As a matter of prudence the UK CSM has recommended that clomifene should not normally be used for more than 6 cycles.[14] However, the UK guidelines[15] on the treatment of infertility considered that the limit of 6 cycles related to one course of treatment only. In practice many women required more than one course and it was considered that benefit may be derived from use of up to 12 cycles.

Effects on the CNS. An infertile woman had convulsions when given clomifene citrate;[1] only 5 other cases had been reported since 1963.

1. Rimmington MR, *et al.* Convulsions after clomiphene citrate. *BMJ* 1994; **309:** 512.

Effects on the eyes. As mentioned above, clomifene may cause visual disturbances, which resolve on stopping treatment. However, visual symptoms have persisted in a few cases.[1]

1. Purvin VA. Visual disturbance secondary to clomiphene citrate. *Arch Ophthalmol* 1995; **113:** 482–4.

Effects on the fetus. After reports of neural tube defects in fetuses conceived after ovulation induction, analyses of congenital defect registers and follow-up studies of clomifene use suggested that the drug might possibly be associated with an increase in risk.[1-5] However, subsequent studies reported no increased risk,[6-8] and a pooled analysis[9] of 10 epidemiological studies found no strong evidence to confirm an association. Further studies have also reported no increased risk of neural tube defects[10] or hypospadias in male offspring[11] after exposure to fertility treatment. However, another case-control study[12] did find a potential association between clomifene and neural tube defects, but noted that because of the low baseline prevalence of the malformation, the absolute risk difference would be small. It is not clear whether the underlying infertility itself affects the risk of congenital defects and whether it may confound the calculated risk associated with clomifene.[9]

Precautions

Clomifene is contra-indicated in patients with liver disease or a history of liver dysfunction. It should not be used in pregnancy. Clomifene should not be used in women with uterine bleeding that is undiagnosed or caused by hormone-dependent tumours, or in patients with pre-existing mental depression or thrombophlebitis because of the risk of exacerbation. Patients should be warned of the possibility of multiple births.

Clomifene should not be given to women with ovarian cysts, except those with polycystic ovary syndrome, and the lowest doses possible should be used to minimise ovarian enlargement or cyst formation; some patients with polycystic ovary syndrome may have an exaggerated response to usual doses of clomifene. Patients should be instructed to report any abdominal or pelvic pain, distension, or weight gain, as this may indicate the presence or enlargement of ovarian cysts. They should also be evaluated for the presence of ovarian cysts before each cycle of treatment. If abnormal enlargement occurs, clomifene should not be given until the ovaries have returned to pre-treatment size, and subsequent doses should be reduced. Clomifene should be used with caution in patients with uterine fibroids, due to the potential for enlargement of the fibroids.

Treatment should be stopped if visual disturbances develop and the patient warned that this might affect their ability to drive or operate machinery. Long-term cyclic therapy is not recommended, because of the uncertainty regarding increased risk of ovarian cancer: a maximum of 6 cycles of treatment has generally been advised, but see also under Carcinogenicity, above.

Pharmacokinetics

Clomifene citrate is absorbed from the gastrointestinal tract. It is metabolised in the liver and slowly excreted via the bile. Unchanged drug and metabolites are excreted in the faeces. The biological half-life is reported to be 5 days although traces are found in the faeces for up to 6 weeks. Enterohepatic recirculation takes place. The *E*-isomer is reported to be less well absorbed and more rapidly eliminated than the *Z*-isomer.

Uses and Administration

Clomifene is a nonsteroidal compound that has both oestrogenic and anti-oestrogenic properties, the latter residing principally in the *E*-isomer. Its action in stimulating ovulation is believed to be related to its anti-oestrogenic properties. It stimulates the secretion of pituitary gonadotrophic hormones, probably by blocking the negative feedback effect of oestrogens at receptor sites in the hypothalamus and pituitary.

Clomifene is the most widely used drug in the treatment of anovulatory infertility (p.2080). Therapy with clomifene will not be successful unless the woman, though anovulatory, is capable of ovulation and her partner is fertile. It is ineffective in primary pituitary or primary ovarian failure. The usual oral dose is 50 mg of clomifene citrate daily for 5 days, starting on or about the 5th day of the menstrual cycle or at any time if there is amenorrhoea. If ovulation does not occur, a course of 100 mg daily for 5 days may be given starting as early as 30 days after the previous one. Women should be examined for pregnancy and ovarian enlargement or cysts between treatment cycles. In general, 3 courses of therapy are adequate to assess whether ovulation is obtainable. If ovulation has not occurred, the diagnosis should be re-evaluated. Once ovulation is established, each treatment cycle of clomifene should be started on or about the 5th day of the menstrual cycle. If pregnancy has not occurred after a total of about 6 treatment cycles, licensed product information recommends that no further clomifene therapy should be given (but see also Carcinogenicity, above). Clomifene has also been used with gonadotrophins.

Clomifene has been used in the treatment of male infertility due to oligospermia to stimulate gonadotrophin release and enhance spermatogenesis, but there is limited convincing evidence of benefit.

Conjugated Oestrogens

Conjugated Estrogens; Estrogeenit, konjugoidut; Estrogena Coniugata; Estrogenai, konjuguoti; Estrogener, konjugerade; Estrogènes conjugués; Estrogeni Coniunct; Estrogeni coniuncti; Estrógenos conjugados; Estrogeny konjugované; Konjugált ösztrogének; Konjüge Östrojen.

Эстрогены Конъюгированные

ATC — G03CA57.

ATC Vet — QG03CA57.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Estrogens, Conjugated). A mixture of various conjugated forms of oestrogens obtained from the urine of pregnant mares or by synthesis, dispersed in a suitable powdered diluent. It contains two principal components, 52.5 to 61.5% of sodium estrone sulfate and 22.5 to 30.5% of sodium equilin sulfate; the total of the combined two is 79.5 to 88.0%. It also contains 2.5 to 9.5% of sodium 17α-estradiol sulfate, 13.5 to 19.5% of sodium 17α-dihydroequilin sulfate, and 0.5 to 4.0% of sodium 17β-dihydroequilin sulfate. All percentages are related to the labelled content.

An almost white brownish amorphous powder.

USP 31 (Conjugated Estrogens). A mixture of sodium estrone sulfate and sodium equilin sulfate, derived wholly or in part from equine urine or synthetically from estrone and equilin. It contains other conjugated oestrogenic substances of the type excreted by pregnant mares. It contains 52.5 to 61.5% of sodium estrone sulfate and 22.5 to 30.5% of sodium equilin sulfate; the total of the two combined should comprise 79.5 to 88.0% of the labelled content of conjugated oestrogens. It should contain, as sulfate conjugates, 13.5 to 19.5% of 17α-dihydroequilin, 2.5 to 9.5% of 17α-estradiol, and 0.5 to 4.0% of 17β-dihydroequilin, relative to the labelled content of conjugated oestrogens.

If it is obtained from natural sources it is a buff-coloured amorphous powder which is odourless or has a slight characteristic odour; the synthetic form is a white to light buff-coloured crystalline or amorphous powder, odourless or with a slight odour. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

As for oestrogens in general (see Estradiol, p.2097). See also under Hormone Replacement Therapy, p.2071.

Effects on the cardiovascular system. In an early study of *men* with a previous myocardial infarction, treatment with conjugated oestrogens 5 mg daily was stopped because of a higher incidence of subsequent coronary events.[1] Moreover, treatment with the lower 2.5 mg dose was later also stopped because of suggestions of adverse trends including a greater incidence of venous thromboembolism.[2]

For the cardiovascular effects of HRT, including conjugated oestrogens, in women, see p.2073.

1. Coronary Drug Project Research Group. The Coronary Drug Project: initial findings leading to modifications of its research protocol. *JAMA* 1970; **214:** 1303–13.
2. Coronary Drug Project Research Group. The Coronary Drug Project: findings leading to discontinuation of the 2.5-mg/day estrogen group. *JAMA* 1973; **226:** 652–7.

Effects on the nervous system. Reversible chorea has been described in 2 women given conjugated oestrogens with a progestogen as postmenopausal HRT;[1,2] in 1 case the patient had a history of migraine and Sydenham's chorea.[1] Chorea also recurred in a postmenopausal woman with a history of chorea gravidarum when she was given vaginal conjugated oestrogens.[3]

3. Caviness JN, Muenter MD. An unusual cause of recurrent chorea. *Mov Disord* 1991; **6:** 355–7.

Hypersensitivity. An anaphylactic reaction after intravenous conjugated oestrogens has been reported.[1]

1. Searcy CJ, *et al.* Anaphylactic reaction to intravenous conjugated estrogens. *Clin Pharm* 1987; **6:** 74–6.

Interactions

See under Hormone Replacement Therapy, p.2076.

Pharmacokinetics

Conjugated oestrogens taken orally are hydrolysed by enzymes present in the intestine that remove the sulfate group and allow absorption of the unconjugated oestrogen. Metabolism occurs primarily in the liver; there is some enterohepatic recycling (see also under Estradiol, p.2098).

Uses and Administration

Conjugated oestrogens have actions and uses similar to those described for estradiol (see p.2098).

When used as menopausal HRT (p.2076) doses of 0.3 to 1.25 mg daily are given orally either cyclically or continuously, with a progestogen either cyclically or continuously in women with a uterus. Doses of 0.3 to 1.25 mg may also be used for the prevention of postmenopausal osteoporosis, but oestrogen therapy is generally reserved for women who are at significant risk and who cannot be given non-hormonal treatment. Topical vaginal therapy may be used specifically for menopausal atrophic vaginitis, atrophic urethritis, and kraurosis vulvae; 0.5 to 2 g of a 0.0625% cream may be used daily for 3 weeks of a 4-week cycle. For women with a uterus, the addition of cyclical progestogen is generally not required during topical vaginal oestrogen therapy. However, the use of a progestogen may be considered, and during long-term therapy these women should be monitored for evidence of endometrial hyperplasia.

When given as replacement therapy on a cyclical basis, oral doses of 1.25 mg daily are used for primary ovarian failure, adjusted according to response. Doses of 300 to 625 micrograms daily are usually given for female hypogonadism, although higher doses were formerly used.

For the palliative treatment of prostatic carcinoma (p.671), an oral dose of 1.25 to 2.5 mg three times daily has been used. A dose of 10 mg three times daily for at least 3 months has been used for palliative treatment of breast carcinoma in men (p.663) and postmenopausal women (p.661).

Abnormal uterine bleeding has been treated acutely by giving 25 mg of conjugated oestrogens by slow intravenous injection, repeated if required after 6 to 12 hours; the intramuscular route has also been used.

Synthetic conjugated oestrogens are derived from plant material, and are not a generic equivalent of Conjugated Estrogens described in USP 31 (see above). Synthetic conjugated estrogens, A, contains a mixture of nine derivatives of estrone, equilin, estradiol, and equilenin. It is used in oral doses of 0.45 to 1.25 mg daily for the relief of vasomotor symptoms associated with the menopause. A dose of 300 micrograms daily may be used for menopausal vulvar and vaginal atrophy, but an alternative topical therapy should be considered if this is the only symptom being treated. Synthetic conjugated estrogens, B, contains a mixture of ten derivatives of estrone, equilin, estradiol, and equilenin. It is used in oral doses of 0.3 to 1.25 mg daily for the relief of vasomotor symptoms associated with the menopause. A dose of 300 micrograms daily may be used for menopausal vulvar and vaginal atrophy, but an alternative topical therapy should be considered if this is the only symptom being treated.

Administration in children. Conjugated oestrogens have been used to reduce final height in girls with constitutional tall stature (see Growth Disorders, under Estradiol, p.2099). They have also been used in children for some haemorrhagic disorders (below).

Haemorrhagic disorders. Case reports and small studies have described the use of high-dose conjugated oestrogens in the management of haemorrhagic disorders associated with renal failure,[1-5] although it is unclear how oestrogens might reduce prolonged bleeding times in these patients.[6] Treatment has been given orally, but an intravenous dose of 600 micrograms/kg given over 30 to 40 minutes, once daily for 5 days, has been reported most often.[6]

Conjugated oestrogens have also been used in various doses in the management of haemorrhagic cystitis (p.2178), particularly that caused by high-dose cyclophosphamide therapy (p.702). The successful use of 25 mg intravenously for 2 consecutive days has been reported,[7] as has a regimen consisting of a 1 mg/kg intravenous dose followed by 5 mg orally for 3 weeks.[8] A report[9] of treatment in 10 patients described the use of oral conjugated oestrogens in doses of 6 to 12 mg daily, usually in three divided doses, for durations of 5 days to 16 weeks.[9] Another report[10] of therapy in 10 children aged between 8 and 19 years described intravenous doses of 12.5 to 50 mg twice daily, often for 2 or 3 days, followed by oral doses ranging from 2.5 mg twice daily to 5 mg four times daily for durations of a few days to about 3 weeks.

Oestrogens have also been used in the treatment of other bleeding disorders (see Estradiol, p.2099).

Cyclofenil *(BAN, rINN)* ⊗

Ciclofenilo; Cyclofénil; Cyclofenilum; Cyklofenil; F-6066; H-3452; ICI-48213; Siklofenil; Syklofeniili. 4,4′-(Cyclohexylidenemethylene)bis(phenyl acetate).

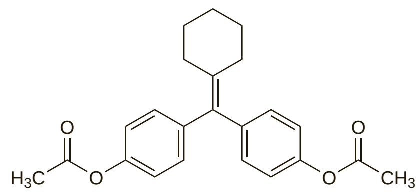
Циклофенил

$C_{23}H_{24}O_4$ = 364.4.

CAS — 2624-43-3.

ATC — G03GB01.

ATC Vet — QG03GB01.



Profile

Cyclofenil is a nonsteroidal anti-oestrogen that has been used in the treatment of menstrual disturbances and anovulatory infertility due to hypothalamic-pituitary dysfunction.

It has been given orally in doses of 200 mg three times daily for 5 days, in a cyclical regimen for 3 or 4 cycles. It has also been given for menopausal symptoms.

Preparations

Cyproterone Acetate *(BANM, USAN, rINNM)*

Acetato de ciproterona; Ciproteron-acetát; Ciproterono acetatas; Cyproteronacetat; Cyproteron-acetát; Cyprotérone, acétate de; Cyproteroni acetas; NSC-81430; SH-714; SH-881 (cyproterone); Siproteron Asetat; Syproteroniasetaatti. 6-Chloro-1β,2β-dihydro-17α-hydroxy-3′*H*-cyclopropa[1,2]pregna-1,4,6-triene-3,20-dione acetate.

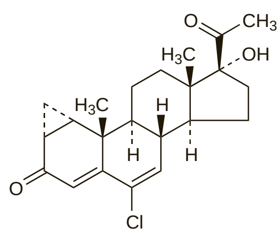
Ципротерона Ацетат

$C_{24}H_{29}ClO_4$ = 416.9.

CAS — 2098-66-0 (cyproterone); 427-51-0 (cyproterone acetate).

ATC — G03HA01.

ATC Vet — QG03HA01.



(cyproterone)

NOTE. Compounded preparations of cyproterone acetate may be represented by the following names:

- Co-cyprindiol (*BAN*)—cyproterone acetate 2000 parts and ethinylestradiol 35 parts (w/w).

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Cyproterone Acetate). A white or almost white, crystalline powder. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in acetone; very soluble in dichloromethane; soluble in methyl alcohol. Protect from light.

Adverse Effects

When given to men cyproterone reduces libido, inhibits spermatogenesis, reduces the volume of ejaculate, and causes infertility. There may be azoospermia after 8 weeks and slight atrophy of the seminiferous tubules, but these changes are slowly reversible and spermatogenesis usually recovers to pre-treatment levels about 3 to 5 months after stopping cyproterone. Abnormal spermatozoa may be produced. Gynaecomastia is common and permanent enlargement of the mammary glands may occur; galactorrhoea and benign nodules have been reported rarely. Fatigue and weakness are common and depressive mood changes can occur occasionally. Patients may experience weight changes, alterations in hair pattern, dry skin, and rarely rashes or hypersensitivity. Shortness of breath may occur, and anaemia and osteoporosis have been reported rarely. Liver function tests may be altered; there have also been reports of hepatitis, jaundice, and hepatic failure, sometimes fatal, developing usually after several months of high-dose cyproterone therapy, but an association with liver cancer is uncertain.

When low-dose cyproterone is given with ethinylestradiol to women, adverse effects associated with combined oral contraceptives (see p.2059) may occur.

Carcinogenicity. See Effects on the Liver, below.

Effects on the cardiovascular system. Combined oral contraceptives are associated with a small increased risk of cardiovascular disease (see p.2062). A case-control study suggested that the risk of venous thromboembolism may be further increased for women taking combined contraceptives containing cyproterone compared with levonorgestrel.[1] A review by the authorities in New Zealand considered the risk to be at least as great as with third-generation oral contraceptives,[2] a conclusion further supported by a study in that country of the contraceptives used by women discharged from hospital with a diagnosis of deep-vein thrombosis or pulmonary embolism.[3] In 2002, the UK CSM[4] warned that preparations containing cyproterone and ethinylestradiol should not be used solely for contraception, but for treatment of severe acne that had not responded to oral antibacterials, or for moderately severe hirsutism, and that they should be withdrawn 3 or 4 cycles after the treated condition has completely resolved. However, others[5,6] have questioned some study results, concluding that preparations containing cyproterone are not associated with a risk in excess of that associated with conventional combined oral contraceptives including those containing levonorgestrel. Some[7] have also called for the removal of the CSM recommendation to limit the duration of therapy, particularly as acne and hirsutism frequently recur after stopping cyproterone therapy. In 2008, the CHM (formerly the CSM) reconfirmed its 2002 advice on the use of cyproterone with ethinylestradiol.[8] However, it added that for women with severe hyperandrogenism, in whom symptoms usually recur when treatment is stopped, therapy could be continued with regular specialist review until the symptoms were judged unlikely to recur. It was also recommended that, for all women, treatment can be restarted at any time if acne or hirsutism recurs after stopping therapy.

The study of any association may be confounded by the adverse cardiovascular risk associated with polycystic ovary disease, an underlying condition in many women given cyproterone with ethinylestradiol to manage acne and hirsutism.[6]

Effects on the eyes. Bilateral optic atrophy in an elderly male patient was thought to be associated with cyproterone.[1] The authors could find no other cases from the published literature or the manufacturers' records. Central retinal vein occlusion occurred in a 28-year-old woman given cyproterone for the treatment of hair loss.[2]

Effects on the liver. There have been numerous reports of hepatic reactions associated with cyproterone acetate. In February 1995, the UK CSM noted that it had received 96 reports of reactions including hepatitis, cholestatic jaundice, and hepatic failure, following cyproterone treatment;[1] 33 cases had led to fatalities. Nearly all cases (91 of 96) were in elderly men typically receiving high doses (300 mg daily) for prostatic cancer, and toxicity usually developed after several months of treatment. In view of this it was recommended that the use of cyproterone acetate in prostatic cancer be restricted to short courses for the testosterone flare associated with the commencement of gonadorelin analogue therapy, or for hot flushes after surgical or chemical castration, or for patients unresponsive to, or intolerant of, other treatments. A retrospective analysis[2] of data from 105 patients with advanced prostate cancer, who had received cyproterone acetate 150 mg daily, found mild to moderate hepatotoxicity in 6 patients and severe toxicity in 4. There was a higher occurrence of hepatotoxicity (19 cases out of 124 patients) in a similar group that had been given flutamide. Fourteen published case reports have also been briefly reviewed.[3] Patients with chronic viral hepatitis might be at higher risk of developing hepatotoxicity from cyproterone therapy.[4]

Although there is little doubt of the risk of hepatotoxicity, suggestions of an association between cyproterone therapy and the development of liver cancer remain contentious. There are individual reports of hepatocellular carcinoma developing in patients receiving cyproterone,[5,6] and some evidence *in vitro* of the formation of DNA adducts in exposed hepatocytes,[7] but there does not seem to be clinical evidence to support any association between use of cyproterone acetate and the development of liver tumours.[7,8]

Precautions

When used for hypersexuality, cyproterone is contra-indicated in men with liver diseases or malignant or wasting diseases. In addition, it should not be given to men with severe chronic depression, severe diabetes with vascular changes, sickle-cell anaemia, or to those with a history of thromboembolic disorders. It may delay bone maturation and testicular development and so should not be given to immature youths. When used for prostate cancer, there are no absolute contra-indications to the use of cyproterone, but the above conditions should prompt cautious consideration of the risks and benefits.

In men treated with cyproterone, liver function should be monitored before starting, and regularly during, treatment, and whenever any symptoms or signs suggestive of hepatotoxicity occur. If cyproterone-induced hepatotoxicity occurs, treatment should be withdrawn. In men with prostate cancer, it may be advisable to limit the duration of treatment (see Effects on the Liver, above). Men with diabetes require careful monitoring of diabetic control. Since anaemia has been seen, regular blood counts are recommended before and during treatment. Adrenocortical suppression has been reported and function should be monitored regularly during treatment. Patients should be advised that fatigue and weakness are common and may interfere with driving and the operation of machinery.

When cyproterone is given with ethinylestradiol to women the precautions for combined oral contraceptives (see p.2065) should be observed.

Pregnancy. Use of cyproterone during pregnancy might carry a risk of feminisation of a male fetus. However, there are a few case reports of healthy male infants born to mothers who had inadvertently taken a combination of cyproterone acetate and ethinylestradiol during the early stages of pregnancy,[1,2] and of a male fetus that was found to have no malformations after abortion was induced.[3] For further information on oral contraceptive use in pregnancy, see p.2067.

Interactions

UK licensed product information states that alcohol may reduce the effectiveness of cyproterone acetate as it is ineffective in chronic alcoholics. Dosage requirements of oral antidiabetics and insulin may be altered because of cyproterone's effects on carbohydrate metabolism.

When given with ethinylestradiol to women, interactions similar to those for combined oral contraceptives (see p.2067) might be anticipated.

Pharmacokinetics

Cyproterone acetate is slowly absorbed from the gastrointestinal tract with peak plasma concentrations being achieved in about 3 hours. It is about 96% bound to plasma proteins, mainly albumin. The terminal elimination half-life is about 43 hours. Cyproterone is metabolised by various pathways including hydroxylation and conjugation; about 35% of a dose is excreted in urine, the remainder being excreted in the bile. The principal metabolite, 15β-hydroxycyproterone, has anti-androgenic activity.

The elderly. In a study[1] of healthy men, a decrease in hepatic clearance of cyproterone acetate was found in elderly men and thought to be due to an age-related reduction in liver volume.

1. Kuhnz W, *et al.* Investigation into the age-dependence of the pharmacokinetics of cyproterone acetate in healthy male volunteers. *Eur J Clin Pharmacol* 1997; **53:** 75–80.

Uses and Administration

Cyproterone acetate is a progestogen (see Progesterone, p.2126) with anti-androgenic properties.

It is used for the **control of libido** in severe hypersexuality or sexual deviation in men (see Disturbed Behaviour, p.954). The usual oral dose is 50 mg twice daily after meals.

It is also used for the palliative treatment of **prostatic carcinoma** (p.671), to control disease flare or hot flushes associated with gonadorelin analogue therapy, and to control hot flushes associated with orchidectomy. In palliative treatment where gonadorelin analogues or surgery are contra-indicated, not tolerated, or where oral therapy is preferred, doses of 200 to 300 mg daily are given in 2 or 3 divided doses after meals. The usual initial dose for disease flare is 300 mg daily in 2 or 3 divided doses after meals, which may be reduced to 200 mg daily if the higher dose is not tolerated. For the treatment of hot flushes, a dose of 50 mg daily is used; this may be increased up to 150 mg daily in 3 divided doses if necessary.

Cyproterone acetate may be used with ethinylestradiol in women for the control of **acne** and **hirsutism** (see below). The usual oral doses are 2 mg of cyproterone acetate with 35 micrograms of ethinylestradiol given daily for 21 days of each menstrual cycle; the first treatment course is started on the first day of the menstrual cycle and each subsequent course is started after 7 tablet-free days have followed the preceding course. This regimen also provides contraception, and patients relying on this effect should be given the same advice regarding missed doses and reduced efficacy due to vomiting and diarrhoea as that given for combined oral contraceptives (see p.2069). Treatment should be withdrawn 3 or 4 cycles after the androgen-dependent condition has completely resolved, but repeat courses may be given if it recurs.

Cyproterone acetate has also been given by depot intramuscular injection. A dose of 300 mg given once every 10 to 14 days has been used to control libido; once a satisfactory effect has been obtained, the dose may be reduced by gradually increasing the interval between injections until a stable maintenance dose is reached. In palliative therapy of prostatic carcinoma, 300 mg may be given once every 2 weeks after orchidectomy, or once weekly without orchidectomy.

Dose-related hepatotoxicity has occurred with cyproterone, particularly in men treated for prostate cancer (see Effects on the Liver and Precautions, above).

Acne. Cyproterone acetate may be used in the management of acne (p.1577), generally in women with signs of hyperandrogenism. An oral combination of cyproterone acetate 2 mg with ethinylestradiol 35 micrograms, which also provides contraception, is often used in women whose condition is moderately severe, and may be considered in women with mild acne who wish to use hormonal contraception. In more severe disease, higher doses of cyproterone may be added to this low-dose regimen; examples include giving cyproterone acetate 50 mg daily for 10 or 21 days of each cycle.[1] A systematic review[2] considered that a combination of ethinylestradiol with low-dose cyproterone acetate was more effective in the treatment of acne than combined oral contraceptives containing levonorgestrel, but noted that this was based on limited evidence.

2. Arowojolu AO, *et al.* Combined oral contraceptive pills for treatment of acne. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2007 (accessed 27/06/08).

Alopecia. Cyproterone acetate has been tried in the treatment of female-pattern alopecia (p.1577). In premenopausal women, oral doses of 50 or 100 mg daily have usually been given in sequential regimens with an oestrogen or combined oral contraceptive; continuous treatment using 50 mg daily has been given to postmenopausal women. It has generally been considered that women with other signs of hyperandrogenism, such as acne and seborrhoea, as well as hair loss are most likely to benefit from cyproterone but results from small studies have been mixed.[1-3]

1. Vexiau P, *et al.* Effects of minoxidil 2% vs. cyproterone acetate treatment on female androgenetic alopecia: a controlled, 12-month randomized trial. *Br J Dermatol* 2002; **146:** 992–9.

3. Sinclair R, *et al.* Treatment of female pattern hair loss with oral antiandrogens. *Br J Dermatol* 2005; **152:** 466–73.

Gender reassignment. Cyproterone acetate is used for its anti-androgenic effects in male-to-female transsexuals.[1,2] An oral dose of 50 mg twice daily is usually given with an oestrogen (see Estradiol, p.2099).

Hidradenitis suppurativa. Beneficial responses to cyproterone acetate with ethinylestradiol have been seen[1-3] in women with hidradenitis suppurativa, an androgen-dependent disorder of the skin and hair in the pubic and axillary regions.

Hirsutism. Hirsutism is an abnormal growth in females of coarse pigmented terminal hair in an adult male pattern, and is one of the clinical expressions of hyperandrogenism. Most women with hirsutism have increased concentrations of circulating androgens from the ovaries associated with polycystic ovary syndrome (p.2080). In rare cases, the adrenal gland is the primary source of increased androgens, for example, in congenital adrenal hyperplasia (p.1502). In a few cases, severe hirsutism is associated with frank virilisation due to massively increased circulating androgen concentrations from an androgen-secreting tumour. Hirsutism is an adverse effect of androgenic progestogens, such as norgestrel, used in hormonal contraceptives and HRT. Androgens and anabolic steroids may also cause hirsutism in females.

Treatment for hirsutism uses topical cosmetic treatments such as bleaching, shaving, plucking, electrolysis, and laser hair removal, and in the mildest cases this may be all that is required. However, such mechanical means of treatment are more usually combined with drug therapy to prevent further conversion of vellus to terminal hair, and to slow the regrowth of terminal hair, which may become lighter and softer. Because the growth cycle of hair is long, a response to therapy may not be seen for 6 to 12 months.[1-3]

Combined *hormonal contraceptives* containing non-androgenic progestogens are widely used for hirsutism but their effects are generally limited.[1-3] The mainstay of oral drug therapy for hirsutism is an anti-androgen, the most commonly used being the steroidal anti-androgens *cyproterone acetate* and *spironolactone*. To increase efficacy (by suppressing ovarian androgen production) and minimise the chance of conception (because of the risk of feminisation of a male fetus), cyclical ethinylestradiol is commonly used with cyproterone acetate. Combined non-androgenic hormonal contraceptives are commonly used with spironolactone, which has no progestogenic activity. Cyproterone acetate may be used in a low-dose combined preparation containing cyproterone acetate 2 mg with ethinylestradiol 35 micrograms.[2-4] In more severe hirsutism, the two drugs may be prescribed separately in a 'reversed sequential regimen'. High-dose regimens[2] have used cyproterone acetate 100 mg daily given on days 5 to 14 of the menstrual cycle with ethinylestradiol 50 micrograms on days 5 to 24. However, lower doses are also effective, with fewer adverse effects; such regimens include[4] cyproterone acetate 50 mg (days 5 to 15) with ethinylestradiol 20 micrograms (days 5 to 25), or cyproterone acetate 12.5 mg (days 5 to 15) with ethinylestradiol 10 to 20 micrograms (days 5 to 25). Alternatively,[2] cyproterone acetate 25 to 50 mg daily may be added to the first 10 days of any low-dose combined oral contraceptive. When a satisfactory response has been achieved, the cyproterone dosage is gradually reduced, and eventually the low-dose combination preparation may be sufficient.

In some countries spironolactone is the drug of choice for the treatment of hirsutism, particularly if there is associated obesity and hypertension; doses of 100 to 200 mg daily are generally used.[1,2,4] Despite its wide use, however, evidence of benefit is considered scanty.[5] *Flutamide*, *finasteride*, and *leuprorelin* have also been shown to be effective, although some consider finasteride to be less active.[4] The condition has also been reported to respond to *ketoconazole*. *Eflornithine* is used topically for the reduction of facial hair.[1,3,4] It is thought to slow hair growth by the inhibition of ornithine decarboxylase in hair follicles.

Corticosteroids can suppress adrenal androgen production, but results with *dexamethasone* have been disappointing and the addition of an anti-androgen is usually needed.[4] Corticosteroids may have a limited role in managing hirsutism associated with congenital adrenal hyperplasia.[1,2]

Precocious puberty. Although cyproterone acetate has been used for the treatment of central precocious puberty (p.2081), it has generally been superseded and is now given in a short course to prevent the initial stimulatory effect of gonadorelin analogue therapy. The use of an oral dose of cyproterone acetate 50 mg twice daily, given from 3 weeks before to 2 weeks after starting the gonadorelin analogue, has been reported.[1] Menstrual-like bleeding may occur in girls after stopping cyproterone, depending on the degree of precocity. Gonadorelin analogue therapy does not control adrenal production of sex hormones, which, if overactive, can stimulate adrenarche and advancement of bone age; cyproterone acetate in usual doses of 10 to 20 mg twice daily has been used to treat this.[1]

Cyproterone acetate may sometimes be used to suppress sexual maturation in the management of peripheral forms of precocious puberty. Although it is not licensed for this, the *BNFC* includes an initial oral dose of 25 mg twice daily, adjusted according to response.

Danazol *(BAN, USAN, pINN)* ⊗

Danatsoli; Danazolum; Win-17757. 17α-Pregna-2,4-dien-20-yno[2,3-*d*]isoxazol-17β-ol.

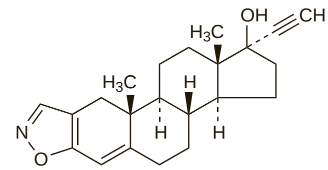
Даназол

$C_{22}H_{27}NO_2$ = 337.5.

CAS — 17230-88-5.

ATC — G03XA01.

ATC Vet — QG03XA01.



Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Danazol). A white to pale yellow crystalline powder. Practically insoluble or insoluble in water and in petroleum spirit; sparingly soluble in alcohol and in benzene; soluble in acetone; freely soluble in chloroform; slightly soluble in ether. Store in airtight containers. Protect from light.

Adverse Effects

Adverse effects of danazol that reflect inhibition of the pituitary-ovarian axis include menstrual disturbances and amenorrhoea (occasionally persistent), hot flushes, sweating, reduction in breast size, changes in libido, vaginal dryness and irritation, emotional lability, and nervousness.

Adverse effects attributable to androgenic activity include acne, oily skin or hair, mild hirsutism, oedema, weight gain, deepening of the voice, androgenic alopecia, and rarely clitoral hypertrophy. Testicular atrophy and a reduction in spermatogenesis may occur.

Other adverse effects include gastrointestinal disturbances, increased or decreased blood cell counts, thrombotic events, headache, backache, dizziness, tremor, depression, fatigue, sleep disorders, muscle spasm or cramp, skin rash, hyperglucagonaemia, abnormal glucose tolerance, decreased serum high-density-lipoprotein cholesterol, increased serum low-density-lipoprotein cholesterol, and elevation of liver-function test values and rarely cholestatic jaundice. Some patients may experience palpitations, tachycardia, and hypertension. Benign intracranial hypertension and visual disturbances have occurred.

Effects on carbohydrate metabolism. Diabetes mellitus developed in a patient given danazol 400 mg twice daily for endometriosis.[1] The diabetes developed 8 weeks after starting danazol therapy and resolved completely after the drug was stopped.

1. Seifer DB, *et al.* Insulin-dependent diabetes mellitus associated with danazol. *Am J Obstet Gynecol* 1990; **162:** 474–5.

Effects on the liver. As with other 17α-alkylated steroids (see p.2130), hepatic adverse effects have been associated with danazol, including hepatitis[1] and cholestasis.[2,3] Hepatic adenoma has occurred after long-term danazol use.[4-7] Adenomas are often removed surgically because of the risks of haemorrhage and malignant transformation, but regression over 18 months and 2 years after stopping danazol has been described in 2 patients.[6] There have also been rare reports of focal nodular hyperplasia,[7,8] hepatocellular carcinoma,[9] and peliosis hepatis.[10]

A case of acute hepatic failure has been attributed to danazol in a patient already taking ciclosporin (see below).

10. Makdisi WJ, *et al.* Fatal peliosis of the liver and spleen in a patient with agnogenic myeloid metaplasia treated with danazol. *Am J Gastroenterol* 1995; **90:** 317–8.

Effects on the pancreas. There have been reports of pancreatitis in patients receiving danazol.[1,2]

1. Chevalier X, *et al.* Danazol induced pancreatitis and hepatitis. *Clin Rheumatol* 1990; **9:** 239–41.
2. Balasch J, *et al.* Acute pancreatitis associated with danazol treatment for endometriosis. *Hum Reprod* 1994; **9:** 1163–5.

Effects on the skin and hair. There have been isolated reports of erythema multiforme occurring in patients given danazol. In 3 cases the reaction developed about 2 weeks after starting danazol, and was effectively managed by stopping danazol and treating with corticosteroids.[1,2]

Hirsutism is a recognised adverse effect of danazol, but is usually mild. Excessive facial hair growth of sudden onset, sufficient to cause distress, has been described in a woman given danazol for mastalgia. The hirsutism improved after stopping the danazol.[3]

1. Gately LE, Andes WA. Danazol and erythema multiforme. *Ann Intern Med* 1988; **109:** 85.

3. Zawar V, Sankalecha C. Facial hirsutism following danazol therapy. *Cutis* 2004; **74:** 301–3.

Precautions

Danazol should be used with caution in conditions that may be adversely affected by fluid retention, such as in cardiovascular, hepatic, and renal disorders; it should be avoided in marked dysfunction. It should also be used with care in patients with diabetes mellitus, polycythaemia, abnormal blood lipids, migraine, or epilepsy. Danazol should not be given to patients with undiagnosed genital bleeding or androgen-dependent tumours. As with other 17α-alkylated compounds, there is an increased risk of liver disorders and liver function should be monitored during therapy. It should not be used in patients with a thromboembolic disorder or a history of thrombosis.

Danazol should not be given during pregnancy because of a possible androgenic effect on the female fetus (see below), and non-hormonal contraception is recommended during treatment. Caution is required in children and adolescents since precocious sexual development may occur in boys and virilisation in girls, and premature epiphyseal closure may occur in both sexes.

In the event of androgenic effects, danazol should be withdrawn, as they may prove irreversible on continued use.

Breast feeding. Licensed product information warns that danazol should be avoided in breast-feeding women because of the theoretical potential for androgenic effects in the infant.

Porphyria. Danazol has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Reports of masculinisation of female infants born to mothers who had received danazol during pregnancy.[1-3]

1. Shaw RW, Farquhar JW. Female pseudohermaphroditism associated with danazol exposure in utero: case report. *Br J Obstet Gynaecol* 1984; **91:** 386–9.

3. Brunskill PJ. The effects of fetal exposure to danazol. *Br J Obstet Gynaecol* 1992; **99:** 212–15.

Interactions

Therapy with danazol may inhibit the hepatic metabolism of a number of drugs including carbamazepine (see p.475), ciclosporin (see below), and possibly tacrolimus (see p.1845). Danazol may also enhance the effects of warfarin (see Sex Hormones under Warfarin, p.1431). Introduction of danazol appeared to reduce the maintenance requirement for alfacalcidol (see p.1988). Rhabdomyolysis has been attributed to use of danazol with statins (see p.1393).

Ciclosporin. Danazol may raise ciclosporin concentrations (see p.1828), possibly by inhibiting its metabolism.

A case of fatal acute hepatic failure due to centrilobular massive hepatic necrosis was attributed to danazol in a patient already taking ciclosporin.[1] Danazol may have raised the ciclosporin concentrations in this case, but the authors speculated that an alternative interaction between the two drugs might have played a role in this reaction to danazol.

1. Hayashi T, *et al.* Fatal acute hepatic failure induced by danazol in a patient with endometriosis and aplastic anemia. *J Gastroenterol* 2001; **36:** 783–6.

Pharmacokinetics

Danazol is absorbed from the gastrointestinal tract and metabolised in the liver; absorption is markedly increased if it is taken with food. A plasma elimination half-life of 3 to 6 hours has been reported after a single dose, but is increased to about 26 hours with repeated dosing. Ethisterone, 2-hydroxymethylethisterone, and 17-hydroxymethylethisterone are the major metabolites, though none have pituitary inhibiting activity. Danazol and its metabolites may undergo enterohepatic circulation. Metabolites are excreted in the urine and faeces.

Uses and Administration

Danazol suppresses the pituitary-ovarian axis by inhibiting pituitary output of gonadotrophins. It has weak androgenic activity.

Danazol has been given orally in the treatment of a variety of conditions including endometriosis, some benign breast disorders such as mastalgia and fibrocystic breast disease, gynaecomastia, menorrhagia associated with dysfunctional uterine bleeding, and prevention of hereditary angioedema. It may also be used for the pre-operative thinning of the endometrium prior to hysteroscopic endometrial ablation, and has been tried in other conditions including various blood disorders.

When given to women, treatment with danazol should be started on day 1 of the menstrual cycle or after pregnancy has been otherwise excluded.

In **endometriosis** the usual dose is 200 to 800 mg daily in 2 to 4 divided doses, adjusted according to the response. Therapy is given for 3 to 6 months or continued for up to 9 months if necessary.

In the treatment of **benign breast disorders** the usual initial dose is 100 to 400 mg daily in 2 divided doses, adjusted according to response, and continued for 3 to 6 months. For **gynaecomastia** 200 mg daily has been given to male adolescents, increased after 2 months to 400 mg daily if no response occurs; adult men have been given 400 mg daily initially, in up to 4 divided doses. Daily doses of up to 800 mg have been used, and therapy is usually tried for 6 months.

In dysfunctional uterine bleeding manifesting as **menorrhagia** doses of 200 mg daily have been given and treatment is reviewed after 3 months.

In the management of **hereditary angioedema** initial doses of 200 mg two or three times daily are given, and then reduced according to the patient's response.

For **pre-operative thinning** of the endometrium danazol has been given in a dose of 400 to 800 mg daily in up to 4 divided doses, for 3 to 6 weeks.

Blood disorders. Although danazol may produce thrombocytopenia and leucopenia its use has also been investigated in some blood disorders. Increased platelet counts have been reported in patients with *idiopathic thrombocytopenic purpura* (p.1505). Small cohort studies have reported response rates of about 60 to 70%, including both partial and complete responses,[1-3] with a mean or median time to response of about 3 months.[1,2] Analysis of data from 96 patients suggested that age, sex, and spleen status may affect the response to danazol.[2] The response in men was not affected by age, but was better in splenectomised patients. However, in women there was a better response rate with advancing age in unsplenectomised patients, and the benefit of splenectomy on rates of response to danazol was only seen in younger women (45 years or younger). A better overall response rate in older patients (60 years and older) was also reported in another group.[4] However, others have found only a trend to less frequent response in younger patients, and no apparent relationship between response and sex or prior splenectomy.[1] *Thrombocytopenia associated with rheumatic disorders*, such as SLE, the antiphospholipid antibody syndrome, and rheumatoid arthritis has also been reported to respond to treatment with danazol.[5-7] For mention of the use of danazol in *Henoch-Schönlein purpura* see Hypersensitivity Vasculitis, p.1505.

Additionally there have been reports of response to danazol therapy in patients with *auto-immune haemolytic anaemia*[8,9] (p.1043), anaemia of *myelofibrosis with myeloid metaplasia*,[10] *paroxysmal nocturnal haemoglobinuria*,[11] *hereditary haemorrhagic telangiectasia*,[12] and *Evan's syndrome* due to SLE.[13] There have been conflicting reports in patients with *myelodysplastic syndromes*.[14-18]

Endometriosis. Endometriosis is a condition affecting women mainly in their reproductive years, and caused by endometrial tissue developing outside the uterine cavity. It occurs most often in the pelvic peritoneal cavity and occasionally elsewhere such as the thoracic cavity. The aetiology is uncertain, although it is widely believed that retrograde flow of menstrual tissue introduces endometrial cells into the pelvic cavity, and that the implantation and growth of these cells may be influenced by genetic, immunologic, hormonal, and environmental factors.[1,2]

The presentation of endometriosis is variable, and while symptoms can range from mild to severe, many affected women are asymptomatic.[3] There is considerable overlap of symptoms with other conditions such as irritable bowel syndrome and pelvic inflammatory disease, but a definitive diagnosis of endometriosis can be made by visualisation at laparoscopy. The most common symptom is pain, usually manifesting as secondary dysmenorrhoea, dyspareunia, or cyclical back or pelvic pain. Pain may occur on micturition or defaecation if endometriosis affects the bladder or bowel; fibrosis and adhesions can develop. Endometriosis is also strongly associated with infertility. Severe endometriosis can distort the pelvic anatomy and thereby reduce fecundity, but how minimal and mild disease might affect fertility is unclear.[1,4] Management will depend in part on the presenting complaint, the extent of disease, and whether fertility is an issue. Conservative laparoscopic surgery or drug therapy may be used, but disease recurrence is common and long-term management is usually needed.[1,5] Nevertheless, spontaneous regression may occur in about a third of patients.[4,5]

Where **infertility** is the presenting symptom, surgery is generally performed in more severe disease, based on the assumption that correction of anatomical defects should improve fecundity although there is a lack of controlled studies to confirm this.[2,3,6,7] There is also limited evidence to suggest that surgery may improve fertility in mild disease,[3] but it is likely that the effect is small.[7] Assisted reproductive techniques such as IVF (see Infertility, p.2080) offer the best chance of conception in more severe disease.[6,7] The extent of benefit in mild or moderate endometriosis is less clear.[6] Superovulation with intra-uterine insemination may be considered in such cases, with IVF an alternative for women aged 35 or more, and postoperative expectant management another option in younger women.[7]

Drug therapy has not been shown to be of direct value for infertility.[7,8] Also, because the drugs used for endometriosis tend to suppress ovulation and are potentially contraceptive, they will delay the opportunity for conception during treatment.[3,6,9] Pre- and postoperative drug therapy have also been tried, but there is insufficient evidence to show that these are any more effective than surgery alone.[10]

For patients whose primary symptom is **pain**, drug treatments that cause anovulatory hypoestrogenism (to induce atrophy and shrinkage of the hormonally sensitive ectopic endometrial deposits) are effective and are the mainstay of treatment.[4] One of the most widely used treatments has been *danazol*, which produces subjective improvement in symptoms of pain and reduction of some pelvic abnormalities and tissue implants.[1,11] Its androgenic effects can be a problem and there is concern about its effect on blood lipids, therefore therapy is restricted to 6 months, or rarely up to 9 months. *Gestrinone* has been shown to be equally effective and may be a useful alternative.[3,8,12] *Progestogens* such as medroxyprogesterone acetate, dydrogesterone, or norethisterone acetate are also commonly used. They appear to be as effective as danazol in relieving pain symptoms[12] and tend to be better tolerated.[1,4] The use of local levonorgestrel from an intra-uterine device is also under investigation.[2]

Combined oral contraceptives are often used to relieve endometriosis pain, although the evidence for their benefit is largely observational[1] and data from controlled studies remain scanty.[13] They have been used in a continuous fashion to induce amenorrhoea, as well as the usual cyclical regimens, but it is unclear which is most effective.[3,8]

The other major group of drugs that are used in endometriosis are *gonadorelin* and its analogues such as buserelin, goserelin, leuprorelin, nafarelin, and triptorelin, which are as effective as danazol.[1,6] Long-term use is limited by the risk of osteoporosis, but concomitant 'add-back' therapy such as low-dose oestrogen and progestogen HRT,[1,3,6,8] or tibolone,[1,3] can be used to prevent this. Adverse effects resembling menopausal symptoms can also be relieved by 'add-back' therapy, which may make gonadorelin analogues more tolerable than danazol.[4] Parathyroid hormone[14,15] may also be effective for 'add-back' therapy to prevent bone loss.

Investigational drugs include the *antiprogestogens* such as mifepristone,[16] and *aromatase inhibitors* such as anastrozole.[17]

There is some evidence that laparoscopic ablation can also reduce pain but controlled studies are limited.[4,6] Ideally, endometrial deposits found during diagnostic laparoscopy should be removed during the procedure.[3,8,18] There is a lack of comparison between surgery and drug treatment. Although there are reports of improved pain control using postoperative medical therapy,[18] study results have been mixed and there is insufficient evidence to confirm whether a combination of surgery and drug therapy has any additional benefit.[6,10]

There is a relatively high recurrence rate of endometriosis after conservative surgery and drug therapy. In women who can accept loss of child-bearing potential, definitive therapy is surgical oophorectomy and hysterectomy with complete excision or ablation of endometrial deposits.[3,8,18] Oestrogen replacement therapy is given, but carries a risk of recurrence of the disease; some have suggested that combined HRT may be preferable (see p.2075).

Gynaecomastia. Gynaecomastia is a common benign glandular enlargement of the male breast, caused either by increased oestrogenic activity or decreased androgenic activity. Examples of gynaecomastia caused by increased oestrogenic activity include oestrogen-secreting malignancies, increased aromatisation of androgens into oestrogens (associated with an increase in adipose tissue), and exposure to drugs with oestrogenic activity such as digitoxin. Neonatal and pubertal gynaecomastia also come into this category, the former due to exposure to maternal oestrogens and the latter because oestrogen levels increase before androgens do. Gynaecomastia caused by decreased androgenic activity may be associated with the natural decline of testosterone concentrations in ageing men, various forms of hypogonadism, increased metabolism of androgens (for example in alcoholism), and exposure to drugs with anti-androgenic properties such as spironolactone, cimetidine, ketoconazole, cyproterone acetate, or flutamide. Some systemic disorders may also be associated with gynaecomastia, including cirrhosis of the liver, hyperthyroidism, and renal failure; it may also occur on refeeding after starvation.

Gynaecomastia has a high rate of spontaneous regression, and specific therapy (other than the removal of any cause) need only be considered if the enlarged breast tissue causes sufficient pain, embarrassment, or emotional discomfort to interfere with the patient's daily life.[1-3] Drug therapy is only likely to be of benefit while tissue is still proliferating; once glandular tissue has become inactive and fibrotic (usually after more than 12 months) a complete response is unlikely.[2,3]

Except in primary hypogonadism,[3] testosterone itself is unlikely to be of benefit (and may be aromatised to oestradiol, exacerbating the situation),[2] but a non-aromatisable androgen such as *androstanolone* (dihydrotestosterone) may produce some benefit.[2,4] *Danazol* has produced marked responses in some patients,[4] but adverse effects may limit its usefulness.[2] Quite good responses have also been reported with *tamoxifen*,[4-6] and this has been recommended as a drug of choice.[2,3] A retrospective review[7] of men treated for idiopathic gynaecomastia found that a complete response occurred in 18 of 23 men treated with tamoxifen, but in only 8 of 20 who received danazol. The decrease in pain was similar for both groups, but relapse occurred in 5 of the men treated with tamoxifen. The use of other drugs with anti-oestrogen effects, such as *clomifene*[8,9] and *raloxifene*,[6] has also been described in small numbers of boys with pubertal gynaecomastia. Aromatase inhibitors have been investigated for their potential to prevent the peripheral aromatisation of androgens to oestrogens. Improvement in pubertal gynaecomastia has been reported with *testolactone*,[10] but a controlled study[11] in 80 boys found 6 months of treatment with *anastrozole* to be no better than placebo. Studies in men being treated for prostate cancer also found anastrozole to be ineffective for the prevention[12,13] and treatment[12] of gynaecomastia associated with bicalutamide therapy; in comparison, tamoxifen was effective in both studies.

Where drug therapy is unsuccessful, or the breast enlargement is long-standing, surgical removal of breast tissue is advocated.[2,3] Prophylactic low-dose radiotherapy to the breast can significantly reduce the risk of gynaecomastia and breast pain in men undergoing anti-androgen treatment for prostate cancer,[2] although comparative studies suggest that it may be less effective than tamoxifen.[14,15]

Hereditary angioedema. Danazol has been used successfully[1,2] to prevent attacks of hereditary angioedema (p.1081). Patients with lupus erythematosus-like syndromes associated with hereditary angioedema have also benefited from danazol therapy.[3-5]

Mastalgia. Mastalgia may occur alone or be associated with nodularity or other fibrocystic changes in the female breast. It is usually divided into cyclical mastalgia, which accounts for about two-thirds of all cases, non-cyclical mastalgia, and chest-wall or costochondral pain (Tietze's syndrome). Cyclical mastalgia has a temporal association with the menstrual cycle and is most common in the third decade of life, with a chronic relapsing course thereafter; it usually resolves at the menopause. Non-cyclical mastalgia tends to present later in life as constant or intermittent pain that is not associated with the menstrual cycle.

Once clear pathological causes of pain have been excluded most patients can be managed by simple reassurance.[1-3] In the management of mild mastalgia, simple measures such as wearing a properly fitting brassiere and the use of relaxation techniques are widely recommended.[1-3] Warm compresses or ice packs and gentle massage may provide relief, particularly when the pain is cyclic or intermittent and of short duration.[1] There is some evidence that a low-fat diet may reduce symptoms of mastalgia, but the evidence to support a restriction of dietary caffeine intake is inconsistent and such a measure is not generally recommended.[1,3] Although few studies have been done to confirm a beneficial effect, many women are likely to self-medicate as required with simple analgesics such as paracetamol and oral or topical NSAIDs.[1] Patients who take an oral contraceptive or HRT may find that symptoms improve on reducing the estrogen dose or stopping treatment.[1,3]

Women with moderate to severe mastalgia that has lasted for more than 6 months may require specific drug treatment. *Danazol* is probably the most effective drug for mastalgia, and studies suggest that it is of benefit in about 70% or more of patients with cyclical mastalgia,[1-3] and somewhat fewer with the non-cyclical form.[2] However, adverse effects may force the dose to be reduced or stopped. Danazol given only during the luteal phase (days 14 to 28) has been reported to be effective in cyclical mastalgia, and to cause few adverse effects.[4] *Gestrinone* has also been reported to be effective in cyclical mastalgia.[1] Although effective in cyclical mastalgia,[3,5] *bromocriptine* is not as effective as danazol, and its use is similarly limited by adverse effects.[1,2] A small study[6] has reported that *lisuride* was effective in cyclical mastalgia.

Gamolenic acid (usually as evening primrose oil) has been widely used in cyclical mastalgia because of early studies suggesting that it was an effective treatment with few adverse effects. Although further studies have produced conflicting results and there is now doubt about its efficacy,[2,3,5] some still suggest that it can be tried as there may be a beneficial effect with minimal risk.[1]

In refractory cyclical or non-cyclical mastalgia *tamoxifen*[3,5] has been shown to be effective; controlled trials have reported efficacy rates of up to 96% in cyclical mastalgia and 56% in non-cyclical mastalgia.[1] However, the concept of using tamoxifen in otherwise healthy premenopausal women has produced some concern.[7-9] *Toremifene* has been reported to be of benefit.[10,11] *Goserelin* has also been shown to be effective,[12,13] but there is limited experience with the use of gonadorelin analogues and severe adverse effects are likely to limit their use.[1] Injection of a *local anaesthetic* with a *corticosteroid* has proved effective for the pain of non-cyclical mastalgia.[14]

Other drugs that have been used for cyclical mastalgia include antibacterials, diuretics, and various vitamins but there is no evidence that they are any better than placebo.[1]

Menorrhagia. Danazol is effective in the treatment of menorrhagia (p.2126) but it is only used short term because of its adverse effects.[1] It may also be used for pre-operative endometrial thinning.[2]

1. Beaumont H, *et al.* Danazol for heavy menstrual bleeding. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2007 (accessed 30/06/08).
2. Sowter MC, *et al.* Pre-operative endometrial thinning agents before endometrial destruction for heavy menstrual bleeding. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2002 (accessed 30/06/08).

Premenstrual syndrome. Danazol may be useful[1-3] in the management of the premenstrual syndrome (p.2099), but some have found it to be of value only for cyclical mastalgia rather than for general symptoms,[4] and in any case adverse effects limit its long-term use.

Skin disorders. Danazol has been reported to relieve pruritus (p.1582) refractory to usual treatment with antihistamines; underlying conditions have included cholinergic urticaria,[1,2] chronic actinic dermatitis,[3] myeloproliferative disorders,[4] and autoimmune disorders.[4] In 2 reports, the skin disorder had been associated with low plasma concentrations of antiprotease.[1,3] Danazol has generally been given in oral doses of 200 to 800 mg daily.[4] Maintenance treatment may be needed, and relapse can occur when the dose is reduced or treatment is withdrawn.

Danazol was also reported to reduce induration and pain in a man with lipodermatosclerosis.[5]

Degarelix *(USAN, rINN)*

Dégarélix; Degarelixum; FE-200486 (degarelix acetate). *N*-Acetyl-3-(naphthalen-2-yl)-D-alanyl-4-chloro-D-phenylalanyl-3-(pyridin-3-yl)-D-alanyl-L-seryl-4-({[(4S)-2,6-dioxohexahydropyrimidin-4-yl]carbonyl}amino)-L-phenylalanyl-4-(carbamoylamino)-Dphenylalanyl-L-leucyl-N^6-(1-methylethyl)-L-lysyl-Lprolyl-D-alaninamide.

Дегареликс

$C_{82}H_{103}ClN_{18}O_{16}$ = 1632.3.

CAS — 214766-78-6.

Profile

Like cetrorelix (p.2084), degarelix is a gonadorelin (gonadotrophin-releasing hormone) antagonist. It is under investigation to reduce testosterone concentrations in hormonal therapy of prostate cancer.

Delmadinone Acetate *(BANM, USAN, rINNM)*

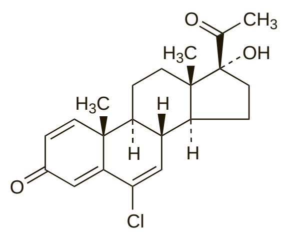
Acetato de delmadinona; Delmadinonacetat; Delmadinone, Acétate de; Delmadinoni Acetas; Delmadinoniasetaatti; RS-1301. 6-Chloro-17α-hydroxypregna-1,4,6-triene-3,20-dione acetate.

Дельмадинона Ацетат

$C_{23}H_{27}ClO_4$ = 402.9.

CAS — 15262-77-8 (delmadinone); 13698-49-2 (delmadinone acetate).

ATC Vet — QG03DX91.



(delmadinone)

Profile

Delmadinone acetate is a progestogen with anti-androgenic and anti-oestrogenic activity. It is used as an anti-androgen in veterinary practice.

Deslorelin *(BAN, USAN, rINN)* ⊗

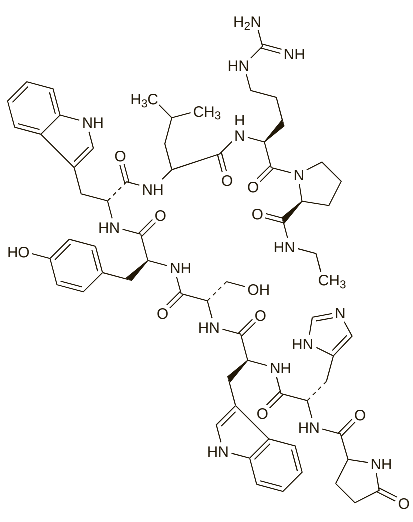
Deslorelina; Desloréline; Deslorelinum; D-Trp LHRH-PEA. 5-Oxo-L-prolyl-L-histidyl-L-tryptophyl-L-seryl-L-tyrosyl-D-tryptophyl-L-leucyl-L-arginyl-*N*-ethyl-L-prolinamide.

Дезлорелин

$C_{64}H_{83}N_{17}O_{12}$ = 1282.5.

CAS — 57773-65-6.

ATC Vet — QH01CA93.



Profile

Deslorelin is an analogue of gonadorelin (p.2106) that has been investigated in the treatment of precocious puberty, short stature, prostate cancer, and endometriosis.

◊ References.

Desogestrel *(BAN, USAN, rINN)*

Desogestreeli; Désogestrel; Desogestrelum; Dezogestrel; Org-2969. 13β-Ethyl-11-methylene-18,19-dinor-17α-pregn-4-en-20-yn-17β-ol.

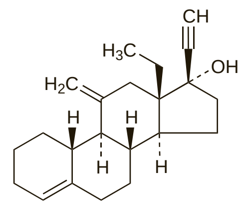
Дезогестрел

$C_{22}H_{30}O$ = 310.5.

CAS — 54024-22-5.

ATC — G03AC09.

ATC Vet — QG03AC09.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Desogestrel). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in dehydrated alcohol and in dichloromethane; very soluble in methyl alcohol.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059. When used as a progestogen-only contraceptive, irregular bleeding is more common with desogestrel than with other progestogen-only preparations. Desogestrel is reported to have few androgenic effects, and to have less adverse effect on the serum lipid profile than older 19-nortestosterone derivatives. However, there is some evidence that desogestrel-containing combined oral contraceptives are associated with a small increased risk of venous thromboembolism (see p.2063, and for precautions, see p.2066).

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Pharmacokinetics

After oral doses, desogestrel undergoes oxidative transformation in the intestinal mucosa and liver to its active metabolite 3-keto-desogestrel (etonogestrel—see p.2103).

Uses and Administration

Desogestrel is a progestogen (see Progesterone, p.2126) structurally related to levonorgestrel that is used as a hormonal contraceptive (see p.2069). A typical daily dose of 150 micrograms is used as the progestogenic component of monophasic combined oral contraceptive preparations. Doses of 50 to 150 micrograms daily may be used in triphasic combined preparations. A dose of 75 micrograms daily is used as an oral progestogen-only contraceptive; unlike traditional progestogen-only contraceptives, desogestrel is said to reliably inhibit ovulation. Progestogen-only contraceptive efficacy is reduced if a dose of desogestrel is delayed by more than 12 hours.

Contraception. The effects of a progestogen-only contraceptive containing desogestrel have been reported.[1-3] Oral desogestrel has also been investigated as a male contraceptive, combined with testosterone given by intramuscular injection,[4] subcutaneous implant,[5,6] or transdermal patch.[7]

1. Collaborative study group on the desogestrel-containing progestogen-only pill. Dienestrol *(BAN, rINN)*

Dehydrostilbestrol; Diènestrol; Dienestroli; Dienestrolis; Dienestrolum; Dienoestrol; Dienoestrolum; Dienösztrol; Oestrodienolum. *(E,E)*-4,4′-[Di(ethylidene)ethylene]diphenol; 4,4′-(1,2-Diethylidene-1,2-ethanediyl)bisphenol.

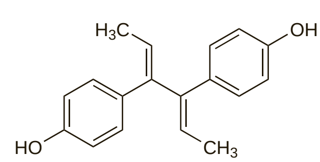
Диенэстрол

$C_{18}H_{18}O_2$ = 266.3.

CAS — 84-17-3 (dienestrol); 13029-44-2 ((E,E)-dienestrol).

ATC — G03CB01.

ATC Vet — QG03CB01; QG03CC02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Dienestrol). A white or almost white, crystalline powder. Practically insoluble in water; freely soluble in alcohol and in acetone; dissolves in dilute solutions of alkali hydroxides. Protect from light.

USP 31 (Dienestrol). Colourless, white, or practically white needle-like crystals, or white or practically white crystalline powder. It is odourless. Practically insoluble in water; soluble in alcohol, in acetone, in ether, in methyl alcohol, in propylene glycol, and in solutions of alkali hydroxides; slightly soluble in chloroform and in fatty oils.

Profile

Dienestrol is a synthetic nonsteroidal oestrogen structurally related to diethylstilbestrol (p.2094). It has been used as a 0.01% cream in the treatment of menopausal atrophic vaginitis. If used on a long-term basis in women with a uterus a progestogen is required.

Dienestrol diacetate has been used as an ingredient of topical preparations for skin disorders.

Porphyria. Dienestrol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Preparations

USP 31: Dienestrol Cream.

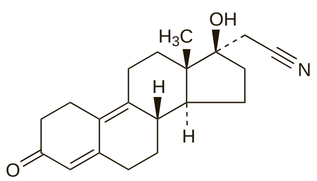
Proprietary Preparations (details are given in Part 3)
Denm.: Sexadien†; ***USA:*** Ortho-Dienestrol.

Dienogest *(BAN, USAN, rINN)*

Diénogest; Dienogesti; Dienogestum; STS-557. 17-Hydroxy-3-oxo-19-nor-17α-pregna-4,9-diene-21-nitrile.

Диеногест

$C_{20}H_{25}NO_2$ = 311.4.
CAS — 65928-58-7.



Profile

Dienogest is a nonethinylated progestogen (see Progesterone, p.2125) structurally related to nortestosterone. It is reported to have anti-androgenic properties. Dienogest is used as the progestogen component of some combined oral contraceptives (see p.2058); a typical daily dose is 2 mg. It is also used as the progestogen component in menopausal HRT (see p.2071) in a daily dose of 2 mg.

Adverse Effects and Precautions

Dose-related adverse effects of diethylstilbestrol include nausea, fluid retention, and arterial and venous thrombosis, and these effects are common at the doses used for palliation of cancer. Impotence and gynaecomastia occur in men, and withdrawal bleeding may occur in women, as may hypercalcaemia and bone pain in women treated for breast cancer. Diethylstilbestrol should be used with caution in those with cardiovascular disease or renal or hepatic impairment. Use of diethylstilbestrol is contra-indicated if pregnancy is suspected.

Adverse effects and precautions of oestrogens in general (steroidal compounds) are covered under Estradiol, on p.2097.

Historically, high doses of diethylstilbestrol and related substances were used for 'hormonal support' in pregnant women to try to prevent miscarriages and preterm births, most commonly in the USA. This practice was later shown to be ineffective. Adverse effects on the genito-urinary tract of offspring of these women have been noted. In particular, an increased incidence of changes in the cervix and vagina including adenosis and rarely clear-cell adenocarcinoma has been seen in postpubertal daughters of women who received diethylstilbestrol or related substances during pregnancy (see below). A possible increased incidence of abnormalities of the genital tract and of abnormal spermatozoa has been reported in male offspring similarly exposed (see below). The recipients themselves appear to be at a small increased risk of breast cancer (see below).

Carcinogenicity. *BREAST.* No statistically significant difference in the incidence of breast cancer was found among a group of 693 women given diethylstilbestrol during pregnancy 25 years earlier compared with a control group of 668 who were not.[1] This finding was, however, criticised[2] on the basis that the study lacked the statistical power to reject the null hypothesis. In another study[3] the incidence of breast cancer in 3033 women who had taken diethylstilbestrol in pregnancy during the period 1940 to 1960 was compared with the incidence in a comparable group of unexposed women. This study involved over 85 000 women-years of follow-up in each group and it was found that the incidence of breast cancer per 100 000 women-years was 134 in the exposed group and 93 in the unexposed group (a relative risk of 1.4). The authors concluded that in those women given diethylstilbestrol there was a moderately increased incidence of breast cancer but that some unrecognised concomitant of exposure could not be excluded as a possibility for the increase. Although this study suggested that the risk increased over time, subsequent follow-up,[4] while confirming a modest increase in risk overall, did not confirm a higher risk in these women as time went on. Further follow-up and analysis[5] of the combined data from these cohort studies[1,3,4] confirmed a modest increase in risk of breast cancer associated with diethylstilbestrol (relative risk 1.27, 95% confidence interval 1.07 to 1.52). Another large population cohort study[6] suggested that the risk of fatal breast cancer might also be increased in women who had been given diethylstilbestrol.

Two cases of breast cancer[7] in premenopausal women exposed to diethylstilbestrol *in utero* have raised the possibility that the risk of breast cancer may be increased in these women, in addition to the known genito-urinary risk (see below under Pregnancy, Effects on Female Offspring). However, a cohort study[8] involving 4536 women exposed *in utero* found no increased risk of other cancers overall, and did not show an increased risk of breast cancer (relative risk 1.18; 95% confidence intervals 0.56 to 2.49). A later study[9] of further follow-up of this cohort, plus additional data from another group, found that although the risk overall and for younger women was not increased, from the age of 40 years the risk increased to 1.91 (95% confidence interval 1.09 to 3.33). The risk appeared to increase further with greater age, but the relatively small number of cases in women aged 50 years and over made this harder to establish.

Effects on the blood. Adverse haematological effects reported with diethylstilbestrol have included severe bone-marrow changes in a 71-year-old man given diethylstilbestrol in a massive dose of 150 mg daily for 7 years[1] and fatal immune haemolytic anaemia in a 69-year-old man given weekly infusions of diethylstilbestrol 1 g for 9 weeks.[2] The latter reaction was due to an IgG antibody specific for diethylstilbestrol.

Pregnancy. *EFFECTS ON FEMALE OFFSPRING.* The DESAD (Diethylstilbestrol and Adenosis) Project carried out by the National Cancer Institute in the USA led to several reports linking exposure to diethylstilbestrol *in utero* to adverse genital-tract effects.[1-3] It was reported that of nearly 300 young females with clear-cell adenocarcinoma of the genital tract, more than 80% had been exposed *in utero* to diethylstilbestrol-type hormones.[1] Patients had been aged 7 to 28 years at the time of diagnosis. Doses and duration of treatment varied widely; the association existed for both 1.5 mg of diethylstilbestrol daily throughout pregnancy and variable amounts for a week or more during the first trimester. Vaginal adenosis, rare in unexposed young women, was present in about a third of those exposed in the first 4 months of pregnancy, and cervical ectropion in more than two-thirds. Vaginal epithelial changes were most closely associated with early exposure to diethylstilbestrol, with the total dose, and with the duration of exposure; their incidence decreased with age. The risk of cancer in the first 25 years after exposure was small.[2] Fertility did not appear to be impaired in women who had been exposed *in utero* to diethylstilbestrol but the relative risk of an unfavourable outcome of pregnancy in such a group was 1.69. However, of the women who became pregnant, 81% of those exposed to diethylstilbestrol and 95% of control subjects had at least one full-term live birth.[3] In a review of vaginal adenosis and its association with maternal diethylstilbestrol ingestion during pregnancy[4] it was noted that the link between diethylstilbestrol and particularly the benign changes in the vagina and cervix (adenosis) seemed well established. The association between this drug and the development of genital malignancies was less clear, and the very low incidence in the prospective studies in the USA supported this concept. The problem was rare in the UK, but clinicians should be aware that it existed. Cases of vaginal adenosis in young women should be investigated and screened appropriately, and preferably referred to centres where colposcopic expertise was available. Treatment of simple vaginal adenosis should be avoided.

Later reviews[5,6] have highlighted the fact that adverse effects were still emerging in women who had been exposed to diethylstilbestrol *in utero* several decades before. The need for thorough medical screening of such women was emphasised; genital-tract examination was particularly important. It was pointed out[6] that many women exposed to diethylstilbestrol *in utero* were in the reproductive stage of their lives and warranted special observation since a diethylstilbestrol-damaged genital tract posed a potential problem during pregnancy.[5,6] It has also been suggested, for example, that such women are at increased risk of developing pre-eclampsia.[7,8]

There has been concern about the possibility of transgenerational effects on the grandchildren of women given diethylstilbestrol during pregnancy. There has been very little reported on *female offspring of exposed women*, but there were no breast or gynaecological abnormalities found on examination of 28 daughters (over 15 years of age) of women who had been exposed *in utero* and had in many cases cervical and/or vaginal changes characteristic of diethylstilbestrol exposure.[9] Limited data from a Dutch cohort[10] of 16 284 mothers and 8934 sons suggested that the *male offspring of exposed women* may in turn be at greatly increased risk of hypospadias, although the absolute risk was small. A case-control study[11] also found an increased risk, but of a much smaller magnitude, and another cohort study[12] (including DESAD data) found no support for a greatly increased risk of hypospadias. The earlier cohort study that reported the greatly increased risk may have been affected by factors related to infertility, as the study was done in a cohort of subfertile women, about half of whom had undergone IVF.

Further information on the adverse effects of diethylstilbestrol in females exposed to the drug *in utero* can be obtained from the references listed below.[13-23] For mention of the possible increased risk of breast cancer in these women, see Carcinogenicity, above.

Effects on male offspring. The effects of exposure to diethylstilbestrol *in utero* have been studied in male offspring.[1-4] Problems in passing urine and abnormalities of the penile urethra were found to be more common in young males exposed to diethylstilbestrol *in utero* than in controls in one study.[1] In another,[2] genital tract abnormalities such as epididymal cysts, capsular induration, and defective testicles occurred in 41 of 163 diethylstilbestrol-exposed men compared with 11 of 168 controls; sperm counts and motility were also reduced in exposed males. In contrast, comparison of 828 men exposed to diethylstilbestrol *in utero* with 676 unexposed men suggested that, overall, diethylstilbestrol exposure did not result in an increased risk of genito-urinary abnormalities, infertility, or testicular cancer.[3] It was suggested that previously reported increased frequencies of such abnormalities may have resulted from a selection bias and/or from a difference in diethylstilbestrol usage. Another study[4] in 253 exposed men found that although there was an increased incidence of congenital malformations of the genitalia (18 cases compared with 5 of 241 controls), this was not associated with any decrease in fertility or impairment of sexual function. An analysis[5] of the combined data from 4 cohorts suggested that there was a small increase in the risk of infertility (relative risk 1.3, 95% confidence interval 1.0 to 1.6) in men who had been exposed to diethylstilbestrol, but that overall this was not associated with an increased likelihood of never fathering a pregnancy or live births, and did not affect the number of pregnancies or live births. Data from these 4 cohorts was also analysed[6] for the development of cancer. The overall rates of cancer were similar to those in unexposed men and to national rates. The rate of testicular cancer was increased in men who had been exposed to diethylstilbestrol *in utero*, but this finding did not reach statistical significance and was limited to only one of the cohorts. Further follow-up will be needed as these men approach the age at which most cancers are diagnosed.

For reference to possible effects on the male *grandchildren* of women who took diethylstilbestrol (the offspring of women exposed *in utero*) see Effects on Female Offspring, above.

Veterinary use. In the EU, the use of diethylstilbestrol or other stilbenes in veterinary medicine is banned unless prior steps are taken to ensure the treated animal and its products are not available for human or animal consumption.

Pharmacokinetics

Diethylstilbestrol is readily absorbed from the gastrointestinal tract. It is slowly metabolised in the liver and excreted in the urine and faeces, mainly as the glucuronide.

Uses and Administration

Diethylstilbestrol is a synthetic nonsteroidal oestrogen that has been used in the palliation of breast and prostate cancer.

Daily oral doses of 10 to 20 mg are occasionally used in the palliative treatment of malignant neoplasms of the breast in postmenopausal women (p.661). The usual oral dose in carcinoma of the prostate (p.671) is 1 to 3 mg daily; higher doses were formerly given. Diethylstilbestrol has also been used in the treatment of prostatic carcinoma in the form of its diphosphate salts (see Fosfestrol, p.2104).

Diethylstilbestrol has been used as pessaries in the short-term management of menopausal atrophic vaginitis.

Preparations

BP 2008: Diethylstilbestrol Pessaries; Diethylstilbestrol Tablets;
USP 31: Diethylstilbestrol Injection; Diethylstilbestrol Tablets.

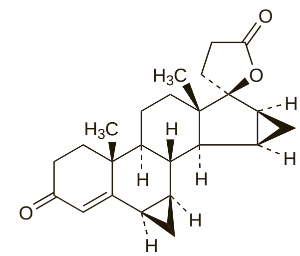
Drospirenone *(BAN, USAN, rINN)*

Dihydrospirenone; Drospirenon; Drospirenona; Drospirénone; Drospirenoni; Drospirenonum; SH-470; ZK-30595. (6*R*,7*R*,8*R*,9*S*,10*R*,13*S*,14*S*,15*S*,16*S*,17*S*)-1,3′,4′,6,6a,7,8,9,10,11,12,13,14,15,15a,16-Hexadecahydro-10,13-dimethylspiro-[17*H*-dicyclopropa[6,7:15,16]cyclopenta[*a*]phenanthrene-17,2′(5′*H*)-furan]-3,5′(2*H*)-dione.

Дроспиренон

$C_{24}H_{30}O_3$ = 366.5.

CAS — 67392-87-4.



Pharmacopoeias. In *US.*

USP 31 (Drospirenone). A white to off-white powder. Practically insoluble in water and in hexane; sparingly soluble in alcohol and in ethyl acetate; soluble in methyl alcohol and in acetone; freely soluble in dichloromethane. Store in airtight containers at a temperature of 20° to 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059. Drospirenone has antimineralocorticoid activity and therefore should not be used in patients at risk of hyperkalaemia, such as those with renal or hepatic impairment or adrenal insufficiency.

◊ Reviews.

1. Heinemann LAJ, Dinger J. Safety of a new oral contraceptive containing drospirenone. *Drug Safety* 2004; **27:** 1001–18.

Effects on the cardiovascular system. As with combined oral contraceptives containing other progestogens, there are reports[1-4] of thrombotic and ischaemic events in patients taking a preparation of ethinylestradiol and drospirenone. The extent of risk associated with hormonal contraceptives that contain drospirenone is mentioned under Venous Thromboembolism, p.2063.

4. Girolami A, *et al.* Retinal central artery occlusion in a young woman after ten days of a drospirenone-containing oral contraceptive (Yasmin). *Thromb Haemost* 2007; **98:** 473–4.

Renal impairment. US licensed product information for preparations containing drospirenone contra-indicates its use in renal impairment, and in the UK it is contra-indicated in severe impairment. A study[1] of women with renal impairment that was mild (creatinine clearance 50 to 80 mL/minute) or moderate (30 to 50 mL/min) found a trend toward increasing drospirenone exposure with decreasing creatinine clearance. Serum-potassium concentrations were not significantly altered by drospirenone, despite the concomitant use of other drugs that can also potentially increase potassium concentrations including beta blockers and ACE inhibitors.

1. Schürmann R, *et al.* Effect of drospirenone on serum potassium and drospirenone pharmacokinetics in women with normal or impaired renal function. *J Clin Pharmacol* 2006; **46:** 867–75.

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067, and Hormone Replacement Therapy, p.2076. Because drospirenone has antimineralocorticoid activity, it may potentially exacerbate the effects of drugs that can increase serum-potassium, such as ACE inhibitors, angiotensin II receptor antagonists, aldosterone antagonists, potassium-sparing diuretics, or NSAIDs. Drospirenone may also reduce blood pressure, such that antihypertensive treatment may require adjustment.

Diuretics. The pharmacokinetics of hydrochlorothiazide were not affected by the addition of drospirenone and estradiol in a placebo-controlled study of 36 hypertensive postmenopausal women.[1] However, those given the combination in this study developed lower blood pressure and higher serum-potassium concentrations, which was attributed to the antimineralocorticoid effect of drospirenone.[2] Nontheless, there were no cases of hyperkalaemia. It has been suggested that these potential antihypertensive and potassium-sparing effects might be beneficial in women requiring treatment for both menopausal symptoms and hypertension (see also Menopausal Disorders, below).

1. Karara AH, *et al.* Pharmacokinetics and pharmacodynamics of drospirenone-estradiol combination hormone therapy product coadministered with hydrochlorothiazide in hypertensive postmenopausal women. *J Clin Pharmacol* 2007; **47:** 1292–1302.
2. Preston RA, *et al.* Randomized, placebo-controlled trial of the effects of drospirenone-estradiol on blood pressure and potassium balance in hypertensive postmenopausal women receiving hydrochlorothiazide. *Menopause* 2007; **14:** 408–14.

NSAIDs. Drospirenone has the potential to exacerbate the effects of other drugs, such as NSAIDs, that can increase serum potassium. Licensed product information suggests that a clinical effect is unlikely in practice, although the use of a number of such drugs together or the presence of renal impairment may increase the risk. In a small study[1] of healthy postmenopausal women, there was no evidence that potassium concentrations were any higher during concomitant use of *indometacin* with a combination of drospirenone plus estradiol compared with indometacin alone.

1. Schütt B, *et al.* Coadministration of estradiol/drospirenone and indomethacin does not cause hyperkalemia in healthy postmenopausal women: a randomized open-label crossover study. *J Clin Pharmacol* 2007; **47:** 774–81.

Pharmacokinetics

After oral doses, drospirenone is rapidly absorbed with a bioavailability of about 76%. It is about 97% bound to plasma proteins, though it does not bind to sex hormone binding globulin or corticosteroid binding globulin. It is extensively metabolised with a terminal half-life of about 30 to 40 hours. The metabolites are excreted in the urine and faeces.

Uses and Administration

Drospirenone is a structural analogue of spironolactone (p.1400); it has the effects of a progestogen (see Progesterone, p.2126) with antimineralocorticoid and anti-androgenic activity. It is used as the progestogenic component of combined oral contraceptives (see p.2069), usually in a dose of 3 mg daily with ethinylestradiol 30 micrograms, for 21 days of each 28-day cycle. A combination of drospirenone 3 mg with ethinylestradiol 20 micrograms, given daily for 24 days of each 28-day cycle, may also be used for contraception and for the management of premenstrual dysphoric disorder (see below) or moderate acne (p.1577) in women who also require an oral contraceptive. Drospirenone is also used as the progestogenic component of menopausal HRT (see below) in a continuous dosage regimen of 0.5 or 2 mg daily.

Menopausal disorders. Drospirenone is used as the progestogenic component of menopausal HRT[1-3] (p.2076). The antimineralocorticoid effect of drospirenone has also been investigated and found to lower blood pressure in postmenopausal women with treated and untreated hypertension.[4]

3. Archer DF, *et al.* Long-term safety of drospirenone-estradiol for hormone therapy: a randomized, double-blind, multicenter trial. *Menopause* 2005; **12:** 716–27.
4. Mallareddy M, *et al.* Drospirenone, a new progestogen, for postmenopausal women with hypertension. *Drugs Aging* 2007; **24:** 453–66.

Premenstrual syndrome. The combination of drospirenone with ethinylestradiol has been studied in the management of premenstrual syndrome (p.2099). A systematic review[1] of 5 studies found some evidence that the combination may be useful in the treatment of premenstrual dysphoric disorder. However, it was not known whether the effect lasted beyond 3 cycles of treatment, whether the combination was effective for less severe symptoms, or whether combinations using drospirenone were any better than combined contraceptives containing other progestogens.

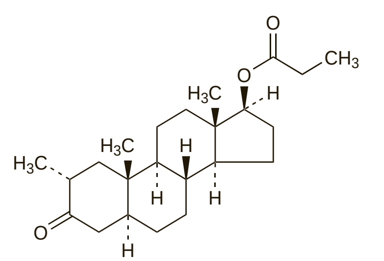
Drostanolone Propionate *(BANM, rINNM)* ⊗

Compound 32379; Dromostanolone Propionate *(USAN)*; Drostanolone, Propionate de; Drostanoloni Propionas; 2α-Methyldihydrotestosterone Propionate; NSC-12198; Propionato de drostanolona. 17β-Hydroxy-2α-methyl-5α-androstan-3-one propionate.

Дростанолона Пропионат

$C_{23}H_{36}O_3$ = 360.5.

CAS — 58-19-5 (drostanolone); 521-12-0 (drostanolone propionate).



Profile

Drostanolone propionate has anabolic and androgenic properties (see Testosterone, p.2129) and has been used in the treatment of advanced malignant neoplasms of the breast in postmenopausal women. It has been subject to abuse in sport.

Dydrogesterone *(BAN, USAN, rINN)*

6-Dehydro-*retro*-progesterone; 6-Dehydro-9β,10α-progesterone; Didrogesteron; Didrogesterona; Dydrogesteron; Dydrogestérone; Dydrogesteroni; Dydrogesteronum; Isopregnenone; NSC-92336. 9β,10α-Pregna-4,6-diene-3,20-dione.

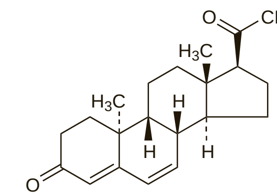
Дидрогестерон

$C_{21}H_{28}O_2$ = 312.4.

CAS — 152-62-5.

ATC — G03DB01.

ATC Vet — QG03DB01.



Pharmacopoeias. In *Br., Jpn,* and *US.*

BP 2008 (Dydrogesterone). A white or almost white crystalline powder; odourless or almost odourless. Practically insoluble in water; sparingly soluble in alcohol and in methyl alcohol; soluble in acetone; freely soluble in chloroform; slightly soluble in ether and in fixed oils. Protect from light.

USP 31 (Dydrogesterone). A white to pale yellow crystalline powder. Practically insoluble in water; soluble 1 in 40 of alcohol, 1 in 2 of chloroform, and 1 in 200 of ether.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormone Replacement Therapy, p.2071.

Porphyria. Dydrogesterone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Anomalies (non-virilising) of the genito-urinary tract were found in a 4-month-old baby whose mother had taken dydrogesterone 20 mg daily from the eighth to twentieth week of pregnancy and 10 mg daily from then until term.[1] She had also been given hydroxyprogesterone caproate 250 mg by intramuscular injection weekly from the eighth to the twentieth week.

1. Roberts IF, West RJ. Teratogenesis and maternal progesterone. *Lancet* 1977; **ii:** 982.

Interactions

As for progestogens in general (see Progesterone, p.2126).

Uses and Administration

Dydrogesterone is a progestogen structurally related to progesterone (p.2126). It does not have oestrogenic or androgenic properties.

Dydrogesterone has been given orally in the treatment of menstrual disorders such as menorrhagia (p.2126), usually in a dose of 10 mg twice daily in a cyclical regimen, and for the treatment of endometriosis (p.2091) in a dose of 10 mg two or three times daily cyclically or continuously. It has also been given cyclically in doses of 10 mg once or twice daily, or continuously in doses of 5 mg daily, for endometrial protection during menopausal HRT (p.2076).

In threatened miscarriage suggested doses have been 40 mg initially followed by 10 mg or more every 8 hours, continued for a week after symptoms cease then gradually reduced unless symptoms return. In recurrent miscarriage suggested doses have been 10 mg twice daily given cyclically until conception then continuously until week 20 of pregnancy, the dose may then be gradually reduced. However, such use is not recommended unless there is proven progesterone deficiency. Cyclical dydrogesterone has also been used in infertility (p.2080) in doses of 10 mg twice daily.

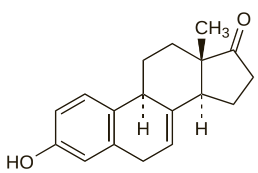
Equilin

Equilina. 3-Hydroxyestra-1,3,5(10),7-tetraen-17-one.

$C_{18}H_{20}O_2$ = 268.4.

CAS — 474-86-2.



Pharmacopoeias. In *US.*

USP 31 (Equilin). Store in airtight containers. Protect from light.

Profile

Equilin is a natural oestrogenic hormone found in horses. Sodium equilin sulfate is one of the components of both conjugated oestrogens (p.2087) and esterified oestrogens (see below) used for menopausal HRT.

Esterified Oestrogens

Esterified Estrogens; Estrógenos esterificados.

Эстрогены Этерифицированные

Pharmacopoeias. In *US.*

USP 31 (Esterified Estrogens). A mixture of the sodium salts of the sulfate esters of the oestrogenic substances, principally estrone. It contains 75 to 85% of sodium estrone sulfate and 6 to 15% of sodium equilin sulfate, in such a proportion that the total of these two components is not less than 90%, of the labelled amount of esterified oestrogens. A white or buff-coloured amorphous powder; odourless or having a slight characteristic odour. Store in airtight containers.

Profile

Esterified oestrogens have actions and uses similar to those described for estradiol (see below). They are used for the same purposes (principally menopausal HRT), and in a similar oral dosage, as conjugated oestrogens (see p.2087), although higher cyclical doses of 2.5 to 7.5 mg daily are still licensed for use in female hypogonadism.

Preparations

USP 31: Esterified Estrogens Tablets.

Proprietary Preparations (details are given in Part 3)

Estradiol Valerate *(BANM, rINN)*

Estradiol, valérate d'; Estradioli valeras; Estradiolio valeratas; Estradiolivaleraatti; Estradiolvalerat; Estradiol-valerát; NSC-17590; Oestradiol Valerate; Östradiol-17-Valerat; Ösztradiol-valerát; Valerato de estradiol. Estra-1,3,5(10)-triene-3,17β-diol 17-valerate.

Эстрадиола Валерат

$C_{23}H_{32}O_3$ = 356.5.

CAS — 979-32-8.

ATC — G03CA03.

ATC Vet — QG03CA03.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Estradiol Valerate). A white or almost white, crystalline powder or colourless crystals. Practically insoluble in water; soluble in alcohol. Protect from light.

USP 31 (Estradiol Valerate). A white crystalline powder which is usually odourless or may have a faint fatty odour. Practically insoluble in water; soluble in benzyl benzoate, in dioxan, in methyl alcohol, and in castor oil; sparingly soluble in arachis oil and in sesame oil. Store in airtight containers. Protect from light.

Adverse Effects

The adverse effects of estradiol and other oestrogens are related, in part, to dose and duration of therapy, and to the gender and age of the recipient. In addition, adverse effects may be modified by a progestogen in combined oral contraceptives or menopausal HRT. Whether adverse effects of natural and synthetic oestrogens differ, and whether the dosage route has an effect, is less clear.

The adverse effects of oestrogens used in hormonal contraceptives are considered in detail starting on p.2059. Those of oestrogens used in HRT are considered in detail starting on p.2071.

The use of oestrogens in children may cause premature closure of the epiphyses resulting in decreased final adult height.

Large doses of oestrogens used in palliation of cancers have also been associated with nausea, fluid retention, venous and arterial thrombosis, and cholestatic jaundice. In men, they cause impotence and feminising effects such as gynaecomastia. In women, they may cause withdrawal bleeding, and, when used for breast cancer, they have caused hypercalcaemia and bone pain.

Effects on the skin. Transdermal patches in which estradiol is dissolved in the adhesive matrix may cause fewer skin reactions than those releasing estradiol from an alcoholic reservoir.

1. Ross D. Randomised crossover comparison of skin irritation with two transdermal oestradiol patches. *BMJ* 1997; **315:** 288.

Precautions

The precautions for the use of estradiol and other oestrogens used as menopausal HRT are considered in detail starting on p.2075. Those for oestrogens used in hormonal contraceptives are considered in detail starting on p.2065.

High doses of oestrogen used in treating malignant disease should be used cautiously in patients with cerebrovascular disorders, coronary artery disease, or venous thromboembolism. They may exacerbate hypercalcaemia of malignancy.

Oestrogens should be used with caution in children because premature closure of the epiphyses may occur resulting in inhibited linear growth and small stature.

Oestrogens have been reported to interfere with some diagnostic tests such as those for thyroid function and glucose tolerance.

Breast feeding. Estradiol has been detected in breast milk after the use of pessaries containing 50 or 100 mg of estradiol.[1] The American Academy of Pediatrics considers that estradiol is usually compatible with breast feeding.[2]

Cosmetic use. Use of cosmetic products containing oestrogens has led to adverse effects such as precocious puberty in children[1,2] and gynaecomastia or postmenopausal bleeding in adults.[1] Such products have been used by a greater proportion of African Americans than any other ethnic group in the USA, and it has been hypothesised that this may have contributed to the observations of earlier onset of puberty in girls[3,4] and increased risk of breast cancer in young women.[4]

4. Donovan M, *et al.* Personal care products that contain estrogens or xenoestrogens may increase breast cancer risk. *Med Hypotheses* 2007; **68:** 756–66.

Porphyria. Oestrogens are considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Pregnancy. Although gross abnormalities of the genito-urinary tract have been reported in the male offspring of women who took diethylstilbestrol during pregnancy there is conflicting evidence as to whether the oestrogen produced an increased risk of abnormalities, infertility, or testicular cancer in such offspring (see p.2095). The male fetus is normally protected from the feminising effects of the natural oestrogens in the uterine environment by the early development of the testes and the secretion of male hormones.[1] However, there has been considerable concern about a rising incidence of disorders of the male reproductive tract, and a reduction in sperm counts, which has been noted in the last 20 to 30 years. It has been hypothesised that overexposure of male fetuses to environmental oestrogens derived from pollutants such as pesticides and plastics may be responsible for this decline,[2,3] although some dispute this.[4] A systematic review[5] of epidemiological data found no strong evidence to link fetal exposure to oestrogens (as pharmaceuticals or pollutants) with reduced sperm count, cryptorchidism, or hypospadias, although there was some evidence to support a possible link with testicular cancer.

For discussion of the lack of effects of hormonal contraceptives on the fetus, including evidence that they are unlikely to increase the risk of hypospadia in the male fetus, see Pregnancy, under Precautions of Hormonal Contraceptives, p.2067.

Veterinary use. An FAO/WHO expert committee examining the risks from residues of veterinary drugs in foodstuffs established an acceptable daily intake for estradiol, but concluded that there would be no need to specify a numerical maximum residue limit for estradiol in the edible tissues of cattle when products are used as growth promotors according to good practice.[1] However, it should be noted that in the EU the use of steroidal hormones such as oestrogens in veterinary practice is restricted, and their use as growth promotors is banned.

There is concern about the effect of environmental oestrogens on male fertility and development, see Pregnancy, above.

Interactions

Interactions involving estradiol and other oestrogens used in menopausal HRT are covered on p.2076. Interactions for oestrogens used in hormonal contraceptives are covered on p.2067.

Pharmacokinetics

In general, estradiol and other oestrogens are readily absorbed from the gastrointestinal tract and through the skin or mucous membranes. However, the natural unconjugated oestrogens such as estradiol undergo extensive first-pass metabolism in the gastrointestinal tract and liver after oral doses. They are, therefore, generally not orally active, although a micronised preparation of estradiol has sufficient bioavailability (3 to 5%) to be orally active. Estradiol is metabolised in part to less active oestrogens such as estriol and estrone. Synthetic oestrogens produced by alkylation of the C17 position, such as ethinylestradiol, are more slowly metabolised and are therefore orally active. Conjugated oestrogens, which are essentially oestrogen metabolites, are also orally active because they are hydrolysed by enzymes in the lower gastrointestinal tract allowing absorption of the active oestrogen. Vaginal, transdermal, intranasal, or parenteral use of oestrogens also avoids first-pass hepatic metabolism. Plasma-estradiol concentrations are reported to reach a peak 1.5 to 2 hours after an oral dose, and again at about 8 hours due to enterohepatic recycling. Estradiol esters are rapidly hydrolysed to free estradiol when given orally. After intramuscular injection of the esters, absorption is prolonged.

Oestrogens are extensively bound to plasma proteins. Naturally occurring oestrogens such as estradiol are principally bound to sex-hormone binding globulin. Conversely, ethinylestradiol is mostly bound to albumin.

Oestrogens are metabolised in the liver. A variety of sulfate and glucuronide conjugates are formed, and these are excreted in the urine and the bile. Those excreted in the bile undergo enterohepatic recycling or are excreted in the faeces.

Uses and Administration

Estradiol is the most active of the naturally occurring oestrogens (for further details, see p.2058). Estradiol and its semisynthetic esters and other natural oestrogens are primarily used as menopausal HRT (see p.2076) whereas synthetic derivatives such as ethinylestradiol and mestranol have a major role as components of combined oral contraceptives (see Hormonal Contraceptives, p.2069). Estradiol may also be used as replacement therapy for female hypogonadism or primary ovarian failure (p.2079). Replacement therapy ('add-back' therapy) may also be given to women in whom the pituitary-ovarian axis is suppressed by therapy with gonadorelin or its analogues.

Estradiol hemihydrate 1.03 mg is equivalent to about 1 mg of the anhydrous substance.

For **menopausal HRT** oral preparations or transdermal patches of estradiol are commonly used. Other transdermal formulations, subcutaneous implants, and a nasal spray are also available. Intramuscular injections were formerly used. In women with a uterus, a progestogen is also required, given cyclically or continuously, usually by mouth although some combined transdermal preparations are available. Local vaginal estradiol preparations are used specifically for the treatment of menopausal atrophic vaginitis; these are generally recommended for short-term use only, if given without a progestogen in women with a uterus, although specific recommendations vary between products.

For use *by mouth* estradiol or estradiol valerate are normally given; doses are 1 or 2 mg daily cyclically or more often continuously. Estradiol acetate may be given in an initial dose of 450 micrograms daily, increasing if necessary to 0.9 or 1.8 mg once daily.

Estradiol may be used topically as *transdermal skin patches* to provide a systemic effect; a variety of patches are available which release between 25 and 100 micrograms of estradiol every 24 hours. A low-dose patch supplying 14 micrograms daily is also available specifically for the prevention of postmenopausal osteoporosis in women at significant risk; with this low dose, the addition of a 14-day course of progestogen in women with a uterus is only required once every 6 to 12 months. Depending on the preparation, patches are replaced once or twice weekly. Each new patch is applied to a different area of skin in rotation, usually below the waistline; patches should not be applied on or near the breasts. *Topical gel* preparations are also used for systemic effect. The usual applied dose is 0.25 to 1.5 mg of estradiol daily, depending on the preparation, but up to 3 mg daily may be required for control of menopausal symptoms in some women. The gel should not be applied on the face or on or near the breasts, vagina, or vulval region. A *topical emulsion* is also available; estradiol hemihydrate 8.7 mg is applied daily to provide a systemic estradiol dose of about 50 micrograms. A *transdermal spray* has also been developed, delivering a single dose of estradiol 1.53 mg onto the skin. It should be applied to the skin of the inner surface of the forearm, and the dose may be increased up to 3 sprays once daily in the morning, at separate sites on the forearm, according to response.

A *nasal spray* is available, delivering 150 micrograms of estradiol hemihydrate per spray. The usual initial dose is 150 micrograms daily (1 spray in 1 nostril). After 2 or 3 cycles the dose may be adjusted according to response; the usual maintenance dose is 300 micrograms daily (1 spray in each nostril once daily) but may range from 150 micrograms once daily up to 450 to 600 micrograms daily in 2 divided doses.

In order to prolong the duration of action *subcutaneous implants* of estradiol may be used. The dose of estradiol is generally 25 to 100 mg with a new implant being given after about 4 to 8 months according to oestrogen concentrations.

Estradiol may be used locally either as 25-microgram *vaginal tablets*, at an initial dose of one tablet daily for 2 weeks followed by a maintenance dose of one tablet twice a week, or as a 0.01% *vaginal cream*, in initial amounts of 2 to 4 g of cream daily for 1 to 2 weeks followed by half the initial dose for a similar period, then a maintenance dose of 1 g up to 3 times weekly. A local delivery system using a 3-month *vaginal ring* contains 2 mg of estradiol hemihydrate, and delivers about 7.5 micrograms of estradiol per 24 hours. Another 3-month vaginal ring system, which contains estradiol acetate, releases either 50 or 100 micrograms of estradiol daily, and is used for the relief of both local and systemic postmenopausal symptoms.

Intramuscular injections of estradiol benzoate or valerate esters have been used as oily depot solutions, usually given once every 3 to 4 weeks. The cipionate, dipropionate, enantate, hexahydrobenzoate, phenylpropionate, and undecylate esters have been used similarly. The enantate and cipionate esters are used as the oestrogen component of combined injectable **contraceptives**.

Estradiol and other oestrogens have sometimes been used in higher doses for palliative treatment in **prostate cancer** (p.671) and **breast cancer** in men and postmenopausal women (p.661).

Administration. ***BUCCAL AND SUBLINGUAL ADMINISTRATION.*** Estradiol is absorbed through the *buccal* route, and has been reported to improve postmenopausal vasomotor symptoms.[1] A pharmacokinetic study[2] of micronised estradiol found the *sublingual* route resulted in more rapid absorption, a higher peak concentration, and more rapid elimination, than oral dosage. Sublingual micronised estradiol has been studied for the management of postpartum depression.[3]

IMPLANTS. There may be a striking interpatient variation in blood-estradiol concentrations in women receiving estradiol implants,[1] and symptoms of oestrogen deficiency have re-appeared in some patients even though serum-estradiol concentrations were within or above the physiological range.[2] After debate on the appropriateness of using serum concentrations of estradiol as a guide to implant use, rather than symptoms,[3-7] it is now recommended that estradiol concentration should be monitored during therapy.

Cyclical progestogen may be required for a prolonged period after removal of estradiol implants in women with a uterus.[7]

INTRANASAL ADMINISTRATION. The intranasal route for estradiol HRT has been reviewed.[1] It appears to be comparable in efficacy to oral[2] or transdermal use[3,4] in the treatment of menopausal symptoms. As with transdermal application, the intranasal route avoids intestinal and hepatic first-pass metabolism.

4. Davis SR, *et al.* Intranasal versus transdermal matrix oestrogen replacement in Australasian women. *Maturitas* 2005; **51:** 163–71.

TRANSDERMAL ADMINISTRATION. Transdermal estradiol given via *patches* applied to the skin has been reviewed.[1-3] This method of delivery has certain advantages over the oral route in that gastrointestinal and hepatic first-pass metabolism is avoided, liver enzymes are not stimulated (although this may also mean that beneficial effects on serum lipids are absent), and the prolonged drug release from the patch means less frequent application is necessary and hence patient compliance may be improved. For oestrogen replacement in menopausal and postmenopausal women estradiol patches are used continuously or in a cyclical manner, with added progestogen for part of the cycle in those women with an intact uterus. This does not lead to drug accumulation and produces blood-estradiol concentrations and estradiol to estrone ratios similar to those normally observed in premenopausal women. The patch is well tolerated with skin irritation being the main problem. Patches are as effective as oral oestrogens in treating menopausal and postmenopausal symptoms such as flushing and vaginal atrophy and in preventing osteoporosis. Combined HRT patches, providing both estradiol and a progestogen, have also been developed.[4]

Estradiol is also effective when applied topically to the skin as a *gel*[5] or *emulsion*.[6]

Depression. The use of oestrogen therapy in the treatment of premenopausal women with **postnatal** depression has been shown to be effective.[1,2] However, although such therapy could be a useful adjunct to conventional treatment (see Depression, p.373), the risk of serious adverse effects including thrombosis may limit its value.[3]

Whether oestrogens are of benefit in older women, typically with depression associated with the **menopause** (p.2077), is less clear. Some studies of transdermal estradiol have reported benefit,[4-6] whereas other studies of transdermal[7] or oral[8] dosage have not found it to be effective. Whether the presence of a progestogen in combination HRT would reduce any purported benefit is also unclear. Antidepressants remain the standard of care in perimenopausal or postmenopausal women with clinical depression.

Gender reassignment. Oestrogens are used in male-to-female transsexuals to develop and maintain secondary sexual characteristics. Although ethinylestradiol and conjugated oestrogens have been used for this purpose, and there is some evidence that such use can improve vascular function,[1] others consider ethinylestradiol too thrombogenic at the doses required [typically 50 to 100 micrograms daily or more] and suggest that estradiol, as the valerate in oral doses of 2 to 4 mg daily, or transdermally as a patch supplying 100 micrograms daily, is the oestrogen of choice.[2,3] Cyproterone acetate is usually also given for its antiandrogenic effect (see p.2089).

3. Gooren LJ, *et al.* Long-term treatment of transsexuals with cross-sex hormones: extensive personal experience. *J Clin Endocrinol Metab* 2008; **93:** 19–25.

Growth disorders. Supraphysiological doses of oestrogens inhibit somatic growth and have been used, with a cyclical progestogen, to reduce final height in girls with constitutional tall stature, although such treatment has declined markedly with changing social norms.[1] In early reports, diethylstilbestrol was used, but this is an unsuitable choice because of the increased risk of cancer. Ethinylestradiol has been given in the past in doses of up to 500 micrograms daily, but doses of 50 to 100 micrograms daily came to be preferred, although lower doses may be equally effective.[2,3] Conjugated oestrogens have also been used, and a study[4] reported that doses of 7.5 to 11.25 mg daily resulted in an average decrease of about 5 cm from final predicted height. In practice, doses as low as 625 micrograms daily have been used.[3] Reported height reductions have ranged from 2 to 10 cm but studies are difficult to compare. Treatment has generally been continued until closure of the epiphyses, but the effects of oestrogen therapy may be influenced by both chronological and bone age at the onset of treatment, duration of treatment, the oestrogen used and its dose, and the point of final height assessment.[2] High-dose oestrogen therapy is also associated with adverse effects such as weight gain, headache, nausea, and pigmentation of the areolae or nipples,[2,3] and there can be adverse changes to haemostatic and lipid measures.[2] A retrospective cohort review[5] has also reported that girls who had been treated with high-dose oestrogens were more likely to report fertility problems in later life than similar girls who had not been treated.

Oestrogen therapy has occasionally been used to help promote growth in girls with constitutional delayed puberty (see p.2079).

Haemorrhagic disorders. Limited evidence supports the use of oestrogens in various bleeding disorders. There have been mixed results from small studies of oestrogens, given alone or with a progestogen, in patients with hereditary haemorrhagic telangiectasia;[1,2] the use of a combined oral contraceptive has been suggested as a suitable option for fertile women with symptomatic epistaxis.[3] There are also some reports[2,4,5] of bleeding being reduced in patients with gastrointestinal vascular malformations from other causes. Conjugated oestrogens have been used in haemorrhagic disorders associated with chronic renal failure and haemorrhagic cystitis (see p.2087).

5. Siple JF, *et al.* Use of estrogen therapy in a patient with gastrointestinal bleeding secondary to arteriovenous malformations. *Ann Pharmacother* 1997; **31:** 1311–14.

Lactation inhibition. Synthetic oestrogens (e.g. quinestrol) and nonsteroidal oestrogens (e.g. diethylstilbestrol) were historically used to suppress lactation (p.2003). However, this use is now considered inappropriate because of an increased risk of puerperal thromboembolism.

Premenstrual syndrome. Premenstrual syndrome (PMS) presents as a variable combination of psychological and somatic symptoms occurring during the luteal phase of the menstrual cycle, which resolve during, and immediately after, menstruation. Another term, premenstrual dysphoric disorder, has been proposed to cover severe cyclical mood disorder that is functionally incapacitating.[1,2] Whereas about 20 to 40% of women have complaints that may be classified as PMS, only 3 to 8% meet criteria for premenstrual dysphoric disorder.[2] The term premenstrual tension (PMT) has sometimes been applied to the psychological symptoms. Many symptoms of PMS are the same as normal premenstrual symptoms, but are more severe. The aetiology of PMS is not fully understood, although it is thought that affected women may be more sensitive to the effects of normal hormonal fluctuations on CNS neurotransmitter function.[2]

Initial management includes non-medical interventions[3] such as education and support, counselling, stress management, relaxation techniques, and exercise; caffeine and salt restriction are of unproven benefit. The herbal remedy agnus castus has been found to be of benefit.[4] For patients with moderate to severe symptoms, a number of drugs have been tried with varying degrees of success; objective assessment of efficacy has been hampered by varying diagnostic criteria, a marked placebo response, and difficulties in obtaining reproducible responses. Treatment may be aimed at modifying the menstrual cycle or treating specific symptoms.

In women with mainly psychological symptoms, *SSRIs* can be helpful.[1,3,5,6] Fluoxetine and sertraline have been shown in controlled studies to alleviate both psychological and somatic symptoms in women with PMS, and may be given intermittently (only in the luteal phase) or continuously. If treatment with one SSRI is ineffective or not tolerated, another SSRI or *venlafaxine* may be substituted.[1,3,6] There is limited information on the use of SSRIs for PMS in adolescents, and precautions regarding suicidal ideation in young adults should be considered.[2] *Clomipramine*, a nonselective serotonin reuptake inhibitor, has been tried for PMS with some success. The anxiolytic *alprazolam* has also been used, but use of this and other benzodiazepines should be restricted to the luteal phase of the cycle in selected patients to minimise the risk of dependence and tolerance.[7]

Abdominal bloating and swelling associated with PMS has traditionally been thought to be due to sodium and water retention. However, in most women with these symptoms there is no evidence of an increase in body-weight or in body sodium or total water, and use of *diuretics* is therefore not justified.[8] Nevertheless, in women with appreciable weight gain and abdominal bloating in the luteal phase, the aldosterone antagonist spironolactone may be useful.[1,6,9] Another symptom of PMS, cyclical mastalgia, is discussed on p.2092.

Pyridoxine has been tried on the basis that it is a cofactor in neurotransmitter (specifically serotonin) synthesis, and has been found to relieve depression induced by oral contraceptives in selected patients. However, its efficacy in PMS is equivocal, and high daily doses have been associated with neurotoxicity.[10] *Calcium* supplementation may relieve symptoms of PMS.[6,11]

Treatments that modify the menstrual cycle have often been used in women with PMS. In general, drugs with proven efficacy such as danazol, oestrogen implants, and gonadorelin analogues are reserved for women with severe PMS unresponsive to other treatments, because of their adverse effects. *Progestogen* therapy was once popular, but beneficial responses have not been universally achieved and the theory that progesterone was necessary to correct a hormone imbalance is now losing ground. In addition, a systematic review[12] of clinical trials found no evidence to support the use of progesterone or progestogens for PMS. *Combined oral contraceptives* have met with limited success.[2] They may be useful in some women for the control of somatic symptoms, but in others, PMS is caused or exacerbated by them. There is some suggestion that combined contraceptives containing drospirenone may be more effective in managing PMS than those containing progestogens such as levonorgestrel or norethisterone.[3] Consideration should be given to continuous rather than cyclical use.[3] Perimenopausal women may benefit from *oestrogen* delivered from transdermal patches. In women with a uterus, use with a cyclical progestogen is required to avoid endometrial hyperplasia; unfortunately, the progestogen may be associated with the return of symptoms. Possible strategies to minimise this include the use of a less androgenic progestogen, reducing the frequency with which it is given, or using an intra-uterine device to deliver the progestogen locally.[13] *Danazol* can be useful,[1,3] but there is concern over its adverse effects on lipids during long-term use and over the risk of masculinisation of a female fetus should pregnancy occur. For patients with severe symptoms not amenable to other treatments, gonadorelin analogues such as *goserelin* can be used to eliminate ovarian function, 'add-back' treatment with oestrogen plus progestogen being given to protect against the adverse effects of oestrogen deficiency including osteoporosis.[3] This treatment is very effective for both physical and psychological symptoms.[14] Short-term use (3 months) of a gonadorelin analogue alone has been used to confirm the diagnosis of PMS, or to predict the response to bilateral oophorectomy.[1,3]

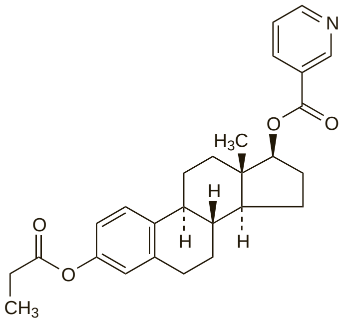
Estrapronicate *(rINN)*

Estrapronicato; Estrapronicatum. Oestradiol 17-nicotinate 3-propionate.

