]

Heparin has an immediate effect whereas oral anticoagulants such as warfarin take several days to achieve their full anticoagulant effect. Heparin is therefore used for initial therapy and oral anticoagulants are used for maintenance. Doses of unfractionated heparin and oral anticoagulants must be adjusted according to laboratory monitoring. In the initial treatment of DVT, unfractionated heparin is given intravenously, as a loading dose of 5000 units, and then continuous infusion at a dose of 18 units/kg per hour, adjusted according to response;[9,56] doses are usually in the range of 1000 to 2000 units/hour. Alternatively, the infusion may be replaced with a similar total daily dose given subcutaneously in 2 divided doses;[9] in the USA, an initial dose of 17 500 units subcutaneously every 12 hours is recommended.[56] However, low-molecular-weight heparins have a number of advantages and are now generally preferred.[9,56] A number of meta-analyses[58,59] have shown them to be at least as effective and safe as unfractionated heparin in the treatment of deep-vein thrombosis and pulmonary embolism, and a systematic review[60] has found that once daily treatment may be as safe and effective as twice daily treatment. They are also safe and effective for the outpatient treatment of DVT[61,62] and have been recommended for outpatient treatment in patients with uncomplicated pulmonary embolism.[6]

Fondaparinux has been reported[63] to be an effective alternative to low-molecular-weight heparin in the initial treatment of venous thromboembolism. Ancrod, argatroban, or the recombinant hirudin, lepirudin, may be used as an alternative to heparin in patients who have developed heparin-induced thrombocytopenia or thrombosis. A heparinoid such as danaparoid or a low-molecular-weight heparin may also be suitable, although there may be cross-reactivity.

Treatment with an oral anticoagulant (usually warfarin) should generally be started at the same time as heparin.[56] A standard loading dose is usually given, and dosage is then adjusted to maintain the INR within recommended limits.[56,64] Heparin should be continued until the INR is stable and in the therapeutic range;[56] 5 to 7 days is usually adequate. The optimum duration of oral anticoagulation is unclear. Meta-analyses[65,66] of studies comparing different lengths of treatment have found that recurrence is reduced for as long as anticoagulation is continued; therefore, to prevent recurrence, treatment should ideally be continued for as long as the patient is at risk. This must be assessed for each patient.[23,67] Thromboembolism is most likely to recur in patients with ongoing risk factors or idiopathic thromboembolism, and men may be at higher risk of recurrence than women.[68] However, risk of recurrence needs to be balanced against the risk of haemorrhage. One of the meta-analyses[65] found that, overall, the absolute risk of recurrence decreased with time but the bleeding risk remained the same, suggesting that lifelong treatment was probably not routinely indicated. The other analysis[66] found that clinical benefit was maintained after stopping anticoagulation, although at a reduced level, but that prolonged treatment did not significantly increase bleeding risk. A shorter duration of therapy is therefore generally considered adequate for patients with transient risk factors, while those with ongoing or unknown risk factors may require longer treatment. How long this should be in each case, however, is less clear. Although one study[69] concluded that 1 month of treatment was adequate in patients with postoperative thromboembolism, analysis of other studies[70] has suggested that patients with transient risk factors should be treated for 3 months. Guidelines reflect this uncertainty. Both UK[64] and US[56] guidelines recommend treatment for at least 3 months in patients with transient risk factors, although in the UK treatment for at least 6 weeks is considered appropriate for patients with calf-vein thromboembolism. For patients with idiopathic venous thromboembolism, periods at least of 6 months[64] or at least 3 months[56] are recommended, and lifelong treatment may be considered.[56] Lifelong treatment may also be considered for patients with repeated thromboembolic events or with a continuing risk factor.

The limitations of long-term oral anticoagulation, including bleeding complications and recurrent thromboembolism, have led to the investigation of other approaches. A meta-analysis[71] has shown that low-molecular-weight heparins may be as safe and effective as warfarin when given for 3 months; they may be more effective than continued warfarin in patients with recurrence during warfarin therapy.[72] They may also be more effective than warfarin as initial therapy in patients with cancer,[73] and are recommended[56] for the first 3 to 6 months of long-term anticoagulant therapy in such patients. Use of lower-intensity warfarin regimens has been tried for extended prophylaxis, and may reduce the risk of recurrence compared with no therapy.[74] However, a study[75] comparing low- and high-intensity regimens found that the lower intensity regimen was less effective and did not reduce the risk of bleeding. Subcutaneous idraparinux, a factor Xa inhibitor, has also been tried,[76] but may cause more bleeding than standard therapy when given for extended periods.[77] In patients who have contra-indications to anticoagulation or in whom thrombosis recurs despite anticoagulation, insertion of a vena caval filter may be appropriate. The use of filters with anticoagulation has also been investigated.[78] Although the incidence of pulmonary embolism was reduced during the first 12 days, no effect on mortality was shown at 2 years.

Therapy with thrombolytics such as streptokinase is generally reserved for very extensive thrombosis. A systematic review[79] showed no effect on mortality in patients with DVT and the main advantages are continued venous patency and reduced incidence of post-phlebitic syndrome. There may be a small risk of increased bleeding. Since thrombolytic activity fades when infusion stops, heparin followed by oral anticoagulation is given to prevent re-occlusion.

Minor *pulmonary embolism* is treated with heparin or low-molecular-weight heparin and oral anticoagulants as described for DVT (above).[6,80-85] Fondaparinux may be an alternative to heparin.[83,84,86] For more severe pulmonary embolism the initial bolus dose of heparin may be doubled. An initial dose of unfractionated heparin may also be given before treatment with low-molecular-weight heparins.[6] Acute massive pulmonary embolism with major haemodynamic disturbance may be treated initially with thrombolytic therapy;[5,6,83,84] surgical methods such as embolectomy or percutaneous catheter fragmentation may be preferred in some patients.[83,84,87,88] Streptokinase, urokinase, and alteplase have all been shown to accelerate the lysis of pulmonary emboli and to decrease pulmonary vascular obstruction. However, their effects on mortality are uncertain and bleeding risk is increased;[89] a meta-analysis[90] found benefit only in studies that included patients at high risk, and they are therefore not recommended in non-massive pulmonary embolism.[6] Comparisons between thrombolytics have been difficult because the doses used in different studies have not always been comparable. Probably more important than the choice of thrombolytic is ensuring that treatment starts quickly in patients where it is indicated.[80]

Venous thromboembolism in children. Venous thromboembolism is relatively rare in children and has differing epidemiology to that in adults.[91,92] Although guidelines[93] for its management have been published they generally rely on extrapolation from studies in adults.

Venous thromboembolism in pregnancy. Pregnancy is a known risk factor for venous thromboembolism and, although the absolute risk is low, pulmonary embolism is the commonest cause of maternal death during pregnancy in the UK. Anticoagulation during pregnancy may be necessary either to prevent or treat venous thromboembolism; continued anticoagulation may also be needed in pregnant patients at risk of systemic embolism because of valvular heart disease or prosthetic heart valves (see above).