Эстрапроникат

$C_{27}H_{31}NO_4$ = 433.5.

CAS — 4140-20-9.



Profile

Estrapronicate is a derivative of estradiol (p.2097) with nicotinic acid. It has been used as an ingredient of a combined preparation with an anabolic steroid and a progestogen for osteoporosis.

Estriol *(BAN, rINNM)*

Estrioli; Estriolis; Estriolum; Follicular Hormone Hydrate; Oestriol; Östriol; Ösztriol; Theelol. Estra-1,3,5(10)-triene-3,16α,17β-triol.

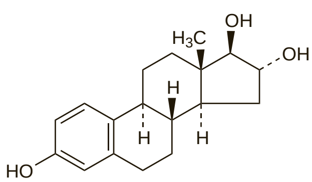
Эстриол

$C_{18}H_{24}O_3$ = 288.4.

CAS — 50-27-1.

ATC — G03CA04.

ATC Vet — QG03CA04; QG03CC06.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Estriol). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol.

USP 31 (Estriol). A white or practically white, odourless, crystalline powder. Insoluble in water; sparingly soluble in alcohol; soluble in acetone, in chloroform, in dioxan, in ether, and in vegetable oils. Store in airtight containers.

Estriol Sodium Succinate *(BAN, rINNM)*

Estriol, Succinate Sodique d'; Estrioli Natrii Succinas; Oestriol Sodium Succinate; Succinato sódico de estriol. Disodium 3-hydroxyestra-1,3,5(10)-triene-16α,17β-diyl disuccinate.

Эстриола Натрия Сукцинат

$C_{26}H_{30}Na_2O_9$ = 532.5.

CAS — 113-22-4.

ATC — G03CA04.

ATC Vet — QG03CA04.

Estriol Succinate *(BAN, rINN)*

Estriol, Succinate d'; Estrioli Succinas; Estriolisuksinaatti; Estriolsuccinat; Oestriol Succinate; Succinato de estriol. 3-Hydroxyestra-1,3,5(10)-triene-16α,17β-diyl di(hydrogen succinate).

Эстриола Сукцинат

$C_{26}H_{32}O_9$ = 488.5.

CAS — 514-68-1.

ATC — G03CA04.

ATC Vet — QG03CA04.

Profile

Estriol is a naturally occurring oestrogen with actions and uses similar to those described for estradiol (p.2097). It is claimed to have only a mild proliferative effect on the endometrium.

It is used for menopausal HRT (p.2071). When oestrogens are given to women with a uterus, a progestogen is required, particularly if used long term. For short-term treatment, oral doses of estriol have been 0.5 to 3 mg daily given for one month followed by 0.5 to 1 mg daily. Estriol has also been given with other natural oestrogens such as estradiol and estrone (see below); usual doses of estriol have ranged from about 0.25 to 2 mg daily. Estriol may be used intravaginally for the short-term treatment of menopausal atrophic vaginitis and kraurosis vulvae. A dose of 500 micrograms may be given as a 0.01% or 0.1% cream or as a pessary; initial treatment may be given once daily, then reduced to twice each week.

Estriol has also been given orally for infertility (p.2080) caused by poor cervical penetration, in a dose of 0.25 to 1 mg daily on days 6 to 15 of the menstrual cycle.

Estriol succinate has also been given orally in the treatment of menopausal disorders. The sodium succinate salt has been used parenterally in the treatment of haemorrhage and thrombocytopenia.

Preparations

BP 2008: Estriol Cream.

Proprietary Preparations (details are given in Part 3)

Estrone *(BAN, rINN)*

Estron; Estrona; Estroni; Estronum; Foliculina; Follicular Hormone; Folliculin; Ketohydroxyoestrin; Oestrone; Östron. 3-Hydroxyestra-1,3,5(10)-trien-17-one.

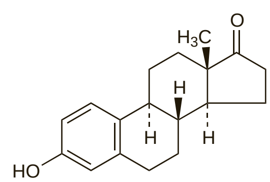
Эстрон

$C_{18}H_{22}O_2$ = 270.4.

CAS — 53-16-7.

ATC — G03CA07.

ATC Vet — QG03CA07; QG03CC04.



Pharmacopoeias. In *US.*

USP 31 (Estrone). Odourless, small white crystals or white to creamy-white crystalline powder. Practically insoluble in water; soluble 1 in 250 of alcohol and 1 in 110 of chloroform at 15°; soluble 1 in 50 of boiling alcohol, 1 in 33 of boiling acetone, 1 in 145 of boiling benzene, and 1 in 80 of boiling chloroform; soluble 1 in 50 of acetone at 50°; soluble in dioxan and in vegetable oils; slightly soluble in solutions of fixed alkali hydroxides. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Profile

Estrone is a naturally occurring oestrogen with actions and uses similar to those described for estradiol (see p.2097).

For menopausal HRT (see p.2071) estrone has been given orally at a dose of 1.4 to 2.8 mg daily in a cyclical or continuous regimen, as a combination product with estradiol and estriol (see above). Estrone has also been given by intramuscular injection in oily solutions and aqueous suspensions. When used specifically for menopausal atrophic vaginitis, estrone has been given vaginally. If used in women with a uterus, estrone by any route should be given with a progestogen.

Preparations

USP 31: Estrone Injectable Suspension; Estrone Injection.

Proprietary Preparations (details are given in Part 3)

USA: Kestrone.

Multi-ingredient: ***Braz.:*** Gineburno†; ***Fin.:*** Senikolp†; ***Fr.:*** Synergon; ***Hong Kong:*** Hormonin; ***Spain:*** Cicatral; Grietalgen; Grietalgen Hidrocort†; ***Thai.:*** Metharmon-F; ***Turk.:*** Synergon; ***UK:*** Hormonin.

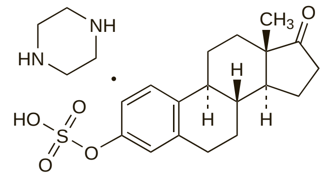
Estropipate *(BAN)*

Estropipato; Piperazine Estrone Sulfate; Piperazine Oestrone Sulphate. Piperazine 17-oxoestra-1,3,5-(10)-trien-3-yl hydrogen sulphate.

Эстропипате

$C_{18}H_{22}O_5S,C_4H_{10}N_2$ = 436.6.

CAS — 7280-37-7.



Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Estropipate). A white or almost white crystalline powder. Very slightly soluble in water, in alcohol, in chloroform, and in ether.

USP 31 (Estropipate). A white to yellowish-white fine crystalline powder, odourless or may have a slight odour. Very slightly soluble in water, in alcohol, in chloroform, and in ether; soluble 1 in 500 of warm alcohol; soluble in warm water. Store in airtight containers.

Adverse Effects and Precautions

As for oestrogens in general (see Estradiol, p.2097). See also under Hormone Replacement Therapy, p.2071.

Interactions

See under Hormone Replacement Therapy, p.2076.

Uses and Administration

Estropipate is a semisynthetic conjugate of estrone with piperazine that is used for menopausal HRT (see p.2076). Its action is due to estrone (see above) to which it is hydrolysed in the body.

Estropipate is given orally for the short-term treatment of menopausal symptoms; suggested doses have ranged from 0.75 to 3 mg daily, given cyclically or continuously; doses up to 6 mg daily have also been given cyclically. When used longer term for the prevention of postmenopausal osteoporosis a daily dose of 0.75 or 1.5 mg is given cyclically or continuously. In women with a uterus estropipate should be used with a progestogen. Estropipate has also been used short term for menopausal atrophic vaginitis as a vaginal cream containing 0.15%; 2 to 4 g of cream is applied daily. It is also given orally in the treatment of female hypogonadism, castration, and primary ovarian failure in doses of 1.5 to 3 mg daily, in a cyclical regimen; higher doses of up to 9 mg daily given cyclically have also been used.

Preparations

BP 2008: Estropipate Tablets;
USP 31: Estropipate Tablets; Estropipate Vaginal Cream.

Proprietary Preparations (details are given in Part 3)

Austral.: Genoral; Ogen; ***Canad.:*** Ogen; ***Indon.:*** Ogen; ***Irl.:*** Harmogen†; ***Mex.:*** Ogen†; ***S.Afr.:*** Ortho-Est; ***UK:*** Harmogen; ***USA:*** Ogen; Ortho-Est†.

Ethinylestradiol *(BAN, rINN)*

Aethinyloestradiolum; Ethinyl Estradiol; Éthinylestradiol; Ethinylestradiolum; Ethinyloestradiol; Etinilestradiol; Etinilestradiolis; Etinilöstradiol; Etinilösztradiol; Etinylestradiol; Etinyyliestradioli; Etynyloestradiol; NSC-10973. 17α-Ethynylestra-1,3,5(10)-triene-3,17β-diol; 19-Nor-17α-pregna-1,3,5(10)-trien-20-yne-3,17β-diol.

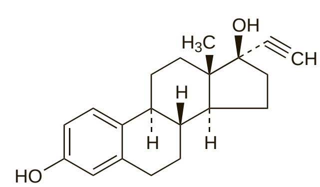
Этинилэстрадиол

$C_{20}H_{24}O_2$ = 296.4.

CAS — 57-63-6.

ATC — G03CA01; L02AA03.

ATC Vet — QG03CA01; QL02AA03.



NOTE. Compounded preparations of ethinylestradiol may be represented by the following names:

- Co-cyprindiol (*BAN*)—ethinylestradiol 35 parts and cyproterone acetate 2000 parts (w/w).

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Ethinylestradiol). A white to slightly yellowish-white, crystalline powder. Practically insoluble in water; freely soluble in alcohol; dissolves in dilute alkaline solutions. Protect from light.

USP 31 (Ethinyl Estradiol). A white to creamy white, odourless, crystalline powder. Insoluble in water; soluble in alcohol, in chloroform, in ether, in vegetable oils, and in solutions of fixed alkali hydroxides. Store in nonmetallic airtight containers. Protect from light.

Adverse Effects and Precautions

As for oestrogens in general (see Estradiol, p.2097). See also under Hormonal Contraceptives, p.2059.

Effects on calcium homoeostasis. Two patients with metastatic breast cancer given ethinylestradiol developed rapidly progressive irreversible and fatal hypercalcaemia, considered to be due to stimulation of osteolysis by the oestrogen.[1]

1. Cornbleet M, *et al*. Fatal irreversible hypercalcaemia in breast cancer. *BMJ* 1977; **1:** 145.

Effects on the liver. Cholestasis and pruritus developed in a liver transplant recipient receiving ethinylestradiol at a dose of 50 micrograms daily for the treatment of menorrhagia.[1] Symptoms subsided on withdrawal of ethinylestradiol but returned on its re-introduction.

1. Fedorkow DM, *et al*. Cholestasis induced by oestrogen after liver transplantation. *BMJ* 1989; **299:** 1080–1.

Interactions

See under Hormonal Contraceptives, p.2067.

◊ Reviews.

1. Zhang H, *et al*. Pharmacokinetic drug interactions involving 17α-ethinylestradiol: a new look at an old drug. *Clin Pharmacokinet* 2007; **46:** 133–57.

Pharmacokinetics

Ethinylestradiol is rapidly and well absorbed from the gastrointestinal tract. The presence of an ethinyl group at the 17-position greatly reduces hepatic first-pass metabolism compared with estradiol, enabling the compound to be much more active by mouth, but there is some initial conjugation by the gut wall, and the systemic bioavailability is only about 40%. Ethinylestradiol is highly protein bound, but unlike naturally occurring oestrogens, which are mainly bound to sex-hormone binding globulin, it is principally bound to albumin. It is metabolised in the liver, initially by aromatic hydroxylation catalysed by the cytochrome P450 isoenzyme CYP3A4, to form 2-hydroxyethinylestradiol and various conjugated metabolites. These are excreted in urine and faeces. Metabolites undergo enterohepatic recycling.

Uses and Administration

Ethinylestradiol is a synthetic oestrogen with actions similar to those of estradiol (see p.2098).

It is frequently used as the oestrogenic component of combined oral **contraceptive** preparations; a typical daily dose is 20 to 40 micrograms (for guidance on appropriate dose, see p.2069). Ethinylestradiol betadex clathrate has been used similarly in combined oral contraceptives. Ethinylestradiol is also used in a combined contraceptive transdermal patch. A dose of 20 micrograms ethinylestradiol is released daily with norelgestromin. A new patch is applied each week for 3 weeks of a 4-week cycle. Oestrogen exposure from such a patch may be higher than with a comparable oral contraceptive. A combined contraceptive vaginal ring device delivering an average of 15 micrograms ethinylestradiol daily with etonogestrel is also available; it remains in the vagina for 3 weeks and is then removed for a one-week break, after which a new ring is inserted. Ethinylestradiol has also been used orally as an emergency contraceptive (p.2071) combined with levonorgestrel or norgestrel. A combined preparation of ethinylestradiol with the anti-androgen cyproterone is used for the hormonal treatment of acne (p.1577) and hirsutism (p.2089), particularly when contraception is also required (see Uses and Administration, under Cyproterone Acetate, p.2089).

Ethinylestradiol has also been used for **menopausal HRT** (p.2076), although natural oestrogens are usually preferred. Oral doses of 10 to 50 micrograms daily have been given cyclically (with a progestogen in women with a uterus), but preparations providing lower doses of 2.5 or 5 micrograms daily are also available.

For the treatment of female **hypogonadism**, doses of 10 to 50 micrograms daily on a cyclical basis have been used.

For the palliative treatment of **prostate cancer** (p.671) doses of 150 micrograms to 3 mg have been given daily. For palliation of malignant neoplasms of the **breast** (p.661) in postmenopausal women doses of 100 micrograms to 1 mg three times daily have been used.

Administration in children. Although unlicensed in the UK for use in children, the *BNFC* does include doses of ethinylestradiol. An initial oral dose of 2 micrograms daily may be used in the management of **delayed puberty** (p.2079) in girls. This may be increased every 6 months to 5 micrograms, then to 10 micrograms, then to 20 micrograms daily, according to response. After 12 to 18 months of treatment, a progestogen should be added for 7 days of each 28-day cycle. A daily dose of ethinylestradiol 20 micrograms with cyclical progestogen may then be used to maintain sexual maturation. For the prevention of constitutional **tall stature**, ethinylestradiol may be given to girls aged 2 to 12 years old in a dose of 20 to 50 micrograms daily (see also Growth Disorders in Estradiol, p.2099).

Growth hormone provocation testing may be used in the diagnosis of growth hormone deficiency in children with growth retardation (p.1798). However, the response can be blunted in prepubertal and peripubertal children, resulting in false negative results. Hormonal **pituitary priming** using ethinylestradiol has been tried in both boys and girls in order to increase responsiveness to the test,[1,2] although there appears to be no consensus on such use.[3] The *BNFC* includes an oral dose of 100 micrograms daily for 3 days before the test, for girls with a bone age above 10 years.

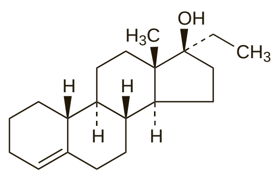
Ethylestrenol *(BAN, USAN, rINN)* ⊗

Éthylestrénol; Ethylestrenolum; Ethyloestrenol; Etilestrenol; Etylestrenol; Etyyliestrenoli. 17α-Ethylestr-4-en-17β-ol; 19-Nor-17α-pregn-4-en-17β-ol.

Этилэстренол

$C_{20}H_{32}O$ = 288.5.
CAS — 965-90-2.
ATC — A14AB02.
ATC Vet — QA14AB02.



Profile

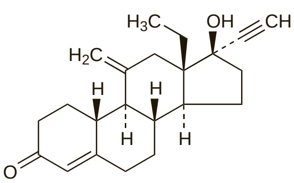
Ethylestrenol is a 17α-alkylated anabolic steroid (see Testosterone, p.2129) with little androgenic effect and slight progestogenic activity. It has been used for the promotion of growth in boys with short stature or delayed bone growth. It is used in veterinary medicine.

Etonogestrel *(BAN, USAN, rINN)*

Etonogestreeli; Étonogestrel; Etonogestrelum; 3-keto-Desogestrel; Org-3236. 13-Ethyl-17-hydroxy-11-methylene-18,19-dinor-17α-pregn-4-en-20-yn-3-one; 17β-Hydroxy-11-methylene-18-homo-19-nor-17α-pregn-4-en-20-yn-3-one.

Этоногестрел

$C_{22}H_{28}O_2$ = 324.5.
CAS — 54048-10-1.
ATC — G03AC08.
ATC Vet — QG03AC08.



Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059.

Breast feeding. Etonogestrel was found in the breast milk of 42 women given a contraceptive etonogestrel implant. Over the 4-month study, compared with a group who used an intra-uterine non-hormonal device, etonogestrel did not affect the volume or composition of breast milk, or the growth of the breast-fed infants.[1] At 3 years of age there was no difference in growth between these 2 groups of children.[2]

1. Reinprayoon D, *et al.* Effects of the etonogestrel-releasing contraceptive implant (Implanon) on parameters of breastfeeding compared to those of an intrauterine device. *Contraception* 2000; **62:** 239–46.

Vaginal bleeding. Prolonged vaginal bleeding, lasting from 2 to 26 weeks, has been reported with the use of etonogestrel subdermal implants. Blood transfusion was needed in the management of one patient.[1] Heavy bleeding has been described in 2 women after the implant had broken while in place.[2,3]

1. Adverse Drug Reactions Advisory Committee (ADRAC). Implanon and vaginal bleeding. *Aust Adverse Drug React Bull* 2003; **22:** 11–12. Also available at: http://www.tga.gov.au/adr/aadrb/aadr0306.pdf (accessed 27/06/08)

3. Agrawal A, Robinson C. Spontaneous snapping of an Implanon in two halves in situ. *J Fam Plann Reprod Health Care* 2003; **29:** 238.

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Pharmacokinetics

Etonogestrel is highly bound to plasma proteins; about 32% is bound to sex hormone binding globulin and 66% to albumin. It is metabolised by the cytochrome P450 isoenzyme CYP3A4, and both metabolites and unchanged drug are excreted in the urine and faeces. The elimination half-life is about 25 to 30 hours. Etonogestrel is distributed into breast milk.

2. Bennink HJ. The pharmacokinetics and pharmacodynamics of Implanon, a single-rod etonogestrel contraceptive implant. *Eur J Contracept Reprod Health Care* 2000; **5** (suppl 2): 12–20.

Uses and Administration

Etonogestrel, the active metabolite of desogestrel (p.2093), is used as a hormonal contraceptive (see p.2069). A subdermal implant containing 68 mg of etonogestrel is used as a progestogen-only contraceptive that is effective for 3 years. Etonogestrel is also used as the progestogen component of a combined contraceptive delivered via a vaginal ring device. The ring releases an average of 120 micrograms daily of etonogestrel and 15 micrograms daily of ethinylestradiol and remains in the vagina for 3 weeks; it is then removed for a one-week break after which a new ring is inserted.

Etonogestrel is under investigation as a male contraceptive, given orally or by implant, with testosterone implants or injections.

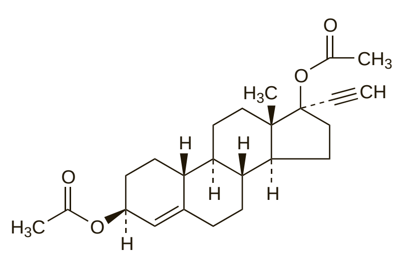
Этинодиола Диацетат

$C_{24}H_{32}O_4$ = 384.5.
CAS — 1231-93-2 (etynodiol); 297-76-7 (etynodiol diacetate).
ATC — G03DC06.
ATC Vet — QG03DC06.



Pharmacopoeias. In *Br.*, *Pol.*, and *US.*

BP 2008 (Etynodiol Diacetate). A white or almost white, odourless or almost odourless, crystalline powder. Very slightly soluble in water; soluble in alcohol; freely soluble in chloroform and in ether. Protect from light.

USP 31 (Ethynodiol Diacetate). A white, odourless, crystalline powder. Insoluble in water; soluble in alcohol; very soluble in chloroform; freely soluble in ether; sparingly soluble in fixed oils. Protect from light.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059.

Pregnancy. Fetal adrenal cytomegaly in a 17-week-old fetus was associated with the maternal ingestion of an oral contraceptive containing etynodiol diacetate 2 mg and mestranol 100 micrograms from the sixth to the fourteenth week of pregnancy.[1]

1. Gau GS, Bennett MJ. Fetal adrenal cytomegaly. *J Clin Pathol* 1979; **32:** 305–6.

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Pharmacokinetics

Etynodiol diacetate is readily absorbed from the gastrointestinal tract and rapidly metabolised, largely to norethisterone (p.2119). About 60% of a dose is stated to be excreted in urine and about 30% in faeces; the half-life in plasma is about 25 hours.

Uses and Administration

Etynodiol diacetate is a progestogen (see Progesterone, p.2126) that is used as the progestogenic component of combined oral contraceptives and also alone as an oral progestogen-only contraceptive (see p.2069); typical daily doses are 1 or 2 mg in combination products and 500 micrograms for progestogen-only contraceptives.

Preparations

USP 31: Ethynodiol Diacetate and Ethinyl Estradiol Tablets; Ethynodiol Diacetate and Mestranol Tablets.

(flugestone)

Profile

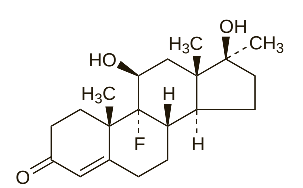
Flugestone acetate is a progestogen (see Progesterone, p.2125) used in veterinary medicine.

Fluoxymesterone *(BAN, rINN)* ⊗

Fluoksimesteroni; Fluoximesteron; Fluoximesterona; Fluoxymestérone; Fluoxymesteronum; Fluximesterona; NSC-12165. 9α-Fluoro-11β,17β-dihydroxy-17α-methylandrost-4-en-3-one.

Флуоксиместерон

$C_{20}H_{29}FO_3$ = 336.4.
CAS — 76-43-7.
ATC — G03BA01.
ATC Vet — QG03BA01.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Fluoxymesterone). A white or practically white, odourless, crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; slightly soluble in chloroform. Protect from light.

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130).

As with other 17α-alkylated compounds fluoxymesterone may cause hepatotoxicity, and is probably best avoided in patients with hepatic impairment, and certainly if this is severe. Hepatic function should be monitored during therapy.

Uses and Administration

Fluoxymesterone has androgenic properties (see Testosterone, p.2131). It is effective when given orally and is more potent than methyltestosterone.

In the treatment of male hypogonadism (p.2079), fluoxymesterone has been given in a dosage of 5 to 20 mg daily. For the use of fluoxymesterone in boys with delayed puberty, see Administration in Children, below. In the palliation of inoperable neoplasms of the breast in postmenopausal women (p.661) it has been given in daily doses of up to 40 mg. Fluoxymesterone has also been used in the treatment of aplastic anaemia.

Administration in children. In the treatment of delayed puberty (p.2079) in boys fluoxymesterone has been given orally in usual daily doses of 2.5 to 10 mg, adjusted according to response (doses up to 20 mg daily have been used). Care is necessary because of the risk of epiphyseal closure and treatment is generally only given for 4 to 6 months.

Preparations

USP 31: Fluoxymesterone Tablets.

Proprietary Preparations (details are given in Part 3)

CAS — 169108-34-3 (follitropin beta); 150490-84-9 (follitropin beta); 56832-30-5 (α-subunit); 110909-60-9 (β-subunit).
ATC — G03GA06.
ATC Vet — QG03GA06.

Units

80 units of human pituitary follicle-stimulating hormone are contained in about 4.17 micrograms (with 5 mg of mannitol and 1 mg human serum albumin) in one ampoule of the first International Standard (1986).

138 units of recombinant human follicle-stimulating hormone for bioassay are contained in one ampoule of the first International Standard (1995).

Adverse Effects and Precautions

As for Human Menopausal Gonadotrophins, p.2109.

Spongiform encephalopathies. In a few countries, gonadotrophins derived from cadaver pituitary glands have been used in the treatment of infertility, and a small number of patients are reported to have acquired Creutzfeldt-Jakob disease from such preparations.[1] However, most countries have preferred to use gonadotrophins derived from urine,[1] and these in their turn are being replaced with recombinant products;[2] such preparations appear to carry negligible risk of transmitting prion disease.[3-5]

5. Jansen C. Bye-bye urinary gonadotrophins? Reply to debate. *Hum Reprod* 2003; **18:** 895–6.

Pharmacokinetics

Follitropins alfa and beta are slowly absorbed after subcutaneous or intramuscular injection, with an absolute bioavailability of about 70 to 80%. Peak plasma concentrations of follitropin beta have been stated to occur about 12 hours after subcutaneous or intramuscular injection. Accumulation occurs with repeated doses, reaching a steady state within 3 to 5 days. Follitropins are slowly eliminated from the body, with a terminal half-life ranging from 12 to 70 hours. About one-eighth of a dose of follitropin alfa is reported to be excreted in the urine.

◊ References.

1. Karlsson MO, *et al*. The population pharmacokinetics of recombinant- and urinary-human follicle stimulating hormone in women. *Br J Clin Pharmacol* 1998; **45:** 13–20.

Uses and Administration

Follicle-stimulating hormone is secreted by the anterior lobe of the pituitary gland, with another gonadotrophin, luteinising hormone (p.2112).

These gonadotrophins stimulate the normal functioning of the gonads and the secretion of sex hormones in both men and women. In women, follicle-stimulating hormone stimulates the development and maturation of the follicles and ova; in men it has a role in spermatogenesis.

Recombinant human follicle-stimulating hormones (follitropins alfa or beta) are used in the treatment of female infertility due to anovulation, in women who have not responded to clomifene therapy. Follitropins are also used for the stimulation of spermatogenesis in the management of male infertility caused by hypogonadotrophic hypogonadism (see Infertility, p.2080).

The dosage and schedule of treatment for **female infertility** must be determined according to the needs of each patient; it is usual to monitor response by studying the patient's urinary oestrogen excretion or by ultrasonic visualisation of follicles or both. In menstruating patients treatment should be started within the first 7 days of the menstrual cycle.

- Treatment is usually begun with 75 to 150 units daily by subcutaneous or intramuscular injection for 7 or 14 days; if there is no response, dosage is increased at 7- or 14-day intervals until an adequate but not excessive response is achieved.
- Treatment is then stopped and followed after 1 or 2 days by a single dose of chorionic gonadotrophin 5000 to 10 000 units to induce ovulation.

It has been suggested in UK licensed product information for follitropin alfa that a daily dose of 225 units is the usual maximum, and that if a patient fails to respond adequately after 4 weeks of treatment that cycle should be abandoned and the patient should subsequently begin the next cycle at a higher starting dose.

Follitropins are also used as part of IVF or other assisted reproductive technologies.

- For this purpose doses of 150 to 225 units daily are generally given, for at least 4 days, commencing on the second or third day of the menstrual cycle. Thereafter the dose may be adjusted individually based on ovarian response to a usual maximum of about 450 units; adequate follicular development generally occurs within about 5 to 10 days of treatment.
- Pituitary downregulation with a gonadorelin analogue may be used with follitropin therapy, in which case the gonadorelin analogue is generally begun about 2 weeks before follitropin, and the 2 are then continued together until follicular development is adequate.
- A single dose of up to 10 000 units of chorionic gonadotrophin is then given to induce final follicular maturation and oocyte retrieval performed about 35 hours later.

Follitropins are used for the stimulation of spermatogenesis in the management of **male infertility** caused by hypogonadotrophic hypogonadism. Before starting follitropin therapy, chorionic gonadotrophin is given to raise serum testosterone concentrations to the normal range, which may take 3 to 6 months. A dose of follitropin alfa or beta of 150 units subcutaneously three times weekly is then used, with continued chorionic gonadotrophin; doses of follitropin alfa up to 300 units three times weekly may be required. Treatment is continued for at least 4 months, and more than 18 months of treatment may be needed. A dose of follitropin beta 75 units daily or two or three times weekly, by subcutaneous or intramuscular injection, has been used similarly.

Other substances with follicle-stimulating activity are used similarly: these include human menopausal gonadotrophins (p.2109), which have both luteinising and follicle-stimulating activity, and urofollitropin (p.2136).

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Gonal-F; Puregon; ***Austral.:*** Gonal-F; Puregon; ***Austria:*** Gonal-F; Puregon; ***Belg.:*** Gonal-F; Puregon; ***Braz.:*** Gonal-F; Puregon; ***Canad.:*** Gonal-F; Puregon; ***Chile:*** Gonal-F†; Puregon; ***Cz.:*** Gonal-F; Puregon; ***Denm.:*** Gonal-F; Puregon; ***Fin.:*** Gonal-F; Puregon; ***Fr.:*** Gonal-F; Puregon; ***Ger.:*** Gonal-F; Puregon; ***Gr.:*** Gonal-F; Puregon; ***Hong Kong:*** Gonal-F; Puregon; ***Hung.:*** Gonal-F; Puregon; ***India:*** Gonal-F; ***Indon.:*** Gonal-F; Puregon; ***Irl.:*** Gonal-F; Puregon; ***Israel:*** Gonal-F; Puregon; ***Ital.:*** Gonal-F; Puregon; ***Malaysia:*** Gonal-F; Puregon; ***Mex.:*** Gonal-F; Puregon; ***Neth.:*** Gonal-F; Puregon; ***Norw.:*** Gonal-F; Puregon; ***NZ:*** Gonal-F; Puregon; ***Philipp.:*** Gonal-F; Puregon; ***Pol.:*** Gonal-F; Puregon; ***Port.:*** Gonal-F; Puregon; ***Rus.:*** Gonal-F (Гонал-Ф); Puregon (Пурегон); ***S.Afr.:*** Gonal-F; Puregon†; ***Singapore:*** Gonal-F; Puregon; ***Spain:*** Gonal-F; Puregon; ***Swed.:*** Gonal-F; Puregon; ***Switz.:*** Gonal-F; Puregon; ***Thai.:*** Gonal-F; Puregon; ***Turk.:*** Gonal-F; Puregon; ***UK:*** Gonal-F; Puregon; ***USA:*** Follistim; Gonal-F; ***Venez.:*** Gonal-F; Puregon.

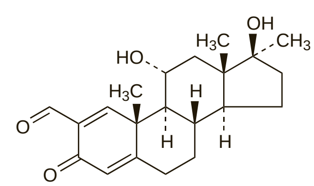
Multi-ingredient: *Cz.:* Pergoveris; ***Port.:*** Pergoveris; ***UK:*** Pergoveris.

Formebolone *(BAN, rINN)* ⊗

Formebolona; Formébolone; Formebolonum; Formyldienolone.
11α,17β-Dihydroxy-17β-methyl-3-oxoandrosta-1,4-diene-2-carbaldehyde.

Формеболон

$C_{21}H_{28}O_4$ = 344.4.
CAS — 2454-11-7.



Profile

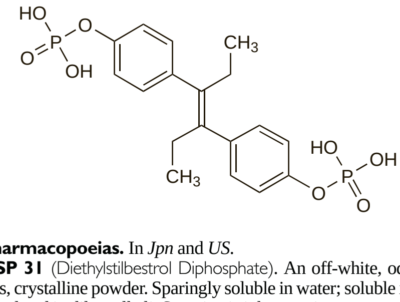
Formebolone has been used for its anabolic properties (see Testosterone, p.2129). It appears to be widely abused by body-builders.

Fosfestrol *(BAN, rINN)*

Diethylstilbestrol Diphosphate; Fosfestroli; Fosfestrolum; Phosphoestrolum; Stilboestrol Diphosphate. (*E*)-α,α′-Diethylstilbene-4,4′-diol bis(dihydrogen phosphate); (*E*)-4,4′-(1,2-Diethylvinylene)bis(phenyl dihydrogen orthophosphate).

Фосфэстрол

$C_{18}H_{22}O_8P_2$ = 428.3.
CAS — 522-40-7.
ATC — L02AA04.
ATC Vet — QL02AA04.



Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Diethylstilbestrol Diphosphate). An off-white, odourless, crystalline powder. Sparingly soluble in water; soluble in alcohol and in dilute alkali. Store in airtight containers at a temperature not exceeding 21°.

Fosfestrol Sodium *(BANM, rINNM)*

Fosfestrol sódico; Fosfestrol Sodique; Natrii Fosfestrolum.

Натрий Фосфэстрол

$C_{18}H_{18}Na_4O_8P_2$ = 516.2.

CAS — 23519-26-8 (fosfestrol tetrasodium xH_2O); 4719-75-9 (anhydrous fosfestrol tetrasodium).

ATC — L02AA04.

ATC Vet — QL02AA04.

Pharmacopoeias. In *Br.*, which specifies xH_2O.

BP 2008 (Fosfestrol Sodium). A white or almost white powder. Freely soluble in water; practically insoluble in dehydrated alcohol and in ether. A 5% solution in water has a pH of 7.0 to 9.0. Protect from light.

Adverse Effects and Precautions

As for Diethylstilbestrol, see p.2094.

After intravenous injection of fosfestrol sodium there may be a temporary burning sensation in the perineal region and pain at the site of bony metastases. Slow infusion is not recommended as cytotoxic concentrations of the drug may not be achieved.

Uses and Administration

Fosfestrol is a synthetic nonsteroidal oestrogen that requires dephosphorylation to diethylstilbestrol (p.2094) before it is active. It is used in the treatment of malignant neoplasms of the prostate (p.671).

Fosfestrol and its sodium salt have both been used, and doses of fosfestrol sodium may be expressed in terms of either the base or the salt; anhydrous fosfestrol sodium 300 mg is equivalent to about 250 mg of fosfestrol. Expressed in terms of fosfestrol sodium, initial doses of 600 to 1200 mg daily by slow intravenous injection over about 1 hour may be given for 5 to 10 days, followed by 300 mg daily for 10 to 20 days. Injections should be given preferably with the patient lying down. Maintenance intravenous doses of fosfestrol sodium 300 to 600 mg may be given, reduced gradually over several months from dosing 4 times a week to once weekly. Fosfestrol sodium may also be given orally. If initial doses cannot be given intravenously, doses of 360 to 480 mg three times daily have been given orally. For maintenance therapy, doses of 120 to 240 mg three times daily may be used, and gradually reduced to 240 mg daily.

Preparations

BP 2008: Fosfestrol Injection; Fosfestrol Tablets;
USP 31: Diethylstilbestrol Diphosphate Injection.

Proprietary Preparations (details are given in Part 3)
Arg.: Fosfostilben†; Honvan†; ***Austria:*** Honvan; ***Belg.:*** Honvan†; ***Braz.:*** Ronvan†; ***Canad.:*** Honvol; ***Fr.:*** ST-52†; ***Ger.:*** Honvan†; ***Gr.:*** Honvan; ***Hong Kong:*** Honvan†; ***India:*** Honvan; ***Mex.:*** Honvan†; ***Neth.:*** Honvan†; ***Port.:*** Honvan†; ***Spain:*** Honvan†; ***Switz.:*** Honvan†.

Ganirelix Acetate *(BANM, USAN, rINNM)*

Acetato de ganirelix; Ganirélix, Acétate de; Ganirelixi Acetas; Org-37462; RS-26306. *N*-Acetyl-3-(2-naphthyl)-D-alanyl-*p*-chloro-D-phenylalanyl-3-(3-pyridyl)-D-alanyl-L-seryl-L-tyrosyl-N^6-(*N*,*N*′-diethylamidino)-D-lysyl-L-leucyl-N^6-(*N*,*N*′-diethylamidino)-L-lysyl-L-prolyl-D-alaninamide acetate.

Ганиреликса Ацетат

$C_{80}H_{113}ClN_{18}O_{13},2C_2H_4O_2$ = 1690.4.

CAS — 124904-93-4 (ganirelix); 129311-55-3 (ganirelix acetate).

ATC — H01CC01.

ATC Vet — QH01CC01.

Adverse Effects and Precautions

As for Cetrorelix, p.2084.

Pharmacokinetics

Ganirelix is rapidly absorbed after subcutaneous injection, with a bioavailability of about 91%. It is metabolised by enzymatic hydrolysis and about 75% of a dose is excreted as metabolites in the faeces. Unchanged drug is found in the urine. The elimination half-life of ganirelix is about 13 hours.

◊ References.

Uses and Administration

Like cetrorelix (p.2084), ganirelix is a gonadorelin (gonadotrophin-releasing hormone) antagonist. It is used as a component of ovarian stimulation regimens for assisted reproduction in infertility (p.2080); ganirelix acetate is given by subcutaneous injection to prevent premature luteinising hormone surges. Doses are expressed in terms of the acetate or the equivalent amount of base. Ganirelix acetate 108 mg is equivalent to about 100 mg of ganirelix. In the UK a dose equivalent to ganirelix 250 micrograms is given once daily, starting on day 6 of ovarian stimulation and continued until ovulation induction. In the USA a dose of ganirelix acetate 250 micrograms is used similarly.

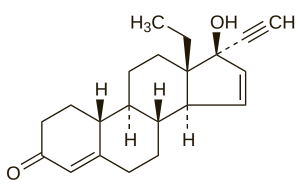
Gestodene *(BAN, USAN, rINN)*

Gestodeeni; Gestoden; Gestodène; Gestodeno; Gestodenum; SH-B-331. 13β-Ethyl-17β-hydroxy-18,19-dinor-17α-pregna-4,15-dien-20-yn-3-one.

Гестоден

$C_{21}H_{26}O_2$ = 310.4.

CAS — 60282-87-3.



Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059. Gestodene is reported to have few androgenic effects, and to have less adverse effect on the serum lipid profile than older 19-nortestosterone derivatives. However, there is some evidence that gestodene-containing combined oral contraceptives are associated with a small increased risk of venous thromboembolism (see p.2063, and for precautions, see under Cardiovascular Disease, p.2066).

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Antiepileptics. *Felbamate* significantly increased gestodene clearance from a low-dose combined oral contraceptive, and might decrease contraceptive efficacy.[1] See also p.2068.

1. Saano V, *et al*. Effects of felbamate on the pharmacokinetics of a low-dose combination oral contraceptive. *Clin Pharmacol Ther* 1995; **58:** 523–31.

Pharmacokinetics

Gestodene is well absorbed with a high bioavailability when given orally. It is extensively bound to plasma proteins; 75 to 87% to sex hormone binding globulin, and 13 to 24% to albumin. Gestodene is metabolised in the liver, less than 1% of a dose being excreted in the urine unchanged. After multiple doses with ethinylestradiol, gestodene has an elimination half-life of about 20 hours.

Uses and Administration

Gestodene is a progestogen (see Progesterone, p.2125) structurally related to levonorgestrel. It is used as the progestogenic component of combined oral contraceptives (see p.2069); a typical daily dose is 75 micrograms in monophasic preparations, and 50 to 100 micrograms in triphasic preparations. Gestodene is also used orally as the progestogenic component of menopausal HRT (see p.2076) in a regimen of 25 or 50 micrograms daily for 12 days of a 28-day cycle.

Gestonorone Caproate *(BANM, USAN, rINN)*

Caproato de gestonorona; Caproato de gestronol; Gestonorone, caproate de; Gestonoroni caproas; Gestronol Hexanoate; Hexanoato de gestonorona; Hexanoato de gestronol; NSC-84054; SH-582. 17α-Hydroxy-19-norpregn-4-ene-3,20-dione hexanoate.

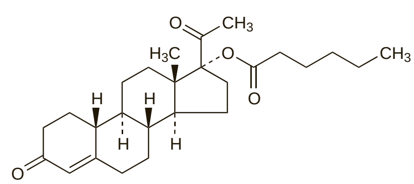
Гестонорона Капроат

$C_{26}H_{38}O_4$ = 414.6.

CAS — 1253-28-7.

ATC — G03DA01; L02AB03.

ATC Vet — QG03DA01; QL02AB03.



Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125).

Local reactions have occurred at the site of injection. Rarely, coughing, dyspnoea, and circulatory disturbances may develop during or immediately after injection but can be avoided by injecting gestonorone very slowly. In males, spermatogenesis is temporarily inhibited.

Interactions

As for progestogens in general (see Progesterone, p.2126).

Uses and Administration

Gestonorone caproate is a long-acting potent progestogen structurally related to progesterone (p.2126). It has been given in an oily solution by intramuscular injection in doses of 200 to 400 mg every 5 to 7 days for the adjunctive treatment of endometrial carcinoma (p.663). It has also been used in the management of benign prostatic hyperplasia (p.2178) in doses of 200 mg weekly, increased to 300 to 400 mg weekly if necessary.

Preparations

Gestrinone *(BAN, USAN, rINN)* ⊗

A-46745; Ethylnorgestrienone; Gestrinon; Gestrinona; Gestrinoni; Gestrinonum; R-2323; RU-2323. 13β-Ethyl-17β-hydroxy-18,19-dinor-17α-pregna-4,9,11-trien-20-yn-3-one.

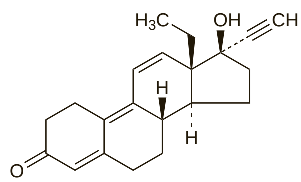
Гестринон

$C_{21}H_{24}O_2$ = 308.4.

CAS — 16320-04-0; 40542-65-2.

ATC — G03XA02.

ATC Vet — QG03XA02.



Adverse Effects and Precautions

As for Danazol, p.2090.

Interactions

Antiepileptic drugs and rifampicin may accelerate the metabolism of gestrinone.

Pharmacokinetics

Gestrinone is well absorbed after oral doses with negligible first-pass hepatic metabolism. Peak plasma concentrations occur about 3 hours after a dose. The plasma half-life is about 24 hours. Gestrinone is metabolised in the liver to form conjugated metabolites.

Uses and Administration

Gestrinone is a synthetic steroidal hormone reported to have antiprogestogenic properties, with some androgenic and anti-oestrogenic activity; it inhibits pituitary gonadotrophin release. It is used in the treatment of endometriosis (p.2091) in oral doses of 2.5 mg twice weekly; the first dose is taken on the first day of the menstrual cycle with the second dose taken three days later; thereafter the doses should be taken on the same two days of each week, usually for a period of 6 months. If a dose is missed it should be given as soon as possible and the original dose sequence maintained thereafter; if 2 or more doses are missed gestrinone should be stopped and restarted on the first day of a new cycle after a negative pregnancy test.

Gestrinone has been studied in the management of cyclical mastalgia (p.2092) and uterine fibroids (p.2107).

Гонадорелина Гидрохлорид

$C_{55}H_{75}N_{17}O_{13},2HCl$ = 1255.2.

CAS — 51952-41-1.

ATC — H01CA01; V04CM01.

ATC Vet — QH01CA01; QV04CM01.

Pharmacopoeias. In *US.*

USP 31 (Gonadorelin Hydrochloride). A synthetic polypeptide hormone having the property of stimulating the release of the luteinising hormone from the hypothalamus. It is extremely hygroscopic. Protect from exposure to moisture and store in airtight well-sealed containers, in a desiccator.

Adverse Effects

Gonadorelin and its analogues are generally well tolerated but may cause gastrointestinal adverse effects, usually nausea and abdominal pain or discomfort. There may be headache or lightheadedness, and an increase in menstrual bleeding. Continued therapy with gonadorelin analogues results in paradoxical suppression of the pituitary gonadal axis; in premenopausal women this may produce menopausal symptoms, including vaginal dryness, hot flushes, and loss of libido. If sufficiently prolonged the suppression of circulating oestrogens may lead to osteoporosis. In men, hot flushes and sexual dysfunction can occur, and breast swelling and tenderness have been reported infrequently with gonadorelin analogues. Long-term treatment can also cause a loss of bone mineral density in men. Other adverse effects reportedly associated with gonadorelin analogue therapy, and presumably related to changes in the hormonal milieu, include mood changes, nervousness, palpitations, acne and dry skin, changes in scalp and body hair, alterations in liver function tests and blood lipids, and decreased glucose tolerance. Arthralgia and paraesthesias have been reported. Ovarian hyperstimulation (as seen with chorionic gonadotrophin, p.2085), although rare, has occurred in women given gonadorelin.

Reactions or pain may occur at the site of injection with rash (local or generalised), thrombophlebitis, swelling, or pruritus. Hypersensitivity reactions, including bronchospasm and anaphylaxis, have been reported.

Other effects may be a consequence of the particular use of gonadorelin or its analogues. Tumour flare, due to an initial surge in testosterone concentrations, has been reported in the initial stages of treatment for cancer of the prostate and prophylactic anti-androgen therapy may be added. Flare may manifest as an increase in bone pain; occasionally there has been spinal cord compression, or a worsening of urinary-tract symptoms with haematuria and urinary obstruction. Acute degeneration of submucous fibroids with severe bleeding has been reported following use of leuprorelin. An initial increase in signs and symptoms has also been reported in women with breast cancer receiving gonadorelin analogues; hypercalcaemia has occurred in those with metastatic disease. In girls being treated for precocious puberty, vaginal bleeding may occur in the first month of treatment because of initial ovarian stimulation followed by treatment-induced oestrogen withdrawal.

Hypersensitivity. Acquired hypersensitivity led to an anaphylactic reaction after an intravenous dose of gonadorelin in a man who had been receiving pulsatile subcutaneous gonadorelin therapy for 10 weeks.[1]

1. Potashnik G, *et al.* Anaphylactic reaction to gonadotropin-releasing hormone. *N Engl J Med* 1993; **328:** 815.

Osteoporosis. Long-term use of a gonadorelin analogue results in oestrogen deficiency-associated osteoporosis and various drugs have been investigated for their ability to reduce this effect. Parathyroid hormone has been reported to prevent bone loss in small studies of young women receiving nafarelin.[1,2] 'Add-back' therapy with tibolone[3,4] or oestrogen plus progestogen[5,6] has also had beneficial effects on bone mineral density in women receiving gonadorelin analogues. However, studies have used various combination regimens and it is not possible to determine which is most effective.[6,7] There is less information available about the management of osteoporosis in men receiving gonadorelin analogues as androgen deprivation therapy, but measures have included supplemental calcium and vitamin D, and the use of bisphosphonates.[8] Raloxifene is also under investigation in both women[9] and men.[10]

Pituitary apoplexy. Pituitary apoplexy has been reported after endocrine stimulation testing using gonadorelin. A review[1] of 14 cases found that 2 patients had received gonadorelin alone but most had also received protirelin (thyrotropin-releasing hormone). The onset of initial symptoms was within 2 hours and pituitary tumour haemorrhage was much more common than infarction alone.

1. Matsuura I, *et al.* Infarction followed by hemorrhage in pituitary adenoma due to endocrine stimulation test. *Endocr J* 2001; **48:** 493–8.

Precautions

Gonadorelin or its analogues should not generally be used in patients with pituitary adenoma as haemorrhagic infarction (pituitary apoplexy) has sometimes occurred. It has also been recommended that patients with weight-related amenorrhoea should not receive these drugs until their weight is corrected. Although at least one manufacturer recommends that gonadorelin should not be used in women with polycystic ovary disease or with endometriotic cysts, gonadorelin and its analogues have been used for ovulation induction in polycystic disease and produced improvement in uterine fibroids; gonadorelin analogues have also been used with benefit in endometriosis. Gonadorelin analogues may increase cervical resistance, making it difficult to dilate the cervix for intra-uterine surgical procedures. Gonadorelin or its analogues should be stopped if the patient becomes pregnant. Contraceptive measures should be taken to protect against unwanted ovulation. Men at risk from tumour flare should be carefully monitored in the first month of therapy.

Interactions

Drugs affecting pituitary secretion of gonadotrophins may alter the response to gonadorelin or its analogues; other hormonal therapy and corticosteroids can affect the response. Spironolactone and levodopa can stimulate gonadotrophins while phenothiazines, dopamine antagonists, digoxin, and sex hormones can inhibit gonadotrophin secretion.

Pharmacokinetics

Gonadorelin is poorly absorbed from the gastrointestinal tract. It has a terminal plasma half-life of only 10 to 40 minutes after intravenous injection. It is hydrolysed in the plasma and excreted in the urine as inactive metabolites.

Gonadorelin analogues are absorbed after oral, intramuscular, intranasal, or rectal doses and have a longer half-life.

Uses and Administration

Gonadorelin is a synthetic form of hypothalamic gonadotrophin-releasing hormone. It stimulates the synthesis and release of follicle-stimulating hormone and, in particular, luteinising hormone in the anterior lobe of the pituitary. The secretion of endogenous gonadotrophin-releasing hormone is pulsatile and is controlled by several factors including circulating sex hormones. Gonadotrophic hormones (gonadotrophins), released from the pituitary gland in response to gonadorelin, stimulate secretion of sex hormones from the gonads. A single dose of gonadorelin or one of its analogues has the effect of increasing circulating sex hormones; continued use leads to down-regulation of gonadorelin-receptor synthesis in the pituitary and results in a paradoxical reduction in sex-hormone secretion.

Gonadorelin may be given as the base, acetate, or hydrochloride, and the dose may be expressed in terms of any of these.

Gonadorelin is used in the **diagnosis of hypothalamic-pituitary-gonadal dysfunction**. Assessment is usually based on the response to a dose of gonadorelin of 100 micrograms by intravenous or subcutaneous injection. In females, where possible, it should be given early in the follicular stage of the menstrual cycle. In the UK, the *BNFC* includes a single dose of 2.5 micrograms/kg, to a maximum of 100 micrograms, for children from the age of 1 year.

Gonadorelin is also used in the treatment of **amenorrhoea** and **infertility** associated with hypogonadotrophic hypogonadism. Weight-related amenorrhoea should have been corrected by diet. Treatment in such conditions is based on an intermittent pulse pump providing 5 to 20 micrograms over one minute every 90 minutes, either subcutaneously or intravenously, for up to 6 months or until conception.

Gonadorelin or, more usually, its analogues such as buserelin, goserelin, leuprorelin, nafarelin, and triptorelin (which are more potent and have a longer duration of action) are used in cryptorchidism, malignant neoplasms (especially of the prostate), and in delayed and precocious puberty.

Benign prostatic hyperplasia. The gonadorelin analogues have been tried in the management of benign prostatic hyperplasia (p.2178) but are considered unsatisfactory for indefinite use. See also under Leuprorelin Acetate, p.2111, and Nafarelin Acetate, p.2118.

Cryptorchidism. Although surgery remains the treatment with the best success rate, primary hormonal therapy with gonadorelin or an analogue is widely used for cryptorchidism (p.2079). Systematic reviews[1,2] suggest a success rate of about 20% overall, although this may be reduced when care is taken to exclude retractile testes. There is some suggestion that medical treatment given either before or after surgery can improve the patient's fertility index, a predictor of future fertility.[3]

2. Henna MR, *et al.* Hormonal cryptorchidism therapy: systematic review with metanalysis of randomized clinical trials. *Pediatr Surg Int* 2004; **20:** 357–9.
3. Tekgül S, *et al.* European Society for Paediatric Urology, European Association of Urology. Guidelines on paediatric urology (issued March 2008). Available at: http://www.uroweb.org/fileadmin/user_upload/Guidelines/Paediatric%20Urology.pdf (accessed 31/03/08)

Delayed and precocious puberty. For mention of the use of gonadorelin or its analogues in delayed and precocious puberty, see p.2079 and p.2081 respectively. Benefit in delayed puberty is most likely in those cases where it is secondary to hypogonadism (see p.2079).

Diagnosis of hypothalamic and pituitary dysfunction. Gonadorelin may be used in the diagnosis of hypothalamic-pituitary-gonadal dysfunction such as in hypogonadism, delayed puberty, and precocious puberty.[1,2]

1. Eckert KL, *et al.* A single-sample, subcutaneous gonadotropin-releasing hormone test for central precocious puberty. *Pediatrics* 1996; **97:** 517–19.
2. De Martino MU, *et al.* Dynamic testing in the evaluation of male gonadal function. *J Endocrinol Invest* 2003; **26** (suppl): 107–13.

Disturbed behaviour. Gonadorelin analogues such as leuprorelin (p.2111) or triptorelin (p.2136) may be tried in men with paraphilias.

Endometriosis. Gonadorelin analogues are effective in the management of endometriosis (p.2091), but the need for long-term therapy to prevent recurrence limits their value, because of the risk of osteoporosis. 'Add-back' therapy (hormone replacement) may be given in an attempt to reduce bone mineral density loss and vasomotor symptoms.

Some references to gonadorelin analogues in endometriosis are listed below. For further references, see Buserelin Acetate, p.2083, Goserelin Acetate, p.2108, Leuprorelin Acetate, p.2112, and Nafarelin Acetate, p.2118.

Fibroids. Uterine fibroids (leiomyomas) are benign tumours of uterine smooth muscle.[1,2] They are found in about 25% of women, most of whom are aged in their 30s or 40s when the condition becomes symptomatic. Fibroids may give rise to menstrual problems, particularly menorrhagia, pelvic discomfort, infertility, and miscarriage. Although small fibroids may not require treatment, the management of symptomatic fibroids has traditionally been surgical. However, because fibroids are oestrogen responsive, gonadorelin analogues have also been tried as medical treatment for their ability to induce a hypogonadotrophic hypogonadal state. These drugs produce a significant reduction in uterine and fibroid volume, and amenorrhoea, but when treatment stops uterine and fibroid volume tend to return to pretreatment values. The hypoestrogenism produced during treatment also causes menopausal symptoms such as hot flushes and vaginal dryness, and bone loss may occur. Giving oestrogens or progestogens, once the uterine fibroid size has significantly reduced, has been tried as 'add-back' therapy to counteract these adverse effects.[3,4] Tibolone has also been reported to reduce bone loss and vasomotor symptoms.[2] Subcutaneous injection of long-acting depot preparations of gonadorelin or its analogues appears to be the preferred method and is considered a valuable pre-operative adjunct to surgery, simplifying the procedure by reducing uterine and fibroid volume and intra-operative blood loss, as well as correcting pre-operative iron-deficiency anaemia.[5,6] However, concern has been expressed that the use of gonadorelin analogues for treating fibroids may complicate the differentiation of benign and malignant growths.[7]

For further references to use of gonadorelin analogues in the treatment of fibroids, see Buserelin Acetate, p.2083, Goserelin Acetate, p.2108, Leuprorelin Acetate, p.2112, Nafarelin Acetate, p.2118, and Triptorelin, p.2136.

Other drugs that are under investigation for fibroids include gonadorelin antagonists such as cetrorelix and ganirelix, and mifepristone. Danazol and gestrinone have also been tried in a small number of patients.[2]

Growth retardation. The use of a gonadorelin analogue to delay precocious puberty may improve the final height of children with the disorder. However, the use of a gonadorelin analogue with growth hormone in short but otherwise normal children is controversial—see under Triptorelin, p.2136.

Hirsutism. For reference to the use of gonadorelin analogues such as leuprorelin in the treatment of hirsutism, see p.2112.

Infertility. Gonadorelin and its analogues are used in the management of infertility related to hypogonadotrophic hypogonadism in both women and men (p.2080). Some further references are given below. See also under Buserelin Acetate, p.2083, Leuprorelin Acetate, p.2112, and Nafarelin Acetate, p.2118.

For mention of the use of gonadorelin and its analogues in the management of infertility in polycystic ovary syndrome, see below.

Malignant neoplasms. Gonadorelin analogues are used in the treatment of prostatic cancer (p.671) where they provide an alternative to orchidectomy in the management of advanced disease. They may also be used for ovarian ablation in premenopausal women with breast cancer (p.661). Gonadorelin analogues have been tried in neoplasms of the endometrium (p.663) and ovary, but their use is much less well established.

Analogues used include buserelin (p.2084), goserelin (p.2108), leuprorelin (p.2112), and triptorelin (p.2136).

Mastalgia. Gonadorelin analogues such as goserelin may be effective in severe refractory mastalgia (p.2092).

Polycystic ovary syndrome. Gonadorelin and its analogues have been used in the management of infertility associated with polycystic ovary syndrome (see Infertility, p.2080), even though some product information contra-indicates their use in this syndrome.

Pulsatile gonadorelin has been tried for ovulation induction but rates of ovulation and pregnancy are poor when it is used alone in women with polycystic ovary syndrome. Pretreatment with a gonadorelin analogue for pituitary desensitisation before starting pulsatile gonadorelin has shown some benefit in patients with polycystic ovary syndrome who have high levels of luteinising hormone.[1] However, there is only limited clinical data from small short-term trials and case series on the use of pulsatile gonadorelin in these women.[2]

Gonadorelin analogues may be used for pituitary desensitisation before the use of gonadotrophins for ovulation induction, and there is a suggestion that this strategy may improve pregnancy rates compared with gonadotrophins alone in women with polycystic ovary syndrome.[3] Gonadorelin analogues are used also in ovarian stimulation protocols for assisted reproduction techniques.[1]

Women with polycystic ovary syndrome are at increased risk of ovarian hyperstimulation syndrome and must be carefully monitored throughout the use of ovulation induction regimens.[1]

Porphyria. For mention of the use of gonadorelin analogues to suppress cyclic premenstrual exacerbations of acute porphyria, see Buserelin, p.2084, Nafarelin, p.2118, and Triptorelin, p.2136.

Premenstrual syndrome. In women in whom other drug treatments for premenstrual syndrome (p.2099) are ineffective, use of a gonadorelin analogue, usually with HRT as 'add-back' therapy to prevent menopausal symptoms, may be considered.[1] Short-term therapy (3 months) has been used to confirm the diagnosis of premenstrual syndrome, or to predict the response to bilateral oophorectomy when this is being considered. Some references to the use of gonadorelin analogues in premenstrual syndrome are given below.[2-7]

ATC Vet — QL02AE03.

Adverse Effects and Precautions

As for Gonadorelin, p.2106. Some women may have vaginal bleeding during initial therapy, which normally resolves spontaneously.

Pituitary apoplexy. Pituitary apoplexy (a clinical syndrome caused by haemorrhage and infarction of a pituitary adenoma) occurred in a few elderly patients with a symptomless pituitary adenoma who were given goserelin for advanced prostate cancer.[1,2] Symptoms included headache, vomiting, visual disturbances, gradual impairment of consciousness, intermittent fever, and progressive hyponatraemia. Symptoms were treated with corticosteroid replacement therapy.

1. Ando S, *et al.* Pituitary apoplexy after goserelin. *Lancet* 1995; **345:** 458.
2. Eaton HJ, *et al.* Rapid onset of pituitary apoplexy after goserelin implant for prostate cancer: need for heightened awareness. *Intern Med J* 2001; **31:** 313–14.

Pharmacokinetics

Goserelin is almost completely absorbed after subcutaneous injection, and has a serum elimination half-life of 2 to 4 hours, which may be increased in renal impairment. More than 90% of a dose is excreted in urine, as unchanged drug and metabolites.

◊ Reviews.

1. Cockshott ID. Clinical pharmacokinetics of goserelin. *Clin Pharmacokinet* 2000; **39:** 27–48.

Uses and Administration

Goserelin is an analogue of gonadorelin (p.2107) with similar properties. It is used for the suppression of gonadal sex hormone production in the treatment of malignant neoplasms of the prostate, in breast cancer in pre- and peri-menopausal women, and in the management of endometriosis and uterine fibroids. It is also given before surgery for endometrial reduction and as an adjunct to ovulation induction with gonadotrophins in the treatment of infertility. Goserelin is usually given as the acetate but doses are expressed in terms of the base; 10.5 mg of goserelin acetate is equivalent to about 10 mg of goserelin.

Goserelin acetate is available as depot preparations; with one such preparation a dose equivalent to 3.6 mg of goserelin injected subcutaneously into the anterior abdominal wall provides effective suppression of oestradiol or testosterone for 28 days. A full response should be achieved by the end of this period and treatment is continued with repeated doses at 28-day intervals; in endometriosis, therapy is given for up to 6 months, while in women with anaemia as a result of uterine fibroids it is continued, with iron supplementation, for up to 3 months before surgery. In men with prostate cancer, preparations supplying the equivalent of 10.8 mg of goserelin, given every 12 weeks, may also be used.

In the treatment of prostatic cancer an anti-androgen such as cyproterone acetate may be given for several days before beginning goserelin therapy and continued for at least 3 weeks, to avoid the risk of a disease flare.

Regimens for oocyte collection for IVF use gonadorelin analogues for pituitary desensitisation before ovulation induction with gonadotrophins. The equivalent of 3.6 mg of goserelin is given as a subcutaneous depot injection and serum-oestradiol concentrations monitored until they decline to levels similar to those in the early follicular phase, a process which usually takes 7 to 21 days. Once downregulation occurs gonadotrophin (follicle stimulating) therapy is begun until an appropriate stage of follicular development, when it is withdrawn and chorionic gonadotrophin is given to induce ovulation.

Goserelin has also been given in other sex-hormone-related conditions.

◊ Reviews of goserelin.

1. Chrisp P, Goa KL. Goserelin: a review of its pharmacodynamic and pharmacokinetic properties, and clinical use in sex hormone-related conditions. *Drugs* 1991; **41:** 254–88.
2. Perry CM, Brogden RN. Goserelin: a review of its pharmacodynamic and pharmacokinetic properties, and therapeutic use in benign gynaecological disorders. *Drugs* 1996; **51:** 319–46.

Endometriosis. Gonadorelin analogues such as goserelin are effective in the management of endometriosis (p.2091), but the need for long-term therapy to prevent recurrence limits their value because of the risk of osteoporosis. 'Add-back' therapy, with concomitant hormone replacement, may be given in an attempt to reduce bone mineral density loss and vasomotor symptoms in women receiving goserelin.

Fibroids. Gonadorelin analogues such as goserelin have been tried as an adjunct or an alternative to surgery in the treatment of uterine fibroids (p.2107) although there has been some concern that this might complicate the diagnosis of malignancy. Some further references are listed below.

1. Lumsden MA, *et al.* Treatment with the gonadotrophin releasing hormone-agonist goserelin before hysterectomy for uterine fibroids. *Br J Obstet Gynaecol* 1994; **101:** 438–42.

Malignant neoplasms. Goserelin is effective in the treatment of prostate cancer (p.671). It has produced a response similar to that of orchidectomy (surgical removal of the testes) in patients with metastatic prostate cancer.[1] Goserelin has been combined with an anti-androgen such as flutamide to provide maximum androgen blockade, but this appears to produce modest additional benefits at most. There is some evidence that adjuvant therapy with goserelin may improve survival in patients with localised or locally advanced prostate cancer when combined with radiotherapy or radical prostatectomy, and adjuvant use of goserelin appears to be more beneficial than neoadjuvant use.[2]

Goserelin may also be used as hormonal therapy in premenopausal women with advanced breast cancer (p.661); it seems to be as effective as oophorectomy,[3] and use with tamoxifen is more effective than goserelin alone.[4] It is also used as an alternative or addition to adjuvant chemotherapy in pre- or peri-menopausal women with oestrogen-receptor positive early breast cancer.[5-9]

ATC Vet — QH01CA03.

Adverse Effects and Precautions

As for Gonadorelin, p.2106.

Uses and Administration

Histrelin is an analogue of gonadorelin (p.2107) with similar properties. A subcutaneous implant containing histrelin acetate 50 mg, and designed to release histrelin 50 to 60 micrograms daily for 12 months, is used in the palliative treatment of advanced prostate cancer (p.671).

Histrelin is used in the treatment of precocious puberty in children (see below). It has also been investigated in disorders related to the menstrual cycle, and in the treatment of acute porphyrias.

Administration in children. For the suppression of gonadal sex hormone production in children with central precocious puberty (p.2081), histrelin acetate has been given by subcutaneous injection in usual doses equivalent to histrelin 10 micrograms/kg daily. Alternatively, a subcutaneous implant containing histrelin acetate 50 mg and designed to release histrelin acetate 65 micrograms daily for 12 months may be used. The implant is not recommended for children under 2 years of age.

Human Menopausal Gonadotrophins *(BAN)* ⊗

Gonadotropina menopáusica humana; HMG; Org-31338; Urogonadotrophin.

ATC — G03GA02.

ATC Vet — QG03GA02.

Description. A purified extract of human postmenopausal urine containing follicle-stimulating hormone (FSH) and luteinising hormone (LH); the relative *in-vivo* activity is expressed as a ratio. Human menopausal gonadotrophins with a ratio of FSH:LH of 1:1 are known as menotrophin (see below).

Menotrophin *(BAN)* ⊗

Menotropiini; Menotropin; Menotropina; Menotropins *(USAN)*; Menotropinum.

CAS — 9002-68-0.

Pharmacopoeias. In *Br., Chin., Jpn,* and *US.*

BP 2008 (Menotrophin). A dry preparation containing glycoprotein gonadotrophins possessing follicle-stimulating and luteinising activities. It contains not less than 40 units of follicle-stimulating hormone activity per mg. The ratio of units of luteinising hormone activity to units of follicle-stimulating hormone activity is about 1. The preparation is exclusively or predominantly of pituitary origin and obtained from the urine of postmenopausal women but, when necessary, chorionic gonadotrophin obtained from the urine of pregnant women may be added to achieve the above ratio. An almost white or slightly yellow powder. Soluble in water. Store in airtight containers. Protect from light.

USP 31 (Menotropins). An extract of human postmenopausal urine containing both follicle-stimulating hormone and luteinising hormone. It has a potency of not less than 40 follicle-stimulating hormone units and not less than 40 luteinising hormone units per mg. The ratio of units is about 1. Chorionic Gonadotropin obtained from the urine of pregnant women may be added to achieve this ratio. Not more than 30% of the luteinising hormone activity is contributed by Chorionic Gonadotropin. Store in airtight containers at 2° to 8°.

Adverse Effects

Human menopausal gonadotrophins may cause dose-related ovarian hyperstimulation varying from mild ovarian enlargement and abdominal discomfort to severe hyperstimulation with marked ovarian enlargement or cyst formation, acute abdominal pain, ascites, pleural effusion, hypovolaemia, shock and thromboembolic disorders. Rupture of ovarian cysts and intraperitoneal haemorrhage has occurred, usually after pelvic examination. Fatalities have been reported.

Hypersensitivity reactions and local reactions at the injection site may occur. Nausea and vomiting, joint pains and fever have been reported; gynaecomastia, acne, and weight gain have occurred in men.

Carcinogenicity. In a case-control study of 4575 women with primary invasive breast cancer, an evaluation of risk factors found that, overall, the use of infertility drugs was not associated with an increased risk of breast cancer.[1] However, subgroup analysis of individual drugs found that the use of human menopausal gonadotrophins for at least 6 months or 6 treatment cycles was associated with a risk of breast cancer that was 2 to 3 times greater than for women who had never received any fertility treatment. The authors of this study noted that these results were based on small numbers and that other studies had failed to show an association between fertility treatment and breast cancer.

Effects on the ovary. Ovarian hyperstimulation syndrome after use of human menopausal gonadotrophins in 4 women progressed to acute adnexal torsion.[1] Deep-vein thrombosis has also been a rare complication of ovarian hyperstimulation syndrome associated with the use of human menopausal gonadotrophins plus chorionic gonadotrophin.[2,3] In another case in which thrombosis followed the use of human menopausal gonadotrophins alone, hereditary activated protein C resistance and smoking may have been contributing factors.[4]

4. Ludwig M, *et al.* Deep vein thrombosis during administration of HMG for ovarian stimulation. *Arch Gynecol Obstet* 2000; **263:** 139–41.

Precautions

Human menopausal gonadotrophins should not be given to pregnant patients. Use should be avoided in patients with abnormal genital bleeding, hormone sensitive malignancies such as those of the breast, uterus, prostate, ovaries or testes, or ovarian cysts or enlargement not caused by the polycystic ovary syndrome. Pituitary or hypothalamic lesions, adrenal or thyroid disorders, and hyperprolactinaemia should be treated appropriately to exclude them as causes of infertility before attempting therapy with human menopausal gonadotrophins. Patients who experience ovarian enlargement are at risk of rupture; pelvic examinations should be avoided or carried out with care and the recommendation has been made that sexual intercourse should be avoided while there is such a risk.

There is a risk of multiple births.

Interactions

In women who show evidence of excessive ovarian stimulation while receiving human menopausal gonadotrophins the use of drugs with luteinising-hormone (LH) activity increases the risk of ovarian hyperstimulation syndrome.

Uses and Administration

Human menopausal gonadotrophins possess both follicle-stimulating hormone (FSH) activity (see p.2104) and luteinising hormone (LH) activity (see p.2112).

Human menopausal gonadotrophins are used in the treatment of male and female infertility due to hypogonadism. In anovulatory infertility unresponsive to clomifene, human menopausal gonadotrophins are given to induce follicular maturation and are followed by treatment with chorionic gonadotrophin to stimulate ovulation and corpus luteum formation, a topic discussed further on p.2080.

The dosage and schedule of treatment for **female infertility** must be determined according to the needs of each patient; it is usual to monitor response by studying the patient's urinary oestrogen excretion or by ultrasonic visualisation of follicles, or both. Human menopausal gonadotrophins may be given daily by intramuscular or subcutaneous injection to provide a dose of 75 to 150 units of FSH and gradually adjusted if necessary until an adequate response is achieved. Treatment is then stopped and followed after 1 or 2 days by single doses of chorionic gonadotrophin 5000 to 10 000 units (see p.2085). In menstruating patients treatment should be started within the first 7 days of the menstrual cycle. In the UK it has been suggested that the treatment course should be abandoned if no response is seen in 3 weeks although in the US the manufacturers recommend that an individual course should not exceed 12 days. This course may be repeated at least twice more if necessary.

An alternative schedule is to give three equal doses by intramuscular or subcutaneous injection, each providing 225 to 375 units of FSH on alternate days followed by chorionic gonadotrophin one week after the first dose.

In IVF and other assisted conception techniques, human menopausal gonadotrophins are used with chorionic gonadotrophin and sometimes also clomifene citrate or a gonadorelin analogue. Stimulation of follicular growth is produced by human menopausal gonadotrophins given by intramuscular or subcutaneous injection, in a dose providing 75 to 300 units of FSH daily, usually beginning on the 2nd or 3rd day of the menstrual cycle. Treatment is continued until an adequate response is obtained and the final injection of human menopausal gonadotrophins is followed 1 to 2 days later with up to 10 000 units of chorionic gonadotrophin. Oocyte retrieval is carried out about 32 to 36 hours later.

In **men with infertility** due to hypogonadotrophic hypogonadism (see Infertility, p.2080), spermatogenesis is stimulated with chorionic gonadotrophin and then human menopausal gonadotrophins are added in a dose of 75 or 150 units of FSH two or three times weekly by intramuscular or subcutaneous injection. Treatment should be continued for at least 3 or 4 months.

Infertility. Systematic reviews have not found evidence of a significant difference in efficacy for human menopausal gonadotrophins compared with urinary-derived gonadotrophins in women with anovulatory infertility[1] (p.2080), or compared with recombinant follicle-stimulating hormone in assisted reproduction cycles.[2] UK guidelines[3] consider that human menopausal gonadotrophins, urinary follicle-stimulating hormone, and recombinant follicle-stimulating hormone are equally effective in achieving pregnancy for women with ovulatory disorders, such as polycystic ovary syndrome, and for IVF treatment.

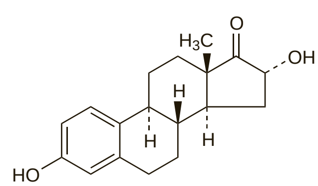
Hydroxyestrone Diacetate

Hidroxiestrona, diacetato de; 16α-Hydroxyoestrone Diacetate. 3,16α-Dihydroxyestra-1,3,5(10)-trien-17-one diacetate.

$C_{22}H_{26}O_5$ = 370.4.

CAS — 566-76-7 (hydroxyestrone); 1247-71-8 (hydroxyestrone diacetate).



(hydroxyestrone)

Profile

Hydroxyestrone diacetate is an oestrogen (see Estradiol, p.2097). It has been given in vulvovaginal disorders and for female infertility.

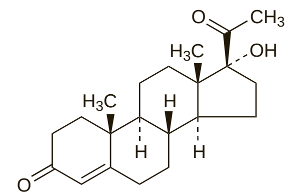
Hydroxyprogesterone Caproate *(BANM, rINN)*

17-AHPC; Caproate d'hydroxyprogestirone; Caproato de hidroxiprogesterona; Hidroksiprogesteron Heksanoat; Hidroksiprogesteron Kaproat; Hydroxyprogesterone Hexanoate; Hydroxyprogesteroni Caproas; NSC-17592. 3,20-Dioxopregn-4-en-17α-yl hexanoate; 17α-Hydroxypregn-4-ene-3,20-dione hexanoate.

Гидроксипрогестерона Капроат

$C_{27}H_{40}O_4$ = 428.6.

CAS — 68-96-2 (hydroxyprogesterone); 630-56-8 (hydroxyprogesterone caproate).
ATC — G03DA03.
ATC Vet — QG03DA03.



(hydroxyprogesterone)

Pharmacopoeias. In *Chin.* and *US.*

USP 31 (Hydroxyprogesterone Caproate). A white or creamy-white, crystalline powder. Odourless or having a slight odour. Insoluble in water; soluble in ether; slightly soluble in benzene. Protect from light. Store at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125).

There may be local reactions at the site of injection. Rarely, coughing, dyspnoea, and circulatory disturbances may occur during or immediately after injection of hydroxyprogesterone caproate but can be avoided by injecting the drug very slowly.

Pregnancy. Abnormalities reported in infants born to mothers who had received hydroxyprogesterone during pregnancy have included tetralogy of Fallot in one infant,[1] genito-urinary abnormalities in 2 infants,[2] and adrenocortical carcinoma in one infant.[3]

3. Mann JR, *et al.* Transplacental carcinogenesis (adrenocortical carcinoma) associated with hydroxyprogesterone hexanoate. *Lancet* 1983; **ii:** 580.

Interactions

As for progestogens in general (see Progesterone, p.2126).

Uses and Administration

Hydroxyprogesterone caproate is a progestogen structurally related to progesterone (p.2125) that has been used for recurrent miscarriage and various menstrual disorders. In recurrent miscarriage associated with proven progesterone deficiency, doses of 250 to 500 mg weekly by intramuscular injection have been given during the first half of pregnancy. Hydroxyprogesterone caproate has also been used to prevent premature labour (see below).

The acetate and the enantate have also been used.

Premature labour. In women who have a history of spontaneous premature delivery (p.2003), there is some evidence to suggest that prophylactic progesterone, may reduce the risk for premature delivery in subsequent pregnancies. A placebo-controlled study[1] has used intramuscular injections of hydroxyprogesterone caproate, starting in weeks 16 to 20 of gestation and continuing until delivery or week 36. The risk of delivery at less than 37 weeks was reduced in women given hydroxyprogesterone, but the rate was still high at 36.3% of 306 women compared with 54.9% of 153 given placebo. Vaginal progesterone has been found to reduce the frequency of uterine contractions and the rate of preterm delivery in women at high risk,[2] and to reduce preterm delivery in women with a short cervix at mid-gestation.[3] The best timing of therapy is unclear, although two retrospective analyses[4,5] found that rates of preterm delivery were similar for two groups of women started on hydroxyprogesterone prophylaxis at either 16 to 20.9 weeks of gestation or 21 to 26.9 weeks. Another retrospective study[6] suggested that early cessation of hydroxyprogesterone was associated with an increased risk of spontaneous recurrent preterm delivery and that treatment should continue until 36 weeks of gestation.

Systematic reviews[7,8] of studies using progestogens (mainly hydroxyprogesterone) have concluded that prophylaxis does reduce the risk of preterm delivery and low birth-weight (less than 2.5 kg). However, further study is required, particularly to identify the optimal timing, route, and dose of treatment, and long-term effects on infant health.[8] Based on limited data, an expert committee in the USA has recommended[9] that the use of progesterone and hydroxyprogesterone should be restricted to women with a history of previous spontaneous delivery at less than 37 weeks. In Canada,[10] a history of preterm labour is considered an indication for intramuscular hydroxyprogesterone caproate 250 mg weekly, or vaginal progesterone 100 mg daily, given from 20 weeks of gestation until the risk of prematurity is low. For women with a short cervix (less than 15 mm at 22 to 26 weeks of gestation), vaginal progesterone 200 mg daily may be used.

There is an increased risk of preterm delivery in twin gestations, but the use of hydroxyprogesterone does not appear to be of benefit.[11]

Pharmacopoeias. In *US.*

USP 31 (Leuprolide Acetate). Store in airtight containers at a temperature not exceeding 30°.

Adverse Effects and Precautions

As for Gonadorelin, p.2106. Thrombocytopenia and leucopenia have been reported rarely.

Benign intracranial hypertension. Increased intracranial pressure associated with leuprorelin treatment has been reported in a few isolated cases.[1,2]

1. Arber N, *et al.* Pseudotumor cerebri associated with leuprorelin acetate. *Lancet* 1990; **335:** 668.
2. Boot JH. Pseudotumour cerebri as a side effect of leuprorelin acetate. *Ir J Med Sci* 1996; **165:** 60.

Effects on the eyes. Leuprorelin may be associated with blurred vision, usually lasting 1 to 2 hours after injection, but in rare instances longer.[1] Haemorrhage or occlusion of intra-ocular blood vessels, ocular pain, and lid oedema have also been reported but the association is less well established.

1. Fraunfelder FT, Edwards R. Possible ocular adverse effects associated with leuprolide injections. *JAMA* 1995; **273:** 773–4.

Hypersensitivity. An anaphylactic reaction started within 5 minutes of the injection of a leuprorelin depot formulation in a patient with prostate cancer.[1] Recurrent anaphylaxis developed in another patient given a depot injection of leuprorelin acetate for endometriosis, requiring both acute and chronic management.[2]

1. Taylor JD. Anaphylactic reaction to LHRH analogue, leuprorelin. *Med J Aust* 1994; **161:** 455.
2. Letterie GS, *et al.* Recurrent anaphylaxis to a depot form of GnRH analogue. *Obstet Gynecol* 1991; **78:** 943–6.

Local reactions. Local reactions, including erythema, pain, induration, granulomas, and sterile abscess are particularly associated with depot injections of gonadorelin analogues such as leuprorelin and triptorelin;[1-5] they may also occur with subcutaneous daily injection.[1] It has been suggested that the depot vehicle, a lactic acid-glycolic acid copolymer, may be responsible for many, although not all, such reactions.[1-5] Reactions are claimed to be more prevalent in children than in adults:[4] an incidence of about 5% of patients has been suggested. Reactions are apparently idiosyncratic and may occur at any time during therapy, may be intermittent, or may never recur.[4]

4. Neely EK, *et al.* Local reactions to luteinizing hormone releasing hormone analog therapy. *J Pediatr* 1995; **126:** 159–60.
5. Yasukawa K, *et al.* Leuprorelin acetate granulomas: case reports and review of the literature. *Br J Dermatol* 2005; **152:** 1045–7.

Pituitary apoplexy. Pituitary apoplexy occurred shortly after the injection of a depot formulation of leuprorelin for the treatment of prostate cancer in 2 patients with occult pituitary adenomas.[1,2] In a woman receiving leuprorelin daily in preparation for oocyte donation, symptoms began after the third dose.[3] Signs and symptoms in these cases included headache, visual disturbances, generalised weakness, nausea and vomiting, and haemorrhagic necrosis of the macroadenoma.

1. Morsi A, *et al.* Pituitary apoplexy after leuprolide administration for carcinoma of the prostate. *Clin Endocrinol (Oxf)* 1996; **44:** 121–4.
2. Reznik Y, *et al.* Pituitary apoplexy of a gonadotroph adenoma following gonadotrophin releasing hormone agonist therapy for prostatic cancer. *J Endocrinol Invest* 1997; **20:** 566–8.
3. Engel G, *et al.* Pituitary apoplexy after leuprolide injection for ovum donation. *J Adolesc Health* 2003; **32:** 89–93.

Interactions

As for Gonadorelin, p.2107.

Pharmacokinetics

Leuprorelin acetate is not active when given orally but is well absorbed on subcutaneous or intramuscular injection. After a parenteral dose it has an elimination half-life of about 3 hours.

◊ References.

Uses and Administration

Leuprorelin is an analogue of gonadorelin (p.2107) with similar properties. Continuous administration is used for the suppression of gonadal sex hormone production in the treatment of malignant neoplasms of the prostate, in central precocious puberty, and in the management of endometriosis and uterine fibroids. It is also given before uterine surgery for endometrial reduction, and may be used in the treatment of breast cancer in premenopausal women. Leuprorelin is used as the acetate.

In the palliative treatment of **advanced prostate cancer**, leuprorelin acetate may be given by subcutaneous injection in a usual single daily dose of 1 mg. It is also given subcutaneously or intramuscularly as depot preparations but the dosage and route of these may differ between countries. In the USA, the dose is 7.5 mg monthly, 22.5 mg every 3 months, or 30 mg every 4 months, given subcutaneously or intramuscularly, depending on the preparation. A depot preparation of 45 mg given subcutaneously once every 6 months is also used. In the UK, leuprorelin acetate may also be used in advanced prostate cancer, as well as medical treatment of locally advanced cancer, as an adjuvant to surgery in locally advanced cancer at high risk of progression, or as an adjuvant to radiotherapy in high-risk localised or locally advanced disease. A dose of 3.75 mg may be given once a month, by subcutaneous or intramuscular injection, or 11.25 mg may be given subcutaneously every 3 months. A nonbiodegradable titanium alloy implant, which is inserted subcutaneously into the inner part of the upper arm, is also available in the USA for advanced disease. It contains 72 mg of leuprorelin acetate and delivers the drug at a controlled rate of 120 micrograms daily. After 12 months it must be removed, but can be replaced by another implant to continue therapy. An anti-androgen such as cyproterone acetate may be given for several days before beginning leuprorelin therapy and continued for about 3 weeks, to avoid the risk of a disease flare.

For the management of **endometriosis** and **uterine fibroids**, leuprorelin acetate 3.75 mg monthly may be given as a single depot injection, intramuscularly or subcutaneously. Alternatively, 11.25 mg may be given as an intramuscular depot every 3 months. Treatment is begun during the first 5 days of the menstrual cycle, and may be continued for up to 6 months for endometriosis, while in women with anaemia due to uterine fibroids it is continued, with iron supplementation, usually for up to 3 months. To prepare for uterine surgery including endometrial ablation or resection, a single 3.75 mg depot injection may be given 5 to 6 weeks before the procedure, or monthly for 3 to 4 months before surgery for uterine fibroids.

In the management of central **precocious puberty** leuprorelin acetate has been given by intramuscular depot injection in a dose of 300 micrograms/kg every 4 weeks, adjusted according to response. Doses of 50 micrograms/kg daily by subcutaneous injection, adjusted according to response, have also been used.

Leuprorelin acetate has also been given in other sex-hormone-related disorders.

3. Saleh FM, *et al.* Treatment of paraphilia in young adults with leuprolide acetate: a preliminary case report series. *J Forensic Sci* 2004; **49:** 1343–8.

Endometriosis. Gonadorelin analogues are effective in the management of endometriosis (p.2091) but the need for long-term therapy to prevent recurrence limits their value because of the risk of osteoporosis; 'add-back' hormone replacement therapy can be used to prevent this.

Fibroids. Gonadorelin analogues may be of some benefit as an adjunct or alternative to surgery in women with uterine fibroids (p.2107), although there has been some concern that this might complicate the diagnosis of malignancy.

Hirsutism. The mainstay of drug treatment for hirsutism (p.2089) has been an anti-androgen, usually cyproterone acetate or spironolactone. Although gonadorelin analogues have been used, and are effective, they must be given parenterally or nasally and may produce menopausal effects, notably osteoporosis.

Malignant neoplasms. Gonadorelin analogues are used as an alternative to orchidectomy in the management of advanced malignant neoplasms of the prostate (p.671). Such therapy is as effective as orchidectomy in prolonging survival;[1] combination of leuprorelin or other gonadorelin analogues with nonsteroidal anti-androgens to produce maximal androgen blockade produces only modest additional benefit.[2] Intermittent maximal androgen blockade is being studied in an attempt to improve results, and leuprorelin is also under investigation as neoadjuvant therapy in localised disease.[3] Leuprorelin is also used for ovarian ablation[4] in premenopausal women with breast cancer (p.661).

There are also isolated reports of endometrial cancer (p.663),[5] and ovarian cancer[6] responding to leuprorelin, but the role of the gonadorelin analogues in these conditions is much less well established.

Luteinising Hormone ⊗

Human Interstitial-cell-stimulating Hormone; ICSH; LH; Lutropin; Lutropina.

CAS — 9002-67-9; 39341-83-8 (human).

Lutropin Alfa *(BAN, USAN, rINN)* ⊗

Lutropina alfa; Lutropine Alfa; Lutropinum Alfa.

Лутропин Альфа

CAS — 152923-57-4 (lutropin alfa); 56832-30-5 (α subunit); 53664-53-2 (β subunit).
ATC — G03GA07.
ATC Vet — QG03GA07.

Units

35 units of human pituitary luteinising hormone are contained in about 5.8 micrograms (with 1 mg of human albumin, 5 mg of mannitol, and 1 mg of sodium chloride) in one ampoule of the second International Standard (1988).

10 units of the alpha subunit of human pituitary luteinising hormone are contained in about 10 micrograms (with 0.5 mg of human albumin, 2.5 mg of lactose, and 45 micrograms of sodium chloride) in one ampoule of the first International Standard (1984).

10 units of the beta subunit of human pituitary luteinising hormone are contained in 10 micrograms (with 0.5 mg of human albumin, 2.5 mg of lactose, and 45 micrograms of sodium chloride) in one ampoule of the first International Standard (1984).

189 units of recombinant human luteinising hormone are contained in about 8.8 micrograms (with 2 mg of human albumin, 10 mg of lactose, and 8.9 mg of sodium chloride) in one ampoule of the first International Standard (2003).

Adverse Effects and Precautions

As for Human Menopausal Gonadotrophins, p.2109.

Pharmacokinetics

The absolute bioavailability of lutropin alfa after subcutaneous doses is about 60%, and the terminal half-life is at least 10 to 12 hours.

Uses and Administration

Luteinising hormone (LH) is secreted with follicle-stimulating hormone (FSH) (p.2104), another gonadotrophin, by the anterior pituitary lobe.

These gonadotrophins stimulate the normal functioning of the gonads and the secretion of sex hormones in both men and women. In women, follicle-stimulating hormone stimulates the development and maturation of the follicles and ova. As the follicle develops it produces oestrogen in increasing amounts which at mid-cycle stimulates the release of LH. This causes rupture of the follicle with ovulation and converts the follicle into the corpus luteum which secretes progesterone. In men, luteinising hormone stimulates the interstitial cells of the testis to secrete testosterone, which in turn has a direct effect on the seminiferous tubules.

Gonadotrophic substances with luteinising or follicle-stimulating activity or both are used in the treatment of infertility (p.2080), chiefly in females but also in males. Such substances include chorionic gonadotrophin (p.2085) which possesses LH activity and human menopausal gonadotrophins (p.2110) which possess both LH and FSH activity.

Lutropin alfa is a recombinant human luteinising hormone used to induce ovulation in women with severe deficiency of luteinising and follicle-stimulating hormones. It is used at the same time as a preparation with follicle-stimulating activity, usually follitropin alfa. The dosage and schedule of treatment must be determined according to the needs of each patient; it is usual to monitor response by studying the patient's urinary oestrogen excretion or by ultrasonic visualisation of follicles or both. Treatment is usually begun with 75 units of lutropin alfa daily by subcutaneous injection for 7 to 14 days, accompanied by FSH. If there is no response, the FSH dosage may be increased at 7- or 14-day intervals until an adequate but not excessive response is achieved. A treatment cycle of up to 5 weeks may be needed. Treatment is then stopped and followed after 1 or 2 days by a single dose of chorionic gonadotrophin 5000 to 10 000 units to induce ovulation. These patients are generally amenorrhoeic and treatment may be started at any time.

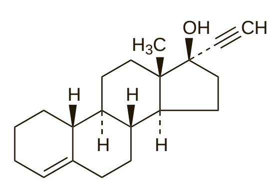
ATC Vet — QG03AC02; QG03DC03.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Lynestrenol). A white or almost white crystalline powder. Practically insoluble in water; soluble in alcohol and in acetone. Protect from light.

Profile

Lynestrenol is a progestogen (see Progesterone, p.2125) structurally related to norethisterone that is used alone or as the progestogenic component of oral contraceptives (see p.2058). Typical oral daily doses for contraception are 500 micrograms when used as a progestogen-only preparation, and 0.75 or 2.5 mg when combined with an oestrogen. When used alone for menstrual disorders, doses of 5 to 10 mg daily are given, often as cyclical regimens.

Porphyria. Lynestrenol has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

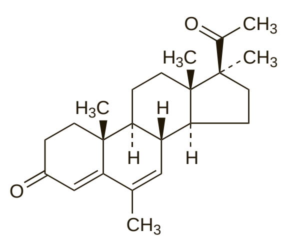
Medrogestone *(BAN, USAN, rINN)*

AY-62022; Medrogeston; Medrogestona; Médrogestone; Medrogestoni; Medrogestonum; Metrogestone; NSC-123018; R-13-615. 6,17α-Dimethylpregna-4,6-diene-3,20-dione.

Медрогестон

$C_{23}H_{32}O_2$ = 340.5.
CAS — 977-79-7.
ATC — G03DB03.
ATC Vet — QG03DB03.



Profile

Medrogestone is a progestogen structurally related to progesterone (p.2125) that is used in the treatment of menstrual disorders, and as the progestogen in menopausal HRT (see p.2071). It is usually given orally in daily doses of 5 to 10 mg, generally in a cyclical regimen. Higher doses were used in the treatment of endometrial carcinoma, prostatic hyperplasia, and breast disorders including carcinoma. It has also been used for threatened or recurrent miscarriage, but such use is not recommended unless there is proven progesterone deficiency.

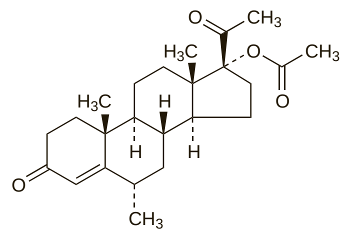
Medroxyprogesterone Acetate

(BANM, rINNM)

Acetato de medroxiprogesterona; Medroksiprogesteron Asetat; Medroksiprogesteroniasetaatti; Medroksiprogesterono acetatas; Medroxyprogesteronu octan; Medroxiprogesteronacetat; Medroxiprogeszteron-acetát; Medroxyprogesteron-acetát; Médroxyprogestérone, acétate de; Medroxyprogesteroni acetas; Methylacetoxyprogesterone; Metipregnone; NSC-26386. 6α-Methyl-3,20-dioxopregn-4-en-17α-yl acetate; 17α-Hydroxy-6α-methylpregn-4-ene-3,20-dione acetate.

Медроксипрогестерона Ацетат

$C_{24}H_{34}O_4$ = 386.5.
CAS — 520-85-4 (medroxyprogesterone); 71-58-9 (medroxyprogesterone acetate).
ATC — G03AC06; G03DA02; L02AB02.
ATC Vet — QG03AC06; QG03DA02; QL02AB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Medroxyprogesterone Acetate). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in acetone; freely soluble in dichloromethane. Protect from light.

USP 31 (Medroxyprogesterone Acetate). A white to off-white, odourless, crystalline powder. Insoluble in water; sparingly soluble in alcohol and in methyl alcohol; soluble in acetone and in dioxan; freely soluble in chloroform; slightly soluble in ether. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059. Medroxyprogesterone acetate may have glucocorticoid effects when given long term at high doses.

Breast feeding. Medroxyprogesterone is reported to be distributed into breast milk when given as a depot progestogen-only contraceptive.[1] No adverse effects have been seen in breast-fed infants of mothers given medroxyprogesterone, and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding. Progestogen-only parenteral contraceptives should not be used until 6 weeks after birth if the woman is breast feeding (see Breast Feeding under Hormonal Contraceptives, p.2066).

1. Schwallie PC. The effect of depot-medroxyprogesterone acetate on the fetus and nursing infant: a review. *Contraception* 1981; **23:** 375–86.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/06/08)

Carcinogenicity. The risk of various cancers associated with the use of depot medroxyprogesterone acetate as a contraceptive has been evaluated by WHO.[1] Overall, there was no increase in risk of breast cancer, although there is some evidence that current or recent use may be associated with a slight increase in risk (see also p.2059). There was no significant increased risk of cervical cancer (see also p.2060), and a protective effect against endometrial cancer (see p.2060). In contrast to combined oral contraceptives, there was no evidence of a protective effect against ovarian cancer (p.2061).

1. Anonymous. Depot-medroxyprogesterone acetate (DMPA) and cancer: memorandum from a WHO meeting. *Bull WHO* 1993; **71:** 669–76.

Effects on bone density. Use of medroxyprogesterone acetate as a parenteral progestogen-only contraceptive has been associated with reductions in bone density (see under Effects on the Musculoskeletal System, p.2064). This effect has also been reported after oral doses for menstrual disorders,[1] and is thought to be due to medroxyprogesterone-induced oestrogen deficiency.

1. Cundy T, *et al.* Short-term effects of high dose oral medroxyprogesterone acetate on bone density in premenopausal women. *J Clin Endocrinol Metab* 1996; **81:** 1014–17.

Effects on the skin. Acute local skin necrosis has been reported[1] after the intramuscular injection of medroxyprogesterone acetate as a depot contraceptive. A case of pigmented purpura on the lower legs, occurring about 4 months after starting medroxyprogesterone acetate injections, has been described.[2]

1. Clark SM, Lanigan SW. Acute necrotic skin reaction to intramuscular Depo-Provera . *Br J Dermatol* 2000; **143:** 1356–7.
2. Tsao H, Lerner LH. Pigmented purpuric eruption associated with injection medroxyprogesterone acetate. *J Am Acad Dermatol* 2000; **43:** 308–10.

Glucocorticoid effects. There have been reports of Cushing's syndrome induced by medroxyprogesterone acetate in patients receiving long-term therapy with high doses for the treatment of malignant neoplasms[1-5] or paraphilia.[6] Cushingoid symptoms regressed when treatment was stopped. Medroxyprogesterone possesses glucocorticoid activity and there is a risk of adrenal insufficiency during periods of stress or after sudden withdrawal of treatment. Some[4] consider that patients should be monitored for glucose intolerance and adrenal insufficiency during treatment.

3. Grenfell A, *et al.* Cushing's syndrome and medroxyprogesterone acetate. *Lancet* 1990; **336:** 256.
4. Merrin PK, Alexander WD. Cushing's syndrome induced by medroxyprogesterone. *BMJ* 1990; **301:** 345.
5. Shotliff K, Nussey SS. Medroxyprogesterone acetate induced Cushing's syndrome. *Br J Clin Pharmacol* 1997; **44:** 304.
6. Krueger RB, *et al.* Prescription of medroxyprogesterone acetate to a patient with pedophilia, resulting in Cushing's syndrome and adrenal insufficiency. *Sex Abuse* 2006; **18:** 227–8.

Porphyria. Medroxyprogesterone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients. However, for a reference to the use of medroxyprogesterone acetate with buserelin acetate in the prevention of premenstrual exacerbations of porphyria in 2 women, see p.2084.

Interactions

As for progestogens in general (see Progesterone, p.2126). Aminoglutethimide markedly reduces plasma concentrations of medroxyprogesterone so that an increase in medroxyprogesterone dosage is likely to be required.

Pharmacokinetics

Medroxyprogesterone is absorbed from the gastrointestinal tract. In the blood, it is highly protein bound, principally to albumin. It is metabolised in the liver and excreted mainly as glucuronide conjugates in the urine and faeces. It has a half-life of about 16 to 30 hours after oral doses; the half-life may be as long as 50 days after intramuscular injection. Medroxyprogesterone is reported to be distributed into breast milk.

Uses and Administration

Medroxyprogesterone acetate is a progestogen structurally related to progesterone, with actions and uses similar to those of the progestogens in general (see Progesterone, p.2126). It is given orally or, for prolonged action, as an aqueous suspension by intramuscular or subcutaneous injection, depending on the product.

It is used for the treatment of **menorrhagia** (p.2126) and **secondary amenorrhoea** in oral doses of 2.5 to 10 mg daily for 5 to 10 days starting on the assumed or calculated 16th to 21st day of the menstrual cycle, although treatment may begin on any day in secondary amenorrhoea.

In the treatment of mild to moderate **endometriosis** (p.2091) usual oral doses are 10 mg three times daily for 90 consecutive days, or 50 mg weekly or 100 mg every 2 weeks by intramuscular injection for at least 6 months. An alternative formulation used for the treatment of pain associated with endometriosis is given in a dose of 104 mg in 0.65 mL by subcutaneous injection once every 12 to 14 weeks.

Medroxyprogesterone acetate is also given by injection as a **contraceptive** (see under Hormonal Contraceptives, p.2069). As a progestogen-only contraceptive an intramuscular dose of 150 mg is given every 12 or 13 weeks. A combined contraceptive injection containing medroxyprogesterone acetate 25 mg with estradiol cipionate 5 mg is given monthly as an intramuscular injection. An alternative formulation used as a progestogen-only contraceptive is given as a dose of medroxyprogesterone acetate 104 mg in 0.65 mL by subcutaneous injection once every 12 to 14 weeks.

When used as the progestogen component of **menopausal HRT** (see p.2076), medroxyprogesterone acetate is given orally in a variety of regimens including 1.5, 2.5, or 5 mg daily continuously, 5 or 10 mg daily for 12 to 14 days of a 28-day cycle, and 20 mg daily for 14 days of a 91-day cycle.

Medroxyprogesterone acetate may also be used in the palliative treatment of some hormone-dependent malignant neoplasms. In **breast carcinoma** (see below) oral doses of 0.4 to 1.5 g daily may be given, although doses up to 2 g daily have been used in the past. Intramuscular medroxyprogesterone acetate has been given in initial doses of 500 mg daily for 4 weeks, then in maintenance doses twice weekly. In **endometrial** (below) and **renal carcinoma** (p.667) oral doses have ranged from 200 to 600 mg daily. Initial doses of 0.6 to 1.2 g weekly have been given by intramuscular injection, reducing to a maintenance schedule of as little as 450 mg monthly. In **prostatic carcinoma** (p.671) oral doses have been 100 to 600 mg daily; 500 mg has also been given by intramuscular injection, initially twice weekly for 3 months then once weekly for maintenance.

Cachexia. Medroxyprogesterone may improve appetite and food intake, and prevent loss of body-weight in cachexia (p.2115) associated with severe chronic disorders,[1,2] although information is limited.

1. Simons JPFHA, *et al.* Effects of medroxyprogesterone acetate on appetite, weight, and quality of life in advanced-stage non-hormone-sensitive cancer: a placebo-controlled multicenter study. *J Clin Oncol* 1996; **14:** 1077–84.
2. Simons JPFHA, *et al.* Effects of medroxyprogesterone acetate on food intake, body composition, and resting energy expenditure in patients with advanced, nonhormone-sensitive cancer: a randomized, placebo-controlled trial. *Cancer* 1998; **82:** 553–60.

Contraception. Medroxyprogesterone acetate has an established use as a parenteral progestogen-only contraceptive (p.2070). It has also been developed as the progestogenic component of a combined injectable contraceptive and has been investigated as a component of hormonal contraceptives for men. References.

Epilepsy. Early findings[1] suggested that medroxyprogesterone acetate might be of value in the management of catamenial epilepsy (p.465). In a later review[2] it was suggested that hormonal manipulation with drugs such as medroxyprogesterone should be reserved for highly selected groups under close supervision.

Male hypersexuality. The anti-androgenic action of medroxyprogesterone has been used for suppression of libido in the control of men with deviant or disinhibited sexual behaviour[1-8] (see Disturbed Behaviour, p.954). Most have received intramuscular medroxyprogesterone acetate; doses of about 300 mg weekly have been used,[3] but ranged from 100 mg each month to 500 mg each week in one report of 5 cases,[8] and up to 750 mg each week in another case.[6] Oral treatment with 30 mg daily was also successful in 1 case.[5]

Malignant neoplasms. *BREAST.* Progestogens are used as second- or third-choice drugs in the hormonal therapy of advanced breast cancer (p.661). Some references to the use of medroxyprogesterone acetate in advanced breast cancer are cited below.[1-8] Comparative studies have shown that patients respond equally well to medroxyprogesterone and either mepitiostane,[1] aminoglutethimide,[2] or oophorectomy.[3]

ENDOMETRIUM. Progestogens are used in the treatment of advanced endometrial carcinoma (p.663) but there are doubts about their value in the earlier stages of disease.[1] Medroxyprogesterone acetate was effective in a rare case of low-grade endometrial stromal sarcoma.[2] It has also been used in a few patients as adjuvant therapy after surgery[3] and for the treatment of metastatic disease.[4]

Respiratory disorders. Reviews of the use of medroxyprogesterone acetate in obstructive sleep apnoea have concluded that it has a limited role.[1,2]

Progesterone and, more commonly, medroxyprogesterone acetate are used in the treatment of pulmonary lymphangioleiomyomatosis, a rare disease affecting only women.[3-7] Anecdotal evidence suggests some patients improve or stabilise on treatment, possibly those with chylous effusions or chylous ascites.[8] However, a more rapid decline in lung function has also been observed with progestogen therapy in some groups.[5,6]

Medroxyprogesterone acetate was reported to be effective in treating congenital central hypoventilation syndrome in 2 children.[9] It has also been used in adults with central hypoventilation resulting from brainstem stroke[10] and other causes.[11] Medroxyprogesterone has also been investigated for its effects on respiration in chronic obstructive pulmonary disease, sometimes with acetazolamide.[12-14]

Sickle-cell disease. The frequency of painful crises has been reduced in women with homozygous sickle-cell disease (p.1044) given intramuscular depot medroxyprogesterone acetate,[1,2] and it is now considered to be a suitable contraceptive for this group (see also Sickle-cell Disease, under Precautions of Hormonal Contraceptives, p.2067).

Megestrol Acetate *(BANM, USAN, rINNM)*

Acetato de megestrol; BDH-1298; Compound 5071; Megestol Asetat; Mégestrol, acétate de; Megestrolacetat; Megestrol-acetát; Megestroli acetas; Megestroliasetaatti; Megestrolio acetatas; Megesztrol-acetát; NSC-71423; SC-10363. 6-Methyl-3,20-dioxopregna-4,6-dien-17α-yl acetate; 17α-Hydroxy-6-methylpregna-4,6-diene-3,20-dione acetate.

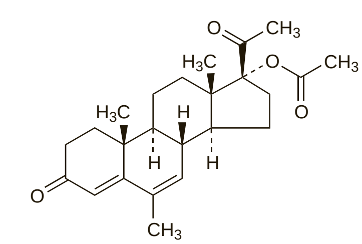
Мегестрола Ацетат

$C_{24}H_{32}O_4$ = 384.5.

CAS — 3562-63-8 (megestrol); 595-33-5 (megestrol acetate).

ATC — G03AC05; G03DB02; L02AB01.

ATC Vet — QG03AC05; QG03DB02; QL02AB01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Megestrol Acetate). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol; soluble in acetone. Protect from light.

USP 31 (Megestrol Acetate). A white to creamy-white, essentially odourless, crystalline powder. Insoluble in water; sparingly soluble in alcohol; soluble in acetone; very soluble in chloroform; slightly soluble in ether and in fixed oils. Protect from light.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). The weight gain that may occur with megestrol acetate appears to be associated with an increased appetite and food intake rather than with fluid retention. Megestrol acetate may have glucocorticoid effects when given long term.

Effects on carbohydrate metabolism. Megestrol therapy has been associated with hyperglycaemia[1-3] or diabetes mellitus[4] in AIDS patients being treated for cachexia. It has been suggested that megestrol produces peripheral insulin resistance due to a glucocorticoid action.[5]

5. Leinung MC, *et al.* Induction of adrenal suppression by megestrol acetate in patients with AIDS. *Ann Intern Med* 1995; **122:** 843–5.

Effects on the musculoskeletal system. Severe pain of the hands similar to carpal tunnel syndrome occurred in 4 women while taking megestrol acetate and melphalan;[1] megestrol appeared to be responsible.

Osteoporosis and vertebral compression fractures occurred in 2 postmenopausal women taking megestrol for anorexia.[2] In both cases there was evidence of adrenocortical insufficiency that recovered after megestrol therapy was stopped, suggesting that the glucocorticoid effect of megestrol may have contributed to the development of osteoporosis.

2. Wermers RA, *et al.* Osteoporosis associated with megestrol acetate. *Mayo Clin Proc* 2004; **79:** 1557–61.

Effects on the respiratory system. Hyperpnoea occurred in 2 patients given megestrol acetate 80 mg three times daily.[1]

1. Fessel WJ. Megestrol acetate and hyperpnea. *Ann Intern Med* 1989; **110:** 1034–5.

Glucocorticoid effects. Megestrol has glucocorticoid-like properties that can cause adrenocortical suppression in a significant number of patients.[1-4] There are also reports of adrenal insufficiency severe enough to require replacement therapy with hydrocortisone.[3,5,6]

6. Stockheim JA, *et al.* Adrenal suppression in children with the human immunodeficiency virus treated with megestrol acetate. *J Pediatr* 1999; **134:** 368–70.

Porphyria. Megestrol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals.*

Interactions

As for progestogens in general (see Progesterone, p.2126).

Pharmacokinetics

Megestrol acetate is absorbed from the gastrointestinal tract and peak plasma concentrations occur 1 to 3 hours after an oral dose. Megestrol acetate is highly protein bound in plasma. It undergoes hepatic metabolism, with 57 to 78% of a dose being excreted in the urine and 8 to 30% in the faeces.

Uses and Administration

Megestrol acetate is a progestogen structurally related to progesterone (p.2125).

It is used for the palliative treatment of some hormone-dependent malignant neoplasms (see below). Oral doses of 40 to 320 mg daily in divided doses may be given in **endometrial carcinoma**, and doses of 40 mg four times daily or 160 mg once daily may be used in **breast cancer**.

Megestrol acetate is also used in the treatment of **anorexia** and **cachexia** (see below) in patients with cancer or AIDS. The usual dose is 400 to 800 mg daily, as tablets or oral suspension. A suspension of megestrol acetate that has an increased bioavailability is also available (*Megace ES; Par Pharmaceutical, USA*) and is given in a dose of 625 mg in 5 mL daily for anorexia, cachexia, or unexplained significant weight loss in patients with AIDS.

Cachexia. In some patients with severe chronic disorders or malignant neoplasms, anorexia (loss of appetite) forms part of a syndrome of metabolic abnormalities and progressive physical wasting known as cachexia. Improved nutrition and dietary counselling are usually insufficient to reverse cachexia, and drug therapy has been tried to stimulate appetite and promote weight gain.