Oral anticoagulants such as warfarin cross the placenta and may harm the fetus; they are generally contra-indicated during pregnancy. Heparin does not appear to cross the placenta and despite potential maternal complications such as osteoporosis and thrombocytopenia remains the anticoagulant of choice in pregnancy. Low-molecular-weight heparins appear to be as safe as unfractionated heparin during pregnancy[94] and may have advantages, including a lower risk of osteoporosis and thrombocytopenia.[95]

The management of venous thromboembolism in pregnancy has been reviewed[96-100] and guidelines have been published in the UK[101,102] and the US.[95] **Prophylactic anticoagulation** is not necessary in all pregnancies, but should be considered in women at special risk of venous thromboembolism either because of a history of thromboembolism and/or a thrombophilic abnormality such as inherited deficiency of antithrombin III, protein C, or protein S or acquired thrombophilia due to antiphospholipid antibodies in plasma. Patients must be managed individually and current strategies differ. In those women with a history of thromboembolism but without thrombophilic abnormalities some authors recommend prophylactic anticoagulation at delivery and for 6 weeks post partum provided there has been only one episode of thromboembolism and there are no additional risk factors; others advocate prophylaxis with subcutaneous heparin throughout pregnancy. However, a prospective study[103] has suggested that it is safe to withhold anticoagulation until after delivery in such patients, and this approach has been recommended.[95] Although standard low-dose heparin has been recommended, higher doses may be necessary during pregnancy.[95-97] Low-molecular-weight heparins may also be used.[95,97,99,102] Those with inherited or acquired thrombophilic abnormalities but no evidence of thrombosis do not necessarily require anticoagulation, but must be assessed carefully.

If acute venous thromboembolism occurs during pregnancy it should be **treated** with low-molecular-weight heparin or intravenous heparin as in non-pregnant patients (see above). Antenatal patients need to continue anticoagulation for the rest of their pregnancy, usually by substituting adjusted-dose subcutaneous heparin every 12 hours after 6 to 10 days of intravenous therapy; low-molecular-weight heparins may be an alternative,[95,97] and may be preferred.[101] Special care must be taken at delivery. Patients given full therapeutic doses of heparin should have their dose reduced or stopped on the day of delivery; this may not be necessary in those on lower prophylactic doses of heparin. Low-molecular-weight heparins should be stopped 24 hours before planned delivery.[95,101] If possible patients taking warfarin should be changed to heparin 2 or 3 weeks before labour or delivery and not later than 36 weeks' gestation. Anticoagulants should be continued after delivery, but can usually be stopped after 6 weeks; the total duration of treatment should be at least 3 months.[101]

During pregnancy, especially the third trimester, laboratory monitoring of anticoagulation may be less reliable because high procoagulant concentrations particularly of factor VIII and fibrinogen, may result in low activated partial thromboplastin time (APTT) values despite adequate heparin concentrations in plasma.

Abciximab *(BAN, USAN, rINN)*

Abciximabum; Absiksimab; Absiksimabi; Absiximab; c7E3; c7E3 Fab; 7E3. Immunoglobulin G (human-mouse monoclonal c7E3 clone p7E3V$_H$hC 4 Fab fragment anti-human platelet glycoprotein IIb/IIIa complex), disulphide with human-mouse monoclonal c7E3 clone p7E3V hC light chain.

Абциксимаб

$C_{2101}H_{3229}N_{551}O_{673}S_{15}$ = 47455.4.

CAS — 143653-53-6.

ATC — B01AC13.

ATC Vet — QB01AC13.

Adverse Effects

Bleeding during the first 36 hours after a dose is the most common adverse effect of abciximab. Other adverse effects include hypotension, nausea and vomiting, back pain, chest pain, headache, haematoma, bradycardia, fever, cardiac tamponade, and thrombocytopenia. Hypersensitivity reactions (see Precautions, below) have occurred on repeated use.

Effects on the blood. In clinical studies increased bleeding has been the most common adverse effect of abciximab, and this has also been reported[1] during clinical use. Thrombocytopenia is also a well documented adverse effect of abciximab therapy. In a review[2] of the major clinical studies of abciximab, mild thrombocytopenia was reported in 4.2% of patients and severe thrombocytopenia in 1.0%; patients also received heparin. There have also been a number of case reports of patients developing severe thrombocytopenia.[3,4] It is recommended that platelet counts should be monitored before and 2 hours after starting abciximab, and that the drug should be withdrawn if thrombocytopenia occurs.[3] However, pseudothrombocytopenia also occurs in some patients and should be excluded before withdrawing therapy.[5,6] Although there have been case reports, the incidence of thrombocytopenia does not appear to be increased with other glycoprotein IIb/IIIa receptor inhibitors,[2] and there have been reports of the successful use of eptifibatide[7] and tirofiban[8] in patients who developed thrombocytopenia with abciximab.

Precautions

Abciximab should not be given to patients who are actively bleeding or to patients at increased risk of haemorrhage. Such patients include: those with haemorrhagic disorders, including thrombocytopenia; those with cerebrovascular disorders, including intracerebral neoplasms, aneurysms, or arteriovenous malformation, and those with a history of stroke; those with uncontrolled hypertension; or those who have recently undergone major surgery or severe trauma. Other patients in whom caution is required include those with severe renal impairment, vasculitis, haemorrhagic retinopathy, acute pericarditis, or aortic dissection. Abciximab should be stopped if serious uncontrolled bleeding occurs or emergency surgery is required. Abciximab should not be given to patients with severe renal impairment requiring haemodialysis, or to those with severe hepatic impairment, in whom coagulation may be affected. Platelet counts should be monitored before and after giving abciximab.

Antibodies may develop 2 to 4 weeks after a dose of abciximab and hypersensitivity reactions could occur when other monoclonal antibodies are used or after readministration of abciximab (see below). Hypersensitivity reactions have not been noted after a single dose but the possibility should be considered.

Readministration. Antibodies to abciximab develop in about 5.8% of patients after use and could lead to hypersensitivity reactions or to reduced efficacy if use of abciximab is repeated. In a retrospective study[1] in 164 patients given a second course of therapy with abciximab, efficacy was not affected and no allergic or anaphylactic reactions occurred. However, severe thrombocytopenia was noted in 4% of patients, and the incidence was highest in those receiving abciximab within 2 weeks of the first course. Similar results were reported from a larger registry study;[2] the patients included had received abciximab at least 7 days previously without developing thrombocytopenia, suggesting that platelet counts need to be monitored in patients receiving a first or repeated course of abciximab.

2. Tcheng JE, *et al.* Abciximab readministration: results of the ReoPro Readministration Registry. *Circulation* 2001; **104:** 870–5.

Interactions

There may be an increased risk of bleeding if abciximab is given with other drugs that affect bleeding, including anticoagulants, other antiplatelet drugs, or thrombolytics.

Pharmacokinetics

After intravenous doses of abciximab free plasma concentrations fall rapidly due to binding to platelet receptors. Platelet function recovers over about 48 hours although abciximab may remain in the circulation for 15 days or more in a platelet-bound state.

Uses and Administration

Abciximab is the Fab fragment of the chimeric monoclonal antibody 7E3. It binds to the glycoprotein IIb/IIIa receptor on the surface of platelets. This prevents binding of fibrinogen, von Willebrand factor, and other adhesive molecules to the receptor sites and inhibits platelet aggregation. It is used as an adjunct to heparin and aspirin therapy for the prevention of acute ischaemic complications in patients undergoing percutaneous transluminal coronary procedures including angioplasty, atherectomy, and stenting. It is also used in patients with unstable angina who are candidates for such procedures. It has been investigated in acute ischaemic stroke.

Abciximab is given intravenously as a bolus injection over 1 minute in a dose of 250 micrograms/kg followed immediately by an infusion of 0.125 micrograms/kg per minute (to a maximum dose of 10 micrograms/minute). For stabilisation in patients with unstable angina the bolus dose followed by the infusion should be started up to 24 hours before the possible intervention and continued for 12 hours after; for other patients the bolus should be given 10 to 60 minutes before the intervention followed by the infusion for 12 hours.

Ischaemic heart disease. Antiplatelet drugs have an established role as adjuncts to medical or interventional treatment in patients with ischaemic heart disease (stable angina, unstable angina, or myocardial infarction) and abciximab has been used to provide additional antiplatelet effects during interventional procedures and in patients with acute myocardial infarction.

In patients undergoing acute or elective *percutaneous coronary intervention* (PCI; see Reperfusion and Revascularisation Procedures, p.1181), use of abciximab as an adjunct to heparin and aspirin improves short-term[1-3] and long-term[4,5] outcomes in various groups of patients, including those receiving coronary stents.[6-8] Most benefit has been seen in patients given abciximab as a bolus injection immediately before intervention followed by intravenous infusion for 12 hours,[1,2] and in a study[9] in which abciximab was given for 18 to 24 hours before angioplasty and for 1 hour after, the initial benefit was not maintained at 6 months.

For patients undergoing PCI who are pretreated with both aspirin and clopidogrel, the role of abciximab is less clear. In stable patients undergoing elective PCI, no benefit was found at 30 days,[10] or at 1 year.[11] A study[12] in diabetic patients also found no effect on mortality or risk of myocardial infarction at 1 year, despite their higher risk, although restenosis was reduced. However, in patients undergoing PCI for non-ST elevation acute coronary syndromes, use of abciximab in addition to aspirin and clopidogrel pretreatment improved clinical outcomes at 30 days, although this effect was restricted to patients with raised troponins.[13] Positive results have also been reported[14,15] with abciximab given as a single bolus injection without subsequent infusion in patients undergoing coronary stenting.

In *acute ST-elevation myocardial infarction* (p.1175), abciximab has been used as an adjunct to primary PCI, including coronary stenting, and has been shown to reduce reinfarction rates and mortality,[16] with benefit persisting long-term.[17] There is some evidence that starting treatment as soon as possible rather than immediately before the procedure may provide additional benefit.[18,19] Abciximab has also been used as an adjunct to thrombolysis and some benefit has been shown,[20] but this appears to be offset by an increased bleeding rate, even when reduced doses of thrombolytics are used.[21,22] In patients with *unstable angina* (p.1157) receiving noninterventional treatment, a large study[23] with abciximab failed to show any benefit over placebo, although other glycoprotein IIb/IIIa inhibitors have a role in such patients.

Some promising results have been reported with intracoronary abciximab in patients with acute coronary syndromes,[24] and with abciximab-coated stents in patients with acute myocardial infarction.[25]

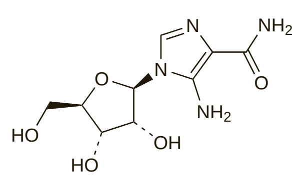
Acadesine *(BAN, USAN, rINN)*

Acadesina; Acadésine; Acadesinum; AICA Riboside; GP-1-110; GP-1-110-0. 5-Amino-1-(β-D-ribofuranosyl)imidazole-4-carboxamide.

Акадезин

$C_9H_{14}N_4O_5$ = 258.2.
CAS — 2627-69-2.
ATC — C01EB13.
ATC Vet — QC01EB13.



Profile

Acadesine is a purine nucleoside analogue reported to have cardioprotective effects. It is being investigated in the management of myocardial ischaemia, particularly in patients undergoing coronary artery bypass graft surgery. Acadesine may protect against further ischaemia by influencing metabolism in ischaemic cells, enhancing the release of adenosine in preference to inosine after the breakdown of adenosine monophosphate.

Acadesine is also under investigation for chronic lymphocytic leukaemia.

ACE Inhibitors

Angiotensin-converting Enzyme Inhibitors; Inhibidores de la ECA.

There appear to be few significant differences between ACE inhibitors. They may be distinguished from each other by the presence or absence of a sulfhydryl group, whether they are prodrugs or not, their route of elimination, and their affinity for angiotensin-converting enzyme in vascular and other tissue, although whether these characteristics modify pharmacodynamics and therefore clinical efficacy is uncertain. Differences in these characteristics do however influence onset and duration of action of ACE inhibitors.

Adverse Effects and Treatment

Many of the adverse effects of ACE inhibitors relate to their pharmacological action and all therefore have a similar spectrum of adverse effects. Some effects, such as taste disturbances and skin reactions, were at one time attributed to the presence of a sulfhydryl group (as in captopril) but have now also been reported with other ACE inhibitors; however, they may be more common with captopril.

The most common adverse effects are due to the vascular effects of ACE inhibitors and include hypotension, dizziness, fatigue, headache, and nausea and other gastrointestinal disturbances.

Pronounced hypotension may occur at the start of therapy with ACE inhibitors, particularly in patients with heart failure and in sodium- or volume-depleted patients (for example, those given previous diuretic therapy). Myocardial infarction and stroke have been reported and may relate to severe falls in blood pressure in patients with ischaemic heart disease or cerebrovascular disease. Other cardiovascular effects that have occurred include tachycardia, palpitations, and chest pain.

Deterioration in renal function, including increasing blood concentrations of urea and creatinine, may occur, and reversible acute renal failure has been reported. Renal effects are most common in patients with existing renal or renovascular dysfunction or heart failure, in whom vasodilatation reduces renal perfusion pressure; it may be aggravated by hypovolaemia. Proteinuria has also occurred and in some patients has progressed to nephrotic syndrome. Hyperkalaemia and hyponatraemia may develop due to decreased aldosterone secretion.

Other adverse effects include persistent dry cough and other upper respiratory tract symptoms, and angioedema; these may be related to effects on bradykinin or prostaglandin metabolism. Skin rashes (including erythema multiforme and toxic epidermal necrolysis) may occur; photosensitivity, alopecia, and other hypersensitivity reactions have also been reported.

Blood disorders have been reported with ACE inhibitors and include neutropenia and agranulocytosis (especially in patients with renal failure and in those with collagen vascular disorders such as systemic lupus erythematosus and scleroderma), thrombocytopenia, and anaemias.

Other less common adverse effects reported with ACE inhibitors include stomatitis, abdominal pain, pancreatitis, hepatocellular injury or cholestatic jaundice, muscle cramps, paraesthesias, mood and sleep disturbances, and impotence.

ACE inhibitors have been associated with fetal toxicity (see Pregnancy under Precautions, below).

Most of the adverse effects of ACE inhibitors are reversible on withdrawing therapy. Symptomatic hypotension, including that after overdosage, generally responds to volume expansion with an intravenous infusion of sodium chloride 0.9%.

Angioedema. See under Hypersensitivity, below.

Cough. Treatment with ACE inhibitors has been associated with the development of cough in up to 20% of hypertensive patients; cough may be less troublesome in those with heart failure,[1] although the incidence may be higher.[2] The cough is reported to be persistent, paroxysmal, and non-productive; it causes irritation of the throat, may be accompanied by voice changes (hoarseness or huskiness), and is often worse when lying down.[1,3,4] It is more common in women and non-smokers, and may be delayed in onset by weeks or even months.

The majority of reports of this adverse effect concern captopril and enalapril,[3,4] but it has also occurred in patients receiving many of the other ACE inhibitors,[5] suggesting that the effect is common to all drugs of this class.