In **cancer-related cachexia**, corticosteroids are frequently used for appetite stimulation in patients with advanced malignancies, although they do not appear to promote weight gain. However, because their effect is usually temporary, and adverse effects occur with prolonged use,[1-3] they tend to be reserved for short-term treatment in patients with a limited life expectancy of weeks.[4] Megestrol has produced weight gain in some randomised controlled studies,[5] although some of this may result from increase in fat mass rather than increase in lean body-mass.[2,3] It is generally used in patients with a longer life expectancy of months.[4] Similar properties have been reported with medroxyprogesterone.[1] A systematic review[6] concluded that only corticosteroids and the progestogens megestrol and medroxyprogesterone had sufficient evidence to support their use in cancer-related anorexia. Anabolic steroids have also been tried, but further evaluation is necessary:[1,7] a comparison of megestrol or dexamethasone with fluoxymesterone found the latter to be less effective than the progestogen or the corticosteroid.[8] Prokinetic drugs such as metoclopramide may be useful in patients whose symptoms are secondary to decreased gastrointestinal motility,[1,2] although relief of nausea may not necessarily lead to improved caloric intake or appetite.[6] It has been suggested that NSAIDs might inhibit the effects of pro-inflammatory cytokines associated with weight loss in cancer patients. The addition of ibuprofen improved the response to megestrol in one small study,[9] but more work is needed. There has also been interest in the effects of eicosapentaenoic acid, which may inhibit muscle protein degradation, but study results have been mixed[3] and a systematic review[10] concluded that there was insufficient evidence to recommend the use of eicosapentaenoic acid. Further investigation is needed to confirm its clinical effects, possibly using higher doses or treating for longer periods than have been so far reported.[6] Thalidomide was found to attenuate weight loss in a study[11] of patients with advanced pancreatic cancer, but quality of life and duration of survival were not significantly improved. Other drugs studied but with little, if any, benefit include cannabinoids, cyproheptadine and hydrazine.[1,2,6] Other compounds under investigation include the endogenous hormones ghrelin and melatonin.[7]

High-dose megestrol[12-14] or oxandrolone[15-17] are effective in **HIV-related cachexia**, a topic discussed under HIV-associated Wasting, p.858.

Hot flushes. Megestrol has been used to treat hot flushes in women with breast cancer (to avoid the potentially tumour-stimulating effects of an oestrogen—see Malignant Neoplasms, under Precautions of HRT, p.2075), as well as in men with hot flushes after orchidectomy or anti-androgen therapy for prostate cancer.[1] Therapy, which involved low oral doses of 20 mg twice daily, was associated with a decrease in frequency of flushes of 50% or more in about three-quarters of all patients. About 3 years after the study had finished, these patients were asked about any ongoing use of megestrol and the occurrence of hot flushes.[2] Although symptoms still occurred in many of the patients taking megestrol, they were less common and less severe than in those who had stopped therapy, which included some who had stopped because of no perceived benefit. In patients taking megestrol, most were on doses of 20 mg or less daily. Information collected about adverse effects of megestrol revealed unexpected reports of chills, but these were described as being not as disabling as the hot flushes had been.

1. Loprinzi CL, *et al.* Megestrol acetate for the prevention of hot flashes. *N Engl J Med* 1994; **331:** 347–52.
2. Quella SK, *et al.* Long term use of megestrol acetate by cancer survivors for the treatment of hot flashes. *Cancer* 1998; **82:** 1784–8.

Malignant neoplasms. Like some other progestogens megestrol acetate is used in endometrial cancer (p.663), and it has been reported to have similar efficacy to anastrozole[1] and tamoxifen[2] in postmenopausal women with advanced breast cancer (p.661). There was no advantage in terms of response or survival in escalating the standard dose of megestrol (160 mg daily) to 800 or 1600 mg daily in a randomised study in women with breast cancer.[3]

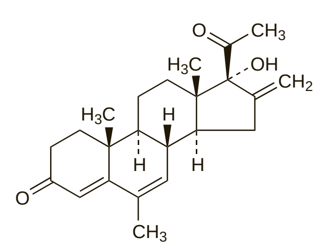
$C_{25}H_{32}O_4$ = 396.5.

CAS — 5633-18-1 (melengestrol); 2919-66-6 (melengestrol acetate).



(melengestrol)

Pharmacopoeias. In *US* for veterinary use only.

USP 31 (Melengestrol Acetate). A white to light yellow, crystalline powder. Insoluble in water; slightly soluble in alcohol; freely soluble in chloroform and in ethyl acetate. Store in airtight containers. Protect from light.

The symbol † denotes a preparation no longer actively marketed

Profile

Melengestrol acetate is a progestogen that is used as an animal feed in beef heifers to improve feed efficiency, increase the rate of body-weight gain, and suppress oestrus.

◊ WHO specifies an acceptable daily intake of melengestrol acetate as a residue in foods, and recommends maximum residue limits in various animal tissues.[1] However, it should be noted that, in the EU the use of melengestrol acetate and other steroidal hormones as growth promotors is banned.

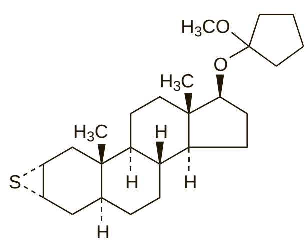
Mepitiostane *(rINN)* ⊗

Mépitiostane; Mepitiostano; Mepitiostanum; S-10364. 17β-(1-Methoxycyclopentyloxy)-2α,3α-epithio-5α-androstane; Cyclopentanone 2α,3α-epithio-5α-androstan-17β-yl methyl acetal.

Мепитиостан

$C_{25}H_{40}O_2S$ = 404.6.
CAS — 21362-69-6.



Pharmacopoeias. In *Jpn.*

Profile

Mepitiostane has androgenic and anabolic properties (see Testosterone, p.2129) and is given in usual oral doses of 10 mg twice daily for the management of neoplasms of the breast and anaemia associated with renal failure.

Preparations

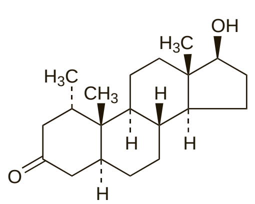
Proprietary Preparations (details are given in Part 3)
Jpn: Thioderon.

Mesterolone *(BAN, USAN, rINN)* ⊗

Mesterolon; Mesterolona; Mesterolonas; Mestérolone; Mesteroloni; Mesterolonum; Meszterolon; NSC-75054; SH-723. 17β-Hydroxy-1α-methyl-5α-androstan-3-one.

Местеролон

$C_{20}H_{32}O_2$ = 304.5.
CAS — 1424-00-6.
ATC — G03BB01.
ATC Vet — QG03BB01.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Mesterolone). A white or yellowish crystalline powder. Practically insoluble in water; sparingly soluble in acetone, in ethyl acetate, and in methyl alcohol.

Adverse Effects and Precautions

As for androgens in general (see Testosterone, p.2130).

Mesterolone is reported not to inhibit gonadotrophin secretion or spermatogenesis.

Pharmacokinetics

Mesterolone is rapidly and almost completely absorbed after an oral dose, producing maximum serum concentrations after about 1.6 hours. It is rapidly metabolised, with an absolute bioavailability of about 3% of the oral dose, and a terminal half-life of 12 to 13 hours. Unlike other androgens (see Testosterone, p.2131), mesterolone is not metabolised to oestrogenic compounds. Mesterolone is bound to serum proteins; about 40% to albumin and 58% to sex-hormone binding globulin. About 77% of the metabolites are excreted in the urine, and about 13% in the faeces.

Uses and Administration

Mesterolone has androgenic properties (see Testosterone, p.2131) but is reported to have less inhibitory effect on intrinsic testicular function than testosterone.

Mesterolone is given orally in the treatment of androgen deficiency or male infertility associated with hypogonadism (p.2079) in initial doses of 75 to 100 mg daily followed by doses of 50 to 75 mg daily for maintenance, in divided doses.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Mestranol). A white or almost white crystalline powder. Practically insoluble in water; sparingly soluble in alcohol. Protect from light.

USP 31 (Mestranol). A white to creamy-white, odourless, crystalline powder. Insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in chloroform; soluble in dioxan; slightly soluble in methyl alcohol. Protect from light.

Adverse Effects and Precautions

As for oestrogens in general (see Estradiol, p.2097). See also under Hormonal Contraceptives, p.2059.

Porphyria. Mestranol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Interactions

See under Hormonal Contraceptives, p.2067.

Pharmacokinetics

Mestranol is readily absorbed from the gastrointestinal tract, and about 70% is rapidly metabolised in the liver to ethinylestradiol (p.2102).

Uses and Administration

Mestranol is a synthetic oestrogen prodrug that is rapidly metabolised to ethinylestradiol; it therefore has actions similar to those of estradiol (see p.2098). It is used as the oestrogen component of combined oral contraceptive preparations (see p.2069) in a usual dose of 50 micrograms daily. The progestogen component is often norethisterone. Mestranol has also been used as the oestrogen component of some preparations for menopausal HRT (see p.2076), although natural oestrogens are often preferred. It has been given in a sequential regimen in a dose of 50 micrograms daily, with a cyclical progestogen.

Preparations

USP 31: Ethynodiol Diacetate and Mestranol Tablets; Norethindrone and Mestranol Tablets.

Profile

Metenolone is an anabolic steroid (see Testosterone, p.2129) that has been used in treating aplastic anaemia, breast cancer, and postmenopausal osteoporosis. Metenolone acetate has been given in oral doses of 100 to 150 mg daily for aplastic anaemia. Intramuscular depot injections of metenolone enantate have been given for osteoporosis in doses of 100 mg every 2 weeks, reducing to once every 3 to 4 weeks after an initial response. The acetate was also used orally in the past for osteoporosis. Intramuscular injections of 100 mg of the enantate every 1 to 2 weeks, or 200 mg every 2 to 3 weeks, have been used in progressive breast cancer.

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of methandienone:
Iron Brew.

Pharmacopoeias. In *Pol.*

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130).

As with other 17α-alkylated compounds, methandienone is associated with hepatotoxicity and hepatic function should be monitored during therapy. It should probably be avoided in patients with hepatic impairment, and certainly if this is severe.

Uses and Administration

Methandienone has anabolic and some androgenic properties (see Testosterone, p.2131). It has little progestogenic activity. Methandienone has been given orally as an anabolic drug.

Preparations

Proprietary Preparations (details are given in Part 3)
Pol.: Metanabol; ***Thai.:*** Anabol; Danabol†; Melic.

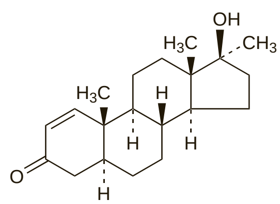
Methyl-1-testosterone ⊗

17β-Hydroxy-17α-methyl-5α-androst-1-en-3-one; M1T.

Метил-1-тестостерон

$C_{20}H_{30}O_2$ = 302.5.

CAS — 65-04-3.



Profile

Methyl-1-testosterone is an anabolic steroid (see Testosterone, p.2129) that appears to be widely abused by body-builders.

◊ References.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Methyltestosterone). A white or slightly yellowish-white, crystalline powder. Practically insoluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Methyltestosterone). White or creamy-white, odourless, slightly hygroscopic, crystals or crystalline powder. Practically insoluble in water; soluble in alcohol, in ether, in methyl alcohol, and in other organic solvents; sparingly soluble in vegetable oils. Protect from light.

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130).

As with other 17α-alkylated compounds, methyltestosterone can produce a cholestatic hepatitis with jaundice, and has caused peliosis hepatis and hepatic neoplasms (see below). Methyltestosterone should be used with caution in patients with liver impairment, and is probably best avoided if this is severe. Liver function should be monitored during therapy.

Effects on the liver. Reports of peliosis hepatis[1] and liver damage[2-4] associated with methyltestosterone.

See also under Malignant Neoplasms, below.

Pregnancy. For reference to virilisation of a female fetus whose mother received methyltestosterone during pregnancy, see p.2131.

Interactions

As for androgens and anabolic steroids in general (see Testosterone, p.2131).

Pharmacokinetics

Methyltestosterone is absorbed from the gastrointestinal tract and from the oral mucosa. It undergoes less extensive first-pass hepatic metabolism than testosterone after oral doses, and has a longer half-life.

Uses and Administration

As for androgens and anabolic steroids in general (see Testosterone, p.2131).

Methyltestosterone is effective when given orally; its effect is increased about twofold when given buccally, as this avoids first-pass hepatic metabolism.

Suggested doses of methyltestosterone for androgen replacement therapy in male hypogonadism (p.2079) have been 10 to 50 mg daily orally or 5 to 25 mg daily buccally. Doses of 50 to 200 mg daily orally or 25 to 100 mg daily buccally have been given for metastatic breast carcinoma (p.661) in postmenopausal women. Oral doses of 1.25 to 2.5 mg daily, for 21 days of a 28-day cycle, have been given with oestrogens for the short-term treatment of menopausal vasomotor symptoms (p.2077) unresponsive to oestrogens alone.

Preparations

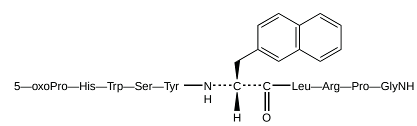
ATC — H01CA02.

ATC Vet — QH01CA02.



(nafarelin)

Adverse Effects and Precautions

As for Gonadorelin, p.2106.

Effects on electrolytes. Severe hyperkalaemia occurred in a woman receiving nafarelin therapy for uterine fibroids.[1] Despite serum-potassium greater than 10 mmol/litre she had no symptoms and the electrocardiogram was normal. Hyperkalaemia resolved without treatment on stopping nafarelin.

1. Hata T, *et al.* Severe hyperkalaemia with nafarelin. *Lancet* 1996; **347:** 333.

Interactions

As for Gonadorelin, p.2107.

Pharmacokinetics

Nafarelin is rapidly absorbed on intranasal use with peak plasma concentrations achieved within 20 minutes of a dose, although bioavailability is only about 3%. The plasma half-life is about 3 to 4 hours. Nafarelin is metabolised by peptidases in the body; after subcutaneous dosage it is excreted in urine, as metabolites and a small amount of unchanged drug, and in the faeces.

Uses and Administration

Nafarelin acetate is an analogue of gonadorelin (p.2107) with similar properties. It is used in the treatment of endometriosis and central precocious puberty, and as an adjunct to ovulation induction with gonadotrophins in the treatment of infertility.

For **endometriosis** it is given in usual doses equivalent to 200 micrograms of nafarelin twice daily intranasally, doubled after 2 months if amenorrhoea has not occurred. Treatment should begin on days 2 to 4 of the menstrual cycle, and may be continued for up to 6 months.

For central **precocious puberty** the usual dose is the equivalent of nafarelin 800 micrograms intranasally (400 micrograms in each nostril) twice daily. If adequate suppression is not achieved at this dose it may be increased to 600 micrograms three times daily in alternate nostrils (1800 micrograms daily).

Regimens for **oocyte collection for IVF** use gonadorelin analogues for pituitary desensitisation before ovulation induction with gonadotrophins; the equivalent of 400 micrograms of nafarelin is given intranasally twice daily, beginning either in the early follicular phase (day 2) or midluteal phase (day 21) of the menstrual cycle. Therapy should be continued until downregulation is achieved; if this does not occur within 12 weeks therapy should be withdrawn. Once downregulation occurs gonadotrophin treatment is added to nafarelin therapy until an appropriate stage of follicular development, when both are withdrawn and chorionic gonadotrophin is given to induce ovulation.

Nafarelin has also been given in other sex hormone-related conditions.

Benign prostatic hyperplasia. For a discussion of the management of benign prostatic hyperplasia, including mention of the use of gonadorelin analogues and the view that they are unsatisfactory for indefinite therapy, see p.2178.

Prostate size decreased by a mean of 24.2% in 9 men treated for benign prostatic hyperplasia for 6 months with nafarelin acetate 400 micrograms daily subcutaneously.[1] Six months after the end of treatment, prostate size approached that of pretreatment values.

1. Peters CA, Walsh PC. The effect of nafarelin acetate, a luteinizing-hormone-releasing hormone agonist, on benign prostatic hyperplasia. *N Engl J Med* 1987; **317:** 599–604.

Endometriosis. Gonadorelin analogues are effective in the management of endometriosis (p.2091), but the need for long-term therapy to prevent recurrence limits their value because of the risk of osteoporosis; 'add-back' therapy (hormone replacement) can be used to prevent this.

References to the use of nafarelin.

Fibroids. Gonadorelin analogues have been tried as an adjunct or alternative to surgery in the treatment of uterine fibroids (see p.2107), although there has been some concern that this might complicate the diagnosis of malignancy.

References to the use of nafarelin.

1. Minaguchi H, *et al.* Clinical use of nafarelin in the treatment of leiomyomas: a review of the literature. *J Reprod Med* 2000; **45:** 481–9.

Infertility. Gonadorelin analogues are used in the treatment of infertility (p.2080). As well as being used directly they are employed in regimens to induce superovulation to enable ova collection and IVF. A meta-analysis[1] found that the outcome of IVF treatment using nafarelin was equivalent to that using other gonadorelin analogues, but that nafarelin was associated with a shorter time needed for ovarian stimulation and a reduced gonadotrophin requirement.

1. Wong JM, *et al.* Efficacy of nafarelin in assisted reproductive technology: a meta-analysis. *Hum Reprod Update* 2001; **7:** 92–101.

Porphyria. Nafarelin nasal spray was used to prevent menstrual exacerbations of acute intermittent porphyria (p.1448) in 2 sisters.[1]

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130).

Abuse. Nandrolone, like other anabolic compounds, has been abused by athletes and bodybuilders. However, controversy has arisen over the methods used to detect abuse, and there is some evidence that metabolites of nandrolone may be produced endogenously (see under Precautions of Testosterone, p.2131).

Effects on the liver. Intrahepatic cholestasis occurred in a patient receiving nandrolone cyclohexylpropionate.[1]

1. Gil VG, *et al.* A non-C17-alkylated steroid and long-term cholestasis. *Ann Intern Med* 1986; **104:** 135–6.

Porphyria. Nandrolone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for androgens and anabolic steroids in general (see Testosterone, p.2131).

Uses and Administration

Nandrolone is an anabolic steroid with some androgenic properties (see Testosterone, p.2131). It is usually given as the decanoate ester in the form of oily intramuscular injections. The hexyloxyphenylpropionate, propionate, phenylpropionate, and undecylate esters have also been used.

Doses of nandrolone decanoate 25 to 100 mg once every 3 to 4 weeks have been used as an anabolic after debilitating illness, for postmenopausal osteoporosis, and for postmenopausal metastatic breast carcinoma. Doses of between 50 and 200 mg weekly have been suggested for the treatment of anaemia of chronic renal failure, and doses of 50 to 150 mg weekly for aplastic anaemia.

Nandrolone sodium sulfate has been used topically in the treatment of corneal damage.

Nandrolone cyclohexylpropionate, laurate, and phenylpropionate are used in veterinary medicine.

Cachexia. Nandrolone increased lean body-mass in patients with HIV-associated wasting[1-4] (p.858) and in one study[5] was found to have greater effect than testosterone on body-weight and BMI but a similar effect on lean body-mass. Nandrolone has also increased lean body-mass in patients with end-stage renal failure undergoing dialysis.[6,7] Although caution is generally advised with the use of androgenic and anabolic steroids in patients with renal impairment (see Testosterone, p.2131), a study[8] of nandrolone given for 3 months to patients with predialysis chronic renal impairment found that lean body-mass increased without fluid retention or adverse effect on renal function or serum-lipids. In these reports, intramuscular doses of nandrolone decanoate have ranged from 100 mg once every 2 weeks[4] up to 600 mg weekly,[2] and treatment has generally been given for 12 to 24 weeks.

8. Eiam-Ong S, *et al.* Nutritional effect of nandrolone decanoate in predialysis patients with chronic kidney disease. *J Ren Nutr* 2007; **17:** 173–8.

Male contraception. Preliminary findings showed that nandrolone suppressed spermatogenesis,[1-3] suggesting potential as a male contraceptive (p.2070), but later studies seem to have favoured other androgens.

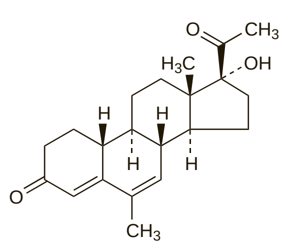
ATC — G03DB04.
ATC Vet — QG03DB04.



(nomegestrol)

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Nomegestrol Acetate). A white or almost white crystalline powder. Practically insoluble in water; soluble in alcohol; freely soluble in acetone. Protect from light.

Profile

Nomegestrol acetate is a progestogen structurally related to progesterone (p.2125) that has been used in the treatment of menstrual disorders and as the progestogen component of menopausal HRT (p.2071). Typical oral doses are 5 mg daily for 10 to 14 days of a 28-day cycle. A subdermal implant is under investigation as a long-acting progestogen-only contraceptive.

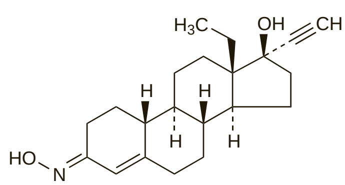
Norelgestromin *(BAN, USAN, rINN)*

17-Deacylnorgestimate; Norelgestromiini; Norelgestromina; Norelgestromine; Norelgestrominum; RWJ-10553. 13-Ethyl-17-hydroxy-18,19-dinor-17α-pregn-4-en-20-yn-3-one oxime.

Норэльгестромин

$C_{21}H_{29}NO_2$ = 327.5.
CAS — 53016-31-2.



Profile

Norelgestromin is a progestogen (see Progesterone, p.2125); it is the primary active metabolite of norgestimate (p.2121). Norelgestromin is used as the progestogenic component of a combined contraceptive transdermal patch. A dose of 150 micrograms of norelgestromin is released daily with ethinylestradiol. A new patch is applied each week for 3 weeks of a 4-week cycle. Norelgestromin exposure from such a patch may be greater than that resulting from a comparable oral contraceptive.

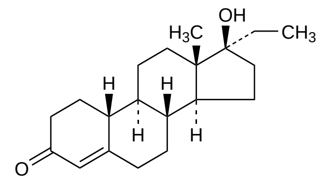
Norethandrolone *(BAN, rINN)* ⊗

17α-Ethyl-17β-hydroxyestr-4-en-3-one; 17β-Hydroxy-19-nor-17α-pregn-4-en-3-one; Noretandrolona; Noréthandrolone; Norethandrolonum.

Норэтандролон

$C_{20}H_{30}O_2$ = 302.5.
CAS — 52-78-8.
ATC — A14AA09.
ATC Vet — QA14AA09.



Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130). As with other 17α-alkylated compounds, norethandrolone may produce hepatotoxicity and liver function should be monitored. It should probably be avoided in patients with impaired liver function, and certainly if this is severe.

Uses and Administration

Norethandrolone is an anabolic steroid with some androgenic properties (see Testosterone, p.2131). It is given in the treatment of aplastic anaemia in an oral dose of 0.25 to 2 mg/kg daily.

Preparations

Proprietary Preparations (details are given in Part 3)

Pharmacopoeias. In *Int.*

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059.

Effects on the liver. There were 6 cases of jaundice among 107 patients with breast cancer treated with high-dose norethisterone acetate;[1] the jaundice was reversible and of an obstructive type. A retrospective analysis[2] found that the use of norethisterone to prevent menstrual haemorrhage during the thrombocytopenic phase of allogeneic bone marrow transplantation was a significant risk factor for hepatic veno-occlusive disease.

1. Langlands AO, Martin WMC. Jaundice associated with norethisterone-acetate treatment of breast cancer. *Lancet* 1975; **i:** 584–5.
2. Hägglund H, *et al.* Norethisterone treatment, a major risk-factor for veno-occlusive disease in the liver after allogeneic bone marrow transplantation. *Blood* 1998; **92:** 4568–72.

Porphyria. Norethisterone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Abnormalities seen in the offspring of women given norethisterone during pregnancy (either alone or with ethinylestradiol) included: hypospadias,[1] masculinisation of female infants,[2] meningomyelocele or hydrocephalus,[3] and neonatal choreoathetosis associated with oral contraceptive use.[4] For reference to the fact that oral contraceptives have not generally been associated with teratogenicity, even when used inadvertently in pregnancy, see p.2067.

1. Aarskog D. Clinical and cytogenetic studies in hypospadias. *Acta Paediatr Scand* 1970; (suppl 203): 1–62.
2. Wilkins L. Masculinization of female fetus due to use of orally given progestins. *JAMA* 1960; **172:** 1028–32.
3. Gal I, *et al.* Hormonal pregnancy tests and congenital malformation. *Nature* 1967; **216:** 83.
4. Profumo R, *et al.* Neonatal choreoathetosis following prenatal exposure to oral contraceptives. *Pediatrics* 1990; **86:** 648–9.

Venous thromboembolism. For mention that combined oral contraceptives containing older progestogens such as norethisterone appear to be associated with a lower incidence of venous thromboembolism than desogestrel- or gestodene-containing preparations, see p.2063.

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Pharmacokinetics

Norethisterone is absorbed from the gastrointestinal tract, undergoing first-pass hepatic metabolism, with peak plasma concentrations occurring 1 to 2 hours after an oral dose. It exhibits biphasic pharmacokinetics; an initial distribution phase is followed by a prolonged elimination phase with a half-life of about 8 hours or more. Norethisterone is highly protein bound; about 60% to albumin and 35% to sex hormone binding globulin. Use with an oestrogen increases the proportion bound to sex hormone binding globulin. It is metabolised in the liver with 50 to 80% of a dose being excreted in the urine and up to 40% appearing in the faeces.

Norethisterone acetate is rapidly hydrolysed to norethisterone, principally by intestinal tissue.

After intramuscular injection of norethisterone enantate peak concentrations of norethisterone in plasma are not attained for several days.

Uses and Administration

Norethisterone and its acetate and enantate esters are progestogens (see Progesterone, p.2126) derived from nortestosterone that have weak oestrogenic and androgenic properties. They are commonly used as **hormonal contraceptives** (see p.2069). Norethisterone and norethisterone acetate are both given orally. Typical daily doses are 350 micrograms for norethisterone and 600 micrograms for norethisterone acetate when used alone, or 0.5 to 1 mg for norethisterone and 1 to 1.5 mg for norethisterone acetate when used with an oestrogen. Norethisterone enantate is given by intramuscular injection; a dose of 200 mg provides contraception for 8 weeks. An intramuscular injection containing norethisterone enantate 50 mg with estradiol valerate 5 mg is given once each month.

Norethisterone and norethisterone acetate are used as the progestogen component of **menopausal HRT** (see p.2076). Typical regimens have included either continuous daily doses of norethisterone 700 micrograms or norethisterone acetate 0.5 to 1 mg, or cyclical regimens of norethisterone or norethisterone acetate 1 mg daily for 10 to 12 days of a 28-day cycle. Norethisterone acetate is also available as transdermal patches supplying 140, 170, or 250 micrograms in 24 hours, that are applied twice weekly for 2 weeks of a 4-week cycle; the lower strengths may also be applied twice weekly on a continuous basis.

Norethisterone and norethisterone acetate may be given orally, usually in divided doses, for the treatment of conditions such as **menorrhagia** (below) and **endometriosis** (p.2091). In menorrhagia (dysfunctional uterine bleeding), norethisterone is given in usual doses of 10 to 15 mg daily and norethisterone acetate in doses of 2.5 to 10 mg daily, in a cyclical regimen. In endometriosis the dosage of norethisterone is 10 to 25 mg daily and of norethisterone acetate 5 to 15 mg daily. Treatment of endometriosis is usually continuous for 4 to 9 months.

Norethisterone has been used in daily doses of up to 15 mg orally in a cyclical regimen in the treatment of **premenstrual syndrome** (p.2099).

In **breast cancer** (p.661) oral doses of up to 60 mg daily of norethisterone have been used.

Administration in children. Although unlicensed in the UK for use in children, the *BNFC* does include norethisterone for the management of delayed puberty (p.2079) in girls. It is added after 12 to 24 months of oestrogen therapy to establish a menstrual cycle and maintain sexual maturation, in an oral dose of 5 mg once daily for the last 7 days of a 28-day cycle.

Menorrhagia. Although cyclical norethisterone has been widely used for menorrhagia (p.2126), it is of limited efficacy during ovulatory cycles[1] being most effective for anovulatory bleeding, which occurs in a minority of women with menorrhagia.

1. Lethaby A, *et al.* Cyclical progestogens for heavy menstrual bleeding. Available in The Cochrane Database of Systematic Reviews; Issue 1. Chichester: John Wiley; 2008 (accessed 27/06/08).

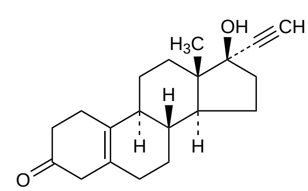
Noretynodrel *(BAN, rINN)*

Norethynodrel *(USAN)*; Noretinodrel; Noretynodreeli; Norétynodrel; Noretynodrelum; NSC-15432; SC-4642. 17β-Hydroxy-19-nor-17α-pregn-5(10)-en-20-yn-3-one.

Норэтинодрел

$C_{20}H_{26}O_2$ = 298.4.

CAS — 68-23-5.



Pharmacopoeias. In *US.*

USP 31 (Norethynodrel). A white or practically white, odourless, crystalline powder. Very slightly soluble in water and in petroleum spirit; sparingly soluble in alcohol; soluble in acetone; freely soluble in chloroform.

Profile

Noretynodrel is a progestogen (see Progesterone, p.2125) structurally related to norethisterone that has been given orally with an oestrogen such as mestranol for the treatment of various menstrual disorders and endometriosis.

Breast feeding. About 1% of an oral dose of radiolabelled noretynodrel was detected in breast milk in a study of 4 women.[1] No adverse effects have been seen in breast-fed infants of mothers given noretynodrel, and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

1. Laumas KR, *et al.* Radioactivity in the breast milk of lactating women after oral administration of H-norethynodrel. *Am J Obstet Gynecol* 1967; **98:** 411–3.
2. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/06/08)

Porphyria. Noretynodrel is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Pregnancy. A woman given noretynodrel during pregnancy to prevent threatened miscarriage gave birth to a female infant showing signs of masculinisation.[1]

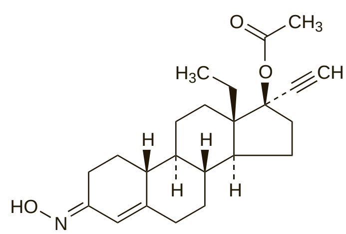
Norgestimate *(BAN, USAN, rINN)*

D-138; Dexnorgestrel Acetime; Norgestimaatti; Norgestimat; Norgestimato; Norgestimatum; ORF-10131; RWJ-10131. 13β-Ethyl-3-hydroxyimino-18,19-dinor-17α-pregn-4-en-20-yn-17β-yl acetate.

Норгестимат

$C_{23}H_{31}NO_3$ = 369.5.

CAS — 35189-28-7.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Norgestimate). A white or almost white powder. Practically insoluble in water; freely soluble in dichloromethane; soluble in acetone.

USP 31 (Norgestimate). A mixture of (*E*)- and (*Z*)-isomers having a ratio of (*E*)- to (*Z*)-isomer between 1.27 and 1.78. A white to pale yellow powder. Insoluble in water; sparingly soluble in acetonitrile; freely to very soluble in dichloromethane.

Profile

Norgestimate is a progestogen (see Progesterone, p.2125) structurally related to levonorgestrel (to which it is partly metabolised) that is used as the progestogenic component of combined oral contraceptives (see p.2058) and in menopausal HRT (see p.2071). A typical daily dose is 250 micrograms in monophasic contraceptive preparations, and 180 to 250 micrograms in triphasic preparations. For HRT, a regimen of estradiol daily for 3 days followed by estradiol with norgestimate 90 micrograms daily for 3 days is used; this 6-day cycle is repeated continuously without interruption.

Preparations

USP 31: Norgestimate and Ethinyl Estradiol Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Cilest; Prefest; Tridette; ***Austria:*** Cileste; Tri-Cilest; Vivelle; ***Belg.:*** Cilest; ***Braz.:*** Prefest; ***Canad.:*** Cyclen; Tri-Cyclen; ***Chile:*** Mactex; Neofam; Orlon; Tri-Mactex; Trifas†; ***Cz.:*** Cilest; Pramino; ***Denm.:*** Cilest; ***Fin.:*** Cilest; ***Fr.:*** Cilest; Effiprev; Triafemi; TriCilest; ***Ger.:*** Cilest; Pramino; ***Hung.:*** Cilest; ***Irl.:*** Cilest; ***Israel:*** Ortho Cyclen; ***Mex.:*** Cilest; Prefest; ***Neth.:*** Cilest; ***Pol.:*** Cilest; ***Rus.:*** Cilest (Силест); ***S.Afr.:*** Cilest; Prefesta; TriCilest; ***Swed.:*** Cilest; ***Switz.:*** Cilest; ***Thai.:*** Cilest; Tri-Cilest; ***UK:*** Cilest; ***USA:*** Ortho Cyclen; Ortho Tri-Cyclen; Prefest; Previfem; Sprintec; Tri-Previfem; Tri-Sprintec; TriNessa; ***Venez.:*** Ortrel.

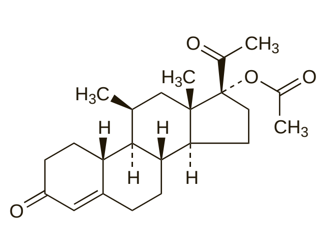
Norgestomet *(BAN, USAN, rINN)*

Norgestometum; SC-21009. 11β-Methyl-3,20-dioxo-19-norpregn-4-en-17α-yl acetate.

Норгестомет

$C_{23}H_{32}O_4$ = 372.5.

CAS — 25092-41-5.



Profile

Norgestomet is a progestogen (see Progesterone, p.2125) used in veterinary medicine with estradiol.

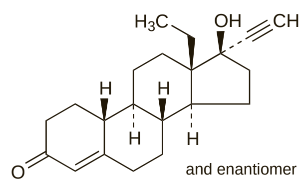
Norgestrel *(BAN, USAN, rINN)*

Norgestreeli; *dl*-Norgestrel; DL-Norgestrel; Norgestrelis; Norgestrelum; Norgesztrel; Wy-3707. (±)-13-Ethyl-17β-hydroxy-18,19-dinor-17α-pregn-4-en-20-yn-3-one.

Норгестрел

$C_{21}H_{28}O_2$ = 312.4.

CAS — 6533-00-2.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Norgestrel). A white or almost white crystalline powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in dichloromethane. Protect from light.

USP 31 (Norgestrel). A white or practically white, practically odourless crystalline powder. Insoluble in water; sparingly soluble in alcohol; freely soluble in chloroform.

Levonorgestrel *(BAN, USAN, rINN)*

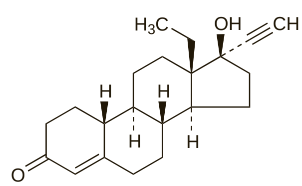
Levonorgestreeli; Lévonorgestrel; Levonorgestrelis; Levonorgestrelum; Levonorgesztrel; D-Norgestrel; Wy-5104. (−)-13β-Ethyl-17β-hydroxy-18,19-dinor-17α-pregn-4-en-20-yn-3-one.

Левоноргестрел

CAS — 797-63-7.

ATC — G03AC03.

ATC Vet — QG03AC03.



NOTE. The name Dexnorgestrel has also been used.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *US.*

Ph. Eur. 6.2 (Levonorgestrel). A white or almost white crystalline powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in dichloromethane. Protect from light.

USP 31 (Levonorgestrel). A white or practically white, odourless powder. Practically insoluble in water; slightly soluble in alcohol; soluble in chloroform. Protect from light.

Adverse Effects and Precautions

As for progestogens in general (see Progesterone, p.2125). See also under Hormonal Contraceptives, p.2059.

Incidence of adverse effects. After the introduction of levonorgestrel in a subdermal implant formulation in February 1991, the US FDA had received about 5800 reports of adverse effects as of December 1993 (out of an estimated 891 000 implants distributed).[1] Serious adverse effects associated with the implant included 24 cases of infection related to insertion of the implant, 15 cases of stroke and 39 of benign intracranial hypertension, 3 cases of thrombocytopenic purpura and 6 of thrombocytopenia (1 fatal). None of the reporting rates for these disorders exceeded the expected rate in this population. In a 5-year cohort study[2] of more than 16 000 women who received either a levonorgestrel implant or an IUD (not progestogen-releasing), or underwent sterilisation, there was no significant risk of major morbidity associated with the implant, although there were moderately elevated risks of gallbladder disease and raised blood pressure in current users.

1. Wysowski DK, Green L. Serious adverse events in Norplant users reported to the Food and Drug Administration's MedWatch Spontaneous Reporting System. *Obstet Gynecol* 1995; **85:** 538–42.
2. Meirik O, *et al.* Safety and efficacy of levonorgestrel implant, intrauterine device, and sterilization. *Obstet Gynecol* 2001; **97:** 539–47.

Benign intracranial hypertension. Intracranial hypertension, presenting as headaches, vomiting, and visual obscuration associated with florid bilateral papilloedema developed in 2 patients 4 to 5 months after subdermal implantation of levonorgestrel.[1] Despite a further 56 cases reported to various drug monitoring centres, and 70 cases known to the manufacturers,[2] it remained unclear whether the drug actually caused intracranial hypertension, but removal of implants was recommended in patients in whom intracranial pressure increased.

1. Alder JB, *et al.* Levonorgestrel implants and intracranial hypertension. *N Engl J Med* 1995; **332:** 1720–1.
2. Weber ME, *et al.* Levonorgestrel implants and intracranial hypertension. *N Engl J Med* 1995; **332:** 1721.

Breast feeding. Levonorgestrel was detected in breast milk and the circulation of breast-fed infants during the use of either a levonorgestrel IUD, subcutaneous implant, or progestogen-only oral contraceptive.[1] A review[2] of studies of a levonorgestrel implant used during lactation concluded that it did not adversely affect the duration of lactation, infant growth or development. Further studies of a levonorgestrel IUD[3] and implant[4] also found no adverse effect on lactation or infant growth. The implant study[4] did find an increased incidence of mild respiratory, skin, and eye diseases in infants in the first year of life, but the possibility of bias or chance could not be excluded. The American Academy of Pediatrics considers that levonorgestrel is usually compatible with breast feeding.[5] Progestogen-only contraceptives should not be started until several weeks after birth if the woman is breast feeding (see Breast Feeding under Hormonal Contraceptives, p.2066).

In a pharmacokinetic study[6] using a single oral dose of levonorgestrel 1.5 mg, the drug concentration peaked between 2 and 4 hours in breast milk and then fell rapidly. The authors suggested that breast-feeding women who are given this dose of levonorgestrel for emergency contraception should be advised to breast feed immediately before the dose, then discard milk for at least 8 hours but not more than 24 hours.

5. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 27/06/08)
6. Gainer E, *et al.* Levonorgestrel pharmacokinetics in plasma and milk of lactating women who take 1.5 mg for emergency contraception. *Hum Reprod* 2007; **22:** 1578–84.

Effects on the blood. Studies[1-3] of women who had been given different levonorgestrel subcutaneous implants found that over 5 years there were various changes in blood clotting factors, fibrinolytic activity, and platelet number and aggregation, some of which persisted even 6 months after removal of the implants. However, these haemostatic changes did not result in activation of the coagulation system or a state of hypercoagulation.

1. Singh K, *et al.* Evaluation of hemostatic function following Norplant implant removal. *Adv Contracept* 1993; **9:** 49–58.
2. Singh K, *et al.* Evaluation of hemostatic function following Norplant-2 rods removal. *Adv Contracept* 1993; **9:** 241–50.
3. Koh SCL, *et al.* A prospective study on the effects of reformulated 2-rod Norplant implant on haemostasis after five years of use. *J Obstet Gynaecol Res* 1999; **25:** 177–83.

Effects on carbohydrate metabolism. For a mention that levonorgestrel has been reported to be the most potent progestogen associated with hyperinsulinaemia when used as a combined oral contraceptive, see p.2061.

Glucocorticoid effects. Reference to the minimal suppressive effect of subdermal levonorgestrel on adrenal function.[1]

1. Toppozada MK, *et al.* Effect of Norplant implants on the pituitary-adrenal axis function and reserve capacity. *Contraception* 1997; **55:** 7–10.

Myasthenia gravis. Myasthenia gravis occurring after insertion of a levonorgestrel implant improved on removal of the implant.[1]

1. Brittain J, Lange LS. Myasthenia gravis and levonorgestrel implant. *Lancet* 1995; **346:** 1556.

Porphyria. Levonorgestrel has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Pregnancy. Adverse effects in infants whose mothers had received oral contraceptives containing norgestrel during early pregnancy have included tracheo-oesophageal fistula in one infant[1] and inoperable hepatoblastoma in another.[2] However, many epidemiological studies have failed to show any association between fetal malformations and oral contraceptives, even when used inadvertently during pregnancy, see p.2067.

1. Frost O. Tracheo-oesophageal fistula associated with hormonal contraception during pregnancy. *BMJ* 1976; **2:** 978.
2. Otten J, *et al.* Hepatoblastoma in an infant after contraceptive intake during pregnancy. *N Engl J Med* 1977; **297:** 222.

Venous thromboembolism. For mention that levonorgestrel-containing combined oral contraceptives appeared to be associated with a lower incidence of venous thromboembolism than desogestrel- or gestodene-containing preparations, see p.2063. See also Effects on the Blood, above.

Interactions

As for progestogens in general (see Progesterone, p.2126). See also under Hormonal Contraceptives, p.2067.

Pharmacokinetics

Levonorgestrel is rapidly and almost completely absorbed after an oral dose, and undergoes little first-pass hepatic metabolism. It is highly bound to plasma proteins; 42 to 68% to sex hormone binding globulin and 30 to 56% to albumin. The proportion bound to sex hormone binding globulin is higher when it is given with an oestrogen. Levonorgestrel and norgestrel are metabolised in the liver to sulfate and glucuronide conjugates, which are excreted in the urine and to a lesser extent in the faeces. Levonorgestrel is distributed into breast milk.

◊ References.

Uses and Administration

Norgestrel and its active (–)-isomer levonorgestrel are progestogens (see Progesterone, p.2126) derived from nortestosterone. They are more potent inhibitors of ovulation than norethisterone and have androgenic activity. Levonorgestrel is more commonly used than norgestrel and is twice as potent. For example, levonorgestrel 37.5 micrograms is equivalent to norgestrel 75 micrograms.

They are both used as **hormonal contraceptives** (see p.2069). The typical daily dose is the equivalent of:

- 30 or 37.5 micrograms of levonorgestrel as an oral progestogen-only contraceptive
- 150 micrograms of levonorgestrel in monophasic combined oral contraceptives (doses may range from a low dose of 100 micrograms of levonorgestrel in some preparations up to 250 micrograms in others; a preparation containing 90 micrograms of levonorgestrel for continuous use without a tablet-free interval is also available)
- 50 to 125 micrograms of levonorgestrel in triphasic preparations

Subcutaneous implants containing levonorgestrel may be used for long-acting progestogen-only contraception. Insertion and removal must be carried out by personnel fully trained in the technique. One available product consists of 2 implants, each containing 75 mg of levonorgestrel. It should be inserted under the skin within the first 7 days of the menstrual cycle, and is effective for up to 5 years. Another product consisting of 6 implants, which also provided up to 5 years of contraception, is no longer widely marketed. Each implant contained 36 mg of levonorgestrel. Uterine, cervical, and vaginal devices containing levonorgestrel have also been investigated. An intra-uterine device is available for contraception or **menorrhagia**, containing a total of 52 mg of levonorgestrel which is released at an initial rate of 20 micrograms per 24 hours. The device is effective for 5 years.

For **emergency contraception** (p.2071), levonorgestrel may be given alone in a single oral dose of 1.5 mg within 72 hours of coitus (preferably as soon as possible). Alternatively, a dose of 750 micrograms is given within 72 hours of coitus (preferably as soon as possible), and repeated after 12 hours. Another regimen uses levonorgestrel 500 micrograms plus ethinylestradiol 100 micrograms, given within 72 hours of coitus and repeated after 12 hours.

Both levonorgestrel and norgestrel are used as the progestogenic component of **menopausal HRT** (see p.2076). Typical regimens are the equivalent of 75 to 250 micrograms of levonorgestrel orally for 10 to 12 days of a 28-day cycle. Levonorgestrel may also be given via a combined transdermal patch, releasing 10 micrograms per 24 hours, which is applied once weekly for 2 weeks of a 4-week cycle. Alternatively, a patch releasing 7 or 15 micrograms per 24 hours with an oestrogen is applied once weekly for continuous HRT. The intra-uterine levonorgestrel device described above may be used for up to 4 years with oestrogen replacement therapy.

Administration. ***IMPLANTS.*** Some references to the use of levonorgestrel by subcutaneous implant for hormonal contraception.[1-3]

Menorrhagia. Although oral cyclical progestogens have limited efficacy in the treatment of menorrhagia (p.2126), the levonorgestrel-containing intra-uterine device appears to be particularly useful in reducing menstrual blood loss. The *BNF* notes that another treatment should be considered if bleeding does not improve within 3 to 6 months of insertion. The use of levonorgestrel has been systematically reviewed.[1]

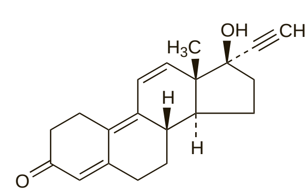
Norgestrienone *(rINN)*

Norgestrienona; Norgestriénone; Norgestrienonum. 17β-Hydroxy-19-nor-17α-pregna-4,9,11-trien-20-yn-3-one.

Норгестриенон

$C_{20}H_{22}O_2$ = 294.4.
CAS — 848-21-5.
ATC — G03AC07.
ATC Vet — QG03AC07.



Profile

Norgestrienone is a progestogen (see Progesterone, p.2125) structurally related to norethisterone that has been used as an oral contraceptive (see p.2058). Typical doses have been 2 mg daily with an oestrogen, and 350 micrograms daily when used alone.

Preparations

Proprietary Preparations (details are given in Part 3)

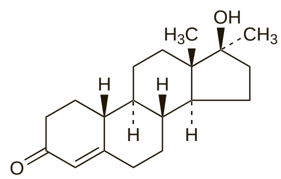
Multi-ingredient: *Fr.:* Planor†.

Normethandrone ⊗

Methylestrenolone; Methylestrenolonum; Methylnortestosterone; 17α-Methyl-19-nortestosterone; Metylöstrenolon; Metyyliestrenoloni; Normethandrolone; NSC-10039. 17β-Hydroxy-17α-methylestr-4-en-3-one.

Норметандрон

$C_{19}H_{28}O_2$ = 288.4.
CAS — 514-61-4.
ATC — G03DC31.
ATC Vet — QG03DC31.



Profile

Normethandrone is a progestogen that also has androgenic and anabolic properties. It has been given orally with an oestrogen for the treatment of amenorrhoea and menopausal disorders.

Preparations

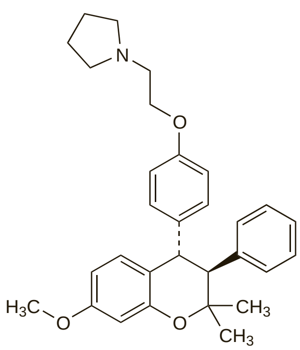
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Braz.:*** Ginecoside†; ***Indon.:*** Mediol; Renodiol; ***Venez.:*** Ginecosid.

Ormeloxifene *(rINN)* ⊗

Centchroman; Orméloxifène; Ormeloxifeno; Ormeloxifenum. *trans*-1-{2-[4-(3,4-Dihydro-7-methoxy-2,2-dimethyl-3-phenyl-2*H*-1-benzopyran-4-yl)phenoxy]ethyl}pyrrolidine.

Ормелоксифен

$C_{30}H_{35}NO_3$ = 457.6.
CAS — 31477-60-8.



Profile

Ormeloxifene is a selective oestrogen receptor modulator with anti-oestrogenic actions and weak oestrogenic activity. It has been given weekly as an oral contraceptive and used for dysfunctional uterine bleeding, and has been investigated in the management of benign breast diseases such as mastalgia. The *l*-isomer, levormeloxifene, which has oestrogenic effects, has been investigated in the management of postmenopausal osteoporosis, but development appears to have been discontinued because of adverse effects.

Pharmacopoeias. In *US.*

USP 31 (Oxandrolone). A white odourless crystalline powder. Soluble 1 in 5200 of water, 1 in 57 of alcohol, 1 in 69 of acetone, 1 in less than 5 of chloroform, and 1 in 860 of ether. Protect from light.

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130). As with other 17α-alkylated compounds, oxandrolone may cause hepatotoxicity, and liver function should be monitored. It should be avoided if hepatic impairment is severe.

Interactions

As for androgens and anabolic steroids in general (see Testosterone, p.2131).

Pharmacokinetics

Oxandrolone is rapidly absorbed from the gastrointestinal tract, and extensively bound to plasma proteins. It is excreted mainly in the urine as unchanged oxandrolone and some metabolites, with an elimination half-life of about 9 to 10 hours. A small amount is excreted in the faeces.

Uses and Administration

Oxandrolone has anabolic and androgenic properties (see Testosterone, p.2131) and is given as adjunctive therapy to promote weight gain in oral doses of 2.5 to 20 mg daily in 2 to 4 divided doses. Treatment is usually given as a course of 2 to 4 weeks, which may be repeated intermittently as required. Elderly patients may be more susceptible to the adverse effects of oxandrolone, and a dose of up to 5 mg twice daily is recommended. See below for doses of oxandrolone used in children.

Administration in children. Oxandrolone has been given to children as adjunctive therapy to promote weight gain in oral doses of up to 100 micrograms/kg daily in 2 to 4 divided doses. Treatment is usually given as a course of 2 to 4 weeks, which may be repeated intermittently as required.

For the promotion of growth in boys with constitutional delay of growth and puberty, and in girls with Turner's syndrome, usual daily doses of 100 micrograms/kg have been used. Treatment may be given for up to a year, but bone age must be assessed during therapy to avoid the risk of premature epiphyseal closure (see also below).

Cachexia. Oxandrolone has been used for its protein anabolic effect in a number of conditions associated with cachexia (p.2115) or wasting,[1] including alcoholic hepatitis, burn injury, HIV-infection, and muscular dystrophy (p.1507).

1. Orr R, Singh MF. The anabolic androgenic steroid oxandrolone in the treatment of wasting and catabolic disorders: review of efficacy and safety. *Drugs* 2004; **64:** 725–50.

Growth retardation. A beneficial effect of oxandrolone on growth rate in *boys* with constitutional delay of growth and puberty (p.2079) has been shown in various studies,[1-6] two of which[2,5] were placebo-controlled. Doses used have included 1.25 or 2.5 mg daily[1-3] and 50 or 100 micrograms/kg daily,[4-6] generally for 3 to 12 months. Although a slight advance in bone age has been noted,[1,4,5] final predicted height[5] and actual adult height[3] was not compromised by oxandrolone therapy. Oxandrolone did not affect the rate of pubertal progression and as the aim of such therapy is primarily to relieve psychosocial difficulties associated with short stature and sexual immaturity, it is not clear that it achieves this.[5]

Oxandrolone is also used for the promotion of growth in *girls* with Turner's syndrome (p.2081), usually added to growth hormone therapy.[7-9]

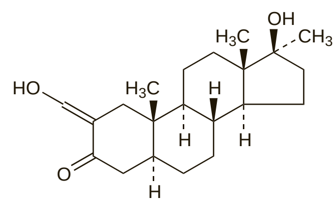
Oxymetholone *(BAN, USAN, rINN)* ⊗

CI-406; HMD; Oksimetolon; Oksimetoloni; Oximetolon; Oximetolona; Oxymétholone; Oxymetholonum. 17β-Hydroxy-2-hydroxymethylene-17α-methyl-5α-androstan-3-one.

Оксиметолон

$C_{21}H_{32}O_3$ = 332.5.
CAS — 434-07-1.
ATC — A14AA05.
ATC Vet — QA14AA05.



Pharmacopoeias. In *Br., Jpn,* and *US.*

BP 2008 (Oxymetholone). A white to creamy-white, odourless or almost odourless, crystalline powder. It exhibits polymorphism. Practically insoluble in water; soluble in alcohol; freely soluble in chloroform; slightly soluble in ether. Protect from light. Avoid contact with ferrous metals.

USP 31 (Oxymetholone). A white to creamy-white, odourless crystalline powder. Practically insoluble in water; soluble 1 in 40 of alcohol, 1 in 5 of chloroform, 1 in 82 of ether, and 1 in 14 of dioxan.

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130).

Liver disturbances and jaundice are common with normal doses and hepatic neoplasms have also been reported (see below). Liver function should be monitored during therapy. As with other 17α-alkylated compounds, oxymetholone should probably be avoided in patients with liver impairment, and certainly if this is severe.

Effects on carbohydrate metabolism. Pronounced hyperglucagonaemia developed in 6 patients receiving oxymetholone.[1]

1. Williams G, *et al.* Severe hyperglucagonaemia during treatment with oxymetholone. *BMJ* 1986; **292:** 1637–8.

Effects on the liver. Peliosis hepatis[1-4] and various liver tumours[4-8] has been associated with oxymetholone use. A review[9] of reports of liver tumours associated with anabolic androgens found that oxymetholone was the androgen most often implicated, and that the majority of tumours were hepatocellular carcinomas.

9. Velazquez I, Alter BP. Androgens and liver tumors: Fanconi's anemia and non-Fanconi's conditions. *Am J Hematol* 2004; **77:** 257–67.

Effects on the nervous system. Toxic confusional state and choreiform movements developed in an elderly man given oxymetholone 200 to 300 mg daily.[1]

1. Tilzey A, *et al.* Toxic confusional state and choreiform movements after treatment with anabolic steroids. *BMJ* 1981; **283:** 349–50.

Uses and Administration

Oxymetholone has anabolic and androgenic properties (see Testosterone, p.2131). It has been used mainly in the treatment of anaemias such as aplastic anaemia at a usual oral dose of 1 to 5 mg/kg daily. Treatment for 3 to 6 months has been suggested, with the drug either withdrawn gradually on remission or reduced to an appropriate maintenance dose.

◊ Reviews.

1. Pavlatos AM, *et al.* Review of oxymetholone: a 17α-alkylated anabolic-androgenic steroid. *Clin Ther* 2001; **23:** 789–801.

Aplastic anaemia. There have been mixed results[1-5] with oxymetholone in the treatment of aplastic anaemia (p.1042); generally, the response and survival rates have been disappointing. Although it was used extensively in the past, oxymetholone is now generally reserved for patients who have failed, or cannot tolerate, immunosuppressant therapy.

Polyestradiol Phosphate *(BAN, rINN)*

Fosfato de poliestradiol; Leo-114; Polyestradiol, Phosphate de; Polyestradiolfosfat; Polyestradioli Phosphas; Polyestradiolifosfaatti; Polyoestradiol Phosphate. A water-soluble polymeric ester of estradiol and phosphoric acid with a molecular weight of about 26 000.

Полиэстрадиола Фосфат

CAS — 28014-46-2.
ATC — L02AA02.
ATC Vet — QL02AA02.

Adverse Effects and Precautions

As for oestrogens in general (see Estradiol, p.2097). Pain may occur at the site of injection, and mepivacaine is included in some preparations to minimise this.

Pharmacokinetics

After intramuscular injection polyestradiol phosphate is released slowly into the bloodstream where it is slowly metabolised to estradiol.

Uses and Administration

Polyestradiol phosphate is a polymer of estradiol (see p.2097) that has a prolonged duration of action, and is used in the treatment of metastatic prostatic carcinoma (p.671). It has been given by deep intramuscular injection in initial doses of 80 to 160 mg every 4 weeks for 2 to 3 months, reduced to 40 to 80 mg every 4 weeks for maintenance. Higher initial doses of 320 mg and maintenance doses of 160 mg have also been used.

Pharmacopoeias. *Chin.* and *Jpn* include the dihydrate.

Profile

Prasterone is a naturally occurring adrenal androgen that is a precursor of androgens and oestrogens. Prasterone enantate, in a dose of 200 mg every 4 weeks, is given by intramuscular depot injection with estradiol valerate as menopausal HRT (p.2076). Prasterone is also being investigated in adrenal insufficiency and in SLE, and the sodium sulfate has been investigated for the treatment of burns and acute asthma.

HIV infection and AIDS. Plasma concentrations of endogenous prasterone are reported to be abnormally low in patients with AIDS, and it has been suggested that use of prasterone might be of benefit; however, large controlled studies are lacking.[1] Small controlled studies have confirmed that oral use increases circulating concentrations of prasterone and its sulfated form, and have reported improvements in quality of life measures[2] and reductions in symptoms of mild depression,[3] but no beneficial antiviral or immunomodulatory effects.[4] Also, there were no significant changes in measures of serum lipids, insulin, growth hormone, or the overall function of the gonadal or hypothalamic-pituitary-adrenal axes.[5]

Replacement therapy. There has been much speculation about the physiological role and importance of prasterone, which is the most abundant steroid hormone in the circulation. It is produced by the adrenal gland and is a precursor of androgens and oestrogens. Serum concentrations peak at about 20 years then gradually decline with age. Epidemiological and *animal* studies suggest that certain age-related diseases may be linked to this decline, including reduced immunocompetence, obesity, diabetes, and cancers.[1] It has been suggested, therefore, that replacement therapy with prasterone might alleviate some of the problems of ageing. Prasterone has been studied for its effect on cognition and memory, sexual function, insulin sensitivity, cardiovascular risk factors, muscle strength and body composition, bone loss, and immune function, but results have generally been conflicting,[1,2] and there is insufficient evidence of safety and efficacy to recommend such use. A systematic review[3] of studies in healthy adults taking prasterone supplementation found no support for an improvement in cognitive function. A review[4] of the use of prasterone as a 'food supplement' noted that although it was being taken in the belief that it could reverse some of the effects of ageing there was no good evidence of this. Various androgenic effects, including hirsutism and voice changes, have been reported in women taking prasterone and there is a theoretical possibility that it might promote growth of hormone-sensitive tumours in both sexes.[1,4]

Prasterone has also been studied as replacement therapy for patients with adrenal insufficiency, who have subnormal levels of prasterone. Such therapy, usually in oral doses of 50 mg daily, has been reported to raise serum levels of prasterone to normal, and improve measures of well-being, mood, and fatigue.[1,5-7] There have been mixed results from studies of the effects of prasterone on carbohydrate metabolism with reports of either no effect[8,9] or increased insulin sensitivity.[10]

Systemic lupus erythematosus. In a number of small studies carried out by one group,[1-5] there was symptomatic improvement in SLE (p.1513), and a reduction in corticosteroid dosage, in women who received oral prasterone 200 mg daily for several months. Although they considered that there was clear evidence of benefit,[6] larger studies[7-9] have produced more statistically ambiguous results. They suggested that prasterone might stabilise or improve disease, and reduce corticosteroid requirements and time to disease flare, but only in patients with active disease. Nested data from one of these studies[10] also showed that prasterone treatment for up to a year improved bone mineral density of the lumbar spine and hip. The results of a larger study designed to confirm this effect on bone were not statistically significant in favour of prasterone, but an open-label 1-year extension study does suggest that long-term treatment might maintain or improve bone mineral density; the full results of these latter studies are yet to be published.[11] In a study[12] of lumbar spine bone mineral density in women with quiescent SLE, prasterone may have had a protective effect in postmenopausal women who were not otherwise treated with oestrogens or bisphosphonates, but there was no change in premenopausal women.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Progesterone). A white or almost white crystalline powder or colourless crystals. It exhibits polymorphism. Practically insoluble in water; freely soluble in dehydrated alcohol; sparingly soluble in acetone and in fatty oils. Protect from light.

USP 31 (Progesterone). A white or creamy-white, odourless, crystalline powder. Practically insoluble in water; soluble in alcohol, in acetone, and in dioxan; sparingly soluble in vegetable oils. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects

Progesterone and the progestogens may cause gastrointestinal disturbances, changes in appetite or weight, fluid retention, oedema, acne, chloasma (melasma), allergic skin rashes, urticaria, mental depression, breast changes including discomfort or occasionally gynaecomastia, changes in libido, hair loss, hirsutism, fatigue, drowsiness or insomnia, fever, headache, premenstrual syndrome-like symptoms, and altered menstrual cycles or irregular menstrual bleeding. Anaphylaxis or anaphylactoid reactions may occur rarely. Alterations in the serum lipid profile may occur, and rarely alterations in liver-function tests and jaundice. Pain, diarrhoea, and flatulence have followed rectal use. Injection-site reactions have followed parenteral use.

Adverse effects vary depending on the dose and type of progestogen. For example, androgenic effects such as acne and hirsutism are more likely to occur with nortestosterone derivatives such as norethisterone and norgestrel. These derivatives may also be more likely to adversely affect serum lipids. Conversely, adverse effects on serum lipids appear less likely with gestodene and desogestrel, but these 2 drugs have been associated with a higher incidence of thromboembolism than norethisterone and norgestrel when used in combined oral contraceptives (see p.2063). High doses of progestogens such as those used in treating cancer have also been associated with thromboembolism. For a discussion of the effect of progestogens on the cardiovascular risk profile of menopausal HRT see p.2073. Breakthrough uterine bleeding is more common with oral progestogen-only contraceptives than when progestogens are used for menstrual irregularities or as part of menopausal HRT.

Some progestogens when given during pregnancy have been reported to cause virilisation of a female fetus. This appears to have been associated with those progestogens with more pronounced androgenic activity such as norethisterone; the natural progestogenic hormone progesterone and its derivatives such as dydrogesterone and medroxyprogesterone do not appear to have been associated with such effects.

For the adverse effects of progestogens when administered either alone or with oestrogens as contraceptives, see p.2059. For those of menopausal HRT, see p.2071.

Carcinogenicity. In a cohort study[1] of women aged 40 to 64 years, the premenopausal use of oral progestogens alone, mainly for benign breast, uterine, and ovarian conditions, and irregular menstruation, was not associated with an increased risk of breast cancer. However, the data did suggest that there was an increased risk for current users of progestogens for longer than 4.5 years (relative risk 1.44, 95% confidence interval 1.03 to 2.00) compared with women who had never used progestogens. Limitations of this study included the lack of analysis of different progestogens or a record of the reasons for progestogen treatment.

1. Fabre A, *et al.* Oral progestagens before menopause and breast cancer risk. *Br J Cancer* 2007; **96:** 841–4.

Effects on the skin. Auto-immune progesterone dermatitis includes reactions such as eczema, urticaria, and angioedema that usually begin 3 to 10 days before the onset of menstrual flow and end 1 to 2 days into menses, which correlates with raised endogenous progesterone concentrations during the luteal phase of the menstrual cycle. The onset of the condition can be as early as menarche, and many women have never been exposed to exogenous progesterone, but it has also occurred in women with a history of oral contraceptive use. Management has been based on the suppression of endogenous progesterone secretion and oral contraceptives are usually tried first, although they appear to have limited success possibly because of the progestogen component. Other drugs that have been used include corticosteroids, conjugated oestrogens, gonadorelin analogues, androgens, and tamoxifen, but all have significant adverse effects associated with long-term use. Bilateral oophorectomy has been used in severe cases, when drug therapy has been unsuccessful.[1]

A woman with a history of auto-immune progesterone dermatitis developed pruritic, pink, oedematous plaques and macules on the upper thighs, axillae, and buttocks after the use of vaginal progestogen gel during infertility treatment.[2] The reaction was managed with topical corticosteroids. In another woman, with a history of chronic urticaria exacerbated by progesterone, the use of progesterone and various other progestogens as a component of HRT after oophorectomy caused urticaria and angioedema.[3] Desensitisation using micronised progesterone was successful in this case.

3. Poole JA, Rosenwasser LJ. Chronic idiopathic urticaria exacerbated with progesterone therapy treated with a novel desensitization protocol. *J Allergy Clin Immunol* 2004; **114:** 456–7.

Precautions

Progesterone and the progestogens should be used with caution in patients with hypertension, cardiac or renal impairment, asthma, epilepsy, and migraine, or other conditions which may be aggravated by fluid retention. Progestogens can decrease glucose tolerance and diabetic patients should be carefully monitored. They should also be used with care in persons with a history of depression. High doses should be used with caution in patients susceptible to thromboembolism.

Progesterone and the progestogens should not be given to patients with undiagnosed vaginal bleeding, nor to those with a history or current high risk of arterial disease and should generally be avoided in hepatic impairment, especially if severe. Unless progestogens are being used as part of the management of breast or genital-tract carcinoma they should not be given to patients with these conditions.

Although progestogens have been given as hormonal support during early pregnancy such use is not now generally advised. However, the use of a progesterone-type progestogen might still be considered for women who are progesterone-deficient. Such use may prevent spontaneous evacuation of a dead fetus, therefore careful monitoring of pregnancy is required. Progestogens should not be used diagnostically for pregnancy testing and should not be given in missed or incomplete abortion.

For precautions to be observed when progestogens are used as contraceptives, see p.2065. For those to be observed when progestogens are used in preparations for menopausal HRT, see p.2075.

Abuse. A case report of abuse of and dependency on progesterone.[1]

1. Keefe DL, Sarrel P. Dependency on progesterone in woman with self-diagnosed premenstrual syndrome. *Lancet* 1996; **347:** 1182.

Breast feeding. A large study[1] compared a contraceptive progesterone-releasing vaginal ring and a copper IUD for 1 year in breast-feeding women. There was little difference in infant weight gain during the study, although at 12 months the infants of mothers using the IUD were breast-fed less frequently, receiving more supplementary feeding, and were heavier. There was no adverse effect of progesterone on lactation or infant growth. Further smaller studies[2,3] have also found no adverse effect on lactation or infant growth. The American Academy of Pediatrics has found no reports of adverse effects in breast-fed infants of mothers given progesterone, and therefore considers it to be usually compatible with breast feeding.[4]

Porphyria. Progesterone and progestogens have been associated with acute attacks of porphyria and are considered unsafe in patients with porphyria (but medroxyprogesterone has been used with buserelin to suppress premenstrual exacerbations of porphyria, see p.2084). Progestogens should generally be avoided by all women with porphyria; however, where non-hormonal contraception is inappropriate, progestogens may be used with extreme caution if the potential benefit outweighs the risk. The risk of an acute attack is greatest in women who have had a previous attack or are under 30 years of age. Long-acting progestogen preparations should never be used in those at risk.

Pregnancy. In Hungary, where 30% of all pregnant women were given hormonal support therapy with progestogens during the early 1980s, a case-control study suggested that there was a causal relationship between such treatment and hypospadias in their offspring.[1] Mixed results have been reported in other studies of the association between maternal progestogen use and the risk of hypospadias, but the indications and types of progestogens used in early pregnancy have also changed over time (for example, withdrawal bleeding induced by progestogens as a form of pregnancy testing is no longer used, and progestogen luteal support in early pregnancy is no longer recommended for routine use; see also Miscarriage, below). Nevertheless, results from a more recent case-control study[2] of deliveries between October 1997 and December 2000 suggested an increase in risk of at least twofold.

There have also been reports of nongenital malformations, including limb reduction defects, neural tube defects, and congenital heart malformations, following intra-uterine exposure to progestogens in early pregnancy. However, numerous analyses of accumulated data have found no evidence of a recognisable malformation syndrome.[3]

For details of individual case reports, see Pregnancy under Dydrogesterone (p.2096), Hydroxyprogesterone (p.2110), Norethisterone (p.2120), and Noretynodrel (p.2121). For the effects of hormonal contraceptive use during early pregnancy, see p.2067. For the risk of ectopic pregnancy with progestogen-only contraceptives, see p.2061.

3. Brent RL. Nongenital malformations following exposure to progestational drugs: the last chapter of an erroneous allegation. *Birth Defects Res A Clin Mol Teratol* 2005; **73:** 906–18.

Veterinary use. An FAO/WHO expert committee examining the risks from residue of veterinary drugs in foodstuffs established an acceptable daily intake for progesterone, but concluded that there would be no need to specify a numerical maximum residue limit for progesterone in the edible tissues of cattle when products are used as growth promotors according to good practice.[1] However, it should be noted that in the EU the use of steroidal hormones such as progestogens in veterinary practice is restricted, and their use as growth promotors is banned.

Interactions

Enzyme-inducing drugs such as carbamazepine, griseofulvin, phenobarbital, phenytoin, and rifampicin may enhance the clearance of progesterone and the progestogens. These interactions are likely to reduce the efficacy of progestogen-only contraceptives (see p.2067), and additional or alternative contraceptive measures are recommended.

Aminoglutethimide markedly reduces the plasma concentrations of medroxyprogesterone acetate and megestrol, possibly through a hepatic enzyme-inducing effect; an increase in progestogen dose is likely to be required.

Since progesterone and other progestogens can influence diabetic control an adjustment in antidiabetic dosage could be required. Progestogens may inhibit ciclosporin metabolism leading to increased plasma-ciclosporin concentrations and a risk of toxicity (see p.1828).

Pharmacokinetics

Progesterone has a short elimination half-life and undergoes extensive first-pass hepatic metabolism when given orally; oral bioavailability is very low although it may be increased somewhat by an oily vehicle and by micronisation. Progesterone is absorbed when given buccally, rectally, or vaginally, and rapidly absorbed from the site of an oily intramuscular injection.

Various derivatives have been produced to extend the duration of action and to improve oral activity. Esters of progesterone derivatives such as hydroxyprogesterone caproate are used intramuscularly, and megestrol acetate is orally active. The ester medroxyprogesterone acetate is used orally and parenterally. 19-Nortestosterone progestogens have good oral activity because the 17-ethinyl substituent slows hepatic metabolism.

Progesterone and the progestogens are highly protein bound; progesterone is bound to albumin and corticosteroid binding globulin; esters such as medroxyprogesterone acetate are principally bound to albumin; and 19-nortestosterone analogues are bound to sex-steroid binding globulin and albumin. Progesterone is metabolised in the liver to various metabolites including pregnanediol, which are excreted in the urine as sulfate and glucuronide conjugates. Similarly, progestogens undergo hepatic metabolism to various conjugates, which are excreted in the urine. Progesterone is distributed into breast milk.

Uses and Administration

Progesterone is a natural hormone whereas progestogens are synthetic compounds, derived from progesterone or 19-nortestosterone, with actions similar to those of progesterone (for further details, see p.2058).

Progestogens derived from 19-nortestosterone are used as **hormonal contraceptives** (see p.2069), either alone or combined with an oestrogen. The progesterone derivative medroxyprogesterone acetate is also used, and progesterone itself has been used.

Progestogens, and sometimes progesterone, are used with oestrogens for **menopausal HRT** (p.2076) to reduce the increased risk of endometrial hyperplasia and carcinoma that occurs when long-term oestrogen therapy is unopposed.

Similarly, drugs with progestogenic actions may be used in **menstrual disorders** such as dysmenorrhoea (p.6) and menorrhagia associated with dysfunctional uterine bleeding (below). Progestogens may also be used in the management of endometriosis (p.2091). Although progestogens and progesterone have been used for the management of the premenstrual syndrome (below), such a practice is of debatable value.

Progestogens may be valuable in advanced **endometrial cancer** (p.663) and have been tried in some other malignancies. The progestogens typically used for malignant disease include medroxyprogesterone acetate, megestrol, and norethisterone. Some progestogens such as megestrol and medroxyprogesterone are used for the **cachexia** or wasting associated with severe illness including cancer and AIDS (p.2115).

Progestogens have been widely advocated for either the prevention of **recurrent miscarriage** or the treatment of threatened miscarriage (below). However, there is little evidence of any benefit from such a practice and the use of progestogens in early pregnancy is not now generally advised, with the exception of the use of progesterone or a progesterone derivative in women who are progesterone deficient (see also Precautions, above). Progesterone is, however, the preferred drug for luteal support in women undergoing **assisted reproductive techniques** such as IVF (see Infertility, p.2080).

USES AND ADMINISTRATION OF PROGESTERONE. Progesterone is usually given as an oily intramuscular injection, a vaginal gel or pessaries, or as suppositories. Preparations containing micronised progesterone are also available for oral and vaginal use.

In dysfunctional uterine bleeding or amenorrhoea 5 to 10 mg daily of progesterone may be given by intramuscular injection for about 5 to 10 days until 2 days before the anticipated onset of menstruation. Alternatively, progesterone may be given for amenorrhoea as a vaginal gel at a usual dose of 45 mg on alternate days for up to 6 doses; the dose may be increased to 90 mg in those who do not respond to the lower dose. An oral dose of 400 mg given daily at bedtime for 10 days may also be used for amenorrhoea.

In women with a history of recurrent miscarriage and proven progesterone deficiency, twice weekly intramuscular injection (increased to daily if necessary) of 25 to 100 mg of progesterone, from about day 15 of the pregnancy until 8 to 16 weeks, has been used. The dose may be increased to 200 mg daily if necessary. Vaginal doses of micronised progesterone 200 to 400 mg daily, in 2 divided doses, have also been given until week 12 of pregnancy. A similar intramuscular schedule has been used for luteal support in IVF or gamete intra-fallopian transfer techniques with treatment beginning on the day of transfer of embryo or gametes. Alternatively, progesterone may be given vaginally in assisted reproduction, but doses can vary widely depending on the preparation. A vaginal gel may be given at a dose of 90 mg daily; it is given for 30 days if pregnancy occurs, and may be continued until there is placental autonomy (up to 10 to 12 weeks). A dose of 90 mg twice daily has been used in women with ovarian failure. A vaginal tablet containing micronised progesterone 100 mg may be given 2 or 3 times daily; treatment is started at oocyte retrieval and continued for up to 10 weeks. Some soft capsules containing micronised progesterone may also be suitable for intravaginal use in a dose of 400 to 600 mg daily, in 2 or 3 divided doses, from the day of gonadotrophin administration until week 12 of pregnancy.

Progesterone may be given vaginally or rectally in doses of 200 mg daily to 400 mg twice daily for the management of the premenstrual syndrome. Treatment usually starts on day 12 to 14 of the menstrual cycle and continues until the onset of menstruation. Similar vaginal or rectal doses have also been used in the treatment of puerperal (post-natal) depression.

Progesterone has been given as the progestogen component of menopausal HRT. Soft capsules containing micronised progesterone are available in some countries for oral use, given in a dose of 200 mg daily at bedtime for 12 to 14 days of each month. Alternatively, a dose of 100 mg daily may be given from day 1 to 25 of each cycle, resulting in less withdrawal bleeding.

A progesterone-releasing intra-uterine device has been used as a hormonal contraceptive; the device contains 38 mg of progesterone and is effective for up to 12 months. A vaginal ring device that releases 10 mg of progesterone daily is used in some countries for contraception in lactating women. The first ring is inserted 6 weeks after delivery, then replaced every 90 days.

Administration. A number of progesterone creams for *topical* application to the skin are promoted in various countries for the management of menopausal symptoms and conditions associated with progesterone deficiency. These are sometimes described as containing 'natural' progesterone or phytoprogesterone from plant sources. However, many of these products are available without prescription or medical consultation and there has been some concern about their safety and efficacy. Reviews[1,2] have found early studies reporting that absorption of progesterone from these creams was minimal. However, a later study[3] using liquid chromatography-tandem spectrometry of whole blood reported that steady-state progesterone exposure was similar for women given either oral micronised progesterone or topical cream.[3] The authors suggested that the differences between their results and previous studies were likely to have been caused by the use of different analytical techniques, and that women using these creams may in fact be exposed to higher systemic concentrations of progesterone than previously thought. Some proponents of topical progesterone therapy have questioned the importance of using serum concentrations as a marker for absorption. A review[4] concluded that available serum-progesterone concentrations probably remain low after topical use and that further studies on the pharmacokinetics of topical progesterone are needed. In terms of efficacy, a number of small controlled studies have not shown progesterone cream to be any better than placebo for the management of menopausal vasomotor symptoms or the prevention of bone loss, and mixed results have been reported regarding the prevention of endometrial proliferation associated with oestrogen therapy.[1,2,4]

Menorrhagia. Menorrhagia, or excessive menstrual bleeding, is usually defined as a blood loss exceeding 80 mL per menstrual period,[1,2] compared with a normal loss of about 30 mL. However, many women consider losses below 80 mL to be excessive particularly if 'flooding' occurs. Although not life-threatening, menorrhagia can lead to iron deficiency anaemia and considerably impair quality of life. Menorrhagia may be associated with pelvic disorders such as fibroids or endometriosis, the use of copper IUDs, or some systemic disorders.[1-3] However, most commonly it is associated with dysfunctional uterine bleeding;[1] a term used to denote frequent, prolonged or heavy uterine bleeding for which no specific cause is found (essential, idiopathic, or primary menorrhagia). Both ovulatory (regular) and anovulatory cycles may give rise to dysfunctional uterine bleeding.[2] In general, medical treatment is used initially in women with no underlying uterine abnormalities.[3] The most commonly used drugs are NSAIDs, tranexamic acid, combined oral contraceptives, and progestogens, and choice of therapy may be influenced by the contraceptive needs of the patient.[1-3] Surgery can be used if medical management is ineffective, and may be considered for first-line treatment in selected patients.[3]

NSAIDs such as mefenamic acid, ibuprofen, and naproxen have been widely used. They reduce menstrual blood loss by about 20 to 50%, and there does not seem to be evidence to suggest that one NSAID is more effective than another.[1] They are taken only during the menstrual phase, which reduces adverse effects, and probably improves patient compliance; they also have the benefit of relieving dysmenorrhoea (p.6).[1] Systematic review[4] suggests that NSAIDs are less effective than tranexamic acid, danazol, and intra-uterine levonorgestrel in reducing bleeding. NSAIDs are considered a suitable option when hormonal therapy is not acceptable. They should be stopped if symptoms do not improve within three menstrual cycles, but can be used for as long as the patient finds them to be beneficial.[3]

Given during menstruation *tranexamic acid* reduces menstrual blood loss by about half;[1] the benefits of tranexamic therapy have been confirmed by systematic review.[5] Like NSAIDs, tranexamic acid is considered a suitable option when hormonal therapy is not acceptable. It should be stopped if symptoms do not improve within three menstrual cycles, but can be used for as long as the patient finds it to be beneficial.[3] *Etamsylate* has been used for menorrhagia, but it is less effective than NSAIDs and tranexamic acid, and is no longer recommended.[1,3]

In women who require contraception, a *combined oral contraceptive* appears to be effective,[1,3] although good evidence of this is actually lacking.[6] It has been suggested that extended-cycle regimens should be considered for women with menorrhagia, as there are fewer bleeding episodes per year of treatment.[2] Traditional therapy with *progestogens* such as norethisterone or medroxyprogesterone given during the luteal phase appears to be ineffective in women with normal ovulatory cycles,[1,3,7] although cyclical therapy may be of benefit in anovulatory patients as it imposes a cycle.[2] Progestogen therapy for 21 days of the cycle results in a significant reduction in menstrual blood loss,[1,3,7] but is associated with adverse effects that may limit its acceptability. Long-acting injectable progestogens, such as medroxyprogesterone acetate, reduce menstrual blood loss or induce amenorrhoea when they are used as contraceptives. They have therefore been used for menorrhagia, although specific studies for this indication are lacking.[1,3]

More recently, a contraceptive *levonorgestrel-containing IUD* has been shown to be very effective in reducing menstrual blood loss in menorrhagia.[1,2] UK guidelines[3] suggest that it should be considered first when either hormonal or non-hormonal treatment is acceptable and long-term use is anticipated, although comparative data are scanty.[8] There is also some evidence that it may be an effective alternative to surgery, but data from long-term follow-up are needed.[9] As there can be changes in bleeding pattern associated with this device, particularly in the first few cycles, use for at least 6 months is advised to enable full assessment of benefit.[3]

Danazol is also effective,[10] producing about a 50% reduction in menstrual blood loss,[1] but has significant adverse effects and treatment is usually limited to 3 to 6 months. *Gonadorelin analogues* are effective for menorrhagia associated with fibroids (p.2107).[1] When used pre-operatively for endometrial thinning, they produce more consistent results than danazol.[11] Gonadorelin analogues may therefore be considered before surgery or when other options for fibroids are contra-indicated, but 'add-back' hormone replacement is recommended for the management of adverse effects from oestrogen deficiency or if they are used for more than 6 months.[3]

In patients who fail to respond to drug treatment, or in whom such therapy is inappropriate, various *surgical options* exist. Conservative surgical techniques, where the endometrium is ablated or resected, are increasingly being used, and are an effective alternative to hysterectomy.[3,12] Hysterectomy is the ultimate therapy, but is associated with significant morbidity.

Miscarriage. Threatened miscarriage is a common complication of pregnancy that presents before 20 weeks of gestation as vaginal bleeding, with or without abdominal pain, while the cervix is closed and the fetus is viable. Endogenous progesterone is normally produced by the corpus luteum to maintain pregnancy, and low concentrations have been associated with pregnancy loss. Progestogen therapy has therefore been widely used in the treatment of threatened miscarriage,[1] but there is a paucity of clinical study data to support routine use.[2] Similarly, progestogens have been used prophylactically to prevent miscarriage, but studies have suffered from various limitations.[3] A systematic review[4] found no evidence to support routine use, but there was limited evidence to suggest that women with a history of recurrent miscarriage (3 or more consecutive miscarriages) might gain some benefit. The *BNF* advises that progestogen prophylaxis in women with a history of recurrent miscarriage is not recommended. (See also Pregnancy, above, for reports of hypospadias in the offspring of women given hormonal support therapy.)

Premature labour. Recommendations have been made regarding progesterone therapy for the prevention of premature birth in women at risk of preterm delivery (see under Hydroxyprogesterone Caproate, p.2110).

Premenstrual syndrome. Progestogen therapy was once popular for premenstrual syndrome, but beneficial responses have not been universally achieved and the theory that progesterone was necessary to correct a hormone imbalance is now losing ground (see p.2099). Progesterone has been given orally, vaginally, and rectally, in continuous and luteal phase regimens. However, systematic reviews[1,2] have found no convincing evidence to support its use.

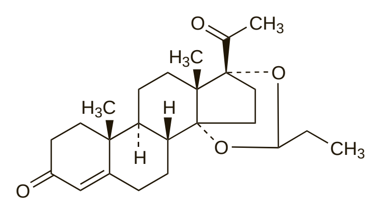
Proligestone *(BAN, rINN)*

Proligeston; Proligestona; Proligestoni; Proligestonum. 14a,17α-Propylidene dioxypregn-4-ene-3,20-dione.

Пролигестон

$C_{24}H_{34}O_4$ = 386.5.
CAS — 23873-85-0.
ATC Vet — QG03DA90.



Profile

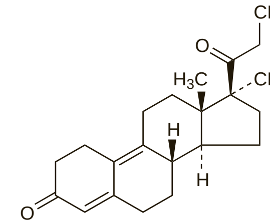
Proligestone is a progestogen used in veterinary medicine.

Promegestone *(rINN)*

Promegestona; Promégestone; Promegestonum; R-5020. 17α-Methyl-17-propionylestra-4,9-dien-3-one.

Промегестон

$C_{22}H_{30}O_2$ = 326.5.
CAS — 34184-77-5.
ATC — G03DB07.
ATC Vet — QG03DB07.



Profile

Promegestone is a progestogen structurally related to progesterone (p.2125). It has been given orally on a cyclical basis, in doses of 125 to 500 micrograms daily, in the treatment of menstrual disorders and mastalgia, and as the progestogen component of menopausal HRT.

Preparations

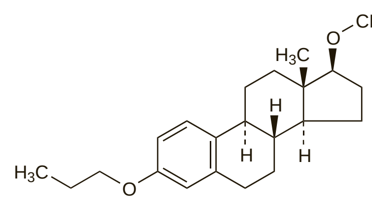
Proprietary Preparations (details are given in Part 3)
Fr.: Surgestone; ***Port.:*** Surgestone.

Promestriene *(rINN)*

Promestrien; Promestriène; Promestrieno; Promestrienum. 17β-Methoxy-3-propoxyestra-1,3,5(10)-triene.

Прометриен

$C_{22}H_{32}O_2$ = 328.5.
CAS — 39219-28-8.
ATC — G03CA09.
ATC Vet — QG03CA09.



Profile

Promestriene is a derivative of estradiol (p.2097) that has been used topically in menopausal atrophic vaginitis, and in seborrhoea and acne.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Colpotrophine; ***Braz.:*** Colpotrofine; ***Cz.:*** Colpotrophine†; ***Hong Kong:*** Colpotrophine; ***Ital.:*** Colpotrophine; ***Mex.:*** Colpotrophine; ***Port.:*** Colpotrophine; ***Singapore:*** Colpotrophine; ***Spain:*** Colpotrofin; Delipoderm; ***Switz.:*** Colpotrophine; ***Turk.:*** Colpotrophine; ***Venez.:*** Colpotrofina†.

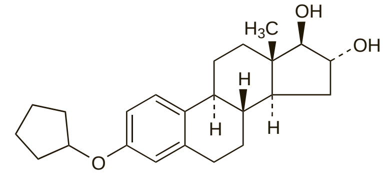
Multi-ingredient: ***Cz.:*** Colposeptine†; ***Hong Kong:*** Colposeptine; ***Port.:*** Trophoseptine; ***Turk.:*** Colposeptine.

Quinestradol *(BAN, rINN)*

Oestriol 3-Cyclopentyl Ether; Quinestradiol; Quinestradolum. 3-Cyclopentyloxyestra-1,3,5(10)-triene-16α,17β-diol.

Хинэстрадол

$C_{23}H_{32}O_3$ = 356.5.
CAS — 1169-79-5.



Profile

Quinestradol is a synthetic oestrogen that has been given orally for the treatment of menopausal vaginal symptoms.

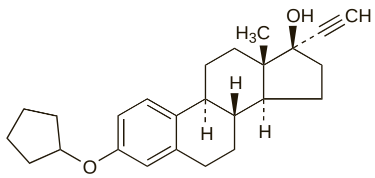
Quinestrol *(BAN, USAN, rINN)*

17α-Ethinyloestradiol 3-cyclopentyl Ether; Quinestrolum; W-3566. 3-Cyclopentyloxy-19-nor-17α-pregna-1,3,5(10)-trien-20-yn-17β-ol.

Хинэстрол

$C_{25}H_{32}O_2$ = 364.5.

CAS — 152-43-2.



Pharmacopoeias. In *Chin.*

Profile

Quinestrol is a synthetic oestrogen that has a prolonged duration of action and is metabolised to ethinylestradiol (p.2101). Quinestrol has been given orally for the treatment of menopausal symptoms and other conditions arising from oestrogen deficiency. It has also been used as the oestrogen component of combined oral contraceptive preparations.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Qui-Lea.
Multi-ingredient: *Arg.:* Soluna.

Raloxifene Hydrochloride

(BANM, USAN, rINNM) ⊗

Hidrocloruro de keoxifeno; Hidrocloruro de raloxifeno; Keoxifene Hydrochloride; LY-156758; LY-139481 (raloxifene); Raloksifen Hidroklorür; Raloxifène, chlorhydrate de; Raloxifeni hydrochloridum. 6-Hydroxy-2-(*p*-hydroxyphenyl)benzo[*b*]thien-3-yl-*p*-(2-piperidinoethoxy)phenyl ketone hydrochloride.

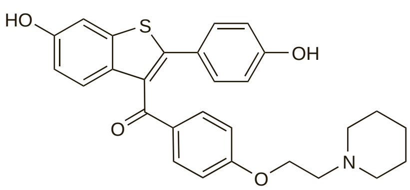
Ралоксифена Гидрохлорид

$C_{28}H_{27}NO_4S,HCl$ = 510.0.

CAS — 84449-90-1 (raloxifene); 82640-04-8 (raloxifene hydrochloride).

ATC — G03XC01.

ATC Vet — QG03XC01.



(raloxifene)

Pharmacopoeias. In *US.*

USP 31 (Raloxifene Hydrochloride). An almost white to pale yellow powder. Very slightly soluble in water, in isopropyl alcohol, and in octanol; slightly soluble in alcohol; sparingly soluble in methyl alcohol; freely soluble in dimethyl sulfoxide; practically insoluble in ether and in ethyl acetate.

Adverse Effects

The most common adverse effects of raloxifene are hot flushes, leg cramps, and a flu-like syndrome. Raloxifene is associated with an increased risk of venous thromboembolic events, particularly during the first 4 months of treatment. Peripheral oedema has also been reported. Rashes, gastrointestinal disturbances, thrombocytopenia, increased blood pressure, headache including migraine, and mild breast symptoms such as pain, enlargement, and tenderness have occurred very rarely.

Incidence of adverse effects. An observational cohort study[1] examined postmarketing adverse events that occurred during raloxifene use in primary care in England. The cohort of 13 987 patients consisted largely of women aged about 62 years, who were receiving raloxifene for the prevention or treatment of osteoporosis. Of the 461 events reported, the most common included flushing, headache or migraine, malaise or lassitude, cramp, oedema, sweating, depression, weight gain, and gastrointestinal disturbances such as nausea, vomiting, dyspepsia, and diarrhoea. Other less common effects included mastalgia and other breast symptoms, vaginal bleeding, thrombophlebitis, and visual disturbances. Rare events included cerebrovascular attack, transient ischaemic attack, pulmonary embolus, deep-vein thrombosis, bullous eruption, leucopenia, thrombocytopenia, upper gastrointestinal haemorrhage, and perforated duodenal ulcer.

The incidence of *cardiovascular* effects associated with raloxifene treatment was examined in the 4-year Multiple Outcomes of Raloxifene Evaluation (MORE), which studied its effects in postmenopausal women with osteoporosis, and in a subsequent 4-year follow-up (Continuing Outcomes Relevant to Evista; CORE).[2] There were 7705 women in the MORE study, of whom 4011 were enrolled in CORE. Overall no significant differences were seen between active treatment and placebo for any cardiovascular event over the 8 years; the calculated incidence was 72 per 10 000 woman-years in those taking raloxifene and 62 per 10 000 in the placebo group. Another large placebo-controlled study[3] (Raloxifene Use for The Heart: RUTH) investigated the cardiovascular effects of raloxifene in postmenopausal women with, or at increased risk of, ischaemic heart disease. After treatment for about 5 years there was no significant difference between the groups for overall cardiovascular events and related deaths. However, in those given raloxifene there was an increased risk of fatal stroke (absolute risk increase, 0.7 per 1000 women-years) and venous thromboembolism (1.2 per 1000 women-years).

3. Barrett-Connor E, *et al.* Effects of raloxifene on cardiovascular events and breast cancer in postmenopausal women. *N Engl J Med* 2006; **355:** 125–37.

Effects on the liver. Hepatitis, probably associated with the drug, occurred in a woman a month after starting raloxifene.[1] Non-alcoholic steatohepatitis was associated with raloxifene in a woman with minor liver dysfunction, a fatty liver, and a family history of cryptogenic liver cirrhosis.[2] Her liver function worsened during the 3 months after starting the drug, and had returned to baseline 3 months after stopping.

1. Vilches AR, *et al.* Raloxifene-associated hepatitis. *Lancet* 1998; **352:** 1524–5.
2. Takamura T, *et al.* Selective estrogen receptor modulator raloxifene-associated aggravation of nonalcoholic steatohepatitis. *Intern Med* 2007; **46:** 579–81.

Precautions

Raloxifene should be avoided in women with active venous thromboembolism, or a history of thromboembolic disorders. It should be stopped at least 72 hours before periods of prolonged immobilisation, such as post-surgical recovery. Raloxifene should be used with caution in women with risk factors for venous thromboembolism including congestive heart failure or active malignancy, or risk factors for stroke such as transient ischaemic attack or atrial fibrillation. It should be avoided in hepatic and severe renal impairment, and used with caution in moderate renal impairment (but see also Administration in Renal Impairment, below).

Raloxifene had adverse effects in *animal* teratogenicity studies and should not be used in women who are or may become pregnant. It should not be given to women with undiagnosed uterine bleeding. An increase in triglycerides has been reported in some women with a history of hypertriglyceridaemia caused by oestrogen therapy.

Interactions

Colestyramine reduces the absorption and enterohepatic recycling of raloxifene, and they should not be given together. Raloxifene may decrease the efficacy of warfarin.

Fibrates. Cholestasis developed when *fenofibrate* was given to a woman who had been on raloxifene therapy for about 3 years.[1] The authors reviewed other rare reports of liver reactions to either raloxifene or fibrates and suggested that the reaction was likely to be due to an interaction, although the mechanism was not clear.

1. Lucena MI, *et al.* Prolonged cholestasis after raloxifene and fenofibrate interaction: a case report. *World J Gastroenterol* 2006; **12:** 5244–6.

Pharmacokinetics

Raloxifene is absorbed from the gastrointestinal tract and undergoes extensive first-pass hepatic metabolism to the glucuronide conjugates. It is highly bound to plasma proteins, principally albumin and α_1-acid glycoprotein. Raloxifene undergoes enterohepatic recycling, and has a half-life of about 27 hours. It is excreted almost entirely in the faeces.

Renal impairment. The pharmacokinetics of raloxifene are not expected to be affected by renal impairment because the renally excreted fraction is only about 6% in healthy subjects. However, a study[1] in male subjects found the clearance of a single oral dose of 120 mg to be significantly reduced in 10 men with renal impairment (creatinine clearance 24 to 51 mL/minute) compared with a group of 10 with normal renal function. It was calculated that steady-state concentrations could be about 2.3 times higher in patients with renal impairment. The authors suggested that this unexpected observation might be caused by reduced metabolic clearance in the renal tubules or by impairment of biliary excretion of raloxifene glucuronides by uraemic toxins.

1. Czock D, *et al.* Raloxifene pharmacokinetics in males with normal and impaired renal function. *Br J Clin Pharmacol* 2005; **59:** 479–82.

Uses and Administration

Raloxifene hydrochloride is a selective oestrogen receptor modulator; it is a benzothiophene that appears to have oestrogen agonist effects on bone and antagonist effects in uterine and breast tissue. It is used, in oral doses of 60 mg daily, for the prevention and treatment of postmenopausal osteoporosis (below). The same dose is also used to reduce the risk of invasive breast cancer in postmenopausal women who have osteoporosis or are at high risk of invasive breast cancer (below).

Administration in renal impairment. Although unexpected, renal impairment reduced raloxifene clearance in a pharmacokinetic study (see above). Licensed product information in the UK contra-indicates the use of raloxifene in severe renal impairment, and in the USA it advises caution in moderate and severe impairment. Nevertheless, raloxifene has been studied in postmenopausal women with renal impairment and severe osteopenia or osteoporosis. An oral dose of 60 mg daily for 1 year was given to 25 women on haemodialysis and found to improve bone mineral density of the lumbar spine, compared with 25 women given placebo; there were no reported adverse effects.[1]

1. Hernández E, *et al.* Effects of raloxifene on bone metabolism and serum lipids in postmenopausal women on chronic hemodialysis. *Kidney Int* 2003; **63:** 2269–74.

Hyperparathyroidism. The effects of raloxifene have been reported in postmenopausal women with mild primary hyperparathyroidism (p.1087). Reductions in markers of bone turnover and plasma concentrations of calcium have been described in an observational report[1] and a small, short-term, placebo-controlled study.[2] An increase in bone mineral density was also detected after 12 months of treatment with raloxifene.[1]

1. Zanchetta JR, Bogado CE. Raloxifene reverses bone loss in postmenopausal women with mild asymptomatic primary hyperparathyroidism. *J Bone Miner Res* 2001; **16:** 189–90.
2. Rubin MR, *et al.* Raloxifene lowers serum calcium and markers of bone turnover in postmenopausal women with primary hyperparathyroidism. *J Clin Endocrinol Metab* 2003; **88:** 1174–8.

Malignant neoplasms of the breast. Studies have found raloxifene to be effective for the prophylaxis of breast cancer (p.662). In a placebo-controlled study[1] of postmenopausal women with osteoporosis and no history of breast cancer (MORE), the use of raloxifene for about 3 years reduced the risk of developing breast cancer. This was seen as a reduction in the risk of invasive oestrogen-receptor positive breast cancer, as there was no effect on the risk of oestrogen-receptor negative disease. The reduction in risk was maintained in an extension[2] of this study (CORE) to a total of 8 years of treatment. Similar results were reported in a large placebo-controlled study (RUTH)[3] of postmenopausal women who were treated for about 5 years. Both MORE/CORE[4] and RUTH[3] reported risk reduction in women at either high or low risk, but the MORE study[4] found the effect to be greater in women with a family history of breast cancer.

In a study[5] of postmenopausal women with a predicted increased risk of breast cancer (STAR), prophylactic raloxifene for up to 5 years was found to be as effective as tamoxifen in reducing the risk of invasive breast cancer.

Osteoporosis. Raloxifene partially mimics the effects of oestrogens in bone to increase bone mineral density in postmenopausal women.[1,2] The MORE study in 7705 postmenopausal women with osteoporosis (p.1084) found that up to 4 years of raloxifene treatment reduced the risk of vertebral fracture,[3-6] but the risk of nonvertebral fracture did not differ significantly from that in women given placebo.[3,5] A meta-analysis[7] of data from this and other smaller studies concluded that raloxifene reduced the risk of vertebral fracture by between 40 and 49% in postmenopausal women with osteoporosis.

Small studies suggest that raloxifene may be effective as 'add-back' therapy to prevent the loss of bone mineral density associated with gonadorelin analogue therapy in women[8,9] and men.[10]

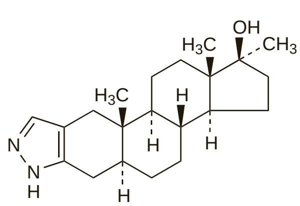
Stanozolol *(BAN, USAN, rINN)* ⊗

Androstanazol; Androstanazole; Estanazol; Estanozolol; Methylstanazole; Metistanazol; NSC-43193; Stanotsololi; Stanozololis; Stanozololum; Stanozolum; Sztanozolol; Win-14833. 17α-Methyl-2′*H*-5α-androst-2-eno[3,2-*c*]pyrazol-17β-ol.

Станозолол

$C_{21}H_{32}N_2O$ = 328.5.
CAS — 10418-03-8.
ATC — A14AA02.
ATC Vet — QA14AA02.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of stanozolol:
Iron Brew.

Pharmacopoeias. In *Chin.* and *US.*
USP 31 (Stanozolol). An odourless crystalline powder occurring in 2 forms; needles melt at about 155° and prisms at about 235°. Insoluble in water; soluble 1 in 41 of alcohol, 1 in 74 of chloroform, and 1 in 370 of ether; slightly soluble in acetone and in ethyl acetate; soluble in dimethylformamide; very slightly soluble in benzene. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

As for androgens and anabolic steroids in general (see Testosterone, p.2130). As with other 17α-alkylated compounds stanozolol may produce hepatotoxicity, and liver function should be monitored. It is probably best avoided in patients with hepatic impairment, and certainly if this is severe. Haematocrit and haemoglobin concentrations should also be monitored.

Because of its androgenic effects it has been recommended that stanozolol should not be used to treat hereditary angioedema in premenopausal women except in life-threatening situations.

Effects on the kidney. Renal failure with cholestatic jaundice has been reported with stanozolol (see below).

Effects on the liver. Cholestatic jaundice has been reported with stanozolol,[1-3] in some cases with acute tubular necrosis and renal failure.[4]

1. Slater SD, *et al.* Jaundice induced by stanozolol hypersensitivity. *Postgrad Med J* 1976; **52:** 229–32.
2. Evely RS, *et al.* Severe cholestasis associated with stanozolol. *BMJ* 1987; **294:** 612–13.
3. Martínez B, *et al.* Colestasis inducida por consumo de estanozolol. *Rev Esp Enferm Dig* 2006; **98:** 219–20.
4. Yoshida EM, *et al.* At what price, glory? Severe cholestasis and acute renal failure in an athlete abusing stanozolol. *Can Med Assoc J* 1994; **151:** 791–3.

Effects on the nervous system. Benign intracranial hypertension developed in an elderly woman receiving stanozolol; CSF pressure returned to normal after stanozolol was stopped.[1]

1. Tully MP, *et al.* Intracranial hypertension associated with stanozolol. *DICP Ann Pharmacother* 1990; **24:** 1234.

Porphyria. Stanozolol is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

As mentioned under Testosterone, p.2131, anabolic steroids may enhance the activity of a number of drugs. For the effect of stanozolol on some anticoagulants, see p.1431.

Uses and Administration

Stanozolol has anabolic and androgenic properties (see Testosterone, p.2131). As with other anabolic steroids, stanozolol has been used for breast cancer in postmenopausal women, and for anaemias, osteoporosis, and catabolic disorders. It has been given in oral doses of 2 mg every 8 to 12 hours, or 50 mg by intramuscular injection every 2 or 3 weeks.

In the management of hereditary angioedema, an initial oral dose of 2.5 to 10 mg daily has been given to prevent attacks. The dosage may then be reduced, according to the patient's response; maintenance doses of 2 mg daily or on alternate days, or 2.5 mg three times weekly have been used successfully. For doses that have been used in children, see below.

Administration in children. Androgens are usually avoided in children with hereditary angioedema (below) because of their adverse effects, but they have been used when other treatments are ineffective. In the USA oral doses of stanozolol 1 mg daily, given only during an attack, have been used in children under 6 years of age, and up to 2 mg daily in those aged 6 to 12 years. Slightly higher doses have been permitted in children in the UK.

Hereditary angioedema. Stanozolol raises serum concentrations of C1 esterase inhibitor and has been used successfully to prevent attacks of hereditary angioedema (p.1081).

Vascular disorders. Stanozolol has been used in the treatment of vascular manifestations of Behçet's syndrome. It has also been reported to promote fibrinolysis in vascular disorders, and has been tried in various conditions. However, most studies have been noncomparative and in small numbers of patients, and results have been variable.

Pharmacopoeias. In *Chin.*

Adverse Effects

Testosterone and other **androgens** may give rise to adverse effects related to their androgenic or anabolic activities. These include increased retention of sodium and water, oedema, hypercalcaemia, and impaired glucose tolerance. Other effects include increased low-density-lipoprotein cholesterol, decreased high-density-lipoprotein cholesterol, increased haematocrit, and suppression of clotting factors. Androgens may cause headache, depression, and gastrointestinal bleeding. It has been suggested that androgens may induce sleep apnoea in susceptible patients.

Abnormal liver function tests may occur and there have been reports of liver toxicity including jaundice and cholestatic hepatitis. There have also been reports of peliosis hepatis and hepatic tumours in patients who have received high doses over prolonged periods. These adverse hepatic effects have occurred primarily with the 17α-alkylated derivatives (e.g. methyltestosterone, stanozolol).

In men, large doses suppress spermatogenesis and cause testicular atrophy. Epididymitis and bladder irritability can occur. Priapism is a sign of excessive dosage and may occur especially in elderly males. Gynaecomastia may occur. Androgens may cause prostatic hyperplasia and accelerate the growth of malignant neoplasms of the prostate.

In women, the inhibitory action of androgens on the activity of the anterior pituitary results in the suppression of ovarian activity and menstruation. Continued use produces symptoms of virilism, such as hirsutism or male-pattern baldness, deepening of the voice, atrophy of the breasts and endometrial tissue, oily skin, acne, and hypertrophy of the clitoris. Virilisation may not be reversible, even after stopping therapy.

Large and repeated doses in early puberty may cause closure of the epiphyses and stop linear growth. Children may experience symptoms of virilisation: in boys there may be precocious sexual development with phallic enlargement and increased frequency of erection, and in girls, clitoral enlargement. Gynaecomastia may also occur in boys.

Masculinisation of the external genitalia of the female fetus may occur if androgens are given during pregnancy.

After transdermal application of testosterone, skin reactions may include irritation, erythema, allergic contact dermatitis, and sometimes burn-like lesions. Skin reactions are more common with patches that contain permeation enhancers.

The **anabolic steroids**, because they generally retain some androgenic activity, share the adverse effects of the androgens described above, but their virilising effects, especially in women, are usually less. There have been reports of adverse psychiatric effects in athletes taking large doses to try and improve performance. For adverse effects following the misuse of anabolic steroids, see Abuse under Precautions, below.

Carcinogenicity. Testosterone therapy is used in healthy older men with low or low-normal serum-testosterone concentrations (see Hypogonadism, under Uses and Administration, below), but there is some concern about a possible associated increase in prostate cancer risk. This concern is based on the fact that, regardless of any treatment, the incidence of prostate cancer increases with age, that normal prostate growth is dependent on androgens, and that androgen deprivation causes regression of advanced prostate cancer.[1] However, the relationship between androgens and the onset of prostate cancer is far from clear. Some data show that low serum-testosterone can predict more aggressive high-grade tumours, with a higher likelihood of metastatic disease and poorer outcome.[1,2] Although there have been reports of prostate cancer developing in men who have been treated with testosterone,[3] small clinical studies have, overall, not shown an increase in the risk of prostate cancer.[4] The effect of 6 months of testosterone enantate therapy on the prostate has been studied in 21 ageing men.[5] Although low serum-testosterone concentrations were normalised, there were no significant changes in androgen concentrations in prostate tissue, prostate volume, prostate specific antigen, or prostate cancer incidence. Further study of longer duration in larger numbers of men is needed to confirm the safety of this therapy.

In men with a history of prostate cancer, testosterone therapy for hypogonadism is generally contra-indicated because of the presumed risk of tumour recurrence. However, there are a small number of reports of testosterone being used safely after curative surgery, suggesting that testosterone therapy with close monitoring may be considered in such men with symptomatic hypogonadism.[6] There is even less data on the use of testosterone for hypogonadism in men who have been treated with radiotherapy with curative intent, or with androgen ablation by gonadorelin analogue therapy. Testosterone has also been used for hypogonadism in a small number of men with high-grade intra-epithelial neoplasia, a precancerous lesion, without increasing the risk of cancer development.[6]

For reference to hepatic malignancies associated with androgens and anabolic steroids, see Effects on the Liver, below. Renal cell carcinoma has also been reported after their abuse (see under Precautions, below).

6. Kaufman J. A rational approach to androgen therapy for hypogonadal men with prostate cancer. *Int J Impot Res* 2006; **18:** 26–31.

Effects on the cardiovascular system. A cerebrovascular accident has been reported in a young man after the overzealous self-administration of testosterone enantate intramuscularly for hypogonadism.[1] It was noted that thromboembolic complications are not generally recognised as adverse effects of androgen therapy although there is some experimental evidence that testosterone stimulates thrombus formation. A systematic review[2] found evidence concerning cardiovascular events in studies of testosterone given to men with low or normal testosterone concentrations to be of poor quality, but some data to suggest that alterations in plasma lipid concentrations and blood pressure were not significant.

1. Nagelberg SB, *et al.* Cerebrovascular accident associated with testosterone therapy in a 21-year-old hypogonadal man. *N Engl J Med* 1986; **314:** 649–50.
2. Haddad RM, *et al.* Testosterone and cardiovascular risk in men: a systematic review and meta-analysis of randomized placebo-controlled trials. *Mayo Clin Proc* 2007; **82:** 29–39.

Effects on the liver. Hepatotoxicity, including elevations in liver enzymes, hepatic cholestasis and jaundice, and rarely peliosis hepatis and hepatic tumours, has occurred with androgens and anabolic steroids, particularly the 17α-alkylated derivatives. Prolonged treatment and high doses may be significant contributory factors. Tumours have included hepatocellular carcinomas, benign adenomas, and less commonly angiosarcomas and cholangiocarcinomas. Tumours and peliosis may regress on stopping therapy, but they can also progress to liver failure and death. Some reviews of the hepatic effects of androgens and anabolic steroids are cited below.[1-5] There has been a specific report of benign hepatic adenoma in a patient treated with testosterone enantate for 11 years,[6] and of hepatocellular carcinoma in a patient given testosterone enantate and methyltestosterone.[7] Further specific references may be found under individual drug monographs.

Precautions

Testosterone and other androgens and anabolic steroids should be used cautiously in patients with cardiovascular disorders, renal or hepatic impairment, epilepsy, migraine, diabetes mellitus or other conditions that may be aggravated by the possible fluid retention or oedema caused. They should not be given to patients with hypercalcaemia or hypercalciuria, and should be used cautiously in conditions in which there is a risk of these developing such as skeletal metastases. The use of the 17α-alkylated derivatives, which are associated with an increased risk of hepatotoxicity, is probably best avoided in patients with hepatic impairment, and certainly if this is severe. Hepatic function should be monitored during therapy.

In men, androgens and anabolic steroids should not be given to those with carcinoma of the breast or prostate (although in women they have been used in the treatment of certain breast carcinomas; see also Carcinogenicity, above, regarding the use of testosterone in men with a history of prostate cancer). The prostate should be examined regularly during treatment.

Androgens and anabolic steroids should not be given during pregnancy because of the risk of virilisation of the female fetus.

Androgens and anabolic steroids should be used with extreme care in children because of the masculinising effects and also because premature closure of the epiphyses may occur resulting in inhibited linear growth and small stature. Skeletal maturation should be monitored during therapy.

Androgens and anabolic steroids may interfere with a number of clinical laboratory tests such as those for glucose tolerance and thyroid function.

Abuse. The adverse effects arising from the illicit use of androgens and anabolic steroids by athletes, often taken together at doses well in excess of those used therapeutically, have been discussed.[1-4] Such misuse is associated with potentially serious health risks. Effects have included abnormal liver function and hepatic neoplasms (see also Effects on the Liver, above), an atherogenic blood lipid profile and increased risk of cardiovascular disease, and reduced glucose tolerance. Hypogonadal states are commonly induced (azoospermia or oligospermia and testicular atrophy in men, and amenorrhoea or oligomenorrhoea in women). Gynaecomastia is relatively common in men, and virilisation in women. Psychiatric disturbances such as mania, hypomania, depression, aggression, and emotional lability, have been described. There is also some evidence that dependence associated with an acute withdrawal syndrome can occur. Rare reports include alterations in immune response, tendon damage, renal cell carcinoma, and peliosis hepatis.

There has been some dispute about the methods used to detect abuse of certain anabolic steroids in athletes. A study in healthy subjects has apparently confirmed endogenous production of small amounts of nandrolone metabolites;[5] a number of different factors might have an influence including genetics, intense exercise, trauma, and hypoglycaemic stress.[6]

Breast feeding. It is not known whether testosterone is distributed into breast milk, but it should be avoided in women who are breast feeding because of the theoretical potential androgenic effect on the infant. High doses of testosterone can suppress lactation.

Porphyria. Androgens are considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

A female patient with acute intermittent porphyria (p.1448) who suffered from severe attacks pre-menstrually was successfully managed with subcutaneous implants of testosterone when suppression of the menstrual cycle with buserelin met with limited success.[1]

1. Savage MW, *et al.* Acute intermittent porphyria treated by testosterone implant. *Postgrad Med J* 1992; **68:** 479–81.

Pregnancy. Reports of female fetal virilisation after maternal use of testosterone[1] or methyltestosterone[2] during pregnancy.

2. Dewhurst J, Gordon RR. Fertility following change of sex. *Lancet* 1984; **ii:** 1461.

Veterinary use. An FAO/WHO expert committee examining the risks from residue of veterinary drugs in foodstuffs established an acceptable daily intake for testosterone, but concluded that there would be no need to specify a numerical maximum residue limit for testosterone in the edible tissues of cattle when products are used as growth promotors according to good practice.[1] However, it should be noted that, in the EU, the use of androgens in veterinary practice is restricted and their use as growth promotors is banned. In addition, the use of anabolic steroids is banned in animals intended for human consumption.

Interactions

Testosterone and other androgens and anabolic steroids have been reported to enhance the activity of a number of drugs, with resulting increases in toxicity. Drugs affected include ciclosporin (see p.1828), levothyroxine (see p.2173), and anticoagulants such as warfarin (see p.1431). Resistance to the effects of neuromuscular blockers (p.1905) has also been reported. As androgens and anabolic steroids can alter glucose metabolism, doses of insulin or oral antidiabetics may need adjustment.

Pharmacokinetics

Testosterone is absorbed from the gastrointestinal tract, the skin, and the oral mucosa. However, testosterone undergoes extensive first-pass hepatic metabolism when given orally and is therefore usually given intramuscularly, subcutaneously, or transdermally. In addition, the basic molecule of testosterone has been modified to produce orally active compounds and to extend the duration of action. Alkylation of the 17α position produces compounds that are more slowly metabolised by the liver, and hence may be administered orally. Esterification of the 17β hydroxyl group increases lipid solubility and results in slower systemic absorption following intramuscular injection. The rate of absorption of the esters is related to the size of the ester group. The undecylate ester undergoes less complete inactivation after oral doses because of distribution into the lymphatic system. Testosterone esters are hydrolysed to testosterone after absorption.

Testosterone is about 80% bound to sex-hormone binding globulin. Derivatives of 19-nortestosterone and 17-α-methylated compounds have reduced binding to this globulin. The plasma half-life of testosterone is reported to range from about 10 to 100 minutes. It is largely metabolised in the liver via oxidation at the 17-OH group with the formation of androstenedione, which is further metabolised to the weakly androgenic androsterone and inactive etiocholanolone which are excreted in the urine mainly as glucuronides and sulfates. About 6% is excreted unchanged in the faeces after undergoing enterohepatic recirculation. Testosterone is converted to the more active dihydrotestosterone in some target organs by 5α-reductase. 19-Nortestosterone derivatives appear to be less susceptible to this enzyme. Small amounts of testosterone are aromatised to form oestrogenic derivatives, particularly oestradiol. Compounds with a saturated A-ring, such as mesterolone, appear to be less likely to be aromatised to oestrogen.

Uses and Administration

The natural hormone testosterone and its derivatives have anabolic and androgenic properties (for further details, see p.2058).

The primary indication for androgens, such as testosterone or its esters, is as replacement therapy in **male hypogonadal disorders** (below) caused by either pituitary or testicular disorders or in hypogonadism following orchidectomy. Testosterone may be used as a subcutaneous implant in a dose of 100 to 600 mg; plasma concentrations of testosterone are usually maintained within the physiological range for 4 to 5 months with a dose of 600 mg. It may also be given by transdermal delivery systems. Patches are applied to the back, abdomen, thighs or upper arms to supply 2.5 to 7.5 mg daily. A scrotal patch containing 10 or 15 mg of testosterone and supplying about 4 or 6 mg of testosterone in 24 hours has been used, but is no longer widely available. Hydroalcoholic gels containing 1 or 2% testosterone are also used; they are applied daily to the shoulders and upper arms, abdomen, or thighs, depending on the preparation. About 10% of the applied dose is absorbed across the skin to provide a systemic dose of testosterone 5 to 10 mg. A sustained-release adhesive buccal system that contains testosterone 30 mg is applied twice daily; by this route the systemic dose is about 3 mg. Testosterone has also been given by intramuscular injection in a dose of up to 50 mg two or three times weekly, but testosterone esters are generally preferred by this route.

The testosterone esters are usually formulated as oily solutions for intramuscular use to give a prolonged duration of action. Doses that have been used for the various esters are:

- testosterone cipionate 50 to 400 mg every 2 to 4 weeks

- testosterone enantate 50 to 400 mg every 2 to 4 weeks, or an initial dose of 250 mg every 2 to 3 weeks followed by maintenance dosing every 3 to 6 weeks
- testosterone propionate up to 50 mg two or three times weekly
- testosterone undecylate 1 g every 10 to 14 weeks

The isocaproate, phenylpropionate, and propionate esters may be given as a combined intramuscular preparation, sometimes also containing testosterone decanoate. Testosterone hexahydrobenzoate, testosterone hexahydrobenzylcarbonate, and testosterone isobutyrate have also been used. The undecylate ester is also given orally in an initial dose of 120 to 160 mg daily, in 2 divided doses, for 2 to 3 weeks, followed by a maintenance dose of 40 to 120 mg daily. See below for some doses of testosterone used in children.

Androgens and anabolic steroids have sometimes been used with oestrogens in the management of certain menopausal disorders, but the use of androgens and anabolic steroids in women with osteoporosis is no longer advocated because their adverse effects essentially outweigh any benefit they may produce. In the UK menopausal women are sometimes given implants of testosterone in a dose of 50 to 100 mg every 4 to 8 months as an adjunct to menopausal HRT for symptoms such as decreased libido. In the USA, preparations containing an androgen and an oestrogen are available for the treatment of menopausal vasomotor symptoms; intramuscular doses of testosterone cipionate 50 mg with estradiol cipionate 2 mg have been given once every 4 weeks, with attempts to taper treatment at 3 to 6 month intervals. However, there are concerns about the use of these preparations and conflicting opinion as to their usefulness (see below). More recently a transdermal patch has become available for the treatment of hypoactive sexual desire disorder in women with surgically induced menopause (bilateral oophorectomy and hysterectomy) who are receiving oestrogen therapy. The patch is applied twice weekly and delivers a daily systemic dose of testosterone 300 micrograms; the initial response to therapy should be evaluated after 3 to 6 months and reassessed every 6 months. In postmenopausal women androgens, and sometimes anabolic steroids are occasionally used in the hormonal therapy of disseminated breast carcinoma but care should be taken to choose a compound with a lower masculinising effect; the short-acting synthetic compounds are usually preferred for such purposes. Testosterone enantate has been used in doses of 200 to 400 mg every 2 to 4 weeks by intramuscular injection.

Anabolic steroids, and sometimes androgens, have been used in the treatment of refractory anaemias characterised by deficient red cell production, such as aplastic anaemia. Anabolic steroids and synthetic androgens with an attenuated action (sometimes known as 'attenuated androgens') such as danazol are also used in the management of hereditary angioedema.

Topical androgens may be used in the treatment of lichen sclerosus.

Androgens and anabolic steroids have been used for their anabolic properties in various catabolic states.

Testosterone hemisuccinate is an ingredient of preparations that have been promoted for the management of cataracts.

Administration in children. Testosterone is used in adolescent males with hypogonadism, and has been used in constitutionally delayed puberty (see below). It has also been used to reduce final height in boys with constitutional tall stature (see below).

For the induction and maintenance of **sexual maturation** in boys over 12 years of age, the *BNFC* includes doses of testosterone undecylate 40 mg orally on alternate days, increasing up to 120 mg daily according to response. Alternatively, testosterone enantate or propionate may be given by deep intramuscular injection in doses of 25 to 50 mg/m^2 every month, increasing every 6 to 12 months according to response. An injection containing a combination of testosterone esters (isocaproate 40 mg, phenylpropionate 40 mg, and propionate 20 mg) has also been given intramuscularly, once each month for 3 doses, for delayed puberty. For boys over 15 years, the adult dose of a transdermal patch may be used, and an implant may be suitable for maintenance in hypogonadal males over 16 years (see above for doses). However, great care is necessary when using androgens for such conditions as bone growth and final height may be inhibited by the early fusion of the epiphyses. Extemporaneously prepared testosterone cream has been applied topically in the management of microphallus (the alcohol in proprietary gels can cause irritation).

Growth hormone provocation testing may be used in the diagnosis of growth hormone deficiency in children with growth retardation (p.1798). However, the response can be blunted in prepubertal and peripubertal children, resulting in false negative results. Hormonal **pituitary priming** using testosterone has been tried in boys in order to increase responsiveness to the test,[1-3] although there appears to be no consensus on such use.[4] The *BNFC* includes a single intramuscular dose of a product containing a combination of testosterone esters (isocaproate 40 mg, phenylpropionate 40 mg, and propionate 20 mg), given 3 to 5 days before the test.

Anabolic effects. The androgens generally possess anabolic activity and were formerly used to increase weight in patients suffering from emaciation or debilitating diseases but effectiveness was doubtful. The anabolic steroids were developed in order to enhance the ability to build proteins and diminish the virilising and masculinising effects of the natural androgens, but all anabolics retain some androgenic activity. The anabolic steroids have again, like the androgens, been used in an attempt to produce weight gain in cachexia and wasting diseases (p.2115).

The anabolic steroids and androgens have been the subject of much misuse and abuse by athletes, sports persons, and body builders (see under Precautions, above) in an attempt to increase muscle mass and body-weight but such use cannot be justified.

Antineoplastic-induced infertility. For reference to the use of testosterone to preserve gonadal function during cyclophosphamide therapy, see Effects on Reproductive Potential, p.702.

Constitutionally delayed puberty. Testosterone enantate given by intramuscular injection every 1 to 2 months for periods ranging from 3 months to several years, produced beneficial effects in boys with constitutionally delayed puberty and growth;[1,2] growth rate increased, sexual and skeletal maturation were stimulated, and full height potential did not appear to be compromised. However, it has been pointed out that repeated intramuscular injections are painful and are disliked by adolescents;[3] oral testosterone undecylate or oxandrolone have been shown to be effective in the treatment of delayed puberty and growth in boys,[4,5] and may be preferred.[3] It should be noted that giving androgens to boys with constitutional delay of growth and puberty is controversial (see p.2079). For reference to the use of testosterone in boys with delayed puberty due to hypogonadism see below.

5. Brown DC, *et al.* A double blind, placebo controlled study of the effects of low dose testosterone undecanoate on the growth of small for age, prepubertal boys. *Arch Dis Child* 1995; **73:** 131–5.

Constitutionally tall stature. Supraphysiological doses of androgens have been used to *reduce* final height in tall adolescent boys. Testosterone esters in monthly doses of up to 1000 mg by intramuscular injection have been used.[1] Preliminary evidence after a mean of 10 years follow-up suggests that there was no long-term effect on reproductive function.[2] For reference to the use of testosterone to *increase* growth rate, see Constitutionally Delayed Puberty, above.

2. de Waal WJ, *et al.* Long term sequelae of sex steroid treatment in the management of constitutionally tall stature. *Arch Dis Child* 1995; **73:** 311–15.

Dementia. There has been some suggestion that age-related reduction in endogenous testosterone may have a role in cognitive decline in men (see Dementia, p.362). In a longitudinal study[1] of 574 men who were followed for about 19 years, a lower calculated concentration of free testosterone was found to be one of a number of risk factors associated with the development of Alzheimer's disease. A possible role for testosterone treatment has therefore been proposed and some preliminary studies have been undertaken. A small short-term study[2] of older men with Alzheimer's disease or mild cognitive impairment reported improvements in some measures of cognitive function in patients given intramuscular testosterone. In another study,[3] however, testosterone applied as a topical gel was reported to improve quality of life as scored by the caregivers of men with mild Alzheimer's disease, but to have no significant effect on quality of life in healthy elderly men or on cognitive function in either group.

3. Lu PH, *et al.* Effects of testosterone on cognition and mood in male patients with mild Alzheimer disease and healthy elderly men. *Arch Neurol* 2006; **63:** 177–85.

Erectile dysfunction. Although testosterone is known to enhance libido its physiological role in erection is still not fully understood. Studies have produced mixed results, but suggest that men with sexual or erectile dysfunction (p.2179) and low baseline concentrations of testosterone may derive some benefit from testosterone monotherapy;[1,2] the use of testosterone may also have some benefit in those who have responded poorly to phosphodiesterase type-5 inhibitors.[1,3] However, because of limited evidence and the potential for adverse effects, therapy should probably be limited to men with severe hypogonadism[1,2] (see also Hypogonadism, below).

For reference to the use of a cream containing testosterone, isosorbide dinitrate, and codergocrine mesilate in the treatment of erectile dysfunction, see under Glyceryl Trinitrate, p.1298.

3. Shabsigh R, *et al.* The evolving role of testosterone in the treatment of erectile dysfunction. *Int J Clin Pract* 2006; **60:** 1087–92.

Gender reassignment. Testosterone is used in female-to-male transsexuals to develop and maintain secondary sexual characteristics.[1,2] A testosterone ester, or a combination of esters, is usually given by intramuscular injection in doses of 200 to 250 mg every 2 weeks, adjusted according to response.[2,3] Alternatively, testosterone undecylate 1 g may be given once every 10 to 12 weeks.[3] Oral or transdermal testosterone is less commonly used, and the addition of a progestogen may be needed to fully suppress menstruation in non-oophorectomised patients.[2]

1. Moore E, *et al.* Endocrine treatment of transsexual people: a review of treatment regimens, outcomes, and adverse effects. *J Clin Endocrinol Metab* 2003; **88:** 3467–73.

3. Gooren LJ, *et al.* Long-term treatment of transsexuals with cross-sex hormones: extensive personal experience. *J Clin Endocrinol Metab* 2008; **93:** 19–25.

Heart failure. Low serum-testosterone concentrations have been reported in men with chronic heart failure (p.1165). A study in men with moderate heart failure and low or low-normal testosterone concentrations found that 12 months of transdermal testosterone therapy improved symptoms of heart failure and exercise capacity.[1] The mechanism of benefit was unclear.

1. Malkin CJ, *et al.* Testosterone therapy in men with moderate severity heart failure: a double-blind randomized placebo controlled trial. *Eur Heart J* 2006; **27:** 57–64.

Hypogonadism. Replacement therapy with testosterone or a testosterone ester is the standard treatment for *primary hypogonadism* in men (see p.2079). The androgen is often given as an intramuscular depot injection of one of the esters, although subcutaneous implants, oral formulations, transdermal systems, topical gel, and a buccal preparation are also used (for doses see above).[1-3] Testosterone is also used to promote masculinisation in hypogonadal adolescent boys,[4,5] and is of value in the prevention of osteoporosis in hypogonadal men.[6,7] Testosterone has a negative feedback effect on gonadotrophin secretion, therefore any remaining spermatogenesis is generally suppressed; androgens are thus rarely useful in reversing male infertility (p.2080). Recommendations for monitoring therapy have been made.[3,8]

Transdermal testosterone may possibly be of benefit as an adjunct to oestrogen replacement in *women* who have undergone hysterectomy and oophorectomy (see Menopausal Hormone Replacement Therapy, below).

There has also been growing interest in the use of testosterone therapy in *healthy older men*, although there is limited evidence to prove a direct association between clinical changes and the natural decline of endogenous hormone concentrations with age.[9] This aspect of ageing is increasingly being described as the andropause, but the fall in testosterone concentrations is gradual, and not a rapid and significant decline of hormones with loss of fertility like that which occurs in the female menopause[9,10] (p.2071); other terms such as partial androgen deficiency or late-onset hypogonadism have also been proposed.[9] Testosterone therapy has been studied in healthy older men with normal or low-normal serum-testosterone concentrations. Modest beneficial changes in body composition (increased lean body-mass and decreased fat-mass) have been reported, but many studies have found no associated improvement in muscle strength, mobility, or functional autonomy, or a reduced risk of falls. Results are also inconsistent or negative from studies measuring skeletal effects, sexual function, cognitive function, mood, and quality of life.[9] A meta-analysis[11] of 8 studies suggested that intramuscular testosterone might be more effective than transdermal administration for increasing lumbar bone mineral density. There are concerns about potential adverse effects of testosterone on the prostate (see Carcinogenicity, above) and the cardiovascular system, and high doses have been reported to cause or exacerbate sleep apnoea.[9,12] Although recommendations have been made for the use and monitoring of testosterone therapy in healthy older men with androgen deficiency,[12-14] many caution that until further clinical studies have been done it should only be used in those with confirmed hypogonadism.[9,10]

Lichen sclerosus. Topical androgens such as androstanolone and testosterone have been used to treat vulvar lichen sclerosus (p.1580) in postmenopausal women.[1-4] However, virilisation can occur and a topical corticosteroid is generally preferred.[5]

Male contraception. In male contraceptive studies it was found that high-dose testosterone severely reduced sperm production.[1] In those in whom azoospermia was not induced there was oligozoospermia with remaining sperm having a markedly reduced fertilising capacity. In a multicentre study carried out by WHO[2] involving 271 healthy fertile men, weekly intramuscular injection of testosterone enantate 200 mg produced azoospermia in 157 men within 6 months. In a subsequent 12-month study of these azoospermic men, during which time testosterone enantate was the only contraceptive measure used, there was only 1 pregnancy. Spermatogenesis was re-established on withdrawal of testosterone. These findings have been confirmed in a larger study of the same regimen, which additionally assessed contraceptive efficacy in men who achieved oligozoospermia (less than 3×10^6/mL).[3] No pregnancies occurred in couples where the man was azoospermic. However, the pregnancy rate was 8.1 per 100-person-years in the subgroup of couples where the man was oligozoospermic. This rate is sixfold higher than is generally seen with hormonal contraceptives in women.[4] Both studies found that consistent azoospermia was achieved in a higher percentage of Asian men (95%) than Western men (70%).[4] Testosterone undecylate has also been studied as a longer-acting intramuscular injection. In a study[5] involving Chinese men, a loading dose of 1000 mg followed by monthly maintenance doses of 500 mg effectively and persistently suppressed spermatogenesis in about 95% of 296 men who had initially responded; pregnancy occurred in the partner of 1 of the 6 men with sperm rebound.

An alternative approach being investigated is the use of testosterone with a progestogen, which enhances the suppression of spermatogenesis and may allow lower doses of androgen to be used with fewer adverse effects. Progestogens under investigation include cyproterone, desogestrel, etonogestrel, levonorgestrel, medroxyprogesterone, and norethisterone.[6,7]

Menopausal hormone replacement therapy. Menopause does not necessarily result in androgen deficiency in women, and androgen replacement is therefore not routinely required (see Menopausal Disorders, p.2077). In the UK menopausal women may nonetheless sometimes be given implants of testosterone as an adjunct to menopausal HRT. In the USA, injectable preparations containing an androgen and an oestrogen are available for the treatment of menopausal vasomotor symptoms, but there is conflicting opinion as to their usefulness, and further data are needed.[1] In Canada, a preparation containing estradiol and testosterone esters for intramuscular injection (*Climacteron; Sabex, Canad.*) was discontinued in 2005 because of concerns that testosterone is partially metabolised to oestrogen, which should be opposed by a progestogen in women with a uterus, and that there was no established dose of progestogen that could be recommended in this situation.[2] A study[3] in healthy postmenopausal women found that oral testosterone alone did not stimulate endometrial proliferation as estradiol did, and that it appeared to reduce the effect of estradiol when they were used together. However, therapy was given for only 3 months and long-term effects need further study. Improvements in mood and libido have been shown when androgens were given to postmenopausal women with an established cause of androgen deficiency such as surgically induced menopause.[4] A systematic review of the addition of testosterone to postmenopausal HRT considered that there was some evidence of benefit on sexual function, but that studies varied too much to estimate the effect of any particular combination.[5] More recently, a number of placebo-controlled studies in women with surgically induced[6-9] or natural[10] menopause have reported improvements in sexual activity and desire with transdermal testosterone. A product (*Intrinsa; Proctor and Gamble, UK*) has been licensed for use in the UK for the treatment of hypoactive sexual desire disorder in women with surgically induced menopause who are also receiving oestrogen replacement therapy, but the FDA has not licensed it in the USA and has expressed concern about the lack of data on long-term safety.[11] However, the North American Menopause Society[12] has recommended that testosterone therapy may be considered for postmenopausal women who present with symptoms of decreased sexual desire associated with personal distress and who have no other identifiable cause for their sexual concerns. Nevertheless, they warn that use of testosterone without estrogen cannot be recommended because there is no information on safety and efficacy in this situation, that topical preparations are preferred over oral products, that the lowest dose should be used for the shortest time, and that there is insufficient efficacy and safety data for therapy beyond 6 months.

The Endocrine Society[13] has evaluated data on the use of testosterone in various groups of women, including those with menopausal symptoms, and advises that although there is some evidence for efficacy in selected populations, such as surgically menopausal women, it cannot be recommended for generalised use because of poorly-defined indications and a lack of evidence on long-term safety.

The use of transdermal testosterone, with oestrogen and progestogen replacement therapy, is also being investigated in young women with spontaneous premature ovarian failure.[14]

Rheumatoid arthritis. A hypogonadal condition characterised by low serum-testosterone concentrations appears to be associated with at least the active stages of rheumatoid arthritis (p.11) in men.[1] Clinical improvement and reductions in IgM rheumatoid factor concentration, tender joint count, and the daily dosage of NSAIDs required, were observed in a small study[1] of men with rheumatoid arthritis and low serum-testosterone concentrations given oral testosterone undecylate 40 mg three times daily for 6 months. Improvements in rheumatoid arthritis were also seen in 12 of 36 postmenopausal women treated with intramuscular testosterone 50 mg plus a low dose of progesterone (2.5 mg) once every 2 weeks compared with 2 of 32 women receiving placebo.[2] However, a placebo-controlled study[3] in 30 men with normal serum-testosterone concentrations found no beneficial effect from intramuscular testosterone enantate on measures of disease activity.

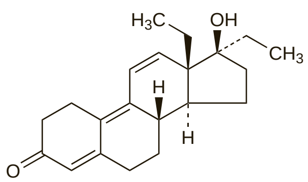
Tetrahydrogestrinone ⊗

THG. 18a-Homo-pregna-4,9,11-trien-17β-ol-3-one; .

$C_{21}H_{28}O_2$ = 312.4.

CAS — 618903-56-3.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of tetrahydrogestrinone: The Clear.

Profile

Tetrahydrogestrinone is a synthetic anabolic steroid that is structurally related to gestrinone (p.2106) and trenbolone (p.2135). It has been subject to abuse in sport.

Action. Tetrahydrogestrinone had androgenic and progestogenic activity in a yeast-based *in-vitro* bioassay study.[1] The anabolic and androgenic properties of tetrahydrogestrinone have also been studied in *animals*.[2-4]

2. Labrie F, *et al.* Tetrahydrogestrinone induces a genomic signature typical of a potent anabolic steroid. *J Endocrinol* 2005; **184:** 427–33.
3. Jasuja R, *et al.* Tetrahydrogestrinone is an androgenic steroid that stimulates androgen receptor-mediated, myogenic differentiation in C3H10T1/2 multipotent mesenchymal cells and promotes muscle accretion in orchidectomized male rats. *Endocrinology* 2005; **146:** 4472–8.
4. Friedel A, *et al.* Tetrahydrogestrinone is a potent but unselective binding steroid and affects glucocorticoid signalling in the liver. *Toxicol Lett* 2006; **164:** 16–23.

Tibolone *(BAN, USAN, rINN)* ⊗

7α-Methylnorethynodrel; Org-OD-14; Tibolon; Tibolona; Tiboloni; Tibolonum. 17β-Hydroxy-7α-methyl-19-nor-17α-pregn-5(10)-en-20-yn-3-one.

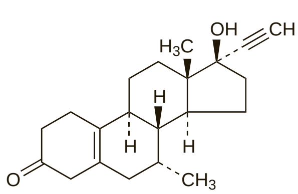
Тиболон

$C_{21}H_{28}O_2$ = 312.4.

CAS — 5630-53-5.

ATC — G03CX01.

ATC Vet — QG03CX01.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Tibolone). A white or almost white, crystalline powder or crystals. It exhibits polymorphism. Practically insoluble in water; soluble in acetone and in methyl alcohol. Store at a temperature of 2° to 8°.

Adverse Effects

Irregular vaginal bleeding or spotting may occur with tibolone, mainly during the first few months of treatment; unlike cyclical, but similar to continuous, combination HRT (p.2071), tibolone does not produce regular withdrawal bleeding. Other effects on the genital tract may include leucorrhoea, pruritus, candidiasis, and vaginitis. Other adverse effects have included breast pain, weight gain, oedema, dizziness, skin reactions, headache, migraine, visual disturbances, gastrointestinal disturbances, hypertrichosis, altered liver function, depression, and arthralgia or myalgia.

Incidence of adverse effects. In 1994, the UK CSM had received reports of 2796 suspected adverse reactions with tibolone over 3 years, out of about 666 000 prescriptions.[1] The commonest reported effects were headache, dizziness, nausea, rash, itching, and weight gain. Vaginal bleeding appeared to occur in about 8 to 9% of recipients. There had also been 52 reports of migraine, 4 of exacerbation of migraine, and 49 reports of visual disturbances, some suggestive of migraine.

1. CSM/MCA. Tibolone (Livial). *Current Problems* 1994; **20:** 14. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2015632&RevisionSelectionMethod=LatestReleased (accessed 18/08/08)

Carcinogenicity. *BREAST.* The large cohort Million Women study[1] examined breast cancer incidence and mortality in relation to HRT use. After an average follow-up of 2.6 years for incidence, and 4.1 years for mortality, data were available for a group of 18 186 women who had used tibolone. There were 184 cases of invasive breast cancer equating to an overall risk of 1.45 (95% confidence interval 1.25 to 1.68) relative to women who had never used HRT. This was between the relative risks calculated for oestrogen-only HRT (1.30) and combined HRT (2.00). The risk was raised for current but not past use of tibolone, and increased with total duration of use.

For comment on the risk of recurrence in women with a history of breast cancer see Malignant Neoplasms under Precautions, below.

1. Million Women Study Collaborators. Breast cancer and hormone-replacement therapy in the Million Women Study. *Lancet* 2003; **362:** 419–27. Correction. *ibid.*; 1160.

ENDOMETRIUM. Endometrial hyperplasia and endometrial carcinoma have been rarely reported after investigation of uterine bleeding in women receiving tibolone therapy,[1-3] as has exacerbation of adenomyosis.[4] Some of these women had previously received oestrogens.

A cohort and nested case-control study[5] found that tibolone might have been associated with an increased risk of endometrial cancer compared with conventional forms of combined HRT, but the data were weak and might have been affected by bias and uncontrolled confounding factors. The large cohort Million Women Study[6] of HRT included a group of 28 028 who had used tibolone for an average of about 3 years. The risk of endometrial cancer was increased to 1.79 (95% confidence interval 1.43 to 2.25) in those who had used tibolone, compared with women who had never used HRT, and the risk was higher with more than 3 years of use compared with shorter durations. In contrast, a smaller randomised study[7] comparing tibolone with combined HRT recorded no cases of endometrial hyperplasia or carcinoma in 1317 women given tibolone for up to 2 years.

2. Cummings SR. LIFT study is discontinued. *BMJ* 2006; **332:** 667.

Precautions

Tibolone is contra-indicated in women with hormone-dependent tumours, cardiovascular or cerebrovascular disorders including thrombophlebitis, thromboembolic processes, or a history of these conditions, undiagnosed vaginal bleeding, untreated endometrial hyperplasia, porphyria, and severe liver disorders. It should not be given to pregnant women and is not intended for use in premenopausal women, except those being treated with a gonadorelin analogue. Use of tibolone within 12 months of a natural menopause is also not recommended because irregular vaginal bleeding is likely. In postmenopausal women, vaginal bleeding starting after 3 months or more of treatment, or recurrent or persistent bleeding, should be investigated.

Care should be taken when giving tibolone to patients with uterine fibroids, endometriosis, liver disease, disorders that may be exacerbated by fluid retention such as cardiac or renal dysfunction, hypertension, epilepsy, or migraine, or with a history of these conditions. It should also be given with caution to patients with dyslipidaemia or diabetes mellitus. Tibolone should be stopped if there are signs of thromboembolism, a significant increase in blood pressure, new onset of migraine-type headache, or if abnormal liver function tests or cholestatic jaundice occur. Consideration should be given to stopping tibolone 4 to 6 weeks before elective surgery when prolonged immobilisation after surgery is likely.

Malignant neoplasms. Licensed product information for tibolone advises that it is contra-indicated in women with a history of hormone-dependent tumours. However, the risk of cancer recurrence associated with tibolone has not been determined and there have been a few reports of its use for menopausal symptoms in such patients. An observational study[1] and a case-control study[2] of women who had been treated for breast cancer found no evidence that tumour recurrence was higher in those subsequently given tibolone than in those who were not. Case-control studies have also suggested that tibolone does not increase the risk of recurrence of treated endometrial[3] or ovarian[4] cancers. Although promising, these data are limited and further studies are needed to confirm the safety of tibolone in these groups of patients, particularly as there is some evidence[5] that in UK general practice it may have been prescribed preferentially to women at increased risk of breast and endometrial cancers, including women with a history of breast cancer.

For reports of the incidence of breast and endometrial cancers in women given tibolone, see Carcinogenicity, above.

Interactions

Compounds that induce liver enzymes, such as phenytoin, carbamazepine, and rifampicin, might theoretically enhance the metabolism of tibolone and thus reduce its activity.

For reference to the effect of tibolone on the activity of oral anticoagulants, see Sex Hormones under Warfarin, p.1431.

Pharmacokinetics

Tibolone is rapidly and extensively absorbed after oral doses and quickly metabolised into three active metabolites, two of which have mainly oestrogenic activity while the third, like the parent compound, has progestogenic and androgenic activity. Peak concentrations of tibolone and its metabolites occur after about 1 to 1.5 hours, and the two main metabolites have an elimination half-life of about 7 hours. Metabolites are excreted in the bile and eliminated in the faeces. About 30% of a dose is excreted in the urine.

Uses and Administration

Tibolone is a steroid derived from noretynodrel that has oestrogenic, progestogenic, and weak androgenic properties. It is used as menopausal HRT (below) for oestrogen deficiency symptoms, including vasomotor symptoms, in postmenopausal women. Tibolone may also be used in the prevention of postmenopausal osteoporosis in women at high risk of fracture who cannot be treated with other therapy. The usual oral dose is 2.5 mg daily in a continuous regimen. Tibolone should not be started for at least 12 months after the last menstrual period of a natural menopause, but may be started immediately in women who have undergone a surgical menopause or who are being treated with a gonadorelin analogue. Unlike oestrogen-based HRT, a progestogen is not added to tibolone therapy for women with an intact uterus.

In women with a uterus who are transferring from an oestrogen-only form of HRT to tibolone, it is suggested that a withdrawal bleed be induced with a progestogen before starting tibolone, and in those transferring from a cyclical combined HRT, tibolone should be started the day after finishing a full cycle. Women taking continuous combined HRT can be transferred to tibolone at any time.

'Add-back' therapy. Tibolone reduces the vasomotor symptoms and bone loss caused by gonadorelin analogues, without impairing their efficacy in the treatment of endometriosis[1,2] (p.2091) and fibroids[3] (p.2107). Tibolone also reduced vasomotor symptoms in a short-term study of women being treated with leuprorelin for premenstrual syndrome[4] (p.2099).

4. Di Carlo C, *et al.* Use of leuprolide acetate plus tibolone in the treatment of severe premenstrual syndrome. *Fertil Steril* 2001; **75:** 380–4.

Menopausal disorders. The oestrogenic effects of tibolone make it effective in the management of menopausal disorders (p.2077) such as vasomotor symptoms and vaginal atrophy. It may also be used for the prevention of postmenopausal bone loss, and there is some evidence that it may be useful for treating postmenopausal osteoporosis and reducing fracture risk. The progestogenic effects of tibolone are thought to be sufficient to prevent endometrial proliferation, so that, unlike the oestrogens that are generally used for menopausal HRT (p.2076), a progestogen is not added to tibolone therapy for women with an intact uterus.

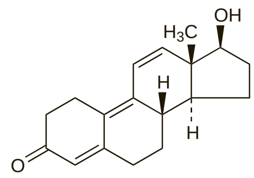
$C_{20}H_{24}O_3$ = 312.4.

CAS — 10161-33-8 (trenbolone); 10161-34-9 (trenbolone acetate).



(trenbolone)

Pharmacopoeias. In *US*, for veterinary use only.

USP 31 (Trenbolone Acetate). Store in airtight containers at a temperature of 2° to 8°.

Profile

Trenbolone acetate has been used as an anabolic agent in veterinary practice. The hexahydrobenzylcarbonate has also been used for its anabolic properties.

◊ WHO specifies an acceptable daily intake of trenbolone acetate as a residue in foods, and recommends maximum residue limits in various animal tissues.[1] However, it should be noted that, in the EU the use of trenbolone acetate and other anabolic steroids is restricted to certain therapeutic indications in non-food producing animals and their use as growth promotors is banned.

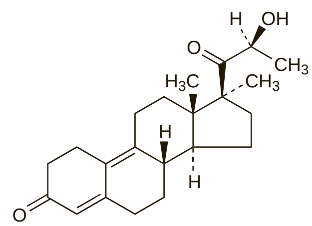
Тримегестон

$C_{22}H_{30}O_3$ = 342.5.

CAS — 74513-62-5.



Profile

Trimegestone is a progestogen (see Progesterone, p.2125) used as the progestogenic component of menopausal HRT (see p.2071). It is given orally in daily doses of 250 or 500 micrograms in a cyclical regimen, or 125 micrograms in a continuous regimen. Trimegestone is also under investigation as a component of a combined oral contraceptive.

Adverse Effects and Precautions

As for Gonadorelin, p.2106.

Local reactions. For reference to local reactions occurring following injection of gonadorelin analogues, including triptorelin, see Leuprorelin Acetate, p.2111.

Sepsis. A report of 2 patients in whom triptorelin therapy led to sepsis caused by expulsion of necrotic fibroids through the cervix.[1]

1. Ellenbogen A, *et al.* Complication of triptorelin treatment for uterine myomas. *Lancet* 1989; **ii:** 167–8.

Interactions

As for Gonadorelin, p.2107.

Pharmacokinetics

Triptorelin is rapidly absorbed after subcutaneous injection, with peak plasma concentrations achieved about 40 minutes after a dose. The biological half-life has been stated to be about 7.5 hours, although longer half-lives have been reported in patients with prostate cancer, and shorter half-lives in some groups of healthy subjects.

◊ References.

1. Müller FO, *et al.* Pharmacokinetics of triptorelin after intravenous bolus administration in healthy males and in males with renal or hepatic insufficiency. *Br J Clin Pharmacol* 1997; **44:** 335–41.

Uses and Administration

Triptorelin is an analogue of gonadorelin (p.2107) with similar properties. It is used for the suppression of gonadal sex hormone production in the treatment of malignant neoplasms of the prostate, deviant sexual behaviour in men, precocious puberty, and in the management of endometriosis, female infertility, and uterine fibroids. Triptorelin may be given as the base, acetate, diacetate, or embonate, although for some preparations stated to contain the acetate or diacetate it is not always clear which has actually been used. Doses are usually given in terms of the base, and the following are each equivalent to about 1 mg of triptorelin:

- triptorelin acetate, 1.05 mg
- triptorelin diacetate, 1.09 mg
- triptorelin embonate, 1.30 mg

Triptorelin is given as a daily subcutaneous injection, or as an intramuscular or subcutaneous depot preparation lasting a month or longer.

In the palliative treatment of advanced **prostate cancer**, a dose equivalent to triptorelin 3 or 3.75 mg is given intramuscularly as a depot preparation every 4 weeks; the first dose may be preceded by 100 micrograms daily for 7 days by subcutaneous injection. In some countries, depot preparations containing 3.75 mg may be given subcutaneously instead. A longer-acting depot preparation that contains the equivalent of triptorelin 11.25 mg is given once every 12 to 13 weeks. In some countries, depot doses of 3 mg once every 4 weeks or 11.25 mg once every 12 to 13 weeks may also be used for medical therapy in locally advanced disease. An anti-androgen such as cyproterone acetate may be given for several days before beginning therapy with triptorelin and continued for about 3 weeks to avoid the risk of a disease flare.

An 11.25-mg intramuscular depot preparation, given every 12 weeks, may be used in the management of **deviant sexual behaviour** in men. The addition of an anti-androgen should be considered when starting therapy, to counteract the initial rise in serum-testosterone concentrations.

Similar doses of the 3- or 3.75-mg depot preparations may be given for up to 6 months in the management of **endometriosis** or **uterine fibroids**, with treatment begun during the first 5 days of the menstrual cycle. The 11.25-mg depot may be used as an alternative for endometriosis. In the management of female infertility doses of 100 micrograms subcutaneously daily, with gonadotrophins, have been recommended from the second day of the menstrual cycle for about 10 to 12 days.

In children with **precocious puberty** a dose equivalent to triptorelin 50 micrograms/kg from the 3-mg depot preparation may be given intramuscularly every 4 weeks. Alternatively, using the 3.75-mg preparation, doses of 1.875 mg for children weighing less than 20 kg, 2.5 mg for children of 20 to 30 kg, or 3.75 mg for children of more than 30 kg may be given intramuscularly or subcutaneously; the first 3 doses should be given at 14-day intervals, with further doses given every 4 weeks. The longer acting 11.25-mg depot preparation, given intramuscularly once every 3 months, is another alternative.

Delayed and precocious puberty. Gonadorelin analogues such as triptorelin[1-6] are used in the management of central precocious puberty (p.2081). They may also be effective in delayed puberty (p.2079) although they are most likely to be helpful where this is due to hypogonadism. Triptorelin has been used to differentiate gonadotrophin deficiency from constitutional delayed puberty,[7,8] although one study[9] found it to be less accurate than a test using human chorionic gonadotrophin.

9. Degros V, *et al.* The human chorionic gonadotropin test is more powerful than the gonadotropin-releasing hormone agonist test to discriminate male isolated hypogonadotropic hypogonadism from constitutional delayed puberty. *Eur J Endocrinol* 2003; **149:** 23–9.

Disturbed behaviour. Combined therapy with triptorelin, which suppressed testosterone secretion by inhibiting the pituitary-gonadal axis, and supportive psychotherapy, has been tried in the treatment of men with paraphilias (see p.954): a reduction in abnormal sexual thoughts and behaviours has been reported, although the study was uncontrolled.[1]

1. Rösler A, Witztum E. Treatment of men with paraphilia with a long-acting analogue of gonadotropin-releasing hormone. *N Engl J Med* 1998; **338:** 416–22.

Endometriosis. Gonadorelin analogues are effective in the management of endometriosis (p.2091), but the need for long-term therapy to prevent recurrence limits their value because of the risk of osteoporosis; 'add-back' therapy (hormone replacement) can be used to prevent this.

4. Vercellini P, *et al.* Treatment with a gonadotrophin releasing hormone agonist before hysterectomy for leiomyomas: results of a multicentre, randomised controlled trial. *Br J Obstet Gynaecol* 1998; **105:** 1148–54.
5. Seracchioli R, *et al.* GnRH agonist treatment before total laparoscopic hysterectomy for large uteri. *J Am Assoc Gynecol Laparosc* 2003; **10:** 316–19.

Growth retardation. As discussed on p.1798 gonadorelin analogues have been given with growth hormone to short girls without growth hormone deficiency, in an attempt to delay puberty and bone maturation and thus maximise the final height achieved. Use in growth hormone-deficient children has also been investigated. However, there is some doubt about the extent of benefit, and in any case the concept of such treatment in children who are not clinically deficient in growth hormone is controversial, and some authorities do not consider it appropriate.

References to the use of triptorelin.

Porphyria. Triptorelin has been used successfully to suppress premenstrual exacerbations of acute intermittent porphyria (p.1448), in doses of 3.75 mg by intramuscular depot injection given monthly.[1,2] To reduce the risk of osteoporosis, 'add-back' therapy with topical oestrogen and oral calcium was used in one case,[1] and tibolone in another.[2]

Urofollitropin *(BAN, USAN, rINN)* ⊗

Ürofolitropin; Urofolitropin; Urofolitropina; Urofolitropinas; Urofollitrophin; Urofollitropiini; Urofollitropine; Urofollitropinum.

Урофоллитропин

CAS — 97048-13-0.

ATC — G03GA04.

ATC Vet — QG03GA04.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Urofollitropin). A dry preparation containing menopausal gonadotrophin obtained from the urine of postmenopausal women. It has follicle-stimulating activity and no or virtually no luteinising activity. The potency is not less than 90 units of follicle-stimulating hormone per mg; the ratio of units of luteinising hormone to units of follicle-stimulating hormone is not more than 1:60. An almost white or slightly yellow powder. Soluble in water. Store in airtight containers at a temperature of 2° to 8°. Protect from light.

Adverse Effects and Precautions

As for Human Menopausal Gonadotrophins, p.2109.

Pharmacokinetics

After multiple intramuscular or subcutaneous dosing of urofollitropin, the maximum plasma concentration of follicle-stimulating hormone occurs about 10 hours after a dose, and has an elimination half-life of about 15 or 20 hours respectively.

Uses and Administration

Urofollitropin is a gonadotrophin, obtained from the urine of postmenopausal women, possessing follicle-stimulating hormone (FSH) activity but virtually no luteinising activity. For details of the actions of FSH, see p.2104.

Urofollitropin is used similarly to human menopausal gonadotrophins (p.2110) in the treatment of **female infertility** with the exception that, being without luteinising hormone activity, it can be used in patients where any increase in luteinising hormone activity is not required, as in polycystic ovarian disease. Urofollitropin is given subcutaneously or intramuscularly in a dosage adjusted according to the patient's response. Usually a dose providing 75 to 150 units of FSH daily is given initially. When an adequate response is achieved, as determined by oestrogen monitoring or ultrasonic visualisation of follicles, treatment is stopped and after 1 or 2 days a single dose of chorionic gonadotrophin 5000 to 10 000 units is given to induce ovulation. Treatment with urofollitropin should be stopped if there is no response after 4 weeks although treatment may be attempted again in future cycles. US product information has recommended that a maximum daily dose of 450 units should not be exceeded, and that courses of treatment should be no longer than 12 days.

Urofollitropin is also used with other drugs as part of IVF procedures. It is typically given in a dose providing 150 to 225 units of FSH daily, usually beginning from day 2 or 3 of the menstrual cycle. Alternatively, therapy has been begun with clomifene citrate and continued with urofollitropin, or urofollitropin may be given after suppression of gonadotrophin release with a gonadorelin analogue. Treatment is continued until an adequate response is obtained and the final injection of urofollitropin is followed 1 to 2 days later by 5000 to 10 000 units of chorionic gonadotrophin. Oocyte retrieval is performed 34 to 35 hours later.

Urofollitropin is also used with chorionic gonadotrophin to stimulate spermatogenesis in the treatment of **male infertility**, although a preparation with combined luteinising activity, such as human menopausal gonadotrophins, may be preferred. The usual dose of urofollitropin provides 150 units of FSH three times a week. Treatment with urofollitropin and chorionic gonadotrophin should be continued for at least 4 months. For a brief discussion of hypogonadism see p.2079.

Infertility. For reference to the use of preparations with follicle-stimulating hormone activity in infertility, see p.2080.

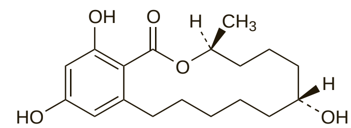
Zeranol *(BAN, USAN, rINN)* ⊗

MK-188; P-1496; THFES (HM); Zearalanol; Zéranol; Zeranolum.
(3*S*,7*R*)-3,4,5,6,7,8,9,10,11,12-Decahydro-7,14,16-trihydroxy-3-methyl-1*H*-2-benzoxacyclotetradecin-1-one.
Зеранол
$C_{18}H_{26}O_5$ = 322.4.
CAS — 26538-44-3.



Profile

Zeranol is a nonsteroidal oestrogen that has been used for the management of menopausal and menstrual disorders. It has also been used as a growth promotor in veterinary practice. Its anabolic properties may be subject to abuse in sport.

◊ WHO specifies an acceptable daily intake of zeranol as a residue in foods and recommends maximum residue limits in various animal tissues.[1] However, it should be noted that, in the European Union the use of zeranol in veterinary medicine is prohibited. Certain other steroidal hormones are permitted for restricted use but their use as growth promotors is banned.

Soaps and Other Anionic Surfactants

Soaps and other anionic surfactants dissociate in aqueous solution to form an anion, which is responsible for the surface activity, and a cation which is devoid of surface-active properties. They are widely used for their emulsifying and cleansing properties. The term **detergent** is used to describe a surface-active agent with such properties that concentrates at oil-water interfaces. Anionic surfactants used in pharmaceutical preparations include:

- **Alkali-metal** and **ammonium soaps** (monovalent alkyl carboxylates) which are the sodium, potassium, and ammonium salts of the higher fatty acids
- **Metallic soaps** (polyvalent alkyl carboxylates), the calcium, zinc, magnesium, and aluminium salts of the higher fatty acids; they produce water-in-oil emulsions and are often formed by chemical reaction during the preparation of the emulsion
- **Amine soaps**, which are salts of amines with fatty acids
- **Alkyl sulfates** or **sulfated fatty alcohols**, salts of the sulfuric acid esters of the higher fatty alcohols
- **Alkyl ether sulfates** or **ethoxylated alkyl sulfates**, formed by sulfating ethoxylated alcohols.
- **Sulfated oils**, which are prepared by treating fixed oils with sulfuric acid and neutralising with sodium hydroxide solution.

Many **sulfonated compounds** have been produced that possess surface-active properties and are used as detergents; they include alkyl sulfonates, alkyl aryl sulfonates, and amide sulfonates. Docusate sodium (p.1725), a sulfonated dibasic acid ester, has medicinal and pharmaceutical uses.

Ampholytic (or amphoteric) surfactants possess at least one anionic group and at least one cationic group in the molecule and can therefore have anionic, nonionic, or cationic properties depending on the pH. When the strength of the cationic portion of the molecule is equivalent to that of the anionic portion the isoelectric point occurs at pH 7 and the molecule is said to be balanced. Ampholytic surfactants have the detergent properties of anionic surfactants and the disinfectant properties of cationic surfactants. Their activity depends on the pH of the media in which they are used. Compounds used include aminocarboxylic acids, aminopropionic acid derivatives, imidazoline derivatives, and dodicin. Long-chain betaines are sometimes classed as ampholytic surfactants.

Balanced ampholytic surfactants are reputed to be non-irritant to the eyes and skin and have therefore been used in baby shampoos.

Aluminium Monostearate

Aluminii monostearas; Aluminium, monostéarate de; Aluminum Monostearate; Glinu monostearynian; Monoestearato de aluminio; Monostearato de aluminio. Dihydroxy(octadecanoato-*O*-)aluminium; Dihydroxy(stearato)aluminium.

Алюминия Моностеарат

CAS — 7047-84-9.

Pharmacopoeias. In *Jpn* and *Pol.* Also in *USNF.*

USNF 26 (Aluminum Monostearate). A compound of aluminium with a mixture of solid organic acids obtained from fats and consisting mainly of variable proportions of aluminium monostearate and aluminium monopalmitate. A fine, white to yellowish-white, bulky powder with a faint characteristic odour. Insoluble in water, in alcohol, and in ether.

Profile

Aluminium monostearate is used as a gelling agent in oil-based cosmetic and pharmaceutical formulations. It may also be used as a stabiliser in cosmetic emulsions.

Calcium Stearate

Calcii stearas; Calcium, stéarate de; Estearato de calcio; Kalcio stearatas; Kalciumstearat; Kalcium-sztearát; Kalsiumstearaatti; Stearan vápenatý. Calcium octadecanoate.

Кальция Стеарат

CAS — 542-42-7 (calcium palmitate); 1592-23-0 (calcium stearate).

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Calcium Stearate). A mixture of calcium salts of different fatty acids consisting mainly of stearic acid ($C_{36}H_{70}CaO_4$ = 607.0) and palmitic acid ($C_{32}H_{62}CaO_4$ = 550.9) with minor proportions of other fatty acids. The fatty acid fraction contains not less than 40.0% of stearic acid and the sum of stearic acid and palmitic acids is not less than 90.0%. A fine, white or almost white, crystalline powder. Practically insoluble in water and in alcohol.

USNF 26 (Calcium Stearate). A compound of calcium with a mixture of solid organic acids obtained from fats, consisting mainly of variable proportions of calcium stearate ($C_{36}H_{70}CaO_4$ = 607.0) and calcium palmitate ($C_{32}H_{62}CaO_4$ = 550.9). A fine, white to yellowish-white bulky, unctuous powder, free from grittiness with a slight characteristic odour. Insoluble in water, in alcohol, and in ether.

Profile

Calcium stearate is added to granules as a lubricant in the manufacture of tablets and capsules.

Adverse effects. Acute eosinophilic pneumonia in 1 patient has been attributed to the presence of calcium stearate used as an additive in an antihistamine tablet formulation.[1]

1. Kurai J, *et al.* Acute eosinophilic pneumonia caused by calcium stearate, an additive agent for an oral antihistaminic medication. *Intern Med* 2006; **45:** 1011–16.

Calcium Stearoyl-lactylate

Calcium Stearoyl-2-lactylate; E482. Calcium 2-(1-Carboxyethoxy)-1-methyl-2-oxoethyloctodecanoate.

Стеароиллактилат Кальция

CAS — 5793-94-2.

Sodium Stearoyl-lactylate

E481; Sodium Stearoyl-2-lactylate. Sodium 2-(1-Carboxyethoxy)-1-methyl-2-oxoethyloctadecanoate sodium salt.

Стеароиллактилат Натрия

CAS — 25383-99-7.

Profile

Sodium stearoyl-lactylate has anionic surfactant properties and is used as an emulsifier and stabilising and suspending agent in the food industry, including in foods for special diets. The calcium salt is used similarly.

Magnesium Stearate

572; Estearato de magnesio; Magnesii stearas; Magnésium, stéarate de; Magnesiumstearaatti; Magnesiumstearat; Magnézium-sztearát; Magnezu stearynian; Magnio stearatas; Stearan hořečnatý.

Стеарат Магния

CAS — 1555-53-9 (magnesium oleate); 2601-98-1 (magnesium palmitate); 557-04-0 (magnesium stearate).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn*, and *Viet.* Also in *USNF.*

Ph. Eur. 6.2 (Magnesium Stearate). A mixture of the magnesium salts of different fatty acids consisting mainly of stearic acid ($C_{36}H_{70}MgO_4$ = 591.2) and palmitic acid ($C_{32}H_{62}MgO_4$ = 535.1) and in minor proportions other fatty acids. The fatty acid fraction contains not less than 40.0% of stearic acid and the sum of stearic acid and palmitic acid is not less than 90.0%. A white or almost white, very fine, light powder, greasy to the touch. Practically insoluble in water and in dehydrated alcohol.

USNF 26 (Magnesium Stearate). A compound of magnesium with a mixture of solid organic acids, and consisting mainly of variable proportions of magnesium stearate ($C_{36}H_{70}MgO_4$ = 591.2) and magnesium palmitate ($C_{32}H_{62}MgO_4$ = 535.1). It is a very fine, light, white powder, slippery to touch. Insoluble in water, in alcohol, and in ether.

Profile

Magnesium stearate is added to granules as a lubricant in the manufacture of tablets and capsules. It has also been used as a dusting powder and in barrier creams.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Philipp.:*** Johnson's Baby Double Protection Powder.

Sodium Cetostearyl Sulfate

Cetoestearilsulfato de sodio; Cétostéaryle (sulfate de) sodique; Cetylstearylschwefelsaures Natrium; Natrii cetylo- et stearylosulfas; Natrio cetostearilo sulfatas; Natrium Cetylosulphuricum; Natrium Cetylstearylosulphuricum; Nátrium-cetil-sztearil-szulfát; Natriumcetostearylsulfat; Natrium-cetylstearyl-sulfát; Natriumsetostearyylisulfaatti; Sodium Cetostearyl Sulphate; Sodu cetostearylosiarczan.

Натрия Цетостеарилсульфат

CAS — 1120-01-0 (sodium cetyl sulfate); 1120-04-3 (sodium stearyl sulfate).

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Cetostearyl Sulphate). A mixture of sodium cetyl sulfate ($C_{16}H_{33}NaO_4S$ = 344.5) and sodium stearyl sulfate ($C_{18}H_{37}NaO_4S$ = 372.5). A white or pale yellow, amorphous or crystalline powder. Soluble in hot water giving an opalescent solution; practically insoluble in cold water; partly soluble in alcohol.

USNF 26 (Sodium Cetostearyl Sulfate). A mixture of sodium cetyl sulfate ($C_{16}H_{33}NaSO_4$ = 344.5) and sodium stearyl sulfate ($C_{18}H_{37}NaSO_4$ = 372.5). It contains not less than 40% of sodium cetyl sulfate and the sum of the sodium cetyl sulfate content and sodium stearyl sulfate content is not less than 90%, both contents calculated on the anhydrous basis. A white or pale yellow, amorphous or crystalline powder. Soluble in hot water giving an opalescent solution; practically insoluble in cold water; partly soluble in alcohol.

Profile

Sodium cetostearyl sulfate is an anionic emulsifying agent. It is used as a detergent and wetting agent.

Sodium Cocoyl Isetionate

Sodium Cocoyl Isethionate.

Кокоил Изетионат Натрия

CAS — 61789-32-0.

Profile

Sodium cocoyl isetionate is the sodium salt of a sulfonated ester of coconut oil fatty acids. It is an anionic surfactant used as a soap substitute. Sodium cocoyl sarcosinate has been used similarly.

Preparations

Proprietary Preparations (details are given in Part 3)

Fr.: Physiogel; ***Hong Kong:*** Physiogel; ***Indon.:*** Physiogel; ***Ital.:*** Physiogel; ***Malaysia:*** Physiogel; ***Singapore:*** Physiogel; ***Thai.:*** Physiogel.

Multi-ingredient: ***Fr.:*** Oilatum AD†; ***Mex.:*** Bonaven; ***Philipp.:*** Physiogel.

Sodium Laurilsulfate *(pINNM)*

Laurilsulfate de Sodium; Laurilsulfato de sodio; Natrii laurilsulfas; Natrio laurilsulfatas; Natrium Lauryl Sulphuricum; Natriumlaurilsulfat; Nátrium-lauril-szulfát; Natrium-lauryl-sulfát; Natriumlauryylisulfaatti; Sodium Dodecyl Sulphate; Sodium, laurilsulfate de; Sodium Lauryl Sulfate; Sodium Lauryl Sulphate; Sodu dodecylosiarczan patrz: Sodu laurylosiarczan; Sodu laurylosiarczan.

Натрий Лаурилсульфат

CAS — 151-21-3.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Sodium Laurilsulfate; Sodium Lauryl Sulphate BP 2008). A mixture of sodium alkyl sulfates, consisting mainly of sodium dodecyl sulfate ($C_{12}H_{25}NaO_4S$ = 288.4). It contains not less than 85% of sodium alkyl sulfates and not more than a total of 8% of sodium chloride and sodium sulfate. A white or pale yellow powder or crystals. Freely soluble in water giving an opalescent solution; partly soluble in alcohol.

USNF 26 (Sodium Lauryl Sulfate). A mixture of sodium alkyl sulfates, consisting mainly of sodium laurilsulfate ($C_{12}H_{25}NaO_4S$ = 288.4). The combined content of sodium chloride and sodium sulfate is not more than 8%. Small, white or light yellow crystals with a slight, characteristic odour. Soluble 1 in 10 of water giving an opalescent solution.

Incompatibility. Sodium laurilsulfate interacts with cationic surfactants such as cetrimide, resulting in a loss of activity. It is also incompatible with salts of polyvalent metal ions (e.g. aluminium, lead, tin, or zinc) and with acids of pH below 2.5. It is not affected by hard water because of the solubility of the corresponding calcium and magnesium salts.

Profile

Sodium laurilsulfate is an anionic emulsifying agent. It is a detergent and wetting agent, effective in both acid and alkaline solution and in hard water. It is used in medicated shampoos and as a skin cleanser and in toothpastes. It is used in the preparation of Emulsifying Wax (p.2029). Prolonged exposure to sodium laurilsulfate may irritate the skin or mucous membranes.

Other salts of laurilsulfate have been used for their surfactant properties. These include monoethanolamine, diolamine, and trolamine laurilsulfates, and magnesium and ammonium laurilsulfates. Similar surfactants include sodium lauril ether sulfate and sodium alkyl sulfoacetates such as sodium lauril sulfoacetate.

Sodium laurilsulfate and related surfactants are also included in some combination preparations used rectally for the management of constipation.

Preparations

BP 2008: Emulsifying Wax.

Proprietary Preparations (details are given in Part 3)

Sodium Oleate

Oleato de sodio.

Олеиновокислый Натрий

CAS — 143-19-1.

Profile

Sodium oleate is an anionic surfactant used as an ingredient in preparations for the symptomatic relief of haemorrhoids and pruritus ani.

Zinc oleate and potassium oleate have also been used in skin preparations, while the sodium, potassium, and calcium salts have had applications as food additives.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Belg.:*** Cose-Anal; ***Ger.:*** Alcos-Anal†; Neo-Ballistol†; ***Neth.:*** Epianal; ***Norw.:*** Alcos-Anal; ***Swed.:*** Alcos-Anal.

Sodium Stearate

Estearato de sodio; Natrii stearas; Natrio stearatas; Natriumstearaatti; Natriumstearat; Sodium, stéarate de; Sodu stearynian; Stearan sodný.

Стеарат Натрия

CAS — 408-35-5 (sodium palmitate); 822-16-2 (sodium stearate).

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Stearate). A mixture of sodium salts of different fatty acids consisting mainly of stearic acid ($C_{18}H_{35}O_2Na$ = 306.5) and palmitic acid ($C_{16}H_{31}O_2Na$ = 278.4). It contains 7.4 to 8.5% of sodium, calculated with reference to the dried substance. The fatty acid fraction contains not less than 40% of stearic acid and the sum of stearic acid and palmitic acid is not less than 90%. A white or yellowish, fine powder, with a greasy touch. Slightly soluble in water and in alcohol. Store in airtight containers. Protect from light.

USNF 26 (Sodium Stearate). A mixture containing not less than 90% of sodium stearate ($C_{18}H_{35}NaO_2$ = 306.5) and sodium palmitate ($C_{16}H_{31}NaO_2$ = 278.4); the content of sodium stearate is not less than 40% of the total. It contains small amounts of the sodium salts of other fatty acids. A fine, white powder, soapy to the touch, usually with a slight tallow-like odour. Slowly soluble in cold water and in cold alcohol; readily soluble in hot water and in hot alcohol. Protect from light.

Profile

Sodium stearate is an emulsifying and stiffening agent used in a variety of topical and rectal preparations.

Sodium Stearyl Fumarate

Fumarato de estearilo y sodio; Natrii stearylis fumaras; Natrio stearilfumaratas; Natriumstearylfumarat; Natrium-stearyl-fumarát; Natriumstearyylifumaraatti; Nátrium-sztearil-fumarát; Stéaryle (fumarate de) sodique.

Натрия Стеарилфумарат

$C_{22}H_{39}NaO_4$ = 390.5.

CAS — 4070-80-8.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Stearyl Fumarate). A fine, white or almost white powder with agglomerates of flat, circular shaped particles. Practically insoluble in water, in alcohol, and in acetone; slightly soluble in methyl alcohol.

USNF 26 (Sodium Stearyl Fumarate). A fine white powder. Practically insoluble in water; slightly soluble in methyl alcohol.

Profile

Sodium stearyl fumarate is used as a lubricant in the manufacture of tablets and capsules.

Sodium Tetradecyl Sulfate *(rINN)*

Natrii Tetradecylis Sulfas; Natriumtetradecylsulfat; Natriumtetradekyylisulfaatti; Sodium Tetradecyl Sulphate; Tetradecilsulfato de sodio; Tétradécyl Sulfate de Sodium. Sodium 4-ethyl-1-isobutyloctyl sulfate.

Натрия Тетрадецил Сульфат

$C_{14}H_{29}NaO_4S$ = 316.4.

CAS — 139-88-8.

ATC — C05BB04.

ATC Vet — QC05BB04.

Pharmacopoeias. *Br.* includes as a concentrated form.

BP 2008 (Sodium Tetradecyl Sulphate Concentrate). A clear, colourless gel. Store at a temperature not exceeding 25°. Protect from light.

Adverse Effects and Precautions

The complications of injection sclerotherapy with sclerosants such as sodium tetradecyl sulfate are discussed under Monoethanolamine Oleate, p.2346.

Uses and Administration

Sodium tetradecyl sulfate is an anionic surfactant. It has sclerosing properties and is used in the treatment of varicose veins (p.2347). It has also been given in the management of bleeding oesophageal varices (p.2346), and tried in endoscopic injection therapy for nonvariceal bleeding associated with peptic ulcer disease (p.1702).

For sclerotherapy of varicose veins a solution of sodium tetradecyl sulfate is injected slowly into the lumen of an isolated segment of an emptied superficial vein, followed by compression. Solutions are available in a variety of strengths (0.2 to 3%); doses depend on the site and condition being treated. A test dose is advisable in patients with a history of allergy. Facilities for treating anaphylaxis should be available.

Preparations

BP 2008: Sodium Tetradecyl Sulphate Injection.

Proprietary Preparations (details are given in Part 3)

Arg.: Fibro-Vein; ***Austral.:*** Fibro-Vein†; ***Canad.:*** Trombojet; Trombovar†; ***Cz.:*** Fibro-Vein†; ***Fr.:*** Trombovar; ***Hung.:*** Fibro-Vein; ***Irl.:*** Fibro-Vein; ***Ital.:*** Fibro-Vein; Trombovar; ***Malaysia:*** Trombovar†; ***Neth.:*** Trombovar; ***NZ:*** Fibro-Vein; ***Rus.:*** Trombovar (Тромбовар); ***S.Afr.:*** Fibrovein; STD; ***UK:*** Fibro-Vein; ***USA:*** Sotradecol.

Soft Soap

Green Soap; Jabón blando; Jabón de potasa; Jabón verde; Medicinal Soft Soap; Mydło potasowe; Potassium Soap; Sabão Mole; Sapo Mollis.

Зелёное Мыло; Калиевое Мыло

Pharmacopoeias. In *Br.*, *Chin.*, and *US.*

BP 2008 (Soft Soap). It is made by the interaction of potassium hydroxide or sodium hydroxide with a suitable vegetable oil or oils or their fatty acids. It may be coloured with chlorophyll or not more than 0.015% of a suitable green soap dye. A yellowish-white to green or brown, unctuous substance. Soluble in water and in alcohol.

USP 31 (Green Soap). It is made by the saponification of suitable vegetable oils, excluding coconut oil and palm kernel oil, without the removal of glycerol. The method given in the USP 31 involves mixing the oil with oleic acid and to the heated mixture adding potassium hydroxide dissolved in glycerol and water. The homogeneous emulsion is then adjusted to weight with hot water. A yellowish-white to brownish- or greenish-yellow, transparent to translucent, soft unctuous mass with a slight, characteristic odour.

Adverse Effects and Treatment

Soaps and anionic detergents, in general, may be irritant to the skin by removing natural oils and may produce redness, soreness, cracking and scaling, and papular dermatitis. There may be some irritation of the mucous membranes and this limits the use of soap enemas; marked irritation may occur if soaps or detergents enter the eye. Ingestion of anionic detergents may cause gastrointestinal irritation with nausea, diarrhoea, intestinal distension, and occasionally vomiting. Treatment is symptomatic.

Uses

Soft soap is used to remove incrustations in chronic scaly skin diseases such as psoriasis (p.1583) and to cleanse the scalp before the application of lotions. A solution of soft soap in warm water has been used as an enema to soften impacted faeces but should be avoided as it may inflame the colonic mucosa; other measures are now preferred (see Constipation, p.1693). Alcoholic solutions of soft soap, such as Soap Spirit (BP 2008) and Green Soap Tincture (USP 31), are used as skin cleansers and detergents.

Potash soap (linseed oil soap) has been used in the preparation of liquid soaps. Hard soap (castile soap) and curd soap were formerly used as pill excipients and hard soap was also formerly used in the preparation of plasters.

Preparations

BP 2008: Soap Spirit;
USP 31: Green Soap; Green Soap Tincture.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Austria:*** Waldheim Abfuhrdragees forte; Waldheim Abfuhrdragees mild; ***Spain:*** Linimento Naion; ***USA:*** Therevac Plus; Therevac SB.

Sulfated Castor Oil

Aceite de ricino sulfatado; Ol. Ricin. Sulphat.; Oleum Ricini Sulphatum; Red Oil; Sulfonated Castor Oil; Sulphated Castor Oil; Turkey-red Oil.

Ализариновое Масло; Сульфированное Касторовое Масло

CAS — 8002-33-3.

Profile

Sulfated castor oil is a detergent and wetting agent derived from castor oil (p.2278); it has been used as a skin cleanser and emulsifying agent. Sodium ricinoleate has been used similarly.

Sulfated hydrogenated castor oil (hydroxystearin sulfate) has been used in the manufacture of hydrophilic ointment bases and other emulsions.

Zinc Stearate

Cinko stearatas; Cink-sztearát; Cynku stearynian; Estearato de zinc; Sinkkistearaatti; Stearan zinečnatý; Zinc, stéarate de; Zinci stearas; Zinkstearat.

Стеарат Цинка

CAS — 4991-47-3 (zinc palmitate); 557-05-1 (zinc stearate).

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Zinc Stearate). Zinc stearate [$(C_{17}H_{35}CO_2)_2Zn$ = 632.3] may contain varying proportions of zinc palmitate [$(C_{15}H_{31}CO_2)_2Zn$ = 576.2] and zinc oleate [$(C_{17}H_{33}CO_2)_2Zn$ = 628.3]. A light, white or almost white, amorphous powder, free from gritty particles. Practically insoluble in water and in dehydrated alcohol.

USP 31 (Zinc Stearate). A compound of zinc with a mixture of solid organic acids obtained from fats and consisting mainly of variable proportions of zinc stearate [$(C_{17}H_{35}CO_2)_2Zn$ = 632.3] and zinc palmitate [$(C_{15}H_{31}CO_2)_2Zn$ = 576.2]. A fine, white, bulky powder, free from grittiness, with a faint characteristic odour. Insoluble in water, in alcohol, and in ether.

Adverse Effects

Zinc stearate inhalation has caused fatal pneumonitis, particularly in infants.

Uses

Zinc stearate is added to granules as a lubricant in the manufacture of tablets and capsules.

Zinc stearate has also been used as a soothing and protective application in the treatment of skin inflammation. It may be used either alone or with other powders or in the form of a cream.

Preparations

USP 31: Compound Clioquinol Topical Powder.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Prurisedan; ***Ital.:*** Steril Zeta; ***Switz.:*** Hydrocortisone compositum; ***Thai.:*** Banocin; ***UK:*** Simpsons.

Stabilising and Suspending Agents

The stabilising and suspending agents described in this chapter have the property of increasing the viscosity of water when dissolved or dispersed. The rheological properties of the dispersions can vary widely from thin liquids to thick gels.

They have wide applications both in pharmaceutical manufacturing and in the food industry. As well as being used as thickening and suspending agents many are used in emulsions as stabilisers and in some cases as emulsifying agents; some are also used in the manufacture of tablets as disintegrants, binding and granulating agents, and for film or enteric coating.

Some are used in artificial tear and artificial saliva preparations which are used in the management of dry eye and dry mouth respectively. Those most commonly used are carbomers, cellulose ethers such as carmellose and hypromellose, polyvinyl alcohol, and povidone. Some, such as the alginates and methylcellulose, are also used in gastrointestinal disorders.

Dry eye

Dry eye is a chronic condition caused by instability of the tear film covering the eye; the tear film breaks up to leave dry spots rather than being maintained between blinks. Tears consist of a slightly alkaline fluid that is spread across the eye by blinking and is lost via the lachrymal ducts or by evaporation. Mucus secreted by the conjunctiva is also required to maintain tear film stability and dry eye can result from reduced production of either tears or conjunctival mucus. Reduced tear secretion is common in the elderly, but also occurs in some systemic disorders or as an adverse effect of drugs such as those, like tricyclic antidepressants, that have antimuscarinic effects. Tear film instability may also result from increased tear evaporation, for example due to corneal exposure in thyroid disease, or from lid, corneal, or other eye disorders.

The main symptoms of dry eye are discomfort, typically with a chronic gritty sensation, visual disturbances, and sometimes photophobia. If left untreated corneal ulceration and eventual loss of sight may occur. Keratoconjunctivitis sicca (corneal inflammation) may result from severe dry eye in Sjögren's syndrome (see below).

Treatment of dry eye is primarily symptomatic using 'artificial tears' preparations; eye drops containing hypromellose or other cellulose ethers (carmellose, hyetellose, methylcellulose), polyvinyl alcohol, or povidone are used. Carbomer, in liquid gel formulations, and ointments containing soft or liquid paraffins are also used. Ointments have a longer duration of action than drops, but tend to blur the vision and are most suitable for use at night. Drops should be used as frequently as required, up to hourly or more often if necessary. Frequent use of eye drops may cause sensitivity to the preservative, in which case preservative-free preparations should be considered. An alternative in patients needing very frequent instillation of drops is a slow-release ophthalmic insert of hyprolose. Punctal occlusion with gelatin rods or collagen implants is used diagnostically to block tear outflow and treatment by permanent occlusion may be considered. Mucus build-up due to reduced tear production may respond to topical mucolytics such as acetylcysteine or bromhexine. Topical immunosuppressants such as ciclosporin may be of benefit in some patients with keratoconjunctivitis sicca;[1] combination of topical ciclosporin with punctal occlusion has been tried.[2]

Sjögren's syndrome is an auto-immune inflammatory disease primarily affecting the lachrymal and salivary glands, and manifests as dry eye and dry mouth. It is often secondary to an auto-immune disorder such as rheumatoid arthritis.[3] Treatment is mainly symptomatic[4] using artificial tears and topical mucolytics for dry eye; dry mouth is treated with artificial saliva as outlined below. Oral pilocarpine may be of benefit for both dry eye and dry mouth;[5,6] systemic treatment with the mucolytic bromhexine has produced conflicting results.[7-9] Corticosteroids and immunosuppressants may have a role in patients with CNS involvement.[10]

Dry mouth

Dryness of the mouth (xerostomia) resulting from decreased salivary secretion is often an adverse effect of therapy with drugs such as antimuscarinics, antihistamines, tricyclic antidepressants, and diuretics. Other causes include dehydration, anxiety, Sjögren's syndrome (see Dry Eye, above), and radiotherapy of the head and neck. Dry mouth can cause eating difficulties and lead to oral disease such as candidiasis, dental caries, and bacterial infections.[1,2] Where possible any underlying disorder should be treated first.

Frequent sips of fluids help to relieve dry mouth. Artificial saliva products are also important in the symptomatic treatment of dry mouth. They aim to mimic normal saliva and generally contain viscosity-increasing agents, such as mucins or cellulose derivatives such as carmellose,[3,4] as well as electrolytes, including fluoride; they seldom relieve symptoms for more than 1 or 2 hours. It may be possible to stimulate saliva production with sialogogues such as sugarless chewing gum or citrus products but the low pH of the latter can damage the teeth. Malic acid has also been used as a sialogogue.

A number of systemic therapies have also been tried. Pilocarpine is an effective sialogogue, increasing salivary production where some function remains,[5] and is used in dry mouth following radiotherapy; it may also be effective in Sjögren's syndrome or other causes of dry mouth. Adverse effects, particularly increased sweating, may, however, limit its use.[6] Carbachol has been suggested as an alternative to pilocarpine with a study[7] reporting comparable efficacy but less sweating. Anethole trithione and cevimeline have been used similarly. Amifostine is used for the prevention of dry mouth associated with radiotherapy.

Acacia

Acac.; Acaciae gummi; Akaasiakumi; Akaciagummi; Arabmézga; Arabská klovatina; E414; Goma arábiga; Gomme arabique; Gomme de Sénégal; Gum Acacia; Gum Arabic; Guma arabska; Gumiarabikas; Gummi Africanum; Gummi Arabicum; Gummi Mimosae.

CAS — 9000-01-5.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Acacia). The air-hardened gummy exudate from the trunk and branches of *Acacia senegal*, other species of *Acacia* of African origin, and *Acacia seyal*. Yellowish-white, yellow, or pale amber tears, sometimes with a pinkish tint. It is friable, opaque, frequently with a cracked surface, easily broken into irregular, whitish or slightly yellowish angular fragments with conchoidal fracture and a glassy and transparent appearance. Very slowly but almost completely soluble, after about 2 hours, in twice its mass of water leaving only a very small residue of vegetable particles; the liquid obtained is colourless or yellowish, dense, viscous, adhesive, translucent, and weakly acid to blue litmus paper. Practically insoluble in alcohol. Protect from light.

Ph. Eur. 6.2 (Acacia, Spray-dried; Acaciae Gummi Dispersione Desiccatum). It is obtained from a solution of acacia. Dissolves, rapidly and completely, after about 20 minutes, in twice its mass of water. The liquid obtained is colourless or yellowish, dense, viscous, adhesive, translucent, and weakly acid to blue litmus paper. Practically insoluble in alcohol. Protect from light.

USNF 26 (Acacia). The dried gummy exudate from the stems and branches of *Acacia senegal* (Leguminosae) or of other related African species of *Acacia*. Spheroidal tears or angular fragments of white to yellowish-white colour. It is translucent or somewhat opaque from the presence of numerous minute fissures. It is very brittle, the fractured surface is glassy and occasionally iridescent. It is also available as flakes, powder, granules, or as a spray-dried form. It is practically odourless. Insoluble in alcohol. Store in airtight containers.

Incompatibility. Incompatibilities of acacia have been reported with a number of substances including alcohol, aminophenazone, apomorphine, cresol, ferric salts, morphine, phenol, physostigmine, tannins, thymol, and vanillin. Acacia contains an oxidising enzyme that may affect preparations containing easily oxidised substances; the enzyme may be inactivated by heating at 100° for a short time.

Adverse Effects

Hypersensitivity reactions have occurred rarely after inhalation or ingestion of acacia.

Uses

Acacia is used in pharmaceutical manufacturing as a suspending and emulsifying agent, as a tablet binder, and in pastilles. It is often used with tragacanth.

It is used as an emulsifier and stabiliser in the food industry.

Preparations

USNF 26: Acacia Syrup.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Indon.:*** Norflam.

Agar

Agar-agar; Agaras; Colle du Japon; E406; Gelosa; Gélose; Japanese Isinglass; Layor Carang.

CAS — 9002-18-0.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Agar). Polysaccharides extracted from various species of Rhodophyceae algae, mainly those belonging to the genus *Gelidium*. It is prepared by treating the algae with boiling water; the extract is filtered while hot, concentrated, and dried. Colourless to pale yellow translucent strips, flakes, or powder; tough when damp but becoming more brittle on drying.

USNF 26 (Agar). The dried, hydrophilic, colloidal substance extracted from *Gelidium cartilagineum* (Gelidiaceae), *Gracilaria confervoides* (Sphaerococcaceae), and related red algae (Class Rhodophyceae). It usually consists of thin, membranous, agglutinated strips, but may occur in cut, flaked, or granulated forms. May be weak yellowish-orange, yellowish-grey to pale yellow, or colourless. It is tough when damp, brittle when dry. Odourless or has a slight odour. Insoluble in cold water; soluble in boiling water.

Uses and Administration

Agar is used as a suspending or thickening agent in pharmaceutical manufacturing and as an emulsifying and stabilising agent in the food industry.

It was formerly used similarly to methylcellulose (p.2145) as a bulk laxative. Preparations containing agar with liquid paraffin and phenolphthalein are available to treat constipation, but the relatively small amount of agar in these probably acts solely as an emulsion stabiliser.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Agarol; Usar Fibras†; ***Austral.:*** Lexat†; ***Braz.:*** Agarol; Fenogar†; ***Chile:*** Agarol; ***Fr.:*** Pseudophage; ***India:*** Agarol†; ***Port.:*** Byl†; ***Switz.:*** Paragar; ***USA:*** Agoral; ***Venez.:*** Agarol†.

Alginic Acid

Acide alginique; Acidum alginicum; Algiinihappo; Algínico, ácido; Algino rūgštis; Alginsav; Alginsyra; Aljinik Asit; E400; Kyselina alginová; Polymannuronic Acid.

CAS — 9005-32-7.
ATC — A02BX13.
ATC Vet — QA02BX13.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.* Also in *USNF.*

Ph. Eur. 6.2 (Alginic Acid). A mixture of polyuronic acids composed of residues of D-mannuronic and L-guluronic acids extracted from algae belonging to the Phaeophyceae. A white or pale yellowish-brown, crystalline or amorphous powder. It swells in water. Very slightly soluble or practically insoluble in alcohol; practically insoluble in organic solvents; dissolves in solutions of alkali hydroxides.

USNF 26 (Alginic Acid). A hydrophilic colloidal carbohydrate extracted with dilute alkali from various species of brown seaweeds (Phaeophyceae). A white to yellowish-white, odourless or practically odourless, fibrous powder. Insoluble in water and in organic solvents; soluble in alkaline solutions. pH of a 3% dispersion in water is between 1.5 and 3.5.

Propylene Glycol Alginate

E405; Propilenglicol, alginato de. Propane-1,2-diol Alginate.
ATC — A02BX13.
ATC Vet — QA02BX13.

Pharmacopoeias. In *USNF.*

USNF 26 (Propylene Glycol Alginate). A white to yellowish, practically odourless, fibrous or granular powder. Soluble in water, in solutions of dilute organic acids, and, depending on the degree of esterification, in hydroalcoholic mixtures containing up to 60% by weight of alcohol, to form stable, viscous colloidal solutions at a pH of 3.

Sodium Alginate

Algin; Alginato sódico; E401; Natrii alginas; Natrio alginatas; Natriumalginaatti; Natriumalginat; Nátrium-alginát; Natrium-alginát; Sodium, alginate de; Sodium Polymannuronate; Sodyum Aljinat.
CAS — 9005-38-3.
ATC — A02BX13.
ATC Vet — QA02BX13.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Alginate). It consists chiefly of the sodium salt of alginic acid. A white or pale yellowish-brown powder. Slowly soluble in water, forming a viscous, colloidal solution; practically insoluble in alcohol.

USNF 26 (Sodium Alginate). A yellowish-white, practically odourless, coarse or fine powder. Soluble in water, forming a viscous, colloidal solution; insoluble in alcohol, in chloroform, and in ether, in hydroalcoholic solutions in which the alcohol content is greater than 30% by weight, and in acids when the pH of the resulting solution becomes lower than about 3. Store in airtight containers.

Incompatibility. Incompatibilities of sodium alginate have been observed with acridine derivatives, methylrosanilinium chloride, phenylmercuric acetate and nitrate, calcium salts, alcohol in concentrations greater than 5%, and heavy metals. High concentrations of electrolytes cause an increase in viscosity until salting-out of sodium alginate occurs; salting-out occurs if more than 4% of sodium chloride is present.

Uses and Administration

Alginic acid and alginates such as propylene glycol alginate and sodium alginate are used in pharmaceutical manufacturing as suspending and thickening agents. They may be used as stabilisers for oil-in-water emulsions and as binding and disintegrating agents in tablets. Various grades are usually available commercially for different applications and yield solutions of varying viscosity. A reduction in viscosity has been said to occur following sterilisation by autoclaving of sodium alginate solutions.

Alginic acid and alginates (ammonium alginate, calcium alginate (p.1058), potassium alginate, propylene glycol alginate, and sodium alginate) are also used as emulsifiers and stabilisers in the food industry.

Alginic acid or the alginates, magnesium alginate and sodium alginate, are given, usually formulated with an antacid, in the management of gastro-oesophageal reflux disease (p.1696). Alginic acid or the alginate reacts with gastric acid to form a viscous gel (often termed a raft) that floats on top of the gastric contents. This raft then acts as a mechanical barrier to reduce reflux.

Alginic acid is also used, usually in the form of a mixed calcium-sodium salt, as a haemostatic and wound dressing; it is employed in the form of a fibre made into a dressing or packing material.

Preparations

BP 2008: Alginate Raft-forming Oral Suspension; Compound Alginate Antacid Oral Suspension.

Proprietary Preparations (details are given in Part 3)

Aluminium Magnesium Silicate

Aliuminio-magnio silikatas; Alumiinimagnesiumsilikaatti; Aluminii magnesii silicas; Aluminium (silicate d') et de magnésium; Aluminiummagnesiumsilikat; Alumínium-magnézium-szilikát; Aluminosilicato magnésico; Křemičitan hořečnato-hlinitý; Magnesium Aluminium Silicate; Magnesium Aluminum Silicate; Saponite.
CAS — 1327-43-1; 12511-31-8.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.* Also in *USNF. USNF* also includes Magnesium Aluminosilicate and Magnesium Aluminometasilicate.

Ph. Eur. 6.2 (Aluminium Magnesium Silicate). A mixture of colloidal-size particles of montmorillonite and saponite, free from grit and nonswellable ore. Almost white powder, granules, or plates. Practically insoluble in water and in organic solvents; swells in water to form a colloidal dispersion. A 5% dispersion in water has a pH of 9.0 to 10.0.

USNF 26 (Magnesium Aluminum Silicate). A blend of colloidal montmorillonite and saponite that has been processed to remove grit and nonswellable ore components. There are several types, differing in viscosity and in ratio of aluminium content to magnesium content. It is an odourless, fine (micronised) powder, small cream to tan granules, or small flakes that are creamy when viewed on their flat surfaces and tan to brown when viewed on their edges. Insoluble in water and in alcohol; swells when added to water or glycerol. pH of a 5% suspension in water is between 9.0 and 10.0. Store in airtight containers.

USNF 26 (Magnesium Aluminosilicate). A synthetic material that contains 20.5 to 27.7% of magnesium oxide, 27.0 to 34.3% of aluminium oxide, and 14.4 to 21.7% of silicon dioxide, calculated on the dried basis. A white powder or granules having an amorphous structure. Practically insoluble in water and in alcohol; partially soluble in acids and alkalis. A 4% suspension in water has a pH of 8.5 to 10.5. Store at a temperature not exceeding 40° in airtight containers.

USNF 26 (Magnesium Aluminometasilicate). A synthetic material that contains 29.1 to 35.5% of aluminium oxide, 11.4 to 14.0% of magnesium oxide, and 29.2 to 35.6% of silicon dioxide, calculated on the dried basis. It exists in two forms, Type I-A and Type I-B. A white powder or granules having an amorphous structure. Practically insoluble in water and in alcohol; partially soluble in acids and alkalis. A 4% suspension in water has a pH of 6.5 to 8.5 (Type I-A) and 8.5 to 10.5 (Type I-B). Store at a temperature not exceeding 40° in airtight containers.

Uses

Aluminium magnesium silicate has a variety of pharmaceutical uses, including use as a suspending and thickening agent, as an emulsion stabiliser, and as a binder and disintegrating agent in tablets.

Other forms of aluminium magnesium silicate include an artificial hydrate known as almasilate (p.1705), which is used as an antacid, and attapulgite (p.1709), a purified native hydrated aluminium magnesium silicate that is highly adsorbent and is used in a wide range of products including fertilisers and pesticides. Activated attapulgite, which is attapulgite that has been carefully heated to increase its adsorptive capacity, is used in preparations for diarrhoea.

Preparations

Proprietary Preparations (details are given in Part 3)
Indon.: Neusilin.

Multi-ingredient: ***Denm.:*** Alkasid†; ***India:*** Digene; ***Indon.:*** Flatucid; Stomadon; ***Jpn:*** Cabe 2; ***Thai.:*** Diasgest; ***UAE:*** Alkasid.

Bentonite

Bentoniitti; Bentonit; Bentonita; Bentonitas; Bentonitum; E558; Mineral Soap; Soap Clay; Wilkinite.
CAS — 1302-78-9.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Jpn.* Also in *USNF*, which also includes a purified form.

Ph. Eur. 6.2 (Bentonite). A natural clay containing a high proportion of montmorillonite, a native hydrated aluminium silicate in which some aluminium and silicon atoms may be replaced by other atoms such as magnesium and iron. A very fine, homogeneous, greyish-white powder with a more or less yellowish or pinkish tint. Practically insoluble in water and in aqueous solutions, but swells with a little water forming a malleable mass.

USNF 26 (Bentonite). A native, colloidal, hydrated aluminium silicate. A very fine, odourless, hygroscopic, pale buff or cream-coloured to greyish powder, free from grit. Insoluble in water, but swells to about 12 times its volume when added to water; insoluble in, and does not swell in, organic solvents. pH of a 2% suspension in water, mixed vigorously to facilitate wetting, is between 9.5 and 10.5. Store in airtight containers.

USNF 26 (Purified Bentonite). A colloidal montmorillonite that has been processed to remove grit and nonswellable ore components. An odourless, fine, micronised powder, or small flakes that are creamy when viewed on their flat surfaces and tan to brown when viewed on their edges. Insoluble in water and in alcohol. Swells when added to water or glycerol. pH of a 5% suspension in water is between 9.0 and 10.0. Store in airtight containers.

Uses

Bentonite absorbs water readily to form sols or gels, depending on its concentration. It is used in pharmaceutical manufacturing as a suspending and stabilising agent and as an adsorbent or clarifying agent. It is also used as an anticaking agent in the food industry.

Bentonite may be used as an oral adsorbent in paraquat poisoning (p.2047).

Preparations

USNF 26: Bentonite Magma.

Proprietary Preparations (details are given in Part 3)
Gr.: Bentonine†.

Multi-ingredient: ***Indon.:*** Stomagel; ***Malaysia:*** Clearasil Pimple Treatment; ***S.Afr.:*** Clearasil T; ***Singapore:*** Clearasil Pimple Treatment.

Carbomers

Acrylic Acid Polymers; Carbomera; Carbomères; Carbómeros; Carbopols; Carboxypolymethylene; Carboxyvinyl Polymers; Karbomeerit; Karbomerai; Karbomerek; Karbomerer; Karbomerler; Karbomery; Poliakrilic Asit; Polyacrylic Acid.
CAS — 9003-01-4; 54182-57-9.

NOTE. Carbomer is *BAN, USAN*, and *rINN*.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Int. USNF* has separate monographs for a range of carbomers.
USNF also includes Carbomer Copolymer and Carbomer Interpolymer.

Ph. Eur. 6.2 (Carbomers). High-molecular-weight polymers of acrylic acid cross-linked with polyalkenyl ethers of sugars or polyalcohols. They are produced in several grades characterised by the viscosity of a defined solution. White or almost white, fluffy, hygroscopic powders. They swell in water and in other polar solvents after dispersion and neutralisation with sodium hydroxide solution. Store in airtight containers.

USNF 26 (Carbomer 934; Carbomer 934P; Carbomer 940; Carbomer 941; Carbomer 1342). Carbomers are high-molecular-weight polymers of acrylic acid cross-linked with allyl ethers of pentaerythritol. The viscosity of a neutralised aqueous dispersion for each carbomer is:

- Carbomer 934 (0.5%), 30 500 to 39 400 cP
- Carbomer 934P (0.5%), 29 400 to 39 400 cP
- Carbomer 940 (0.5%), 40 000 to 60 000 cP
- Carbomer 941 (0.5%), 4000 to 11 000 cP
- Carbomer 1342 (1.0%), 9500 to 26 500 cP

They are white, fluffy, hygroscopic powders having a slight characteristic odour. pH of a 1% dispersion in water is about 3. When neutralised with alkali hydroxides or with amines, they dissolve in water, in alcohol, and in glycerol. Store in airtight containers.

USNF 26 (Carbomer Copolymer). A high-molecular-weight copolymer of acrylic acid and a long chain alkyl methacrylate cross-linked with allyl ethers of polyalcohols. Different types of Carbomer Copolymer are characterised by the viscosity of a defined solution. Carbomer Copolymer does not constitute the official title when benzene is used in the manufacturing process, in which case the name will be Carbomer 1342 if it complies with the requirements of that monograph. Store in airtight containers at a temperature not exceeding 45°.

USNF 26 (Carbomer Interpolymer). A carbomer homopolymer or copolymer that contains a block copolymer of macrogol and a long chain alkyl acid ester. Different types of Carbomer Interpolymer are characterised by the viscosity of a defined solution. Store in airtight containers at a temperature not exceeding 45°.

Uses and Administration

Carbomers are used in pharmaceutical manufacturing as suspending agents, gel bases, emulsifiers, and binding agents in tablets.

Carbomers, in liquid gel formulations containing typically 0.2 or 0.3%, are used topically as tear substitutes in the management of dry eye (p.2140).

Preparations

BP 2008: Carbomer Eye Drops.

Proprietary Preparations (details are given in Part 3)
Arg.: Acrylarm; Lacryvisc†; Liposic; Refresh Gel; Siccafluid; Teargel†; Viscotears; ***Austral.:*** Poly Gel; Viscotears; ***Austria:*** AquaTears; Liposic; Tears Naturale; Vidisic; ***Belg.:*** Alcon Eye Gel; Lacrinorm; Liposic; Ocugel; Thilo Tears; Vidisic; ***Braz.:*** Refresh Gel; Vidisic†; Viscotears; ***Canad.:*** Lacrinorm†; Tear-Gel; ***Chile:*** Feels; Lacryvisc; Nicotears; Viscotears; ***Cz.:*** Lacryvisc†; Oftagel; Vidisic; ***Denm.:*** Oftagel; Viscotears; ***Fin.:*** Oftagel; Viscotears; ***Fr.:***

Carmellose *(rINN)*

Carboxymethylcellulose; Carmellosum; Carmelosa; CMC; E466.

Кармеллоза

CAS — 9000-11-7.

Pharmacopoeias. In *Jpn.*

Carmellose Calcium *(rINNM)*

Calcii Carmellosum; Calcium Carboxymethylcellulose; Carboxymethylcellulose Calcium; Carmellose calcique; Carmellosum calcicum; Carmellosum Calcium; Carmelosa cálcica; Karmeliozės kalcio druska; Karmelloosikalsium; Karmelloskalcium; Karmellóz-kalcium; Karmelosa vápenatá sůl.

Кальций Кармеллоза

CAS — 9050-04-8.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Carmellose Calcium). A white or yellowish-white, hygroscopic powder. It swells in water to form a suspension; practically insoluble in alcohol, in acetone, and in toluene. Store in airtight containers.

USNF 26 (Carboxymethylcellulose Calcium). A white to yellowish-white, hygroscopic powder. It swells in water to form a suspension; practically insoluble in alcohol, in acetone, in chloroform, in ether, and in benzene. pH of a 1% suspension in water is between 4.5 and 6.0. Store in airtight containers.

Carmellose Sodium *(BAN, rINNM)*

Carboxymethylcellulose Sodium; Carboxymethylcellulosum Natricum; Carmellose sodique; Carmellosum natricum; Carmelosa sódica; Cellulose Gum; E466; Karmeliozės natrio druska; Karmelloosinatrium; Karmellosnatrium; Karmellóz-nátrium; Karmelosa sodná sůl; Karmeloza sodowa; Natrii Carmellosum; SCMC; Sodium Carboxymethylcellulose; Sodium Cellulose Glycollate.

Натрий Кармеллоза

CAS — 9004-32-4.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Eur. and *USNF* also include low-substituted carmellose sodium.

USNF also includes Carboxymethylcellulose Sodium 12.

Eur also includes a mixture of microcrystalline cellulose with carmellose sodium.

Ph. Eur. 6.2 (Carmellose Sodium). A white or almost white, hygroscopic granular powder. It has a sodium content of 6.5 to 10.8% calculated on the dry substance. Easily dispersed in water forming colloidal solutions; practically insoluble in dehydrated alcohol, in acetone, in ether, and in toluene. A 1% colloidal solution in water has a pH of 6.0 to 8.0.

Ph. Eur. 6.2 (Carmellose Sodium, Low-substituted; Carmellosum Natricum, Substitutum Humile). It contains not less than 2.0% and not more than 4.5% of sodium, calculated with reference to the dried substance. A white or almost white powder or short fibres. It swells in water to form a gel; practically insoluble in dehydrated alcohol, in acetone, and in toluene. A 1% suspension in water has a pH of 6.0 to 8.5.

Ph. Eur. 6.2 (Microcrystalline Cellulose and Carmellose Sodium). A colloid-forming, powdered mixture of microcrystalline cellulose with 5 to 22% of carmellose sodium. It contains 75 to 125% of the nominal amount of carmellose sodium, calculated with reference to the dried substance. A white or off-white, coarse or fine powder. Dispersible in water producing a white, opaque colloidal dispersion; practically insoluble in organic solvents and in dilute acids. pH of a 2% dispersion in water is 6 to 8.

USP 31 (Carboxymethylcellulose Sodium). A white to cream-coloured, hygroscopic powder or granules. It contains not less than 6.5% and not more than 9.5% of sodium, calculated on the dried basis. Easily dispersed in water to form colloidal solutions; insoluble in alcohol, in ether, and in most other organic solvents. pH of a 1% solution in water is between 6.5 and 8.5. Store in airtight containers.

USNF 26 (Low-Substituted Carboxymethylcellulose Sodium). It has a sodium content of 2.0 to 4.5%, calculated on the dried basis. A white or almost white powder or short fibres. Practically insoluble in alcohol, in acetone, and in toluene. It swells in water to form a gel. pH of a 1% suspension in water is between 6.0 and 8.5. Store in airtight containers.

USNF 26 (Carboxymethylcellulose Sodium 12). A colourless or white to off-white, odourless, powder or granules. Water solubility depends on degree of substitution (easily dispersed in water at all temperatures, forming a clear, colloidal solution). Insoluble in alcohol, in acetone, in ether, and in toluene. It has a sodium content of 10.4 to 12.0%, calculated on the dry substance. Store in airtight containers.

Incompatibility. Incompatibilities of carmellose sodium have been reported with strongly acidic solutions, with soluble salts of iron and some other metals, and with xanthan gum.

Croscarmellose Sodium *(USAN)*

Carmellosum natricum conexum; Croscarmellose sodique; Croscarmelosa sódica; Crosslinked Carboxymethylcellulose Sodium; E468; Kroskarmeliozės natrio druska; Kroskarmelloosi natrium; Kroskarmellosnatrium; Kroskarmelosa sodná sůl; Kroskarmeloza sodowa; Kroszkarmellóz-nátrium; Modified Cellulose Gum.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Croscarmellose Sodium). A cross-linked polymer of carmellose sodium. A white or greyish-white powder. Practically insoluble in dehydrated alcohol, in acetone, and in toluene. A 1% suspension in water has a pH of 5.0 to 7.0.

USNF 26 (Croscarmellose Sodium). The sodium salt of a cross-linked partly *O*-(carboxymethylated) cellulose. A white, free-flowing powder. Partially soluble in water; insoluble in alcohol, in ether, and in other organic solvents. pH of a dispersion containing 1 g mixed with 100 mL of water for 5 minutes is between 5.0 and 7.0.

Uses and Administration

Carmellose calcium and carmellose sodium have a variety of pharmaceutical uses, including use as suspending, thickening, and emulsifying agents, and as disintegrants, binders, and coating agents in tablets. Carmellose sodium is also used as an emulsifier or stabiliser in the food industry. Croscarmellose sodium is used as a tablet disintegrant.

Carmellose sodium is used topically as an ingredient of protective preparations for stoma care, in the management of wounds, and for the mechanical protection of oral and perioral lesions, such as mouth ulceration (p.1700). It is also used, in concentrations of up to 1%, in artificial saliva preparations for the treatment of dry mouth (p.2140), and in eye drops for the management of dry eye (p.2140).

Carmellose sodium given orally absorbs water and acts as a bulk-forming agent; the volume of faeces is increased and peristalsis promoted. It is used in the treatment of constipation (p.1693). Carmellose sodium has been included in preparations to control appetite in the management of obesity (p.2149) but there is little evidence of efficacy. For precautions to be observed with bulk-forming agents, see under Methylcellulose, p.2145.

Preparations

BP 2008: Carmellose Sodium Eye Drops;
USP 31: Carboxymethylcellulose Sodium Paste; Carboxymethylcellulose Sodium Tablets.

Proprietary Preparations (details are given in Part 3)

Carrageenan

Carrageenanum; Carrageenin; Carragenina; Carraghénanes; Carraghénates; Chondrus Extract; E407; Irish Moss Extract.

CAS — 9000-07-1 (carrageenan); 11114-20-8 (κ-carrageenan); 9064-57-7 (λ-carrageenan).

Pharmacopoeias. In *Fr.* Also in *USNF.*

USNF 26 (Carrageenan). The hydrocolloid obtained by extraction with water or aqueous alkali from some members of the class Rhodophyceae (red seaweeds). It consists chiefly of a mixture of the ammonium, calcium, magnesium, potassium, and sodium sulfate esters of galactose and 3,6-anhydrogalactose copolymers. The prevalent copolymers in the hydrocolloids are κ-carrageenan, ι-carrageenan, and λ-carrageenan.

A yellowish or tan to white, coarse to fine, practically odourless, powder. Soluble in water at 80° forming a viscous, clear or slightly opalescent solution that flows readily. It disperses more readily in water if first moistened with alcohol, with glycerol, or with a saturated solution of glucose in water. Store in airtight containers at a temperature of 8° to 15°.

Uses and Administration

Carrageenan is used in pharmaceutical manufacturing and the food industry as a suspending and gelling agent.

It has been used as a bulk-forming laxative to treat constipation; for precautions to be observed with bulk-forming laxatives, see under Methylcellulose, p.2145. Carrageenan is also included in topical preparations for the symptomatic relief of anorectal disorders. A gel containing carrageenan has been investigated as a topical microbicide.

A degraded form of carrageenan was formerly used in gastrointestinal disorders but it was associated with lesions in *animals* and is no longer used.

Irish moss (*Chondrus crispus*), a source of carrageenan, is used in herbal medicine.

◊ Refined non-degraded carrageenan and furcellaran, a similar extract from Rhodophyceae that is included in the specifications for food-grade carrageenan, have generally been considered safe for use as food additives, although this may not be the case with degraded and 'semi-refined' forms.[1] However, in the UK the Food Advisory Committee has recommended that carrageenan should not be permitted as an additive for infant formulas because of the possibility of immunological consequences after absorption from the immature gut.[2] Carrageenans affect the immune system of experimental *animals* after parenteral or oral use, and small amounts of food-grade carrageenan cross the intestinal epithelium in *rats* and are taken up by gut-associated lymphoid tissue.[3]

Preparations

Proprietary Preparations (details are given in Part 3)

Austria: Coreine.

Multi-ingredient: ***Austral.:*** Bonningtons Irish Moss; ***Austria:*** Anoreine; Anoreine mit Lidocain; ***Cz.:*** Titanoreine†; ***Fr.:*** Anoreine; Titanoreine; Titanoreine Lidocaine; ***Ger.:*** Saseem; ***Ital.:*** Resource Gelificata; ***NZ:*** Bonningtons Irish Moss; ***Pol.:*** Tytanoreina†; ***Spain:*** Titanorein; ***Switz.:*** Flogecyl; Titanoreine†; ***UK:*** Fam-Lax Senna.

Cellacefate *(BAN, rINN)*

CAP; Celacefát; Celacefat; Celacefato; Celiuliozės acetatas-ftalatas; Cellacéfate; Cellacefatum; Cellacephate; Cellulosaacetatftalat; Cellulose, acétate phtalate de; Cellulose Acetate Phthalate; Cellulosi acetas phthalas; Cellulosum Acetylphthalicum; Cellulóz-acetát-ftalát; Celophthalum; Selluloosa-asetaattiftalaatti.

Целлацефат

CAS — 9004-38-0.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Cellulose Acetate Phthalate; Cellacefate BP 2008). Cellulose in which some of the hydroxyl groups are acetylated (21.5 to 26.0%) and some are phthalylated (30.0 to 36.0%), both calculated with reference to the anhydrous, acid-free substance.

A hygroscopic, white or almost white, free-flowing powder or colourless flakes. Practically insoluble in water, in dehydrated alcohol, and in dichloromethane; freely soluble in acetone; soluble in diethylene glycol; it dissolves in dilute solutions of alkalis. Store in airtight containers.

USNF 26 (Cellacefate). A reaction product of phthalic anhydride and a partial acetate ester of cellulose. It contains 21.5 to 26.0% of acetyl groups, and 30.0 to 36.0% of phthalyl(*o*-carboxy-benzoyl) groups, calculated on the anhydrous, acid-free basis. A white, free-flowing powder that may have a slight odour of acetic acid. Insoluble in water and in alcohol; soluble in acetone and in dioxan. Store in airtight containers.

Uses

Cellacefate is unaffected by immersion in acid media in the stomach but softens and swells in intestinal fluid. It is used in pharmaceutical manufacturing as an enteric-coating material for tablets and capsules, usually with a plasticiser. Films of cellacefate are reported to be permeable to some ionic substances such as ammonium chloride and potassium iodide, and such substances require a sealing coat.

Cellulose

Celulosa.

Description. Cellulose is an unbranched polysaccharide polymer consisting of 1,4-β-linked glucopyranose units. It is the chief constituent of fibrous plant material.

Dispersible Cellulose *(BAN)*

Cellulose microcristalline et carmellose sodique; Cellulosum microcristallinum et carmellosum natricum; Celulosa dispersable; Microcrystalline Cellulose and Carboxymethylcellulose Sodium; Microcrystalline Cellulose and Carmellose Sodium.

Pharmacopoeias. In *Br.* Also in *USNF.*

BP 2008 (Dispersible Cellulose). An odourless or almost odourless, white or off-white, coarse or fine powder consisting of a colloid-forming attrited mixture of microcrystalline cellulose and carmellose sodium. Disperses in water to produce a white, opaque dispersion or gel; practically insoluble in organic solvents and in dilute acids. Store at a temperature between 8° and 15°.

USNF 26(Microcrystalline Cellulose and Carboxymethylcellulose Sodium). A colloid-forming, attrited mixture of microcrystalline cellulose and carmellose sodium. A white to off-white, odourless, coarse to fine, powder. It swells in water, producing, when dispersed, a white, opaque dispersion or gel; insoluble in organic solvents and in dilute acids. Store in airtight containers in a dry place, and at a temperature not exceeding 40°.

Microcrystalline Cellulose

Celiuliozė, mikrokristalinė; Cellulosa Microgranulare; Cellulosa, mikrokristallin; Cellulose Gel; Cellulose microcristalline; Cellulosum microcristallinum; Cellulosum Microcrystallinum; Cellulosum Microristallinum; Celulosa microcristalina; Celulosa mikrokrystalická; Celuloza mikrokrystaliczna; Crystalline Cellulose; E460; Mikrokristályos cellulóz; Selluloosa, mikrokiteinen.

CAS — 9004-34-6.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *Jpn.* Also in *USNF.*

Eur also includes a mixture of microcrystalline cellulose with carmellose sodium.

Ph. Eur. 6.2 (Cellulose, Microcrystalline). A purified, partly depolymerised cellulose, prepared by treating alpha-cellulose, obtained as a pulp from fibrous plant materials, with mineral acids. It is a white or almost white, fine or granular powder. Practically insoluble in water, in dehydrated alcohol, in acetone, in toluene, in dilute acids, and in sodium hydroxide solution (1 in 20). The pH of the supernatant liquid obtained from a 12.5% mixture in water after 20 minutes of shaking is 5.0 to 7.5.

Ph. Eur. 6.2 (Microcrystalline Cellulose and Carmellose Sodium). A colloid-forming, powdered mixture of microcrystalline cellulose with 5 to 22% of carmellose sodium. It contains 75 to 125% of the nominal amount of carmellose sodium, calculated with reference to the dried substance. A white or off-white, coarse or fine powder. Dispersible in water producing a white, opaque colloidal dispersion; practically insoluble in organic solvents and in dilute acids. pH of a 2% dispersion in water is 6 to 8.

USNF 26 (Microcrystalline Cellulose). A purified, partially depolymerised cellulose, prepared by treating alpha-cellulose, obtained as a pulp from fibrous plant material, with mineral acids. It is a fine, white or almost white powder consisting of free-flowing, nonfibrous particles. Insoluble in water, in dilute acids, and in most organic solvents; practically insoluble in sodium hydroxide solution (1 in 20). The pH of the supernatant liquid obtained from a 12.5% mixture in water after 20 minutes of shaking is between 5.0 and 7.5. Store in airtight containers.

Powdered Cellulose

Celiuliozės milteliai; Cellulosapulver; Cellulose en poudre; Cellulose Powder; Cellulosi pulvis; Cellulózpor; Celulosa en polvo; Celulosový prášek; E460; Selluloosajauhe.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Cellulose, Powdered). A purified mechanically disintegrated cellulose prepared from alpha-cellulose obtained as a pulp from fibrous plant materials. It is a white or almost white, fine or granular powder. Practically insoluble in water, in dehydrated alcohol, in acetone, in toluene, in most organic solvents, and in dilute acids; slightly soluble in sodium hydroxide solution (1 in 20). The pH of the supernatant liquid of an 11.1% mixture in water is between 5.0 and 7.5 one hour after preparation.