The mechanism that produces the reaction is uncertain but appears to be related to the non-specific blockade of ACE since angiotensin II receptor antagonists are associated with a much lower incidence of cough.[6] The sensitivity of the cough reflex is increased.[7] Prostaglandins released in the respiratory tract have been proposed as mediators,[3] but other mediators such as bradykinin[8] or substance P,[9] both of which are substrates for ACE, have been suggested. However, attempts to show a link between the effects of ACE inhibitors on cough, and bronchial hyperreactivity of the type found in obstructive airways disease and asthma have produced conflicting evidence, with bronchial hyperreactivity being shown in some studies[10] but not in others.[11]

Where the patient can tolerate the cough, it may be reasonable to continue treatment; in some cases reducing the dose may help. Spontaneous recovery or improvement in the cough has been reported.[12] Changing to an alternative ACE inhibitor is not advised since it is rarely effective.[7] Drugs that inhibit prostaglandin synthesis, including the NSAIDs sulindac[13] and indometacin,[14] have been reported to suppress the cough, but NSAIDs and ACE inhibitors may interact adversely (see under Interactions, below). The calcium-channel blocker nifedipine also reduced cough, although to a lesser extent than indometacin, possibly by a similar mechanism.[14] Inhaled bupivacaine,[15] inhaled sodium cromoglicate,[16,17] oral baclofen,[18] oral picotamide,[19] and oral ferrous sulfate,[20] have also been reported to be of help. However, in many patients there will be no alternative but to withdraw the ACE inhibitor, and this is recommended by some in all patients presenting with ACE-inhibitor induced cough.[21] Angiotensin II receptor antagonists may be a suitable alternative in patients with hypertension.[21]

Effects on the blood. Blood disorders have occurred in patients receiving ACE inhibitors, although there have been few reports in the literature. A reduction in haemoglobin concentration and haematocrit may occur but is not usually clinically significant, although an unfavourable effect on recovery from anaemia has been reported;[1] ACE inhibitors have also been used therapeutically to reduce the haematocrit (see Erythrocytosis under Uses, below). Cases of neutropenia and agranulocytosis (particularly in patients with renal or collagen vascular disorders), and thrombocytopenia have been noted. Aplastic anaemia has also occurred[2,3] and may be fatal.[3]

Effects on the kidneys. ACE inhibitors have complex effects on the kidney;[1,2] they have established renoprotective effects but also cause acute deterioration in renal function in some patients. These apparently contradictory effects are related to the action of ACE inhibitors on the renin-angiotensin-aldosterone system.

The renin-angiotensin-aldosterone system has an important role in maintaining normal renal blood flow and renal function. A reduction in renal perfusion, for example due to hypovolaemia, heart failure, or renal artery stenosis, leads to activation of this system and an increase in angiotensin II release. This results mainly in post-glomerular renal vasoconstriction, which maintains renal glomerular pressure and thus glomerular filtration, despite the fall in renal blood flow.

In normal individuals with unrestricted sodium intake, the renin-angiotensin-aldosterone system is suppressed and ACE inhibitors have little effect on renal function. In patients with essential hypertension ACE inhibitors generally increase renal blood flow despite the reduction in arterial blood pressure, since this is exceeded by the effects of renal vasodilatation. However, filtration fraction falls since the pressure within the glomerulus is reduced, and there are only minor changes in glomerular filtration rate. The increase in renal blood flow is more pronounced during sodium restriction and in younger patients.

These effects are generally beneficial. However, in patients with reduced renal perfusion, glomerular filtration rate may be critically dependent on the renin-angiotensin-aldosterone system and the use of ACE inhibitors may provoke problems. Severe renal function loss or even anuria have been reported in patients with a single transplanted kidney with renal artery stenosis, or patients with bilateral renal artery disease. The stenotic kidney maintains its filtering capacity by preferential vasoconstriction of the efferent arterioles, a mechanism mainly mediated by the renin-angiotensin system; under ACE inhibition, vasodilatation of the efferent arterioles combined with the drop in arterial pressure can result in a critical decrease in filtration pressure. Hypovolaemia or sodium depletion, for example due to diuretics, also leads to activation of the renin-angiotensin-aldosterone system and predisposes patients to renal impairment. Most patients developing renal insufficiency have been using diuretics and sodium repletion can restore renal function despite continuing ACE inhibition.

Patients with heart failure may also be at risk of a decline in renal function on long-term ACE inhibitor therapy. This is because in chronic heart failure, angiotensin-II mediated systemic and renal vasoconstriction is again important in the maintenance of renal perfusion pressure. The decline may be alleviated by reduction of the dosage of diuretics or liberalisation of dietary salt intake, despite continuing the ACE inhibitor. An additional risk factor in elderly patients with heart failure is the high incidence of occult renovascular disease in these patients.[3]

Moderate impairment of renal function either before or during use of ACE inhibitors is not necessarily an indication to stop therapy. The effects of ACE inhibitors on renal function are generally reversible, and the reduction in filtration pressure may result in renoprotection. A review[4] of studies of the use of ACE inhibitors in patients with renal impairment found that those who initially lost renal function had the greatest long-term benefit.

In addition to pathophysiological effects ACE inhibitors may induce membranous glomerulopathy or interstitial nephritis. The former has been associated with captopril use, particularly at high doses, but is rare, and seems less likely to occur at the lower doses favoured today. The proteinuria usually clears without appreciable renal function loss irrespective of whether or not the drug is continued, although persistent proteinuria and renal function loss have been described. Proven interstitial nephritis has also been reported rarely, and may possibly be due to an allergic mechanism.

Effects on the liver. Hepatotoxicity has been reported with ACE inhibitors, including captopril,[1,2] enalapril,[2] lisinopril,[2] and ramipril.[3] Most reports have been associated with captopril. In a report[1] of 3 cases of liver disease apparently caused or aggravated by captopril, it was noted that jaundice due to captopril is usually mainly cholestatic in nature but acute hepatocellular injury has also been seen. Of 29 cases of liver dysfunction due to captopril and reported to the UK CSM, 9 had hepatocellular jaundice, with 2 deaths; 8 were cholestatic jaundice, with 1 fatality; and 3 patients had hepatorenal syndrome, all of whom died. Worldwide, excluding the UK, 164 cases of hepatic adverse reactions had been notified to the WHO by January 1989. The incidence of such reactions is estimated at 0.09 per 1000 patients but this is likely to be an underestimate. Resolution may take a long time and captopril should be withdrawn immediately at the earliest hint of liver sensitivity.

Effects on the mouth. Aphthous and tongue ulcers may occur during treatment with ACE inhibitors. There have been a few reports of a 'scalded mouth syndrome', described as similar to being scalded by hot liquids, associated with captopril,[1] enalapril,[1] and lisinopril[2] therapy.

2. Savino LB, Haushalter NM. Lisinopril-induced "scalded mouth syndrome." *Ann Pharmacother* 1992; **26:** 1381–2.

Effects on the nervous system. Encephalopathy and focal neurological signs,[1] and peripheral neuropathy,[2,3] including Guillain-Barré neuropathy,[3] have been reported in patients receiving captopril. Some CNS effects of captopril may be attributable to alterations in cerebral blood flow. In a study in patients with severe heart failure, cerebral blood flow in patients aged under 65 was improved by a single dose of captopril 12.5 mg, but in patients aged over 70 there was a 13% reduction.[4] Two patients in whom captopril 6.25 mg produced impaired consciousness and paraesthesias, and dizziness, blurred vision, and aphasia, were found to have stenosis of the carotid arteries.[5] Agitation, panic, extreme depression, and insomnia was reported in a patient 4 weeks after starting treatment with enalapril; depressive episodes recurred on rechallenge.[6] There have been reports of mania possibly precipitated by captopril,[7] and visual hallucinations have been reported in association with captopril and enalapril therapy.[8]

Effects on the pancreas. The manufacturers of captopril, enalapril, and lisinopril have all been reported[1] to have data on file on drug-associated pancreatitis. In 1994 the UK CSM[2] noted that there had been 23 reports of pancreatitis associated with ACE inhibitors (captopril 11, enalapril 10, fosinopril 1, and quinapril 1) although whether or not this was causal was not certain.

Effects on the respiratory system. Cough is a recognised adverse effect of ACE inhibitors but evidence for a link with bronchial hyperreactivity or airways obstruction is controversial (see Cough, above). In reports of adverse respiratory reactions to ACE inhibitors submitted to the Swedish Adverse Drug Reactions Advisory Committee and to WHO, symptoms of airway obstruction such as dyspnoea, asthma, and bronchospasm occurred rarely, usually within the first few weeks of treatment.[1] However, the evidence for a causal link between ACE inhibitors and these symptoms was questioned.[2]

Severe nasal obstruction was associated with enalapril treatment in a 45-year-old woman with a history of mild rhinorrhoea and sneezing. Symptoms cleared within 2 days of stopping enalapril and recurred on rechallenge.[3] Another woman taking enalapril developed obstructive sleep apnoea,[4] which improved when the enalapril was stopped.

There have been case reports of pneumonitis associated with treatment with captopril[5] and perindopril.[6]

Effects on the skin. Skin rashes may occur during treatment with ACE inhibitors; they have been reported in 1 to 6% of patients receiving captopril. Angioedema is also an adverse effect of ACE inhibitors (see Hypersensitivity, below). There have been reports of bullous pemphigoid,[1] hyperhidrosis,[2] Kaposi's sarcoma,[3] lichen planus,[4] onycholysis,[5,6] pemphigus,[7,8] and cutaneous hypersensitivity vasculitis[9] associated with use of captopril. Kaposi's sarcoma has also been reported[10] with lisinopril. Onycholysis has also occurred with enalapril,[11] pemphigus with enalapril[12,13] and ramipril,[14] and bullous pemphigoid with lisinopril.[15] Lichen planus pemphigoides has been reported with ramipril.[16] A severe cutaneous reaction, resembling early mycosis fungoides, and possibly allergic in nature, has been reported after use of captopril or enalapril.[17] Captopril has also been reported to exacerbate psoriasis.[18] Vulvovaginal pruritus with dysuria[19] has been noted in a patient receiving enalapril.

Gynaecomastia. Painful unilateral gynaecomastia was reported in a patient with systemic lupus erythematosus and renal impairment who was given captopril for hypertension.[1] In view of reports of breast enlargement in women given penicillamine it was suggested that the sulfhydryl structure might be responsible; however, gynaecomastia has also been reported in 2 patients receiving enalapril,[2,3] which does not contain the sulfhydryl grouping.

Hypersensitivity. Some of the adverse effects of ACE inhibitors might be mediated by the immune system, but evidence of specific **hypersensitivity reactions** seems to be limited. The presence of an IgG antibody to captopril was demonstrated in the serum of 2 of 45 patients taking the drug but the clinical significance was unclear.[1] A reaction resembling serum sickness was reported in a patient given captopril, with deposition of immune complexes in the glomerular basement membrane, and symptoms of rash, arthralgia, epidermolysis, fever, and lymphadenopathy.[2] Eosinophilia has also been reported in a number of patients.[3] The formation of antinuclear antibodies and lupus-like reactions have been described.[4,5]

Treatment with ACE inhibitors (enalapril, captopril, or lisinopril) has been associated with the development of **anaphylactoid reactions** in patients undergoing high-flux haemodialysis using polyacrylonitrile membrane (AN69).[6,7] The UK CSM has advised that the combined use of ACE inhibitors and such membranes should be avoided.[8] Similar anaphylactoid reactions have occurred in patients taking ACE inhibitors while being treated for severe hypercholesterolaemia by extracorporeal removal of low-density lipoproteins (LDL-apheresis) with dextran sulfate columns.[9] These reactions are thought to be bradykinin-mediated. Prolonging the interval between the last dose of ACE inhibitor and dextran sulfate apheresis has averted the reaction;[10] successful prevention has also been reported with the bradykinin receptor antagonist icatibant acetate (p.2324).[11] Hypotensive reactions associated with blood transfusion through bedside leucoreduction filters in patients taking ACE inhibitors have also been attributed to bradykinin.[12] There have also been rare reports of severe allergic reactions, including anaphylaxis, occurring in patients taking ACE inhibitors who were stung by insects or during desensitisation with Hymenoptera venom (e.g. bee or wasp venom).[13]

Angioedema, a known adverse effect of ACE inhibitors,[14-17] is reported to occur in 0.1 to 0.2% of patients.[16,17] The incidence may be higher in black American[18] or Afro-Caribbean[19] patients. There is no evidence that it results from an immunological mechanism in these patients and it has been suggested that the effect is due to impaired kinin degradation. However, angioedema has been reported with lisinopril in a patient who had previously tolerated captopril.[20] The onset of angioedema has usually been within hours or at most a week of starting treatment with the ACE inhibitor,[16] but can occur after prolonged therapy for several months or years.[21-24] It may also occur episodically with long symptom-free intervals.[24] Visceral angioedema presenting as abdominal pain with diarrhoea, nausea, and vomiting, has also been reported.[25,26] If angioedema occurs the ACE inhibitor should be withdrawn and if there is swelling affecting the tongue, glottis, or larynx likely to cause airway obstruction, adrenaline should be given (see p.1204). Fatalities have occurred.[27] Angiotensin II receptor antagonists have been suggested as an alternative in patients unable to tolerate ACE inhibitors, but there have also been reports of angioedema associated with their use (see under Losartan Potassium, p.1326). For a report of angioedema occurring after use of alteplase for stroke in patients taking ACE inhibitors, see under Interactions of Alteplase, p.1207.

Overdosage. There have been reports of overdosage with captopril,[1,2] enalapril,[3-6] and lisinopril.[7,8] The main adverse effect is hypotension which usually responds to supportive treatment and volume expansion. Activated charcoal may be given in severe overdosage if the patient presents within 1 hour of ingestion. If hypotension persists, sympathomimetics may be given, although they are not usually required. Specific therapy with angiotensinamide (p.1216) may be considered if conventional therapy is ineffective,[5,6,8] but it is not widely available. There has also been a report[9] of the successful use of naloxone after captopril overdosage.

Precautions

ACE inhibitors are usually contra-indicated in patients with aortic stenosis or outflow tract obstruction (but see below). They should not generally be used in patients with renovascular disease or suspected renovascular disease, but are occasionally necessary for severe resistant hypertension in such patients, when they should only be given with great caution and under close specialist supervision. The elderly, or patients with peripheral vascular diseases or generalised atherosclerosis, may be at high risk because they may have clinically silent renovascular disease. Renal function should be assessed in all patients before use of ACE inhibitors and should be monitored during therapy. Patients with existing renal disease or taking high doses should be monitored regularly for proteinuria. Regular white blood cell counts may be necessary in patients with collagen vascular disorders, such as systemic lupus erythematosus and scleroderma, or in patients receiving immunosuppressive therapy, especially when they also have impaired renal function. ACE inhibitors should be used with caution in patients with a history of idiopathic or hereditary angioedema.

Patients with heart failure and patients who are likely to be sodium or water depleted (for example, those receiving treatment with diuretics or dialysis) may experience symptomatic hypotension during the initial stages of ACE inhibitor therapy. Treatment should therefore be started under close medical supervision, using a low dose and with the patient in a recumbent position to minimise this effect.

Anaphylactoid reactions have occurred in patients taking ACE inhibitors during haemodialysis using high-flux polyacrylonitrile membranes, during LDL-apheresis with dextran sulfate columns, and during desensitisation with wasp or bee venom (see Hypersensitivity under Adverse Effects, above).

ACE inhibitors have been associated with fetal toxicity and should not be used during pregnancy (see below).