USNF 26 (Powdered Cellulose). A purified, mechanically disintegrated cellulose prepared by processing alpha-cellulose obtained as a pulp from fibrous plant materials. It is a white or almost white powder. Exhibits degrees of fineness ranging from a free-flowing, dense powder to a coarse, fluffy, nonflowing material. Insoluble in water, in nearly all organic solvents, and in dilute acids; slightly soluble in sodium hydroxide solution (1 in 20). The pH of the supernatant liquid of an 11.1% mixture in water is between 5.0 and 7.5 one hour after preparation. Store in airtight containers.

Uses and Administration

Powdered cellulose and microcrystalline cellulose are used in pharmaceutical manufacturing as tablet binders and disintegrants and as capsule and tablet diluents. These two forms of cellulose are also used in the food industry. Dispersible cellulose (which also contains some carmellose sodium) forms a thixotropic gel with water and is used pharmaceutically as a suspending and thickening agent.

Various forms of cellulose have been included in preparations used in the management of constipation and obesity. Cellulose is also used in adsorbent powder preparations used for skin disorders including hyperhidrosis.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Fibrasan; ***UK:*** Nasaleze; Sterigel; ***USA:*** Unifiber.

Multi-ingredient: ***Arg.:*** Usar Fibras†; ZeaSorb; ***Austral.:*** ZeaSorb; ***Canad.:*** ZeaSorb; ***Chile:*** ZeaSorb†; ***Cz.:*** Systogen†; ***Fr.:*** Gelopectose; Hydroclean; ZeaSorb; ***Irl.:*** ZeaSorb; ***Israel:*** Celluspan; ***Thai.:*** ZeaSorb; ***UK:*** ZeaSorb.

Ceratonia

Carob Bean Gum; Carob Gum; Cerat.; Ceratonia Gum; E410; Goma de garrofín; Gomme de Caroube; Guma z nasion Carobe; Locust Bean Gum.

CAS — 9000-40-2.
ATC — A07XA02.
ATC Vet — QA07XA02.

Uses

Ceratonia consists of the endosperms separated from the seeds of the locust bean tree, *Ceratonia siliqua* (Leguminosae). It is used as a thickening agent and stabiliser in the food industry.

Preparations

Proprietary Preparations (details are given in Part 3)
Austria: Arobon; ***Irl.:*** Carobel; ***Ital.:*** Arobon; ***Switz.:*** Nestargel; ***UK:*** Carobel; Nestargel.

Multi-ingredient: ***Austria:*** China-Eisenwein; ***Belg.:*** Kestomatine Baby†; ***Fr.:*** Gumilk; ***Indon.:*** Polysilane; ***Switz.:*** Kestomatine Bebe†.

Dextrates *(USAN)*

Dextratos.

CAS — 39404-33-6.

Pharmacopoeias. In *USNF.*

USNF 26 (Dextrates). A purified, anhydrous or hydrated, mixture of saccharides obtained by the controlled enzymatic hydrolysis of starch. Free-flowing, porous, white, odourless, spherical granules consisting of aggregates of microcrystals. Freely soluble in water (heating increases its solubility in water); soluble in dilute acids and alkalis and in basic organic solvents such as pyridine; insoluble in the common organic solvents. pH of a 20% solution in water is between 3.8 and 5.8. Store in a dry place at a temperature of 8° to 15°.

Uses

Dextrates is used as a capsule and tablet diluent and as a tablet binding agent.

Ethylcellulose *(rINN)*

Cellulose Ethyl Ether; E462; Éthylcellulose; Ethylcellulosum; Ethylcelulosa; Etilceliuliozė; Etilcellulóz; Etilcelulosa; Etylcellulosa; Etyyliselluloosa.

Этилцеллюлоза

CAS — 9004-57-3.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Int.* Also in *USNF.*

Ph. Eur. 6.2 (Ethylcellulose). A partly *O*-ethylated cellulose. It contains 44 to 51% of ethoxy ($-OC_2H_5$) groups, calculated on the dried basis. A white to yellowish-white, odourless or almost odourless, powder or granular powder. Solutions of ethylcellulose may show a slight opalescence. Practically insoluble in water, in glycerol (85%), and in propylene glycol; soluble in dichloromethane and in a mixture of 20 parts alcohol and 80 parts toluene (w/w); slightly soluble in ethyl acetate and methyl alcohol.

USNF 26 (Ethylcellulose). A partly *O*-ethylated cellulose. It contains 44.0 to 51.0% of ethoxy groups, calculated with reference to the dried substance. A free-flowing white to light tan powder. Its aqueous suspensions are neutral to litmus. Insoluble in water, in glycerol, and in propylene glycol. Ethylcellulose containing less than 46.5% of ethoxy groups is freely soluble in chloroform, in methyl acetate, in tetrahydrofuran, and in mixtures of aromatic hydrocarbons with alcohol; ethylcellulose containing 46.5% or more of ethoxy groups is freely soluble in alcohol, in chloroform, in ethyl acetate, in methyl alcohol, and in toluene.

Uses

Ethylcellulose is used as a binder in tablets and as a coating material for tablets, granules, and microcapsules. It is also used as a thickening agent.

Preparations

USNF 26: Ethylcellulose Aqueous Dispersion.

Gastric Mucin *(BAN)*

Mucina gástrica.

Uses and Administration

Gastric mucin is a high-molecular-weight glycoprotein precipitated by alcohol (60%) after digestion of hogs' stomach linings by pepsin and hydrochloric acid. It is used in artificial saliva formulations for dry mouth (p.2140) as an oral spray containing 3.5% or as lozenges.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: Saliva medac; ***Neth.:*** Saliva Orthana.

Multi-ingredient: ***UK:*** Saliva Orthana.

Hyetellose *(rINN)*

Hidroksietilceliuliozė; Hidroxietilcellulóz; Hidroxietilcelulosa; Hydroksietyyliselluloosa; Hydroksyetyloceluloza; Hydroxietylcellulosa; Hydroxyethyl Cellulose; Hydroxyéthylcellulose; Hydroxyethylcellulose; Hydroxyethylcellulosum; Hyétellose; Hyetellosum; Hyetelosa.

Гиетэллоза

CAS — 9004-62-0.

NOTE. HECL is a code approved by the BP 2008 for use on single unit doses of eye drops containing hyetellose and sodium chloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.* Also in *USNF.*

Ph. Eur. 6.2 (Hydroxyethylcellulose). A partially substituted 2-hydroxyethyl ether of cellulose. Various grades are available and are distinguished by appending a number indicative of the apparent viscosity in millipascal seconds of a 2% solution measured at 25°. A white, yellowish-white, or greyish-white, powder or granules. Soluble in cold or hot water, forming colloidal solutions; practically insoluble in alcohol, in acetone, and in toluene. A 1% solution in water has a pH of 5.5 to 8.5.

USNF 26 (Hydroxyethyl Cellulose). A partially substituted poly(hydroxyethyl) ether of cellulose. It is available in several grades, varying in viscosity and degree of substitution, and some grades are modified to improve their dispersion in water. It may contain suitable anticaking agents. A white to light tan, practically odourless, hygroscopic, powder. Soluble in cold or hot water, giving a colloidal solution; practically insoluble in alcohol and in most organic solvents. pH of a 1% solution in water is between 6.0 and 8.5.

Uses and Administration

Hyetellose is used in pharmaceutical manufacturing as a thickener and stabiliser and as a tablet coating and binding agent. It is present in lubricant preparations for dry eye (p.2140), contact lens care (p.1622), and dry mouth (p.2140).

Гимэтеллоза

CAS — 9032-42-2.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Methylhydroxyethylcellulose; Hydroxyethylmethylcellulose BP 2008). A partially substituted ether of cellulose containing methoxyl and 2-hydroxyethyl groups. Various grades are available and are distinguished by appending a number indicative of the apparent viscosity in millipascal seconds of a 2% w/w solution measured at 20°. A white, yellowish-white, or greyish-white powder or granules; hygroscopic after drying. Practically insoluble in hot water, in dehydrated alcohol, in acetone, and in toluene; dissolves in cold water forming a colloidal solution. A 1% w/w solution in water has a pH of 5.5 to 8.0.

USNF 26 (Hymetellose). A partly *O*-(methylated) and *O*-(2-hydroxyethylated) cellulose. Various grades are available, labelled with the viscosity of a 2% w/w solution measured at 20°. A white, yellowish-white, or greyish-white powder or granules; hygroscopic after drying. Insoluble in hot water, in alcohol, in acetone, in ether, and in toluene; dissolves in cold water forming a colloidal solution. pH of a 1% w/w solution in water is between 5.5 and 8.0.

Uses

Hymetellose is used similarly to other cellulose ethers, such as methylcellulose (p.2145), as a pharmaceutical excipient.

Preparations

Proprietary Preparations (details are given in Part 3)

Austria: Cellobexon.

Multi-ingredient: ***Fr.:*** Pharmatex.

Hyprolose *(rINN)*

E463; Hidroksipropilceliuliozė; Hidroxipropilcellulóz; Hidroxipropilcelulosa; Hydroksipropyyliselluloosa; Hydroxipropylcellulosa; Hydroxypropyl Cellulose; Hydroxypropylcellulose; Hydroxypropylcellulosum; Hydroxypropylcelulosa; Hyprolosum.

Гипролоза

CAS — 9004-64-2.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, and *Jpn*. Also in *USNF* which has two separate monographs, for Hydroxypropyl Cellulose and for Low-substituted Hydroxypropyl Cellulose.

Ph. Eur. 6.2 (Hydroxypropylcellulose). A partially substituted 2-hydroxypropyl ether of cellulose. Various grades are available and may be distinguished by appending a number indicative of the apparent viscosity in millipascal seconds of a 2% w/w solution measured at 20°. White or yellowish-white, granules or powder; hygroscopic after drying. Soluble in cold water, in dehydrated alcohol, in glacial acetic acid, in methyl alcohol, in propylene glycol, and in a mixture of 10 parts methyl alcohol and 90 parts dichloromethane, forming colloidal solutions; practically insoluble in hot water, in ethylene glycol, and in toluene; sparingly soluble or slightly soluble in acetone. A 1% w/w solution in water has a pH of 5.0 to 8.5.

USNF 26 (Hydroxypropyl Cellulose). A partially substituted poly(hydroxypropyl) ether of cellulose. When dried at 105° for 1 hour, it contains not more than 80.5% of hydroxypropoxy groups. It may contain not more than 0.60% of silica or other suitable anticaking agent. A white to cream-coloured, practically odourless, granular solid or powder, hygroscopic after drying. Soluble in cold water, in alcohol, in chloroform, and in propylene glycol, giving a colloidal solution; insoluble in hot water. pH of a 1% solution in water is between 5.0 and 8.0.

USNF 26 (Low-Substituted Hydroxypropyl Cellulose). It contains not less than 5.0% and not more than 16.0% of hydroxypropoxy groups. A white to yellowish-white, practically odourless, hygroscopic, fibrous or granular powder. Practically insoluble in dehydrated alcohol and in ether; dissolves in a solution of sodium hydroxide (1 in 10) and produces a viscous solution; swells in water, in sodium carbonate, and in 2N hydrochloric acid. pH of the suspension obtained by shaking 1.0 g with 100 mL of water is between 5.0 and 7.5. Store in airtight containers.

Adverse Effects

Hyprolose used as a solid ocular insert may result in blurred vision and ocular discomfort or irritation including hypersensitivity and oedema of the eyelids.

Hypersensitivity. Allergic contact dermatitis was reported in a patient, associated with the hyprolose present in the reservoir layer of a transdermal estradiol patch.[1]

1. Schwartz BK, Clendenning WE. Allergic contact dermatitis from hydroxypropyl cellulose in a transdermal estradiol patch. *Contact Dermatitis* 1988; **18:** 106–7.

Uses and Administration

Hyprolose is used in pharmaceutical manufacturing in the film coating of tablets, as a tablet excipient, as a thickener, and in microencapsulation. It is used as an emulsifier and stabiliser in the food industry.

Hyprolose is also used as a modified-release solid ophthalmic insert in the management of dry eye (p.2140).

Preparations

USP 31: Hydroxypropyl Cellulose Ocular System.

NOTE. HPRM is a code approved by the BP 2008 for use on single unit doses of eye drops containing hypromellose where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Hypromellose). A mixed ether of cellulose containing a variable proportion of methoxy and 2-hydroxypropoxy groups. Various grades are available (see Labelling, below). A white, yellowish-white, or greyish-white powder or granules; hygroscopic after drying. Dissolves in cold water, forming a colloidal solution; practically insoluble in hot water, in dehydrated alcohol, in acetone, and in toluene. A 1% w/w solution in water has a pH of 5.0 to 8.0.

USP 31 (Hypromellose). A methyl and hydroxypropyl mixed ether of cellulose It contains methoxy and hydroxypropoxy groups conforming to the limits for the types 1828, 2208, 2906, and 2910, calculated on the dried basis (see Labelling, below). A white to slightly off-white fibrous or granular powder. Swells in water and produces a clear to opalescent, viscous, colloidal mixture; insoluble in dehydrated alcohol, in chloroform, and in ether.

Labelling. In Europe, grades of hypromellose are distinguished by appending a number indicative of the apparent viscosity in millipascal seconds of a 2% w/w solution measured at 20° (e.g. hypromellose 4500). In the USA, they are distinguished by appending a number in which the first 2 digits represent the approximate percentage content of methoxy groups, and the third and fourth digits the approximate percentage content of hydroxypropoxy groups.

Hypromellose Phthalate *(BANM, rINNM)*

Ftalát hypromelosy; Ftalato de hipromelosa; Hipromeliozės ftalatas; Hipromellóz-ftalát; Hydroxypropyl Methylcellulose Phthalate; Hypromelloosiftalaatti; Hypromellose, phtalate d'; Hypromellosftalat; Hypromellosi phthalas; Methylhydroxypropylcellulose Phthalate; Methylhydroxypropylcellulosi Phthalas.

Гипромеллозы Фталат

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Hypromellose Phthalate). A monophthalic acid ester of hypromellose containing methoxy, 2-hydroxypropoxy, and phthalyl groups, calculated with reference to the anhydrous substance. White or slightly off-white, free-flowing flakes or a granular powder. Practically insoluble in water and in dehydrated alcohol; very slightly soluble in acetone and in toluene; soluble in a mixture of equal volumes of acetone and methyl alcohol, and of dichloromethane and methyl alcohol. Store in airtight containers.

USNF 26 (Hypromellose Phthalate). A monophthalic acid ester of hypromellose. It contains methoxy, hydroxypropoxy, and phthalyl groups. It contains 21.0 to 35.0% of phthalyl groups, calculated on the anhydrous basis. Store in airtight containers. A white, odourless, powder or granules. Practically insoluble in water, in dehydrated alcohol, and in hexane; produces a viscous solution in a mixture of dehydrated alcohol and acetone (1:1), or in a mixture of methyl alcohol and dichloromethane (1:1); dissolves in 1N sodium hydroxide. Store in airtight containers.

Labelling. Different grades of hypromellose phthalate in the USA are distinguished by appending a number in which the first 2 digits represent the approximate percentage content of the methoxy groups, the next 2 digits the approximate percentage content of hydroxypropoxy groups, and the last 2 digits the approximate percentage content of the phthalyl groups. Another system of nomenclature involves appending a number which indicates the pH value (× 10) at which the polymer dissolves in aqueous buffer solutions; letters such as S or F may also be used to indicate grades of high molecular-weight or small particle size respectively.

Uses and Administration

Hypromellose has properties similar to those of methylcellulose (below). It is used in pharmaceutical manufacturing for film-coating tablets, as a tablet binder, as a modified-release matrix, and as an emulsifier, suspending agent, and stabiliser in topical gels and ointments. Hypromellose may also be used as an emulsifier and stabiliser in the food industry.

Hypromellose phthalate is used to provide enteric coating for tablets and granules, for the preparation of modified-release granules, and as a coating to mask the unpleasant taste of some tablets.

Hypromellose is widely used clinically in ophthalmic solutions; it is preferred to methylcellulose since mucilages of hypromellose have greater clarity and usually contain fewer undispersed fibres. Hypromellose is used to prolong the action of medicated eye drops and, either alone or with other viscosity-increasing agents, in artificial tears preparations for the management of dry eye (p.2140); solutions containing 0.3 to 1% of hypromellose are commonly used. Solutions for contact lens care (p.1622) and for lubricating artificial eyes contain similar concentrations. Hypromellose is also used intra-ocularly, usually as a 2% solution, as an adjunct in ophthalmic surgery (below) and concentrations of up to 2.5% may be used topically to protect the cornea during gonioscopy procedures.

Hypromellose has been included in artificial saliva preparations used in the management of dry mouth (p.2140), but other drugs are usually preferred.

Ophthalmic surgery. Intra-ocular hypromellose may be used as a visco-elastic agent to protect the eye during surgery. In cataract extraction it is used to maintain the anterior chamber and to coat the intra-ocular lens to facilitate its implantation. Although intra-ocular hypromellose is generally considered to be well tolerated, some[1] have reported an increased incidence of pupil abnormalities (non-reactive semi-dilated pupils) after such use; others[2] did not confirm this. There has also been a report[3] of corneal opacities in a number of patients after use of intra-ocular hypromellose.

1. Tan AKK, Humphry RC. The fixed dilated pupil after cataract surgery—is it related to intraocular use of hypromellose? *Br J Ophthalmol* 1993; **77:** 639–41.
2. Eason J, Seward HC. Pupil size and reactivity following hydroxypropyl methylcellulose and sodium hyaluronate. *Br J Ophthalmol* 1995; **79:** 541–3.
3. Newton JN, *et al.* Corneal opacities after cataract surgery with hypromellose. *Lancet* 2000; **355:** 290.

Magnesium Silicate

E553(a); Silicato de magnesio.

CAS — 1343-88-0.
ATC — A02AA05.
ATC Vet — QA02AA05.

NOTE. The code E553(a) has also been applied to magnesium trisilicate.

Pharmacopoeias. In *Jpn.* Also in *USNF.*

USNF 26 (Magnesium Silicate). A compound of magnesium oxide and silicon dioxide. It contains not less than 15.0% of magnesium oxide and not less than 67.0% of silicon dioxide, calculated on the ignited basis. It is a fine, white, odourless powder, free from grittiness. Insoluble in water and in alcohol. It is readily decomposed by mineral acids. pH of a well-mixed 10% suspension in water is between 7.0 and 10.8.

Uses

Magnesium silicate is used in the food industry and in pharmaceutical manufacturing as an anticaking agent.

Preparations

Proprietary Preparations (details are given in Part 3)
Port.: Acnoil Free.

Multi-ingredient: ***Braz.:*** Cutisanol; ***Fr.:*** ZeaSorb; ***Port.:*** Mucal†.

Methylcellulose *(rINN)*

E461; Méthylcellulose; Methylcellulosum; Methylcelulosa; Metilceliuliozė; Metilcellulóz; Metilcelulosa; Metylcellulosa; Metyloceluloza; Metyyliselluloosa.

Метилцеллюлоза

CAS — 9004-67-5.
ATC — A06AC06.
ATC Vet — QA06AC06.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Methylcellulose). A cellulose having some of the hydroxyl groups in the form of the methyl ether. Various grades of methylcellulose are available and are distinguished by appending a number indicating the apparent viscosity in millipascal seconds of a 2% w/w solution at 20°. It is a white, yellowish-white, or greyish-white powder or granules; hygroscopic after drying. Practically insoluble in hot water, in dehydrated alcohol, in acetone, and in toluene; dissolves in cold water, forming a colloidal solution. A 1% w/w solution in water has a pH of 5.0 to 8.0.

USP 31 (Methylcellulose). A methyl ether of cellulose. When dried at 105° for 2 hours, it contains 27.5 to 31.5% of methoxy groups. It is a white, fibrous powder or granules. It swells in water and produces a clear to opalescent, viscous, colloidal suspension; insoluble in alcohol, in chloroform, and in ether; soluble in glacial acetic acid and in a mixture of equal volumes of alcohol and chloroform. Its aqueous suspensions are neutral to litmus.

Incompatibility. Incompatibilities of methylcellulose have been reported with a number of compounds including chlorocresol, hydroxybenzoates, and phenol. Large amounts of electrolytes increase the viscosity of methylcellulose mucilages owing to salting-out of the methylcellulose; in very high concentrations of electrolytes, the methylcellulose may be completely precipitated.

Adverse Effects

Large quantities of methylcellulose may temporarily increase flatulence and distension and there is a risk of intestinal obstruction. Oesophageal obstruction may occur if compounds such as methylcellulose are swallowed dry.

Precautions

Methylcellulose and other bulk-forming agents should not be given to patients with intestinal obstruction or conditions likely to lead to intestinal obstruction. They should be taken with sufficient fluid to prevent faecal impaction or oesophageal obstruction, and should not be taken immediately before going to bed. Methylcellulose should not be used in infective bowel disease.

Interactions

Bulk laxatives such as methylcellulose lower the transit time through the gut and could affect the absorption of other drugs.

Uses and Administration

The various grades of methylcellulose are widely used in pharmaceutical manufacturing as emulsifying, suspending, and thickening agents and as binding, disintegrating, and coating agents in tablet manufacturing. Low-viscosity grades are preferred for use as emulsifying agents as the surface tension produced is lower than with the higher-viscosity grades. Low-viscosity grades may also be used as suspending or thickening agents for liquid oral dosage forms and solutions of methylcellulose may be used as replacements for sugar-based syrups or other suspension bases. For thickening topically applied products such as gels and creams a high-viscosity grade is usually used. In tablet technology low- or medium-viscosity grades are used as binding agents while high-viscosity grades act as tablet disintegrants by swelling on contact with the disintegration medium. For tablet coating, highly substituted low-viscosity grades are usually used. Methylcellulose may also be included in modified-release tablet formulations.

Methylcellulose is also used as an emulsifier and stabiliser in the food industry.

Methylcellulose is used clinically as a bulk-forming agent. Medium- or high-viscosity grades are used as bulk laxatives in the treatment of constipation (p.1693); by taking up moisture they increase the volume of the faeces and promote peristalsis. Methylcellulose is usually given in an oral dosage of up to 6 g daily in divided doses, taken with plenty of fluid. In the UK, the *BNFC* recommends a dose of 1 g twice daily for children aged from 7 to 12 years. Methylcellulose is also given in similar doses but with a minimum amount of water for the control of diarrhoea (p.1694) and for the control of faecal consistency in ostomies. It is also used in the management of diverticular disease (p.1695). Methylcellulose has also been used as an aid to appetite control in the management of obesity (p.2149) but there is little evidence of efficacy.

Solutions of high-viscosity grade methylcellulose (usually 0.5 to 1%) have been used as a vehicle for eye drops, as artificial tears, and in contact lens care, but hypromellose (above) is now generally preferred for this purpose.

Preparations

BP 2008: Methylcellulose Granules; Methylcellulose Tablets;
USP 31: Methylcellulose Ophthalmic Solution; Methylcellulose Oral Solution; Methylcellulose Tablets.

Pectin

E440 (amidated pectin or pectin); Pectina; Pektin.

CAS — 9000-69-5.
ATC — A07BC01.
ATC Vet — QA07BC01.

Pharmacopoeias. In *US.*

USP 31 (Pectin). A purified carbohydrate product obtained from the dilute acid extract of the inner portion of the rind of citrus fruits or from apple pomace; it consists mainly of partially methoxylated polygalacturonic acids. A yellowish-white, almost odourless, coarse or fine powder. Almost completely soluble in 1 in 20 of water, forming a viscous, opalescent, colloidal solution which flows readily and is acid to litmus; practically insoluble in alcohol or in diluted alcohol and in other organic solvents. It dissolves more readily in water if first moistened with alcohol, glycerol, or simple syrup, or if mixed with 3 or more parts of sucrose. Store in airtight containers.

Interactions

Bulk-forming agents such as dietary fibre lower the transit time through the gut and may affect the absorption of other drugs.

Lipid regulating drugs. Pectin, used as a source of fibre, with a lipid-lowering diet and *lovastatin*, has resulted in a paradoxical increase in low-density lipoprotein (LDL)-cholesterol in patients with hypercholesterolaemia. It was believed the pectin reduced the absorption of lovastatin from the gut.[1]

1. Richter WO, *et al.* Interaction between fibre and lovastatin. *Lancet* 1991; **338:** 706.

Uses and Administration

Pectins are used as emulsifiers and stabilisers in the food industry. They are non-starch polysaccharide constituents of dietary fibre (see under Dietary Role in Bran, p.1713).

Pectin is an adsorbent and bulk-forming agent and is present in multi-ingredient preparations for the management of diarrhoea, constipation, and obesity. Pectin has also been tried for reducing or slowing carbohydrate absorption in the dumping syndrome (p.1695).

Polyethylene Oxide

Polietileno, óxido de.

Pharmacopoeias. In *USNF.*

USNF 26 (Polyethylene Oxide). A nonionic homopolymer of ethylene oxide, represented by the formula $(OCH_2CH_2)_n$, in which *n* represents the average number of oxyethylene groups (about 2000 to over 100 000). It is obtainable in several grades, varying in viscosity profile in an aqueous isopropyl alcohol solution. It may contain not more than 3% of silicon dioxide. A white to off-white powder. Miscible with water; freely soluble in acetonitrile, in dichloromethane, in ethylene dichloride, and in trichloroethylene; insoluble in aliphatic hydrocarbons, in ethylene glycol, in diethylene glycol, and in glycerol. Store in airtight containers. Protect from light.

Uses

Polyethylene oxide is used as a tablet binder and as a suspending and thickening agent in pharmaceutical preparations. Polyethylene oxide has been used in hydrogel wound dressings.

Preparations

Polyvinyl Acetate

Poli(vinil-acetát); Polivinilacetatas; Poly(acétate de vinyle); Poly(vinylacetat); Polyvinyl-acetát; Polyvinylis Acetas; Poly(vinylis acetas); Poly(vinyyliasetaatti).

CAS — 9003-20-7.

Pharmacopoeias. In *Eur.* (see p.vii). *Eur.* also includes a 30% dispersion.

Ph. Eur. 6.2 (Poly(vinyl acetate)). A white or almost white powder or colourless granules or beads. Practically insoluble in water; soluble in alcohol; freely soluble in ethyl acetate. It is hygroscopic and swells in water. It softens at temperatures above 40° to 50°.

Ph. Eur. 6.2 (Poly(Vinyl Acetate) Dispersion 30 per cent). A dispersion in water of polyvinyl acetate having a mean relative molecular mass of about 450 000. It may contain povidone and a suitable surface-active agent, such as sodium laurilsulfate, as stabilisers.

An opaque, white or almost white, slightly viscous liquid. Miscible with water and with alcohol. It is sensitive to spoilage by microbial contaminants. Store at a temperature of 5° to 30°.

Polyvinyl Acetate Phthalate

Polivinilo, acetato ftalato de.

Pharmacopoeias. In *USNF.*

USNF 26 (Polyvinyl Acetate Phthalate). A reaction product of phthalic anhydride and a partially hydrolysed polyvinyl acetate. It contains 55.0 to 62.0% of phthalyl groups, calculated on an anhydrous acid-free basis. It is a free-flowing white powder that may have a slight odour of acetic acid. Insoluble in water, in chloroform, and in dichloromethane; soluble in alcohol and in methyl alcohol. Store in airtight containers.

Uses

Polyvinyl acetate phthalate is a viscosity-modifying agent that is used in the manufacture of enteric coating for tablets. Polyvinyl acetate is used in tablet coating; it is also widely used as a glue.

Polyvinyl Alcohol

Alcohol polivinílico; Alcohol Polyvinylicus; Alkohol poliwinylowy; Polivinil Alkol; Poli(vinil-alkohol); Polivinilo alkoholis; Poly(alcohol vinylicus); Poly(alcool vinylique); Polyvinylalkohol; Poly(vinylalkohol); Poly(vinyylialkoholi).

CAS — 9002-89-5.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Poly(Vinyl Alcohol)). It is obtained by polymerisation of vinyl acetate followed by partial or complete hydrolysis of polyvinyl acetate in the presence of catalytic amounts of alkali or mineral acids. Various grades are available and they differ in their degree of polymerisation and their degree of hydrolysis, which determine the physical properties of the different grades. They are characterised by the viscosity and the ester value of the substance. The mean relative molecular mass lies between 20 000 and 150 000. The viscosity is 3 to 70 millipascal seconds. The ester value, which characterises the degree of hydrolysis, is not greater than 280.

Polyvinyl alcohol occurs as a yellowish-white powder or translucent granules. Soluble in water; slightly soluble in dehydrated alcohol; practically insoluble in acetone. A 4% solution in water has a pH of 4.5 to 6.5.

USP 31 (Polyvinyl Alcohol). A synthetic resin represented by the formula $(CH_2CHOH)_n$, where the average value of *n* is 500 to 5000. It is prepared by 85 to 89% hydrolysis of polyvinyl acetate. White to cream-coloured, odourless, granules or powder. Freely soluble in water at room temperature; solution may be effected more rapidly at somewhat higher temperatures. pH of a 4% solution in water is between 5.0 and 8.0.

Uses and Administration

Polyvinyl alcohol is a nonionic surfactant that is used in pharmaceutical manufacturing as a stabilising agent and as a viscosity-increasing agent and lubricant.

Polyvinyl alcohol has also been used in the preparation of jellies that dry rapidly when applied to the skin to form a soluble plastic film.

Polyvinyl alcohols of various grades are used for a wide variety of industrial applications.

Polyvinyl alcohol has been used to increase the viscosity of ophthalmic preparations thus prolonging contact of the active ingredient with the eye. It is included in artificial tears preparations used for dry eye (p.2140) and in contact lens solutions (p.1622). For dry eye it is often used in a concentration of 1.4% with or without povidone.

Povidone *(BAN, USAN, rINN)*

E1201; Polivinilpirolidon; Polyvidone; Polyvidonum; Polyvinylpyrrolidone; Povidon; Povidona; Povidonas; Povidoni; Povidonum; Powidon; PVP; Vinylpyrrolidinone Polymer. Poly (2-oxopyrrolidin-1-ylethylene).

Повидон

$(C_6H_9NO)_n$.

CAS — 9003-39-8.
ATC — A07BC03.
ATC Vet — QA07BC03.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Povidone). Linear polymers of 1-ethenylpyrrolidin-2-one. The different types of povidone are characterised by their viscosity in solution. A white or yellowish-white, hygroscopic powder or flakes. Freely soluble in water, in alcohol, and in methyl alcohol; very slightly soluble in acetone. A 5% solution in water has a pH of 3.0 to 7.0 depending on the viscosity. Store in airtight containers.

USP 31 (Povidone). A synthetic polymer consisting essentially of linear 1-vinyl-2-pyrrolidinone groups, the degree of polymerisation of which results in polymers of various molecular weights. The different types of povidone are characterised by their viscosity in aqueous solution, relative to that of water, expressed as a K-value. A white to slightly creamy-white, hygroscopic powder. Freely soluble in water, in alcohol, and in methyl alcohol; slightly soluble in acetone; practically insoluble in ether. pH of a 5% solution in water is between 3.0 and 7.0. Store in airtight containers.

Copovidone

Copolyvidone; Copolyvidonum; Copovidona; Copovidonum; Kopovidon; Kopovidonas; Kopovidoni.

ATC — A07BC03.
ATC Vet — QA07BC03.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Copovidone). A copolymer of 1-vinylpyrrolidin-2-one and vinyl acetate in the mass proportion 3:2. A white or yellowish-white, hygroscopic powder or flakes. Freely soluble in water, in alcohol, and in dichloromethane. Protect from moisture.

USNF 26 (Copovidone). A copolymer of 1-vinyl-2-pyrrolidone and vinyl acetate in a mass proportion of 3:2. A white to yellowish-white, hygroscopic, powder or flakes. Freely soluble in water, in alcohol, and in dichloromethane; practically insoluble in ether. Store in airtight containers.

Crospovidone *(BAN, rINN)*

Crospovidona; Crospovidonum; Krospovidon; Krospovidonas; Krospovidoni; Kroszpovidon; Polyplasdone XL.

Кросповидон

CAS — 9003-39-8.
ATC — A07BC03.
ATC Vet — QA07BC03.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Crospovidone). A cross-linked homopolymer of 1-vinylpyrrolidin-2-one. A white or yellowish-white, hygroscopic powder or flakes. Practically insoluble in water, in alcohol, and in dichloromethane. Protect from moisture.

USNF 26 (Crospovidone). A synthetic cross-linked homopolymer of *N*-vinyl-2-pyrrolidinone. A white to creamy-white, hygroscopic powder having a faint odour. Insoluble in water and in ordinary organic solvents. pH of a 1% suspension in water is between 5.0 and 8.0. Store in airtight containers.

Adverse Effects

Some products intended for parenteral use contain povidone as an excipient and injection has led to deposition of povidone in the tissues with consequent lesions and pain. There have been occasional reports of liver involvement.

◊ Reviews of adverse effects associated with pharmaceutical excipients including povidone.

1. Golightly LK, *et al.* Pharmaceutical excipients: adverse effects associated with 'inactive ingredients' in drug products (part II). *Med Toxicol* 1988; **3:** 209–40.

Hypersensitivity. For reference to anaphylaxis caused by the povidone component of povidone-iodine, see p.1659.

Uses and Administration

Povidone is used in pharmaceutical manufacturing as a suspending and dispersing agent and as a tablet binding, granulating, and coating agent. It is used as a carrier for iodine (see Povidone-Iodine, p.1659). An insoluble cross-linked form of povidone known as crospovidone is used as a tablet disintegrant. Copovidone, a copolymer with vinyl acetate, is used as a tablet binding and coating agent.

Povidone is included in artificial tears preparations used in the management of dry eye (p.2140) and in solutions for contact lens care (p.1622). For dry eye it is often used in a concentration of 0.6% with other viscosity-increasing agents (such as polyvinyl alcohol); it may also be used alone in solutions containing 1.5 to 5%.

Povidone has also been used as an adsorbent in gastrointestinal disorders.

Povidone was formerly used as a plasma expander but other compounds are now preferred.

Preparations

Proprietary Preparations (details are given in Part 3)

Silicas

Silice.

Purified Siliceous Earth

Diatomaceous Earth; Diatomite; Purified Infusorial Earth; Purified Kieselguhr; Terra Silicea Purificada; Tierra de diatomeas; Ziemia okrzemkowa.

CAS — 7631-86-9.

Pharmacopoeias. In *USNF.*

USNF 26 (Purified Siliceous Earth). A form of silicon dioxide consisting of frustules and fragments of diatoms purified by calcining. A very fine, white, light grey, or pale buff mixture of amorphous powder and lesser amounts of crystalline polymorphs, including quartz and cristobalite. It is gritty and readily absorbs moisture, and retains about four times its weight of water before becoming fluid. Insoluble in water, in acids, and in dilute solutions of alkali hydroxides.

Silicon Dioxide

Colloidal Hydrated Silica; E551; Kiseldioxid, kolloidal, hydratiserad; Koloidinis silicio dioksidas, hidratuotas; Oxid křemičitý koloidní hydratovaný; Piidioksidi, kolloidinen, hydratoitu; Precipitated Silica; Silica colloidalis hydrica; Silica Gel; Silice colloïdale hydratée; Silicio, dióxido de; Víztartalmú, kolloid szilicium-dioxid.

$SiO_2.xH_2O$ = 60.08 (anhydrous).
CAS — 63231-67-4; 7631-86-9.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF. Eur.* and *USNF* also include dental-type silica.

Ph. Eur. 6.2 (Silica, Colloidal Hydrated). A light, fine, white or almost white, amorphous powder. Practically insoluble in water, and in mineral acids except hydrofluoric acid; dissolves in hot solutions of alkali hydroxides.

Ph. Eur. 6.2 (Silica, Dental Type). An amorphous silica (precipitated, gel, or obtained by flame hydrolysis). A white or almost white, light, fine amorphous powder. Practically insoluble in water and in mineral acids; dissolves in hydrofluoric acid and in hot solutions of alkali hydroxides.

USNF 26 (Silicon Dioxide). It is obtained by insolubilising the dissolved silica in sodium silicate solution. Where obtained by the addition of sodium silicate to a mineral acid, the product is termed silica gel; where obtained by the destabilisation of a solution of sodium silicate in such a manner as to yield very fine particles, the product is termed precipitated silica. A fine, white, odourless, hygroscopic, amorphous powder in which the diameter of the average particles ranges from 2 to 10 micrometres. Insoluble in water, in alcohol, and in other organic solvents; soluble in hot solutions of alkali hydroxides. pH of 5% slurry in water is between 4.0 and 8.0. Store in airtight containers. Protect from moisture.

USNF 26 (Dental-Type Silica). It is obtained from sodium silicate solution by destabilising with acid in such a way as to yield very fine particles. A fine, white, odourless, hygroscopic, amorphous powder in which the diameter of the average particles ranges from 0.5 to 40 micrometres. Insoluble in water, in alcohol, and in acid (except hydrofluoric acid); soluble in hot solutions of alkali hydroxides. pH of 5% slurry in water is between 4.0 and 8.5. Store in airtight containers.

Colloidal Silicon Dioxide

Acidum Silicicum Colloidale; Colloidal Anhydrous Silica; Colloidal Silica; Hochdisperses Silicumdioxid; Kiseldioxid, kolloidal, vattenfri; Koloidinis silicio dioksidas, bevandenis; Krzemu dwutlenek koloidalny; Oxid křemičitý koloidní bezvodý; Piidioksidi, kolloidinen, vedetön; Silica colloidalis anhydrica; Silice colloïdale anhydre; Silicii Dioxidum Colloidalle; Silicio coloidal, dióxido de; Vízmentes, kolloid, szilicium-dioxid.

SiO_2 = 60.08.
CAS — 7631-86-9.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Eur. and *USNF* also include hydrophobic colloidal silica.

Ph. Eur. 6.2 (Silica, Colloidal Anhydrous). A light, fine, white or almost white, amorphous powder. It has a particle size of about 15 nm. Practically insoluble in water and in mineral acids except hydrofluoric acid; dissolves in hot solutions of alkali hydroxides. A 3.3% suspension in water has a pH of 3.5 to 5.5.

Ph. Eur. 6.2 (Silica, Hydrophobic Colloidal; Silica Hydrophobica Colloidalis). Colloidal silicon dioxide partly alkylated for hydrophobation. A light, fine, white or almost white, amorphous powder, not wettable by water. Practically insoluble in water and mineral acids except hydrofluoric acid. It dissolves slowly in hot solutions of alkali hydroxides.

USNF 26 (Colloidal Silicon Dioxide). A submicroscopic fumed silicon dioxide, prepared by the vapour-phase hydrolysis of a silicon compound. A light, white, non-gritty powder of extremely fine particle size (about 15 nm). Insoluble in water and in acid (except hydrofluoric acid); soluble in hot solutions of alkali hydroxides. pH of a 4% dispersion in water is between 3.5 and 5.5.

USNF 26 (Hydrophobic Colloidal Silica). Prepared by partial alkylation for hydrophobation. A light, fine, white or almost white, amorphous powder, not wettable by water. Practically insoluble in water and in mineral acids, except hydrofluoric acid; dissolves slowly in hot solutions of alkali hydroxides.

Adverse Effects

Prolonged inhalation of some forms of silica dust may be associated with the development of fibrosis of the lung (silicosis). The forms of silica described here and used as pharmaceutical excipients may cause irritation of the respiratory tract if inhaled but do not appear to be associated with silicosis.

Uses

The different forms of silica have various pharmaceutical uses. Purified siliceous earth is used as a filtering medium and adsorbent. Silicon dioxide is used as a suspending and thickening agent and, in the form of silica gel, as a desiccant. Colloidal silicon dioxide is used as a suspending agent and thickener, as a stabiliser in emulsions, and as an anticaking agent and desiccant. Silicon dioxide is also used as an anticaking agent in the food industry.

Homoeopathy. Silicon dioxide has been used in homoeopathic medicines under the following names: Acidum silicicum; Silicea; Sil.

Sodium Starch Glycolate

Carboxyméthylamidon sodique; Carboxymethylamylum natricum; Glicolato sódico de almidón; Karboksymetyloskrobia sodowa; Karboximetilkeményítő-nátrium; Karboxymethylškrob sodná sůl; Natriumstärkelseglykolat; Natriumtärkkelysglykolaatti; Sodium Carboxymethyl Starch; Sodium Starch Glycollate; Starch Sodium Glycolate.

CAS — 9063-38-1.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Sodium Starch Glycolate (Type A); Carboxymethylamylum Natricum A). The sodium salt of a cross-linked partly *O*-carboxymethylated potato starch. It contains 2.8 to 4.2% of sodium, calculated with reference to the substance washed with alcohol (80%) and dried. A fine, white or almost white, very hygroscopic, free-flowing powder. It forms a translucent suspension in water; practically insoluble in dichloromethane. pH of a 3.33% dispersion in water is 5.5 to 7.5. Store in airtight containers. Protect from light.

Ph. Eur. 6.2 (Sodium Starch Glycolate (Type B); Carboxymethylamylum Natricum B). The sodium salt of a cross-linked partly *O*-carboxymethylated potato starch. It contains 2.0 to 3.4% of sodium, calculated with reference to the substance washed with alcohol (80%) and dried. A fine, white or almost white, very hygroscopic, free-flowing powder. It forms a translucent suspension in water; practically insoluble in dichloromethane. pH of a 3.33% dispersion in water is 3.0 to 5.0. Store in airtight containers. Protect from light.

Ph. Eur. 6.2 (Sodium Starch Glycolate (Type C); Carboxymethylamylum Natricum C). The sodium salt of a cross-linked by physical dehydration, partly *O*-carboxymethylated starch. It contains 2.8 to 5.0% of sodium, calculated with reference to the substance washed with alcohol (80%) and dried. A fine, white or almost white, very hygroscopic, free-flowing powder. It forms a translucent gel-like product in water; practically insoluble in dichloromethane. pH of a 3.33% gel in water is 5.5 to 7.5. Store in airtight containers. Protect from light.

USNF 26 (Sodium Starch Glycolate). The sodium salt of a carboxymethyl ether of starch or of a cross-linked carboxymethyl ether of starch. It may contain not more than 7.0% of sodium chloride. The sodium content is 2.8 to 4.2% (Type A) or 2.0 to 3.4% (Type B). pH of a 1 g in 30 mL suspension in water is between 5.5 and 7.5 (Type A) or between 3.0 and 5.0 (Type B).

A white, odourless, relatively free-flowing powder available in several different viscosity grades. A 2% dispersion in cold water settles, on standing, in the form of a highly hydrated layer. Protect from wide variations in temperature and humidity which may cause caking.

Uses

Sodium starch glycolate is used as a disintegrating agent in tablet manufacture.

Tragacanth

Dragant; E413; Goma Alcatira; Goma de tragacanto; Gomme adragante; Gum Dragon; Gum Tragacanth; Trag.; Tragacanta; Tragacantha; Tragacanto; Tragakanta; Tragakantas; Tragant; Tragantti.

CAS — 9000-65-1.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Tragacanth). The air-hardened gummy exudation flowing naturally or obtained by incision from the trunk and branches of *Astragalus gummifer* and some other species of *Astragalus* (Leguminosae) from western Asia. It occurs as thin, flattened, ribbon-like, white or pale yellow, translucent, horny strips. When reduced to a powder it forms a mucilaginous gel with about ten times its weight of water. Protect from light.

USNF 26 (Tragacanth). The dried gummy exudation from *Astragalus gummifer* or other Asiatic species of *Astragalus* (Leguminosae). It occurs as odourless, flattened, lamellated, frequently curved fragments or straight or spirally twisted linear pieces. It is white to weak yellow, translucent, and horny in texture. Powdered tragacanth is white to yellowish-white.

Adverse Effects

Hypersensitivity reactions, sometimes severe, have occurred rarely after the ingestion of products containing tragacanth. Contact dermatitis has been reported following the external use of tragacanth.

Uses

Tragacanth forms viscous solutions or gels with water, depending on the concentration. It is used in pharmaceutical manufacturing as a suspending agent and as an emulsifying agent. In dispensing aqueous preparations of tragacanth, the powdered tragacanth is first dispersed in a wetting agent, such as alcohol, to prevent agglomeration on the addition of water.

Tragacanth is also used for similar purposes in the food industry.

Xanthan Gum

Corn Sugar Gum; E415; Goma de xantána; Gomme xanthane; Ksantaanikumi; Ksantano lipai; Polysaccharide B 1459; Xantán gumi; Xantangummi; Xantham Gum; Xanthani gummi; Xanthanová klovatina.

CAS — 11138-66-2.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Xanthan Gum). A gum produced by fermentation of a carbohydrate with *Xanthomonas campestris* and purified. It is the sodium, potassium, or calcium salt of a high-molecular-weight polysaccharide containing D-glucose, mannose, and glucuronic acid. It also contains not less than 1.5% of pyruvic acid, calculated with reference to the dried substance. A white or yellowish-white, free-flowing powder. Soluble in water giving a highly viscous solution; practically insoluble in organic solvents. A 1% solution in water has a pH of 6.0 to 8.0.

USNF 26 (Xanthan Gum). A high-molecular-weight polysaccharide gum produced by a pure-culture fermentation of a carbohydrate with *Xanthomonas campestris* and purified. It contains D-glucose, D-mannose, and D-glucuronic acid. It is prepared as the sodium, potassium, or calcium salt. A cream-coloured powder. Soluble in hot or cold water. Its solutions are neutral to litmus.

Uses

Xanthan gum is used in pharmaceutical manufacturing as a suspending, stabilising, thickening, and emulsifying agent. It is also used similarly in the food industry.

◊ Suspensions of crushed tablets or insoluble powders made with xanthan gum were reported to be preferable to those made with tragacanth.[1]

The stability was generally good and only a small number of drugs had been found to be incompatible (amitriptyline, tamoxifen, and verapamil).[1] For extemporaneous dispensing, a 1% solution of xanthan gum with hydroxybenzoate, prepared in advance, was diluted to 0.5% with water when preparing the suspension.

Xanthan gum was found to be a suitable suspending vehicle for delivering antispasmodics topically along the length of the oesophagus in patients with oesophageal spasm.[2] Coagulation of the gum had been observed when it was used for suspensions of certain film-coated tablets.

Stimulants and Anorectics

Hyperactivity, p.2148
Narcoleptic syndrome, p.2148
Obesity, p.2149
Prader-Willi syndrome, p.2149

This chapter includes compounds used, generally under specialist supervision, for their central stimulant or their anorectic effects. Many are sympathomimetics and are subject to extensive abuse, which has led to strict limitations on their availability.

Hyperactivity

Attention deficit hyperactivity disorder (ADHD) is a syndrome of developmentally inappropriate and socially disruptive behaviour beginning in childhood and characterised by varying degrees of hyperactivity, inattention, and impulsiveness. Children with ADHD are easily distracted and have difficulty in completing tasks. Associated features may include low frustration tolerance, mood lability, and defiance. Some children continue to have symptoms throughout adolescence and into adulthood. The terms hyperkinesis, hyperkinetic syndrome, minimal brain dysfunction, attention deficit disorder, and attention deficit disorder with hyperactivity have sometimes been used synonymously for ADHD, but patients described as having these disorders do not necessarily satisfy the diagnostic criteria for ADHD.

Both drug and behaviour therapy may be used for the management of ADHD. Drug therapy is useful for the control of symptoms but is not curative. In the USA drug treatment for ADHD is quite common even in mild forms, and in the hands of specialists appears superior to behavioural therapy, but in the UK drugs are generally reserved for the more severely affected child who fails to respond to counselling and behaviour therapy.

Dexamfetamine and methylphenidate are usually the drugs of first choice but there is no consensus on which is the more effective; some also recommend the use of the selective noradrenaline reuptake inhibitor atomoxetine. Pemoline has been used but is associated with hepatotoxicity. Most children who benefit from drug therapy appear to require several years of treatment. Prolonged use of central stimulants can retard growth and some recommend occasional drug holidays to allow catch-up growth and determine whether continued therapy is necessary; many authorities consider that young children should not receive stimulants. Stimulants appear to be of use when the disorder persists into adulthood.

Tricyclic antidepressants such as imipramine and desipramine are also used for ADHD in both children and adults and their effect appears to be independent of their antidepressant action. However, they tend to be reserved for patients who fail to respond to, or are intolerant of, central stimulants. Tricyclic antidepressants may be useful in patients with co-existing Tourette's syndrome or in those with a family history of the disorder, as stimulants are believed to precipitate or exacerbate associated tics (p.954). Tricyclic antidepressants might also be preferred in patients with co-existing anxiety, depression, or enuresis, or in those with a history of drug abuse. Use with central stimulants has been studied but careful monitoring is advised (see also Interactions under Dexamfetamine, p.2153). MAOIs have been used successfully but problems with dietary restriction and potential drug interactions have limited their use. SSRIs such as fluoxetine have produced beneficial results as an adjunct to central stimulants in a small number of patients with associated depression or obsessive-compulsive disorder, but their value in ADHD alone is unclear. Bupropion has shown promising results in controlled studies in children but may exacerbate tics and increase the risk of seizures in predisposed patients. Venlafaxine has been effective in open trials in a small number of adult patients.

There is some evidence that carbamazepine may be an effective alternative to central stimulants. Clonidine has been used successfully with stimulants in children with an inadequate response to stimulants alone. However, there have been reports of adverse cardiac events associated with such combinations. Antipsychotics can produce severe adverse effects and are probably only warranted as adjunctive therapy to central stimulants in severe cases or when there is also extremely violent or destructive behaviour. Dopaminergics such as levodopa or pergolide have been tried with beneficial results for the treatment of restless legs syndrome and periodic limb movements in sleep associated with ADHD; some improvements in ADHD symptoms were also noted on resolution of the parasomnias.

Much controversy has surrounded the hypothesis that certain synthetic food additives including preservatives and artificial flavours and colours are aetiological agents in ADHD. Controlled studies have not proved the efficacy of dietary manipulation.

Narcoleptic syndrome

Narcolepsy is characterised by excessive daytime sleepiness and irresistible sleep attacks that last from a few minutes to hours. The narcoleptic syndrome often includes **cataplexy**, a sudden short-lived loss of muscle tone and paralysis of voluntary muscles induced by strong emotions. The severity of the attack can vary and some patients experience complete collapse but there is no loss of consciousness. **Sleep paralysis** consists of transient episodes of complete paralysis while falling asleep or during waking; respiration is unaffected. Some patients also have vivid auditory or visual hallucinations while falling asleep (**hypnagogic hallucinations**) or disturbed sleep.

For the management of narcoleptic syndrome the patient is initially encouraged to take planned regular short periods of sleep during the day and to avoid stressful events that may provoke attacks. If drug treatment is required then central stimulants are the main drugs used for the sleep attacks of narcolepsy. However, most are ineffective against cataplexy. The selection, dose, and timing of these drugs needs to be titrated for each patient, and drug holidays have been suggested to reduce the risk of developing tolerance. Amfetamines were the first drugs used. However, methylphenidate is often preferred to dexamfetamine as it has a rapid action and is considered to have fewer adverse effects. Alternative non-amfetamine stimulants used in the treatment of narcolepsy include mazindol, which also appears to be effective in cataplexy, and modafinil. Selegiline has been reported to improve excessive daytime sleepiness and cataplexy. There is a wide range of other drugs for which there is anecdotal or other limited evidence of efficacy in narcolepsy but there appears to be no evidence that they are superior to the central stimulants.

Tricyclic antidepressants are the primary treatment for cataplexy and sleep paralysis. However, a recent systematic review concluded that evidence supporting the use of antidepressants in cataplexy is scarce. Imipramine and clomipramine appear to have been widely used (some consider that clomipramine is the most effective of the tricyclics for this indication); desipramine and protriptyline have also been given. The onset of action is quicker, and the effective doses seem to be lower, than when tricyclics are used for depression, although tolerance to the effect may develop after 6 to 8 months, requiring an increase in dose. The daily dose should be titrated to provide maximal protection for the time of day when symptoms usually occur.

The use of sodium oxybate at night with stimulants during the day has been reported to improve the symptoms of patients with narcoleptic syndrome.

Patients requiring treatment for both narcolepsy and cataplexy may be given central stimulants and tricyclic antidepressants but require careful monitoring as the combination may produce serious adverse effects such as cardiac arrhythmias or hypertension; see also Interactions of Dexamfetamine, p.2153.

Obesity

Obesity results from an imbalance between energy intake and energy expenditure and increases the risk of cardiovascular disease, diabetes mellitus, gallstones, respiratory disease, osteoarthritis, and some forms of cancer. The prevalence of obesity is increasing especially in developed countries. Obesity may be defined in terms of the body-mass index (BMI), which is the weight (kg) divided by the square of the height (m^2):

- BMI 25.0 to 29.9: overweight
- BMI 30.0 to 34.9: obese, moderate risk of co-morbidity
- BMI 35.0 to 39.9: obese, severe risk of co-morbidity
- BMI 40.0 or more: obese, very severe risk of co-morbidity

Weight loss appears to improve control of diabetes mellitus and hypertension, and to reduce cardiovascular risk factors but long-term benefits are difficult to assess as weight is often regained.

Initial management involves dietary modification and includes calorie restriction and changes in the dietary proportions of fat, protein, and carbohydrates. Physical activity should also be increased and excess alcohol avoided. These measures should be followed for at least 3 months. If there has then been less than 10% reduction in weight and the BMI is still above 30, drug treatment may be considered. For patients with associated risk factors such as diabetes mellitus, ischaemic heart disease, hyperlipidaemias, hypertension, or sleep apnoea, drugs may be considered when the BMI is 27 or 28. Combination drug therapy is not recommended. Drugs should be given initially for 12 weeks. If weight loss is less than 5% then they should be considered a failure and stopped. If weight loss is more than 5% they may be continued and the patient monitored at monthly intervals. Treatment should be stopped once the BMI falls below 30 (or 27/28 as appropriate, see above), or if weight is regained, or there is any suspicion of toxicity.

Many drugs are capable of reducing appetite and have been used as such in the treatment of obesity. Both centrally acting (appetite suppressant, anorectic) drugs and those with a local action on the gastrointestinal tract have been used. However, toxicity has been a major problem with centrally acting drugs and very few are still in current use.

Appetite suppressants can be divided into two main groups: central stimulants that act on central catecholamine pathways and drugs acting on central serotonin pathways. Stimulants such as the amfetamines and phenmetrazine are no longer recommended because of their addictive potential. Other stimulants that have been used include diethylpropion, phentermine, mazindol, and phenylpropanolamine but they are also no longer recommended. The serotonergic drugs dexfenfluramine and fenfluramine were formerly used in long-term therapy (up to 1 year) but have both been associated with valvular heart defects and have generally been withdrawn worldwide. There have also been reports of valvular heart defects in patients receiving combinations of anorectics. UK and US guidelines therefore emphasise the centrally acting serotonin and noradrenaline reuptake inhibitor sibutramine, and the gastric lipase inhibitor orlistat, as appropriate choices for the drug treatment of obesity, in combination with diet and exercise. Rimonabant, a cannabinoid type-1 receptor antagonist, is also used as an adjunct in the treatment of obesity (although it was not mentioned in the guidelines). A systematic review of long-term studies (1 year or more) found orlistat, rimonabant, and sibutramine to be modestly effective in reducing weight; however, further studies, particularly on safety, are warranted.

Many other drugs have been tried, including fluoxetine, which has met with some success, and ephedrine with caffeine. The antiepileptics topiramate and zonisamide have also been investigated. Bulk-forming drugs such as methylcellulose and sterculia have been used in an attempt to control appetite by the local effect they might exert when they swell in the gastrointestinal tract, but there is little evidence of efficacy. Nondigestible fat substitutes such as sucrose polyesters have been promoted by the food industry, as part of a strategy to reduce fat and calories in the diet to aid body-weight control.

The control of appetite and the mechanisms of obesity are under investigation. A gene, called the ob-gene, and its protein product, leptin, have been identified and appear to be involved in regulation of food intake.

Prader-Willi syndrome

Compulsive eating and a voracious appetite are two of the many clinical features of Prader-Willi syndrome, a congenital disorder characterised by infantile hypotonia, hypogonadism, and facial dysmorphism, with subsequent development of abnormalities of behaviour and intellect.[1,2] Supervision and restricted access to food are the mainstay in preventing obesity, but are commonly not sufficient. Fluoxetine may decrease food intake in some patients. It has also been tried for associated self-mutilatory behaviour (skin picking) with variable results.[3,4] Growth hormone may be of benefit in increasing associated short stature and decreasing percentage body fat,[5-11] but close surveillance of glucose homoeostasis is advisable and there have been reports of fatalities in patients with severe obesity or risk factors for respiratory impairment or obstruction.[12] Anorectics have been ineffective.[2]

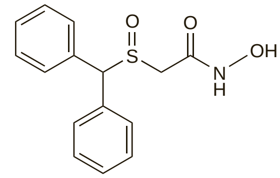
Adrafinil *(rINN)* ⊗

Adrafinilo; Adrafinilum; CRL-40028. 2-[(Diphenylmethyl)sulfinyl]acetohydroxamic acid.

Адрафинил

$C_{15}H_{15}NO_3S$ = 289.3.
CAS — 63547-13-7.
ATC — N06BX17.
ATC Vet — QN06BX17.



Profile

Adrafinil is a central stimulant and alpha$_1$-adrenergic agonist chemically related to modafinil (p.2160). It is given orally for mental function impairment in the elderly in doses of 600 mg to 1.2 g daily.

Preparations

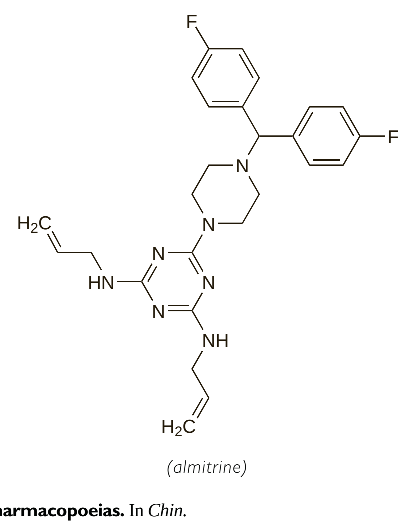
Proprietary Preparations (details are given in Part 3)
Fr.: Olmifon.

Almitrine Dimesilate *(BANM, rINNM)*

Almitrine Bismesylate; Almitrine, Dimésilate d'; Almitrine Dimesylate; Almitrine Mesylate *(USAN)*; Almitrini Dimesilas; Dimesilato de almitrina; S-2620 (almitrine or almitrine dimesilate). *NN'*-Diallyl-6-[4-(4,4'-difluorobenzhydryl)piperazin-1-yl]-1,3,5-triazine-2,4-diyldiamine bis(methanesulphonate).

Альмитрина Димезилат

$C_{26}H_{29}F_2N_7,2CH_4SO_3$ = 669.8.
CAS — 27469-53-0 (almitrine); 29608-49-9 (almitrine dimesilate).
ATC — R07AB07.
ATC Vet — QR07AB07.



(almitrine)

Pharmacopoeias. In *Chin.*

Profile

Almitrine dimesilate has been used as a respiratory stimulant in acute respiratory failure associated with conditions such as chronic obstructive pulmonary disease. Usual oral doses range from 50 to 100 mg daily and treatment may be intermittent. Up to 3 mg/kg has been given daily by intravenous infusion in 2 or 3 divided doses, each dose being infused over 2 hours. It is also available in a compound preparation with raubasine for mental function impairment in the elderly.

Respiratory system disorders. Respiratory stimulants (such as almitrine) have a limited and short-term role in acute respiratory failure in chronic obstructive pulmonary disease (p.1112). Almitrine has been reported[1-4] to improve ventilation and blood oxygenation, and to decrease the number of episodes of dyspnoea and hospital admissions, although others[5] have failed to note benefit. There are also reports[6,7] of beneficial effects when used with inhaled nitric oxide in patients with severe hypoxaemic acute respiratory distress syndrome (p.1498) as well as in patients with hypoxia caused by focal lung lesions.[8] However, any modest benefits may be outweighed by the adverse effects, which have included peripheral paraesthesia and weight loss,[1] and headache, urticaria, breathlessness, diarrhoea, chest pain, nausea, and vomiting.[3] The peripheral neuropathy that sometimes occurs during long-term use of almitrine[9,10] may be due to an underlying feature of the pulmonary disease being treated,[11-13] although some disagree with this.[14]

ATC — N06BA01.

ATC Vet — QN06BA01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Amfetamine Sulphate). A white or almost white powder. Freely soluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Amphetamine Sulfate). A white odourless crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in ether. Its solutions are acid to litmus, having a pH of 5 to 6.

Incompatibility. Amfetamine sulfate is incompatible with alkalis and calcium salts.

Profile

Amfetamine is an indirect-acting sympathomimetic with actions and uses similar to those of its isomer dexamfetamine (p.2153). Amfetamine, amfetamine sulfate, and amfetamine aspartate are given orally in doses similar to those of dexamfetamine sulfate. The laevo-isomer, levamfetamine was formerly used in a similar manner. Amfetamine, being volatile, was formerly given by inhalation.

Breast feeding. Amfetamine is concentrated in breast milk and the American Academy of Pediatrics has stated[1] that it has caused irritability and poor sleep pattern in breast-feeding infants when used as a drug of abuse by mothers.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 15/04/04)

Preparations

USP 31: Amphetamine Sulfate Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Belg.:*** Epipropane; ***Canad.:*** Adderall; ***USA:*** Adderall.

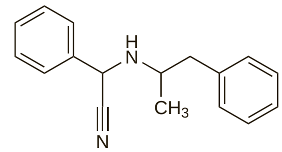
Amfetaminil *(rINN)* ⊗

Amfétaminil; Amfetaminilum; Amphetaminil; Anfetaminilo. α-(α-Methylphenethylamino)-α-phenylacetonitrile.

Амфетаминил

$C_{17}H_{18}N_2$ = 250.3.

CAS — 17590-01-1.



Profile

Amfetaminil is a central stimulant that has been given orally in the treatment of narcolepsy.

Preparations

Proprietary Preparations (details are given in Part 3)
Ger.: AN 1†.

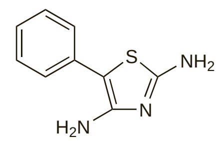
Amiphenazole Hydrochloride *(BANM, rINNM)* ⊗

Amiphénazol, Chlorhydrate d'; Amiphenazole Chloride; Amiphenazoli Hydrochloridum; Hidrocloruro de amifenazol. 5-Phenylthiazole-2,4-diamine hydrochloride.

Амифеназола Гидрохлорид

$C_9H_9N_3S,HCl$ = 227.7.

CAS — 490-55-1 (amiphenazole); 942-31-4 (amiphenazole hydrochloride).



(amiphenazole)

Profile

Amiphenazole hydrochloride has properties similar to those of doxapram hydrochloride (p.2155) and has been used intramuscularly or intravenously as a respiratory stimulant.

Lichenoid reactions have been reported in addition to those reactions expected from its central activity.

Ammonium Camphocarbonate

Canfocarbonato de amonio.

$C_{11}H_{19}NO_3$ = 213.3.

CAS — 5972-75-8.

Profile

Ammonium camphocarbonate has been used in preparations for the treatment of respiratory-tract disorders.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Spain:*** Pulmofasa.

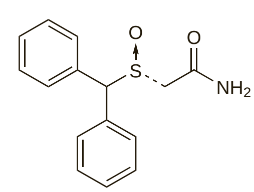
Armodafinil *(USAN, rINN)* ⊗

Armodafinilo; Armodafinilum; CEP-10953; CRL-40982. 2-[(*R*)-(Diphenylmethyl)sulfinyl]acetamide.

Армодафинил

$C_{15}H_{15}NO_2S$ = 273.4.

CAS — 112111-43-0.



Profile

Armodafinil is the *R*-enantiomer of modafinil (p.2160) and is used similarly in the treatment of excessive daytime sleepiness associated with the narcoleptic syndrome (p.2148), obstructive sleep apnoea, and shift-work sleep disorder. In the treatment of the narcoleptic syndrome or obstructive sleep apnoea, armodafinil is given orally in a single dose of 150 or 250 mg in the morning. For the management of shift-work sleep disorder, the daily dose is 150 mg taken as a single dose 1 hour before starting work. Reduced doses are recommended in the elderly and in patients with severe hepatic impairment.

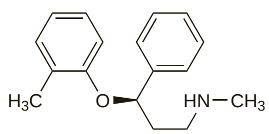
ATC — N06BA09.

ATC Vet — QN06BA09.



(atomoxetine)

Adverse Effects and Precautions

Adverse effects reported in patients receiving atomoxetine include dyspepsia and other gastrointestinal disturbances, anorexia and weight loss, fatigue, sleep disturbances, dizziness, irritability and emotional lability, cough, sinusitis or rhinorrhoea, urinary hesitancy or retention, decreased libido and sexual dysfunction, priapism, skin rashes, increased sweating, and hot flushes. Suicidal behaviour has been reported in children (see Effects on Mental State, below). Hypersensitivity reactions have occurred rarely. There have also been rare reports of severe hepatotoxicity (see Effects on the Liver, below).

There may be increases in blood pressure and heart rate, and atomoxetine should be given with caution to patients with hypertension, tachycardia, or cardiovascular or cerebrovascular disease (see also Effects on the Cardiovascular System, under Dexamfetamine Sulfate, p.2153). Orthostatic hypotension and syncope have also been reported. QT prolongation has been associated with atomoxetine therapy and it should be used with caution in patients with known or suspected prolonged QT interval. Use with drugs liable to inhibit the cytochrome P450 isoenzyme CYP2D6, other drugs that may prolong the QT interval, or drugs likely to cause electrolyte imbalance may also increase the risk (see Interactions, below). Sudden death, stroke, and myocardial infarction have also been reported in patients given atomoxetine. All patients should be assessed for cardiovascular disease before treatment is started. Atomoxetine should generally not be used in those with known serious structural cardiac abnormalities, cardiomyopathy, serious heart rhythm abnormalities, or other serious cardiac problems

Seizures are a potential risk with atomoxetine therapy and it should be used with caution in patients with a history of seizures; treatment may need to be stopped in those who develop seizures or have an increase in seizure frequency.

Atomoxetine is contra-indicated in patients with angle-closure glaucoma as it may increase the risk of mydriasis.

The weight and height gain of children receiving atomoxetine has been reported to lag behind that of the predicted norm for about the first 9 to 12 months of treatment and generally normalises within about 3 years of treatment; licensed product information recommends that growth be monitored and consideration given to dose reduction or interrupting treatment in patients who are not growing or gaining weight satisfactorily.

Poor metabolisers of atomoxetine (see Pharmacokinetics, below) may have an increased risk of adverse reactions.

Effects on the liver. In December 2004, the US manufacturer stated that 2 cases of severe hepatotoxicity had been reported with atomoxetine treatment since the drug was launched in 2002.[1] In both cases the patients recovered; however, because of the risk of acute hepatic failure resulting in death or the need for transplantation, it was recommended that atomoxetine should be permanently discontinued in patients with jaundice or markedly increased liver enzyme values.

Similar advice has also been issued in the UK by the CSM.[2] Up to February 2005, the CSM were aware of 3 reports of hepatic disorders (one each of hepatitis, jaundice, and increased bilirubin) with atomoxetine treatment in the UK; a total of 41 reports of hepatic disorders had been received worldwide.

Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON019459&RevisionSelectionMethod=LatestReleased (accessed 08/08/08)

Effects on mental state. Irritability and mood swings have been reported with the use of atomoxetine in children. In an observational study of 153 children, irritability, aggression, mania, or hypomania were associated with atomoxetine in 51 cases. Of these, 31 had a family history, and 41 a personal history, of mood disorders; 27 had both and 6 had neither. The authors therefore recommended that all patients receiving atomoxetine should be monitored closely.[1]

Subsequently, the FDA[2] requested the US manufacturer (*Eli Lilly*) to conduct an analysis of adverse events from 12 clinical trials involving 2208 patients. The risk of suicidal behaviour during the first few months of treatment was found to be 0.4% in children receiving atomoxetine compared with no risk in those on placebo; no suicides were reported although there was one unsuccessful suicide attempt in the atomoxetine-treated group. This finding resulted in the inclusion of a warning in US labelling about the increased risk of suicidal ideation in children and adolescents being treated with atomoxetine; it was also recommended that changes in behaviour must be closely monitored, particularly during the initial months of therapy or when the dose is changed. Similar warnings have been issued by the UK CSM[3] and regulatory authorities in other countries.[4]

In light of these concerns a review of available data in Europe was conducted; it was considered that the overall risk to benefit ratio of atomoxetine in children remained favourable.[5]

Handling. Atomoxetine is an ocular irritant and atomoxetine capsules should not therefore be opened. If the capsule contents do accidentally come into contact with the eye, the affected eye must be flushed immediately with water; hands and other potentially contaminated surfaces should be washed as soon as possible.

Interactions

Atomoxetine should not be taken with an MAOI, or within 2 weeks of stopping MAOI therapy, nor should MAOI therapy be started for 2 weeks after stopping atomoxetine. Care should be taken if given with other drugs that raise blood pressure, because of a possible additive affect; the actions of salbutamol on the cardiovascular system may be potentiated. In addition, there is a risk of cardiac events in patients receiving atomoxetine who are also taking drugs that affect cardiac conduction or electrolyte balance, or that inhibit the cytochrome P450 isoenzyme CYP2D6 (see below).

Seizures have been noted with atomoxetine and caution is advised when used with drugs known to lower the seizure threshold.

Atomoxetine is metabolised via the isoenzyme CYP2D6 and inhibitors of this enzyme such as paroxetine, fluoxetine, and quinidine may increase plasma concentrations of atomoxetine in extensive, but not poor, metabolisers.

Antidepressants. *Paroxetine* was found to inhibit atomoxetine's metabolism by cytochrome P450 isoenzyme CYP2D6 in extensive metabolisers resulting in pharmacokinetics for atomoxetine similar to those in poor metabolisers.[1]

1. Belle DJ, *et al.* Effect of potent CYP2D6 inhibition by paroxetine on atomoxetine pharmacokinetics. *J Clin Pharmacol* 2002; **42:** 1219–27.

Pharmacokinetics

Atomoxetine is well absorbed after oral doses, with peak plasma concentrations being achieved 1 to 2 hours later. Bioavailability is about 94% in poor metabolisers but only 63% in extensive metabolisers. Atomoxetine is about 98% bound to plasma proteins. Atomoxetine is metabolised primarily via the cytochrome P450 isoenzyme CYP2D6 to the active metabolite 4-hydroxyatomoxetine; a minority of the population are poor metabolisers and experience plasma concentrations about 5 times those in extensive metabolisers. It is excreted in the urine as glucuronide metabolites and a small amount of unchanged drug; less than 17% of a dose is excreted in the faeces. The half-life of atomoxetine is about 5.2 hours in extensive and 21.6 hours in poor metabolisers.

Uses and Administration

Atomoxetine hydrochloride is a selective noradrenaline reuptake inhibitor used in the treatment of attention deficit hyperactivity disorder (p.2148) in adults and children aged 6 years and over. It is given as the hydrochloride although doses are expressed in terms of the base; atomoxetine hydrochloride 11.4 mg is equivalent to about 10 mg of atomoxetine.

In *adults and adolescents and children weighing over 70 kg*, the initial dose is the equivalent of 40 mg daily, gradually increased after at least 7 days to 80 mg daily; in the USA an increase in dose may be made after a minimum of 3 days. A further increase to a maximum of 100 mg daily may be made after 2 to 4 weeks. In *children and adolescents of 70 kg and under*, the initial dose is the equivalent of about 500 micrograms/kg daily; this may be gradually increased to about 1.2 mg/kg daily. The total daily dose in this group should not exceed 1.4 mg/kg or 100 mg, whichever is less. Doses may be given as either a single dose in the morning or as equally divided doses in the morning and late afternoon or early evening.

Reduced doses are recommended in patients with hepatic impairment, see below. A lower initial dose and slower titration of atomoxetine may be required in patients who are poor CYP2D6 metabolisers (see Adverse Effects and Precautions, and Pharmacokinetics, above) and in those also taking CYP2D6 inhibitors (see Interactions, above). US licensed product information recommends increasing to the usual target dose only if symptoms fail to improve after 4 weeks and the initial dose is well tolerated in these patients.

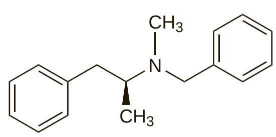
CAS — 156-08-1 (benzfetamine); 5411-22-3 (benzfetamine hydrochloride).



(benzfetamine)

Profile

Benzfetamine hydrochloride is a central stimulant and sympathomimetic with properties similar to those of dexamfetamine (below). It has been used as an anorectic in the treatment of obesity (p.2149), although amfetamines are no longer recommended for this indication. The usual initial oral dose is 25 to 50 mg given once daily, subsequently adjusted, according to requirements, to a dose of 25 to 50 mg up to three times daily.

Preparations

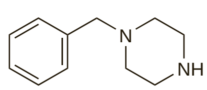
Proprietary Preparations (details are given in Part 3)
USA: Didrex.

Benzylpiperazine ⊗

N-Benzylpiperazine; 1-Benzylpiperazine. 1-(Phenylmethyl)piperazine.

Бензилпиперазин

$C_{11}H_{16}N_2$ = 176.3.
CAS — 2759-28-6.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of benzylpiperazine:
A2; Blast; BZP; Charge; Charlie; Cosmic Kelly; ESP; Euphoria; Exodus; Frenzy; Legal E; Legal X; Nemesis; Pep; Pep Love; Pep Stoned; Pep Twisted; Rapture; The Good Stuff.

Profile

Benzylpiperazine is reported to produce CNS stimulant effects similar to those of the amfetamines (see Dexamfetamine, p.2153) and is subject to abuse.

Other piperazine derivatives subject to abuse include:

- 1-(3,4-methylenedioxybenzyl)piperazine (MDBP)
- 1-(3-trifluoromethylphenyl)piperazine (TFMPP)
- 1-(3-chlorophenyl)piperazine (mCPP)
- 1-(4-methoxyphenyl)piperazine (MeOPP)

Catha ⊗

Abyssinian, African, or Arabian Tea; Kat; Kath; Khat; Miraa; Qat; Somali Tea.

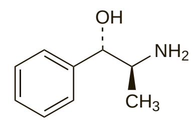
Description. Catha consists of the leaves of *Catha edulis* (Celastraceae), and contains cathine, cathinone, celastrin, choline, tannins, and inorganic salts.
The following terms have been used as 'street names' (see p.vi) or slang names for various forms of catha:
Cat; Chat; Feline; Kat; Miraa; Pootie; Qat; Quaadka.

Cathine *(pINN)* ⊗

Cathinum; Catina; (+)-Norpseudoephedrine. *threo*-2-Amino-1-phenylpropan-1-ol.

Катин

$C_9H_{13}NO$ = 151.2.
CAS — 492-39-7; 36393-56-3.
ATC — A08AA07.
ATC Vet — QA08AA07.



Cathinone *(pINN)* ⊗

Cathinonum; Catinona. (*S*)-2-Aminopropiophenone.

Катинон

$C_9H_{11}NO$ = 149.2.
CAS — 71031-15-7.

Profile

Catha, the leaves of *Catha edulis* (Celastraceae), is used for its stimulant properties among some cultures of Africa and the Middle East, usually by chewing the leaves. Its effects are reported to resemble those of the amfetamines (see Dexamfetamine Sulfate, below), and are thought to be largely due to the content of cathinone. Dependence and psychotic reactions have been reported. Cathine, another constituent, has been used as the hydrochloride as an anorectic.

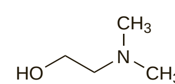
Deanol *(BAN)* ⊗

Démanol. 2-Dimethylaminoethanol.

$C_4H_{11}NO$ = 89.14.
CAS — 108-01-0 (deanol); 3342-61-8 (deanol aceglumate); 3635-74-3 (deanol acetamidobenzoate); 968-46-7 (deanol benzilate); 71-79-4 (deanol benzilate hydrochloride); 15585-86-1 (deanol cyclohexylpropionate); 5988-51-2 (deanol tartrate).
ATC — N06BX04.
ATC Vet — QN06BX04.



NOTE. Deanol Aceglumate is *pINN.*

Profile

Deanol, a precursor of choline, may enhance central acetylcholine formation. It has been used as a central stimulant in the treatment of hyperactivity in children but its efficacy is not proven. It has been included in preparations used as tonics and for the management of impaired mental function.

It has been used as a variety of salts and esters including deanol aceglumate, deanol acetamidobenzoate, deanol bisorcate, deanol cyclohexylpropionate (cyprodenate; cyprodemanol), deanol hemisuccinate, deanol pidolate, and deanol tartrate. Deanol benzilate (deanol diphenylglycolate; benzacine) has been used as the hydrochloride in antispasmodic preparations.

(dexamfetamine)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of dexamfetamine:
Dex; Dexies; Dexy; Oranges; Panama; Peaches.

Pharmacopoeias. In *Br.*, *Swiss*, and *US.*

BP 2008 (Dexamfetamine Sulphate). A white or almost white, odourless or almost odourless, crystalline powder. Freely soluble in water; slightly soluble in alcohol; practically insoluble in ether.

USP 31 (Dextroamphetamine Sulfate). A white, odourless, crystalline powder. Soluble 1 in 10 of water and 1 in 800 of alcohol; insoluble in ether. pH of a 5% solution in water is between 5.0 and 6.0.

Adverse Effects

The adverse effects of dexamfetamine are commonly symptoms of overstimulation of the CNS and include insomnia, night terrors, nervousness, restlessness, irritability, and euphoria that may be followed by fatigue and depression. There may be dryness of the mouth, anorexia, abdominal cramps and other gastrointestinal disturbances, headache, dizziness, tremor, sweating, tachycardia, palpitations, myocardial infarction, increased or sometimes decreased blood pressure, altered libido, and impotence. Psychotic reactions, such as hallucinations and delusional thinking, mania, seizures, and stroke have occurred, as has muscle damage with associated rhabdomyolysis and renal complications. Rarely, cardiomyopathy has occurred with chronic use. Sudden death has been reported in patients with structural cardiac abnormalities (see also Effects on the Cardiovascular System, below). In addition in children, growth retardation may occur during prolonged treatment.

In *acute overdosage*, the adverse effects are accentuated and may be accompanied by hyperpyrexia, mydriasis, hyperreflexia, chest pain, cardiac arrhythmias, confusion, panic states, aggressive behaviour, hallucinations, delirium, convulsions, respiratory depression, coma, circulatory collapse, and death. Individual patient response may vary widely and toxic manifestations may occur with quite small overdoses.

Tolerance can develop to some of dexamfetamine's central effects leading to increased doses and habituation. Abrupt cessation after prolonged treatment or abuse of amfetamines has been associated with extreme fatigue, hyperphagia, and depression. However, it is generally accepted that the amfetamines, although widely abused, are not associated with substantial physical dependence.

Abuse of amfetamines for their euphoriant effects has resulted in personality changes, compulsive and stereotyped behaviour, and may induce a toxic psychosis with auditory and visual hallucinations and paranoid delusions.

Abuse. Abuse of amfetamines can lead to toxicity affecting many organs or body systems. There have been reports of *intracerebral haemorrhage*[1-3] and of *cardiomyopathy*.[4-6] *Acute myocardial infarction* has also occurred.[7]

A syndrome characterised by *circulatory collapse, fever, leukaemoid reaction, disseminated intravascular coagulation*, and *rhabdomyolysis* with *diffuse myalgias* and *muscle tenderness* has been described[8] in 5 drug abusers who had used amfetamines or phenmetrazine intravenously. In an earlier study,[9] *necrotising angiitis* was associated with intravenous metamfetamine abuse. A 30-year-old man who had ingested 50 amfetamine sulfate tablets developed *rhabdomyolysis* and *myoglobinuric renal failure*, possibly secondary to a crush syndrome, but in the absence of prolonged coma or other major myotoxic factors.[10] However, *acute interstitial nephritis* and *acute renal failure* have followed oral amfetamine abuse without the associated factors of rhabdomyolysis, hyperpyrexia, or necrotising angiitis.[11]

Chronic use may result in adverse effects such as *hallucinations*, a *delusional disorder* resembling *paranoid schizophrenia*, *stereotyped behaviour*, and *movement disorders*.[12] Although chronic intoxication is the most common precondition for psychosis, individual sensitivities are an important aspect of the drug reaction.

Increased serum concentrations of *levothyroxine* have been associated with heavy amfetamine abuse in 4 psychiatric patients.[13]

Abrupt cessation after prolonged treatment or abuse of amfetamines may cause *extreme fatigue, hyperphagia*, and *depression*. *Depressive stupor* has been reported in 3 long-term abusers of amfetamine after sudden withdrawal.[14]

Effects on the cardiovascular system. There have been very rare reports of sudden death in children and adults taking *Adderall* (*Shire*), a combination preparation of amfetamine salts. In February 2005 Health Canada[1] reported that, worldwide, there have been 20 cases of sudden death in patients taking the product at usual recommended doses; 14 of these deaths occurred in children. In some cases there was no history of cardiac disorders nor any structural abnormalities. Health Canada considered the incidence of fatal adverse effects to be greater with this combination preparation than with other stimulants and consequently withdrew the product from the Canadian market. However, a subsequent independent review committee recommended[2] that *Adderall* be allowed back onto the Canadian market although they did warn that it should not be used in patients with structural cardiac abnormalities.[3]

The committee also recommended that all stimulants used in attention deficit hyperactivity disorder undergo enhanced postmarketing surveillance and consequently, in May 2006, Health Canada[4] revised the labelling of amfetamine, atomoxetine, dexamfetamine, dexmethylphenidate, and methylphenidate to include warnings about their effects on the cardiovascular system. However, it was also noted that the incidence or reporting rates of serious cardiovascular adverse effects with these drugs, including fatal cases, were no greater than background rates.

Effects on growth. The Pediatric Subcommittee of the FDA Psychopharmacologic Drugs Advisory Committee reviewed the growth-suppressing effects of stimulant medication in hyperkinetic children.[1] There was reasonable evidence that stimulant drugs, particularly in higher doses, moderately suppressed growth in weight and might have a minor suppressing effect on growth in stature. There were indications that some growth caught up during drug holidays, and that early growth suppression was not evident in adulthood. Careful monitoring during treatment was recommended.

See also under Methylphenidate Hydrochloride, p.2159.

1. Roche AF, *et al.* The effects of stimulant medication on the growth of hyperkinetic children. *Pediatrics* 1979; **63:** 847–50.

Treatment of Adverse Effects

Activated charcoal may be given to delay absorption if the patient presents within 1 hour; gastric lavage may be considered in recent large ingestions. In general the management of overdosage with amfetamines involves supportive and symptomatic therapy. Sedation is usually sufficient. Forced acid diuresis has been advocated to increase amfetamine excretion but is seldom necessary and should only be considered in severely poisoned patients; it requires close supervision and monitoring.

Precautions

Dexamfetamine is contra-indicated in patients with cardiovascular disease including moderate to severe hypertension and those with structural cardiac abnormalities, cardiomyopathy, or advanced arteriosclerosis. It should also not be used in patients with hyperthyroidism, glaucoma, hyperexcitability, or agitated states. Dexamfetamine should not be given to those with a history of drug or alcohol abuse and it should be avoided in pregnant or breast-feeding women.

It should be given with caution to patients with mild hypertension, renal impairment, bipolar disorder, or unstable personality. Behavioural disturbances and thought disorders may be exacerbated in psychotic patients.

Height and weight in children should be monitored as growth retardation may occur.

Care may be needed in certain patients predisposed to tics or Tourette's syndrome as symptoms may be provoked. Dexamfetamine is likely to reduce the convulsive threshold; caution is therefore advised in patients with epilepsy. However, it appears that in some countries amfetamines have been included in antiepileptic preparations containing phenytoin or phenobarbital in an attempt to increase their antiepileptic action. Amfetamines may impair patients' ability to drive or to operate machinery.

Diabetic control should be monitored when central stimulants are used for the control of obesity.

Prolonged high doses may need gradual withdrawal as abrupt cessation may produce fatigue and mental depression.

Abuse. Dexamfetamine is subject to extensive abuse and for this reason its availability is severely curtailed. For adverse effects associated with abuse, see above.

Porphyria. Amfetamines are considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity. Metamfetamine has been associated with acute attacks of porphyria.

Pregnancy. No difference was found in the incidence of severe congenital anomalies between 1824 children of mothers prescribed amfetamines or phenmetrazine during pregnancy and 8989 children of mothers who had not received these drugs.[1] Though an excess of oral clefts was noted in the offspring of mothers prescribed amfetamines, there was no excess of congenital heart disease.[1] This was contrary to a previous suggestion[2] in which congenital heart disease in 184 infants had been studied and a link to maternal dexamfetamine exposure postulated. There has been a report of a bradycardia followed by death in a fetus due to maternal intravenous self-administration of 500 mg of amfetamine.[3]

3. Dearlove JC, Betteridge TJ. Stillbirth due to intravenous amphetamine. *BMJ* 1992; **304:** 548.

Tourette's syndrome. A review[1] of clinical reports concluded that there was virtually no evidence that central stimulants caused or provoked Tourette's syndrome and weak or inadequate evidence that clinically appropriate doses of central stimulants caused tics in previously asymptomatic patients or exacerbated pre-existing symptoms. However, the authors suggested that there was evidence that high or toxic doses might exacerbate or provoke tics in predisposed patients. Long-term methylphenidate therapy did not appear to exacerbate motor or vocal tics in a study[2] of 34 children with ADHD and chronic multiple tic disorder who were followed up for 2 years. However, the authors did point out that careful clinical monitoring is essential to eliminate the possibility of drug-induced exacerbation in individual patients. In contrast, a report[3] on 15 children who developed Tourette's syndrome while receiving stimulant medication for hyperactivity considered that such therapy was contra-indicated in children with motor tics or diagnosed Tourette's syndrome and should be used with caution in children with a family history of these symptoms. In addition, it suggested that the development of motor tic symptoms in any child given stimulants should be a clear indication for stopping immediately to minimise the possibility of eliciting a full-blown Tourette's syndrome.

Interactions

Dexamfetamine is an indirect-acting sympathomimetic and may interact with a number of other drugs. To avoid precipitating a hypertensive crisis, it should not be given to patients being treated with an MAOI or within 14 days of stopping such treatment. Use of beta blockers with amfetamines may produce severe hypertension. Dexamfetamine may also diminish the effects of other antihypertensives, including guanethidine and similar drugs, and concurrent use should be avoided. Patients receiving amfetamines and tricyclic antidepressants require careful monitoring as the risk of cardiovascular effects including arrhythmias may be increased. The urinary excretion of amfetamines is reduced by urinary alkalinisers, which may enhance or prolong their effects; excretion is increased by urinary acidifiers.

Amfetamines may delay the absorption of ethosuximide, phenobarbital, and phenytoin. The stimulant effects of amfetamines are inhibited by chlorpromazine, haloperidol, and lithium. Disulfiram may inhibit the metabolism and excretion of amfetamines.

Use of sympathomimetics with volatile liquid anaesthetics such as halothane is associated with an increased risk of cardiac arrhythmias.

Pharmacokinetics

Amfetamines are readily absorbed from the gastrointestinal tract and are distributed into most body tissues with high concentrations in the brain and CSF. They are partially metabolised in the liver but a considerable fraction may be excreted in the urine unchanged. Urinary elimination is pH-dependent and enhanced in acid urine. Amfetamines are distributed into breast milk.

Uses and Administration

Dexamfetamine, the dextrorotatory isomer of amfetamine, is an indirect-acting sympathomimetic with alpha- and beta-adrenergic agonist activity. It has a marked stimulant effect on the CNS, particularly the cerebral cortex.

Dexamfetamine is used in the treatment of narcolepsy (p.2148). It is also used in the treatment of attention deficit hyperactivity disorder (p.2148); in the UK, this use is limited to refractory hyperactivity disorders in children. Dexamfetamine has been given in the treatment of obesity (p.2149), although amfetamines are no longer recommended for this indication. Amfetamines have also been used to overcome fatigue but, again, such use is considered undesirable. In some countries dexamfetamine has been tried for motion sickness (p.1700), but safer drugs are available.

Dexamfetamine is generally used as the sulfate and is given by mouth.

In the treatment of **narcolepsy**, the usual initial dose is 5 to 10 mg daily in divided doses, increased if necessary by 5 to 10 mg at weekly intervals to a maximum of 60 mg daily. The lower initial dose of 5 mg daily is recommended for the elderly and any weekly increments should also be restricted to 5 mg in such patients.

In children with **hyperactivity** individualisation of treatment is especially important. Children aged 6 years and over usually start with a dose of 5 mg once or twice daily; the dose may be increased if necessary by 5 mg at weekly intervals to an upper limit of 20 mg daily, although older children might require up to 40 mg or more daily. Although dexamfetamine is licensed for the treatment of children younger than 6 years of age in some countries, including the UK and the USA, many authorities consider that stimulants should not be used in young children.

In the USA, an immediate-release, combination preparation containing dexamfetamine sulfate and saccharate, with amfetamine sulfate and amfetamine aspartate monohydrate (*Adderall, Shire*), is licensed for the treatment of narcolepsy and attention deficit hyperactivity disorder. This formulation is given by mouth in doses similar to those for dexamfetamine (see above). A modified-release formulation is also available for the treatment of attention deficit hyperactivity disorder in adults and children. The initial dose in adults is 20 mg of total amfetamine salts once daily. In children, it is given as for dexamfetamine in initial doses of 10 mg of total amfetamine salts once daily increased gradually up to a maximum of 30 mg daily; in older children aged 13 to 17 years the dose may be increased to a maximum of 20 mg once daily after 1 week if necessary.

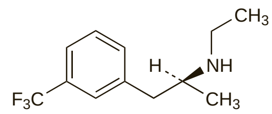
$C_{12}H_{16}F_3N,HCl = 267.7.$

CAS — 3239-44-9 (dexfenfluramine); 3239-45-0 (dexfenfluramine hydrochloride).

ATC — A08AA04.

ATC Vet — QA08AA04.



(dexfenfluramine)

Profile

Dexfenfluramine is the *S*-isomer of fenfluramine (p.2156). It stimulates the release of serotonin and selectively inhibits its reuptake, but differs from fenfluramine in not possessing any catecholamine agonist activity.

Dexfenfluramine was formerly given orally as the hydrochloride in the treatment of obesity but, like fenfluramine, was withdrawn worldwide after reports of valvular heart defects.

Porphyria. Dexfenfluramine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Isolipan†; ***Hung.:*** Isolipan†.

Dexmethylphenidate Hydrochloride

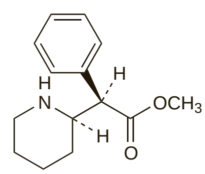
(USAN, rINNM) ⊗

Dexméthylphénidate, Chlorhydrate de; Dexmethylphenidati Hydrochloridum; d-MPH; Hidrocloruro de dexmetilfenidato; *d-threo*-Methylphenidate; *d*-Methylphenidate Hydrochloride. Methyl (2*R*)-phenyl[(2*R*)-piperidin-2-yl]acetate hydrochloride.

Дексметилфенидата Гидрохлорид

$C_{14}H_{19}NO_2,HCl = 269.8.$

CAS — 40431-64-9 (dexmethylphenidate); 19262-68-1 (dexmethylphenidate hydrochloride).



(dexmethylphenidate)

Profile

Dexmethylphenidate hydrochloride is the *d-threo*-enantiomer of racemic methylphenidate hydrochloride (p.2159). It is used as a central stimulant in the treatment of attention deficit hyperactivity disorders.

Dexmethylphenidate hydrochloride is licensed for use in children aged 6 years and older. For patients new to methylphenidate the starting dose of dexmethylphenidate hydrochloride is 2.5 mg twice daily. Each dose should be given at least four hours apart. Dosage may be adjusted in 2.5 to 5 mg increments weekly to a maximum of 10 mg twice daily.

For patients currently using methylphenidate the starting dose of dexmethylphenidate hydrochloride is half the dose of the racemic substance. The maximum recommended dose is 10 mg twice daily.

A modified-release formulation is also available for once-daily dosing.

Dexmethylphenidate should be stopped if there is no improvement in symptoms after appropriate adjustments in dosage over one month. It also needs to be stopped from time to time in those who do respond to assess the patient's condition.

Preparations

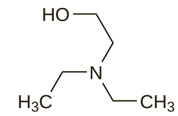
Proprietary Preparations (details are given in Part 3)
USA: Focalin.

Diethylaminoethanol ⊗

Dietilaminoetanol. 2-Diethylaminoethanol.

$C_6H_{15}NO = 117.2.$

CAS — 100-37-8.



Profile

Diethylaminoethanol is an analogue of deanol (p.2152) and has been used similarly as the malate. The hydrochloride has also been used.

Preparations

Proprietary Preparations (details are given in Part 3)
Gr.: Durobion.

Multi-ingredient: *Austria:* Barokaton.

Diethylpropion Hydrochloride *(BANM)* ⊗

Amfepramone Hydrochloride *(pINNM)*; Amfépramone, Chlorhydrate d'; Amfepramoni Hydrochloridum; Hidrocloruro de anfepramona. *N*-(1-Benzoylethyl)-*NN*-diethylammonium chloride; 2-Diethylaminopropiophenone hydrochloride; (*RS*)-α-Diethylaminopropiophenone hydrochloride.

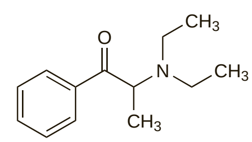
Амфепрамона Гидрохлорид

$C_{13}H_{19}NO,HCl = 241.8.$

CAS — 90-84-6 (diethylpropion); 134-80-5 (diethylpropion hydrochloride).

ATC — A08AA03.

ATC Vet — QA08AA03.



(diethylpropion)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of diethylpropion:
Blue; Blues.

Pharmacopoeias. In *US.*

USP 31 (Diethylpropion Hydrochloride). A white to off-white, fine crystalline powder. Is odourless or has a slight characteristic odour. It may contain tartaric acid as a stabilising agent. Soluble 1 in 0.5 of water, 1 in 3 of alcohol, and 1 in 3 of chloroform; practically insoluble in ether. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153. In addition gynaecomastia has been reported rarely. The incidence of central adverse effects may be lower with diethylpropion than with dexamfetamine. Diethylpropion should not be given to patients with emotional instability or a history of psychiatric illness. It should be avoided in children and the elderly. Diethylpropion hydrochloride is subject to abuse.

Porphyria. Diethylpropion is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

Diethylpropion is an indirect-acting sympathomimetic and, similarly to dexamfetamine (p.2153), may interact with a number of other drugs.

Pharmacokinetics

Diethylpropion is readily absorbed from the gastrointestinal tract. It is extensively metabolised in the liver and possibly the gastrointestinal tract and is excreted in the urine. Diethylpropion crosses the blood-brain barrier and the placenta. Diethylpropion and its metabolites are distributed into breast milk.

Uses and Administration

Diethylpropion hydrochloride is a central stimulant and indirect-acting sympathomimetic with the actions of dexamfetamine (p.2154). It is used as an oral anorectic in the short-term treatment of obesity (p.2149), although stimulants are not generally recommended for this indication.

Doses of 25 mg three times daily 1 hour before meals or 75 mg once daily in mid-morning as a modified-release preparation, are given. To reduce the risk of dependence, diethylpropion should not be given for more than a few weeks at a time.

Regulatory authorities in the EU have called for the withdrawal of diethylpropion from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156).

Preparations

USP 31: Diethylpropion Hydrochloride Tablets.

Dimefline Hydrochloride *(BANM, USAN, rINNM)*

Diméfline, Chlorhydrate de; Dimeflini Hydrochloridum; DW-62; Hidrocloruro de dimeflina; NSC-114650; Rec-7/0267. 8-Dimethylaminomethyl-7-methoxy-3-methyl-2-phenylchromen-4-one hydrochloride.

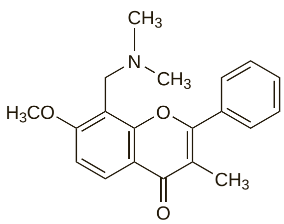
Димефлина Гидрохлорид

$C_{20}H_{21}NO_3,HCl = 359.8.$

CAS — 1165-48-6 (dimefline); 2740-04-7 (dimefline hydrochloride).

ATC — R07AB08.

ATC Vet — QR07AB08.



(dimefline)

Profile

Dimefline has actions similar to those of doxapram (below) and has been used orally as the hydrochloride and parenterally as a respiratory stimulant.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Remeflin.

Doxapram Hydrochloride *(BANM, USAN, rINNM)*

AHR-619; Doksapraamihydrokloridi; Doksapram Hidroklorür; Doksapramo hidrochloridas; Doxapram, chlorhydrate de; Doxaprám-hidroklorid; Doxapram-hydrochlorid monohydrát; Doxapramhydroklorid; Doxaprami hydrochloridum; Doxaprami Hydrochloridum Monohydricum; Hidrocloruro de doxapram. 1-Ethyl-4-(2-morpholinoethyl)-3,3-diphenyl-2-pyrrolidinone hydrochloride monohydrate.

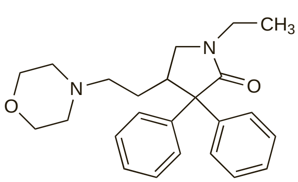
Доксапрама Гидрохлорид

$C_{24}H_{30}N_2O_2,HCl,H_2O = 433.0.$

CAS — 309-29-5 (doxapram); 113-07-5 (anhydrous doxapram hydrochloride); 7081-53-0 (doxapram hydrochloride monohydrate).

ATC — R07AB01.

ATC Vet — QR07AB01.



(doxapram)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Doxapram Hydrochloride). A white or almost white crystalline powder. Sparingly soluble in water, in alcohol and in dichloromethane. A 1% solution in water has a pH of 3.5 to 5.0.

USP 31 (Doxapram Hydrochloride). A white to off-white, odourless, crystalline powder. Soluble 1 in 50 of water; soluble in chloroform; sparingly soluble in alcohol; practically insoluble in ether. pH of a 1% solution in water is between 3.5 and 5.0. Store in airtight containers.

Incompatibility. The commercial injection of doxapram hydrochloride is reported to be incompatible with alkaline solutions such as aminophylline, furosemide, or thiopental sodium.

Adverse Effects

As with other respiratory stimulants, there is a risk that doxapram will produce adverse effects due to general stimulation of the CNS.

Doxapram may produce dyspnoea and other respiratory problems such as coughing, bronchospasm, laryngospasm, hiccup, hyperventilation, and rebound hypoventilation. Muscle involvement may range from fasciculations to spasticity. Convulsions, headache, dizziness, hyperactivity, and confusion can occur as can sweating, flushing, fever or a sensation of warmth, particularly in the genital or perineal regions. Hallucinations may occur rarely. There may be nausea, vomiting, diarrhoea, and problems with urination. Cardiovascular effects include hypertension and various arrhythmias although sudden hypotension may also occur.

Thrombophlebitis may follow extravasation of doxapram during injection.

Effects on the heart. Second-degree AV block caused by prolongation of the QT interval has been associated with doxapram use in 3 neonates.[1] Although the preparation used contained benzyl alcohol this was not considered to play a role in the adverse effect. A prospective study[2] involving 40 premature infants given doxapram for apnoea of prematurity also found QT interval lengthening at 48 and 72 hours of treatment, even when the drug plasma concentrations were kept within therapeutic ranges. In 6 infants, the QT interval lengthened to a degree considered to be life-threatening. There was also a trend towards moderate increases in blood pressure. The authors recommended heart monitoring when doxapram was given to premature infants.

2. Maillard C, *et al.* QT interval lengthening in premature infants treated with doxapram. *Clin Pharmacol Ther* 2001; **70:** 540–5.

Effects on the liver. Acute hepatic necrosis in a patient was attributed to a 24-hour infusion of doxapram.[1] Liver function tests returned to normal over 3 weeks.

1. Fancourt GJ, *et al.* Hepatic necrosis with doxapram hydrochloride. *Postgrad Med J* 1985; **61:** 833–5.

Precautions

Doxapram should not be given to patients with epilepsy or other convulsive disorders, cerebral oedema, cerebrovascular accident, head injury, acute severe asthma, physical obstruction of the airway, severe hypertension, ischaemic heart disease, hyperthyroidism, or phaeochromocytoma. Caution is also advisable if doxapram is used in patients with less severe degrees of hypertension or impaired cardiac reserve. It should be given with care to patients with significant hepatic or renal impairment.

Patients should be carefully supervised during use of doxapram; special attention should be paid to changes in blood gas measurements. Doxapram should be given with oxygen in severe irreversible airways obstruction or severely decreased lung compliance because of the increased work of breathing. A $beta_2$ agonist should also be given to patients with bronchoconstriction.

Interactions

Additive pressor effects may occur when doxapram is used with sympathomimetics or MAOIs. Cardiac arrhythmias may occur when doxapram is given with anaesthetics known to sensitise the myocardium, such as halothane, enflurane, and isoflurane; it has been recommended that doxapram should not be given for at least 10 minutes after stopping these anaesthetics. Doxapram may temporarily mask the residual effects of neuromuscular blockers. The manufacturers have reported that there may be an interaction between doxapram and aminophylline manifested by agitation and increased skeletal muscle activity.

Pharmacokinetics

After intravenous doses doxapram is rapidly distributed into the tissues. Onset of respiratory stimulation usually occurs in 20 to 40 seconds, with a peak effect achieved in 1 to 2 minutes. Duration of effect following a single dose varies from 5 to 12 minutes. Doxapram is extensively metabolised in the liver. The major route of excretion of metabolites and a small amount of unchanged drug is thought to be via bile to the faeces. It is also excreted in the urine.

Some absorption occurs when doxapram is given orally.

Uses and Administration

Doxapram hydrochloride is a central and respiratory stimulant with a brief duration of action. It acts by stimulation of peripheral chemoreceptors and central respiratory centres; at higher doses, it stimulates other parts of the brain and spinal cord. Doxapram has a pressor action and may also increase catecholamine release.

Doxapram has limited uses in the treatment of acute respiratory failure (for example where this is superimposed on chronic obstructive pulmonary disease), and of postoperative respiratory depression (see Respiratory Failure under Oxygen, p.1691).

Doxapram hydrochloride may be infused at a rate of 1.5 to 4 mg/minute in the treatment of acute respiratory failure.

For postoperative respiratory depression it has been given in a dose of 0.5 to 1.5 mg/kg by intravenous injection over a period of at least 30 seconds. This dose may be repeated at hourly intervals. It may also be given by intravenous infusion, initially at a rate of 2 to 5 mg/minute and then reduced, according to response, to 1 to 3 mg/minute; a recommended maximum total dosage is 4 mg/kg.

Doxapram hydrochloride has also been used to treat respiratory and CNS depression following drug overdose but its use for this indication is no longer recommended.

Chronic obstructive pulmonary disease. Respiratory stimulants such as doxapram have a limited and short-term role in hypercapnic respiratory failure in patients with chronic obstructive pulmonary disease (p.1112). Benefit has been reported in such patients in whom doxapram was used as an alternative to intubation.[1,2] However, a systematic review suggested that despite short-term improvements in blood-gas exchange with doxapram, techniques such as non-invasive ventilation might be more effective.[3]

Neonatal apnoea. Doxapram is effective in neonatal apnoea (p.1118) and may be considered as an alternative, or in addition, to xanthines in infants with apnoea that does not respond to xanthine therapy alone. However, it is less convenient to use as it must be given by continuous intravenous infusion and blood pressure must be monitored (although it has also been suggested that the oral route may be used after the initial intravenous dose—see *BNFC* doses below). Additionally, some preparations may contain benzyl alcohol as a preservative making them unsuitable for use in neonates. It has been used in intravenous doses of 2.5 mg/kg per hour.[1-3] Adverse CNS effects have been reported.[3] Lower doses of 0.25 or 1.5 mg/kg per hour have been shown to be effective.[4,5] However, use of low doses of 500 micrograms/kg per hour in very low birth-weight premature infants produced higher than expected plasma-doxapram concentrations and a greater increase in systolic blood pressure compared with controls.[6] A systematic review[7] concluded that the place of doxapram in the management of neonatal apnoea had not yet been properly established.

Although unlicensed, the *BNFC* suggests giving neonates doxapram hydrochloride intravenously in an initial dose of 2.5 mg/kg over 5 to 10 minutes followed by 300 micrograms/kg per hour by continuous infusion, adjusted according to response, to a maximum dose of 1.5 mg/kg per hour; alternatively, 6 mg/kg may be given orally 4 times daily after the initial intravenous dose.

(fenfluramine)

Adverse Effects and Precautions

As for Dexamfetamine, p.2153, but fenfluramine usually depresses rather than stimulates the CNS. Fenfluramine has been associated with serious cardiovascular toxicity. Pulmonary hypertension led to certain precautions being imposed upon its use and subsequent reports of valvular heart defects led to its general withdrawal worldwide.

Effects on the cardiovascular system. The association of primary *pulmonary hypertension* with the use of anorectics including fenfluramine, dexfenfluramine, and phentermine is well recognised.[1-3] Both reversible and irreversible cases have been reported and in some cases it has proved fatal.[1,4-9] The condition appears to be linked to prolonged or repeated therapy.[1,10] In 1992 the UK CSM advised that treatment should not exceed 3 months[1] but later in 1997 it revised its recommendations for fenfluramine and dexfenfluramine allowing treatment for up to 12 months under certain conditions.[2] The CSM stated that treatment could be continued beyond 3 months only if there had been a satisfactory response (more than 10% weight loss) and that this loss was maintained. Patients should also be monitored for symptoms of pulmonary hypertension. For other anorectics such as phentermine the maximum duration of treatment remained 3 months.

However, shortly after this, a report was published[11] that outlined an association between the use of a fenfluramine-phentermine combination and the development of *valvular heart disease* in 24 patients. Initially, the response by the CSM was to advise against the use of combinations of anorectics[12] although subsequently fenfluramine, along with dexfenfluramine, was withdrawn from the world market after more cases became known.[13,14] By September 1997 the FDA in the USA[14] had received 144 reports of valvulopathy, including the original 24, associated with fenfluramine or dexfenfluramine, with or without phentermine; none were associated with phentermine treatment alone. As a consequence the US authorities made recommendations[14] for the screening of all patients who had previously received fenfluramine or dexfenfluramine in order to detect heart valve lesions and to provide optimal care. Further studies[15-20] have supported the association with valvular abnormalities, and suggested that prolonged exposure or exposure to high doses of dexfenfluramine or fenfluramine increased the risk; clinically important disease would probably not develop in most patients with only short-term exposure.[21]

In 2000, the European Commission called for the withdrawal of all anorectics from the European market. Those anorectics involved in the decision included clobenzorex, diethylpropion, fenproporex, mazindol, mefenorex, phendimetrazine, phenmetrazine, and phentermine. However in 2002, after an appeal by some manufacturers, the European Court ruled that the Commission did not have the authority to withdraw marketing authorisations. Subsequently, some anorectics have been allowed back onto the European market.

Effects on the liver. The UK MHRA had warned[1] that there had been cases of hepatotoxicity associated with adulteration of traditional Chinese slimming medicines with fenfluramine and/or nitrosofenfluramine. Nitrosofenfluramine was known to be hepatotoxic.