Aortic stenosis. Vasodilators, including ACE inhibitors, are usually contra-indicated in obstructive cardiac disorders such as aortic stenosis since cardiac output cannot increase to compensate for systemic vasodilatation and there is a risk of severe hypotension. However, a study[1] in patients with symptomatic aortic stenosis found that enalapril was well-tolerated and improved symptoms, and a drug withdrawal study[2] in hypertensive patients with asymptomatic aortic stenosis suggested that ACE inhibitors had beneficial haemodynamic effects. Another study[3] in patients with heart failure and perceived contra-indications to ACE inhibitors (including 17.3% with aortic stenosis) found that survival was improved in those given ACE inhibitors. There is also some evidence that ACE inhibitors may slow the progression of calcific aortic stenosis, but this remains to be confirmed.[4]

1. Chockalingam A, *et al.* Safety and efficacy of angiotensin-converting enzyme inhibitors in symptomatic severe aortic stenosis: Symptomatic Cardiac Obstruction-Pilot study of Enalapril in Aortic Stenosis (SCOPE-AS). *Am Heart J* 2004; **147:** E19.

3. Ahmed A, *et al.* A propensity score analysis of the impact of angiotensin-converting enzyme inhibitors on long-term survival of older adults with heart failure and perceived contraindications. *Am Heart J* 2005; **149:** 737–43.
4. Newby DE, *et al.* Emerging medical treatments for aortic stenosis: statins, angiotensin converting enzyme inhibitors, or both? *Heart* 2006; **92:** 729–34.

Diarrhoea. Several reports have indicated that life-threatening hypotension and signs of renal failure may develop in patients receiving captopril[1-3] or enalapril[3] after volume depletion due to diarrhoea.

1. McMurray J, Matthews DM. Effect of diarrhoea on a patient taking captopril. *Lancet* 1985; **i:** 581.
2. Benett PR, Cairns SA. Captopril, diarrhoea, and hypotension. *Lancet* 1985; **i:** 1105.
3. McMurray J, Matthews DM. Consequences of fluid loss in patients treated with ACE inhibitors. *Postgrad Med J* 1987; **63:** 385–7.

Ethnicity. ACE inhibitors are less effective as antihypertensives in Afro-Caribbean black patients than in white patients. A similar difference has been reported in heart failure; in a pooled analysis[1] of the Studies of Left Ventricular Dysfunction (SOLVD) treatment and prevention trials, treatment with enalapril significantly reduced the risk of hospitalisation for heart failure in white patients with left ventricular dysfunction, but not in similar black patients. However, analysis[2] of the prevention arm alone showed that enalapril reduced the relative risk of disease progression to a similar extent in black and white patients.

1. Exner DV, *et al.* Lesser response to angiotensin-converting-enzyme inhibitor therapy in black as compared with white patients with left ventricular dysfunction. *N Engl J Med* 2001; **344:** 1351–7.
2. Dries DL, *et al.* Efficacy of angiotensin-converting enzyme inhibition in reducing progression from asymptomatic left ventricular dysfunction to symptomatic heart failure in black and white patients. *J Am Coll Cardiol* 2002; **40:** 311–17. Correction. *ibid.*; 1019.

Hepatic cirrhosis. It has been suggested that in patients with cirrhosis, captopril could cause a marked reduction in arterial pressure and severely compromise renal function, since maintenance of glomerular filtration rate might be mediated by angiotensin II in these patients.[1] This theory was supported by a report of a reduction in glomerular filtration rate in response to a fall in mean arterial pressure in 4 patients with resistant ascites secondary to hepatic cirrhosis.[2] The fall in mean arterial pressure was associated with orthostatic hypotension and increasing encephalopathy. Severe confusion has also been reported in 2 patients with cirrhosis during treatment with captopril 6.25 to 12.5 mg three times daily.[3]

3. Jørgensen F, *et al.* Captopril and resistant ascites. *Lancet* 1983; **ii:** 405.

Huntington's disease. The condition of a woman with Huntington's disease deteriorated dramatically during treatment with captopril and improved on withdrawal of the drug.[1]

1. Goldblatt J, Bryer A. Huntington's disease: deterioration in clinical state during treatment with angiotensin converting enzyme inhibitor. *BMJ* 1987; **294:** 1659–60.

Peripheral vascular disease. Patients with peripheral vascular disease may have a high incidence of renal artery stenosis and are therefore at high risk of renal failure with ACE inhibitor therapy (see Effects on the Kidneys, above). Mild renal artery stenosis was found in 64 of 374 patients (17%) with peripheral vascular disease, and severe renal artery stenosis in 52 (14%); the stenosis was bilateral in 43 (12%).[1] Renal function should be carefully monitored in any patient with peripheral vascular disease who receives ACE inhibitors.

1. Salmon P, Brown MA. Renal artery stenosis and peripheral vascular disease: implications for ACE inhibitor therapy. *Lancet* 1990; **336:** 321.

Pregnancy. There is evidence from *animal* studies that use of ACE inhibitors during pregnancy is associated with fetal toxicity and an increase in still-births.[1] In humans, the main effect of ACE inhibitors is on the kidneys. Several case reports have described the development of fetal renal failure, with oligohydramnios or neonatal anuria, in the offspring of mothers receiving captopril[2-4] or enalapril;[5] there have been fetal[4] and neonatal[3] deaths. A literature search up to the end of 1989 indicated that the use of ACE inhibitors during pregnancy can cause severe disturbances of fetal and neonatal renal function, long-lasting neonatal anuria, and pulmonary hypoplasia.[6] There are also 2 case reports in which maternal captopril[7] or enalapril[8] therapy, in association with other drugs, was associated with birth defects including defective ossification of the skull. A registry study[9] found that 2 of 19 infants exposed to ACE inhibitors during pregnancy had serious life-threatening conditions: one had prolonged anuria requiring dialysis; the other had microcephaly and a large occipital encephalocele.

The FDA has re-emphasised that ACE inhibitors can cause injury and even death to the developing fetus in the second and third trimester.[10] Although use of ACE inhibitors in the first trimester had been thought to carry a lesser risk,[11-13] a review of the available experimental and clinical data concluded that the use of ACE inhibitors should be avoided throughout pregnancy.[14] Also, a later cohort study[15] of 29 507 infants found a significantly increased risk of major congenital malformations in 209 who had been exposed to ACE inhibitors alone in the first trimester and concluded that such use should be avoided.

Interactions

Excessive hypotension may occur when ACE inhibitors are used with diuretics, other antihypertensives, or other agents, including alcohol, that lower blood pressure. An additive hyperkalaemic effect is possible in patients receiving ACE inhibitors with potassium-sparing diuretics, potassium supplements (including potassium-containing salt substitutes), or other drugs that can cause hyperkalaemia (such as ciclosporin or indometacin), and serum-potassium concentrations should be monitored. Potassium-sparing diuretics and potassium supplements should generally be stopped before starting ACE inhibitors in patients with heart failure. However, ACE inhibitor therapy does not obviate the possible need for potassium supplementation in patients given potassium-wasting diuretics and potassium concentrations should also be monitored in these patients. The adverse effects of ACE inhibitors on the kidneys may be potentiated by other drugs, such as NSAIDs, that can affect renal function.

Allopurinol. For reports of reactions in patients taking captopril and allopurinol, see p.553.

Antacids. Use of captopril with antacids reduced the bioavailability of captopril although this did not significantly alter the effects on blood pressure and heart rate.[1] The bioavailability of fosinopril, and possibly other ACE inhibitors, may also be reduced by use with antacids.

1. Mäntylä R, *et al.* Impairment of captopril bioavailability by concomitant food and antacid intake. *Int J Clin Pharmacol Ther Toxicol* 1984; **22:** 626–9.

Antidiabetics. Hypoglycaemia was noted in 3 type 1 diabetics when captopril was added to their therapeutic regimen; it was also seen in a type 2 diabetic, in whom withdrawal of hypoglycaemic drugs became necessary.[1] Subsequent study suggested that the effect was due to enhanced insulin sensitivity.[1] Similar instances of a reduction in blood sugar in both non-diabetic[2] and diabetic[3] patients given enalapril have occurred. Two case-control studies in diabetic patients receiving insulin or oral hypoglycaemics suggested that patients treated with ACE inhibitors were at increased risk of developing severe hypoglycaemia.[4,5] However, other studies in diabetic patients given captopril or enalapril have failed to find any significant alterations in blood-glucose control,[6,7] and ACE inhibitors are widely used in the treatment of hypertension in diabetic patients (see p.1171) and also have a role in the management of diabetic complications such as nephropathy (see Kidney Disorders under Uses, below).

Azathioprine. Leucopenia has been reported in a patient given captopril with azathioprine; the effect did not occur when either drug was given alone.[1] In a similar report, neutropenia in a patient taking a regimen including azathioprine and captopril did not recur when captopril was reintroduced after stopping azathioprine.[2]

Digoxin. For reports of an increase in serum-digoxin concentrations during therapy with ACE inhibitors, see p.1261.

Diuretics. Excessive hypotension may occur when ACE inhibitors are used with diuretics. Deterioration in renal function has also been reported with *metolazone* (see p.1337). Severe hyperkalaemia may occur if ACE inhibitors are used with *spironolactone* (see p.1401).

Epoetins. An additive hyperkalaemic effect may occur when ACE inhibitors are given with epoetins. ACE inhibitors have also been reported to antagonise the haematopoietic effects of epoetins.

General anaesthetics. Marked hypotension may occur during general anaesthesia in patients taking ACE inhibitors. In addition corrected cerebral blood flow was significantly lower in 11 patients who took captopril before general anaesthesia induced with thiopental and maintained with nitrous oxide and enflurane, than in 9 patients pretreated with metoprolol and 9 untreated controls.[1] Although there were no complications of anaesthesia associated with captopril pretreatment, stopping ACE inhibitor therapy before anaesthesia should be considered. However, others have suggested[2] that since there is no clear evidence for stopping them, ACE inhibitors may be continued with care.

Gold salts. The nitritoid reaction (flushing, nausea, dizziness, and hypotension associated with the first weeks of gold treatment) occurred soon after commencing treatment with an ACE inhibitor (captopril, lisinopril, or enalapril) in 4 patients who had been receiving sodium aurothiomalate for at least 2 years.[1]

1. Healey LA, Backes MB. Nitritoid reactions and angiotensin-converting-enzyme inhibitors. *N Engl J Med* 1989; **321:** 763.

Interferons. Severe granulocytopenia has been reported[1] in 3 patients with mixed cryoglobulinaemia treated with interferon alfa-2a who also received ACE inhibitors. The effect was considered to be due to synergistic haematological toxicity. However, in a further report,[2] 2 patients developed only mild granulocytopenia that was reversible despite continued therapy, while a third patient retained a normal granulocyte count.

1. Casato M, *et al.* Granulocytopenia after combined therapy with interferon and angiotensin-converting enzyme inhibitors: evidence for a synergistic hematologic toxicity. *Am J Med* 1995; **99:** 386–91.

Lithium. For reports of lithium toxicity in patients taking ACE inhibitors, see p.404.

Muscle relaxants. For a report of severe hypotension in a patient taking lisinopril and tizanidine, see p.1898.

NSAIDs. *Indometacin* and possibly other NSAIDs, including aspirin, have been reported to reduce or abolish the hypotensive action of ACE inhibitors. A similar effect has been reported[1] with *rofecoxib*. NSAIDs cause sodium and water retention and thus may attenuate the effects of various antihypertensives. It has also been suggested that part of the hypotensive effect of ACE inhibitors is prostaglandin-dependent, which might explain this interaction with drugs such as NSAIDs that block prostaglandin synthesis. However, in a double-blind study designed to assess the role of prostaglandins,[2] indometacin did not influence the hypotensive effect of captopril or enalapril, suggesting that the effects on prostaglandins are not significant.

The possibility of an interaction between low-dose *aspirin* and ACE inhibitors has caused concern.[3-5] Retrospective analysis of some studies of ACE inhibitors in patients with heart failure after myocardial infarction suggested that outcome was poorer in those who were also receiving aspirin. A number of small studies have investigated the effects of aspirin plus ACE inhibitors on haemodynamic parameters, but results have been conflicting and the clinical relevance of these findings is not clear. Given the well-established benefits of both ACE inhibitors and aspirin in patients with heart failure associated with ischaemic heart disease, it is generally recommended that patients should continue to receive treatment with both.[4,5] A systematic review[6] of long-term studies using ACE inhibitors came to a similar conclusion, and an observational study[7] in patients with both ischaemic and non-ischaemic heart failure found that ACE inhibitors improved outcomes, irrespective of whether or not patients were taking aspirin.

The combination of NSAIDs and ACE inhibitors may also have variable effects on renal function since they act at different parts of the glomerulus.[8] When given to patients whose kidneys are underperfused, for example because of heart failure, liver cirrhosis, or haemorrhage, renal function may deteriorate. Use of NSAIDs in patients taking ACE inhibitors with diuretics may be particularly hazardous.[9] However, specific patient groups without reduced renal perfusion may benefit from combining an NSAID with an ACE inhibitor.

Indometacin, and possibly other NSAIDs, may have an additive hyperkalaemic effect.

Probenecid. Giving probenecid to 4 healthy subjects during intravenous infusion of captopril caused increases in the steady-state plasma-captopril concentration. The interaction was considered to be due to a reduction of tubular secretion of captopril by probenecid.[1]

Pharmacokinetics

Most ACE inhibitors are given orally. Apart from captopril and lisinopril, they are generally prodrugs and after absorption undergo rapid metabolism by ester hydrolysis to the active diacid form; for example, enalapril is converted to enalaprilat. Metabolism occurs mainly in the liver. Excretion as active drug or active metabolite is principally in the urine; some, such as benazeprilat and fosinoprilat, are also excreted via the biliary tract. Elimination of the diacid is polyphasic and there is a prolonged terminal elimination phase, which is considered to represent binding to the angiotensin-converting enzyme at a saturable binding site. This bound fraction does not contribute to accumulation of drug following multiple doses. The terminal elimination half-life does not therefore predict the kinetics observed with multiple dosing and the effective half-life for accumulation is the value usually quoted.

Uses and Administration

ACE inhibitors are antihypertensive drugs that act as vasodilators and reduce peripheral resistance. They inhibit angiotensin-converting enzyme (ACE), which is involved in the conversion of angiotensin I to angiotensin II. Angiotensin II stimulates the synthesis and secretion of aldosterone and raises blood pressure via a potent direct vasoconstrictor effect. ACE is identical to bradykininase (kininase II) and ACE inhibitors also reduce the degradation of bradykinin, which is a direct vasodilator and is also involved in the generation of prostaglandins. The pharmacological actions of ACE inhibitors are thought to be primarily due to the inhibition of the renin-angiotensin-aldosterone system, but since they also effectively reduce blood pressure in patients with low renin concentrations other mechanisms are probably also involved. ACE inhibitors produce a reduction in both preload and afterload in patients with heart failure. They also reduce left ventricular remodelling, a process that sometimes follows myocardial infarction. Normally, renal blood flow is increased without a change in glomerular filtration rate. ACE inhibitors also reduce proteinuria associated with glomerular kidney disease.