1. Medicines and Healthcare products Regulatory Agency (MHRA). Shubao slimming capsules containing fenfluramine and nitrosofenfluramine (issued 28th April, 2004). Available at: http://www.mhra.gov.uk/home/groups/es-herbal/documents/websiteresources/con009291.pdf (accessed 11/08/08)

Porphyria. Fenfluramine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Uses and Administration

Fenfluramine is an indirect-acting sympathomimetic related to amfetamine, but at standard doses it usually depresses rather than stimulates the CNS. It appears to stimulate the release of serotonin and selectively inhibits its reuptake resulting in increased CNS serotonin concentrations. It may also increase glucose utilisation and lower blood-glucose concentrations.

Fenfluramine was formerly given by mouth as the hydrochloride in the treatment of obesity (p.2149) but was generally withdrawn worldwide after reports of valvular heart defects.

Preparations

Chile: Megaval†.

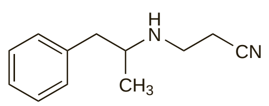
Fenproporex Hydrochloride *(rINNM)* ⊗

N-2-Cyanoethylamphetamine Hydrochloride; Fenproporex, Chlorhydrate de; Fenproporexi Hydrochloridum; Hidrocloruro de fenproporex. (±)-3-(α-Methylphenethylamino)propionitrile hydrochloride.

Фенпропорекса Гидрохлорид

$C_{12}H_{16}N_2,HCl = 224.7.$

CAS — 15686-61-0 (fenproporex); 18305-29-8 (fenproporex hydrochloride).



(fenproporex)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of fenproporex:
Pasexes.

Profile

Fenproporex is a central stimulant and indirect-acting sympathomimetic with actions similar to those of dexamfetamine (p.2153). After oral doses it is reported to be metabolised to amfetamine. Fenproporex has been given as the hydrochloride, the diphenylacetate, and as a resinate.

Fenproporex hydrochloride has been used as an anorectic in the treatment of obesity (p.2149) although the use of stimulants in this way is no longer recommended. Regulatory authorities in the EU have called for the withdrawal of all anorectics from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156).

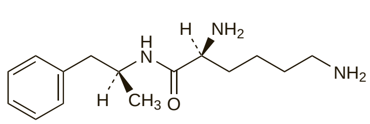
Lisdexamfetamine Dimesylate *(USAN)*; Lisdexamfétamine, Mésilate de; Lisdexamfetamini Mesilas; Mesilato de lisdexanfetamina; NRP-104. (2*S*)-2,6-Diamino-*N*-[(1*S*)-1-methyl-2-phenylethyl]hexanamide dimethanesulfonate.

Лисдексамфетамина Мезилат

$C_{15}H_{25}N_3O,(CH_4O_3S)_2 = 455.6.$

CAS — 608137-32-2 (lisdexamfetamine); 608137-33-3 (lisdexamfetamine mesilate).



(lisdexamfetamine)

Profile

Lisdexamfetamine is a prodrug of dexamfetamine (p.2153). It is used as a central stimulant in the treatment of attention deficit hyperactivity disorders (p.2148).

Lisdexamfetamine is given orally as the mesilate and doses are expressed in terms of this salt. For adults, and children between 6 and 12 years of age, the starting dose is 30 mg once daily in the morning, increased if necessary in increments of 10 or 20 mg daily at approximately weekly intervals, up to a total maximum dose of 70 mg daily. If therapy is continued for longer than 4 weeks, use of lisdexamfetamine should be periodically stopped to evaluate the necessity for continued administration.

Лобелина Сульфат

$(C_{22}H_{27}NO_2)_2,H_2SO_4 = 773.0.$

CAS — 134-64-5.

Adverse Effects

Adverse effects of lobelia and lobeline include nausea and vomiting, coughing, tremor, and dizziness. Symptoms of overdosage include profuse diaphoresis, paresis, tachycardia, hypothermia, hypotension, and coma; fatalities have occurred.

Uses and Administration

Lobelia is the dried aerial parts of *Lobelia inflata* (Lobeliaceae). Lobeline is the main alkaloidal constituent and has peripheral and central effects similar to those of nicotine (p.2352).

Lobelia has been used mainly in preparations aimed at relieving respiratory-tract disorders. Lobeline has been given by mouth as the hydrochloride or sulfate as a smoking deterrent (see Smoking Cessation, p.2354). Lobelia has been used similarly given either orally or incorporated into herbal cigarettes.

Smoking cessation. Reviews of smoking cessation therapy generally consider lobeline to have little benefit compared with placebo.[1-3]

Pharmacopoeias. In *US.*
USP 31 (Mazindol). A white to off-white crystalline powder, having not more than a faint odour. Insoluble in water; slightly soluble in chloroform and in methyl alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153.

Effects on the testes. Testicular pain developed in 8 men after taking mazindol.[1]

1. McEwen J, Meyboom RHB. Testicular pain caused by mazindol. *BMJ* 1983; **287:** 1763–4.

Interactions

As for Dexamfetamine Sulfate, p.2153.

Lithium. For a report of mazindol interacting with lithium to cause lithium toxicity, see Central Stimulants, p.405.

Pharmacokinetics

Mazindol is readily absorbed from the gastrointestinal tract and is excreted in the urine, partly unchanged and partly as metabolites.

Uses and Administration

Mazindol is a central stimulant with actions similar to those of dexamfetamine (p.2154), although structurally the two compounds are unrelated. It appears to inhibit reuptake of dopamine and noradrenaline. It has been used as an anorectic, given orally in the treatment of obesity (p.2149), although stimulants are no longer recommended for this indication. Regulatory authorities in the EU have called for the withdrawal of all anorectics from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156).

Mazindol has been investigated in the treatment of Duchenne muscular dystrophy.

Narcolepsy. Mazindol has been reported[1-4] to be beneficial in patients with narcolepsy and associated cataplexy (p.2148). A wide range of doses has been used: 3 to 8 mg daily in one study,[1] 1 mg weekly to 16 mg daily in another;[3] children have been given 1 to 2 mg daily.[4]

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Methamphetamine Hydrochloride). White, odourless or practically odourless, crystals or crystalline powder. Freely soluble in water, in alcohol, and in chloroform; very slightly soluble in ether. Its solutions in water have a pH of about 6. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153.

Metamfetamine is subject to extensive abuse.

Abuse. Pulmonary oedema,[1,2] cardiomyopathy,[2,3] and choreoathetosis and rhabdomyolysis[4] have occurred after smoking of metamfetamine crystals. It is also abused orally and intravenously, and has been associated with fatalities.[5] Dental problems such as rampant caries and tooth wear and fracture, colloquially termed "meth mouth", have been reported with long-term abuse.[6,7] A marked increase in prevalence of abuse in recent years, particularly in the USA, has led to increased research into the consequences of such abuse and methods for management.[8-11]

A study of former users suggests that metamfetamine abuse may cause long-term neuronal damage.[12]

Porphyria. Metamfetamine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

As for Dexamfetamine Sulfate, p.2153.

Pharmacokinetics

Like most amfetamines (see Dexamfetamine Sulfate, p.2154) metamfetamine is readily absorbed from the gastrointestinal tract and is distributed into most body tissues. It is partially metabolised in the liver and excreted in the urine.

◊ References.

Uses and Administration

Metamfetamine hydrochloride is a central stimulant and indirect-acting sympathomimetic with actions and uses similar to those of dexamfetamine (p.2154).

It has been given orally in the treatment of attention deficit hyperactivity disorder in children aged 6 years and over, although dexamfetamine and methylphenidate are the main stimulants used (p.2148). Initial doses are 5 mg once or twice daily, increased if necessary by 5 mg at weekly intervals to the optimum effective dose, usually 20 to 25 mg daily given in 2 divided doses.

Metamfetamine hydrochloride has also been used as an anorectic in the management of obesity (p.2149), although amfetamines are no longer recommended for this indication. A dose of 5 mg before each meal has been given orally. Treatment should be for no longer than a few weeks.

Metamfetamine hydrochloride has also been used parenterally as a pressor agent.

The laevorotatory form, levmetamfetamine (p.1564) is used as a nasal decongestant.

Preparations

USP 31: Methamphetamine Hydrochloride Tablets.

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of methylenedioxymethamfetamine:

007s; 69s; Adam; Adam MTX; Anastasia; Apples; Baby slits; Bacalao; Batmans; B-bombs; Bean; Beans; Bens; Benzedrine; Bermuda triangles; Bibs; Bicho; Bickies; Bikkies; Biphetamine; Biscuits; Blue kisses; Blue lips; Blue nile; Booty juice; Bomber; Brownies; Burgers; Candies; Candy; Care bears; Cat in the hats; Charity; Chocolate chips; Chrystal methadrine; Clarity; Cloud nine; Clovers; Cowies; Cristal; Crowns; Dancing Shoes; Dead road; Debs; Decadence; Deccadence; Dennis the Menaces; Dex; Dexedrine; Diamonds; Diamond Whites; Disco biscuit; Disco biscuits; Doctor; Dollars; Dolls; Dolphins; Doobies; Dove; Doves; Drivers; E; EA1475; Eazy; Eazy E; E-ball; Ebeneezer; E-bomb; E-bombs; Eccies; Ecstacy; Ecstasy; Ecstasy Tablets; Eddie Bo; Egg Rolls; Egyptians; Ekies; Elaine; Elephants; Em; Empathy; Essence; Eve; Ex; Exiticity; Extasy; Fantasia; Fantasy; Fastin; Fizzle; Flipper; Flipping; Four leaf clover; Fuckstasy; Gaggler; Gary Abletts; Garys; Go; Googs; Green triangles; Greenies; Grey biscuits; Gum; Gurners; Gurns; GWM; Hamburger; Hamburgers; Happy drug; Happy pill; Herbal bliss; Hug drug; Hug-Drug; Huggers; Hydro; Hype; Iboga; Ice; Igloo; Illies; Jack and jills; Jellies; Jerry Garcias; Jiggas; Jills; Junnov; Khat; Kiks; Kleenex; Letter biscuits; Light meth; Lollies; Long lasting lollies; Louie Vuitton; Love-Bug; Love doctor; Love Doves; Love drug; Love drug of the '80s; Love drug of the '90s; Love Medicine; Love pill; Love potion #9; Lovers' special; Lover's speed; Lucky charmz; "M"; M25; Madman; Malcolm; Mandy; MAO; MDM; MDMA; Mercedes; Meth amps; Methedrine; Mini beans; Mitsibushis; Mitsies; Mitsu's; Mitsubishi; Mitsubishis; M&M; M&Ms; Mellow drug of America; Molly; Mollys; Monoamine oxidase; Morning shot; New Yorkers; Nineteen; Number 9; Orange bandits; Orbit; Pasti; Pillage; Pills; Pilules d'Amour; Pingers; Pink Calis; Pink panthers; Pink studs; Playboy bunnies; Playboys; Pollutants; Pressies; Rave energy; Red devils; Rhubarb & Custards; Rib; Ritual spirit; Road Runner; Roca; Roker's Barnet; Rolexes; Roll; Rolling; Rolls Royce; Running; Scooby snacks; Scum; Shabu; Skates; Slammin'; Slamming; Slits; Slows; Smartees; Smurfs; Speed for lovers; Spivias; Stars; Strawberry shortcake; Supermans; Swadger; Swans; Sweeties; Sweets; Tablets; Tabs; Tacha; Tachas; Tangos; Tens; The love drug; Thizz; Tom and Jerries; Triple crowns; Triple rolexes; Triple stacks; Tutus; Tweety Birds; Ultimate Xphoria; U.S.P.; Vitamin E; Vitamin X; Vowels; Wafers; Wee Boys; West Coast turnarounds; Wheels; Whiffledust; White diamonds; White dove; White doves; Whiz bombs; Wigits; Wingers; X; X-ing; X-Men; X-Men 2; X-Pills; XTC; Yips; Yokes; Yuppie psychedelic.

Profile

Methylenedioxymethamfetamine is a phenylethylamine compound structurally related to amfetamine and mescaline and is an analogue of tenamfetamine (p.2164). It is subject to abuse. Its toxicity is similar to that of dexamfetamine (see Abuse, below and under Dexamfetamine, p.2153) and may be treated similarly.

Abuse. Methylenedioxymethamfetamine may be ingested as tablets, capsules, or inhaled as a powder. It is often mixed with a combination of adulterants such as other amfetamines, caffeine, ephedrine, and pseudoephedrine.[1]

The toxicity associated with abuse of methylenedioxymethamfetamine has been the subject of a number of discussions.[2-7] Acute effects can be severe and symptoms have included cardiac arrhythmias, fulminant hyperthermia, convulsions, disseminated intravascular coagulation, rhabdomyolysis, and acute renal failure; fatalities may occur. Repeated use may cause hepatic damage. Psychiatric effects reported include psychosis[8-10] and depression.[9-11] Damage to central serotonergic nerves has been implicated[8-12] and hence there is some concern regarding the long-term effects of methylenedioxymethamfetamine abuse.[13,14] Hyponatraemia, inappropriate antidiuretic hormone secretion, and cerebral oedema have also been reported;[15-20] the severity may be increased by excessive fluid intake that is frequently advocated to prevent dehydration and hyperthermia.[18-22] Urinary retention has also been reported.[23]

Concern has been expressed regarding abuse during *pregnancy*. Twelve congenital malformations, including 2 cases of congenital heart disease, have been noted among 78 liveborn infants whose mothers had taken methylenedioxymethamfetamine, often with other drugs of abuse, during their pregnancies.[24]

For reviews of the properties of other phenylethylamine compounds, see under Tenamfetamine, p.2164.

Interactions. A psychotic reaction has been reported in a patient who took methylenedioxymethamfetamine while receiving therapy with *citalopram*.[1]

A patient receiving *phenelzine* and lithium therapy experienced a serotonin syndrome (p.416) after ingesting methylenedioxymethamfetamine.[2] Symptoms included markedly increased muscle tension, tremulousness, abnormal posturing, limited pain response, tachycardia, hypertension, hyperthermia, increased white blood cell count, increased creatine phosphokinase concentration, respiratory acidosis, metabolic acidosis, delirium, and agitation. Within 15 minutes of methylenedioxymethamfetamine ingestion the patient was comatose; within 5 hours the patient was alert with a normal muscle tone. An interaction between phenelzine and methylenedioxymethamfetamine was suggested as the cause of the serotonin syndrome.

A fatal serotonergic reaction to methylenedioxymethamfetamine possibly due to an interaction with *ritonavir* has been described.[3] A prolonged and exaggerated effect from a small dose of methylenedioxymethamfetamine has been reported[4] in another patient also receiving ritonavir. Although this patient was also receiving saquinavir, the authors postulated that the mechanism may be ritonavir-induced inhibition of the cytochrome P450 isoenzyme CYP2D6.

Methylphenidate Hydrochloride *(BANM, rINNM)* ⊗

Hidrocloruro de metilfenidato; Methyl Phenidate Hydrochloride; Méthylphénidate, chlorhydrate de; Methylphenidati hydrochloridum; Metilfenidat Hidroklorür. Methyl α-phenyl-2-piperidylacetate hydrochloride.

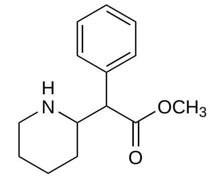
Метилфенидата Гидрохлорид

$C_{14}H_{19}NO_2$,HCl = 269.8.

CAS — 113-45-1 (methylphenidate); 298-59-9 (methylphenidate hydrochloride).

ATC — N06BA04.

ATC Vet — QN06BA04.



(methylphenidate)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of methylphenidate: Rities; Vitamin R; West coast.

Pharmacopoeias. In *Chin.*, *Swiss*, and *US.*

USP 31 (Methylphenidate Hydrochloride). A white, odourless, fine crystalline powder. Freely soluble in water and in methyl alcohol; soluble in alcohol; slightly soluble in acetone and in chloroform. Solutions are acid to litmus.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153. Hypersensitivity reactions have been reported. Skin reactions have included exfoliative dermatitis and erythema multiforme. Purpura, thrombocytopenia, and leucopenia have occurred. Blood counts should be monitored periodically during prolonged therapy.

Abuse. Reports of adverse effects after the abuse of methylphenidate by injecting solutions of crushed tablets.[1-3] Intravenous abuse of methylphenidate with pentazocine has also been reported.[4,5] In addition, there are also reports of intranasal methylphenidate abuse,[6-8] including fatalities.[8]

Breast feeding. No adverse effects were noted[1] in a 6-month-old breast-fed infant whose 26-year-old mother had been taking methylphenidate 40 mg twice daily for about 5 weeks. Despite the relatively high milk-to-plasma ratio of 2.7 the relative infant dose was low, at 0.2% of the maternal dose. Nonetheless the authors recommended caution when giving methylphenidate to breast-feeding mothers. Licensed product information also recommends that methylphenidate should be used with caution or avoided during breast feeding.

1. Hackett LP, *et al.* Methylphenidate and breast-feeding. *Ann Pharmacother* 2006; **40:** 1890–1.

Effects on the cardiovascular system. For mention of the adverse cardiovascular effects of stimulants, see under Dexamfetamine Sulfate, p.2153.

Effects on growth. Concern has been expressed about the effects of central stimulants such as methylphenidate on growth rate when used to treat hyperactivity in children. One study showed that methylphenidate produced decreases in weight percentiles after 1 year of therapy and progressive decrement in height percentiles that became significant after 2 years of use.[1] However, another suggested that moderate doses might have a lower risk for long-term height suppression than dexamfetamine.[2] There has also been a study which showed that, even when methylphenidate had an adverse effect on growth rate during active treatment, final height was not compromised and that a compensatory rebound of growth appeared to occur on stopping stimulant treatment.[3]

Effects on the liver. Hepatotoxicity with raised liver enzyme values in a 67-year-old woman was associated with the use of methylphenidate hydrochloride 30 mg daily by mouth.[1] Methylphenidate-induced hepatocellular injury was reported in a 19-year-old woman who developed jaundice, fever, and malaise after intravenous abuse of methylphenidate hydrochloride tablets.[2]

Tourette's syndrome. For a discussion on whether central stimulants provoke Tourette's syndrome, see Dexamfetamine Sulfate, p.2153.

Interactions

As for Dexamfetamine Sulfate, p.2153.

Anticoagulants. For the effect of methylphenidate on *ethyl biscoumacetate*, see Central Stimulants under the Interactions of Warfarin, p.1430.

Antidepressants. For the effect of methylphenidate on *tricyclic antidepressants*, see under Amitriptyline, p.379.

Antiepileptics. Methylphenidate blood concentrations decreased, and symptoms of attention deficit hyperactivity disorder worsened, in a 13-year-old girl after starting therapy with *carbamazepine*.[1]

For the effect of methylphenidate on antiepileptics, see under Phenytoin, p.500.

1. Schaller JL, *et al.* Carbamazepine and methylphenidate in ADHD. *J Am Acad Child Adolesc Psychiatry* 1999; **38:** 112–13.

Pharmacokinetics

Methylphenidate is readily absorbed from the gastrointestinal tract. The presence of food in the stomach accelerates the rate of absorption but not the total amount absorbed. Peak plasma concentrations are reached about 2 hours after oral doses; methylphenidate undergoes extensive first-pass metabolism. Protein binding is low. It is excreted as metabolites mainly in the urine with small amounts appearing in the faeces; less than 1% appears in the urine as unchanged methylphenidate. The major metabolite is ritalinic acid (2-phenyl-2-piperidyl acetic acid). The plasma elimination half-life is about 2 hours. Methylphenidate is distributed into breast milk.

Uses and Administration

Methylphenidate hydrochloride is a central stimulant and indirect-acting sympathomimetic with actions and uses similar to those of dexamfetamine (p.2154). It is used in the treatment of narcolepsy (p.2148) and as an adjunct to psychological, educational, and social measures in the treatment of hyperactivity disorders in children.

In the treatment of **narcolepsy** the usual oral dose is 20 to 30 mg daily in divided doses, normally 30 to 45 minutes before meals, but the effective dose may range from 10 to 60 mg daily.

In **hyperactivity disorders** in children aged 6 years and over, the usual initial dose is 5 mg once or twice daily by mouth, increased if necessary by 5 to 10 mg at weekly intervals to a maximum of 60 mg daily in divided doses. Methylphenidate may be given before breakfast and lunch. A later dose may be considered if the effect wears off in the evening causing rebound hyperactivity.

Methylphenidate hydrochloride is also available as modified-release preparations for the treatment of hyperactivity disorders. Some modified-release preparations also contain immediate-release methylphenidate within the formulation. Doses of modified-release preparations may vary according to the brand chosen. Recommended doses for one brand of modified-release tablets (*Concerta*: *Janssen-Cilag, UK*; *McNeil, USA*) are as follows:

- children and adolescents aged 6 to 17 years and not currently taking conventional methylphenidate should be started on 18 mg once daily in the morning
- the dose may then be increased at weekly intervals to a maximum of 54 mg once daily; the USA permits a maximum of 72 mg once daily in those aged 13 to 17 years
- the dose in patients already taking conventional methylphenidate should be based on their current dose although the initial dose should not exceed 54 mg once daily

Transdermal patches delivering amounts of methylphenidate ranging from 1.1 to 3.3 mg/hour are available for once-daily application in the treatment of hyperactivity disorders in children aged 6 to 12 years. Patients should be started on the lowest strength patch regardless of any previous methylphenidate use; thereafter, doses should be individually titrated for each patient according to response and increased at weekly intervals if necessary to a maximum of 3.3 mg/hour (at week 4). Patches should be applied to the hip area 2 hours before an effect is needed and removed after a maximum of 9 hours later.

Methylphenidate should be stopped if there is no improvement in symptoms after appropriate adjustments in dosage over one month. It also needs to be stopped from time to time in those who do respond, to assess the patient's condition. Treatment is not usually continued beyond puberty, however, in some patients drug therapy may be required into adulthood. In such cases doses are similar to those used in the treatment of narcolepsy.

A single isomer form of methylphenidate, dexmethylphenidate (p.2154) is also used for hyperactivity disorders.

Depression. Stimulants are no longer recommended as sole treatment for depression (p.373), although they have been tried in augmenting the effect of standard antidepressants such as the SSRIs[1] in patients with refractory depressive disorders.

1. Stoll AL, *et al.* Methylphenidate augmentation of serotonin selective reuptake inhibitors: a case series. *J Clin Psychiatry* 1996; **57:** 72–6.

Disturbed behaviour. Disturbed behaviour can have a number of causes and is usually treated with an antipsychotic or benzodiazepine (see p.954). A review[1] of the published clinical trials between 1966 and June 2004 found that although methylphenidate was likely to improve memory, attention, concentration, and mental processing in patients with traumatic brain injury, its effect on behaviour remains to be determined; the most commonly used dosage was 300 micrograms/kg twice daily.

1. Siddall OM. Use of methylphenidate in traumatic brain injury. *Ann Pharmacother* 2005; **39:** 1309–13.

Hyperactivity. Methylphenidate is one of the main drugs used in hyperactivity, including attention deficit hyperactivity disorder (ADHD) (p.2148).

Small studies have indicated that different aspects of attention deficit disorders in children might respond to different doses of methylphenidate.[1-4] In addition to the morning and noon doses commonly used in hyperactivity disorders, studies[5,6] have shown improved clinical outcome with little adverse effect on sleep patterns if a third late afternoon dose is given.

Modified-release preparations with a slow onset of action have been developed to overcome the short duration of action of methylphenidate although they may be less effective than immediate-release preparations. A study,[7] using a regimen to simulate the prolonged steady plasma concentration profile obtained with the slow-onset, modified-release preparations, has suggested that unlike twice-daily treatment acute tolerance might develop with the use of modified-release preparations. However, a newer modified-release preparation has been reported to be as effective as an immediate-release preparation in short-term studies.[8,9] Transdermal patches containing methylphenidate released over 9 hours are available in the USA.[10]

UK guidelines for the use of methylphenidate in children and adolescents with ADHD are available.[11]

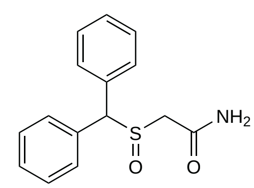
Modafinil *(BAN, USAN, rINN)* ⊗

CEP-1538; CRL-40476; Modafinilo; Modafinilum. 2-[(Diphenylmethyl)sulfinyl]acetamide.

Модафинил

$C_{15}H_{15}NO_2S$ = 273.4.
CAS — 68693-11-8.
ATC — N06BA07.
ATC Vet — QN06BA07.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Modafinil). A white or almost white, crystalline powder. It exhibits polymorphism. Very slightly soluble or practically insoluble in water; sparingly soluble in methyl alcohol; slightly soluble in alcohol.

USP 31 (Modafinil). A white, odourless, crystalline powder. Practically insoluble in water; slightly soluble in alcohol; sparingly soluble in methyl alcohol. Store at a temperature of 20° to 25°, excursions permitted between 15° and 30°.

Adverse Effects, Treatment, and Precautions

The most commonly reported adverse effect of modafinil, affecting about 21% of patients, is headache, which is usually mild or moderate, dose-dependent, and disappears within a few days. Other adverse effects may be a result of CNS stimulation and effects such as nervousness, insomnia, agitation, confusion, personality disorder, tremor, and anxiety have been noted. There may also be gastrointestinal disturbances, including nausea and abdominal pain, dry mouth, diarrhoea, dyspepsia, and constipation, dizziness, and anorexia. Cardiovascular effects such as hypertension, palpitations, and tachycardia have been reported.

Rare cases of serious or life-threatening rash, including Stevens-Johnson syndrome, erythema multiforme, and toxic epidermal necrolysis, have been reported (see also Effects on the Skin, below). Benign pruritic rashes have also occurred and since it is not possible to predict which skin rashes will become serious, modafinil should be stopped at the first sign of rash unless it is clearly not drug-related. Other hypersensitivity reactions such as angioedema have also been reported rarely.

Psychiatric symptoms including psychosis, depression, hallucinations, suicidal ideation, and mania have been reported. Abnormal liver function tests including dose-related increases in alkaline phosphatase, and dyskinesia have been observed.

Modafinil is contra-indicated in patients with uncontrolled, moderate to severe hypertension or cardiac arrhythmias. It is not recommended in patients with a history of left ventricular hypertrophy or ischaemic ECG changes, chest pain, or other signs of mitral valve prolapse. Modafinil should be given with caution to those with a history of psychosis, depression, or mania.

As with other stimulants, there is the possibility of dependence with long-term use. Modafinil has been misused as a so-called 'lifestyle drug' to promote alertness and wakefulness in otherwise healthy subjects.

Effects on the skin. The FDA[1] reported that it had received 6 cases of severe cutaneous adverse effects associated with modafinil from its initial marketing in December 1998 to January 2007; of these, 5 required hospitalisation. The cutaneous effects, which included erythema multiforme, Stevens-Johnson syndrome, toxic epidermal necrolysis, and drug rash with eosinophilia and systemic symptoms, were reported in adults and children although use in patients under 16 years of age is unlicensed. The median time to onset was 17.5 days with a range of 5 days to 5 weeks.

1. Modafinil (marketed as Provigil): serious skin reactions. *FDA Drug Safety Newsletter* 2007; **1:** 5–7. Available at: http://www.fda.gov/cder/dsn/2007_fall/2007_fall.pdf (accessed 20/05/08)

Interactions

Modafinil is partially metabolised by the cytochrome P450 isoenzymes. In addition, it also has enzyme-inducing and -inhibiting activity. Use with other drugs that inhibit, induce, or act as a substrate to these isoenzymes such as oral contraceptives and antiepileptics may result in changes in plasma concentration of modafinil and/or the other drug.

Pharmacokinetics

Modafinil is well absorbed from the gastrointestinal tract after oral doses with peak plasma concentrations occurring after 2 to 4 hours. Plasma protein binding is about 60%, mainly to albumin. Modafinil is metabolised in the liver, partially by the cytochrome P450 isoenzymes CYP3A4 and CYP3A5; two major metabolites have been identified: acid modafinil and modafinil sulfone, both of which are inactive. Excretion is mainly through the kidneys with less than 10% of the dose being eliminated unchanged. The elimination half-life after multiple doses is 15 hours.

Uses and Administration

Modafinil is a central stimulant chemically related to adrafinil (p.2149). It is used in the treatment of excessive daytime sleepiness associated with the narcoleptic syndrome (p.2148), obstructive sleep apnoea, and shift-work sleep disorder. In the treatment of the narcoleptic syndrome or obstructive sleep apnoea, modafinil is given orally in a dose of 200 to 400 mg daily, in two divided doses, in the morning and at midday, or as a single dose in the morning. For the treatment of shift-work sleep disorder, the daily dose is 200 mg taken as a single dose 1 hour before starting work. An initial dose of 100 mg daily should be used in the elderly and adjusted as necessary. For doses in hepatic and renal impairment, see below.

Modafinil is usually given as a racemic mixture but preparations containing only the *R*-isomer, armodafinil, are also available, see Armodafinil, p.2150.

Modafinil has also been investigated for the treatment of fatigue associated with multiple sclerosis and for the treatment of hyperactivity disorders.

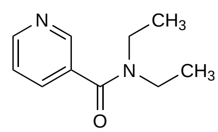
Никетамид

$C_{10}H_{14}N_2O$ = 178.2.
CAS — 59-26-7.
ATC — R07AB02.
ATC Vet — QR07AB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), and *Viet.*

Ph. Eur. 6.2 (Nikethamide). A colourless or slightly yellow oily liquid or crystalline mass. Miscible with water and with alcohol. A 25% solution in water has a pH of 6.0 to 7.8.

Profile

Nikethamide has actions similar to those of doxapram (p.2155). It was formerly used as a respiratory stimulant but has largely been abandoned because of toxicity. Nikethamide and its calcium thiocyanate salt have also been used in some countries as central stimulants and for hypotensive disorders.

Porphyria. Nikethamide has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Preparations

BP 2008: Nikethamide Injection.

Proprietary Preparations (details are given in Part 3)
Pol.: Cardiamidum.

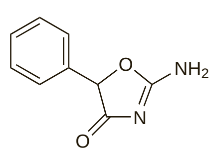
Multi-ingredient: ***Fr.:*** Coramine Glucose; ***Ger.:*** Zellaforte N Plus†; ***Pol.:*** Cardiamid-Coffein; Glucardiamid; ***Switz.:*** Gly-Coramin.

Pemoline *(BAN, USAN, rINN)* ⊗

LA-956; NSC-25159; Pemoliini; Pemolin; Pemolina; Pémoline; Pemolinum; Phenoxazole; Phenylisohydantoin; Phenylpseudohydantoin. 2-Imino-5-phenyl-4-oxazolidinone.

Пемолин

$C_9H_8N_2O_2$ = 176.2.
CAS — 2152-34-3 (pemoline); 68942-31-4 (pemoline hydrochloride); 18968-99-5 (magnesium pemoline).
ATC — N06BA05.
ATC Vet — QN06BA05.



Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153; however, the effects of over-stimulation and sympathomimetic activity are considered to be less with pemoline.

Reports of liver toxicity in patients taking pemoline (see Effects on the Liver, below) have led to its withdrawal in many countries including the UK and USA. Where available, it is contra-indicated in patients with liver disorders and there are stringent precautions to be observed with its use. Treatment should be initiated only in patients with normal baseline liver function tests and liver function should be monitored every 2 weeks. Pemoline should be stopped if serum alanine aminotransferase is increased to a clinically significant level or there is any increase greater than or equal to twice the upper limit of normal, or if any clinical signs or symptoms suggestive of liver failure develop. Pemoline should also be withdrawn from patients who have failed to show a substantial clinical response within 3 weeks of completing dose titration. There have also been rare or isolated reports of chorea, tics, mania, and neutropenia.

Abuse. Paranoid psychosis was observed in a 38-year-old man taking pemoline 75 to 225 mg daily.[1] His compulsive use of the drug, development of tolerance, depressive withdrawal syndrome, and inability to abstain indicated dependence and it was evident that the patient was addicted to pemoline.

Choreoathetosis and rhabdomyolysis developed in a patient following a marked increase in intake of pemoline.[2] Abnormal movements responded to diazepam.

2. Briscoe JG, *et al.* Pemoline-induced choreoathetosis and rhabdomyolysis. *Med Toxicol* 1988; **3:** 72–6.

Effects on growth. Results of a study in 24 hyperkinetic children suggested that growth suppression was a potential adverse effect of prolonged treatment with clinically effective doses of pemoline and that this effect might be dose-related.[1]

See also under Dexamfetamine Sulfate, p.2153.

1. Dickinson LC, *et al.* Impaired growth in hyperkinetic children receiving pemoline. *J Pediatr* 1979; **94:** 538–41.

Effects on the liver. Pemoline has been associated with hepatotoxicity.

Elevated concentrations of serum aspartate aminotransferase and serum alanine aminotransferase have been noted in 2% of children taking pemoline for hyperactivity; the effect was stated to be transient and reversible.[1]

However, more serious reactions have also occurred. Acute hepatitis[2] was associated with pemoline in a 10-year-old boy and the drug was believed to be the cause of fatal fulminant liver failure[3] in a 14-year-old boy and in 2 previously published cases. The UK CSM[4] subsequently became aware of 33 reports of serious hepatic reactions in the USA, including a total of 6 fatalities and the need for liver transplantation in 2 cases; this prompted the withdrawal of pemoline for the treatment of hyperactivity in the UK. Following further reports of liver failure resulting in transplantation or death, the FDA[5] similarly withdrew pemoline in the USA.

4. CSM/MCA. Volital (pemoline) has been withdrawn. *Current Problems* 1997; **23:** 10. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2023240&RevisionSelectionMethod=LatestReleased (accessed 23/05/06)
5. FDA. Alert for healthcare professionals: pemoline tablets and chewable tablets (marketed as Cylert) (issued 24/10/05). Available at: http://www.fda.gov/cder/drug/InfoSheets/HCP/pemolineHCP.pdf (accessed 24/04/06)

Effects on the prostate. Experience in one patient suggested that pemoline might adversely affect the prostate gland or interfere with tests for prostatic acid phosphatase used in the diagnosis of prostatic carcinoma.[1]

1. Lindau W, de Girolami E. Pemoline and the prostate. *Lancet* 1986; **i:** 738.

Interactions

Hypertensive crisis may possibly occur if pemoline is given with MAOIs. Reduced seizure threshold has been reported in epileptic patients taking pemoline and antiepileptics.

Pharmacokinetics

Pemoline is readily absorbed from the gastrointestinal tract. About 50% is bound to plasma proteins. It is metabolised in the liver and excreted in the urine as unchanged pemoline and metabolites.

◊ References.

1. Vermeulen NPE, *et al.* Pharmacokinetics of pemoline in plasma, saliva and urine following oral administration. *Br J Clin Pharmacol* 1979; **8:** 459–63.
2. Sallee F, *et al.* Oral pemoline kinetics in hyperactive children. *Clin Pharmacol Ther* 1985; **37:** 606–9.
3. Collier CP, *et al.* Pemoline pharmacokinetics and long term therapy in children with attention deficit disorder and hyperactivity. *Clin Pharmacokinet* 1985; **10:** 269–78.

Uses and Administration

Pemoline is a central stimulant with actions similar to those of dexamfetamine (p.2154).

It has been used in the management of hyperactivity disorders in children (p.2148). In many countries pemoline was withdrawn from use after reports of serious hepatotoxicity.

Pemoline has been included in preparations also containing yohimbine hydrochloride and methyltestosterone that are claimed to combat failure of sexual desire and functioning in males and females; such preparations are not recommended.

Pemoline has been given with magnesium hydroxide (magnesium pemoline) in an attempt to increase its absorption.

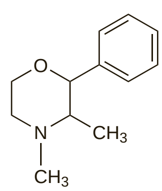
Phendimetrazine Tartrate *(BANM, rINNM)* ⊗

Phendimetrazine Acid Tartrate; Phendimetrazine Bitartrate; Phendimétrazine, Tartrate de; Phendimetrazini Tartras; Tartrato de fendimetrazina. (+)-3,4-Dimethyl-2-phenylmorpholine hydrogen tartrate.

Фендиметразина Тартрат

$C_{12}H_{17}NO,C_4H_6O_6$ = 341.4.
CAS — 634-03-7 (phendimetrazine); 7635-51-0 (phendimetrazine hydrochloride); 50-58-8 (phendimetrazine tartrate).



(phendimetrazine)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of phendimetrazine: Fringas; Prelo.

Pharmacopoeias. In *US.*

USP 31 (Phendimetrazine Tartrate). A white odourless crystalline powder. Freely soluble in water; sparingly soluble in warm alcohol; insoluble in acetone, in chloroform, in ether, and in benzene. pH of a 2.5% solution in water is between 3.0 and 4.0. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153.

Pulmonary hypertension and valvular heart defects have been reported in patients receiving phendimetrazine with other anorectics; these adverse effects, with the relevant precautions to be observed, are discussed under Fenfluramine Hydrochloride, p.2156. Phendimetrazine should not be used with other anorectics nor within a year of their use.

Interactions

Phendimetrazine is an indirect-acting sympathomimetic and may interact with other drugs similarly to dexamfetamine (p.2153).

Pharmacokinetics

Phendimetrazine tartrate is readily absorbed from the gastrointestinal tract and is excreted in the urine, partly unchanged and partly as phenmetrazine and other metabolites.

Uses and Administration

Phendimetrazine tartrate is a central stimulant and indirect-acting sympathomimetic with actions similar to those of dexamfetamine (p.2154). It has been used as an anorectic in the short-term treatment of obesity (p.2149), although stimulants are no longer recommended for this indication. The usual oral dose is 35 mg two or three times daily before food. An alternative dose is 105 mg once daily in the morning as a modified-release preparation.

Phendimetrazine hydrochloride has been used similarly.

Regulatory authorities in the EU have called for the withdrawal of all anorectics from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156).

Preparations

USP 31: Phendimetrazine Tartrate Capsules; Phendimetrazine Tartrate Tablets.

(phenmetrazine)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of Phenmetrazine: Preludes.

Pharmacopoeias. In *US.*

USP 31 (Phenmetrazine Hydrochloride). A white to off-white crystalline powder. Soluble 1 in 0.4 of water, 1 in 2 of alcohol, and 1 in 2 of chloroform. pH of a 2.5% solution in water is between 4.5 and 5.5. Store in airtight containers.

Profile

Phenmetrazine hydrochloride is a central stimulant and indirect-acting sympathomimetic with actions similar to those of dexamfetamine (p.2153). It has been used as an anorectic in the treatment of obesity. Regulatory authorities in the EU have called for the withdrawal of all anorectics from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156). It has been subject to extensive abuse.

Abuse. For reference to a serious syndrome involving rhabdomyolysis after intravenous abuse of phenmetrazine, see Dexamfetamine Sulfate, p.2153.

Preparations

USP 31: Phenmetrazine Hydrochloride Tablets.

ATC Vet — QA08AA01.

Pharmacopoeias. In *US.*

USP 31 (Phentermine Hydrochloride). A white, odourless, hygroscopic, crystalline powder. Soluble in water and in the lower alcohols; slightly soluble in chloroform; insoluble in ether. pH of a 2% solution in water is between 5.0 and 6.0. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Dexamfetamine Sulfate, p.2153. Urticaria may occur with use of phentermine.

Pulmonary hypertension has been reported in patients receiving phentermine and valvular heart defects in patients receiving the drug with other anorectics such as fenfluramine or dexfenfluramine; these adverse effects, with the relevant precautions to be observed, are discussed under Fenfluramine Hydrochloride (see Effects on the Cardiovascular System, p.2156).

Interactions

Phentermine is an indirect-acting sympathomimetic and may interact with other drugs, similarly to dexamfetamine (p.2153).

Pharmacokinetics

Phentermine is readily absorbed from the gastrointestinal tract and is excreted in the urine, partly unchanged and partly as metabolites.

Uses and Administration

Phentermine is a central stimulant and indirect-acting sympathomimetic with actions similar to those of dexamfetamine (p.2154). It has been given orally as the base or hydrochloride as an anorectic in the short-term treatment of moderate to severe obesity (p.2149), although stimulants are no longer recommended for this indication.

The usual dose of phentermine is 15 to 30 mg once daily before breakfast given as an ion-exchange resin complex that provides modified release. A suggested dose for phentermine hydrochloride is 8 mg three times daily before meals or 15 to 37.5 mg once daily in the morning. It should not be given for longer than a few weeks.

Regulatory authorities in the EU have called for the withdrawal of phentermine from the market (see under Effects on the Cardiovascular System in Fenfluramine, p.2156).

Preparations

USP 31: Phentermine Hydrochloride Capsules; Phentermine Hydrochloride Tablets.

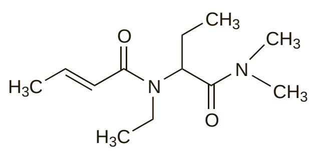
Crotetamida; Crotétamide; Crotetamidum; Crotethamide. 2-(*N*-Ethylcrotonamido)-*N,N*-dimethylbutyramide.

Кротетамид

$C_{12}H_{22}N_2O_2$ = 226.3.

CAS — 6168-76-9.



Profile

Prethcamide, a mixture of equal parts by weight of cropropamide and crotetamide, has actions similar to those of doxapram (p.2155) and has been used as a respiratory stimulant. Oral doses of 100 mg have been given three times daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Micoren.

Prolintane Hydrochloride (BANM, USAN, rINNM) ⊗

Hidrocloruro de prolintano; Prolintane, Chlorhydrate de; Prolintani Hydrochloridum; SP-732. 1-(α-Propylphenethyl)pyrrolidine hydrochloride.

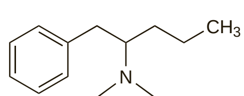
Пролинтана Гидрохлорид

$C_{15}H_{23}N,HCl$ = 253.8.

CAS — 493-92-5 (prolintane); 1211-28-5 (prolintane hydrochloride).

ATC — N06BX14.

ATC Vet — QN06BX14.



(prolintane)

Profile

Prolintane hydrochloride is a mild central stimulant and has properties similar to those of dexamfetamine (p.2153). It has been available mainly in tonic preparations that also contained vitamin supplements. It has also been used in narcolepsy.

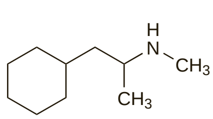
Propylhexedrine (BAN, rINN) ⊗

Hexahydrodesoxyephedrine; Propilhexedrina; Propylhexed; Propylhexédrine; Propylhexedrinum. 2-Cyclohexyl-1-methylethyl-(methyl)amine; (±)-*N*-α-Dimethylcyclo-hexaneethylamine.

Пропилгекседрин

$C_{10}H_{21}N$ = 155.3.

CAS — 101-40-6; 3595-11-7 ((±)-propylhexedrine).



Pharmacopoeias. In *US.*

USP 31 (Propylhexedrine). A clear colourless liquid having a characteristic amine-like odour. It slowly volatilises at room temperature and absorbs carbon dioxide from the air. Very slightly soluble in water; soluble 1 in 0.4 of alcohol, 1 in 0.2 of chloroform, and 1 in 0.1 of ether. Its solutions are alkaline to litmus. Store in airtight containers.

Propylhexedrine Hydrochloride (BANM, rINNM) ⊗

Hidrocloruro de propilhexedrina; Propylhexédrine, Chlorhydrate de; Propylhexedrini Hydrochloridum.

Пропилгекседрина Гидрохлорид

$C_{10}H_{21}N,HCl$ = 191.7.

CAS — 1007-33-6; 6192-95-6 ((±)-propylhexedrine hydrochloride).

Adverse Effects, Treatment and Precautions

As for Dexamfetamine Sulfate, p.2153.

Nasal inhalation may cause transient burning, stinging, mucosal dryness, and sneezing. Prolonged use can cause rebound congestion, redness, swelling, and rhinitis. Systemic effects such as headache, hypertension, nervousness, and increased heart rate may occur.

Propylhexedrine is subject to abuse by mouth or intravenously; fatalities due to myocardial infarction, heart failure, or pulmonary hypertension have been reported. Psychosis may occur.

Abuse. References.

2. Anderson RJ, *et al.* Intravenous propylhexedrine (Benzedrex) abuse and sudden death. *Am J Med* 1979; **67:** 15–20.
3. Cameron J, *et al.* Possible association of pulmonary hypertension with an anorectic drug. *Med J Aust* 1984; **140:** 595–7.

Uses and Administration

Propylhexedrine is a central stimulant and indirect-acting sympathomimetic with actions similar to those of dexamfetamine (p.2154). It has been used as an inhalant for nasal decongestion (p.1548).

Propylhexedrine hydrochloride has been given orally as an anorectic in the treatment of obesity (p.2149) but stimulants are no longer recommended for this indication. The (–)-isomer, levopropylhexedrine hydrochloride, has been used similarly.

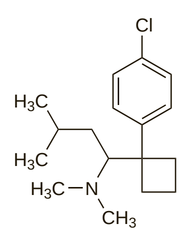
ATC — A08AA10.

ATC Vet — QA08AA10.



(sibutramine)

Adverse Effects

Commonly reported adverse effects of sibutramine are dry mouth, headache, insomnia, and constipation. Diarrhoea, back pain, increased appetite, dizziness, flu-like symptoms, and rhinitis have also occurred. Less frequently reported adverse effects include dyspepsia, nausea, dysmenorrhoea, increased sweating and thirst, oedema, paraesthesia, skin rashes, taste perversion, palpitations, vasodilatation, anxiety, nervousness, drowsiness, and depression. Abnormal bleeding including Henoch-Schönlein purpura and thrombocytopenia, acute interstitial nephritis, glomerulonephritis, emotional lability, seizures, and blurred vision have been reported rarely. Clinically significant increases in heart rate and blood pressure may occur. Sibutramine may decrease salivary flow and therefore increase the risk of dental caries, periodontal disease, or other oral disorders. It may also produce mydriasis. Reversible increases in liver enzymes have been reported.

Precautions

Sibutramine should be avoided in patients with a history of eating disorders such as anorexia nervosa and bulimia nervosa. It is also contra-indicated in patients with uncontrolled or poorly controlled hypertension and should be used with caution in patients with a history of, or with, well-controlled hypertension. Blood pressure and heart rate should be monitored (see below for details). In the event of sustained elevations, the dose should be reduced or treatment discontinued.

Sibutramine should not be used in patients with a history of cerebrovascular disease or cardiovascular disorders such as cardiac arrhythmias, heart failure, peripheral arterial occlusive disease, and coronary artery disease. It should be avoided in patients with severe hepatic or renal impairment; caution has been advised when using sibutramine in those with mild to moderate renal impairment. Sibutramine should also not be used in patients with bipolar disorder, Tourette's syndrome, hyperthyroidism, phaeochromocytoma, benign prostatic hyperplasia, or a history of drug or alcohol abuse. It should be used with caution, if at all, in patients with glaucoma. Sibutramine should also be used with caution in patients with a history of depression, seizures or gallstones (which may be precipitated or exacerbated by weight loss), or a family history of motor or verbal tics.

Any centrally-acting drug such as sibutramine may impair the ability to perform tasks requiring judgement or motor or cognitive skills; if affected, patients should not drive or operate machinery.

Bleeding disorders. Because other drugs that inhibit reuptake of serotonin have occasionally been associated with bleeding disorders and other effects on the blood (see under Fluoxetine, p.392) UK licensed product information for sibutramine recommends that it should be used with caution in patients predisposed to bleeding disorders and in those taking other drugs known to affect haemostasis or platelet function.

Cardiovascular monitoring. Sibutramine may cause clinically significant increases in blood pressure and heart rate and monitoring is recommended in the product information for all patients during treatment. In the first 3 months, blood pressure and heart rate should be checked every 2 weeks; this may be reduced to every month for the next 3 months, and at least every 3 months thereafter. Treatment should be stopped if resting heart rate increases by 10 beats/minute or more, or blood pressure by 10 mmHg or more, at two consecutive visits. In patients with previously well-controlled hypertension, treatment should be stopped if their blood pressure exceeds 145/90 mmHg at two consecutive visits.

Interactions

Sibutramine should not be given with, or within at least 2 weeks of stopping an MAOI; at least 2 weeks should elapse between discontinuation of sibutramine and starting therapy with an MAOI. There is a risk of the serotonin syndrome (p.416) developing if sibutramine is used with other serotonergic drugs such as SSRIs, sumatriptan, lithium, pethidine, fentanyl, dextromethorphan, and pentazocine. Caution is advised when sibutramine is given with other drugs that may increase heart rate or blood pressure such as ephedrine, phenylpropanolamine, and pseudoephedrine. It should not be used with other centrally acting anorectics. Alcohol should be avoided.

Inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole and erythromycin, may increase plasma concentrations of sibutramine. Conversely, inducers of this isoenzyme, such as rifampicin, phenytoin, carbamazepine, and phenobarbital, may reduce plasma concentrations of sibutramine.

Antibacterials. A study in 12 obese subjects indicated that addition of *erythromycin* to sibutramine therapy resulted in little significant alteration in sibutramine pharmacokinetics beyond a modest increase in maximum plasma concentration of one of the active metabolites.[1] A small increase in the QT interval was not considered clinically meaningful.

1. Hinson JL, *et al.* Steady-state interaction study of sibutramine (Meridia™) and erythromycin in uncomplicated obese subjects. *Pharm Res* 1996; **13** (suppl): S116.

Antifungals. A study in 12 obese subjects given sibutramine found that *ketoconazole* moderately increased steady-state plasma concentrations of sibutramine and its active metabolites.[1] There was a significant increase in heart rate but no clinically relevant change in the QT interval.

1. Hinson JL, *et al.* Steady-state interaction study of sibutramine (Meridia™) and ketoconazole in uncomplicated obese subjects. *Pharm Res* 1996; **13** (suppl): S116.

Pharmacokinetics

Sibutramine is well absorbed from the gastrointestinal tract; peak plasma concentrations appear after 1.2 hours (parent drug) and 3 to 4 hours (metabolites). It undergoes extensive first-pass hepatic metabolism, mediated mainly by the cytochrome P450 isoenzyme CYP3A4. Demethylation produces mono- and di-desmethylsibutramine (both of which are pharmacologically active) and is followed by hydroxylation and conjugation to inactive metabolites. Protein binding is 97%. Plasma-elimination half-life is 14 to 16 hours. Elimination is mainly in the urine as inactive metabolites, and partly in the faeces.

◊ References.

1. Hind ID, *et al.* Sibutramine pharmacokinetics in young and elderly healthy subjects. *Eur J Clin Pharmacol* 1999; **54:** 847–9.

Uses and Administration

Sibutramine, which is structurally related to amfetamine (p.2150), is a serotonin and noradrenaline reuptake inhibitor; it also inhibits dopamine reuptake but to a lesser extent. Sibutramine is used in the management of obesity (p.2149). It may also be used in overweight patients (body-mass index of 27 kg/m^2 or more) if other risk factors such as hypertension (but see Precautions, above), diabetes mellitus, or hyperlipidaemias are present.

Sibutramine hydrochloride is given orally in an initial daily dose of 10 mg, usually taken in the morning. Patients who cannot tolerate 10 mg daily may benefit from a dose of 5 mg daily. Treatment with sibutramine should be re-evaluated if weight loss is less than 2 kg in the first 4 weeks of therapy. At this stage, the dose may be increased to a maximum of 15 mg daily, taking into consideration effects on heart rate and blood pressure, or treatment may need to be stopped. It should be re-assessed again after a further 4 weeks at maximum dose, and stopped if weight loss is less than 2 kg. Treatment should also be stopped if:

- weight loss stabilises at less than 5% of the initial body-weight
- weight loss after 3 months is less than 5% of the initial body-weight
- weight gain of 3 kg or more occurs after previous weight loss

Treatment should not be given for longer than 1 year.

In patients with other risk factors (see Precautions, above), it is recommended that sibutramine is continued only if weight loss is associated with other clinical benefits.

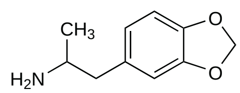
Tenamfetamine *(rINN)* ⊗

MDA; Methylenedioxyamphetamine; 3,4-Methylenedioxyamphetamine; SKF-5; Ténamfétamine; Tenamfetaminum; Tenanfetamina. α-Methyl-3,4-methylenedioxyphenethylamine.
Тенамфетамин
$C_{10}H_{13}NO_2$ = 179.2.
CAS — 4764-17-4; 51497-09-7.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of tenamfetamine:
EA1299; Eve; Love Drug; Love Pill; MDMA; Mellow Drug of America.

Profile

Tenamfetamine is a phenylethylamine compound, structurally related to amfetamine and mescaline, with hallucinogenic effects. It has been subject to abuse and dependence. A number of similar compounds are known because of their abuse and include:

- brolamfetamine (4-bromo-2,5-dimethoxyamfetamine; bromo-DMA; bromo-DOM; 2,5-dimethoxy-4-bromoamfetamine; DOB)
- 4-bromo-2,5-methoxyphenylethylamine (afterburner; 2-CB; MFT)
- 2,5-dimethoxy-4-metamfetamine (DOM; methyl-2,5-dimethoxyamfetamine; Serenity, Tranquillity and Peace; STP)
- *N*-ethyltenamfetamine (Eve; MDE; MDEA; 3,4-methylenedioxyethamfetamine)
- *N*-hydroxytenamfetamine (*N*-hydroxy MDA; 3,4-methylenedioxy-*N*-hydroxyamfetamine)
- methoxyamfetamine (Death; 4-methoxyamfetamine; *p*-methoxyamfetamine; PMA)
- methylenedioxymethamfetamine (Ecstasy) (see p.2159)
- 2,4,5-trimethoxyamfetamine (TMA; TMA-2)

In large doses the adverse effects of tenamfetamine and related compounds are similar to those of dexamfetamine and may be treated similarly (see p.2153). Fatalities have been associated with the abuse of some of these compounds.

Thyroid and Antithyroid Drugs

The principal role of the thyroid gland is to regulate tissue metabolism through production of the **thyroid hormones** 3,5,3′,5′-tetra-iodo-L-thyronine (levothyroxine, L-thyroxine, thyroxine; T_4) and, in smaller amounts, 3,5,3′-tri-iodo-L-thyronine (liothyronine, L-tri-iodothyronine, tri-iodothyronine; T_3). In infants and children thyroid hormones are also necessary for the development of the CNS and for normal growth and bone maturation.

The production of thyroid hormones is dependent on an adequate supply of dietary iodine. Iodine is reduced to iodide in the gastrointestinal tract and is then readily absorbed and actively transported into the thyroid, where it undergoes oxidation, catalysed by thyroid peroxidase. Oxidised iodide is incorporated into the glycoprotein thyroglobulin to form L-mono-iodotyrosine (MIT) and L-di-iodotyrosine (DIT), which are inactive. A coupling reaction, also catalysed by thyroid peroxidase, yields the hormonally active iodothyronines, T_3 and T_4, joined by a peptide bond to thyroglobulin for storage in the follicular colloid. The release of proteolytic enzymes from lysosomes degrades the thyroglobulin into its constituent amino acids to release T_3 and T_4 into the circulation; iodide resulting from this reaction is recycled.

Whereas T_4 enters the circulation only by direct glandular secretion, most of the T_3 in the body is produced by the mono-deiodination of T_4 in the peripheral tissues. About 40% of secreted T_4 is converted to T_3 and about 40% is converted to inactive reverse tri-iodothyronine (reverse T_3; rT_3). The metabolic activity of T_3 is about 3 to 5 times that of T_4 and it has been suggested that T_3 is the active thyroid hormone with T_4 acting primarily as a prohormone.

Thyroid hormones are extensively protein bound in plasma, principally to thyroxine-binding globulin (TBG) but also to a lesser extent to thyroxine-binding pre-albumin (TBPA) or to albumin.

Thyroid hormone homoeostasis is maintained by autoregulatory mechanisms within the gland, and by the hypothalamic-pituitary-thyroid axis. In response to falling plasma concentrations of unbound T_3 and T_4, the hypothalamus secretes thyrotropin releasing hormone (protirelin; TRH—see p.2175), which in turn stimulates the synthesis and release of thyroid stimulating hormone (thyrotropin; TSH—see p.2177) by the anterior pituitary gland. TSH acts on its receptor in the thyroid gland to increase production of T_3 and T_4, and also to release hormone stored in the gland. As thyroid hormone concentrations in blood increase, the secretion of TSH, and possibly TRH, will be suppressed. The term euthyroidism is used when the thyroid gland is functioning normally and there are normal amounts of thyroid hormone in the blood.

Goitre and thyroid nodules

Goitre is the enlargement of the thyroid gland. The swelling may be focal (caused by a solitary thyroid nodule, adenoma, or cyst) or generalised, in which case it is usually diffuse at first, later becoming multinodular. Non-toxic goitres may be associated with hypothyroidism (see below) or euthyroidism. The management of toxic goitres is discussed under Hyperthyroidism, below.

Non-toxic goitres may be associated with intrinsic defects in hormone production, or extrinsic factors such as dietary-iodine deficiency in endemic goitre (see Iodine Deficiency Disorders, p.2170). Decreased secretion of thyroid hormone results in an excessive output of thyroid-stimulating hormone (TSH) from the pituitary. This stimulates thyroid-hormone production but also leads to hypertrophy and hyperplasia of the thyroid gland. If the response to TSH overcomes the deficiency in thyroid-hormone synthesis then the patient is goitrous and euthyroid but if the compensatory response to TSH is inadequate then goitre with hypothyroidism is observed. Other factors can also contribute, such as autoantibody-stimulated thyroid growth, and thyroid autonomy, in which the gland functions independently of TSH control.

The general aims in the management of thyroid masses are:

- the detection and treatment of malignancy
- the reduction of goitre or prevention of further enlargement, and the relief of obstructive symptoms
- the maintenance of a euthyroid state

A review[1] of clinical investigations for thyroid nodules found fine-needle aspiration biopsy to provide the most accurate information; US guidelines consider it an integral part of thyroid nodule evaluation.[2] Ultrasonography can also estimate the nodule size and goitre volume. It can differentiate between simple cysts, solid nodules, or mixed cystic and solid nodules, although it cannot reliably distinguish between benign and cancerous lesions. For the latter, fludeoxyglucose (^{18}F) may be used to evaluate glucose metabolism by positron-emission tomography, although this method is not as economical as fine-needle aspiration biopsy. Radionuclide scanning with iodine isotopes may be used to identify whether a nodule is functioning (these are nearly always benign). Nodule size cannot be measured accurately by radionuclide scanning.

In established **malignancy**, surgery, followed by levothyroxine replacement therapy, is the usual course (for further discussion of the treatment of thyroid cancer, see p.674).

The treatment of non-toxic **benign solitary nodules** is a matter of dispute. Many prefer simply to monitor patients with benign solitary nodules. Alternatively suppressive therapy with doses of levothyroxine (or, less often, liothyronine) sufficient to suppress TSH production and reduce the size of the nodule has been widely practised, but results conflict as to whether such therapy is effective.[3] A meta-analysis of 7 studies[4] suggested that although levothyroxine treatment produced some benefit, the number of patients who responded was quite small. Another meta-analysis[5] (which included 5 of the same studies and a later one) found an overall non-significant treatment response; the authors concluded that routine suppressive levothyroxine for single benign thyroid nodules could not be recommended, but that a subgroup of patients with small, solid nodules might benefit from therapy. US guidelines[2] consider that it should generally be avoided, but may be considered in patients from areas of iodine deficiency, young patients with small nodules, and in nodular goitres with no evidence of autonomous thyroid hormone production. There has been some concern about the possible risk of osteoporosis[6] with levothyroxine (see Effects on the Bones, p.2171). An alternative to levothyroxine is treatment with potassium iodide, although it is somewhat less effective,[7] and has adverse effects of its own.[6] Sclerotherapy by alcohol injection can produce substantial reductions,[2,8,9] but is painful and requires considerable skill.[1,2]

Levothyroxine suppression therapy is effective in patients with **diffuse** non-toxic goitre, and may be of benefit in some patients with **multinodular** disease. However, many patients with large multinodular goitres have autonomous thyroid hormone production, and in such patients levothyroxine is of no benefit and may cause overt hyperthyroidism. Radio-iodine (^{131}I) treatment appears to be more effective and better tolerated than levothyroxine,[10] and has been a useful alternative to surgery in selected cases of multinodular non-toxic goitre.[2,11]

Hyperthyroidism

Hyperthyroidism is overactivity of the thyroid gland, with consequent excess secretion of hormones. The terms thyrotoxicosis and hyperthyroidism are used interchangeably, although some apply ‘thyrotoxicosis’ to the *effects* of excessive thyroid hormone. The most common causes of hyperthyroidism are Graves’ disease (diffuse toxic goitre) and hyperactivity arising from single or multiple thyroid nodules (toxic nodular goitre). Graves’ disease (or Basedow’s disease) is an auto-immune condition in which thyroid-stimulating antibodies bind to thyroid-stimulating hormone (TSH) receptors, mimicking the effect of prolonged TSH stimulation. Graves’ disease, which is more prevalent in females, frequently occurs with other diseases such as Addison’s disease, type 1 diabetes mellitus, and pernicious anaemia, and there may be a genetic predisposition. Iodine and its salts, or iodine-containing drugs such as amiodarone, can also be a cause of both hyperthyroidism and hypothyroidism.

The major clinical manifestations associated with clinical hyperthyroidism include goitre, nervousness, agitation, tremor, tachycardia or atrial fibrillation, weight loss (often despite increased appetite), emotional lability, muscle weakness, fatigue, heat intolerance and excessive perspiration, and increased bowel frequency. Exaggerated growth may occur in children. Females may occasionally experience amenorrhoea or oligomenorrhoea and males may develop gynaecomastia. Occasionally there is subcutaneous deposition of mucopolysaccharides around the shins, causing a non-pitting oedema (pretibial myxoedema).

A **diagnosis** of primary hyperthyroidism may be confirmed by demonstration of a low TSH value and a high concentration of free T_4 or T_3 in the circulation. Determination of TSH, which is low in hyperthyroidism due to negative feedback, allows differential diagnosis of hyperthyroidism from a TSH-secreting pituitary tumour.

Subclinical hyperthyroidism is characterised by normal thyroid hormone concentrations, decreased TSH concentrations, but no clinical symptoms. It has been reported to occur less frequently than subclinical hypothyroidism. Consensus on management has been lacking;[1-6] while treatment is not routinely recommended for mild subclinical hyperthyroidism, certain subgroups of patients, such as those at risk of atrial fibrillation or osteoporosis, may benefit from therapy.[7] Treatment may also be warranted in those with subclinical hyperthyroidism caused by toxic multinodular goitre or Graves’ disease in order to prevent progression to overt hyperthyroidism.[4]

There are three main forms of **treatment** for hyperthyroidism: drug therapy, use of radio-iodine, or surgery.

Drug therapy. The main **antithyroid drugs** are all thiourea derivatives that block the production of thyroid hormones through inhibition of thyroid peroxidase. Carbimazole (in the UK) or thiamazole (in the USA), or propylthiouracil, are the mainstays of treatment.[8] Antithyroid drugs do not block the release of stored thyroid hormones and it is only when the preformed hormones are depleted and concentrations of circulating hormones decline that clinical effects become apparent. An additional action of propylthiouracil is inhibition of the peripheral deiodination of thyroxine to tri-iodothyronine. The place of immunosuppression in the antithyroid activity of these drugs is subject to debate.

Many patients begin treatment with an antithyroid drug; they receive high doses initially until they become euthyroid, generally within 1 to 2 months. Once a response to the antithyroid drug has been obtained, patients with more severe or recurrent disease may require ablative treatment with either radio-iodine or surgery (see below), while those with mild to moderate disease may be best managed with lower maintenance doses of antithyroid drugs. These are either given indefinitely, or more usually for at least a year (often 18 months), followed by observation to see if remission is maintained in the absence of drug therapy.[2,8-14] Relapse at some stage after stopping therapy occurs in about 50 to 60% of cases, usually within 3 to 6 months after stopping the drugs, but is unpredictable.[8] Addition of levothyroxine to the maintenance dose of thiamazole has been reported to reduce the rate of relapse in patients with Graves' disease when therapy is subsequently withdrawn,[12,15] but later studies have not shown benefit.[14,16-19]

An alternative maintenance regimen is to add the thyroid hormone while maintaining the high initial doses of antithyroid drug. This '*blocking-replacement therapy*' has been suggested to help to prevent hypothyroidism which may be induced when antithyroid drugs are used alone. Because of the high doses of thioureas required and the insufficient placental transfer of levothyroxine,[20,21] the blocking-replacement regimen should not be used in pregnancy.

More rapid relief of the symptoms of hyperthyroidism can be achieved with beta blockers or iodide.[9,11] Beta blockers usually achieve a response within 48 hours, and are given as short-term adjuncts to antithyroid drugs to control severe sympathetic overactivity in patients such as those with thyroid storm (see below), but their use in heart failure associated with thyrotoxicosis is controversial because of the risk of cardiac deterioration.[22] The use of beta blockers in patients with mild to moderate hyperthyroidism is usually unnecessary.

Iodine and iodides are given with antithyroid drugs for 7 to 14 days as pre-operative preparation for patients who are to undergo thyroidectomy (but see also under Surgical Therapy, below); a combination of iodide and a beta blocker has also been used. Iodide has been used with antithyroid drugs, for control of thyroid storm. It is suggested that the antithyroid drugs should always be given first to prevent incorporation of iodide into new hormone stores.[9]

Other drugs tried in hyperthyroidism have included lithium, though its practical value is a matter of debate.[9] Potassium and sodium perchlorate have also been used; they increase responsiveness to conventional antithyroid drugs and may be useful in patients with iodine-induced hyperthyroidism.[23]

In those patients in whom drug therapy fails to achieve long-term remission, ablative therapy may be considered in the form of radio-iodine therapy or surgery.

Radio-iodine therapy with ^{131}I as oral ^{131}I-sodium iodide treats hyperthyroidism by destroying the functioning cells of the thyroid gland. It is increasingly used as initial therapy,[9,12,20,24,25] especially in the USA.[6,26] It is also useful for patients who have not responded to antithyroid drug therapy or who have relapsed after it.[2,10]

Pretreatment of patients with an antithyroid drug for 2 to 8 weeks before radio-iodine therapy has been advocated, to avoid the risk of precipitating thyroid storm. However, many no longer consider this to be necessary for all patients,[9,20,24] although it is generally agreed that the elderly or those with severe disease or increased risk of cardiac symptoms should receive some form of pretreatment.[6] In younger patients, a study has suggested that antithyroid pretreatment may exacerbate the risks when the drugs are withdrawn.[27] Such withdrawal, 2 to 4 days before radio-iodine is given, is standard practice to maximise the latter's effect, although some consider it unnecessary.[9] Meta-analysis has shown that use of antithyroid drugs in the week before or after radio-iodine therapy decreases its effectiveness, increasing the risk of treatment failure.[28] Although it has been considered that a poor response to radio-iodine was more likely with propylthiouracil than thiamazole,[8] this was not supported by meta-analysis.[28] An increased dose of radio-iodine has been advocated in pretreated patients.[24] Pretreatment or ancillary treatment with a beta blocker is a possible alternative to antithyroid drugs in patients receiving radio-iodine.[6,9,11,20,24]

The dose of radio-iodine needed to achieve euthyroidism is difficult to predict and there is little agreement on the most appropriate dosage schedule.[2,11,24] Radio-iodine therapy may take up to 10 weeks to achieve a clinical response, and cover with an antithyroid drug may be required during this period. Radio-iodine is not generally considered to increase the risk of malignancy,[9,24,29] or teratogenicity[20] but it is contra-indicated in pregnancy and while breast feeding.[6] The commonest unwanted effect of radio-iodine therapy is hypothyroidism and all patients require long-term follow-up and possible levothyroxine replacement therapy.[6] Iodide may be given after radio-iodine therapy to help the return of normal thyroid function.[9] Controversy exists as to whether radio-iodine therapy exacerbates Graves' ophthalmopathy[9,30,31] although it is considered to worsen disease in smokers.[20,25] Cohort studies have found increased mortality in those patients with hyperthyroidism treated with radio-iodine.[32,33] However, this risk was no longer evident once patients with overt hypothyroidism (induced by radio-iodine therapy) were given thyroxine replacement therapy. The authors considered these findings to strongly support a definitive treatment of hyperthyroidism with doses of radio-iodine sufficient to cause overt hypothyroidism, and the prompt treatment of subclinical hypothyroidism after radio-iodine therapy.[33]

Surgical treatment is usually reserved for patients with severe hyperthyroidism or for those with extreme thyroid enlargement or a single nodule. Euthyroidism is first established using antithyroid drugs and then iodide is given for 7 to 14 days before surgery to reduce the vasculature of the gland. Alternatively, a beta blocker and iodide may be used together for pre-operative preparation. However, a consensus view[1] suggested that pre-operative iodine probably has no beneficial effect. Levothyroxine replacement therapy may be required following surgical treatment.

Arterial embolisation. There are some patients who cannot, or choose not to, receive any of the three main forms of treatment for hyperthyroidism. Thyroid arterial embolisation has been used as an alternative with an outcome similar to that of subtotal thyroidectomy.[34]

If untreated or inadequately controlled, hyperthyroidism can complicate **pregnancy** and have adverse perinatal effects.[20,21,25,35] Hyperthyroidism is generally treated throughout pregnancy with an antithyroid drug, usually propylthiouracil[6,8,20,21,25,35] at the minimum dose needed to maintain a borderline euthyroid state. Occasionally, the antithyroid drug can be withdrawn in the third trimester.[8,20,25,26] Drug therapy during pregnancy may cause fetal or neonatal hypothyroidism, with or without goitre. This risk appears unrelated to the dose of the drug,[21,35] and the condition may mask neonatal hyperthyroidism[35] (see below).

Failure to control symptoms of hyperthyroidism with antithyroid drugs during pregnancy may indicate the need for surgery which is often delayed where possible until after the first trimester.[21,25,35,36] Iodide and radio-iodine are contra-indicated during pregnancy,[6,11,20,21,25,35,36] as is the blocking-replacement regimen.[20,21,26,35]

Neonatal hyperthyroidism may occur rarely due to transfer of thyroid-stimulating immunoglobulins across the placenta, and should be treated with antithyroid drugs, iodide, and appropriate therapy for cardiovascular complications.[37]

Thyroid storm (also known as thyroid crisis or thyrotoxic crisis) is an extreme accentuation of the hyperthyroid state and should be treated as a medical emergency. It is usually abrupt in onset and is often related to some precipitating factor such as inadequate preparation for thyroidectomy or radio-iodine therapy, or infection in previously unrecognised hyperthyroid subjects. The most common clinical manifestations are hyperpyrexia and extreme tachycardia; others may include arrhythmia, heart failure, shock, agitation, tremor, mania, delirium, stupor, coma, abdominal pain, diarrhoea, vomiting, jaundice, and hepatomegaly. Treatment consists of high-dose antithyroid drugs, gradually reduced as the condition improves, along with a beta blocker and iodide to control cardiovascular symptoms and prevent thyroid hormone release from the thyroid gland. Additional symptomatic treatment may also be required.

The clinical manifestations of **Graves' ophthalmopathy** may not occur with those of systemic hyperthyroidism, and it has been characterised as an independent manifestation of the immunological abnormality in Graves' disease.[38]

In Graves' ophthalmopathy, oedema and inflammation of the muscles around the eyes produces exophthalmos or proptosis and diplopia. On rare occasions patients may develop papilloedema and loss of vision. Treatment is generally unsatisfactory and signs of disease may persist indefinitely.[39] Opinions differ as to whether controlling associated hyperthyroidism improves ocular symptoms.[38] Reports that radio-iodine therapy may exacerbate Graves' ophthalmopathy are disputed,[6,9,20,24,30,31] but some prefer to avoid its use in active ocular disease.[1] Most patients with mild ocular involvement in hyperthyroidism require no specific therapy; dry eye should be managed appropriately (see p.2140). There is evidence indicating that glucocorticoids are effective in patients with Graves' ophthalmopathy, especially in patients with moderate and severe disease of recent onset. Glucocorticoids have a synergistic effect with orbital radiotherapy and the combination has been shown to be effective. If orbital radiotherapy is contra-indicated, ciclosporin with oral glucocorticoids is an effective alternative.[40] Surgical decompression may be required if patients do not respond to such therapy or cannot tolerate its adverse effects, or if vision is threatened by severe optic nerve compression.

Hypothyroidism

Hypothyroidism is the clinical syndrome resulting from deficiency of thyroid hormones. It mainly affects women and is more prevalent in the middle-aged and elderly. The symptoms of hypothyroidism may be due to general deceleration of metabolism or to accumulation of mucopolysaccharide in the subcutaneous tissues and vocal cords. Common clinical manifestations include weakness, fatigue, lethargy, physical and mental slowness, and weight gain; puffy, nonpitted swelling of subcutaneous tissue often develops, particularly around the eyes. Menstrual disorders, hyperlipidaemia, and constipation can occur and goitre may develop despite associated cell destruction.

The term **myxoedema** is often reserved for severe or advanced hypothyroidism. In the most severely affected patients, progressive somnolence and torpor combine with cold intolerance and bradycardia to induce a state of coma often known as 'hypothyroid' or 'myxoedema coma' (see below).

In children, untreated hypothyroidism results in retardation of growth and mental development. Endemic cretinism is a result of maternal, and hence fetal, iodine deficiency and consequent lack of thyroid hormone production (see Iodine Deficiency Disorders, p.2170).

Hypothyroidism is usually primary, resulting from malfunction of the thyroid gland. In areas where iodine intake is sufficient the commonest cause of hypothyroidism is auto-immune lymphocytic thyroiditis of which there are two major variants. In **Hashimoto's thyroiditis** there is also goitre whereas in **idiopathic** or **primary myxoedema** (**atrophic thyroiditis**) there is no thyroid enlargement. Hypothyroidism can also be caused by either an excess or a deficiency of iodine. An excess may result from intake of iodine or its salts or iodine-containing drugs such as amiodarone. Drugs that decrease thyroid hormone synthesis such as lithium can also be a cause of hypothyroidism. In some patients hypothyroidism may be secondary to disorders of the hypothalamus or pituitary gland.

The **diagnosis** of hypothyroidism is essentially clinical but, given the non-specific nature of many of the symptoms, biochemical tests are performed for confirmation.[1-3] A raised thyroid stimulating hormone (TSH) value and a low free T_4 or T_3 concentration indicates primary hypothyroidism. Protirelin and thyrotrophin have also been used for the differential diagnosis of hypothyroidism.

Subclinical hypothyroidism is a condition in which there are normal concentrations of thyroid hormones, raised concentrations of TSH, but no clinical symptoms. Patients with subclinical hypothyroidism are at a greater risk of developing clinical hypothyroidism if they also have thyroid antibodies against thyroid peroxidase/microsomal antigen, although the best strategy for identifying those at risk is not yet known.[2]

Hypothyroidism is readily **treated** by lifelong replacement therapy with levothyroxine.[1,2,4-7] Although the thyroid gland produces both T_3 (liothyronine) and T_4 (thyroxine), T_3 is mainly produced by peripheral monodeiodination of circulating T_4 and it is therefore sufficient to give levothyroxine alone. There is no rationale for the use of combined preparations containing liothyronine and levothyroxine, or of dried thyroid hormone extracts, which may lead to elevated serum concentrations of T_3 and thyrotoxic symptoms. Liothyronine may, however, be used initially for its rapid onset of action in severe hypothyroid states such as myxoedema coma (see below). Initial checks should be made to ensure that thyroid replacement treatment is restoring deficiencies in thyroid hormone but not providing an excess. This is best done by monitoring hormone concentrations and the goal of replacement therapy is a normal TSH value, which is generally associated with a normal or slightly elevated T_4 value.[2,5]

In subclinical hypothyroidism, treatment with levothyroxine is controversial. It has been recommended[2-4,7,8] if antibodies to thyroid peroxidase are present, or if TSH levels are above 10 milliunits/litre. Some also recommend treatment if TSH levels are between 5 and 10 milliunits/litre and goitre or antibodies (or both) are evident.[7]

Although titres of antithyroid antibodies may fall during **pregnancy**, some patients may require progressive increases in levothyroxine dosage,[9,10] and therefore it has been recommended that thyroid function tests should be performed in each trimester;[1,2,4,11] some[7,12] currently advocate monitoring every 6 to 8 weeks.

The diagnosis of **congenital hypothyroidism** (neonatal hypothyroidism) is now most commonly made on the basis of screening programmes.[13] Early treatment with adequate doses of levothyroxine is required to minimise the effects of hypothyroidism on mental and physical development. It should be started as soon as possible after birth and should be reviewed regularly.[13,14] However, it is generally accepted that in those with more severe hypothyroidism at diagnosis some small degree of deficit and incoordination remains, although they should be mild enough to permit a normal life.[15]

Hypothyroid (myxoedema) coma is a medical emergency requiring prompt treatment usually with liothyronine given by intravenous injection because of its rapid action, although some centres use intravenous levothyroxine. Alternatively, the nasogastric route may be used. Other treatment includes intravenous hydrocortisone (because of the likelihood of adrenocortical insufficiency) and intravenous fluids (to maintain plasma-glucose and electrolyte concentrations). Respiratory function should be supported by assisted ventilation and oxygen. Hypothyroid coma carries a poor prognosis, with mortality around 50% even with treatment.

Benzylthiouracil

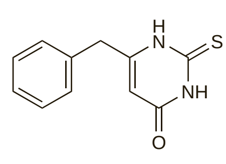
Benciltiouracilo. 6-Benzyl-2,3-dihydro-2-thioxopyrimidin-4(1*H*)-one; 6-Benzyl-2-mercaptopyrimidin-4-ol; 6-Benzyl-2-thiouracil.

$C_{11}H_{10}N_2OS = 218.3$.

CAS — 33086-27-0; 6336-50-1.

ATC — H03BA03.

ATC Vet — QH03BA03.



Profile

Benzylthiouracil is a thiourea antithyroid drug. It is given by mouth in the treatment of hyperthyroidism (p.2165) in an initial dose of 150 to 200 mg daily, reducing to a maintenance dose of 100 mg daily; it is given in divided doses, preferably with food.

Porphyria. Benzylthiouracil is considered to be unsafe in patients with porphyria although there is conflicting experimental evidence of porphyrinogenicity.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Basdene.

Carbimazole *(BAN, rINN)*

Carbimazol; Carbimazolum; Karbimatsoli; Karbimazol; Karbimazolas. Ethyl 3-methyl-2-thioxo-4-imidazoline-1-carboxylate.

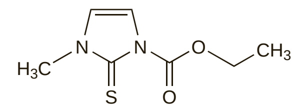
Карбимазол

$C_7H_{10}N_2O_2S = 186.2$.

CAS — 22232-54-8.

ATC — H03BB01.

ATC Vet — QH03BB01.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Carbimazole). A white or yellowish-white crystalline powder. Slightly soluble in water; soluble in alcohol and in acetone.

Adverse Effects and Precautions

Adverse effects from carbimazole and other thiourea antithyroid drugs occur most frequently during the first 8 weeks of treatment. The most common minor adverse effects are nausea and vomiting, gastric discomfort, headache, arthralgia, skin rashes, and pruritus. Hair loss has also been reported.

Bone-marrow depression may occur and mild leucopenia is common. Rarely, agranulocytosis can develop, and is the most serious adverse reaction associated with this class of drugs. Patients or their carers should be told how to recognise such toxicity and should be advised to seek immediate medical attention if mouth ulcers or sore throat, fever, bruising, malaise, or non-specific illness develop. Full blood counts should be performed, and treatment should be stopped immediately if there is any clinical or laboratory evidence of neutropenia. Aplastic anaemia or isolated thrombocytopenia have been reported rarely, as has hypoprothrombinaemia.

There have been several reports of liver damage, most commonly jaundice, in patients taking thiourea antithyroid drugs; the drug should be withdrawn if hepatic effects occur.

Other adverse effects sometimes observed with the thiourea antithyroid compounds include fever, a lupus-like syndrome, myopathy, vasculitis and nephritis, and taste disturbances. Creatine phosphokinase values should be measured if patients experience myalgia.

Excessive doses of antithyroid drugs may cause hypothyroidism and goitre. High doses in pregnancy may result in fetal hypothyroidism and goitre (see Pregnancy, below).

An immune mechanism has been implicated in many of these reactions and cross-sensitivity between the thiourea antithyroid drugs may occur.

Breast feeding. The safety of breast feeding during maternal treatment depends partly on how much drug is distributed into the breast milk. Thiourea antithyroid drugs may be used with care in breast-feeding mothers; neonatal development and thyroid function of the infant should be closely monitored and the lowest effective dose used.

Propylthiouracil has been preferred to carbimazole or thiamazole since it enters breast milk less readily.[1-3] In a small study[4] of breast-feeding mothers taking doses of propylthiouracil as high as 750 mg daily for Graves' disease, no adverse effects were observed on the thyroid status of their infants.

Thiamazole enters breast milk freely, with plasma to milk ratios of almost one.[3,5] The infant's intake of thiamazole after maternal use of carbimazole (or thiamazole) might be greatly reduced by discarding the breast milk produced 2 to 4 hours after a dose,[6] since the highest concentration was found at this time. Two studies found no adverse effects on thyroid function,[7,8] thyroid hormone levels,[7] or physical and intellectual development, in breast-fed infants during up to 6 months[7] to 1 year[8] of maternal treatment with thiamazole. Maximum maternal daily doses of 10 mg of thiamazole,[3] 15 mg of carbimazole, and 150 mg of propylthiouracil[9] have been recommended, although thiamazole 20 to 30 mg has been given to thyrotoxic lactating women for the first month of a year of therapy with no observable adverse effects on the thyroid function of their breast-fed infants.[10] Despite stating that goitre has been associated with the use of carbimazole, the American Academy of Pediatrics considers the use of all three drugs to be compatible with breast feeding.[11]

Effects on the blood. While **leucopenia** is considered to be a common adverse effect of the thiourea antithyroid drugs, occurring in up to a quarter of patients, it is usually mild and improves as treatment continues.[1]

Agranulocytosis, a more serious hazard, is usually reported to affect 0.03% of patients in Europe,[2] who are mostly treated with carbimazole. However, the incidence has been reported to be higher (0.4%) in areas where thiamazole is used.[3,4] Fatalities have been reported.[1,2,4,5] Although a direct toxic effect had been suggested, the agranulocytosis associated with the thiourea drugs is generally considered to be immunologically mediated.[1,6] The onset of agranulocytosis is usually rapid and monitoring of the blood count is not always of predictive value;[3] routine monitoring is not indicated.[2] Agranulocytosis has occurred in patients receiving propylthiouracil for a second time who had no such complications in their first course of therapy.[7] There is limited evidence that agranulocytosis is more common at higher doses, and in older patients. However, this has not been proved conclusively.[1]

There have been some case reports of **aplastic anaemia** being produced by antithyroid drugs, but the excess risk associated with their use is considered to be very low[6,8] and complete recovery has been reported after withdrawal of the antithyroid drug. An immune mechanism has been implicated.

Carbimazole has produced **haemolytic anaemia**.[9] In this case the immune reaction was specific to carbimazole and could not be demonstrated with thiamazole.

On very rare occasions patients taking propylthiouracil have experienced a reduction in prothrombin values and bleeding.[10-12] In one patient bleeding was linked to propylthiouracil-induced **thrombocytopenia**.[13]

13. Ikeda S, Schweiss JF. Excessive blood loss during operation in the patient treated with propylthiouracil. *Can Anaesth Soc J* 1982; **29:** 477–80.

Effects on the ears. Earache, high-frequency hearing loss, and tinnitus in a patient with Graves' disease were attributed to hypersensitivity to carbimazole;[1] hearing loss, but not the tinnitus, resolved when carbimazole was replaced with propylthiouracil.

1. Hill D, *et al.* Hearing loss and tinnitus with carbimazole *BMJ* 1994; **309:** 929.

Effects on the kidneys. Glomerulonephritis associated with the development of antineutrophil cytoplasmic antibodies has been reported in patients receiving thiourea antithyroid drugs.[1-5]

1. Vogt BA, *et al.* Antineutrophil cytoplasmic autoantibody-positive crescentic glomerulonephritis as a complication of treatment with propylthiouracil in children. *J Pediatr* 1994; **124:** 986–8.

Effects on the liver. Jaundice, usually cholestatic, has been reported with thiamazole and carbimazole.[1-5] An immune-mediated mechanism rather than a toxic reaction has been proposed. Hepatitis (sometimes progressing to cirrhosis[6]) and hepatic necrosis have been associated with propylthiouracil,[6-9] sometimes with fatal consequences.[7,8] However, in one study[10] almost 30% of patients being treated with propylthiouracil developed asymptomatic liver changes (increased alanine aminotransferase values). Dose reduction resulted in a return to normal values in 13 of the 15 patients affected.

Despite reports of liver damage, propylthiouracil has been investigated in the treatment of patients with alcoholic liver disease (see p.2175).

10. Liaw Y-F, *et al.* Hepatic injury during propylthiouracil therapy in patients with hyperthyroidism. *Ann Intern Med* 1993; **118:** 424–8.

Effects on the lungs. Diffuse interstitial pneumonitis occurred in 2 patients given propylthiouracil[1] and a hypersensitivity reaction was suggested. Propylthiouracil was also implicated in 2 cases of alveolar haemorrhage associated with antineutrophil cytoplasmic antibody.[2,3]

1. Miyazono K, *et al.* Propylthiouracil-induced diffuse interstitial pneumonitis. *Arch Intern Med* 1984; **144:** 1764–5.

3. Dhillon SS, *et al.* Diffuse alveolar hemorrhage and pulmonary capillaritis due to propylthiouracil. *Chest* 1999; **116:** 1485–8.

Effects on the muscles. Myositis with pain, weakness, and increased creatine kinase concentrations has been reported with carbimazole.[1,2] This effect might be explained by 'tissue hypothyroidism', and might respond to dosage reduction.[3]

3. O'Malley B. Carbimazole-induced cramps. *Lancet* 1989; **i:** 1456.

Hypersensitivity. Many of the adverse effects associated with the thiourea antithyroid drugs appear to have an immune basis. These effects may be associated with polyarthritis[1] or hypersensitivity vasculitis.[2-7] The latter is sometimes severe and multisystemic, and fatalities have occurred.

Hypersensitivity reactions may also be associated with the development of antineutrophil cytoplasmic antibodies (ANCA), or sometimes with a lupus-like syndrome with or without the presence of antinuclear antibodies.[2,5]

Serum sickness with arthralgias and raised immunoglobulin M (IgM) concentrations has been reported with thiamazole,[8] and the production of antibodies to insulin, resulting in episodes of hypoglycaemia, has been associated with thiamazole[9] and carbimazole.[10]

The thiourea antithyroid drugs all contain a thioamide group and cross-sensitivity between them might be expected. In particular, complete cross-reactivity may be expected between thiamazole and carbimazole since the latter is converted *in vivo* to thiamazole, although one report[11] suggests this is not necessarily the case. Cross-sensitivity between propylthiouracil and carbimazole[12] or thiamazole[13] has been reported but the incidence and clinical importance is not clear. Although it has been suggested that carbimazole or thiamazole may be substituted for propylthiouracil in hypersensitive patients, it is safer to stop antithyroid drugs in such patients.[12]

Pregnancy. Thiourea antithyroid drugs have been used successfully in pregnancy (see Hyperthyroidism, p.2165).

Thiamazole (the metabolite of carbimazole) has been the drug most frequently involved in the few reports of **congenital defects** following maternal use of such compounds. Several infants exposed to thiamazole *in utero* have been born with scalp defects (aplasia cutis congenita—a localised absence of skin at birth)[1,2] although hyperthyroidism itself may give rise to such defects.[3] Individual cases of other congenital defects associated with thiamazole have included choanal atresia (an upper respiratory-tract defect), oesophageal atresia, and tracheo-oesophageal fistula[3] but the incidence of congenital abnormalities is not increased compared with the general population.[4] Gastroschisis (an abdominal wall defect) has been reported in an infant after maternal exposure to carbimazole.[5] There have been some reports of neonates exposed to thiourea antithyroid drugs *in utero* displaying signs of **hypothyroidism** including goitre.[6,7]

Pharmacokinetics

The pharmacokinetics of carbimazole and thiamazole can be considered together since carbimazole is rapidly and completely metabolised to thiamazole in the body. The antithyroid activity of carbimazole is dependent upon this conversion to thiamazole.

Carbimazole and other thiourea antithyroid drugs are rapidly absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 1 to 2 hours after oral doses.

They are concentrated in the thyroid gland; since their duration of action is more closely related to the intrathyroidal drug concentration than their plasma half-life, prolonged antithyroid activity results from single daily doses. Thiamazole is not bound to plasma proteins.

Thiamazole has an elimination half-life from plasma of about 3 to 6 hours and is metabolised, probably by the liver, and excreted in the urine. Less than 12% of a dose of thiamazole may be excreted as unchanged drug. 3-Methyl-2-thiohydantoin has been identified as a metabolite of thiamazole. The elimination half-life may be increased in hepatic and renal impairment.

Thiamazole crosses the placenta and is distributed into breast milk.

Uses and Administration

Carbimazole is a thiourea antithyroid drug that acts by blocking the production of thyroid hormones (see p.2165). It is used in the management of hyperthyroidism (p.2165), including the treatment of Graves' disease, the preparation of hyperthyroid patients for thyroidectomy, as an adjunct to radio-iodine therapy, and in the treatment of thyroid storm.

Carbimazole is completely metabolised to thiamazole and it is this metabolite that is responsible for the antithyroid activity of carbimazole.

Carbimazole is given orally in a typical initial dosage of 15 to 40 mg daily, in divided doses; occasionally up to 60 mg daily may be required. Control of symptoms is usually achieved in 1 to 2 months. When the patient is euthyroid the dose is gradually reduced to the smallest amount that will maintain the euthyroid state. Typical maintenance doses are 5 to 15 mg daily, which may be given as a single daily dose.

Treatment in children should be undertaken by a specialist. The *BNFC* recommends an initial dose of 250 micrograms/kg three times daily for neonates and children up to 12 years of age. Children aged 12 to 18 years may be given 10 mg three times daily initially. Doses are adjusted according to response; higher initial doses may be needed in thyrotoxic crisis.

Carbimazole is also given orally in a dose of 20 to 60 mg daily, with supplemental levothyroxine, as a *blocking-replacement regimen*.

Either form of maintenance treatment is usually continued for at least a year, and often for 18 months; up to 2 years of treatment may be required.

Preparations

BP 2008: Carbimazole Tablets.

Proprietary Preparations (details are given in Part 3)

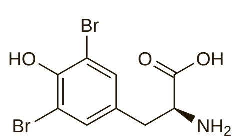
Dibromotyrosine

Dibromotirosina. 3,5-Dibromo-L-tyrosine.

$C_9H_9Br_2NO_3$ = 339.0.
CAS — 300-38-9.
ATC — H03BX02.
ATC Vet — QH03BX02.



Profile

Dibromotyrosine is an antithyroid drug used in the treatment of hyperthyroidism (p.2165) in doses of 300 to 900 mg daily by mouth.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Bromotiren.
Multi-ingredient: *Ital.:* Bromazolo.

Iodine

Iod; Iode; Iodium; Iodo; Iodum; Iyot; Jód; Jod; Jodas; Jodi; Jodum; Yodo.

I_2 = 253.80894.
CAS — 7553-56-2.
ATC — D08AG03.
ATC Vet — QD08AG03.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Iodine). Greyish-violet, brittle plates or fine crystals, with a metallic sheen. It is slowly volatile at room temperature. Very slightly soluble in water; soluble in alcohol; slightly soluble in glycerol; very soluble in concentrated solutions of iodides.

USP 31 (Iodine). Heavy, greyish-black plates or granules with a metallic sheen and a characteristic odour. Soluble 1 in 3000 of water, 1 in 13 of alcohol, 1 in 4 of carbon disulfide, and 1 in 80 of glycerol; freely soluble in chloroform, in ether, and in carbon tetrachloride; soluble in solutions of iodides. Store in airtight containers.

Incompatibility. With acetone, iodine forms a pungent irritating compound.

Potassium Iodate

Iodato potásico; Potasu jodan.

KIO_3 = 214.0.
CAS — 7758-05-6.

Pharmacopoeias. In *Br., Chin.,* and *It.*

BP 2008 (Potassium Iodate). A white crystalline powder with a slight odour. Slowly soluble in water; insoluble in alcohol. A 5% solution in water has a pH of 5.0 to 8.0.

Potassium Iodide

Iodeto de Potássio; Ioduro potásico; Jodid draselný; Kalii Iodetum; Kalii iodidum; Kalii Jodidum; Kalio jodidas; Kalium Iodatum; Kalium Jodatum; Kaliumjodid; Kálium-jodid; Kaliumjodidi; Pot. Iod.; Potassii Iodidum; Potassium (Iodure de); Potassium, iodure de; Potasu jodek; Potasyum Iyodür.

KI = 166.0.
CAS — 7681-11-0.
ATC — R05CA02; S01XA04; V03AB21.
ATC Vet — QR05CA02; QS01XA04; QV03AB21.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Potassium Iodide). A white or almost white powder or colourless crystals. Very soluble in water; soluble in alcohol; freely soluble in glycerol. Protect from light.

USP 31 (Potassium Iodide). Hexahedral crystals, either transparent and colourless or somewhat opaque and white, or a white, granular powder. It is slightly hygroscopic. Soluble 1 in 0.7 of water and 1 in 0.5 of boiling water, 1 in 22 of alcohol, and 1 in 2 of glycerol. Its solutions are neutral or alkaline to litmus.

Sodium Iodide

Iodeto de Sódio; Ioduro sódico; Jodid sodný; Natrii Iodetum; Natrii iodidum; Natrii Jodidum; Natrio jodidas; Natrium Iodatum; Natriumjodid; Nátrium-jodid; Natriumjodidi; Sod. Iod.; Sodii Iodidum; Sodium (Iodure de); Sodium, iodure de; Sodu jodek; Sodyum Iyodür.

NaI = 149.9.
CAS — 7681-82-5.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Sodium Iodide). Colourless crystals or white or almost white, crystalline powder. It is hygroscopic. Very soluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Sodium Iodide). Colourless, odourless crystals, or white crystalline powder. It is deliquescent in moist air and develops a brown tint upon decomposition. Soluble 1 in 0.6 of water, 1 in 2 of alcohol, and 1 in 1 of glycerol. Store in airtight containers.

Adverse Effects and Treatment

Iodine and iodides, whether applied topically or given systemically, can give rise to hypersensitivity reactions which may include urticaria, angioedema, cutaneous haemorrhage or purpuras, fever, arthralgia, lymphadenopathy, and eosinophilia.

Inhalation of iodine vapour is very irritating to mucous membranes.

Iodine and iodides have variable effects on the thyroid (see below) and can produce goitre and hypothyroidism as well as hyperthyroidism (the Iod-Basedow or Jod-Basedow phenomenon). Goitre and hypothyroidism have also occurred in infants born to mothers who had taken iodides during pregnancy.

Prolonged use may lead to a range of adverse effects, often called 'iodism', some of which may again be due to hypersensitivity. Adverse effects include metallic taste, increased salivation, burning or painful mouth; there may be acute rhinitis, coryza-like symptoms, and swelling and inflammation of the throat. Eyes may be irritated and swollen and there may be increased lachrymation. Pulmonary oedema, dyspnoea, and bronchitis may develop. Skin reactions include acneform or, more rarely, severe eruptions (iododerma). Other reported effects include depression, insomnia, impotence, headache, and gastrointestinal disturbances, notably nausea, vomiting, and diarrhoea.

The symptoms of acute poisoning from ingestion of iodine are mainly due to its corrosive effects on the gastrointestinal tract; a disagreeable metallic taste, vomiting, abdominal pain, and bloody diarrhoea occur. Thirst and headache have been reported. Systemic toxicity may lead to shock, tachycardia, hypotension, fever, metabolic acidosis and renal impairment. Death may be due to circulatory failure, oedema of the epiglottis resulting in asphyxia, aspiration pneumonia, or pulmonary oedema. Oesophageal stricture may occur if the patient survives the acute stage.

Victims of acute poisoning have been given copious draughts of milk or starch mucilage; lavage should probably not be attempted, and certainly not unless the ingested iodine was in sufficiently dilute form not to produce gastrointestinal corrosion. Other possible oral treatments include activated charcoal or sodium thiosulfate solution (usually as a 1% solution) to reduce iodine to the less toxic iodides.

Effects on the thyroid. Iodide may be isolated by the body from a variety of sources, including an iodine-rich diet, or some disinfectants and drugs containing iodine (see also under Amiodarone, p.1212). Although iodine is required for the production of thyroid hormones, excessive quantities can cause hyperthyroidism, or even paradoxical goitre and hypothyroidism.

The normal daily requirement ranges from 100 to 300 micrograms.[1,2] Quantities of 500 micrograms to 1 mg daily probably have no untoward effects on thyroid function in most cases.[2] When progressively larger doses are given there is an initial rise in thyroid hormone production, but at still higher doses, production decreases (the Wolff-Chaikoff effect). This effect is usually seen with doses of more than about 2 mg daily, but is normally transient, adaptation occurring on repeated dosage. In certain individuals a lack of adaptation produces a chronic inhibition of thyroid hormone synthesis leading to goitre and **hypothyroidism**.[1,2]

Excess iodine may also induce **hyperthyroidism** (the Iod-Basedow or Jod-Basedow phenomenon). Iodine-induced hyperthyroidism has been associated with iodine prophylaxis programmes in developing countries.[3] The highest incidence of hyperthyroidism has been reported to occur 1 to 3 years after supplementation begins, with the incidence returning to normal within 3 to 10 years despite continued iodine exposure.[4] Elderly subjects and those with nodular goitres have been found to be at greatest risk.

To overcome any adverse effects on thyroid function as a result of iodine prophylaxis during **pregnancy**, WHO has issued guidelines on the safe use of iodised oil during gestation.[5,6] There is some evidence that the use of iodine-containing antiseptics on pregnant women and neonates may cause disturbances in thyroid function.[7,8]

Precautions

Caution is necessary if preparations containing iodine or iodides are taken for long periods, and such preparations should not be taken regularly during pregnancy except when iodine supplementation is required. Caution is also required when giving iodine or iodides to children. Patients over the age of 45 years or with nodular goitres are especially susceptible to hyperthyroidism when given iodine supplementation. Reduced doses should therefore be used and supplementation with iodised oil may not be appropriate.

Solutions of iodine applied to the skin should not be covered with occlusive dressings. The disinfectant activity of iodine is reduced by alkalis as well as by protein.

As iodine and iodides can affect the thyroid gland, their use may interfere with tests of thyroid function.

Breast feeding. Iodine is concentrated by the mammary gland into breast milk to ensure an adequate supply to the breast-fed infant. Since this is dependent on the maternal dietary intake,[1] WHO recommends a daily iodine intake of 200 micrograms for lactating women, see Iodine Deficiency Disorders, below.

The *BNFC* considers treatment with iodine or iodides to be a contra-indication to breast feeding. However, the American Academy of Pediatrics[2] considers that such treatment is usually compatible with breast feeding although it is noted that goitre or effects on thyroid function have been reported. Any risk is not confined to oral treatment: transient neonatal hypothyroidism has been reported in a breast-fed infant whose mother was treated with iodine tampons,[3] and for a report of increased milk-iodine concentrations associated with vaginal povidone-iodine see p.1659.

Interactions

The effects of iodine and iodides on the thyroid may be altered by other compounds including amiodarone and lithium.

Pharmacokinetics

Iodine is slightly absorbed when applied to the skin. When taken by mouth, iodine preparations (which are converted to iodide) and iodides are transported to, and concentrated in, the thyroid gland (see p.2165). Iodides not taken up by the thyroid are excreted mainly in the urine, with smaller amounts appearing in the faeces, saliva, and sweat. They cross the placenta and are distributed into breast milk.

Uses and Administration

Iodine is an essential trace element in the human diet, necessary for the formation of thyroid hormones (see p.2165), and consequently it is used in iodine deficiency and thyroid disorders. It also has antimicrobial activity.

For the prophylaxis and treatment of **iodine deficiency disorders** (below) it may be given as potassium or sodium iodide, iodised oil, or potassium iodate. Each g of potassium iodide represents about 6 mmol of potassium and of iodine. Each g of sodium iodide represents about 6.7 mmol of sodium and of iodine. Each g of potassium iodate represents about 4.7 mmol of potassium and of iodine.

In the pre-operative management of **hyperthyroidism** (p.2165) iodine and iodides are used with antithyroid drugs such as carbimazole, thiamazole, or propylthiouracil. Such use has been thought to render the thyroid firm and avoid the increased vascularity and friability (with increased risk of haemorrhage) that may result from the use of an antithyroid drug alone. However, there is little evidence of a beneficial effect.

Iodine may be given as a solution with potassium iodide (Aqueous Iodine Oral Solution BP 2008; Lugol's Solution or Strong Iodine Solution USP 31) which contains in each mL 130 mg of free and combined iodine; a dose of 0.1 to 0.3 mL in milk or water is given three times daily for 10 to 14 days. Alternatively, potassium iodide has been given in doses of up to 250 mg three times daily with food. Solutions of potassium iodide intended for oral use should be given well diluted to avoid gastric irritation. Potassium iodide may also be given 1 hour after an antithyroid drug as part of the management of thyroid storm; doses as high as 500 mg every 4 hours have been suggested. Sodium iodide has been given by intravenous injection as part of the management of thyroid storm.

Radioactive sodium iodide (see Iodine-131, p.2054) is also used for the treatment of hyperthyroidism, especially when medical treatment or compliance is problematic, in patients with cardiac disease, or in patients who relapse after thyroidectomy.

Potassium iodide has been tried in the treatment of benign **thyroid nodules** (p.2165).

Potassium iodide or potassium iodate are taken by mouth for **radiation protection** (below) to saturate the thyroid when uptake of radio-iodine by the gland is not desired.

Iodine has a powerful bactericidal action. It is also active against fungi, viruses, protozoa, cysts, and spores. Potassium iodide has been used in the treatment of fungal infections such as sporotrichosis (below). Iodine is used as an **antiseptic** and **disinfectant** generally as a 2% or 2.5% solution. Its activity is reduced in the presence of organic matter, though not to the same extent as with the other halogen disinfectants. If industrial methylated spirit is used for the solution, it should be free from acetone, with which iodine forms an irritant and lachrymatory compound. Iodine solutions may be applied to small wounds or abrasions as well as to unbroken skin, but an iodophore such as povidone-iodine (p.1659) may be preferred.

Iodine may also be used to sterilise drinking water; 5 drops of a 2% alcoholic solution added to about one litre (one US quart) of water is reported to kill amoebae and bacteria within 15 minutes. Water contaminated with *Giardia* requires 12 drops of a 2% alcoholic solution for each litre which may take one hour to achieve its effect. Tablets containing tetraglycine hydroperiodide (p.1663) may be preferred.

When iodine combines chemically it is decolorised and so-called colourless iodine preparations do not have the disinfectant properties of iodine.

Iodine stains the skin a deep reddish-brown; the stain can be readily removed by dilute solutions of alkalis or sodium thiosulfate. A dilute solution of iodine (Schiller's Iodine) may also be used as a **diagnostic** stain in colposcopy.

There have been numerous other uses of iodine and iodides. Iodides have long been used as ingredients of expectorant mixtures (see Cough, p.1547) but there has been concern over their safety because of their potential for thyroid suppression. A diatomic iodine formulation is under investigation for the treatment of fibrocystic breast disease. Iodinated organic compounds including iodised oil are used as X-ray contrast media (p.1474). Potassium iodide has been given in the treatment of Sweet's syndrome (acute febrile neutrophilic dermatosis). A mixture of iodine and sodium iodide is used as sclerotherapy for varicose veins (p.2347).

Fungal infections. Potassium iodide is used in the treatment of cutaneous sporotrichosis (p.522), although how it acts is unclear since antifungal activity was not found *in vitro* against *Sporothrix schenkii*.[1] It has also been shown to be effective in the treatment of phycomycosis caused by *Basidiobolus haptosporus*[2,3] but again the mode of action is unclear.[4] Potassium iodide is usually given orally in a gradually increasing dosage up to the limit of tolerance. The WHO recommended initial dose is 1 mL [1 g] of a saturated solution of potassium iodide (1 g/mL) given three times daily; treatment should be continued for at least 1 month after the disappearance or stabilisation of the lesions.

Potassium iodide and sodium iodide have been tried by local intracavitary instillation for the treatment of life-threatening haemoptysis from pulmonary aspergillomas.[5] Mechanical factors may have accounted for a beneficial effect rather than any antifungal action. Aspergillomas are usually managed conservatively or, in more severe disease, with antifungals or surgery (see p.517).

Iodine deficiency disorders. Iodine is an essential trace element required for thyroid hormone production. In the UK the reference nutrient intake (RNI) for adults is 140 micrograms (1.1 micromoles) of iodine daily[1] and in the USA the recommended dietary allowance (RDA) is 150 micrograms daily.[2] A full explanation of the terms RNI and RDA can be found under Human Requirements of Vitamins, p.1925. In 1996, WHO[3] recommended the following daily iodine intakes:

- 50 micrograms up to 12 months of age
- 90 micrograms from 1 to 6 years
- 120 micrograms from 7 to 12 years
- 150 micrograms from 12 years of age
- 200 micrograms during pregnancy and lactation.

A subsequent document from the International Council for Control of Iodine Deficiency Disorders, UNICEF, and WHO recommended 90 micrograms daily for all infants and children up to 59 months of age and 120 micrograms from 6 to 12 years.[4]

When iodine requirements are not met, a range of disorders can develop. These iodine deficiency disorders include endemic goitre (enlargement of the thyroid), endemic cretinism (a syndrome characterised by deaf-mutism, intellectual deficit, spasticity, and sometimes hypothyroidism), impaired mental function in children and adults, and an increased incidence of still-births as well as perinatal and infant mortality.[3,5]

Iodine deficiency disorders can be prevented by iodine supplementation. The incidence of endemic goitre, endemic cretinism, and mental retardation can be reduced and some of the effects of established iodine deficiency ameliorated, with only modest risks.[6]

Although various methods of iodine supplementation, including iodination of sugar, water, and bread, as well as giving potassium iodide, have been investigated, the two methods generally used are iodination of culinary salt and the use of iodised oil.[3]

Salt may be iodinated by the addition of potassium iodide or potassium iodate. The concentration used in different countries varies over a wide range from 10 to about 80 ppm of elemental iodine.[4]

The chief alternative to supplementation with iodinated salt is *iodised oil*, usually by intramuscular injection; it is useful where salt consumption is unreliable or inadequate or where immediate action is necessary to correct severe iodine deficiency.[3] A commonly used type of iodised oil has been a poppyseed oil containing about 38% w/w or 480 mg/mL of iodine (see Iodised Oil, p.1482). Some countries have produced iodised oil based on alternatives such as peanut or rapeseed oil.[7,8] Single intramuscular doses can provide adequate protection from iodine deficiency for up to 3 years. WHO has recommended[9] that infants up to 1 year receive 190 mg iodine, as iodised oil (480 mg/mL iodine), by intramuscular injection; children and adults up to age 45 are given 380 mg. Subjects over the age of 45 years and those with nodular goitre are susceptible to hyperthyroidism when given iodine, and iodised oil may not be a suitable means of supplementation. If it is used, doses of 76 mg are given.[9]

Iodised oil may also be given orally once yearly. WHO recommends[9] that infants up to 1 year be given a single dose of 100 mg iodine, children from 1 to 5 years 200 mg, and those over 6 years 400 mg. The evidence suggests that oral iodised oil is as effective as intramuscular for preventing iodine deficiency disorders in children.[10] Adults are also given 400 mg, except during pregnancy, when a single dose of 200 mg is recommended.[9]

Iodine or iodides may suppress neonatal thyroid function and it is generally recommended that iodine compounds should be avoided during **pregnancy**. However, where it is essential to prevent neonatal goitre and cretinism, iodine supplementation should not be withheld from pregnant women.[11,12] Iodine supplementation has been found to be effective in preventing brain-damage in the fetus provided it is given to the mother in the first or second trimester;[11] treatment later in pregnancy was not effective in improving neurological status, although some developmental improvement was seen and hypothyroidism will be corrected. WHO has stated that in areas where iodine deficiency disorders are moderate to severe, iodised oil given either before or at any stage of gestation is beneficial.[9,12] A dose of 480 mg iodine intramuscularly each year, or 300 to 480 mg iodine by mouth each year, or 100 to 300 mg iodine by mouth every 6 months, is recommended for pregnant women and for at least one year postpartum. Similar intramuscular doses are recommended for non-pregnant fertile women with oral doses being 400 to 960 mg iodine every year, or 200 to 480 mg every 6 months.[9]

Indirect iodine supplementation, by addition of potassium iodate to the water used to irrigate crops, has been tried in areas of iodine deficiency where other methods had proved difficult to implement.[13]

Radiation protection. Giving a radiologically stable form of iodine to saturate the thyroid gland confers thyroid protection from iodine radionuclides.[1,2] When thyroid protection from a *medical procedure* involving radio-iodine is needed 100 to 150 mg of iodide as potassium iodide may be given orally 24 hours before the procedure and daily for up to 10 days following it.