ACE inhibitors are used in the treatment of hypertension and heart failure and are given to improve survival after myocardial infarction and for the prophylaxis of cardiovascular events in patients with certain risk factors. They are also used in the treatment of diabetic nephropathy. They are generally given orally.

In some hypertensive patients there may be a precipitous fall in blood pressure when starting therapy with an ACE inhibitor and the first dose should preferably be given at bedtime; if possible, any diuretic therapy should be stopped a few days beforehand and resumed later if necessary.

In patients with heart failure taking loop diuretics, severe first-dose hypotension is common on introduction of an ACE inhibitor, but temporary withdrawal of the diuretic may cause rebound pulmonary oedema. Thus treatment should start with a low dose under close medical supervision.

Action. The renin-angiotensin system plays a major role in regulation of cardiovascular and renal function and blockade of this system has complex physiological effects.[1] Although the main target for ACE inhibitors was initially thought to be the endocrine renin-angiotensin system in the circulation this mechanism alone cannot readily explain all the actions of ACE inhibitors.[2] Endogenous renin-angiotensin systems exist in many tissues and ACE inhibitors also have localised effects.[3] This may underlie some of the long-term effects of ACE inhibition, including improved endothelial function, increased arterial wall compliance, improved left ventricular function in heart failure, regression of vascular and left ventricular hypertrophy, and delayed progression of diabetic nephropathy. ACE inhibitors differ in their degree of binding to tissue ACE and in their tissue distribution, but the clinical significance of this is not clear. In one study[4] endothelial function improved with quinapril, which has high tissue specificity, but a similar effect was not seen with the less-specific enalapril, despite an earlier study[5] showing it to be effective.

ACE inhibitors also have effects on the kinin system and there is some evidence that the cardiovascular actions of ACE inhibitors also involve localised accumulation of kinins.[6-8] It has been suggested[9] that the free radical scavenging property of captopril may contribute to some of its actions, although not all studies have confirmed this effect.[10]

Bartter's syndrome. Captopril has been reported to produce beneficial responses in patients with Bartter's syndrome[1-5] (p.1670), which is characterised by hyperaldosteronism, hypokalaemia, and hyperreninaemia, but with normal or reduced blood pressure. Captopril may also be used diagnostically with scintigraphy.[6]

Diabetic complications. Control of blood pressure plays a major role in the prevention of the sequelae of diabetes mellitus (p.433). ACE inhibitors have been reported[1] to reduce the risk of major cardiovascular events in patients, including a broad range of diabetics, with either a history of cardiovascular disease or at least one additional cardiovascular risk factor. A study[2] of diabetics with no cardiovascular disease (but unknown risk factors) also found a reduction in mortality with use of ACE inhibitors. Some of the studies of ACE inhibitors for cardiovascular risk reduction have also suggested that ACE inhibitors may prevent the development of diabetes in non-diabetic patients,[3-7] but a randomised study[8] in subjects with moderately impaired glucose metabolism but low cardiovascular risk was unable to confirm this effect.

ACE inhibitors may also have benefits in other diabetic complications. They have an established role in the management of nephropathy in patients with type 1 and type 2 diabetes (see Kidney Disorders, below).

It has been reported[9] that ACE inhibitors may reduce the progression of retinopathy in normotensive patients with type 1 diabetes mellitus. However, progression of retinopathy was a secondary end-point of the study and it was suggested that further studies were needed to confirm the beneficial results.

A preliminary report[10] has suggested that ACE inhibitors may improve peripheral neuropathy in diabetic patients, but again further studies are needed.

Erythrocytosis. Secondary erythrocytosis (secondary polycythaemia) is an absolute increase in red cell mass that may occur as a result of tissue hypoxia (as in chronic obstructive airways disease), or excessive erythropoietin production (as in some renal tumours or after renal transplantation). Treatment may be necessary for hyperviscosity symptoms and to reduce the risk of thromboembolic complications, and mainly involves removal of red blood cells by venesection and the use of drugs such as ACE inhibitors that inhibit erythropoiesis.

Post-transplantation erythrocytosis may resolve spontaneously in some patients but for the remainder the aim of therapy is to minimise the risk of thromboembolic and other complications by reducing the haematocrit to less than 45%. Originally treatment was by venesection but this led to severe iron deficiency. There is now evidence of beneficial effects using ACE inhibitors[1-4] or angiotensin II receptor antagonists such as losartan[5-9] and current guidelines recommend these drugs for first-line therapy.[10,11] Theophylline may also be used but appears to be less effective than ACE inhibitors[1] and is usually reserved for patients who do not respond to first-line therapy; it may also be used with an ACE inhibitor but venesection may need to be used until the haematocrit falls to 45%.

Guidelines[11] recommend that patients who develop **erythrocytosis secondary to hypoxic pulmonary disease** should first be considered for methods to improve oxygenation, including long-term oxygen therapy. Those who have hyperviscosity or a haematocrit greater than 56% should undergo venesection. ACE inhibitors or angiotensin II receptor antagonists might be of use for patients who do not tolerate venesection;[11] beneficial responses have been reported with enalapril in altitude polycythaemia,[12] and with losartan in erythrocytosis secondary to chronic obstructive pulmonary disease.[13] Theophylline has also been reported to be of benefit.

Heart failure. ACE inhibitors given orally produce clinical benefit in all stages of chronic heart failure (p.1165) additional to that seen with diuretics. They relieve symptoms and improve survival and reduce the progression of mild or moderate heart failure to more severe stages. Thus, it is now recommended that all patients with heart failure due to left ventricular systolic dysfunction should receive ACE inhibitors, even if they are asymptomatic with diuretics alone. The studies that have shown a benefit with ACE inhibitors have tended to use higher doses than those used in practice. A study[1] with lisinopril found that higher doses reduced the combined end-point of death or hospitalisation more than low doses and were equally well tolerated, suggesting that higher doses should be used. Studies with enalapril have failed to show a benefit of standard doses over lower doses,[2] or high doses over standard doses.[3] It is now recommended[4,5] that doses should be titrated to those found to be effective in randomised trials, rather than according to symptomatic response, although lower doses may still be of benefit if higher doses are not tolerated.[4] Combination of ACE inhibitors with angiotensin II receptor antagonists to produce a more complete blockade of the renin-angiotensin system may also be of benefit,[6-8] and may therefore be considered[4,5] in patients who remain symptomatic despite standard therapy, including patients receiving beta blockers. ACE inhibitors may also have a role in patients with asymptomatic left ventricular dysfunction, although this is less well established; no effect on short-term mortality was found in asymptomatic patients in the SOLVD trial, but a significant survival benefit was found on long-term follow-up.[9] In patients with heart failure and preserved left ventricular function (diastolic dysfunction) the role of ACE inhibitors is unclear, although they may provide symptomatic benefit.[10] ACE inhibitors may be beneficial in patients with heart failure associated with valve disorders (but see under Precautions, above for discussion of their use in aortic stenosis). There is also some evidence that ACE inhibitors may prevent the development of antineoplastic-induced cardiotoxicity,[11] although this remains to be confirmed.

The mechanism of action in heart failure is not established. ACE inhibitors have beneficial haemodynamic effects; they produce arterial and venous dilatation,[12] reducing both preload and afterload and thus improving cardiac output without increasing heart rate. Their neurohormonal effects also play a part,[13] as do their effects on cytokines. Further actions that may contribute include reduction of left ventricular hypertrophy, and an indirect action to prevent cardiac arrhythmias.[14-16]

Captopril and enalapril have both been used in infants with severe heart failure (see Administration in Children, p.1240, and p.1277, respectively).