In the event of a *nuclear accident* authorities in the USA recommend[1,3] an oral dose of 130 mg of potassium iodide daily in adults (including pregnant and lactating women). Daily doses should be given until risk of exposure has passed and adjunctive measures have been implemented. Recommended daily doses of potassium iodide for children are:

- up to 1 month of age, 16 mg
- 1 month to 3 years, 32 mg
- 3 to 12 years (up to 18 years if body-weight is less than 70 kg), 65 mg

In the UK the oral dose recommended[4,5] is 100 mg of stable iodine (as 170 mg of potassium iodate) for adults (including pregnant women and women who are breast feeding) as soon as possible after exposure and before evacuation. Dosages for children are:

- 3 to 12 years, 50 mg of stable iodine (85 mg of potassium iodate)
- 1 month to 3 years, 25 mg of stable iodine (42.5 mg of potassium iodate)
- neonates, 12.5 mg of stable iodine (21.25 mg of potassium iodate) given as a single dose.

When evacuation is delayed, repeated daily doses may become necessary.

Levothyroxine Sodium *(BANM, rINN)*

Levothyroxin sodná sůl hydrát; Lévothyroxine sodique; Levothyroxinnatrium; Levothyroxinum natricum; Levothyroxinum Natricum Hydricum; Levotiroksin Sodyum; Levotiroksino natrio druska; Levotiroxina sódica; Levotiroxin-nátrium; Levotyroksiininatrium; Levotyroxinnatrium; Lewotyroksyna sodowa; 3,5,3′,5′-Tetraiodo-L-thyronine Sodium; Thyroxine Sodium; L-Thyroxine Sodium; Thyroxinum Natricum; Tirossina; Tiroxina Sodica. Sodium 4-*O*-(4-hydroxy-3,5-di-iodophenyl)-3,5-di-iodo-L-tyrosine hydrate.

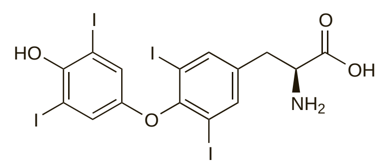
Левотироксин Натрий

$C_{15}H_{10}I_4NNaO_4,xH_2O$ = 798.9 (anhydrous).

CAS — 51-48-9 (levothyroxine); 55-03-8 (anhydrous levothyroxine sodium); 25416-65-3 (levothyroxine sodium, hydrate); 8065-29-0 (liotrix).

ATC — H03AA01.

ATC Vet — QH03AA01.



(levothyroxine)

NOTE. The abbreviation T_4 is often used for endogenous thyroxine in medical and biochemical reports. Liotrix is *USAN* for a mixture of liothyronine sodium with levothyroxine sodium.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Int. includes the anhydrous form.

Ph. Eur. 6.2 (Levothyroxine Sodium). An almost white or slightly brownish-yellow powder or a fine, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol. It dissolves in dilute solutions of alkali hydroxides. Store at 2° to 8° in airtight containers. Protect from light.

USP 31 (Levothyroxine Sodium). The sodium salt of L-3,3′,5,5′-tetraiodothyronine. A light yellow to buff-coloured, odourless, hygroscopic, powder. It may assume a slight pink colour on exposure to light. Soluble 1 in 700 of water and 1 in 300 of alcohol; insoluble in acetone, in chloroform, and in ether; soluble in solutions of alkali hydroxides and in hot solutions of alkali carbonates. pH of a saturated solution in water is about 8.9. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

The adverse effects of levothyroxine are generally associated with excessive dosage and correspond to symptoms of hyperthyroidism. They may include tachycardia, palpitations, cardiac arrhythmias, increase in blood pressure, anginal pain, headache, restlessness, excitability, insomnia, tremors, muscle weakness and cramps, heat intolerance, sweating, flushing, fever, weight loss, menstrual irregularities, diarrhoea, and vomiting. These adverse reactions usually disappear after dosage reduction or temporary withdrawal of treatment. Thyroid storm has occasionally been reported after massive or chronic intoxication and convulsions, cardiac arrhythmias, heart failure, coma, and death have occurred.

In acute overdosage, activated charcoal may be used to reduce gastrointestinal absorption if ingestion of more than 10 mg by an adult, or 5 mg by a child, has occurred within 1 hour. Treatment is usually symptomatic and supportive; propranolol may be useful in controlling the symptoms of sympathetic overactivity. Levothyroxine overdosage requires an extended follow-up period as symptoms may be delayed for up to 6 days due to the gradual peripheral conversion of levothyroxine to tri-iodothyronine. US licensed product information has suggested that glucocorticoids may be given to inhibit this conversion.

Carcinogenicity. An association between the use of thyroid hormones and an increased risk of breast cancer in women has been proposed,[1] but a further analysis of the data did not confirm such an association,[2] and nor did later studies.[3-5]

5. Hoffman DA, *et al.* Breast cancer in hypothyroid women using thyroid supplements. *JAMA* 1984; **251:** 616–19.

Effects on the bones. Hyperthyroidism is a known risk factor for osteoporosis and theoretically thyroid hormone therapy may also be a risk factor. A review of over 3000 patients from 63 studies summarised the available evidence on the association of levothyroxine and bone mineral density.[1] It was stressed that current findings are complex and confusing and poor methodological quality makes comparison of results difficult. However, it was concluded that neither dose of levothyroxine nor duration of therapy had any relationship with bone mineral density: 31 studies showed no overall effect of levothyroxine, 23 studies provided partial negative and/or positive effects, while 9 showed overall negative effects. For postmenopausal women, particularly those with a history of hyperthyroidism, the review[1] recommended monitoring of thyroid hormone levels to avoid clinical hyperthyroidism, and screening for risk factors of osteoporosis; if warranted, bone densitometry, and appropriate management of any decline in bone mineral density, should be used.

1. Schneider R, Reiners C. The effect of levothyroxine therapy on bone mineral density: a systematic review of the literature. *Exp Clin Endocrinol Diabetes* 2003; **111:** 455–70.

Effects on the muscles. A woman with previous normal thyroid function developed periodic paralysis affecting the limbs after abusing levothyroxine, 100 micrograms twice daily for 2 weeks, in order to lose weight.[1] The attack subsided after treatment with intravenous potassium and withdrawal of the levothyroxine.

1. Chen YC, *et al.* Thyrotoxic periodic paralysis in a patient abusing thyroxine for weight reduction. *Ren Fail* 2001; **23:** 139–42.

Effects on the nervous system. Two children aged 8 and 11 years developed pseudotumor cerebri (benign intracranial hypertension) shortly after starting levothyroxine for hypothyroidism.[1] There have been further reports on individual children[2,3] and infants.[4]

Partial complex status epilepticus, with confusion, agitation, and continuous myoclonic jerks in the left side of the face and left hand, was seen in a hypothyroid patient with Turner's syndrome who was receiving levothyroxine for myxoedema coma.[5] The condition responded to anticonvulsants; the patient subsequently remained seizure-free on a reduced dose of levothyroxine and concomitant phenytoin.

Hypersensitivity. A hypersensitivity reaction (fever, eosinophilia, and liver dysfunction) was reported[1] in a 63-year-old hypothyroid woman with Hashimoto's thyroiditis during treatment with liothyronine or levothyroxine. Symptoms disappeared when the drugs were stopped. After an interval of 4 months liothyronine was gradually reintroduced without adverse effect.

Urticaria and angioedema have been described in a patient who received thyroid and levothyroxine.[2] In a further case similar reactions were attributed to the presence of sunset yellow as colouring agent in the proprietary levothyroxine preparation.[3]

3. Lévesque H, *et al.* Reporting adverse drug reactions by proprietary name. *Lancet* 1991; **338:** 393.

Overdosage. In overdosage with thyroid drugs aggressive therapy is not normally justified in asymptomatic patients, although various regimens have been tried in large overdosage.

Massive overdoses of levothyroxine and liothyronine (up to 1000 times the normal dose over 2 to 12 days) have been described in small numbers of patients.[1-6] Symptoms of thyrotoxicosis can occur within the first 6 hours after ingestion of liothyronine but can be delayed for 2 to 5 days after levothyroxine, due to the time taken for metabolic conversion to liothyronine. Symptoms of thyrotoxicosis that have been reported include fever, arrhythmias, tachycardia, increased blood pressure, confusion, agitation, neurological complications, and coma.[1,2,5] Treatment of overdosage includes consideration of the use of activated charcoal and a beta blocker such as propranolol or metoprolol to treat tachyarrhythmia.[2,4,5] In most cases serious toxicity does not occur and patients recover with supportive therapy. Diuresis and haemodialysis do not enhance elimination because thyroid hormones are highly protein bound. It has also been concluded that plasmapheresis and haemoperfusion provide no significant clinical benefit.[4,6]

Precautions

Levothyroxine is contra-indicated in untreated hyperthyroidism. It has a narrow therapeutic index and should be used with extreme caution in patients with cardiovascular disorders including angina, heart failure, myocardial infarction, and hypertension; lower initial doses, smaller increments, and longer intervals between increases should be used as necessary. An ECG performed before starting treatment with levothyroxine may help to distinguish underlying myocardial ischaemia from changes induced by hypothyroidism. Levothyroxine should also be introduced very gradually in elderly patients and those with long-standing hypothyroidism to avoid any sudden increase in metabolic demands. It should not be given to patients with adrenal insufficiency without adequate corticosteroid cover otherwise the thyroid replacement therapy might precipitate an acute adrenal crisis. Care is also required when levothyroxine is given to patients with diabetes mellitus or diabetes insipidus.

Tests of thyroid function are subject to alteration by a number of nonthyroidal clinical conditions and by a wide variety of drugs, some of which are mentioned under Interactions, below.

Abuse. For mention of abuse of levothyroxine by athletes for weight loss see Obesity, under Uses and Administration, below. For reference to periodic paralysis in a woman abusing levothyroxine as a slimming aid, see under Effects on the Muscles, above.

Adrenocortical insufficiency. Thyroid-hormone replacement without additional corticosteroids may precipitate acute adrenocortical insufficiency in patients with impaired adrenocortical function, including those with subclinical or unrecognised adrenocortical disease.[1] Prompt diagnosis and replacement of corticosteroids can prevent the development of a potentially fatal crisis. It has been pointed out that a raised concentration of thyroid-stimulating-hormone alone may not necessarily imply hypothyroidism in patients with chronic adrenocortical insufficiency.[2] Even confirmed hypothyroidism in these patients may not be permanent.

2. Davis J, Sheppard M. Acute adrenal crisis precipitated by thyroxine. *BMJ* 1986; **292:** 1595.

Anaemia. Four patients with iron deficiency anaemia and primary hypothyroidism developed palpitations and restlessness on treatment with levothyroxine sodium, and the drug had to be stopped. Upon correction of the anaemia with ferrous sulfate, all were able to tolerate levothyroxine therapy.[1] For a warning that ferrous sulfate reduces absorption of levothyroxine from the gastrointestinal tract, see Iron Salts under Interactions, below.

1. Shakir KMM, *et al.* Anemia: a cause of intolerance to thyroxine sodium. *Mayo Clin Proc* 2000; **75:** 189–92.

Breast feeding. Minimal amounts of thyroid hormones are distributed into breast milk.[1] Although levothyroxine in breast milk will be insufficient to treat any hypothyroidism in the suckling newborn, it has been suggested that it may mask detection of any hypothyroidism in such a neonate.[2] However, the *BNF* considers that the amounts involved are too small to affect tests for neonatal hypothyroidism. The American Academy of Pediatrics noted that no effects have been seen in breast-fed infants whose mothers were taking levothyroxine and as such considers its use to be usually compatible with breast feeding.[3]

1. Bennett PN, ed. *Drugs and human lactation.* Amsterdam: Elsevier, 1988.
2. Anonymous. Can a woman on thyroxine safely breast-feed her baby? *BMJ* 1977; **2:** 1589.

Cardiovascular disorders. There is a complex relationship between the heart and thyroid.[1] Cardiovascular abnormalities may be associated with hypothyroidism as well as with levothyroxine replacement therapy, hence the need for caution.

1. Gammage M, Franklyn J. Hypothyroidism, thyroxine treatment, and the heart. *Heart* 1997; **77:** 189–90.

Myasthenia. Thyroid hormones may occasionally precipitate or exacerbate a pre-existing myasthenic syndrome.[1,2]

2. Lane RJM, Routledge PA. Drug-induced neurological disorders. *Drugs* 1983; **26:** 124–47.

Pregnancy. Most authorities consider that thyroid hormones do not readily cross the placenta. Placental transfer has been reported,[1] but in amounts so limited that a mother with physiological concentrations of thyroxine and tri-iodothyronine would not provide normal thyroid hormone concentrations to a fetus with congenital hypothyroidism.[2-4]

Levothyroxine requirements increase in hypothyroid women during early pregnancy. A small study involving 20 pregnancies found that the dose requirement rose from the sixth to the sixteenth week of gestation before reaching a plateau; a mean dose increase of nearly 50% was eventually required in 17 cases.[5] The authors recommended that all hypothyroid women should have their levothyroxine dose increased by 30% as soon as pregnancy was confirmed, to avoid any risk of an initial period of hypothyroxinaemia before the first obstetric visit. Thereafter, dosage should be adjusted according to serum-thyrotropin concentrations.

5. Alexander EK, *et al.* Timing and magnitude of increases in levothyroxine requirements during pregnancy in women with hypothyroidism. *N Engl J Med* 2004; **351:** 241–9.

Interactions

Antiarrhythmics. *Amiodarone*[1] may inhibit the de-iodination of thyroxine to tri-iodothyronine resulting in a decreased concentration of tri-iodothyronine with a rise in the concentration of inactive reverse tri-iodothyronine.

1. Hershman JM, *et al.* Thyroxine and triiodothyronine kinetics in cardiac patients taking amiodarone. *Acta Endocrinol (Copenh)* 1986; **111:** 193–9.

Antibacterials. Enzyme induction by *rifampicin*[1,2] enhances thyroid hormone metabolism resulting in reduced serum concentrations of thyroid hormones.

Two patients with previously stable thyroid function while receiving levothyroxine were found to have developed hypothyroidism 3 to 4 weeks after starting oral treatment with *ciprofloxacin*.[3] In one patient increasing the dose of levothyroxine was ineffective and thyroid function only returned to normal after ciprofloxacin was withdrawn. In the other patient, giving the drugs 6 hours apart was sufficient to overcome the interaction.

2. Nolan SR, *et al.* Interaction between rifampin and levothyroxine. *South Med J* 1999; **92:** 529–31.
3. Cooper JG, *et al* Ciprofloxacin interacts with thyroid replacement therapy. *BMJ* 2005; **330:** 1002.

Anticoagulants. Thyroid hormones enhance the effects of *oral anticoagulants* (see under the interactions of Warfarin, p.1432). Patients on anticoagulant therapy therefore require careful monitoring when treatment with thyroid drugs is started or altered as the oral anticoagulant dose may need to be adjusted.

Antidepressants. Some drugs such as *lithium* act directly on the thyroid gland and inhibit the release of thyroid hormones leading to clinical hypothyroidism.[1]

The effects of levothyroxine in hypothyroid patients may be decreased by use with *sertraline*, and the dose of levothyroxine may need to be increased.[2]

For the effects of thyroid hormones on *tricyclic antidepressants* see under Amitriptyline, p.381.

2. McCowen KC, *et al.* Elevated serum thyrotropin in thyroxine-treated patients with hypothyroidism given sertraline. *N Engl J Med* 1997; **337:** 1010–11.

Antidiabetics. As thyroid status influences metabolic activity and most body systems, correction of hypothyroidism may affect other disease states and dosage of any drug treatment. In hypothyroid diabetics for instance, starting thyroid replacement therapy may increase their *insulin* or *oral hypoglycaemic* requirements.[1]

1. Refetoff S. Thyroid hormone therapy. *Med Clin North Am* 1975; **59:** 1147–62.

Antiepileptics. Enzyme induction by drugs such as *carbamazepine*,[1,2] *phenytoin*,[2,3] or *barbiturates*[4] enhances thyroid hormone metabolism resulting in reduced serum concentrations of thyroid hormones. Therefore, patients on thyroid replacement therapy may require an increase in their dose of thyroid hormone if these drugs are also given[5] and a decrease if the enzyme-inducing drug is withdrawn.[6] *Phenytoin*,[3] and *carbamazepine* may reduce protein binding by displacing the thyroid hormones from their plasma-binding sites. As thyroid hormones are highly protein bound, changes in binding might be expected to influence requirements in thyroid replacement therapy, but in practice there is little clinical evidence of any problems except with thyroid-function testing.

1. Connell JMC, *et al.* Changes in circulating thyroid hormones during short-term hepatic enzyme induction with carbamazepine. *Eur J Clin Pharmacol* 1984; **26:** 453–6.

6. Hoffbrand BI. Barbiturate/thyroid-hormone interaction. *Lancet* 1979; **ii:** 903–4.

Antimalarials. Increased thyroid-stimulating hormone concentration has been noted after the use of *chloroquine* with *proguanil* for malaria prophylaxis in a patient stabilised on levothyroxine.[1] Induction of liver enzymes by chloroquine resulting in increased metabolism of levothyroxine was suggested as the mechanism.

1. Munera Y, *et al.* Interaction of thyroxine sodium with antimalarial drugs. *BMJ* 1997; **314:** 1593.

Antineoplastics. Eight patients taking levothyroxine, subsequent to thyroidectomy, developed raised concentrations of thyroid-stimulating hormone (TSH) and clinical hypothyroidism when they were given *imatinib*. Increasing the levothyroxine dose reversed hypothyroidism in only 3 patients, but TSH concentrations returned to normal in all patients when imatinib was stopped. In contrast, these effects did not occur in 3 other patients with a normal functioning thyroid. The authors reasoned that imatinib might have stimulated the clearance of thyroxine and tri-iodothyronine by inducing uridine diphosphate glucuronosyltransferases, but evidence is needed to confirm this mechanism. They suggested that the dose of levothyroxine should be at least doubled, with close monitoring of thyroid function, before imatinib is given to patients with hypothyroidism.[1]

1. de Groot JWB, *et al.* Imatinib induces hypothyroidism in patients receiving levothyroxine. *Clin Pharmacol Ther* 2005; **78:** 433–8.

Antivirals. There have been reports of interactions between HIV protease inhibitors and levothyroxine. An increased dose of levothyroxine was necessary with *ritonavir*[1] whereas a decreased dose was needed with *indinavir*.[2]

1. Tseng A, Fletcher D. Interaction between ritonavir and levothyroxine. *AIDS* 1998; **12:** 2235–6.
2. Lanzafame M, *et al.* Interaction between levothyroxine and indinavir in a patient with HIV infection. *Infection* 2002; **30:** 54–5.

Beta blockers. Studies have indicated that plasma concentrations of *propranolol* are reduced in hyperthyroidism compared with the euthyroid state, probably due to increased clearance[1-4] and hypothyroid patients receiving chronic propranolol therapy have had a reduction in plasma-propranolol concentrations when given levothyroxine treatment.[2]

Propranolol may inhibit the de-iodination of thyroxine to tri-iodothyronine resulting in a decreased concentration of tri-iodothyronine and a rise in the concentration of inactive reverse tri-iodothyronine.[5,6]

6. Wilkins MR, *et al.* Effect of propranolol on thyroid homeostasis of healthy volunteers. *Postgrad Med J* 1985; **61:** 391–4.

Cardiac glycosides. Serum-digoxin concentrations appear to be lower in hyperthyroidism and higher in hypothyroidism,[1] which may contribute in part to the observed insensitivity of hyperthyroid patients to *digoxin* therapy,[2] although other mechanisms have been proposed.[3]

1. Croxson MS, Ibbertson HK. Serum digoxin in patients with thyroid disease. *BMJ* 1975; **3:** 566–8.
2. Huffman DH, *et al.* Digoxin in hyperthyroidism. *Clin Pharmacol Ther* 1977; **22:** 533–8.
3. Lawrence JR, *et al.* Digoxin kinetics in patients with thyroid dysfunction. *Clin Pharmacol Ther* 1977; **22:** 7–13.

Gastrointestinal drugs. *Sucralfate* reduces absorption of levothyroxine from the gastrointestinal tract[1,2] as does *aluminium hydroxide*,[3] and *calcium carbonate*.[4,5]

1. Sherman SI, *et al.* Sucralfate causes malabsorption of L-thyroxine. *Am J Med* 1994; **96:** 531–5.
2. Campbell JA, *et al.* Sucralfate and the absorption of -thyroxine. *Ann Intern Med* 1994; **121:** 152.

4. Schneyer CR. Calcium carbonate and reduction of levothyroxine efficacy. *JAMA* 1998; **279:** 750.
5. Singh N, *et al.* Effect of calcium carbonate on the absorption of levothyroxine. *JAMA* 2000; **283:** 2822–5.

General anaesthetics. Severe hypertension and tachycardia have been reported[1] when *ketamine* was used in patients taking levothyroxine.

1. Kaplan JA, Cooperman LH. Alarming reactions to ketamine in patients taking thyroid medication-treatment with propranolol. *Anesthesiology* 1971; **35:** 229–30.

Ion-exchange resins. *Colestyramine* significantly reduces the absorption of levothyroxine by binding with thyroid hormones in the gastrointestinal tract. The malabsorption of levothyroxine is minimised by allowing an interval of 4 to 5 hours to elapse between taking the two drugs.[1] A similar effect has been seen with *sodium polystyrene sulfonate*.[2]

1. Northcutt RC, *et al.* The influence of cholestyramine on thyroxine absorption. *JAMA* 1969; **208:** 1857–61.
2. McLean M, *et al.* Cation-exchange resin and inhibition of intestinal absorption of thyroxine. *Lancet* 1993; **341:** 1286.

Iron salts. *Ferrous sulfate* reduces absorption of levothyroxine from the gastrointestinal tract.[1]

1. Campbell NRC, *et al.* Ferrous sulfate reduces thyroxine efficacy in patients with hypothyroidism. *Ann Intern Med* 1992; **117:** 1010–13.

Lipid regulating drugs. Both decreased efficacy[1] and increased efficacy[2] of levothyroxine have been reported in individual patients given *lovastatin.* Increased thyroid stimulating hormone concentrations, requiring increased doses of levothyroxine, have been reported when *simvastatin* was begun.[3]

1. Demke DM. Drug interaction between thyroxine and lovastatin. *N Engl J Med* 1989; **321:** 1341–2.
2. Gormley GJ, Tobert JA. Drug interaction between thyroxine and lovastatin. *N Engl J Med* 1989; **321:** 1342.
3. Kisch E, Segall HS. Interaction between simvastatin and -thyroxine. *Ann Intern Med* 2005; **143:** 547.

NSAIDs. Falsely low concentrations of levothyroxine (T_4) or tri-iodothyronine (T_3) have been reported during treatment with some anti-inflammatory drugs. Serum TSH measurements are less affected by NSAIDs and therefore TSH would be the optimal screening test in patients receiving an NSAID.[1]

1. Samuels MH, *et al.* Variable effects of nonsteroidal antiinflammatory agents on thyroid test results. *J Clin Endocrinol Metab* 2003; **88:** 5710–16.

Sex hormones. *Oestrogen* therapy increases serum concentrations of thyroxine-binding globulin, thus increasing the amount of bound thyroxine. Normal thyroid function stimulates thyroxine synthesis to compensate for this effect and maintain normal free-thyroxine serum concentrations. In hypothyroidism, however, patients treated with exogenous levothyroxine who receive oestrogens, as in oral contraceptives or HRT,[1] may require an increase in levothyroxine dose. In contrast, *androgens* reduce the concentration of the binding globulin, which has resulted in clinical hyperthyroidism when given to postmenopausal women maintained on levothyroxine replacement therapy.[2]

Increased levothyroxine requirements were noted in a 79-year-old woman when she took *raloxifene* at the same time as her levothyroxine; absorption studies indicated that the effect could be reversed by separating doses of the two drugs by about 12 hours.[3]

1. Arafah BM. Increased need for thyroxine in women with hypothyroidism during estrogen therapy. *N Engl J Med* 2001; **344:** 1743–9.
2. Arafah BM. Decreased levothyroxine requirement in women with hypothyroidism during androgen therapy for breast cancer. *Ann Intern Med* 1994; **121:** 247–51.
3. Siraj ES, *et al.* Raloxifene causing malabsorption of levothyroxine. *Arch Intern Med* 2003; **163:** 1367–70.

Sympathomimetics. Thyroid drugs increase metabolic demands and should therefore be used with caution with other drugs known to influence cardiac function, such as the *sympathomimetics*, as they may enhance this effect. In addition, thyroid hormones may increase receptor sensitivity to catecholamines.

Pharmacokinetics

Levothyroxine is variably absorbed from the gastrointestinal tract after oral doses. Fasting increases absorption. Once in the circulation, levothyroxine is extensively protein bound, principally to thyroxine-binding globulin (TBG) but also to a lesser extent to thyroxine-binding pre-albumin (TBPA) or to albumin. Levothyroxine has a plasma half-life of about 6 to 7 days in euthyroid subjects; the half-life is prolonged in hypothyroidism and reduced in hyperthyroidism.

Levothyroxine is primarily metabolised in the liver and kidney to tri-iodothyronine (liothyronine) and, about 40%, to inactive reverse tri-iodothyronine (reverse T_3) both of which undergo further deiodination to inactive metabolites. Further metabolites result from the deamination and decarboxylation of levothyroxine to tetra-iodothyroacetic acid.

Levothyroxine undergoes enterohepatic recycling and excretion in the faeces.

The distribution of thyroid hormones into breast milk and across the placenta is discussed under Breast Feeding and Pregnancy (above).

Uses and Administration

Levothyroxine is a thyroid hormone (see p.2165 for a description of the endogenous hormones) used as replacement therapy in the treatment of hypothyroidism (p.2167). It is given in conditions such as diffuse non-toxic goitre (see Goitre and Thyroid Nodules, p.2165) and Hashimoto's thyroiditis (see Hypothyroidism, p.2167) to suppress the secretion of thyroid-stimulating hormone (TSH) and hence prevent or reverse enlargement of the thyroid gland. Levothyroxine is also used to suppress TSH production in the treatment of thyroid carcinoma (p.674) and as a diagnostic agent for the differential diagnosis of hyperthyroidism. It is given with antithyroid drugs in the blocking-replacement regimen for the management of hyperthyroidism (p.2165).

The peak therapeutic effect of regular oral levothyroxine may not be achieved for several weeks and there is a slow response to changes in dosage. Similarly, effects may persist for several weeks after withdrawal. Levothyroxine is given as the sodium salt in a single daily dose. Its absorption can be irregular and it is probably best taken on an empty stomach, usually before breakfast.

The dose of levothyroxine sodium for the treatment of any thyroid disorder should be individualised on the basis of clinical response and biochemical tests and should be monitored regularly.

In hypothyroidism an initial adult oral dose of 50 to 100 micrograms of levothyroxine sodium daily may be increased by 25 to 50 micrograms at intervals of about 4 weeks until the thyroid deficiency is corrected and a maintenance dose is established. The adult maintenance dose is usually between 100 and 200 micrograms daily. In elderly patients, in those with cardiovascular disorders, or in those with severe hypothyroidism of long standing, treatment should be introduced more gradually: an initial dose of 12.5 to 50 micrograms daily increased by increments of 12.5 to 25 micrograms at intervals of about 4 weeks may be appropriate.

In children, individualisation of dosage and monitoring of treatment is especially important. In the UK, the *BNFC* recommends the following oral doses:

- neonates: 10 to 15 micrograms/kg once daily initially, adjusted in steps of 5 micrograms/kg every 2 weeks or as needed, to a usual dose of 20 to 50 micrograms daily
- children aged 1 month to 2 years: 5 to 10 micrograms/kg once daily initially, adjusted in steps of 25 micrograms daily every 2 to 4 weeks until metabolism is normalised, to a usual dose of 25 to 100 micrograms daily
- children aged 2 to 12 years: 5 micrograms/kg once daily initially, adjusted in steps of 25 micrograms daily every 2 to 4 weeks until metabolism is normalised, to a usual dose of 75 to 100 micrograms daily
- children aged 12 to 18 years: 50 to 100 micrograms once daily initially, adjusted in steps of 25 to 50 micrograms daily every 3 to 4 weeks until metabolism is normalised, to a usual dose of 100 to 200 micrograms daily

Doses are reduced by 50% in cardiac disease, and increased more slowly.

Levothyroxine sodium may be given by intravenous injection. It has also been given intramuscularly. In myxoedema (hypothyroid) coma doses of 200 to 500 micrograms by intravenous injection may be given initially. A further dose of 100 to 300 micrograms is given on the second day if no improvement is evident, and followed by daily supplements of about 100 to 200 micrograms until the patient is euthyroid and can tolerate oral doses.

Dextrothyroxine, the D-isomer of levothyroxine, has lipid regulating properties and has been used in the management of hypercholesterolaemia, but its use is severely limited by cardiotoxicity; it has only weak thyroid hormone activity.

Administration. There has been controversy over the bioequivalence or otherwise of different brands of levothyroxine. Most studies and reports have come from the USA and results may have depended to some extent on the particular brands compared. Formulations may also have changed which makes comparison of results difficult. One study[1] concluded that 2 generic levothyroxine products were bioequivalent and interchangeable with 2 branded products.

In 2004 the FDA issued guidance on the bioequivalence of several levothyroxine products on the US market but this was heavily criticised in a joint statement by several American professional societies.[2] In response these societies recommended to physicians that patients should be maintained on the same brand of levothyroxine and if the brand were changed then the patient's serum TSH should be retested and the dosage of levothyroxine re-titrated as necessary.

1. Dong BJ, *et al.* Bioequivalence of generic and brand-name levothyroxine products in the treatment of hypothyroidism. *JAMA* 1997; **277:** 1205–13.

Joint Statement on the U.S. Food and Drug Administration's decision regarding bioequivalence of levothyroxine sodium. *Thyroid* 2004; **14:** 486.

Cardiomyopathies. Management of dilated cardiomyopathy (p.1163) usually involves conventional therapy for heart failure, but a small study has reported benefit from short-term use of levothyroxine.[1] Levothyroxine was well tolerated but thyroid-stimulating hormone levels were reduced, which might limit long-term therapy.

1. Moruzzi P, *et al.* Medium-term effectiveness of L-thyroxine treatment in idiopathic dilated cardiomyopathy. *Am J Med* 1996; **101:** 461–7.

Depression. While thyroid hormones may increase the activity of tricyclic antidepressants (see Thyroid Hormones, under Interactions of Amitriptyline, p.381), the benefits in the augmentation treatment of depression (p.373) are debatable. A meta-analysis[1] of 8 studies involving 292 patients with refractory depression treated with liothyronine in addition to tricyclic antidepressants indicated that such therapy was effective in a subgroup of cases but that the small number of patients studied made additional placebo-controlled data desirable.

In non-refractory depression a meta-analysis[2] also indicated a benefit when liothyronine was added to tricyclic antidepressants although it was acknowledged that many of the studies were old with methodological limitations. However, a controlled trial of liothyronine with paroxetine could not confirm any advantage of additive therapy.[3]

3. Appelhof BC, *et al.* Triiodothyronine addition to paroxetine in the treatment of major depressive disorder. *J Clin Endocrinol Metab* 2004; **89:** 6271–6.

Obesity. Thyroid drugs have been tried in the treatment of obesity (p.2149) in euthyroid patients, but they produce only temporary weight loss, mainly of lean body-mass, and can produce serious adverse effects, especially cardiac complications.[1] Hypothyroidism has also been reported[2] when these drugs were withdrawn from previously euthyroid patients being treated for simple obesity. Levothyroxine appears to have been abused by some athletes to promote weight loss.[3]

3. MacAuley D. Drugs in sport. *BMJ* 1996; **313:** 211–15.

Urticaria. There is some suggestion that chronic urticaria (p.1584) may be associated with thyroid autoimmunity and that treatment with thyroid hormones may result in clinical remission.[1] In one study, a nine-year-old boy was successfully treated for chronic urticaria with levothyroxine therapy at doses of 50 to 100 micrograms daily.[2] The authors advised screening for thyroid function and anti-thyroid microsomal antibodies in cases of chronic urticaria as these patients may benefit from thyroid hormone therapy. A small investigative study concluded that treatment with levothyroxine sodium (in hypothyroid patients) or antithyroid drugs (in patients with Graves' disease) is of benefit in patients with severe chronic urticaria associated with thyroid autoimmunity.[3]

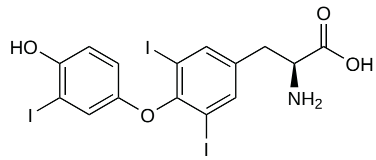
Натрий Лиотиронин

$C_{15}H_{11}I_3NNaO_4$ = 673.0.

CAS — 6893-02-3 (liothyronine); 55-06-1 (liothyronine sodium); 8065-29-0 (liotrix).

ATC — H03AA02.

ATC Vet — QH03AA02.



(liothyronine)

NOTE. The abbreviation T_3 is often used for endogenous tri-iodothyronine in medical and biochemical reports. Liotrix is *USAN* for a mixture of liothyronine sodium with levothyroxine sodium.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Liothyronine Sodium). A white or almost white or slightly coloured powder. Practically insoluble in water; slightly soluble in alcohol. It dissolves in dilute solutions of alkali hydroxides. Store at 2° to 8° in airtight containers. Protect from light.

USP 31 (Liothyronine Sodium). A light tan, odourless, crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; practically insoluble in most other organic solvents. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Levothyroxine Sodium, p.2171.

Interactions

As for Levothyroxine Sodium, p.2172.

Pharmacokinetics

Liothyronine is readily and almost completely absorbed from the gastrointestinal tract. Once in the circulation, liothyronine binds principally to thyroxine-binding globulin (TBG), although less strongly than levothyroxine; some is also bound to thyroxine-binding pre-albumin (TBPA) or to albumin. Liothyronine has a plasma half-life in euthyroidism of about 1 to 2 days; the half-life is prolonged in hypothyroidism and reduced in hyperthyroidism.

Liothyronine is metabolised by deiodination to inactive di-iodothyronine and mono-iodothyronine. Iodine released by deiodination is largely reused within the thyroid cells. Further metabolites result from deamination and decarboxylation to tiratricol (triac).

Uses and Administration

Liothyronine is a thyroid hormone (see p.2165). It is used in the treatment of hypothyroidism (p.2167), and is believed to be more active than levothyroxine (p.2173). The onset of action of liothyronine is rapid, developing within a few hours, and therefore it tends to be used in circumstances where this, and its short duration of action, are useful, particularly in hypothyroid (myxoedema) coma.

With regular dosing the peak therapeutic effect is usually achieved after 3 days; on withdrawal its effects may persist for 1 to 3 days.

The dose of liothyronine should be individualised on the basis of clinical response and biochemical tests and should be monitored regularly. Although liothyronine is given as the sodium salt, doses can be expressed in terms of liothyronine sodium or liothyronine; the doses below are in terms of liothyronine sodium. Liothyronine sodium 10.3 micrograms is equivalent to about 10 micrograms of liothyronine. Liothyronine sodium 20 to 25 micrograms is generally considered to be equivalent in activity to about 100 micrograms of levothyroxine sodium.

In **hypothyroidism** a usual initial adult oral dose is 5 to 25 micrograms daily, increased gradually to a maintenance dose of 60 to 75 micrograms daily in 2 to 3 divided doses, although up to 100 micrograms daily may be required in some patients. In elderly patients, in those with cardiovascular disorders, or in those with severe long-standing hypothyroidism, treatment should be introduced with doses at the low end of the range, with smaller increments, and longer intervals between increases, as necessary.

In **myxoedema coma** liothyronine sodium may be given intravenously in a dose of 5 to 20 micrograms by slow intravenous injection, repeated as necessary, usually at intervals of 12 hours; the minimum interval between doses is 4 hours. An alternative regimen advocates an initial dose of 50 micrograms intravenously followed by further injections of 25 micrograms every 8 hours until improvement occurs; the dosage may then be reduced to 25 micrograms intravenously twice daily.

Liothyronine has also been given in the **diagnosis** of hyperthyroidism in adults. Failure to suppress the uptake of radio-iodine after several days of receiving liothyronine sodium suggests a diagnosis of hyperthyroidism.

Liothyronine hydrochloride has also been used.

Preparations

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Potassium Perchlorate). A white or almost white crystalline powder or colourless crystals. Sparingly soluble in water; practically insoluble in alcohol.

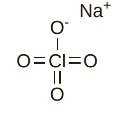
USP 31 (Potassium Perchlorate). pH of a 0.1M solution in water is between 5.0 and 6.5.

Sodium Perchlorate

Perclorato sódico; Sodu nadchloran.

$NaClO_4$ = 122.4.

CAS — 7601-89-0 (anhydrous sodium perchlorate); 7791-07-3 (sodium perchlorate monohydrate).



(anhydrous sodium perchlorate)

Handling. Potassium and sodium perchlorate have been used for the illicit preparation of explosives or fireworks; care is required with their supply. Great caution should be taken in handling perchlorates in solution or in the dry state as explosions may occur if brought into contact with organic or other readily oxidisable substances.

Adverse Effects

Fever and rashes have occurred after use of perchlorate. Some patients may experience nausea and vomiting. Potassium perchlorate seldom produces adverse effects when given as a single dose for diagnostic purposes. Prolonged use as an antithyroid drug has been associated with serious dose-related adverse effects. Aplastic anaemia (with some fatalities), agranulocytosis, leucopenia, pancytopenia, and the nephrotic syndrome have been reported. Excessive doses may cause hypothyroidism and goitre.

Effects on the blood. There have been reports of fatal aplastic anaemia[1,2] and of leucopenia and agranulocytosis[1] associated with the use of potassium perchlorate for the treatment of hyperthyroidism. A review[3] in 1998 noted that despite an increase in perchlorate use in recent years there did not appear to have been any further cases of aplastic anaemia since the 1960s.

2. Krevans JR, *et al.* Fatal aplastic anemia following use of potassium perchlorate in thyrotoxicosis. *JAMA* 1962; **181:** 182–4.
3. Wolff J. Perchlorate and the thyroid gland. *Pharmacol Rev* 1998; **50:** 89–105.

Uses and Administration

Potassium and sodium perchlorate reduce the uptake and concentration of iodide, pertechnetate, and other anions by the thyroid, choroid plexus, gastric mucosa, and salivary glands, probably by competitive inhibition of active transport mechanisms.

They are used **diagnostically** as adjuncts to pertechnetate (^{99m}Tc) to enhance visualisation of the brain, Meckel's diverticulum, or the placenta by reducing unwanted images of other organs. The usual oral dose of either potassium or sodium perchlorate is 200 to 400 mg given 30 to 60 minutes before the use of sodium pertechnetate (^{99m}Tc).

Potassium and sodium perchlorate are also used with sodium iodide (^{131}I) in the perchlorate discharge test of thyroid function. The release of radio-iodine from the gland following an oral dose of perchlorate indicates a defect in the binding of iodide by the thyroid and thus a defect in thyroid hormone synthesis. The test has also been used to investigate the action of antithyroid drugs.

Potassium and sodium perchlorate have been used in the treatment of **hyperthyroidism** (p.2165), but because of toxicity have been largely replaced by alternative treatments. However, perchlorates may be useful in patients with iodine-induced hyperthyroidism such as that associated with amiodarone therapy, by increasing responsiveness to conventional antithyroid drugs. A typical dose of potassium perchlorate in amiodarone-induced hyperthyroidism is 1 g daily.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Propylthiouracil). White or almost white crystals or crystalline powder. Very slightly soluble in water; sparingly soluble in alcohol; dissolves in solutions of alkali hydroxides. Protect from light.

USP 31 (Propylthiouracil). A white, powdery, crystalline substance. It is starch-like in appearance and to the touch. Slightly soluble in water, in chloroform, and in ether; sparingly soluble in alcohol; soluble in ammonium hydroxide and in alkali hydroxides. Protect from light.

Adverse Effects and Precautions

As for Carbimazole, p.2167, although cross-sensitivity to carbimazole does not necessarily occur.

Propylthiouracil has been associated with greater hepatotoxicity than other thiourea antithyroid drugs (such as carbimazole or thiamazole). Rarely hepatitis, hepatic necrosis, encephalopathy, and death have occurred; asymptomatic liver damage is more common (see Effects on the Liver, under Carbimazole, p.2168).

Propylthiouracil should be given with care, and in reduced doses, to patients with renal impairment.

Breast feeding. Propylthiouracil has been preferred to carbimazole or thiamazole since it enters breast milk less readily, see Breast Feeding, under Carbimazole, p.2167.

Pharmacokinetics

Propylthiouracil is rapidly absorbed from the gastrointestinal tract with a 50 to 75% bioavailability and with peak plasma concentrations occurring about 2 hours after oral doses. It is concentrated in the thyroid gland; since its duration of action is more closely related to the intrathyroidal drug concentration than its plasma half-life, prolonged antithyroid activity results from single daily doses. Propylthiouracil is about 80% bound to plasma proteins.

Propylthiouracil has an elimination half-life of about 1 to 2 hours. It undergoes rapid first-pass metabolism in the liver, and is mainly excreted in the urine as the glucuronic acid conjugate, with less than 2% excreted as unchanged drug. The elimination half-life may be increased in renal or hepatic impairment.

Propylthiouracil crosses the placenta and is distributed into breast milk.

Uses and Administration

Propylthiouracil is a thiourea antithyroid drug that acts by blocking the production of thyroid hormones (see p.2165); it also inhibits the peripheral deiodination of thyroxine to tri-iodothyronine. It is used in the management of hyperthyroidism (p.2165), including the treatment of Graves' disease, preparation of hyperthyroid patients for thyroidectomy, use as an adjunct to radioiodine therapy, and the treatment of thyroid storm.

Propylthiouracil is usually given orally. Initial doses range from 150 to 450 mg daily (the *BNF* recommends 200 to 400 mg daily), although in severe cases initial doses of 600 to 1200 mg daily have been used. It has often been given in divided daily doses but once daily dosage is also possible. Improvement is usually seen in 1 to 3 weeks and control of symptoms is achieved in 1 to 2 months. When the patient is euthyroid the dose is gradually reduced to a maintenance dose, usually 50 to 150 mg daily. Treatment is usually continued for 1 to 2 years. In the UK, the *BNFC* recommends the following initial doses by mouth for children:

- in neonates: 2.5 to 5 mg/kg twice daily
- in those aged 1 month to 1 year: 2.5 mg/kg three times daily
- in those aged 1 to 5 years: 25 mg three times daily
- in those aged 5 to 12 years: 50 mg three times daily
- in those aged 12 to 18 years: 100 mg three times daily

These doses are given until the patient is euthyroid and then adjusted as needed; higher doses may be required, especially in thyrotoxic crises.

Doses should be reduced in renal impairment (below). Doses may also need to be reduced in hepatic impairment.

Administration in renal impairment. The dosage of propylthiouracil should be reduced in patients with renal impairment according to creatinine clearance (CC) as follows:

- CC 10 to 50 mL/minute, doses should be reduced by 25%
- CC less than 10 mL/minute, reduce doses by 50%

Alcoholic liver disease. Propylthiouracil has been said to reduce hyperoxic liver injury in hypermetabolic *animals* and despite reports of hepatotoxicity, including some fatalities, associated with propylthiouracil (see Effects on the Liver, under Carbimazole, p.2168), it has been investigated in the treatment of patients with alcoholic liver disease. A systematic review[1], however, concluded that there is no evidence to substantiate this use. Propylthiouracil was associated with adverse effects and it could not be shown to have any significant effects on mortality, liver related mortality, liver complications, and liver histology.

1. Rambaldi A, Gluud C. Propylthiouracil for alcoholic liver disease. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2005 (accessed 01/08/08).

Psoriasis. Several reports have described benefit in patients with psoriasis (p.1583) given propylthiouracil. An oral dose of 300 mg daily for 8 to 12 weeks has been used and is said not to produce clinical hypothyroidism.[1]

1. Elias AN. Anti-thyroid thioureylenes in the treatment of psoriasis. *Med Hypotheses* 2004; **62:** 431–7.

Preparations

BP 2008: Propylthiouracil Tablets;

Protirelin *(BAN, USAN, rINN)*

Abbott-38579; Lopremone; Protireliini; Protirelina; Protirelinas; Protiréline; Protirelinum; Synthetic TRH; Thyrotrophin-releasing Hormone; Thyrotropin-releasing Hormone; TRF; TRH. L-Pyroglutamyl-L-histidyl-L-prolinamide; 1-[*N*-(5-Oxo-L-prolyl)-L-histidyl]-L-prolinamide; Glu-His-Pro-NH_2.

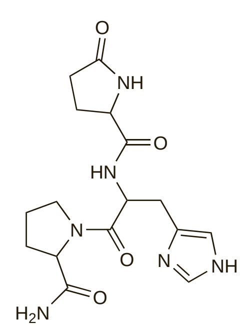
Протирелин

$C_{16}H_{22}N_6O_4 = 362.4.$

CAS — 24305-27-9.

ATC — V04CJ02.

ATC Vet — QV04CJ02.



Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn*, which also includes the tartrate.

Ph. Eur. 6.2 (Protirelin). A synthetic tripeptide with the same sequence of amino acids as the natural hypothalamic neurohormone, that stimulates the release and synthesis of thyrotrophin.

A white or yellowish-white hygroscopic powder. Very soluble in water; freely soluble in methyl alcohol. Store at a temperature of 2° to 8°. Protect from light and moisture.

Adverse Effects

Protirelin given by intravenous injection may cause headache, nausea, a desire to micturate, flushing, dizziness, and a strange taste. These effects have been attributed to contraction of smooth muscles by the bolus injection. Hypertension and an increased pulse rate, or hypotension, have occasionally been reported as have a few cases of amaurosis and convulsions.

Amaurosis. Of 4 patients with pituitary tumours who developed severe headache after protirelin injection, one also developed amaurosis, apparently associated with pituitary apoplexy.[1] Visual acuity improved after surgery.

1. Drury PL, *et al*. Transient amaurosis and headache after thyrotropin releasing hormone. *Lancet* 1982; **i:** 218–19.

Effects on the cardiovascular system. Increased blood pressure has been reported in women given protirelin antenatally,[1,2] and the view has been expressed that although the magnitude of the change is unlikely to be clinically significant in normotensive women, much greater rises have been seen in pre-eclamptic women[2,3] and may be severe enough to increase the risk of cerebral haemorrhage.[2]

1. ACTOBAT Study Group. Australian collaborative trial of antenatal thyrotropin-releasing hormone (ACTOBAT) for prevention of neonatal respiratory disease. *Lancet* 1995; **345:** 877–82.
2. Peek MJ, *et al*. Hypertensive effect of antenatal thyrotropin-releasing hormone in pre-eclampsia. *Lancet* 1995; **345:** 793. Correction. *ibid*.; 1124.
3. Tan ASA, *et al*. Is maternal thyrotropin releasing hormone administration safe in the pregnant women with preeclampsia? *Am J Perinatol* 1997; **14:** 5–6.

Effects on the CNS. Adverse effects reported after injection of 400 micrograms of protirelin included unconsciousness, hypotension, and convulsions.[1] In another patient with a history of convulsions, a 500-microgram injection induced epileptic seizures.[2]

1. Dolva LØ, *et al*. Side effects of thyrotrophin releasing hormone. *BMJ* 1983; **287:** 532.
2. Maeda K, Tanimoto K. Epileptic seizures induced by thyrotropin releasing hormone. *Lancet* 1981; **i:** 1058–9.

Effects on the respiratory system. Bronchospasm occurred in an asthmatic boy given protirelin intravenously.[1]

For a report that protirelin provoked bronchospasm in patients with motor neurone disease, see under Precautions, below.

1. McFadden RG, *et al*. TRH and bronchospasm. *Lancet* 1981; **ii:** 758–9.

Effect on sexual function. On questioning, 7 of 16 women reported a sensation of mild vaginal sexual arousal occurring 1 to 3 minutes after intravenous injection of protirelin.[1] Four women also had urinary sensations, and 3 described an urge to urinate with no sexual component.

1. Blum M, Pulini M. Vaginal sensations after injection of thyrotropin releasing hormone. *Lancet* 1980; **ii:** 43.

Pituitary apoplexy. Pituitary apoplexy has been reported after combined testing of anterior pituitary function in patients with a pituitary tumour.[1,2] Of the drugs given, protirelin was thought most likely to have an aetiological role. Pituitary apoplexy has also been reported after the use of protirelin alone.[3]

Precautions

Protirelin should be given with care to patients with ischaemic heart disease, obstructive airways disease, or severe hypopituitarism. Giving protirelin while the patient is lying down may reduce the incidence of hypotension.

Eclampsia. For the suggestion that the hypertensive effects of protirelin increase the risk of cerebral haemorrhage in pre-eclamptic women, see Effects on the Cardiovascular System under Adverse Effects, above.

Motor neurone disease. In some patients with amyotrophic lateral sclerosis, intravenous injection of protirelin resulted in acute bronchospasm.[1] Five of 25 patients had falls in FEV_1 of more than 20%; in 2, a 15% decrease in arterial-oxygen pressure occurred. Patients with sclerosis and weakened respiratory muscles should be warned of this potential adverse effect.

1. Braun SR, *et al*. Pulmonary effects of thyrotropin-releasing hormone in amyotrophic lateral sclerosis. *Lancet* 1984; **ii** 529–30.

Interactions

◊ Drugs influencing the response to protirelin have been reviewed.[1] The secretion of thyrotrophin appears to be modulated by dopaminergic and noradrenergic pathways at both the hypothalamic and pituitary level. Dopamine and bromocriptine have depressed the response to protirelin; levodopa is a powerful depressant. Partial depression has been reported after the use of chlorpromazine, thioridazine, and phentolamine, all of which have alpha-receptor blocking properties. Beta-receptors do not appear to be involved in the thyrotrophin response to protirelin whereas the antiserotonin drug, cyproheptadine, has an inhibitory effect. Aspirin and corticosteroids with mainly glucocorticoid activity have also depressed the response. An enhanced response to protirelin has been seen after theophylline. Oestrogens may also increase the response in men but not usually in women; when combined with a progestogen a slightly depressed response has been reported.

Other drugs reported to depress the response to protirelin include lithium[2] and ranitidine.[3]

Uses and Administration

Protirelin is a hypothalamic releasing hormone that stimulates the release of thyrotrophin (p.2177) from the anterior lobe of the pituitary. It also has prolactin-releasing activity. It may be obtained by synthesis.

Protirelin may be used in the assessment of the hypothalamic-pituitary-thyroid axis in the diagnosis of mild hyperthyroidism (p.2165) or hypothyroidism (p.2167), and ophthalmic Graves' disease, although in many cases immunoassays for thyroid-stimulating hormone are now preferred. The response to protirelin may be used for differentiating between primary and secondary hypothyroidism but care is required in interpreting the results of the test and it should not be used alone in establishing the diagnosis. Protirelin is given with gonadorelin (p.2107) in the assessment of anterior pituitary function.

Protirelin is given intravenously, usually in doses of 200 to 400 micrograms. A suggested intravenous dose in children is 1 microgram/kg for the assessment of thyroid function. The *BNFC* gives a dose of 7 micrograms/kg (to a maximum of 200 micrograms) for the diagnosis of hypopituitarism and hypothalamic disease.

Protirelin has been investigated in the treatment of neurological diseases, and in the prevention of neonatal respiratory distress syndrome, but results have been variable.

Protirelin tartrate has been given in the treatment of neurological disorders.

Lactation induction. Intranasal protirelin has been tried for stimulation of lactation (p.2003) but there is no suitable commercial preparation, and in any case mechanical stimulation is preferable to drug treatment.

Neonatal respiratory distress syndrome. The regulation of fetal lung development is under multihormonal control and thyroid hormones appear to stimulate pulmonary maturation. However, the thyroid hormones and thyrotrophin do not cross the placenta sufficiently for them to be given in premature labour where neonatal respiratory distress syndrome (p.1508) may develop; therapy with protirelin has therefore been investigated.[1]

Protirelin has been given with corticosteroids to the mother and some beneficial effects have been noted.[1] One study using protirelin 400 micrograms every 8 hours for 4 doses indicated that antenatal protirelin reduced the incidence of chronic lung disease when given with corticosteroids but did not affect the incidence of respiratory distress syndrome.[2] However, 2 large multicentre studies had found that addition of protirelin to corticosteroid treatment had no beneficial effects on outcome compared with corticosteroids only;[3,4] in fact, in the earlier of these studies,[3] respiratory distress syndrome and the need for ventilation were greater in the offspring of mothers given protirelin. Subsequent follow-up appeared to confirm the disadvantages of protirelin in this cohort;[5] however the unexpected conclusions of this study aroused some controversy.[6-8] The second study noted no difference in outcome in the 2 groups of infants.[4] A meta-analysis concluded[9] that prenatal treatment with protirelin was not beneficial, and that it was associated with more adverse effects than the use of corticosteroids alone.

Thiamazole *(BAN, rINN)*

Mercazolylum; Methimazole; Methylmercaptoimidazole; Metimazol; Thiamazol; Thiamazolum; Tiamatsoli; Tiamazol; Tiamazolas. 1-Methylimidazole-2-thiol.

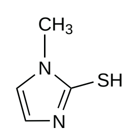
Тиамазол

$C_4H_6N_2S$ = 114.2.

CAS — 60-56-0.

ATC — H03BB02.

ATC Vet — QH03BB02.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Thiamazole). A white or pale brown, crystalline powder. Freely soluble in water and in dichloromethane; freely soluble or soluble in alcohol.

USP 31 (Methimazole). A white to pale buff crystalline powder having a faint characteristic odour. Soluble 1 in 5 of water, 1 in 5 of alcohol, 1 in 4.5 of chloroform, and 1 in 125 of ether. Its solutions are practically neutral to litmus. Protect from light.

Adverse Effects and Precautions

As for Carbimazole, p.2167.

Breast feeding. The use of thiamazole during breast feeding is discussed under Carbimazole, p.2167.

Pharmacokinetics

The pharmacokinetics of thiamazole can be considered with those of carbimazole (p.2168) since the latter is rapidly and completely metabolised to thiamazole in the body.

Uses and Administration

Thiamazole is a thiourea antithyroid drug that acts by blocking the production of thyroid hormones (see p.2165). It is used in the management of hyperthyroidism (p.2165), including the treatment of Graves' disease, the preparation of hyperthyroid patients for thyroidectomy, use as an adjunct to radio-iodine therapy, and the treatment of thyroid storm.

Thiamazole is given orally usually in an initial dosage of 15 to 60 mg daily. It is usually given in three divided doses but a single daily dose is also possible. Improvement is usually seen in 1 to 3 weeks and control of symptoms in 1 to 2 months. When the patient is euthyroid the dose is gradually reduced to a maintenance dose, usually 5 to 15 mg daily. Alternatively, the dose may be continued at the initial level with supplemental levothyroxine as a *blocking-replacement regimen*. Either form of maintenance treatment is usually continued for 1 to 2 years. The initial dose for children is 400 micrograms/kg daily in 3 divided doses; for maintenance this dose may be halved.

Thiamazole doses of 80 to 240 mg daily, usually in 3 or 4 divided doses, have been given intravenously in the management of thyroid storm.

Preparations

USP 31: Methimazole Tablets.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: *Ital.:* Bromazolo.

Thyroglobulin *(USAN, rINN)*

Thyroglobuline; Thyroglobulinum; Tiroglobulina.

Тироглобулин

CAS — 9010-34-8.

Profile

Thyroglobulin is an extract obtained by the fractionation of porcine thyroid glands, that yields levothyroxine and liothyronine on hydrolysis. It has been used in the treatment of hypothyroidism, but such treatment with mixtures of thyroid hormones or preparations of animal extracts is not recommended.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Tiroide Vister.

Thyroid

Dry Thyroid; Getrocknete Schilddrüse; Glándula tiroides, extracto de; NSC-26492; Thyreoidin; Thyroid Extract; Thyroid Gland; Thyroidea; Thyroideum Siccum; Tiroide Secca.

ATC — H03AA05.
ATC Vet — QH03AA05.

Pharmacopoeias. In *Chin.*, *Jpn*, and *US*.

USP 31 (Thyroid). It is the cleaned, dried, and powdered thyroid gland, previously deprived of connective tissue and fat, obtained from domesticated animals used for food by humans. On hydrolysis it yields not less than 90% and not more than 110% each of the labelled amounts of levothyroxine and liothyronine calculated on the dried basis. It is free from iodine in inorganic or any form of combination other than that peculiar to the thyroid gland. It may contain a suitable diluent such as glucose, lactose, sodium chloride, starch, or sucrose. A yellowish to buff-coloured amorphous powder, having a slight, characteristic, meat-like odour. Store in airtight containers.

Profile

Thyroid has been used in the treatment of hypothyroidism, but treatment with mixtures of thyroid hormones or preparations of animal extracts is not recommended.

Preparations

USP 31: Thyroid Tablets.

Proprietary Preparations (details are given in Part 3)
Ital.: Cinetic; ***Mex.:*** Amet; ***Thai.:*** Thiroyd; ***USA:*** Nature Throid.

Multi-ingredient: *Braz.:* Emagrex†; Obesidex†; Obesifran†; ***India:*** Ebexid; ***Thai.:*** Metharmon-F.

Thyrotrophin *(BAN, rINN)*

Thyroid-stimulating Hormone; Thyrotrophic Hormone; Thyrotrophine; Thyrotrophinum; Thyrotropin; Thyrotropinum; Tirotrofina; TSH; Tyrotropiini; Tyrotropin.

Тиротропин

CAS — 9002-71-5.
ATC — H01AB01; V04CJ01.
ATC Vet — QH01AB01; QV04CJ01.

Description. Thyrotrophin is a glycoprotein from the anterior pituitary with a molecular weight in man of about 30 000.

Thyrotropin Alfa *(BAN, USAN, rINN)*

rhTSH; Thyrotropine Alfa; Thyrotropinum Alfa; Tirotropina alfa.

Тиротропин Альфа

CAS — 194100-83-9.
ATC — V04CJ01.
ATC Vet — QV04CJ01.

Units

0.037 units of human pituitary thyrotrophin for immunoassay and bioassay are contained in about 7.5 micrograms of thyrotrophin, with albumin 1 mg and lactose 5 mg, in one ampoule of the second International Reference Preparation (1983).

Adverse Effects

Infrequent adverse effects of thyrotrophin include nausea, vomiting, headache, a desire to micturate, and flushing. High doses may produce excessive thyroid stimulation, with angina, tachycardia or arrhythmias, dyspnoea, sweating, nervousness and irritability. Hypersensitivity reactions, including skin rash and urticaria, erythema and swelling at the injection site, and anaphylaxis have occurred, particularly on repeated use.

Precautions

Thyrotrophin should not be given to patients with recent myocardial infarction or uncorrected adrenocortical insufficiency, including adrenocortical insufficiency secondary to hypopituitarism. Care is also required in patients with cardiovascular disease.

Uses and Administration

Thyrotrophin is a glycoprotein that is secreted by the anterior lobe of the pituitary and has an alpha subunit essentially the same as that of the gonadotrophins. Its main actions are to increase iodine uptake by the thyroid and the formation and secretion of the thyroid hormones. It may produce hyperplasia of thyroid tissue. Thyrotrophin secretion is controlled by a hypothalamic releasing hormone (Protirelin, p.2175) and by circulating thyroid hormones; somatostatin (p.1809) inhibits the release of thyrotrophin.

Thyrotrophin has been used with radio-iodine in the diagnosis of hypothyroidism (p.2167) and to differentiate between primary and secondary hypothyroidism, but direct radio-immunoassay of circulating endogenous thyroid-stimulating hormone may be preferred. Thyrotrophin increases the uptake of radio-iodine by the thyroid and has been used as a diagnostic tool and as an adjunct in the treatment of certain types of thyroid cancer.

Thyrotropin alfa is a recombinant form of thyrotrophin used as an adjunctive diagnostic tool for serum-thyroglobulin testing, with or without radio-iodine imaging, in the follow-up of patients with thyroid cancer. It is also used to increase radio-iodine uptake for ablation of thyroid remnant tissue after thyroidectomy. The usual thyrotropin alfa regimen consists of 2 intramuscular doses of 900 micrograms given 24 hours apart. Radio-iodine is given 24 hours after the second dose of thyrotropin alfa for radio-iodine imaging or remnant ablation. Diagnostic scanning is performed 48 to 72 hours after the radio-iodine has been given, but post-therapy scanning may be delayed by additional days to allow background activity to decline. Samples for serum-thyroglobulin testing should be taken 72 hours after the second thyrotropin alfa dose.

Goitre and thyroid nodules. Thyrotropin alfa is under investigation[1-4] as an adjunct to increase thyroid uptake of radio-iodine (^{131}I) in the treatment of selected patients with nodular goitre (p.2165).

4. Albino CC, *et al.* Recombinant human thyrotropin as adjuvant in the treatment of multinodular goiters with radioiodine. *J Clin Endocrinol Metab* 2005; **90:** 2775–80.

Malignant neoplasms of the thyroid. Patients with well-differentiated thyroid carcinoma (p.674) undergo surgery, with or without iodine-131 treatment. They then receive thyroid hormone therapy to suppress thyrotrophin (TSH), because most differentiated thyroid cancers express TSH receptors and grow in response to thyrotrophin stimulation. Monitoring for tumour recurrence in subsequent years requires interruption of thyroid hormone treatment so that thyrotrophin levels rise, and stimulate the uptake of a subsequent dose of iodine-131 by any residual or recurrent tumour. However, this results in hypothyroidism, with associated symptoms that may be severe in some patients.[1]

Studies[2,3] have examined the use of thyrotropin alfa as an alternative prelude to radio-iodine scanning, and found that it did stimulate radio-iodine uptake, although the sensitivity of scanning may depend on the technique used; thyrotropin alfa might be considered a suitable alternative to thyroid hormone withdrawal. In patients with CNS or spinal metastases, or who have substantial disease in the thyroid bed, thyrotropin alfa may cause tumour expansion with acute complications; it has been recommended[1] that prophylactic corticosteroid therapy should be considered in these cases.

Thyroid hormone withdrawal is also used in the treatment of differentiated thyroid cancer, to increase uptake of radio-iodine for thyroid remnant ablation and treatment of metastatic disease. The use of thyrotropin alfa as an alternative adjunct is under investigation.[4]

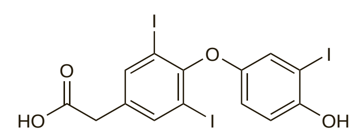
Tiratricol *(rINN)*

Tiratricolum; Tiratrikol; Tiratrikoli; Triac; Triiodothyroacetic Acid. [4-(4-Hydroxy-3-iodophenoxy)-3,5-di-iodophenyl]acetic acid.

Тиратрикол

$C_{14}H_9I_3O_4$ = 621.9.
CAS — 51-24-1.
ATC — D11AX08; H03AA04.
ATC Vet — QD11AX08; QH03AA04.



NOTE. Tri-ac has also been used as a name for proprietary preparations containing other drugs.

Profile

Tiratricol, a metabolite of tri-iodothyronine, is reported to be less active than the thyroid hormones but is given orally to suppress the secretion of thyroid-stimulating hormone.

Obesity. Abnormal thyroid function tests, severe diarrhoea, fatigue, lethargy, and profound weight loss have occurred in patients taking dietary supplements containing tiratricol.[1,2] The FDA has warned that tiratricol may cause heart attacks and strokes, and has advised consumers not to take these products.[3]

This chapter includes a number of drugs used in the management of certain urological or urogenital conditions such as urinary incontinence, benign prostatic hyperplasia, and erectile dysfunction.

Other drugs used in these conditions may be found elsewhere in *Martindale*: they include the tricyclic antidepressants such as imipramine (p.400) and the serotonin and noradrenaline reuptake inhibitor duloxetine (p.389), which are in the chapter on Antidepressants (p.372); some alpha blockers such as doxazosin (p.1275), phentolamine (p.1370), and prazosin (p.1375), as well as, more generally, diuretics and drugs such as ACE inhibitors which may be used to alter urological function, all of which are to be found in the chapter on Cardiovascular Drugs (p.1152); and the various electrolytes (see p.1667).

For the treatment of urogenital infections, see under Choice of Antibacterial, p.162. For the management of urological and reproductive tract malignancies, see under Choice of Antineoplastic, p.643.

Benign prostatic hyperplasia

Benign enlargement of the prostate gland is common in men with increasing age: at least 50% of men aged over 60 years have histological evidence of hyperplasia. Men with an enlarged prostate may exhibit symptoms of lower urinary tract obstruction, such as acute or chronic urinary retention, or irritative symptoms such as frequency, urgency, nocturia, or occasionally urge incontinence, resulting from secondary bladder instability. Therapy is influenced by the severity of symptoms and their effect on the patient's quality of life. The three main options for management are watchful waiting (monitoring without active intervention), drug treatment, and surgery.[1-7]

Watchful waiting is suitable for men with mild to moderate symptoms that are not bothersome,[3] and for some men with moderate to severe symptoms who have not yet developed complications of benign prostatic hyperplasia such as renal impairment, urinary retention, or recurrent infection.[2] The patient is monitored and advised on lifestyle measures that may improve symptoms; these include decreasing fluid intake at specific times such as bedtime or when going out, reducing caffeine and alcohol intake in general, and bladder re-training techniques.

Drug treatment is essentially based on the use of alpha$_1$-adrenoceptor blockers and 5α-reductase inhibitors, and is begun once symptoms become bothersome.

- Alpha$_1$-adrenoceptor blockers (such as alfuzosin, doxazosin, prazosin, indoramin, tamsulosin, or terazosin) apparently act on the smooth muscle tone within the prostate and the bladder neck, and can produce symptomatic relief within weeks.[1,3] They are considered to have similar efficacy[1-3,8] and choice between them may be influenced by adverse effect profile and ease of use.[8]
- The 5α-reductase inhibitors (finasteride and dutasteride) reduce prostate volume, although this takes a number of months.[1,3,8] They reduce the risk of progression to urinary retention and prostatic surgery, and are given particularly to men with urinary symptoms and large prostates.[1-3,8] However, they are less effective for symptomatic improvement than alpha$_1$-adrenoceptor blockers.[2]
- Combined treatment using an alpha$_1$-adrenoceptor blocker and a 5α-reductase inhibitor may be more effective than monotherapy,[1,3] and is considered to be suitable for patients with symptoms associated with demonstrable prostatic enlargement who are at significant risk of progression.[2,8]

Other drug therapies exist but are largely unproven or unsuitable for general use. Gonadorelin analogues such as leuprorelin or nafarelin can produce a reduction in prostate size, but adverse effects make these drugs unsuitable for indefinite therapy. More recently, gonadorelin antagonists such as cetrorelix have been tried. The antifungal mepartricin has been reported to produce symptomatic improvement, possibly by binding to oestrogen in the intestinal lumen and lowering plasma-oestrogen concentrations. Injection of botulinum A toxin into the prostate gland, for the treatment of chronic urinary retention, has shown some promise in small studies. A number of plant extracts such as saw palmetto (*Serenoa repens*)[9] and *Pygeum africanum*[10] are also in use, and the phytosterol sitosterol, which is a constituent of these, is reported to be effective.[11]

Surgery is recommended for men with more severe symptoms that do not respond to drug therapy, or who have complications such as acute urinary retention, gross haematuria, renal failure, bladder calculi, or recurrent urinary-tract infection. The mainstay of treatment is transurethral resection of the prostate (TURP),[1-3] which is more effective than drug treatment but is associated with a risk of complications such as impotence (although this may not be attributable to the surgery in all cases) and bladder neck contracture.[2,3] Transurethral incision of the prostate may be used as an alternative for smaller prostates[1-3] and open prostatectomy may be indicated for removal of very large glands.[3] Various surgical alternatives to TURP use heat to destroy prostatic tissue surrounding the urethra.[1-3,12] These minimally invasive therapies include transurethral microwave thermotherapy, water-induced thermotherapy, radiofrequency transurethral needle ablation, interstitial laser treatment, and transrectal high-intensity focused ultrasound.

Cystitis

Signs and symptoms of cystitis (inflammation of the bladder) include suprapubic pain, dysuria, frequency and urgency of urination, nocturia, and haematuria. It may have various causes but is usually associated with urinary-tract infections (see p.199). Non-infectious cystitis can occur as an adverse effect of some drugs such as NSAIDs (notably tiaprofenic acid).[1] Pelvic radiotherapy and some drugs used for cancer chemotherapy can also cause haemorrhagic cystitis (below). Other inflammatory non-infectious forms of cystitis include interstitial cystitis (see below) and rare conditions such as eosinophilic cystitis.[2]

2. Teegavarapu PS, *et al.* Eosinophilic cystitis and its management. *Int J Clin Pract* 2005; **59:** 356–60.

Haemorrhagic cystitis. Haemorrhagic cystitis results from damage to the bladder wall that causes diffuse bleeding from the endothelial lining; damage may range from minor telangiectatic bleeding to diffuse necrotic ulceration.[1] Signs and symptoms include haematuria, dysuria, urgency, and increased frequency of urination.

Haemorrhagic cystitis may be associated with various diseases, drug and radiation therapies, infections, and toxins. Associated diseases include carcinoma of the bladder, rheumatoid arthritis, and amyloidosis.[1] Drugs that are often associated with haemorrhagic cystitis are antineoplastics, particularly the oxazaphosphorine alkylating agents cyclophosphamide and ifosfamide[1,2] (see also Effects on the Bladder under Cyclophosphamide, p.702). Other drugs with which haemorrhagic cystitis has been reported include penicillins and NSAIDs.[2] Pelvic irradiation[3] for genito-urinary malignancies may cause acute symptoms that can occur up to 6 months after irradiation; some patients will develop chronic symptoms and in a small number the symptoms may become debilitating and refractory to conservative management. Viruses such as adenovirus, BK virus, and CMV can cause haemorrhagic cystitis, particularly in immunocompromised patients.[1] In some cases, bacterial or fungal infection, or parasitical infestation may be responsible.[2] Other causative agents have included toxins such as dyes, insecticides, and turpentine.[1]

Initial supportive **treatment** of haemorrhagic cystitis involves increasing fluid intake to hydrate the bladder and dilute the concentration of any toxic agent in the urine. Symptomatic relief with antispasmodics and analgesics may be indicated.[1] If haematuria does not improve or resolve, intravesical treatment may be considered. This usually begins with a continuous bladder irrigation of *sodium chloride 0.9%*, to remove existing clots.[1-3] For bleeding that persists or worsens, other treatments have been described, mostly in case reports or small series.[1-4] *Alum* irrigation has been used for its astringent properties, but its effect is rarely permanent. Adverse effects include suprapubic pain, fever, bladder spasm, and urinary retention or frequency; alum precipitation can block the catheter and aluminium toxicity may occur rarely. *Silver nitrate* instillation has a cauterising effect by coagulating proteins on the bladder mucosa, *phenol* causes a chemical cauterisation, and *formaldehyde* hydrolyses protein on the bladder wall, coagulating tissue and controlling bleeding in the mucosa and submucosa. However, the duration of effect of these cauterising agents is often short, they are contra-indicated in patients with ureteric reflux, and treatments are painful, necessitating anaesthesia. *Prostaglandins*, such as alprostadil, carboprost, and dinoprostone, have been instilled into the bladder for a cytoprotective effect, to stimulate platelet aggregation, and to cause local vasoconstriction.

There are also reports of successful systemic treatment in some cases that were refractory to intravesical therapy. *Conjugated oestrogens* have been given intravenously and orally.[1] The *antifibrinolytic drugs*, aminocaproic acid[1,2] and tranexamic acid[2] have been given intravenously and orally; aminocaproic acid has also been given intravesically. Oral *pentosan polysulfate sodium* has been used in radiation-induced haemorrhagic cystitis.[3] *Hyperbaric oxygen* therapy increases tissue oxygenation and has been used particularly in radiation-induced haemorrhagic cystitis to treat radionecrosis and tissue ischaemia.[3,4] Cryosurgery using *liquid nitrogen* has been used rarely.[1]

In cases that do not respond to drug treatment, *surgical* options include urinary diversion, internal iliac artery embolisation, unilateral hypogastric artery ligation, and if all else fails, cystectomy.[1-3] Hydrodistension, the application of pressure to the bladder wall by an inflated balloon, has also been used.[4] However, anaesthesia is required, its effect is short-lived, and it is associated with the risk of bladder perforation.[1,2,4]

Prophylaxis to reduce the risk of haemorrhagic cystitis associated with high-dose cyclophosphamide and ifosfamide includes intravenous hydration with diuresis, frequent voiding of the bladder or bladder catheterisation with sodium chloride 0.9% irrigation, and the use of *mesna* as a uroprotectant.[1,2] Improvements in radiotherapy techniques are reducing the risk of radiation-induced haemorrhagic cystitis.[3]

4. Choong SKS, *et al.* The management of intractable haematuria. *BJU Int* 2000; **86:** 951–9.

Interstitial cystitis. Interstitial cystitis is a chronic inflammatory condition of the bladder that mainly affects middle-aged women.[1-4] There are also rare reports of the condition occurring in children, usually girls.[5] Symptoms include perineal and pelvic pain (that is often relieved by voiding), urinary frequency, urgency, and nocturia. Interstitial cystitis is a disease of unknown aetiology and suggested possible causes have included abnormal bladder epithelial permeability, neurogenic abnormalities, autoimmune disorders, and allergic reactions with increased mast-cell activation.[1,2] It is considered to be incurable; attempts at management have included local and systemic drug therapy and surgery.

Non-drug therapies that may be tried include exercise, stress management, bladder training, and the avoidance of foods that patients have found to exacerbate symptoms, such as caffeine, artificial sweeteners, and acidic juices.[1,2,5] However, scientific data to support these strategies are lacking.[1,5]

Pentosan polysulfate sodium has been given orally to improve the protective glycosaminoglycan layer of the bladder, and has reduced symptoms in some patients. Benefits may take more than 3 months to become apparent.[1,2] Other oral treatments that have been used for symptom relief include amitriptyline and hydroxyzine;[1-3] cimetidine[3] and gabapentin[2] have also been tried. Intravesical instillation of dimethyl sulfoxide has been shown to improve symptoms of interstitial cystitis.[1-3] Heparin has also been given intravesically.[1,2] Cystoscopy under anaesthesia with bladder distension, a diagnostic procedure, has been reported to relieve symptoms by destruction of the mucosal nerve plexus and tension receptors in the bladder wall. Although some[1,3,5] support its use for diagnosis and treatment, others[2] suggest that it has limited efficacy. Surgery is reserved for intractable symptoms that have failed to respond to less drastic treatments.[1]

Diabetes insipidus

Diabetes insipidus deprives the kidney of its capacity to produce a concentrated urine, resulting in the passage of large volumes of dilute urine (polyuria) and excessive thirst (polydipsia). Patients generally have moderately raised serum-sodium concentrations but are prone to more severe hypernatraemia (p.1670) when fluid is restricted.

The syndrome of diabetes insipidus is caused either:

- by a deficiency in secretion of antidiuretic hormone (ADH; vasopressin) from the posterior pituitary gland (cranial, pituitary, or neurogenic diabetes insipidus)
- or by a failure in activity of secreted ADH on renal tubules (nephrogenic diabetes insipidus)

Cranial diabetes insipidus is most commonly idiopathic (although it is now increasingly suspected to have an autoimmune basis) or occurs following surgery or trauma when it may be temporary. More rarely, it results from neoplasms, infections, or infiltrations of the CNS, or forms part of the familial DIDMOAD syndrome (diabetes insipidus, diabetes mellitus, optic atrophy, and deafness). Nephrogenic diabetes insipidus may occur as a familial X-linked recessive disorder in male infants, but is more often secondary to hypercalcaemia, hypokalaemia, or drug therapy (including lithium salts, foscarnet, and demeclocycline).

The mainstay of **diagnosis** of diabetes insipidus is measurement of serum and urine osmolality, urine specific gravity, and serum-sodium concentration. If these are found to be normal a formal water deprivation test may be performed, with careful monitoring of urine volume, osmolality, and body-weight. The test should be stopped if more than 3 litres of urine is passed or 3% of total body-weight is lost, although this is in any case virtually diagnostic of diabetes insipidus. A dose of ADH in the form of desmopressin is then given to test renal responsiveness—prompt urine concentration is indicative of cranial diabetes insipidus, while failure indicates the nephrogenic form.

Cranial diabetes insipidus is usually **treated** by replacement therapy with ADH in the form of intranasal desmopressin, although tablets are now also available and may be preferred in children; desmopressin has greater antidiuretic efficacy and considerably less vasoconstrictor activity than lypressin or vasopressin itself.

Nephrogenic diabetes insipidus is by definition unresponsive to ADH therapy and water replacement tends to be the mainstay of treatment. Thiazide diuretics, notably hydrochlorothiazide, are given with some restriction of sodium intake to patients with nephrogenic diabetes insipidus; the resultant mild sodium depletion enhances proximal renal tubular sodium and water resorption. Giving them with amiloride has been reported to have an additive effect while also preventing hypokalaemia.

Other drugs have also been tried in the management of diabetes insipidus. Chlorpropamide stimulates ADH secretion and augments the activity of residual ADH in patients with partial cranial disease and as in nephrogenic disease the thiazides may be useful. Clofibrate and carbamazepine have also been found to promote ADH secretion in these patients. Indometacin and other prostaglandin synthetase inhibitors decrease urine volume in all types of the condition. Combination of indometacin with a thiazide and desmopressin has been investigated.

Erectile dysfunction

Erectile dysfunction (impotence) signifies inability of a male to achieve satisfactory erection of the penis during sexual intercourse. Estimates of prevalence depend to some extent upon the definitions that are used, but the problem is thought to be not uncommon, particularly in older men. The causes of erectile dysfunction may be psychological, organic, or a combination of both. Psychological factors include stress, mental depression, and anxieties about sexual performance. Organic causes include androgen deficiency as a result of hypogonadism, neurological dysfunction (including central or peripheral lesions due to malignancy or trauma), peripheral vascular disorders, and penile abnormalities such as Peyronie's disease or microphallus. Sometimes organic dysfunction may be secondary to another disease, such as diabetes mellitus in which neurological and vascular damage lead to erectile dysfunction in over one-third of all patients. In addition, erectile dysfunction may be drug-induced.

Approaches to the management of erectile dysfunction depend to some extent upon the causative factors.

In those few patients in whom erectile dysfunction is secondary to androgen deficiency in hypogonadism, androgen replacement, preferably by the intramuscular injection or transdermal application of a suitable testosterone ester, may be of value. Androgen replacement therapy is inappropriate in patients with normal testosterone concentrations and may carry significant health risks. In patients with hypogonadism secondary to hyperprolactinaemia addition of bromocriptine is often effective in improving sexual function.

Psychotherapy or behavioural therapy alone may be adequate in patients in whom no organic cause is detected, but even when organic factors play a role psychosocial factors are also important and should be addressed by appropriate counselling.

When causes of erectile dysfunction are partly or primarily organic, the main options are:

- use of a vacuum pump to induce erection by negative pressure, followed by constriction of the base of the penis with a band to maintain tumescence
- oral or sublingual drugs
- injection of vasoactive substances into the corpora cavernosa
- transurethral dosage of vasoactive substances
- implantation of a penile prosthesis is generally reserved for patients in whom other therapy has failed or is refused, but it may also be a suitable first-line choice for some patients

Vascular surgery may have a limited application, in vasogenic dysfunction, but its role is not clearly defined and there are some doubts about its long-term effectiveness.

Oral therapy for erectile dysfunction has had a chequered history, and most of the drugs tried have proved little more effective than placebo. However, with the advent of sildenafil and other inhibitors of phosphodiesterase type-5, oral therapy is now established in erectile dysfunction. Data from randomised controlled studies have shown efficacy of sildenafil in erectile dysfunction compared with placebo, including in men with diabetes mellitus and spinal-cord injury; it has no effect on the penis in the absence of sexual stimulation. It is generally more effective in erectile dysfunction of psychogenic origin and in mild to moderate cases of organic origin. There has, however, been concern about cardiac-related deaths associated with the use of sildenafil, although causality has not been firmly established. Visual disturbances and sudden hearing loss have also been reported. Other phosphodiesterase type-5 inhibitors also used are tadalafil and vardenafil.

Yohimbine, an α_2-adrenoceptor antagonist, may have some benefit, although more in erectile dysfunction of psychological than organic origin. Oral phentolamine is available for the treatment of erectile dysfunction in some countries and has been reported to be of benefit. Trazodone, a serotonin antagonist and reuptake inhibitor used in the treatment of depression, may rarely cause priapism and has therefore been investigated for the treatment of erectile dysfunction. Beneficial effects have been reported either alone or with yohimbine. Oral L-arginine, the precursor of nitric oxide, has also shown some promise in studies.

Sublingual apomorphine, a dopaminergic (D_1 or D_2) agonist, has also shown efficacy, but nausea may be a problem.

Intracavernosal injection therapy is the most effective pharmacological method of treating erectile dysfunction and, until the advent of effective oral therapy, was the most widely used. Unfortunately, one major disadvantage of this method is the need for repeated self-injection of the penis, and studies suggest that the long-term drop-out rate is high. However, it is still a valuable option in men unresponsive to, or unable to take, oral therapy. The drugs most commonly used are alprostadil, papaverine, and phentolamine. Alprostadil is preferred because it is more effective than papaverine (with or without phentolamine), and is associated with a lower incidence of priapism and fibrosis. However, the erection is frequently painful. Papaverine, a non-specific phosphodiesterase inhibitor, has been used alone or with phentolamine, an α-adrenoceptor antagonist. Erectile dysfunction of neurogenic or psychogenic origin generally responds better to papaverine than dysfunction of vascular origin. However, long-term use of intracavernosal papaverine may result in fibrosis, and it has been suggested that it should not be used more than three times a week or on two successive days. Priapism may also be a problem. Triple therapy, involving the combination of alprostadil, papaverine, and phentolamine, has been reported to be effective and to have a relatively low incidence of adverse effects. Other drugs that have been used for intracavernosal therapy include aviptadil, a smooth muscle relaxant used with phentolamine, ketanserin used with alprostadil, and moxisylyte.

The **transurethral route** is a less invasive but also less effective option than intracavernosal therapy. A transurethral pellet of alprostadil is reported to be effective, although efficacy is inconsistent; common adverse effects include penile pain and urethral pain or burning. Transurethral alprostadil as a cream or gel has also shown promise.

A number of studies have also investigated **transcutaneous** therapy. Results from pilot studies investigating transcutaneous delivery of glyceryl trinitrate, papaverine, minoxidil, or alprostadil from creams, gels, or pastes have been variable. Topical treatment with a cream containing codergocrine mesilate, isosorbide dinitrate, and either aminophylline or testosterone has also been tried, with mixed results.

Glomerular kidney disease

For a description of the various forms of glomerular kidney disease and their management, see p.1504.

Malignant neoplasms

Malignant neoplasms of the bladder are relatively common malignancies in the developed world; the management of bladder cancer is discussed on p.659. Prostate cancer is one of the most common malignancies in men and a leading cause of cancer death; its management is covered on p.671. For malignancies of the kidney see p.667.

Micturition disorders

Normal micturition (awareness of the need to void urine as a result of bladder filling, postponement of urination until convenient, and the ability to empty the bladder voluntarily) is controlled by the detrusor muscle of the bladder (smooth muscle innervated mainly by parasympathetic nerves) and the external sphincter (sympathetic innervation). During urination parasympathetic stimulation causes the detrusor muscle to contract while reduced sympathetic tone allows the external sphincter to relax. Micturition disorders can occur through local effects on the bladder or urethra or may result through disturbances of their nervous control. They include nocturnal enuresis, urinary incontinence, and urinary retention. The terms 'neurogenic bladder' and 'neuropathic bladder' are used loosely to describe any bladder dysfunction resulting from neurological disturbance.

Nocturnal enuresis. Involuntary discharge of urine during sleep, termed nocturnal enuresis (bed-wetting), is a normal occurrence in young children, but may persist in up to 5% by the age of 10 years. Nocturnal enuresis is defined as primary if there has never been a period of dryness for more than 6 months, and secondary if the child was dry for such a period before the onset of bed-wetting. Nonpharmacological approaches to treatment include bladder retention training, motivational therapy, and behaviour modification or conditioning therapy using moisture-sensitive alarms. Drug therapy may initially produce a more rapid response, but training and the use of alarms has generally appeared to be more effective and to have a lower relapse rate. Although preparations are available to treat children as young as 5 years of age the *BNFC* states that drug therapy is inappropriate for this age group, and that treatment is usually unnecessary for children under 7 years and in cases where the child and parents are not anxious about the bed-wetting; however, children over 10 years of age are usually considered to require prompt treatment. Drug therapy is probably most useful for intermittent use on special occasions such as sleeping away from home or when added to treatment in children who fail to respond to nonpharmacological methods alone. The long-term use of drugs for enuresis is controversial.

Use of oral *desmopressin* at night can be effective in the short-term control of nocturnal enuresis and many now consider it to be the drug of choice in terms of safety. However, it should not be given when enuresis is due to polydipsia as desmopressin may provoke water intoxication and convulsions due to hyponatraemia.

Tricyclic antidepressants have also been used and of these most experience has been with *imipramine.* Their mechanism of action in nocturnal enuresis is unclear. It may be partly the result of their antimuscarinic and antispasmodic actions.

Antimuscarinics such as *oxybutynin* reduce uninhibited bladder contractions, but although they may be of benefit in diurnal enuresis they are rarely of benefit in nocturnal enuresis alone.

Urinary incontinence and retention. Urinary incontinence is defined as an involuntary loss of urine that is objectively demonstrable and a social or hygienic problem. Nocturnal enuresis in children is discussed above. Depending on the cause patients may have symptoms of urinary frequency, nocturia, urgency, dribbling, or dysuria. Classifications of incontinence vary but the main types include: stress incontinence, urge incontinence and overactive bladder, and overflow incontinence (a consequence of urinary retention). Patients may also have mixed types, for example combined stress and urge incontinence. The term functional incontinence is used when the patient's condition is due to impaired mobility or mental function. It is important to determine the type and, where possible, cause of urinary incontinence before attempting treatment. Urinary-tract infections, constipation, and benign prostatic hyperplasia may mimic or cause the symptoms of urinary incontinence and should be excluded.

Stress incontinence is the commonest form of incontinence in women. The patient usually has urethral sphincter incompetence and loss of urine is associated with increases in intra-abdominal pressure such as may occur on standing or coughing. Initial management should be conservative: first-line treatment is likely to be pelvic floor exercises; other treatments may include electrical stimulation or biofeedback, the use of devices such as vaginal cones, surgery, or drugs.

- Drug therapy has had only a secondary role in the treatment of stress incontinence although the serotonin and noradrenaline reuptake inhibitor *duloxetine* is now licensed in several countries to increase urethral tone in the treatment of moderate to severe stress urinary incontinence, and may be an alternative to surgical treatment. Alpha-adrenoceptor agonists such as *ephedrine, phenylpropanolamine*, and *pseudoephedrine* have been used to increase tone in the muscles of the urethra and at the base of the bladder; they may prevent incontinence in certain stress situations, but long-term experience has been mostly disappointing. *Oestrogens* used with an alpha-adrenoceptor agonist such as phenylpropanolamine appear to be effective and may be of use for postmenopausal women with mild stress incontinence; unfortunately, addition of a progestogen (necessary in women with an intact uterus) might exacerbate the incontinence. The value of oestrogens used without an alpha-adrenoceptor agonist is less clear. Intra-urethral injections of *collagen* or *polytef* appear to be effective, but there are concerns over migration and granuloma formation with polytef.

In **urge incontinence**, also known as unstable bladder or detrusor instability, contractions of the detrusor muscle occur without warning and overcome urethral sphincter resistance, despite any attempt the patient might make to prevent it. Urge incontinence is the most common form of incontinence in the elderly and is often refractory to treatment. The cause is usually unknown and these cases are referred to as being due to **idiopathic detrusor instability**. When there is overt neurological disease, such as upper motor neurone lesions in spinal cord injury or multiple sclerosis, the term **detrusor hyperreflexia** is used. **Overactive bladder syndrome** is defined as urgency (a compelling desire to urinate) with or without actual urge incontinence; patients usually exhibit urinary frequency and nocturia. Reduction of excessive fluid intake and avoidance of drinks containing alcohol or caffeine may control mild symptoms of urge incontinence or overactive bladder. Behavioural therapy may be helpful: bladder training for at least 6 weeks is a first-line option in women with urge or mixed incontinence. Women with mixed incontinence may also benefit from pelvic floor exercises. Other treatments that have been tried include hypnotherapy, acupuncture, and biofeedback.

- No drug treatment has been found to be universally effective. Drugs with antimuscarinic activity may inhibit unstable detrusor muscle contractions but the incidence of adverse effects can be high. As these drugs can increase bladder volume they should not be used in patients with urinary retention. The antimuscarinic *oxybutynin* also has direct smooth muscle relaxant properties and has been most widely used, but adverse effects are common. Transdermal or extended-release formulations may be considered in women who cannot tolerate conventional formulations of oxybutynin. *Tolterodine*, *trospium*, and *propiverine* are other alternatives. (In the UK, propiverine is suggested for overactive bladder but not for incontinence.) Selective M_3 antimuscarinics, *darifenacin* and *solifenacin*, may also be considered. They appear to be at least as effective as less selective antimuscarinics. The older antimuscarinics *flavoxate*, *propantheline*, and *emepronium* are not now recommended.

  Tricyclic antidepressants have also been used in urge incontinence because of their antimuscarinic activity but their main use has been in nocturnal enuresis and nocturia (see above). *Desmopressin* is also mainly used in nocturnal enuresis and nocturia. Evidence for *oestrogens* is inconclusive, but they may be useful as adjuncts in postmenopausal women with vaginal atrophy and symptoms of urgency, frequency, and nocturia. Injection of *botulinum A toxin* into the detrusor muscle may be effective in the treatment of detrusor hyperreflexia that is resistant to antimuscarinics. Sacral nerve stimulation, using an implantable device, may be an option in cases that are resistant to drug treatment. Surgery is reserved for intractable cases.

Urge incontinence can also be due to abnormalities in bladder sensation; the causes of **sensory urgency** are often unknown but may be due to conditions such as urinary-tract infections or interstitial cystitis. Bladder retraining techniques and antimuscarinic therapy have been suggested when no underlying disorder can be identified.

Patients with **overflow incontinence** suffer from a continuous or frequent dribbling of urine as a consequence of an overdistended bladder produced by **urinary retention**. It may result from some form of urethral blockage or may be associated with drug treatment or conditions that reduce detrusor contractions or interfere with relaxation of the urethra. Overflow incontinence is uncommon in women and most patients are elderly men with urethral blockage due to benign prostatic hyperplasia (p.2178). However, urinary retention may also occur postpartum or postoperatively. Treatment depends on the underlying condition. Catheterisation is used to relieve acute painful urinary retention or when no cause can be found. Surgical procedures or dilatation are often used to correct any mechanical outflow obstruction.

- Alpha-adrenoceptor blocking drugs such as *alfuzosin, doxazosin, indoramin, prazosin, tamsulosin,* and *terazosin* may be given to patients waiting for surgery or to those unfit for surgery. They decrease outflow resistance and improve bladder emptying. Patients with detrusor hypotonicity have been given parasympathomimetics such as *bethanechol, carbachol,* and *distigmine* to increase detrusor muscle contractions but there have been doubts about their efficacy. Use of parasympathomimetics for postoperative urinary retention has been superseded by catheterisation.

Premature ejaculation

A universally accepted definition of premature ejaculation has not yet been established, but the American Urological Association has defined it as ejaculation that occurs sooner than desired, either before or shortly after penetration, causing distress to either one or both partners.[1]

Management may include psychological, behavioural, and drug treatment.[1] Several antidepressants have been evaluated for a therapeutic effect in premature ejaculation,[1-3] based on their adverse effects of anorgasmia and delayed ejaculation. The SSRIs fluoxetine, paroxetine, and sertraline, and the tricyclic antidepressant clomipramine, have been used successfully. However, the optimal dosing regimen for these drugs has not been established, and they have been given either on a continuous daily basis or as single doses only before intercourse. Doses that have been effective in premature ejaculation have usually been lower than those recommended for the treatment of depression. A rapidly absorbed short-acting SSRI, dapoxetine, is under development specifically for on-demand treatment of premature ejaculation. Topical anaesthetics, such as lidocaine/prilocaine cream, have been applied to the penis to delay ejaculation.[1-3] Disadvantages of this therapy include loss of erection due to numbness associated with prolonged application, and numbness in the partner caused by residual topical anaesthetic.[1,3] Available commercial preparations intended for such use include benzocaine gels and lidocaine sprays. Sildenafil, a phosphodiesterase type-5 inhibitor used for erectile dysfunction, has also been tried with some success;[1] however, some consider that such drugs should only be used in patients with co-morbid erectile dysfunction.[3]

Prostatitis

The term prostatitis is used to describe several clinical syndromes, including well-defined bacterial infections of the prostate gland, poorly-defined chronic pelvic pain, and asymptomatic inflammation of the prostate. Prostatitis is relatively common as a urological diagnosis, with about 30% of men having such symptoms at some time in their life.[1] The US National Institutes of Health classification system[1] for prostatitis consists of categories:

- I: acute bacterial prostatitis
- II: chronic bacterial prostatitis
- III: chronic prostatitis/chronic pelvic pain syndrome (subdivided into IIIA inflammatory and IIIB non-inflammatory)
- IV: asymptomatic inflammatory prostatitis

Acute bacterial prostatitis (category I) is most often due to Gram-negative pathogens, particularly *Escherichia coli* and other enterobacteriaceae. Symptoms include fever, chills, malaise and myalgia, with rectal, low back, or perineal pain. There is often bacteriuria with frequent and urgent dysuria. The prostate is enlarged, tender, and warm.[1,2] Chronic bacterial prostatitis (category II) is relatively rare, and may develop from acute bacterial prostatitis in some men. It is characterised by pelvic pain and recurrent urinary-tract infections. The prostate appears to be normal but in some cases is swollen or firm.[1] Bacterial prostatitis should be managed with appropriate antibacterial therapy[2-4] (see under Urinary-tract Infections, p.199).

Chronic prostatitis/chronic pelvic pain syndrome (category III), which has also been described as abacterial prostatitis, is the most common form of prostatitis. The aetiology and pathogenesis remain unclear, and suggestions have included infection with atypical organisms that cannot be detected by conventional techniques, intraprostatic reflux, or immunological processes.[1] Neurological[5] or psychological factors[1,5] may also play a role in some patients. Symptoms of chronic pelvic pain syndrome include pelvic, perineal, and genital pain, lower urinary-tract symptoms, sexual dysfunction, and general symptoms such as headache and fatigue.[1] In inflammatory chronic pelvic pain syndrome (category IIIA), leucocytes can be found in expressed prostatic secretion, in the urine after prostatic massage, and in semen; no leucocytes can be detected in non-inflammatory chronic pelvic pain syndrome (category IIIB; previously called prostatodynia).[1,5]

There are no universally effective treatments for chronic pelvic pain syndrome; treatment trials overall have been small and of poor quality.[2,4-6] Many clinicians favour initial management with antibacterials despite negative cultures, in order to treat occult atypical infection.[2] An oral fluoroquinolone is the antibacterial of choice (or a tetracycline for patients allergic to fluoroquinolones). Recommended duration of treatment varies, but courses are generally of 4 to 8 weeks, depending on response in the first few weeks.[2,3,5] However, there is no strong evidence to support this practice,[6] and although there are some studies to suggest that antibacterial treatment may be beneficial in inflammatory chronic pelvic pain syndrome, there is less evidence for the non-inflammatory form.[3] Other treatments that have been tried, with variable results, include[2,4-6] the 5α-reductase inhibitor finasteride, alpha blockers such as alfuzosin, terazosin, or tamsulosin, pentosan polysulfate sodium, mepartricin, pollen extract, quercetin, and NSAIDs. The role of allopurinol is controversial. Non-drug treatments that have shown some promise include transurethral or transrectal microwave thermotherapy[2,4-6] and sacral nerve stimulation.[5] Stress management therapy has also been tried.[2] Drugs used for symptomatic relief of neuropathic pain may include tricyclic antidepressants such as amitriptyline, or antiepileptics such as gabapentin. Anticholinergics such as oxybutynin or tolterodine may be used for urinary frequency.[5]

Asymptomatic inflammatory prostatitis (category IV) is often detected coincidentally during examination for other disorders.[1]

Renal calculi

The solubility of calcium, oxalate, and phosphate in normal urine is maintained by a variety of inhibitors of crystallisation, both organic and inorganic. However, increases in the concentrations of crystalline substances in the urine, or decreases in the relative proportions of crystallisation inhibitors, may render individuals susceptible to urolithiasis, the formation of renal calculi (kidney stones). Renal calculi consist of crystalline components arranged around an organic matrix. They are typically formed in the calices or renal pelvis, and may become lodged in the ureter. Calcium-containing stones (usually calcium oxalate and calcium phosphate in variable proportions) account for the vast majority of occurrences although stones of other compositions including cystine, uric acid, or magnesium ammonium phosphate (also called struvite or infection stones), are occasionally seen.

The incidence and prevalence of renal calculi is increasing.[1,2] The lifetime risk of stone development varies between populations but is about 15% for white men and 6% for white women, with a lifetime recurrence rate of up to 50%.[3] Risk factors include obesity, low fluid intake, and a diet high in protein, refined carbohydrates, and salt.[1] Some conditions can promote calculi formation, including renal tubular acidosis, primary hyperparathyroidism, sarcoidosis, primary hyperoxaluria, inflammatory bowel disease, hyperuricaemic conditions, and cystic fibrosis.[4] Drug-induced calculi can be formed by crystallisation of poorly soluble drugs with a high urinary excretion, or by an effect on calcium oxalate or purine metabolism.[5]

Treatment. Most renal calculi are small, and stones that are less than 5 mm in diameter will usually pass spontaneously.[6-9] Patients may be asymptomatic or may pass small stones with relatively little discomfort, but passage of a larger stone down the ureter can be accompanied by excruciating pain (renal or ureteral colic) requiring analgesia (see Biliary and Renal Colic, p.5). If there is no obstruction, infection, or other complication, conservative treatment is favoured, with the patient being monitored radiographically over several weeks to see if the stone will pass of its own accord.[10] There is some interest in the possible use of drug treatment to ease the spontaneous passage of the stone. Small studies using a calcium-channel blocker (usually nifedipine) or an alpha$_1$-adrenoceptor blocker such as tamsulosin, sometimes with a corticosteroid such as deflazacort, have reported improvements in the rate of stone expulsion and expulsion time, and reductions in analgesic requirements, in patients with uncomplicated lower ureteral stones. A meta-analysis[11] of 9 such studies confirmed the apparent benefit of such treatment; patients had a 65% greater likelihood of spontaneous stone passage than those not given these drugs. Although a suitable randomised controlled study is required to confirm efficacy, such treatment may offer a viable alternative to lithotripsy or uteroscopy.[11] A literature review[12] suggested that daily doses of nifedipine 30 mg, doxazosin 4 mg, tamsulosin 400 micrograms, or terazosin 5 mg given for 28 to 45 days are effective in enhancing expulsion of ureteral stones that are less than 15 mm in diameter.

Where intervention is considered necessary for stone removal the choice of technique depends on the size, composition, and location of the stone. Extracorporeal shock wave lithotripsy is generally favoured, but other procedures such as ureteroscopy or percutaneous nephrolithotomy are used for more complex cases.[7,8,13] Antibacterials may be needed for infection (see Urinary-tract Infections, p.199).

Prevention. In the prevention of recurrence it is important to identify, and where possible correct, any underlying disease process or biochemical or anatomical abnormality. Certain general measures are also appropriate. Patients should drink at least 2 to 3 litres of fluid daily in order to maintain an adequate volume of urine.[1,3,7,14] In hot climates or working environments a higher volume of fluid should be taken.

In preventing the recurrence of *calcium stones*, a balanced diet that is low in protein and salt[1,3,10,15] and high in fibre[1,7] is generally advocated. In the past patients were advised to decrease their calcium intake, but studies have found an inverse relationship between dietary calcium intake and stone formation.[3,7,14,15] Also, because oxalate is bound by calcium in the gut, preventing its absorption, a low calcium intake can increase oxalate absorption and the risk of stone formation. Therefore, a normal level of dietary intake of calcium is now advised[1,3,7,15,16] (an exception to this is in patients with absorptive hypercalciuria type I, a rare condition of intestinal calcium hyperabsorption).[1] However, calcium supplements appear to increase the risk of stone formation and are generally avoided.[3,7,15] If they are used, they should be taken with meals to avoid hypercalciuria.[1,16] Excessive dietary oxalate intake should also be avoided;[3,7,10,15] foods containing large quantities of bioavailable oxalate include spinach, rhubarb, nuts, and cocoa.[15]

Where pharmacological therapy is indicated, choice of treatment depends on the underlying metabolic abnormality and stone composition. Alkaline citrate, usually given as potassium citrate, is commonly used to prevent the recurrence of calcium stones. It acts as a urinary alkaliniser and increases citrate excretion; citrate forms complexes with calcium to reduce urinary saturation of calcium salts and inhibits crystallisation.[2,7,14,16] Potassium citrate is the main treatment option in patients with hypocitraturia and renal tubular acidosis.[1,3,7] In hypercalciuria, a thiazide diuretic or indapamide can also be used to increase distal tubular calcium reabsorption;[1-3,6,7,10,14,17] potassium citrate can also prevent diuretic-induced hypokalaemia in these patients. In the prevention of calcium stones with hyperoxaluria, a restriction of oxalate-rich food and an adequate dietary calcium intake (or calcium supplements taken with meals) are advocated.[6,10,15,16] The use of magnesium has also been suggested[1] although it may be no better than placebo.[3,7] Some patients with primary hyperoxaluria may respond to high doses of pyridoxine.[1,3,7,10,16] In hyperuricosuria, reduced purine intake and allopurinol may be effective.[1,3,7,10]

Prevention of *uric acid stones* is based on adequate fluid intake, a low purine diet, and urinary alkalinisation with potassium citrate. Allopurinol may be used if there are high levels of urate.[1-3,6,7] Acetazolamide has been used short term.[6]

Struvite stones are caused by urease-producing bacteria. Antibacterials are used, and may be required long term, with urinary acidification using ammonium chloride[7] or methionine.[1,7] Dietary phosphate restriction may also be appropriate for patients with phosphate excretion of more than 35 mmol/day.[1] Acetohydroxamic acid, an inhibitor of bacterial urease, may be used as an adjunct in selected cases of severe infection,[7] but its use has been limited by adverse effects.[3,10]

Cystine stones are associated with cystinuria (p.1459) and are prevented by alkalinisation of the urine and a high fluid intake (3 to 4 litres daily).[2,3,6,7] Penicillamine may be used as a chelating agent.[3,6,10] Ascorbic acid, tiopronin,[1,7] and captopril[7] have also been suggested.

Sexually transmitted diseases

For discussion of sexually transmitted diseases and their treatment see p.191.

Syndrome of inappropriate ADH secretion

In some patients secretion of antidiuretic hormone (ADH; vasopressin) occurs despite hypotonicity of the extracellular fluid and normal or raised fluid volume, and such patients are said to have the syndrome of inappropriate ADH secretion (SIADH). With severe water excess, the resultant hyponatraemia may result in symptoms ranging from lassitude or headache to profound neurological symptoms such as confusion, convulsions, or coma. Some patients may experience inappropriate thirst as well as ADH secretion, thus exacerbating their condition. For a discussion of sodium homoeostasis and dilutional hyponatraemia, see p.1670.

Conditions that can precipitate SIADH include CNS disorders, infections such as encephalitis and meningitis, head trauma, porphyria, or pulmonary diseases such as tuberculosis and pneumonia. ADH may also be secreted ectopically from malignancies, most commonly from small-cell bronchial carcinoma. SIADH may also be drug-induced; drugs associated with the condition include carbamazepine, chlorpropamide, cytotoxic drugs such as cyclophosphamide and the vinca alkaloids, oxytocin, some antipsychotics, tricyclic antidepressants, and SSRIs.

Diagnosis of SIADH is initially prompted by the presence of hyponatraemia and corresponding plasma hypo-osmolality with or without neurological symptoms. Hypervolaemia, persistent excess sodium excretion, lack of oedema, and normality of both renal and adrenal function are confirmatory.

Mild water excess is frequently asymptomatic and may not require specific therapy, but patients with SIADH often have a more severe disorder and treatment is best aimed at the underlying cause. If such treatment is not possible or if symptoms persist, water restriction may be considered. However, fluid restriction is unpleasant, particularly for patients who retain inappropriate thirst, and may not be tolerable. In these patients demeclocycline may be given to antagonise the effect of ADH on the renal tubules. Lithium has been given as an alternative but has a high frequency of adverse effects, and phenytoin has been used occasionally to inhibit pituitary ADH secretion. Diuretics such as furosemide (used with oral sodium chloride) have also been tried in an attempt to optimise diuresis while retaining sodium. In patients with life-threatening severe acute water intoxication (see Hyponatraemia, p.1670), treatment initially involves cautious improvement of the profound hyponatraemia by intravenous infusion of hypertonic (usually 3%) or isotonic sodium chloride, often with furosemide or another loop diuretic to avoid volume expansion. Drugs that act directly in the renal tubules as vasopressin V_2 receptor antagonists are under investigation.

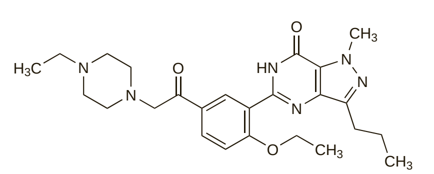
$C_{25}H_{34}N_6O_3$ = 466.6.



Profile

Acetildenafil is an analogue of sildenafil (p.2193) that has been used in various preparations or dietary supplements and illegally promoted in some countries for the management of erectile dysfunction. Other analogues of sildenafil detected in similar products include homosildenafil and hydroxyhomosildenafil.

Alfuzosin Hydrochloride

(BANM, USAN, rINNM)

Alfutsosiinihydrokloridi; Alfuzosin Hidroklorür; Alfuzosine, chlorhydrate d'; Alfuzosin-hydrochlorid; Alfuzosinhydroklorid; Alfuzosini hydrochloridum; Alfuzosin-hidroklorid; Alfuzozino hidrochloridas; Hidrocloruro de alfuzosina; SL-77499-10; SL-77499 (alfuzosin). *N*-{3-[4-Amino-6,7-dimethoxyquinazolin-2-yl(methyl)amino]propyl}tetrahydro-2-furamide hydrochloride.

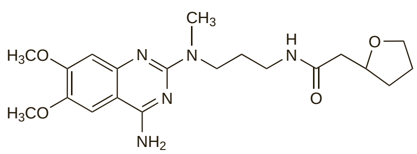
Альфузозина Гидрохлорид

$C_{19}H_{27}N_5O_4$,HCl = 425.9.

CAS — 81403-80-7 (alfuzosin); 81403-68-1 (alfuzosin hydrochloride).

ATC — G04CA01.

ATC Vet — QG04CA01.



(alfuzosin)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Alfuzosin Hydrochloride). A white or almost white, slightly hygroscopic, crystalline powder. Freely soluble in water; sparingly soluble in alcohol; practically insoluble in dichloromethane. A 2% solution in water has a pH of 4.0 to 5.5. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Prazosin Hydrochloride, p.1375. Alfuzosin may be more selective for the urinary tract and vasodilator effects may be less frequent. It should be avoided in severe hepatic impairment, and doses may need to be reduced in mild to moderate hepatic impairment and in renal impairment (see below).

Incidence of adverse effects. In postmarketing surveillance involving 13 389 patients given alfuzosin 2.5 mg three times daily by mouth for benign prostatic hyperplasia, about 3.7% of patients failed to complete treatment because of adverse effects. These were mostly vasodilatory in nature (vertigo or dizziness, syncope or malaise, hypotension, and headache), and were more common in patients over 75 years of age and during the first week of treatment.[1]

1. Lukacs B, *et al.* Safety profile of 3 months' therapy with alfuzosin in 13,389 patients suffering from benign prostatic hypertrophy. *Eur Urol* 1996; **29:** 29–35.

Surgical procedures. Alpha blockers, including alfuzosin, have been associated with intraoperative floppy iris syndrome in cataract surgery patients. For further details, see under Tamsulosin, p.2197.

Interactions

As for Prazosin Hydrochloride, p.1376. Potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole, itraconazole, and ritonavir, may increase blood concentrations of alfuzosin.

Pharmacokinetics

Alfuzosin is readily absorbed after oral doses and peak plasma concentrations generally occur 0.5 to 3 hours after a dose; bioavailability is about 64%. Absorption from modified-release preparations is improved if given with food. It is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP3A4, to inactive metabolites that are excreted primarily in faeces via the bile. Only about 11% of a dose is excreted unchanged in the urine. Alfuzosin has a plasma elimination half-life of 3 to 5 hours. It is 90% bound to plasma proteins.

Uses and Administration

Alfuzosin is an $alpha_1$-adrenoceptor blocker (p.1153) with actions similar to those of prazosin (p.1376). It acts preferentially on receptors in the lower urinary tract and is therefore used in benign prostatic hyperplasia (p.2178) to relieve symptoms of urinary obstruction, including acute urinary retention.

Alfuzosin is given orally as the hydrochloride. Like other $alpha_1$-adrenoceptor blockers, it may cause collapse in some patients after the first dose, which should therefore be given just before bedtime to reduce the risk. Doses may need to be reduced in patients with hepatic or renal impairment (see below); the initial dose should also be reduced in the elderly.

In **benign prostatic hyperplasia,** the usual dose of alfuzosin hydrochloride is 2.5 mg three times daily, increased to 10 mg daily if necessary. In elderly patients, and those receiving treatment for hypertension, a lower initial dose of 2.5 mg twice daily should be considered. A modified-release preparation may also be given in a dose of 10 mg once daily after a meal.

In patients aged over 65 years catheterised for **acute urinary retention** associated with benign prostatic hyperplasia, a modified-release preparation may be given in a dose of 10 mg once daily after a meal for 3 to 4 days.

Administration in hepatic or renal impairment. In patients with mild to moderate hepatic impairment the initial dose of alfuzosin hydrochloride should be 2.5 mg daily, increased to 2.5 mg twice daily according to response; modified-release preparations are not recommended.

In patients with renal impairment, 2.5 mg twice daily should be given initially, adjusted according to response. Although UK and US licensed product information advises caution with the use of modified-release preparations in severe renal impairment (creatinine clearance below 30 mL/minute), a study[1] in patients with varying degrees of renal impairment (including severe) suggested that no dose reduction was necessary.

Pharmacopoeias. In *Jpn.*

Adverse Effects, Treatment, and Precautions

The adverse effects reported most commonly in **infants** with congenital heart disease treated with alprostadil are apnoea, fever, flushing, hypotension, bradycardia, tachycardia, diarrhoea, and convulsions. Other adverse effects reported include oedema, cardiac arrest, hypokalaemia, disseminated intravascular coagulation, and cortical proliferation of the long bones. Weakening of the wall of the ductus arteriosus and pulmonary artery may occur on prolonged infusion. Alprostadil should be avoided in neonates with respiratory distress syndrome and should be used with caution in those with bleeding tendencies; blood pressure and respiratory status should be monitored during infusion.

Adverse effects reported in **adults** given alprostadil have included headache, flushing, hypotension, diarrhoea, and pain and inflammation at the infusion site.

After intracavernosal or intra-urethral alprostadil for the treatment of erectile dysfunction, the most frequently reported adverse effect is pain during erection. Local reactions including penile fibrosis, fibrotic nodules, and Peyronie's disease have been reported. Priapism may occur (see below). Systemic effects are less common but hypotension and other adverse effects have been reported. Intracavernosal or intra-urethral use should be avoided in patients with complicating penile deformities or with sickle-cell disease, myeloma, leukaemias, or other conditions predisposing to prolonged erection.

In children. Reviews[1,2] of adverse effects associated with alprostadil in infants with congenital heart disease.

1. Lewis AB, *et al.* Side effects of therapy with prostaglandin E in infants with critical congenital heart disease. *Circulation* 1981; **64:** 893–8.
2. Lucron H, *et al.* Complications du traitement par prostaglandines E1 des cardiopathies congénitales en réanimation médicale pédiatrique. *Arch Mal Coeur Vaiss* 2005; **98:** 524–30.

Effects on the bones. Periosteal or cortical hyperostosis has been reported in infants given alprostadil for cyanotic congenital heart disease.[1-4] A retrospective review of 30 infants[2] treated with alprostadil revealed radiographic signs of periosteal reactions in 5. Changes could be detected after even short courses of therapy; 3 developed relatively mild periosteal changes in the ribs after infusions ranging from 9 to 205 hours and one had involvement of the left femur after infusion for 71 hours. Resolution of lesions had occurred in most bones 6 to 12 months later. In a further study,[5] radiological evidence of cortical hyperostosis was found in 53 of 86 infant heart transplant recipients who had received alprostadil infusion pre-operatively. Of 53 of the infants who had received alprostadil for less than 30 days, 21 were affected (2 severely). Correspondingly, of those treated for 30 to 60 days, 18 of 22 were affected (13 severely). All 14 infants treated for more than 60 days were affected (7 severely). Since the associated bone changes may persist for months after stopping alprostadil, caution should be exercised to avoid misdiagnosis.

5. Woo K, *et al.* Cortical hyperostosis: a complication of prolonged prostaglandin infusion in infants awaiting cardiac transplantation. *Pediatrics* 1994; **93:** 417–20.

Effects on the gastrointestinal tract. Hyperplasia of the gastric mucosa, resulting in gastric outlet obstruction, has been reported in several neonates receiving alprostadil infusion.[1-3] It was suggested that this effect was dose-dependent.[1] Regression of the obstruction usually occurred after cessation of therapy.

For a report of necrotising enterocolitis in infants receiving alprostadil for congenital heart disease, see Dinoprostone, p.2007.

1. Peled N, *et al.* Gastric-outlet obstruction induced by prostaglandin therapy in neonates. *N Engl J Med* 1992; **327:** 505–10.
2. Merkus PJFM, *et al.* Prostaglandin E1 and gastric outlet obstruction in infants. *Lancet* 1993; **342:** 747.
3. Kobayashi N, *et al.* Acute gastric outlet obstruction following the administration of prostaglandin: an additional case. *Pediatr Radiol* 1997; **27:** 57–9.

Effects on the metabolism. Severe hyperglycaemia with apparent ketoacidosis occurred during postoperative infusion of alprostadil in the infant of a diabetic mother.[1] The manufacturers had received reports of hyperglycaemia associated with alprostadil in 5 infants, one of whom had a diabetic mother. Hypoglycaemia has also been reported in a few infants.[2]

1. Cohen MH, Nihill MR. Postoperative ketotic hyperglycaemia during prostaglandin E infusion in infancy. *Pediatrics* 1983; **71:** 842–4.
2. Lewis AB, *et al.* Side effects of therapy with prostaglandin E in infants with critical congenital heart disease. *Circulation* 1981; **64:** 893–8.

Effects on the skin. A 63-year-old man with Peyronie's disease[1] developed toxic pustuloderma (acute generalised exanthematous pustulosis) 6 days after receiving a single intracavernosal injection of alprostadil to define the penile morphology. He was treated with antihistamines and topical corticosteroids and the condition resolved completely within a week.

1. Gallego I, *et al.* Toxic pustuloderma induced by intracavernous prostaglandin E . *Br J Dermatol* 1997; **136:** 975–6.

Priapism. If priapism (p.1333) occurs after the use of alprostadil for erectile dysfunction, its treatment should not be delayed more than 6 hours. Initial therapy is by penile aspiration. If aspiration is unsuccessful a sympathomimetic with action on alpha-adrenergic receptors is given by cautious intracavernosal injection, with continuous monitoring of blood pressure and pulse. Extreme caution is necessary in patients with coronary heart disease, hypertension, cerebral ischaemia, or if taking an antidepressant. Low doses and dilute solutions are recommended as follows:

- intracavernosal injection of phenylephrine 100 to 200 micrograms (0.5 to 1 mL of a 200 micrograms/mL solution) every 5 to 10 minutes; maximum total dose 1 mg

alternatively

- intracavernosal injection of adrenaline 10 to 20 micrograms (0.5 to 1 mL of a 20 micrograms/mL solution) every 5 to 10 minutes; maximum total dose 100 micrograms

alternatively

- intracavernosal injection of metaraminol may be used, but it should be noted that fatal hypertensive crises have been reported; metaraminol 100 micrograms (5 mL of a 20 micrograms/mL solution) may be given by careful slow injection every 15 minutes; a maximum total dose of up to 1 mg has been suggested

If necessary the sympathomimetic injections can be followed by further penile aspiration. If sympathomimetics are unsuccessful, urgent surgical referral is required.

Pharmacokinetics

On infusion alprostadil is rapidly metabolised by oxidation during passage through the pulmonary circulation. It is excreted in the urine as metabolites within about 24 hours. Systemic absorption of alprostadil occurs after intracavernosal injection.

Uses and Administration

Alprostadil is a prostaglandin (p.2374) that causes vasodilatation and prevents platelet aggregation. The endogenous substance is termed prostaglandin E_1. Alprostadil is used mainly in congenital heart disease and in erectile dysfunction (p.2179).

In the management of **erectile dysfunction**, alprostadil is given by intracavernosal injection; preparations may contain alprostadil or alprostadil alfadex, but the dose is expressed in terms of the base. Alprostadil may also be given as an intra-urethral application.

By *intracavernosal injection*, the initial dose should be low, for example 2.5 micrograms, and is increased incrementally until a suitable dose is established. Normally, the second dose should be 5 micrograms if some response to the first dose is observed, or 7.5 micrograms if there is no response; increments should then be of 5 to 10 micrograms until an effective dose is reached. The usual dose range is 5 to 20 micrograms and the maximum recommended dose is 60 micrograms. In cases of erectile dysfunction of neurogenic origin secondary to spinal cord injury an initial dose of 1.25 micrograms has been given, with a second dose of 2.5 micrograms, a third dose of 5 micrograms, and subsequent increments of 5 micrograms. While finding a suitable dose, the interval between doses should be at least 1 day if there has been a partial response. If there is no response however, the next, higher dose may be given within 1 hour. Once established, the optimal dose should be given not more than once daily and not more than three times per week.

Alprostadil may also be injected intracavernosally in the diagnosis of erectile dysfunction in doses ranging from 5 to 20 micrograms.

By *intra-urethral (transurethral) application*, the initial dose is 250 micrograms. The dose may be increased incrementally to 500 or 1000 micrograms or decreased to 125 micrograms according to response. The optimal dose should be given not more than twice daily or seven times per week. A dose of 500 micrograms may be used diagnostically.

Alprostadil is also available in some countries as a *topical* formulation for the treatment of erectile dysfunction. There is also ongoing investigation of the use of topical formulations for female sexual dysfunction.

Alprostadil is used to maintain the patency of the ductus arteriosus in neonates with **congenital heart disease** until surgery is possible. It is given by continuous intravenous infusion beginning with doses of 50 to 100 nanograms/kg per minute; doses should be reduced as soon as possible to the minimum necessary to maintain response. Lower starting doses may be effective in some patients. The dose can be increased to 400 nanograms/kg per minute but, in general, higher infusion rates do not improve effect. Alprostadil may also be given by continuous infusion through an umbilical artery catheter placed at the ductal opening.

Ergotamine poisoning. Alprostadil[1,2] is one of many drugs that have been used to treat the circulatory disturbances in ergotamine poisoning (p.620).

1. Levy JM, *et al.* Prostaglandin E for alleviating symptoms of ergot intoxication: a case report. *Cardiovasc Intervent Radiol* 1984; **7:** 28–30.
2. Horstmann R, *et al.* Kritische Extremitätenischämie durch Ergotismus. *Dtsch Med Wochenschr* 1993; **118:** 1067–71.

Haemorrhagic cystitis. Bladder irrigation with alprostadil produced resolution of severe haemorrhagic cystitis in 5 of 6 children who had undergone bone marrow transplantation.[1] Alprostadil was given via a catheter and retained for 1 hour each day for at least 7 consecutive days.

1. Trigg ME, *et al.* Prostaglandin E bladder instillations to control severe hemorrhagic cystitis. *J Urol (Baltimore)* 1990; **143:** 92–4.

Hepatic disorders. Benefit has been reported in patients with *viral hepatitis* (p.851) given intravenous alprostadil alone or followed by oral dinoprostone or misoprostol.[1,2] Prostaglandins were studied because they had previously been shown to have a cytoprotective effect in experimentally induced hepatitis or in isolated hepatocytes, but the mechanism by which they exerted a beneficial effect was uncertain.

Combined intravenous therapy with glucagon, insulin, and alprostadil formulated in lipid microspheres has also been found effective in preventing *acute fulminant hepatic failure* after hepatic arterial infusion of antineoplastic chemotherapy.[3]

Darifenacin *(BAN, USAN, rINN)*

Darifenacina; Darifénacine; Darifenacinum; UK-88525. (*S*)-1-[2-(2,3-Dihydro-5-benzofuranyl)ethyl]-α,α-diphenyl-3-pyrrolidineacetamide.

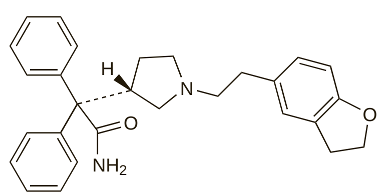
Дарифенацин

$C_{28}H_{30}N_2O_2 = 426.6.$

CAS — 133099-04-4.

ATC — G04BD10.

ATC Vet — QG04BD10.



Darifenacin Hydrobromide *(BANM, USAN, rINNM)*

Darifénacine, Bromhydrate de; Darifenacini Hydrobromidum; Hidrobromuro de darifenacina; UK-88525-04. (*S*)-2-{1-[2-(2,3-Dihydrobenzofuran-5-yl)ethyl]-3-pyrrolidnyl}-2,2-diphenylacetamide hydrobromide.

Дарифенацина Гидробромид

$C_{28}H_{30}N_2O_2,HBr = 507.5.$

CAS — 133099-07-7.

ATC — G04BD10.

ATC Vet — QG04BD10.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Darifenacin should be used with caution in patients also receiving inhibitors of cytochrome P450 isoenzymes (see Interactions and Uses and Administration, below). It should also be used with caution in hepatic impairment (see Administration in Hepatic Impairment, below).

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220). Exposure to darifenacin may be increased by drugs that inhibit the cytochrome P450 isoenzymes CYP2D6 and CYP3A4. Inducers of CYP3A4 may reduce plasma concentrations of darifenacin. Dosage adjustment for darifenacin may be necessary (see Uses and Administration, below). Darifenacin itself is also a moderate inhibitor of CYP2D6.

Pharmacokinetics

After an oral dose, darifenacin is subject to extensive first-pass metabolism and has a bioavailability of about 15 to 19%. It is about 98% bound to plasma proteins. Darifenacin is metabolised in the liver by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4. The pharmacokinetics of darifenacin at steady state are dose-dependent because of the saturation of CYP2D6 metabolism. Most of a dose is excreted as metabolites in the urine and faeces.

3. Skerjanec A. The clinical pharmacokinetics of darifenacin. *Clin Pharmacokinet* 2006; **45:** 325–50.

Uses and Administration

Darifenacin is a selective M_3 antimuscarinic with actions similar to those of atropine (p.1220); it is claimed to have a greater selectivity for the muscarinic receptors of the bladder.

Darifenacin is used in the management of urinary frequency, urgency, and incontinence in detrusor instability (p.2180). It is given orally as the hydrobromide but doses are described in terms of the base: darifenacin hydrobromide 8.9 mg is equivalent to about 7.5 mg of darifenacin. The usual initial dose is the equivalent of darifenacin 7.5 mg once daily; after 2 weeks of treatment this may be increased to 15 mg once daily if necessary.

The starting dose of 7.5 mg should only be increased with caution in patients also receiving potent inhibitors of the cytochrome P450 isoenzyme CYP2D6, such as paroxetine and terbinafine. Darifenacin should be avoided, or a dose of 7.5 mg daily not exceeded, in patients also receiving potent inhibitors of CYP3A4, such as HIV-protease inhibitors, ketoconazole, and itraconazole. The dose of darifenacin should be increased with caution in the presence of moderate inhibitors of CYP3A4, such as macrolide antibacterials, fluconazole, and grapefruit juice.

Darifenacin should be used with caution in hepatic impairment, see below.

Darifenacin is being studied in irritable bowel syndrome.

Administration in hepatic impairment. Licensed product information states that the dose of darifenacin should not exceed 7.5 mg once daily in patients with moderate hepatic impairment (Child-Pugh category B), and its use should be avoided in severe impairment (Child-Pugh category C).

ATC — H01BA02.

ATC Vet — QH01BA02.

Pharmacopoeias. In *US.*

USP 31 (Desmopressin Acetate). A white, fluffy powder. Soluble in water, in alcohol, and in acetic acid. Store in airtight containers at a temperature not exceeding 25°, but preferably between 2° and 8°. Protect from light.

Units

27 units of desmopressin are contained in about 27 micrograms of desmopressin (with 5 mg of human albumin and citric acid) in one ampoule of the first International Standard (1980).

Adverse Effects and Precautions

Adverse effects of desmopressin include headache, nausea, and mild abdominal cramps; there may be pain and swelling at the site of injection. With large intravenous doses hypotension, with tachycardia and facial flushing, may occur; some patients may experience an increase in blood pressure. Occasionally there may be cerebral or coronary thrombosis. Hypersensitivity reactions have also occurred. The antidiuretic action of desmopressin can produce water intoxication and hyponatraemia, occasionally leading to convulsions. The incidence of hyponatraemia may be higher with nasal formulations than with oral formulations. Nasal doses may cause local irritation, congestion, and epistaxis.

Precautions to be observed with desmopressin are similar to those for vasopressin (see p.2412). It should not be given to patients with type IIB von Willebrand's disease, in whom the release of clotting factors may lead to platelet aggregation and thrombocytopenia. When desmopressin is used diagnostically, or for the treatment of enuresis, the fluid intake should be limited to a minimum and only to satisfy thirst from 1 hour before to 8 hours after use (see also Effects on Electrolytes, below).

Effects on the cardiovascular system. Facial flushing and warmth after intravenous desmopressin reflect a vasodilator action[1] or may be due to an opioid mechanism in the CNS.[2] A drop in diastolic blood pressure of about 14 mmHg and an increase in heart rate of 20 beats/minute are the rule during intravenous infusion of desmopressin in doses of 400 nanograms/kg or more.[1] The hypotensive effects of desmopressin were responsible for a serious reaction, involving cyanosis and dyspnoea, in a 21-month-old child with cyanotic heart disease.[3] Thrombosis (including myocardial infarction)[4-6] and cerebral infarction[7] have been associated rarely with the use of intravenous desmopressin. An analysis[8] of events in patients undergoing major surgery suggested, however, that co-existing conditions in elderly patients and the surgical procedures themselves were associated with a high risk of thrombosis, and that desmopressin did not increase the incidence of thrombotic events.

Licensed product information also warns of the possibility of an increase in blood pressure.

Effects on electrolytes. There have been a number of reports of seizures due to hyponatraemia and water intoxication after intranasal[1-8] or intravenous[9] desmopressin. The UK CSM noted in March 1996 that it had received reports of hyponatraemic convulsions in 21 children and 3 adults receiving desmopressin (which it somewhat inaccurately described as vasopressin).[10] It was recommended that when this drug was used to treat primary nocturnal enuresis the risks of hyponatraemia should be minimised by

- avoiding concomitant use of drugs, such as *tricyclic antidepressants*, that increase endogenous ADH secretion
- keeping to the recommended starting dose
- avoiding excessive fluid intake, including ingestion of water during swimming
- stopping treatment temporarily if vomiting or diarrhoea occurred, to allow recovery of normal fluid and electrolyte balance

Some have suggested that no more than 240 mL of fluid should be ingested on nights when desmopressin is given.[7] Others have suggested that serum-sodium concentrations be measured 24 to 48 hours, 1 week, and 1 month after starting treatment with desmopressin.[8] A systematic review[11] of the risk in older patients being treated for nocturia, which found the incidence of hyponatraemia to be about 8%, also recommended regular monitoring.

In April 2007, the MHRA requested that the indication for the treatment of primary nocturnal enuresis be removed from desmopressin nasal spray formulations in the UK. Compared with oral formulations, nasal forms were associated with most of the serious adverse effects reported in patients with primary nocturnal enuresis; these included hyponatraemia, water intoxication, and convulsions. Hyponatraemia was reported at a rate of about 15 cases per 100 000 years of patient exposure for nasal dosage forms, compared with 6 cases per 100 000 patient years for oral formulations; hyponatraemia was mainly associated with overdose, excessive fluid intake, or inappropriate use.[12] The FDA has issued similar warnings.[13]

13. FDA. Information for healthcare professionals: desmopressin acetate (marketed as DDAVP Nasal Spray, DDAVP Rhinal Tube, DDAVP, DDVP, Minirin, and Stimate Nasal Spray) (issued 4th December 2007). Available at: http://www.fda.gov/ cder/drug/InfoSheets/HCP/desmopressinHCP.htm (accessed 11/06/08)

Effects on the eyes. Pseudotumor cerebri associated with desmopressin treatment has been reported in a patient.[1]

1. Neely DE, *et al.* Desmopressin (DDAVP)-induced pseudotumor cerebri. *J Pediatr* 2003; **143:** 808.

Effects on mental function. Paranoid psychosis occurred after desmopressin therapy in a patient with Alzheimer's dementia.[1]

1. Collins GB, *et al*. Paranoid psychosis after DDAVP therapy for Alzheimer's dementia. *Lancet* 1981; **ii:** 808.

Tolerance. In 3 uraemic patients desmopressin infusion produced an initial shortening of the bleeding time but after repeated infusions this response was reduced and there was even some increase in baseline bleeding times.[1] Two infusions of desmopressin 300 nanograms/kg in one day appear to induce a near maximum response; different treatment is required subsequently.

1. Canavese C, *et al*. Reduced response of uraemic bleeding time to repeated doses of desmopressin. *Lancet* 1985; **i:** 867–8.

Interactions

As for Vasopressin, p.2412. See also Effects on Electrolytes, above. NSAIDs, such as ibuprofen (see Effects on Electrolytes under Ibuprofen, p.64) and indometacin, may enhance the antidiuretic effect of desmopressin.

Gastrointestinal drugs. In a study[1] in healthy subjects, *loperamide* caused a threefold increase in the gastrointestinal absorption of oral desmopressin, presumably by slowing gastrointestinal motility. In the same study, however, increased motility caused by *erythromycin* did not affect desmopressin absorption.

1. Callréus T, *et al.* Changes in gastrointestinal motility influence the absorption of desmopressin. *Eur J Clin Pharmacol* 1999; **55:** 305–9.

Pharmacokinetics

Desmopressin is absorbed from the nasal mucosa with a bioavailability of 10 to 20%. After oral doses it is largely destroyed in the gastrointestinal tract but sufficient is absorbed from high doses to produce therapeutic effects. When given intravenously desmopressin exhibits biphasic pharmacokinetics, with half-lives of about 8 minutes and 75 minutes for the 2 phases respectively.

Uses and Administration

Desmopressin is a synthetic analogue of vasopressin (p.2411). It has greater antidiuretic activity and a more prolonged action than vasopressin or lypressin. It also stimulates factor VIII and plasminogen activator activity in the blood, but has little pressor activity.

Desmopressin is used in the diagnosis and treatment of cranial diabetes insipidus, in the treatment of nocturnal enuresis, and in tests of renal function. It is also used in the management of mild or moderate haemophilia and type I von Willebrand's disease, and in tests of fibrinolytic response.

It is given as the acetate, orally, as a solution intranasally, and by injection. The intranasal dose is about ten times that required intravenously and the oral dose about ten times greater than the intranasal dose. Doses are usually expressed in terms of desmopressin acetate, but for some preparations they are given in terms of the base; 110.7 micrograms of desmopressin acetate is equivalent to about 100 micrograms of desmopressin.

In the control of **cranial diabetes insipidus**, desmopressin acetate is given orally in usual initial doses of 100 micrograms three times daily. Doses may be adjusted according to response, with maintenance doses usually between 100 and 200 micrograms three times daily though total doses of between 100 micrograms and 1200 micrograms daily have been used.

A sublingual lyophilisate preparation containing desmopressin acetate is also available in the UK, but doses are expressed in terms of the base. The initial dose is equivalent to 60 micrograms of desmopressin given sublingually three times daily. The dose may be adjusted, with usual maintenance doses between 60 and 120 micrograms three times daily, though total doses of up to 720 micrograms daily have been used.

Desmopressin acetate may also be used intranasally in usual doses of 10 to 40 micrograms daily as a single dose or in divided doses.

It may also be given subcutaneously, intramuscularly, or intravenously in a dose of 1 to 4 micrograms daily.

A single intranasal dose of 20 micrograms or 2 micrograms subcutaneously or intramuscularly has been given in the **diagnosis** of diabetes insipidus.

In the **testing of renal function**, desmopressin acetate has been given intranasally in single doses of 40 micrograms and subcutaneously or intramuscularly in doses of 2 micrograms.

In the management of **primary nocturnal enuresis**, desmopressin acetate is given in usual oral doses of 200 to 400 micrograms. The sublingual lyophilisate preparation may be given in a dose equivalent to desmopressin 120 micrograms at bedtime, increasing to 240 micrograms if needed. The need for continued treatment should be reassessed after 3 months by withdrawing desmopressin for at least 1 week. For the view that nasal preparations should not be used for primary nocturnal enuresis, see Effects on Electrolytes, under Adverse Effects, above. For the control of **nocturia** in multiple sclerosis desmopressin acetate 10 to 20 micrograms intranasally at bedtime is recommended (but see Urinary Incontinence, below).

Desmopressin acetate is given by intravenous infusion to boost concentrations of factor VIII before surgical procedures in patients with mild to moderate **haemophilia** or **type I von Willebrand's disease**. The usual dose is 300 or 400 nanograms/kg by slow intravenous infusion over 15 to 30 minutes just before surgery. It may be used similarly to treat spontaneous or trauma-induced bleeding episodes in these patients. It is also given intranasally in doses of 150 micrograms (in patients weighing less than 50 kg) or 300 micrograms; it should be given within 2 hours before surgery.

For **testing of fibrinolytic response** desmopressin acetate may be given by intravenous infusion in doses of 400 nanograms/kg over 20 minutes; a sample of venous blood is taken 20 minutes after completing the infusion and tested for fibrinolytic activity on fibrin plates. Alternatively, a dose of 300 micrograms may be given intranasally 60 minutes before collecting the blood sample.

For details of uses and doses in children, see below.

Administration in children. Although some desmopressin preparations are licensed in the UK and the USA for paediatric use, the indications are generally fewer than for adults and the age ranges are often not specified.

The *BNFC*, however, lists doses for both licensed and unlicensed indications, and the full range of *BNFC* doses, given according to age, is as follows:

Treatment of diabetes insipidus

orally

- neonate: initially 1 to 4 micrograms 2 or 3 times daily, adjusted according to response
- 1 month to 2 years: initially 10 micrograms 2 or 3 times daily, adjusted according to response (range 30 to 150 micrograms daily)
- 2 to 12 years: initially 50 micrograms 2 or 3 times daily, adjusted according to response (range 100 to 800 micrograms daily)
- 12 to 18 years: initially 100 micrograms 2 or 3 times daily, adjusted according to response (range 200 to 1200 micrograms daily)

sublingually

- 2 to 18 years: initially 60 micrograms 3 times daily, adjusted according to response (range 40 to 240 micrograms 3 times daily)

intranasally

- neonate: initially 100 to 500 nanograms, adjusted according to response (range 1.25 to 10 micrograms daily as a single dose or in 2 divided doses)
- 1 month to 2 years: initially 2.5 to 5 micrograms once or twice daily, adjusted according to response
- 2 to 12 years: initially 5 to 20 micrograms once or twice daily, adjusted according to response
- 12 to 18 years: initially 10 to 20 micrograms once or twice daily, adjusted according to response

subcutaneously or *intramuscularly*

- neonate: initially 100 nanograms once daily, adjusted according to response (use the intramuscular route only)

- 1 month to 12 years: initially 400 nanograms once daily, adjusted according to response
- 12 to 18 years: initially 1 to 4 micrograms once daily, adjusted according to response

Test for suspected diabetes insipidus

intranasally

- 1 month to 2 years: 5 to 10 micrograms as a single dose (although this test is not usually recommended in young children)
- 2 to 12 years: 10 to 20 micrograms as a single dose
- 12 to 18 years: 20 micrograms as a single dose

subcutaneously or *intramuscularly*

- 1 month to 2 years: 400 nanograms as a single dose (although this test is not usually recommended in young children)
- 2 to 12 years: 0.5 to 1 microgram as a single dose
- 12 to 18 years: 1 to 2 micrograms as a single dose

Testing of renal function

intranasally

- 1 month to 1 year: 10 micrograms
- 1 to 15 years: 20 micrograms
- 15 to 18 years: 40 micrograms

subcutaneously or *intramuscularly*

- 1 month to 1 year: 400 nanograms
- 1 to 18 years: 2 micrograms

Primary nocturnal enuresis

orally

- 5 to 18 years (but preferably over 7 years): 200 micrograms at bedtime, increased if necessary to 400 micrograms

sublingually

- 5 to 18 years (but preferably over 7 years): 120 micrograms at bedtime, increased if necessary to 240 micrograms

The need for continued treatment with either route should be reassessed after 3 months by withdrawing desmopressin for at least 1 week

Mild to moderate **haemophilia** or **von Willebrand's disease**

intravenously (infusion over 20 minutes) or *subcutaneously*

- 1 month to 18 years: 300 nanograms/kg as a single dose immediately before surgery or after trauma; the dose may be repeated at intervals of 12 hours if no tachycardia occurs

intranasally

- 1 to 18 years: 4 micrograms/kg as a single dose; for pre-operative use give 2 hours before the procedure

Testing of fibrinolytic response

intravenously (infusion over 20 minutes) or *subcutaneously*

- 2 to 18 years: 300 nanograms/kg as a single dose; blood is sampled after 20 minutes for fibrinolytic activity

Diabetes insipidus. Desmopressin is the usual treatment for cranial diabetes insipidus (p.2179).

Haemorrhagic disorders. Desmopressin is used in the management of patients with mild haemophilia A, carriers of haemophilia with low factor VIII concentrations, and patients with acquired haemophilia who have low titres of antibodies to factor VIII (see Haemophilias, p.1048). Desmopressin is also used in von Willebrand's disease (p.1051). The use of desmopressin results in a two- to sixfold increase in plasma concentrations of factor VIII and von Willebrand factor,[1] and patients must have measurable baseline concentrations of these factors in order to respond to desmopressin.[1,2] In general, a baseline factor VIII concentration of 0.1 to 0.15 units/mL is needed to achieve post-injection concentrations of about 0.3 to 0.5 units/mL, which are generally sufficient for minor bleeding or lesser procedures. Concentrations of at least 0.7 to 1 unit/mL must be achieved for major surgery.[1] Desmopressin can be given subcutaneously, but the peak levels of factor VIII are reached later than after intravenous use. Intranasal use is also effective and allows patients to treat bleeding episodes themselves, without delay, outside hospital.[1] The use of desmopressin as an alternative to blood products has been recommended whenever possible in the treatment of these disorders, as a precaution against blood-borne infection.[1]

Bleeding due to liver disease has been controlled by desmopressin,[3,4] as has that associated with uraemia[5-8] (but for a report of tolerance to the effects of repeated doses of desmopressin in uraemic patients, see under Adverse Effects and Precautions, above), and there are reports of bleeding being controlled in other disorders such as telangiectasia[9] and platelet storage deficiency.[10-12] See also Haemorrhagic Disorders in Vasopressin (p.2412), and Variceal Haemorrhage in Vasopressin (p.2413) and Terlipressin (p.2396).

Desmopressin has been tried in surgical procedures with conflicting results.[2] A meta-analysis, which mainly included trials in cardiac surgery, found no evidence that desmopressin reduces perioperative blood transfusion in patients who do not have congenital bleeding disorders.[13] A possible role for desmopressin has been proposed in the control of surgical bleeding in patients whose religious beliefs preclude the use of blood products.[14,15] It has also been reported to be effective in postoperative aspirin-related bleeding that was previously unresponsive to clotting factors.[16] However, studies of prophylactic desmopressin given to patients who had received aspirin in the 7 days before cardiac bypass surgery have produced conflicting results, with desmopressin either reducing blood loss[17] or having no effect.[18]

Nocturnal enuresis. Desmopressin is one of the main drugs used as an alternative or adjunct to nonpharmacological methods for the treatment of nocturnal enuresis in children (p.2180). Secretion of vasopressin during the night in normal individuals reduces urine output and it has been suggested that nocturnal enuresis in some children might be due to impaired nocturnal secretion of vasopressin. However, other possible mechanisms include bladder instability and reduced nightly functional bladder capacity, and it has been proposed that treatment should be based on a greater consideration of nocturnal enuresis as a multifactorial condition.[1]

The synthetic vasopressin analogue desmopressin is used for its presumed antidiuretic effect on the kidney,[2] although there is some evidence that it may act by some other mechanism, possibly having a central effect.[3,4] It has been shown that desmopressin given at night can be effective in the short-term control of nocturnal enuresis[2,5] and many now consider it to be the drug of choice in terms of safety. There is some evidence[6,7] that long-term use of desmopressin is also effective. However, a meta-analysis suggested that benefit might not be sustained once the drug was stopped.[8] It should not be given when enuresis is due to polydipsia as desmopressin may provoke water intoxication and convulsions due to hyponatraemia. For precautions to be observed when desmopressin is used to treat enuresis, and the view that nasal formulations should not be used for this indication, see Effects on Electrolytes, above.

Orthostatic hypotension. The first drug tried in patients with orthostatic hypotension (p.1530) who cannot be managed by nonpharmacological methods is usually fludrocortisone, but desmopressin is sometimes useful in patients with central neurological abnormalities.[1]

1. Mathias CJ, *et al.* The effect of desmopressin on nocturnal polyuria, overnight weight loss, and morning postural hypotension in patients with autonomic failure. *BMJ* 1986; **293:** 353–4.

Post-dural puncture headache. Desmopressin acetate has been given to adults in a dose of 4 micrograms subcutaneously or intramuscularly for the treatment or prophylaxis of headache due to lumbar puncture, repeated if necessary after 24 hours. However, results have generally been disappointing and many patients respond to conservative treatment (see p.1851).

Renal colic. Intranasal desmopressin is being studied[1] in the management of the pain of acute renal colic (p.5).

1. Zabihi N, Teichman JMH. Dealing with the pain of renal colic. *Lancet* 2001; **358:** 437–8.

Urinary incontinence. Desmopressin given intranasally appeared to be effective in reducing voiding frequency/incontinence when studied in 26 patients with multiple sclerosis whose bladder dysfunction had previously been unresponsive to antimuscarinics;[1] similar results have been reported in other small studies in patients with multiple sclerosis.[2] However, a review of studies using desmopressin to treat nocturia in such patients cast doubt on the clinical relevance of the limited reductions achieved in voiding frequency.[3] Nevertheless, beneficial long-term use of desmopressin for nocturia has been described, with some patients also using it intermittently during the daytime to control symptoms for special occasions.[4] Oral desmopressin has been reported to have a favourable effect on measures such as the number of nocturnal voids and duration of sleep until the first nocturnal void in women[5] and men[6] with nocturia. Beneficial effects were maintained or improved in many responders who were treated for a further 10 or 12 months.[7] In the management of daytime urinary incontinence in women, an improvement in the incidence of periods without leakage during the 4 hours after an intranasal dose of desmopressin has been reported.[8]

For the usual treatment of incontinence, see Urinary Incontinence and Retention, p.2180.

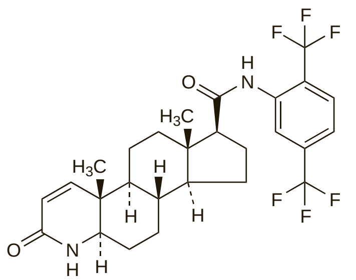
Dutasteride *(BAN, USAN, rINN)* ⊗

Dutasterid; Dutasterida; Dutastéride; Dutasteridum; GG-745; GI-198745; GI-198745X. α,α,α,α′,α′,α′-Hexafluoro-3-oxo-4-aza-5α-androst-1-ene-17β-carboxy-2′,5′-xylidide; 3-Oxo-2′,5′-bis-(trifluoromethyl)-4-aza-5α-androst-1-ene-17β-carboxanilide.

Дутастерид

$C_{27}H_{30}F_6N_2O_2$ = 528.5.
CAS — 164656-23-9.
ATC — G04CB02.
ATC Vet — QG04CB02.



Adverse Effects and Precautions

As for Finasteride, p.2188.

Pharmacokinetics

Dutasteride is absorbed from the gastrointestinal tract, reaching a peak serum concentration in 1 to 3 hours, with a bioavailability of about 60%. It is highly bound to plasma proteins. Dutasteride is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP3A5, and most of a dose is excreted as metabolites in the faeces. At steady state the elimination half-life is about 3 to 5 weeks.

Uses and Administration

Dutasteride, like finasteride (p.2189), is an inhibitor of 5α-reductase. Unlike finasteride, it is claimed to inhibit both the type-1 and type-2 isoforms of the enzyme. Dutasteride is used in the treatment of benign prostatic hyperplasia (p.2178); it may reduce the incidence of acute urinary retention and the need for surgery. Dutasteride is given in doses of 500 micrograms daily by mouth. Response may be delayed and treatment for 6 months may be required to assess whether benefit has been achieved.

Dutasteride is under investigation for the prevention of prostate cancer, and has been investigated in the treatment of alopecia.

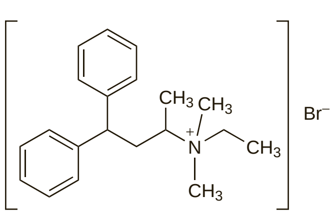
Emepronium Bromide *(BAN, rINN)*

Bromuro de emepronio; Emepronii Bromidum; Émépronium, Bromure d'; Emeproniumbromid; Emeproniumbromidi. Ethyldimethyl(1-methyl-3,3-diphenylpropyl)ammonium bromide.

Эмепрония Бромид

$C_{20}H_{28}BrN$ = 362.3.
CAS — 27892-33-7 (emepronium); 3614-30-0 (emepronium bromide).
ATC — G04BD01.
ATC Vet — QG04BD01.



Emepronium Carrageenate *(BAN)*

Emepronio, carragenato de.
ATC — G04BD01.
ATC Vet — QG04BD01.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

To avoid oesophageal ulceration, tablets of emepronium bromide should always be swallowed with an adequate volume of water, and patients should always be in the sitting or standing position while, and for 10 to 15 minutes after, taking the tablets. Emepronium is contra-indicated in patients with symptoms or signs of oesophageal obstruction or with pre-existing oesophagitis.

Buccal and oesophageal ulceration. Tablet-induced oesophageal damage is a widely recognised problem and is related to direct mucosal injury by the medication. Emepronium bromide has been frequently implicated in this type of mucosal injury, although it rarely results in stricture formation.[1]

1. McCord GS, Clouse RE. Pill-induced esophageal strictures: clinical features and risk factors for development. *Am J Med* 1990; **88:** 512–18.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Pharmacokinetics

Emepronium is incompletely absorbed from the gastrointestinal tract and is mainly excreted unchanged in the urine and faeces. It does not readily cross the blood-brain barrier at therapeutic doses.

Uses and Administration

Emepronium is a quaternary ammonium antimuscarinic with peripheral effects similar to those of atropine (p.1220). It has been used orally as the bromide and the carrageenate in the treatment of urinary frequency and incontinence (p.2180); the bromide has also been given by subcutaneous or intramuscular injection.

Urinary incontinence. In the UK, guidelines issued by NICE suggest that emepronium should not be recommended for the treatment of urinary incontinence or overactive bladder in women; other antimuscarinics are preferred.[1]

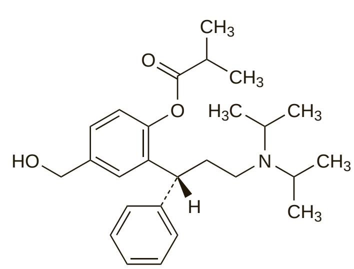
CAS — 286930-02-7.
ATC — G04BD11.
ATC Vet — QG04BD11.



Fesoterodine Fumarate *(USAN, rINNM)*

Fésotérodine, Fumarate de; Fesoterodini Fumaras; Fumarato de fesoterodina; SPM-907; SPM-8272.

Фезотеродина Фумарат

$C_{26}H_{37}NO_3,C_4H_4O_4$ = 527.6.
CAS — 286930-03-8.

Profile

Fesoterodine is a selective M_3 antimuscarinic used in the management of urinary frequency, urgency, and incontinence in overactive bladder syndrome (p.2180). It is given orally as the fumarate; the usual initial dose is 4 mg once daily, increased to a maximum of 8 mg once daily if necessary, according to response. Patients should be re-evaluated after 8 weeks of treatment. The dose of fesoterodine fumarate should not exceed 4 mg once daily in patients receiving potent CYP3A4 or CYP2D6 inhibitors. For doses in hepatic and renal impairment, see below.

Administration in hepatic impairment. UK licensed product information for fesoterodine fumarate states that patients with mild hepatic impairment should increase their dose with caution; those also receiving moderate CYP3A4 inhibitors should not exceed a dose of fesoterodine fumarate 4 mg once daily, and concomitant potent CYP3A4 inhibitors are not recommended. Patients with moderate impairment should not exceed a dose of 4 mg once daily and concomitant moderate or potent CYP3A4 inhibitors are not recommended. Fesoterodine fumarate is contra-indicated in those with severe impairment.

Administration in renal impairment. UK licensed product information for fesoterodine fumarate states that patients with mild (GFR 50 to 80 mL/minute) or moderate (GFR 30 to 50 mL/minute) renal impairment, should increase their dose with caution; those also receiving moderate CYP3A4 inhibitors should not exceed a dose of fesoterodine fumarate 4 mg once daily, and concomitant potent CYP3A4 inhibitors are not recommended. Patients with severe impairment (GFR less than 30 mL/minute) should not exceed a dose of 4 mg once daily and concomitant moderate or potent CYP3A4 inhibitors are not recommended.

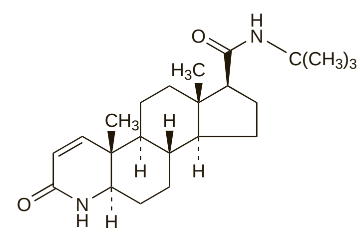
CAS — 98319-26-7.
ATC — D11AX10; G04CB01.
ATC Vet — QD11AX10; QG04CB01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Finasteride). A white or almost white crystalline powder. It exhibits polymorphism. Practically insoluble in water; freely soluble in dehydrated alcohol and in dichloromethane. Protect from light.

USP 31 (Finasteride). A white to off-white crystalline solid. Very slightly soluble in water; freely soluble in alcohol and in chloroform. Store in airtight containers.

Adverse Effects

The most commonly reported adverse effects of finasteride are decreased libido, erectile dysfunction, ejaculation disorders, and reduced volume of ejaculate.

Breast tenderness and enlargement (gynaecomastia) may occur, and there have been reports of hypersensitivity reactions such as swelling of the lips and face, pruritus, urticaria, and rashes. Testicular pain has also been reported.

Incidence of adverse effects. In a study using prescription event monitoring data,[1] the most commonly reported adverse effects of finasteride in 14 772 patients were impotence or ejaculatory failure (2.1% of patients), reduced libido (1%), and breast disorders such as gynaecomastia (0.4%). Adverse effects reported in a single patient each, and verified on rechallenge, were exfoliative dermatitis, perioral numbness, and swollen glands. Finasteride appeared to be associated with ataxia in 1 patient and wheeziness in another.

1. Wilton L, *et al.* The safety of finasteride used in benign prostatic hypertrophy: a non-interventional observational cohort study in 14 772 patients. *Br J Urol* 1996; **78:** 379–84.

Effects on the breast. Gynaecomastia was the adverse effect of finasteride most frequently reported to the FDA between June 1992 and February 1995 (a total of 214 reports).[1] The onset after therapy ranged from 14 days to 2.5 years, and the condition could be unilateral or bilateral. Mastectomy was performed in 12 men. Of the 86 men for whom follow-up information was available, partial or complete remission of gynaecomastia occurred in 80%, and no change occurred in 20%. In 2 of the cases, primary intraductal breast carcinoma was subsequently found, although 1 probably had breast cancer before finasteride therapy. Continued surveillance of the relationship between finasteride and breast cancer is required.

1. Green L, *et al.* Gynecomastia and breast cancer during finasteride therapy. *N Engl J Med* 1996; **335:** 823.

Effects on mental function. Depression has been reported[1,2] in 20 patients given finasteride for the treatment of alopecia. In most cases the depression began about 3 to 4 months after starting finasteride, and resolved within a few weeks of stopping it. In 2 patients rechallenged with finasteride, depression recurred within 2 weeks of restarting the drug.[1]

1. Altomare G, Capella GL. Depression circumstantially related to the administration of finasteride for androgenetic alopecia. *J Dermatol* 2002; **29:** 665–9.
2. Health Canada. Finasteride: suspected association with depression. *Can Adverse React News* 2004; **14** (1): 3. Also available at: http://www.hc-sc.gc.ca/dhp-mps/alt_formats/hpfb-dgpsa/pdf/medeff/carn-bcei_v14n1-eng.pdf (accessed 02/09/08)

Precautions

Finasteride should be used with caution in hepatic impairment. When used for benign prostatic hyperplasia, finasteride should be used with caution in men at risk of obstructive uropathy. Patients should be evaluated for prostatic carcinoma before and during therapy. Use of finasteride decreases concentrations of serum markers of prostate cancer such as prostate specific antigen (PSA) by up to 50% even when cancer is present, and reference values should be adjusted accordingly; the ratio of free to total PSA (percent free PSA) remains constant.

Studies in *animals* suggest finasteride could produce feminisation (hypospadia) of a male fetus if used in pregnant women; therefore, its use is contra-indicated in women who are or may become pregnant. In addition, it is recommended that women in this category should not handle crushed or broken finasteride tablets. Finasteride has been detected in semen, therefore use of a condom is recommended if the patient's sexual partner is, or may become, pregnant.

Pharmacokinetics

Finasteride is absorbed after oral doses, and peak plasma concentrations are achieved in 1 to 2 hours. The mean bioavailability has variously been reported as 63% and 80%. It is about 90% bound to plasma protein. Finasteride crosses the blood-brain barrier, and is distributed into semen. It is metabolised in the liver, primarily by the cytochrome P450 isoenzyme CYP3A4, and excreted in urine and faeces as metabolites. The mean terminal half-life is about 6 hours in patients under 60 years of age but may be prolonged to about 8 hours in those 70 years of age or older.

◊ References.

1. Steiner JF. Clinical pharmacokinetics and pharmacodynamics of finasteride. *Clin Pharmacokinet* 1996; **30:** 16–27.

Uses and Administration

Finasteride is an azasteroid that inhibits the type-2 isoform of 5α-reductase, the enzyme responsible for conversion of testosterone to the more active dihydrotestosterone, and therefore has anti-androgenic properties. It is given orally in a dose of 5 mg daily in the management of benign prostatic hyperplasia to cause regression of the enlarged prostate and to improve symptoms; it may reduce the incidence of acute urinary retention and the need for surgery. Response may be delayed and treatment may be required for 6 months or more to assess whether benefit has been achieved.

In the treatment of male-pattern baldness (alopecia androgenetica) in men, finasteride is given orally in a dose of 1 mg daily. In general, use for 3 months or more is required before benefit is seen, and effects are reversed within 12 months of ceasing therapy.

Alopecia. In men with male-pattern baldness (alopecia—see p.1577), treatment with oral finasteride for 12 months resulted in an 11% increase in vertex hair count, which was maintained in those who continued therapy.[1] Extension of this study to 5 years found that long-term treatment with finasteride maintained beneficial effects, or at least slowed hair loss.[2] The use of oral finasteride for this purpose has been reviewed.[3-5] Some efficacy has also been found with topical finasteride.[6]

Although finasteride is contra-indicated in women who are or may become pregnant (see Precautions, above), it has been investigated in the treatment of male-pattern baldness in postmenopausal women. However, a 1-year placebo-controlled study[7] found no benefit from finasteride. There has been a report[8] of benefit from finasteride in 4 women with hair loss due to hyperandrogenism.

Benign prostatic hyperplasia. Finasteride[1] is used in the management of benign prostatic hyperplasia (p.2178). It produces moderate reductions in prostate volume, although this takes a number of months and is not always associated with much symptomatic improvement; therapy must be continued indefinitely for benefit to be maintained. A 4-year study found that finasteride reduced the probability of surgery and acute urinary retention in men with symptomatic benign prostate hyperplasia with prostatic enlargement.[2] Although the need for prostatectomy was reduced by 55% it was pointed out[3] that only 6% extra patients would benefit from treatment with finasteride. For every 100 men treated, 7 finasteride and 13 placebo recipients required surgery. A 2-year, open-label follow-up[4] of this study reported that the reductions in probability of surgery and acute urinary retention were maintained. It was also found that in patients who switched from placebo to finasteride, these measures decreased to become similar to those recorded in men already receiving finasteride. A comparative 12-month study[5] found the alpha blocker terazosin to be more effective than finasteride in relieving symptoms and improving peak urine flow rates; the combination of finasteride plus terazosin was no more effective than terazosin alone. Moreover, although finasteride reduced prostatic volume, it was no more effective than placebo, a finding that is at odds with previous placebo-controlled studies. It has been suggested that the smaller median prostate size in this study may explain the negative findings,[6] and that men with larger prostates do benefit from finasteride. Similar results were reported in a 12-month study using doxazosin.[7] Later results[8,9] from a large study showed that over a longer period of 4 or more years the combination of doxazosin and finasteride reduced the risk of clinical progression more than either drug alone. The combination of an alpha blocker and 5α-reductase inhibitor is therefore considered to be a suitable option for patients with urinary symptoms and demonstrable prostatic enlargement, and who are at significant risk of progression.

Hirsutism. Finasteride is reported to be effective for the treatment of hirsutism (p.2089) in women.[1-7] It should be noted that finasteride should not be used in women who are or may become pregnant (see Precautions, above).

Malignant neoplasms of the prostate. Finasteride appears to have little effect in established prostate cancer,[1,2] but is under investigation for its prevention (p.671). The results of 1 small study[3] of its effects on the prostate found little evidence to support its use for prevention of malignancy in patients at high risk. In healthy men, a large controlled study, the Prostate Cancer Prevention Trial (PCPT),[4] found that 7 years of finasteride prophylaxis reduced the incidence of prostate cancer by about 25% compared with placebo, but this benefit was offset by an increased risk of high-grade tumours associated with finasteride. The risk-benefit implications of these results have been debated, although some commentaries[5-7] suggest that preventive use would be justified, at least in selected patients. Further analysis[8] of the PCPT data found that finasteride had introduced a detection bias for both prostate cancer and for high-grade prostate cancer. Finasteride increased the sensitivity of prostate specific antigen (PSA) testing, implying that the PCPT primary findings of increased risk of high-grade tumours were due, at least in part, to improved detection. The reported 25% decrease in prostate cancer incidence was also likely to be an underestimate. The European Association of Urology has endorsed a recommendation that prostate cancer management guidelines be updated to reflect these findings.[9]

Flavoxate Hydrochloride

(BANM, USAN, rINNM)

DW-61; Flavoksat Hidroklorür; Flavoxate, chlorhydrate de; Flavoxati hydrochloridum; Hidrocloruro de flavoxato; NSC-114649; Rec-7-0040. 2-Piperidinoethyl 3-methyl-4-oxo-2-phenyl-4*H*-chromene-8-carboxylate hydrochloride.

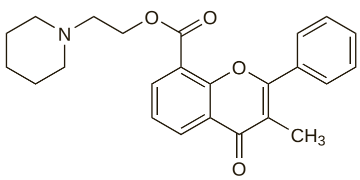
Флавоксата Гидрохлорид

$C_{24}H_{25}NO_4,HCl$ = 427.9.

CAS — 15301-69-6 (flavoxate); 3717-88-2 (flavoxate hydrochloride).

ATC — G04BD02.

ATC Vet — QG04BD02.



(flavoxate)

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Flavoxate Hydrochloride). A white or almost white crystalline powder. Slightly soluble in water and in alcohol; sparingly soluble in dichloromethane. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Ocular effects, including increased intra-ocular pressure, are occasionally troublesome. Other adverse effects include sedation or fatigue, vertigo, and hypersensitivity reactions. Leucopenia or eosinophilia has been reported rarely.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Pharmacokinetics

Flavoxate is readily absorbed from the gastrointestinal tract and rapidly metabolised, about 50 to 60% of a dose being excreted in the urine within 24 hours as methyl flavone carboxylic acid.

Uses and Administration

Flavoxate hydrochloride is described as a smooth muscle relaxant but it also has antimuscarinic effects (see, p.1221); it is a tertiary amine. It is used for the symptomatic relief of pain, urinary frequency, and incontinence associated with inflammatory disorders of the urinary tract. It is also used for the relief of vesico-urethral spasms resulting from instrumentation or surgery. A usual dose is 200 mg orally three times daily.

Urinary incontinence. Flavoxate is indicated mainly in the treatment of urge incontinence (p.2180). Results of studies have sometimes been disappointing,[1,2] although adverse effects are said to be less marked than those seen with other antimuscarinics such as oxybutynin.[3] In the UK, guidelines issued by NICE suggest that flavoxate should not be recommended for the treatment of urinary incontinence or overactive bladder in women; other antimuscarinics are preferred.[4]

1. Chapple CR, *et al.* Double-blind, placebo-controlled, cross-over study of flavoxate in the treatment of idiopathic detrusor instability. *Br J Urol* 1990; **66:** 491–4.

Multi-ingredient: ***Arg.:*** Algio-Bladuril; ***Ital.:*** Cistalgan.

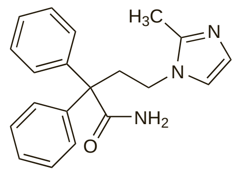
Imidafenacin *(rINN)*

Imidafenacina; Imidafénacine; Imidafenacinum; KRP-197; KRP-1979; Ono-8025. 4-(2-Methyl-1*H*-imidazol-1-yl)-2,2-diphenylbutanamide.

Имидафенацин

$C_{20}H_{21}N_3O$ = 319.4.

CAS — 170105-16-5.



Profile

Imidafenacin is an antimuscarinic that is used in the treatment of urinary frequency, urgency, and incontinence (p.2180). It is given in an oral dose of 100 micrograms twice daily, after food.

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Staybla; Uritos.

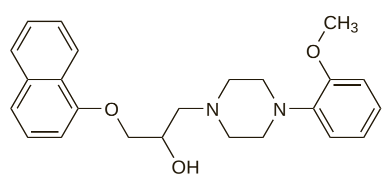
Naftopidil *(rINN)*

BM-15275; KT-611; Naftopidilum. (±)-4-(*o*-Methoxyphenyl)-α-[(1-naphthyloxy)methyl]-1-piperazineethanol.

Нафтопидил

$C_{24}H_{28}N_2O_3$ = 392.5.

CAS — 57149-07-2.



Profile

Naftopidil is a peripheral alpha$_1$-adrenoceptor blocker that is structurally related to urapidil (p.1419) and has similar general properties. It is used in benign prostatic hyperplasia to relieve symptoms of urinary obstruction.

Preparations

Proprietary Preparations (details are given in Part 3)

Jpn: Avishot; Flivas.

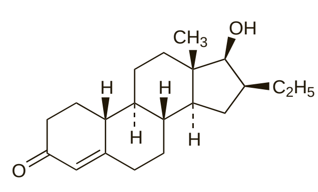
Oxendolone *(USAN, rINN)*

Oxendolona; Oxendolonum; TSAA-291. 16β-Ethyl-17β-hydroxyestr-4-en-3-one.

Оксендолон

$C_{20}H_{30}O_2$ = 302.5.

CAS — 33765-68-3.



Profile

Oxendolone is an anti-androgen that has been used in the treatment of benign prostatic hyperplasia.

Oxybutynin *(BAN, USAN, rINN)*

Oxibutinina; Oxybutynine; Oxybutyninum. 4-Diethylaminobut-2-ynyl 2-cyclohexyl-2-phenylglycolate; 4-(Diethylamino)-2-butynyl α-phenylcyclohexaneglycolic acid ester.

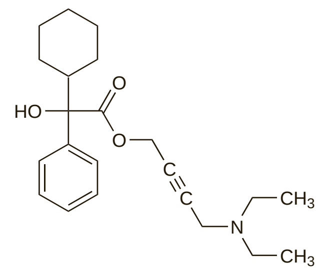
Оксибутинин

$C_{22}H_{31}NO_3$ = 357.5.

CAS — 5633-20-5.

ATC — G04BD04.

ATC Vet — QG04BD04.



Oxybutynin Hydrochloride *(BANM, rINNM)*

5058; Hidrocloruro de oxibutinina; MJ-4309-1; Oksibütinin Hidroklorür; Oksibutinino hidrochloridas; Oksibutyniinihydrokloridi; Oksybutyniny chlorowodorek; Oxibutinin-hidroklorid; Oxibutyninhydroklorid; Oxybutynin Chloride *(USAN)*; Oxybutynin hydrochlorid; Oxybutynine, chlorhydrate d'; Oxybutynini hydrochloridum. 4-Diethylaminobut-2-ynyl α-cyclohexylmandelate hydrochloride; 4-(Diethylamino)but-2-ynyl (*RS*)-2-cyclohexyl-2-hydroxy-2-phenylacetate hydrochloride.

Оксибутинина Гидрохлорид

$C_{22}H_{31}NO_3,HCl$ = 393.9.

CAS — 1508-65-2.

ATC — G04BD04.

ATC Vet — QG04BD04.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Oxybutynin Hydrochloride). A white or almost white, crystalline powder. Freely soluble in water and in alcohol; soluble in acetone; practically insoluble in cyclohexane. Protect from light.

USP 31 (Oxybutynin Chloride). A white, practically odourless, crystalline powder. Freely soluble in water and in alcohol; soluble in acetone; very soluble in chloroform and in methyl alcohol; slightly soluble in ether; very slightly soluble in hexane.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

Animal studies have shown reproductive toxicity with high doses of oxybutynin, hence the recommendation that it should be avoided during pregnancy; caution should also be observed during breast feeding.

Effects on body temperature. A 76-year-old man taking oxybutynin hydrochloride 5 mg three times daily suffered heatstroke on a day when the ambient temperature was about 37°. He had had a similar febrile episode the previous summer while taking oxybutynin.[1]

1. Adubofour KO, *et al.* Oxybutynin-induced heatstroke in an elderly patient. *Ann Pharmacother* 1996; **30:** 144–7.

Effects on the eyes. After 4 weeks of treatment, the adverse ocular effects of oxybutynin and tolterodine were evaluated in 24 and 28 women, respectively, being treated for urge incontinence.[1] The incidence of adverse effects reported by the patients was similar for the 2 drugs. A burning sensation in the eyes occurred in about half the women, but reports of a foreign-body sensation and dry eyes were less frequent. There was a reduction in accommodation amplitude although this was statistically significant only for oxybutynin, and pupillary diameter in dim light was only significantly larger for tolterodine. Tear film stability was found to be reduced for both drugs, but intra-ocular pressure was not significantly affected.

Acute angle-closure glaucoma has been reported in an elderly woman taking oxybutynin for urge incontinence.[2]

1. Altan-Yaycioglu R, *et al.* Ocular side-effects of tolterodine and oxybutynin, a single-blind prospective randomized trial. *Br J Clin Pharmacol* 2005; **59:** 588–92.
2. Sung VCT, Corridan PG. Acute-angle closure glaucoma as a side-effect of oxybutynin. *Br J Urol* 1998; **81:** 634–5.

Effects on the gastrointestinal tract. Reflux oesophagitis has been reported[1] in a 36-year-old woman with cerebral palsy and hiatus hernia who had taken oxybutynin for 5 years to prevent urinary incontinence. Symptoms of gastro-oesophageal reflux resolved when oxybutynin was stopped.

1. Lee M, Sharifi R. Oxybutynin-induced reflux esophagitis. *DICP Ann Pharmacother* 1990; **24:** 583–5.

Effects on mental function. Oxybutynin was associated with the development of acute confusional states in 4 patients with Parkinson's disease and some cognitive impairment.[1] A study[2] of healthy subjects, aged 65 years or older, also found oxybutynin to cause cognitive impairment.

1. Donnellan CA, *et al.* Oxybutynin and cognitive dysfunction. *BMJ* 1997; **315:** 1363–4.
2. Katz IR, *et al.* Identification of medications that cause cognitive impairment in older people: the case of oxybutynin chloride. *J Am Geriatr Soc* 1998; **46:** 8–13.

Night terrors. Night terrors have been reported in 5 patients taking oxybutynin.[1] Four of the patients were young children and the fifth was an elderly woman. Rechallenge was positive in 2 cases.

1. Valsecia ME, *et al.* New adverse effect of oxybutynin: "night terror". *Ann Pharmacother* 1998; **32:** 506.

Overdosage. A report[1] of a 34-year-old woman who ingested 100 mg of oxybutynin. The main symptoms were antimuscarinic effects and included drowsiness, hallucinations, dilatation of pupils, and urinary retention. Tachycardia resolved shortly after admission to hospital but ventricular ectopic beats and bigeminy persisted for over 24 hours. The patient recovered with symptomatic treatment.

1. Banerjee S, *et al.* Poisoning with oxybutynin. *Hum Exp Toxicol* 1991; **10:** 225–6.

Porphyria. Oxybutynin hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals* or *in-vitro* systems.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Itraconazole. Use of itraconazole with oxybutynin resulted in moderate increases of serum concentrations of the latter.[1] However, concentrations of the active metabolite of oxybutynin, *N*-desethyloxybutynin, were virtually unchanged and the interaction was considered to be of minor clinical significance.

1. Lukkari E, *et al.* Itraconazole moderately increases serum concentrations of oxybutynin but does not affect those of the active metabolite. *Eur J Clin Pharmacol* 1997; **52:** 403–6.

Pharmacokinetics

After oral doses of oxybutynin, peak plasma concentrations are reached within one hour. Oxybutynin is also absorbed after application to the skin. It is highly bound to plasma proteins. Oxybutynin undergoes extensive first-pass metabolism, particularly by the cytochrome P450 isoenzyme CYP3A4, and systemic oral bioavailability has been reported to be only 6%. *N*-desethyloxybutynin is an active metabolite. Oxybutynin and its metabolites are excreted in the urine and faeces, and an elimination half-life of 2 to 3 hours has been reported. Oxybutynin has been detected in breast milk. Evidence suggests that it may cross the blood-brain barrier.

Uses and Administration

Oxybutynin hydrochloride is a tertiary amine antimuscarinic with actions similar to those of atropine (p.1220); it also has direct effects on smooth muscle. It is used for the management of urinary frequency, urgency, and incontinence in neurogenic bladder disorders and in idiopathic detrusor instability, and as an adjunct to nonpharmacological therapy for nocturnal enuresis.

Usual oral doses of oxybutynin hydrochloride are 5 mg two or three times daily, increased to 5 mg four times daily if required. In elderly patients lower doses of 2.5 or 3 mg twice daily initially, increased to 5 mg twice daily if necessary, may be adequate. Modified-release preparations of oxybutynin hydrochloride are also available. The initial dose is 5 mg once daily, increased by 5 mg at weekly intervals if necessary, up to a maximum of 20 or 30 mg daily, depending on the preparation. Oxybutynin is also given via a transdermal patch that supplies 3.9 mg of oxybutynin daily. The patch should be applied to intact skin on the abdomen, hip, or buttocks and replaced every 3 to 4 days; re-application to the same site should be avoided for 7 days.

In the UK, oxybutynin hydrochloride is licensed for neurogenic bladder disorders in children from the age of 5 years; in both the UK and the USA it is licensed from the age of 6 years as a modified-release formulation. The initial oral dose of conventional formulations is 2.5 or 3 mg twice daily, increased to 5 mg two or three times daily according to response; as a modified-release tablet the initial dose is 5 mg once daily, increased by 5-mg increments to a maximum daily dose of 15 or 20 mg, depending on the preparation, and according to response. Modified-release preparations are not recommended for children who are unable to swallow the tablet whole. The *BNFC* suggests that children aged 2 to 5 years may be given a dose of 1.25 to 2.5 mg as a conventional oral formulation 2 or 3 times daily. Children from the age of 2 years may also be given oxybutynin by intravesical instillation, in a dose of 5 mg (as the hydrochloride) in 30 mL of solution, 2 or 3 times daily.

Oxybutynin is also licensed in the treatment of nocturnal enuresis in children over 5 years, as the conventional formulations, in similar doses to those used for neurogenic bladder disorders; the last dose should usually be given before bedtime. However, the *BNFC* considers that drug therapy for nocturnal enuresis is usually not needed in children under 7 years of age.

Nocturnal enuresis. Antimuscarinics such as oxybutynin reduce uninhibited bladder contractions but, although they may be of use in diurnal enuresis, they are rarely of benefit in nocturnal enuresis (p.2180) alone. Oxybutynin did not appear to be effective in treating primary nocturnal enuresis in children with normal bladders.[1] However, children with low bladder capacity and detrusor instability may derive some benefit from oxybutynin.[2,3]

2. Koşar A, *et al.* Effectiveness of oxybutynin hydrochloride in the treatment of enuresis nocturna: a clinical and urodynamic study. *Scand J Urol Nephrol* 1999; **33:** 115–18.
3. Nevéus T. Oxybutynin, desmopressin and enuresis. *J Urol (Baltimore)* 2001; **166:** 2459–62.

Urinary incontinence. In addition to its antimuscarinic effect, oxybutynin has a direct antispasmodic effect which also contributes to reducing the number of uninhibited bladder contractions in urge incontinence (see p.2180). It is effective when given orally[1-4] or via a transdermal patch.[5-7] NICE considers conventional oral oxybutynin formulations to be the drug of first choice in women with overactive bladder syndrome or mixed incontinence if bladder training has been ineffective.[8] However, adverse effects may limit its use; if immediate-release oxybutynin is not well tolerated, a controlled-release or transdermal formulation may be considered as an alternative.[8]

Oxybutynin given orally can be useful in the management of neurogenic detrusor hyperreflexia in adults[9,10] and children.[11] Direct instillation of oxybutynin into the bladder has also been tried. In one study[12] that included patients aged 1 to 34 years, 21 out of 32 patients became totally continent using an intravesical dose of 300 micrograms/kg daily, given in 3 divided doses. A further 7 patients became continent with doses titrated up to a maximum of 900 micrograms/kg daily, but another 4 remained incontinent. Other reports[13,14] have used single or multiple doses of 5 mg, often prepared by dispersing a crushed 5-mg tablet in 30 mL of distilled water or sodium chloride 0.9%.

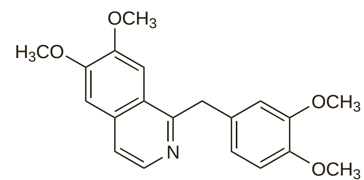
Papaverine *(BAN)*

Papaveriini; Papaverin; Papaverina; Papaverinum. 6,7-Dimethoxy-1-(3,4-dimethoxybenzyl)isoquinoline.

$C_{20}H_{21}NO_4$ = 339.4.
CAS — 58-74-2.
ATC — A03AD01; G04BE02.
ATC Vet — QA03AD01; QG04BE02.



NOTE. Papaverine should not be confused with papaveretum (p.105).

Papaverine Hydrochloride *(BANM)*

Papaveriinihydrokloridi; Papaverina, hidrocloruro de; Papavérine, chlorhydrate de; Papaverin-hidroklorid; Papaverin-hydrochlorid; Papaverinhydroklorid; Papaverini hydrochloridum; Papaverinii Chloridum; Papaverinium Chloride; Papaverino hidrochloridas; Papaweryny chlorowodorek. 6,7-Dimethoxy-1-(3,4-dimethoxybenzyl)isoquinoline hydrochloride.

$C_{20}H_{21}NO_4,HCl$ = 375.8.
CAS — 63817-84-5 (papaverine cromesilate); 61-25-6 (papaverine hydrochloride); 39024-96-9 (papaverine monophosadenine); 2053-26-1 (anhydrous papaverine sulfate).
ATC — A03AD01; G04BE02.
ATC Vet — QA03AD01; QG04BE02.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Papaverine Hydrochloride). White or almost white crystals or crystalline powder. Sparingly soluble in water; slightly soluble in alcohol. A 2% solution in water has a pH of 3.0 to 4.0.

USP 31 (Papaverine Hydrochloride). Odourless white crystals or white, crystalline powder. Soluble 1 in 30 of water and 1 in 120 of alcohol; soluble in chloroform; practically insoluble in ether. pH of a 2% solution in water is between 3.0 and 4.5. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Adverse Effects and Precautions

Adverse effects of oral papaverine include gastrointestinal disturbance, flushing of the face, headache, malaise, drowsiness, skin rash, sweating, orthostatic hypotension, and dizziness. Jaundice, eosinophilia, and signs of altered liver function may occur, sometimes due to hypersensitivity. In addition high parenteral doses can result in cardiac arrhythmias; intravenous or intramuscular doses should be given slowly. Thrombosis has been reported at the injection site.

Intracavernosal injection can cause dose-related priapism and local fibrosis has been reported after long-term therapy.

Papaverine should be given with caution to patients with reduced gastrointestinal motility. Caution is also advised in the presence of cardiac conduction disorders or unstable cardiovascular disease, especially when papaverine is given parenterally. Intravenous dosage is contra-indicated in patients with complete AV block.

Glaucoma. There appeared to be no basis for the manufacturers' recommendation that papaverine should be used with caution in patients with glaucoma.[1] There was no obvious mechanism to support such a warning and only 1 report of an adverse reaction had been received by the FDA. The author had given papaverine intracavernosally to patients with glaucoma and had observed no deterioration.

1. Swartz DA, Todd MW. Intracavernous papaverine and glaucoma. *JAMA* 1990; **264:** 570.

Intracavernosal administration. Systemic adverse effects occurring after intracavernosal injection of papaverine are infrequent but include dizziness and syncope,[1,2] probably related to the hypotensive effects of papaverine; abnormal liver function test results have also occurred.[1-3]

The most serious acute adverse effect is priapism[1,2,4] and patients should be instructed to seek medical help if an erection lasts for more than 4 hours. Detumescence can be effected by aspiration of blood from the corpus or by local injection of an alpha-adrenergic agonist such as adrenaline, metaraminol, or phenylephrine (see Priapism under Alprostadil, p.2184). Other local effects include haematoma, infection, and, on long-term therapy, fibrosis and penile distortion.[1,2]

Dispensing errors have resulted in inadvertent injection of *papaveretum* with potentially fatal consequences.[2,5,6]

Interactions

Levodopa. For the effects of papaverine on levodopa, see p.808.

Pharmacokinetics

The biological half-life of papaverine given orally is reported to be between 1 and 2 hours, but there is wide interindividual variation. It is about 90% bound to plasma proteins.

Papaverine is mainly metabolised in the liver and excreted in the urine, almost entirely as glucuronide-conjugated phenolic metabolites.

The reports of infrequent systemic effects after intracavernosal injection of papaverine indicate that there is some distribution to the systemic circulation from the corpus cavernosus.

Uses and Administration

Papaverine is an alkaloid present in opium, although it is not related chemically or pharmacologically to the other opium alkaloids. Papaverine has a direct relaxant effect on smooth muscle which is attributed in part to its ability to inhibit phosphodiesterase. It has been given in the management of cerebral, peripheral, and coronary vascular disorders; it is also given as an antispasmodic for gastrointestinal disorders and coughs. However, there is little evidence to justify its clinical use in these conditions.

Papaverine hydrochloride has been given orally in doses of up to 600 mg daily. Sustained-release preparations have been used. The codecarboxylase derivative, cromesilate, hydrobromide, monophosadenine, nicotinate, sulfate, and teprosilate have also been used. Papaverine hydrochloride has also been given in doses of 30 to 120 mg by intramuscular or slow intravenous injection, repeated every 3 hours as needed (but see Adverse Effects and Precautions, above).

Papaverine hydrochloride has been given by injection into the corpus cavernosum of the penis for the treatment of erectile dysfunction (p.2179). Doses have ranged from 2.5 to 60 mg, but must be initially titrated by the prescriber. Doses up to about 30 mg have been combined with phentolamine.

Preparations

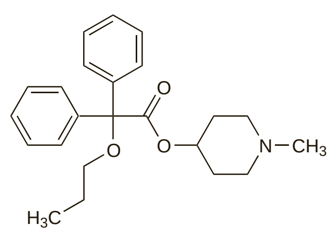
Propiverine Hydrochloride *(BANM, rINNM)*

BUP-4 (propiverine); Hidrocloruro de propiverina; Propiverin Hidroklorür; Propivérine, Chlorhydrate de; Propiverini Hydrochloridum. 1-Methyl-4-piperidyl diphenylpropoxyacetate hydrochloride.

Пропиверина Гидрохлорид
$C_{23}H_{29}NO_3,HCl = 403.9.$
CAS — 60569-19-9 (propiverine); 54556-98-8 (propiverine hydrochloride).
ATC — G04BD06.
ATC Vet — QG04BD06.



(propiverine)

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Hypotension and drowsiness may also occur with propiverine. Propiverine is contra-indicated in patients with moderate or severe hepatic impairment (but see below). Liver enzyme values should be monitored in patients receiving long-term therapy. Skeletal retardation has occurred in the offspring of *animals* given high doses of propiverine during pregnancy and therefore its use is not recommended during pregnancy.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220). Hypotension may occur in patients treated with propiverine and isoniazid. Drowsiness may be enhanced by drugs with CNS-depressant properties.

Pharmacokinetics

Propiverine is absorbed from the gastrointestinal tract and peak plasma concentrations are achieved about 2.3 hours after oral doses. It undergoes extensive first-pass metabolism and the average absolute bioavailability is reported to be about 41%. Plasma concentrations of the principal metabolite, the *N*-oxide, greatly exceed those of the parent compound. Protein binding is about 90% for propiverine and 60% for the *N*-oxide metabolite. Propiverine and its metabolites are excreted in the urine, bile, and faeces. The elimination half-life is about 20 hours.

◊ References.

1. Haustein K-O, Hüller G. On the pharmacokinetics and metabolism of propiverine in man. *Eur J Drug Metab Pharmacokinet* 1988; **13:** 81–90.

Uses and Administration

Propiverine hydrochloride is a tertiary antimuscarinic with actions similar to those of atropine (p.1220). It is used for the management of urinary frequency, urgency, and incontinence (p.2180) in neurogenic bladder disorders and in idiopathic detrusor instability. Usual oral doses of propiverine hydrochloride are 15 mg two or three times daily, increased to 4 times daily if required. Some patients may respond to 15 mg once daily. A daily dose of 60 mg should not be exceeded. Propiverine hydrochloride can also be given as a modified-release preparation in a dose of 30 mg once daily.

Administration in hepatic impairment. Although UK licensed product information for propiverine does not recommend its use in patients with moderate or severe hepatic impairment some[1] suggest that on pharmacokinetic grounds it may be given to those with mild to moderate degrees of impairment at recommended doses without increasing the risk of adverse effects.

1. Siepmann M, *et al.* Pharmacokinetics and safety of propiverine in patients with fatty liver disease. *Eur J Clin Pharmacol* 1998; **54:** 767–71.

Urinary incontinence. Although propiverine is licensed in the UK for use in urinary frequency, urgency, and incontinence (see above), guidelines subsequently issued by NICE consider that although it should be an option for urinary frequency in women with overactive bladder syndrome, use in women with overt incontinence is not recommended.[1]

ATC — G04CX02.
ATC Vet — QG04CX02.

Pharmacopoeias. In *Eur.* (see p.vii) and *US. US* also includes the extract and the powdered form.

Ph. Eur. 6.2 (Saw Palmetto Fruit). The dried, ripe fruit of *Ser-*

enoa repens (*Sabal serrulata*). It contains not less than 11.0% of total fatty acids, calculated with reference to the dried drug. Protect from light.

USP 31 (Saw Palmetto). The partially dried, ripe fruit of *Serenoa repens* (Arecaceae). Store in airtight containers. Protect from light.

Profile

Saw palmetto is the dried fruit of the American dwarf palm tree, *Serenoa repens* (Arecaceae). It contains various steroidal compounds with anti-androgenic and oestrogenic activities, one of which is sitosterol (p.1373). Saw palmetto is used for the treatment of benign prostatic hyperplasia. Preparations of alcoholic or lipophilic extracts have typically been given in oral doses of 160 mg twice daily, or 320 mg once daily.

Adverse effects. ***EFFECTS ON THE LIVER.*** Cholestatic hepatitis occurred in a man who took a herbal preparation containing saw palmetto for 2 weeks to treat nocturia and hesitancy.[1]

1. Hamid S, *et al.* Protracted cholestatic hepatitis after the use of Prostata. *Ann Intern Med* 1997; **127:** 169–70.

Uses. ***BENIGN PROSTATIC HYPERPLASIA.*** A lipid hexane extract of saw palmetto has been shown to be generally superior to placebo,[1,2] and of similar efficacy to finasteride[3] in the treatment of benign prostatic hyperplasia (p.2178). A systematic review of randomised studies of various saw palmetto extracts concluded that they improve urological symptoms and flow measures.[4] However, a more recent double-blind study[5] concluded that treatment for one year was not superior to placebo for improving urinary symptoms and objective measures.

Sildenafil Citrate *(BANM, USAN, rINNM)*

Citrato de sildenafilo; Sildénafil, citrate de; Sildenafil Sitrat; Sildenafili citras; UK-92480-10. 5-[2-Ethoxy-5-(4-methylpiperazin-1-ylsulfonyl)phenyl]-1,6-dihydro-1-methyl-3-propylpyrazolo[4,3-*d*]pyrimidin-7-one citrate; 1-{[3-(6,7-Dihydro-1-methyl-7-oxo-3-propyl-1*H*-pyrazolo[4,3-*d*]pyrimidin-5-yl)-4-ethoxyphenyl]sulfonyl}-4-methylpiperazone citrate.

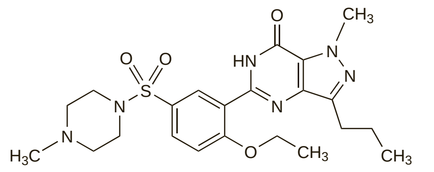
Сильденафила Цитрат

$C_{22}H_{30}N_6O_4S,C_6H_8O_7 = 666.7.$

CAS — 139755-83-2 (sildenafil); 171599-83-0 (sildenafil citrate).

ATC — G04BE03.

ATC Vet — QG04BE03.



(sildenafil)

Stability. Sildenafil citrate tablets were ground to a powder and combined with a 1:1 mixture of methylcellulose 1% and simple syrup (USNF), or with a 1:1 mixture of *Ora-Plus* and *Ora-Sweet* (both *Paddock, USA*), to a nominal concentration of 2.5 mg/mL sildenafil citrate in each suspension.[1] Both suspensions were found to be chemically and physically stable for 91 days in plastic bottles, at both 4° and 25°.

Adverse Effects

Adverse effects most commonly reported with sildenafil are headache, flushing, and dyspepsia. Also common are visual disturbances such as blurred vision, photophobia, chromatopsia, cyanopsia, eye irritation, pain and redness of the eyes. Retinal haemorrhage has occurred, and non-arteritic anterior ischaemic optic neuropathy (NAION) causing permanent loss of vision has been reported rarely. Other common adverse effects include dizziness, insomnia, anxiety, vertigo, epistaxis, nasal congestion, pyrexia, and gastrointestinal disturbances such as diarrhoea and vomiting. Priapism can occur.

Other adverse effects include skin rashes, erythema, alopecia, limb and/or back pain, myalgia, facial oedema, fluid retention, paraesthesia, and urinary-tract infection. Dyspnoea, cough, rhinitis, sinusitis, bronchitis, and cellulitis can occur. Sudden decrease or loss of hearing has been reported. Other reported effects include anaemia, leucopenia, gynaecomastia, urinary frequency or incontinence, haematuria, and seizures.

Cerebrovascular haemorrhage and transient ischaemic attacks have occurred. There have also been reports of palpitations, syncope, hypertension, hypotension, and serious cardiovascular events including myocardial infarction, arrhythmias, tachycardia, unstable angina, and sudden cardiac death.

Effects on the cardiovascular system. The effects of phosphodiesterase type-5 inhibitors (sildenafil, tadalafil, and vardenafil) on the cardiovascular system,[1,2] and the potential risks of sexual activity in men with cardiovascular disease,[3] have been reviewed.

There has been considerable uncertainty about the potential cardiovascular risk associated with sildenafil treatment. Minor effects associated with vasodilatation, such as headache and flushing are relatively common, but in patients without pre-existing cardiovascular risk factors the risk of serious cardiovascular events associated with the drug appears to be low. However, there have been reports of myocardial infarction in patients who had no apparent risk factors,[4,5] and a consensus document issued by the American College of Cardiology and the American Heart Association (ACC/AHA) has pointed out that patients with erectile dysfunction are mostly over 45 years of age and are more likely to have risk factors predisposing them to cardiovascular disease.[6]

As of November 1998, 130 deaths in US patients taking sildenafil had been reported to the FDA; 3 of these were due to stroke and 77 to some other cardiovascular event.[7] The nature of the relationship between drug and event was considered unclear, but some of these patients were also receiving nitrates, a combination now contra-indicated because of the greatly increased risk of potentially life-threatening hypotension.[6] The Australian Adverse Drug Reactions Advisory Committee[8] stated in June 2002 that it had received 773 reports of adverse reactions associated with the use of sildenafil. There were 20 reports of myocardial infarction, including 4 fatalities; 9 of these 20 patients had pre-existing cardiovascular disease or diabetes or were considered to be at high risk of cardiovascular disease, and 1 patient was taking nitrates. Other cardiovascular effects reported included 26 reports of chest pain and 10 other fatalities (6 sudden unexplained deaths, 2 strokes, and 2 subarachnoid haemorrhages). However, it was pointed out that the timing of these adverse effects in relation to sildenafil ingestion was often not reported and that, since sildenafil is taken in the context of sexual activity and, in some cases, underlying coronary disease, the contribution of sildenafil to cardiac events was difficult to assess.

It is still uncertain whether patients with **pre-existing** cardiovascular disease are at increased risk when taking sildenafil without concomitant nitrates. The ACC/AHA consensus statement noted that the evidence was scanty and suggested that sildenafil could be used, but with caution, in patients with stable *coronary artery disease* provided that nitrates were not taken.[6] A later review[9] and studies using exercise testing[10,11] also concluded that sildenafil appeared to be well tolerated in most patients with chronic stable coronary artery disease. In men with mild to moderate chronic *heart failure*, small studies have found that sildenafil was well tolerated and effective for erectile dysfunction,[12-14] and improved measures of exercise capacity.[12] Analyses[15,16] of combined trial data have examined the effects of sildenafil in men stabilised on antihypertensive treatment (including diuretics, beta blockers, alpha blockers, ACE inhibitors, and calcium-channel blockers) compared with men who did not have *hypertension*. Similar results were found for both groups in terms of sildenafil's efficacy for erectile dysfunction.[16] Also, changes in blood pressure and heart rate after a dose of sildenafil,[15] and the incidence of treatment-related adverse effects that were potentially related to blood pressure decrease,[16] were not significantly different between the groups. Evidence to assess the risk in other cardiovascular disorders is less extensive, although a case report of a patient with hypertrophic *cardiomyopathy* who had cardiovascular adverse effects after a dose of sildenafil suggested that the drug may precipitate an unstable haemodynamic state in this condition.[17]

Effects on the ears. As of October 2007, the US FDA had received a total of 29 postmarketing reports of sudden hearing loss with phosphodiesterase type-5 inhibitors. The problem was sometimes accompanied by tinnitus, vertigo, or dizziness. In most of the cases, the hearing loss involved one ear, and it was either a partial or complete loss of hearing. In about one-third of cases, the loss was temporary. While a causal relationship could not be established, patients should be advised that hearing loss may be related to these drugs, and to seek medical attention if affected.[1]

Effects on the eyes. The Australian Adverse Drug Reactions Advisory Committee[1] stated in June 2002 that it had received 65 reports of abnormal vision from a total of 773 adverse reactions associated with use of sildenafil reported over 3 years. A bluish tinge or haze to vision and some increased light sensitivity has been reported by patients taking sildenafil, with the percentage of reports increasing with increasing dose.[2] The visual symptoms usually peak 1 to 2 hours after ingestion and resolve about 3 to 4 hours later. The effects of a single dose of sildenafil 100 mg were studied in 5 healthy subjects.[3] Electroretinogram measurements showed significant changes that correlated well with plasma-sildenafil concentrations, peaking at 1 hour after administration and showing complete recovery at the 6-hour measurements. Inhibition of phosphodiesterase type-6 in rod photoreceptors is the most likely mechanism of sildenafil-associated retinal dysfunction. However, there is as yet no clear evidence of retinal toxic effects or whether repeated dosing with sildenafil causes prolonged or further retinal dysfunction.[2,3] Likewise, it remains to be determined whether recovery of function as plasma-sildenafil concentrations subside also occurs in older patients or those with retinal degenerative disorders such as retinitis pigmentosa.

Other visual disturbances reported in patients taking sildenafil have included temporary loss of vision and increased intra-ocular pressure.[4] A 69-year-old man who had permanent loss of vision in one eye a few hours after taking sildenafil 100 mg was found to have an occlusion in a retinal artery.[5] In another similar case of retinal artery occlusion[6] the patient also had uncontrolled hypertension; the authors suggested that embolisation by a pre-existing arteriosclerotic plaque of the carotid artery resulted from elevated blood pressure and cardiac workload during sexual activity, rather than as a direct adverse effect of sildenafil.

Several cases of persistent blurred vision and visual loss caused by nonarteritic anterior ischaemic optic neuropathy (NAION; vascular insufficiency and ischaemia at the optic nerve head) associated with sildenafil use have been reported.[7-10] Generally, visual defects developed in one eye only within 24 hours of sildenafil ingestion, although many of these men had taken doses of sildenafil on past occasions without adverse effect. A small number of cases have also been reported for tadalafil[10-13] and vardenafil.[10] However, many of these men had underlying anatomic or vascular risk factors for NAION, including low cup to disc ratio (crowded disc), age over 50, diabetes, hypertension, ischaemic heart disease, hyperlipidaemia, and smoking. As of May 2005 the FDA had concluded that it was not possible to determine whether NAION was directly related to the use of phosphodiesterase type-5 inhibitors, the patients' underlying vascular risk factors or anatomical defects, a combination of these factors, or other factors.[10]

Effects on mental function. There have been a few cases reported[1-3] of transient global amnesia after the use of sildenafil or tadalafil. Between January 1998 and February 2001, the FDA had received 35 reports of amnesia in which sildenafil was listed as the primary causal suspect.[4]

Precautions

Caution is required in patients with hepatic or severe renal impairment, and dosage reduction of sildenafil may be necessary. Care is also needed in patients with anatomical deformation of the penis or haematological disorders that may predispose them to priapism. In the event of prolonged erection (for more than 4 hours), patients should seek medical assistance, as penile tissue damage and permanent loss of potency can occur. Patients are also advised to stop taking sildenafil and seek medical advice in cases of sudden visual or hearing loss. Sildenafil should not be given to those with loss of vision in one eye caused by non-arteritic anterior or ischaemic optic neuropathy (NAION), regardless of whether this was in connection with previous phosphodiesterase type-5 inhibitors or not. Patients who experience dizziness or visual disturbances should not drive or operate hazardous machinery.

The safety of sildenafil is uncertain in patients with severe hepatic impairment, bleeding disorders, active peptic ulceration, hypotension, hypertension, a recent history of stroke, myocardial infarction, or life-threatening arrhythmia, unstable angina, heart failure, or retinal disorders such as retinitis pigmentosa (a minority of whom have genetic disorders of retinal phosphodiesterases). Licensed product information advises that it should not be used in these groups.

Cardiovascular disease. For mention of a consensus statement on the use of sildenafil in patients with cardiovascular disease, see above.

Interactions

Sildenafil or other phosphodiesterase type-5 inhibitors may potentiate the hypotensive effects of organic nitrates, and are therefore contra-indicated in patients receiving such drugs. Sildenafil may also enhance the hypotensive effect of nicorandil and use of the two drugs together should be avoided. Symptomatic hypotension may also occur when phosphodiesterase type-5 inhibitors are given with alpha blockers. Generally, the patient should be stabilised on alpha blocker therapy before the phosphodiesterase type-5 inhibitor is started at a low dose and adjusted according to response. Drugs that inhibit the cytochrome P450 isoenzyme CYP3A4, such as cimetidine, delavirdine, erythromycin, itraconazole, and ketoconazole, may reduce the clearance of phosphodiesterase type-5 inhibitors, necessitating a reduction in dosage. Plasma concentrations of phosphodiesterase type-5 inhibitors are significantly increased by HIV-protease inhibitors, and particularly so by ritonavir-boosted regimens. Such combinations should not be given unless absolutely essential. Grapefruit juice should be avoided with sildenafil or other phosphodiesterase type-5 inhibitors as it may increase their plasma concentrations. Inducers of CYP3A4, such as rifampicin, are likely to decrease plasma concentrations of phosphodiesterase type-5 inhibitors. Bosentan also reduces exposure to sildenafil.

Specific dosage recommendations have been made for the use of phosphodiesterase type-5 inhibitors with many of these drugs; see Uses and Administration under Sildenafil (below), Tadalafil (p.2196), and Vardenafil (p.2199).

Antivirals. Rises in sildenafil concentrations after use of *saquinavir* or *ritonavir* were consistent[1] with inhibition of metabolism mediated by the cytochrome P450 isoenzyme CYP3A4. The larger increases seen with ritonavir may be due to its additional inhibition of the isoenzyme CYP2C9. Fatal myocardial infarction has been reported[2] in a 47-year-old patient who took sildenafil 25 mg with ritonavir and saquinavir. In a study[3] of 6 HIV-positive men being treated with triple antiretroviral therapy that included *indinavir*, plasma concentrations of sildenafil were found to be significantly increased compared with historical controls.

Cardiovascular drugs. For the effects of sildenafil in men stabilised on *antihypertensives* in general, see Effects on the Cardiovascular System, above. For mention of a possible interaction between sildenafil and *verapamil*, see Immunosuppressants, below.

The plasma concentration of sildenafil was reduced by *bosentan* in a study[1] of 10 patients with pulmonary hypertension, probably by induction of the cytochrome P450 isoenzyme CYP3A4, which would increase the metabolism of sildenafil. The use of bosentan with sildenafil in pulmonary hypertension has been reported (see below) and this potential interaction should be taken into account.

1. Paul GA, *et al.* Bosentan decreases the plasma concentration of sildenafil when coprescribed in pulmonary hypertension. *Br J Clin Pharmacol* 2005; **60:** 107–12.

Dihydrocodeine. The use of dihydrocodeine with sildenafil was associated with priapism in 2 men who had previously been treated successfully with sildenafil.[1] The first patient had two prolonged erections, lasting 4 and 5 hours, and the effect did not recur when the dihydrocodeine was stopped. The second patient had priapism on 3 occasions in the first week of dihydrocodeine treatment, but not in the subsequent 2 weeks despite continuing both drugs.

1. Goldmeier D, Lamba H. Prolonged erections produced by dihydrocodeine and sildenafil. *BMJ* 2002; **324:** 1555.

Food. *Grapefruit juice* has been shown to increase bioavailability but delay absorption of sildenafil in healthy subjects.[1]

1. Jetter A, *et al.* Effects of grapefruit juice on the pharmacokinetics of sildenafil. *Clin Pharmacol Ther* 2002; **71:** 21–9.

Immunosuppressants. Studies in men with erectile dysfunction who were receiving *tacrolimus* after kidney transplantation found that sildenafil had no effect on tacrolimus pharmacokinetics.[1,2] However, the pharmacokinetic profile of sildenafil differed from that reported in healthy subjects; the maximal plasma concentration was higher, the area under the concentration-time curve was increased, and the elimination half-life was prolonged.[1] Reductions in blood pressure were also found when sildenafil was given, although this may have been due to an interaction with *verapamil*. The authors suggested that an initial dose of 25 mg sildenafil should be used, and that on the days of sildenafil use the doses of antihypertensive drugs may need to be adjusted according to blood pressure response.[1,2]

2. Christ B, *et al.* Investigation on interaction between tacrolimus and sildenafil in kidney-transplanted patients with erectile dysfunction. *Int J Clin Pharmacol Ther* 2004; **42:** 149–56.

Nitrates. Giving sildenafil 50 mg to patients receiving *isosorbide mononitrate*, or sublingual *glyceryl trinitrate* given 1 hour after sildenafil, resulted in substantially greater decreases in blood pressure than when the nitrate was given alone in 2 crossover studies in patients with angina.[1] Treatment-related adverse effects were reported in 8 of 16 patients who received sildenafil with isosorbide mononitrate and 3 of 15 who took sildenafil with glyceryl trinitrate. The authors confirmed that sildenafil should not be taken with nitrates.

1. Webb DJ, *et al.* Sildenafil citrate potentiates the hypotensive effects of nitric oxide donor drugs in male patients with stable angina. *J Am Coll Cardiol* 2000; **36:** 25–31.

Pharmacokinetics

Sildenafil is rapidly absorbed after an oral dose, with a bioavailability of about 40%. Peak plasma concentrations are attained within 30 to 120 minutes; the rate of absorption is reduced when sildenafil is given with food.

Sildenafil is widely distributed into tissues and is about 96% bound to plasma proteins. It is metabolised in the liver mainly by cytochrome P450 isoenzymes CYP3A4 (the major route) and CYP2C9. The major metabolite, *N*-desmethylsildenafil (UK-103320) also has some activity. The terminal half-lives of sildenafil and the *N*-desmethyl metabolite are about 4 hours.

Sildenafil is excreted as metabolites, mainly in the faeces, and to a lesser extent the urine. Clearance may be reduced in the elderly and in patients with hepatic or severe renal impairment.

Uses and Administration

Sildenafil is a phosphodiesterase type-5 inhibitor used in the management of erectile dysfunction and pulmonary arterial hypertension. It is given orally as the citrate although doses are expressed in terms of the base; 14 mg of sildenafil citrate is equivalent to about 10 mg of sildenafil.

In **erectile dysfunction** the usual dose is equivalent to sildenafil 50 mg about one hour before sexual intercourse. The dose may be increased or decreased depending on response. The maximum recommended dose is 100 mg, and sildenafil should not be taken more than once in 24 hours.

- An initial dose of 25 mg has been suggested in the USA for patients over 65 years of age, though such initial reductions are not considered necessary in the UK.
- An initial dose of no more than 25 mg daily is advised in patients taking sildenafil with inhibitors of cytochrome P450 isoenzyme CYP3A4; the dose should not exceed 25 mg every 48 hours if given with ritonavir-boosted HIV-protease inhibitors, although such a combination is best avoided entirely (see Interactions, above).
- In patients stabilised on alpha blocker therapy, an initial dose of sildenafil 25 mg should be considered.

To improve exercise ability in **pulmonary arterial hypertension**, sildenafil is given orally in a dose of 20 mg three times daily. The dose may need adjustment to account for drug interactions (see above) although licensed product information suggests that in these patients no adjustment is required when sildenafil is given with erythromycin or saquinavir. It also suggests that no adjustment is generally needed for pulmonary hypertension patients with renal or hepatic impairment, although patients with severe hepatic impairment (Child-Pugh category C) have not been studied. Although not licensed in the UK for children, the *BNFC* allows for a dose in neonates and children up to 18 years of age, of 250 to 500 micrograms/kg given orally every 4 to 8 hours, adjusted according to response up to a maximum of 2 mg/kg every 4 hours. Treatment should be withdrawn gradually in neonates.

For doses in hepatic and renal impairment, see below.

Administration in hepatic impairment. Sildenafil clearance is reduced in patients with hepatic impairment. Safety has not been established in patients with severe hepatic impairment (Child-Pugh class C) and its use is contra-indicated in these patients for this reason.

Licensed product information for patients with **erectile dysfunction** recommends an initial dose of 25 mg in patients with hepatic impairment.

Licensed product information for patients with **pulmonary arterial hypertension** states that initial dose adjustments are not needed for patients with mild or moderate hepatic impairment (Child-Pugh class A or B); in the UK, it is recommended that a reduction to 20 mg twice daily should be considered if therapy is not well tolerated.

Administration in renal impairment. Sildenafil clearance is reduced in patients with severe renal impairment.

Licensed product information for patients with **erectile dysfunction** recommends that in these patients, an initial dose of 25 mg should be considered. In the UK it is stated that the dose may be increased to 50 or 100 mg, if needed and tolerated.

Licensed product information for patients with **pulmonary arterial hypertension** states that no dose adjustments are required for patients with renal impairment, including those with severe renal impairment (creatinine clearance less than 30 mL/minute). However, in the UK, consideration of a reduction to 20 mg twice daily is suggested if therapy is not well tolerated.

Erectile dysfunction. Sildenafil, an inhibitor of phosphodiesterase type-5, is used as an oral therapy for erectile dysfunction (p.2179). It is effective in erectile dysfunction of psychogenic causes and organic causes such as diabetes mellitus, spinal-cord injury, and prostatectomy.

Premature ejaculation. Early reports have suggested that sildenafil may be effective in the management of premature ejaculation (p.2181) and the rationale for such use has been reviewed.[1]

1. Abdel-Hamid IA. Phosphodiesterase 5 inhibitors in rapid ejaculation: potential use and possible mechanisms of action. *Drugs* 2004; **64:** 13–26.

Priapism. Sildenafil has been reported to be effective in the treatment of priapism in 3 patients with sickle-cell disease.[1] In 2 of these patients, sildenafil was also successful in preventing further episodes of priapism when it was taken at the onset of symptoms.

1. Bialecki ES. Sildenafil relieves priapism in patients with sickle cell disease. *Am J Med* 2002; **113:** 252.

Pulmonary hypertension. Oral sildenafil has produced beneficial responses in patients with pulmonary arterial hypertension (p.1179) and may have a role, particularly in patients who fail to respond to other therapies. It has been given either alone[1-7] or with other treatments such as inhaled nitric oxide,[6] inhaled iloprost,[1] intravenous epoprostenol,[8,9] or oral beraprost.[10] Sildenafil has also been added to bosentan therapy, with some benefit, in a small number of patients.[11] For a report on the pharmacokinetic interaction of these 2 drugs see Cardiovascular Drugs, above. The results of short-term and long-term studies of sildenafil have been reviewed.[12,13] In a study[14] using single doses of phosphodiesterase type-5 inhibitors, it was found that sildenafil and tadalafil had greater selectivity for the pulmonary circulation than vardenafil, and that arterial oxygenation was improved by sildenafil only. In a pivotal study,[7] sildenafil improved exercise capacity and haemodynamics in patients. Sildenafil was given at 20, 40, or 80 mg orally three times daily. While there was no evidence of a dose-response relationship in the primary end-point of exercise capacity, there was a linear trend in the response in haemodynamic measures. In an extension study, all patients were treated with 80 mg orally three times daily if tolerated. Some have questioned whether the licensed dose of 20 mg three times daily is sufficient,[15] especially if patients are given bosentan at the same time, leading the authors of the original study to suggest that this may be used as an initial dose, with an increase to 40 or 80 mg three times daily in order to achieve or maintain favourable effects.[16]

Sildenafil has also been studied for paediatric pulmonary hypertension. Some consider that it may have a role in persistent pulmonary hypertension in neonates,[17,18] as well as in those with pulmonary arterial hypertension associated with congenital heart disease, or secondary to lung disease, or in postoperative pulmonary hypertension and in neonates who are difficult to wean from inhaled nitric oxide.[18] However, further controlled studies are needed.[17,18] Nevertheless, although unlicensed in the UK, the *BNFC* suggests that sildenafil may be given orally to neonates and children for pulmonary hypertension after cardiac surgery, weaning from nitric oxide, idiopathic pulmonary arterial hypertension, and persistent pulmonary hypertension of the newborn (see above for details of doses).

Sildenafil has also been reported to be of benefit in high-altitude pulmonary hypertension.[19]

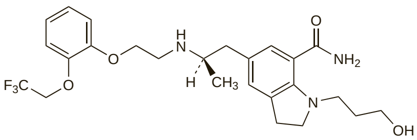
Silodosin *(rINN)*

KMD-3213; Silodosina; Silodosine; Silodosinum. (−)-1-(3-Hydroxypropyl)-5-[(2*R*)-2-({2-[2-(2,2,2-trifluoroethoxy)phenoxy]-ethyl}amino)propyl]-2,3-dihydro-1*H*-indole-7-carboxamide.

Сильодозин

$C_{25}H_{32}F_3N_3O_4$ = 495.5.
CAS — 160970-54-7.



Profile

Silodosin is an $alpha_1$-adrenoceptor blocker (p.1153) that is reported to be selective for the $alpha_{1A}$-adrenoceptor subtype. It is used orally in benign prostatic hyperplasia (p.2178) to relieve symptoms of urinary obstruction.

Preparations

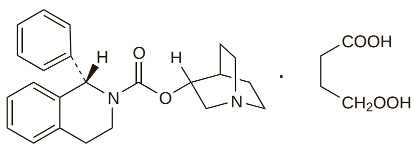
Proprietary Preparations (details are given in Part 3)
Jpn: Urief.

Solifenacin Succinate *(BANM, USAN, rINNM)*

Solifénacine, Succinate de; Solifenacini Succinas; Succinato de solifenacina; YM-905; YM-67905. (3*R*)-1-Azabicyclo[2.2.2]oct-3-yl (1*S*)-1-phenyl-3,4-dihydroisoquinoline-2(1*H*)-carboxylate compound with butanedioic acid (1:1).

Солифенацина Сукцинат

$C_{23}H_{26}N_2O_2,C_4H_6O_4$ = 480.6.
CAS — 242478-37-1 (solifenacin); 242478-38-2 (solifenacin succinate).
ATC — G04BD08.
ATC Vet — QG04BD08.



Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Solifenacin succinate should be used with caution in patients also receiving inhibitors of the cytochrome P450 isoenzyme CYP3A4 (see Interactions and Uses and Administration, below). It should also be used with caution in hepatic and renal impairment.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220). Exposure to solifenacin succinate may be increased by drugs that inhibit the cytochrome P450 isoenzyme CYP3A4. Although there is a lack of data, licensed product information also warns of the potential for interaction between solifenacin succinate and substrates or inducers of CYP3A4. Dosage adjustment for solifenacin succinate may be necessary (see Uses and Administration, below).

Pharmacokinetics

After an oral dose, solifenacin succinate is absorbed from the gastrointestinal tract, with peak plasma concentrations reached after 3 to 8 hours and a bioavailability of about 90%. Solifenacin is about 98% bound to plasma proteins. It is extensively metabolised in the liver, mainly by the cytochrome P450 isoenzyme CYP3A4, and has a terminal half-life of 45 to 68 hours. Solifenacin is excreted mainly as metabolites in urine and faeces.

◊ References.

1. Kuipers ME, *et al.* Solifenacin demonstrates high absolute bioavailability in healthy men. *Drugs R D* 2004; **5:** 73–81.
2. Smulders RA, *et al.* Pharmacokinetics and safety of solifenacin succinate in healthy young men. *J Clin Pharmacol* 2004; **44:** 1023–33.

Uses and Administration

Solifenacin succinate is a selective M_3 antimuscarinic with actions similar to those of atropine (p.1220). It is used in the treatment of urinary frequency, urgency, and incontinence in detrusor instability (p.2180). Usual doses of solifenacin succinate are 5 mg once daily by mouth, increased to 10 mg once daily if required. Maximum doses of 5 mg once daily are recommended in patients receiving drugs such as ketoconazole or ritonavir that are strong inhibitors of the cytochrome P450 isoenzyme CYP3A4. For doses in hepatic or renal impairment, see below.

6. Payne CK. Solifenacin in overactive bladder syndrome. *Drugs* 2006; **66:** 175–90.

Administration in hepatic and renal impairment. Doses of 5 mg of solifenacin succinate once daily by mouth are recommended in patients with moderate hepatic impairment (Child-Pugh category B) or severe renal impairment (creatinine clearance less than 30 mL/minute). It should not be used in patients with severe hepatic impairment (Child-Pugh category C) or in those undergoing haemodialysis.

Preparations

Proprietary Preparations (details are given in Part 3)

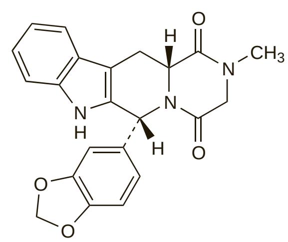
Tadalafil *(BAN, USAN, rINN)*

GF-196960; IC-351; Tadalafiili; Tadalafilo; Tadalafilum. (6*R*,12a*R*)-2,3,6,7,12,12a-Hexahydro-2-methyl-6-[3,4-(methylenedioxy)-phenyl]pyrazino[1′,2′:1,6]pyrido[3,4-*b*]indole-1,4-dione.

Тадалафил

$C_{22}H_{19}N_3O_4$ = 389.4.
CAS — 171596-29-5.
ATC — G04BE08.
ATC Vet — QG04BE08.



NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of tadalafil:
Weekend Pill.

Adverse Effects and Precautions

As for Sildenafil, p.2193. Visual disturbances may occur less frequently with tadalafil than with sildenafil. Dosage reductions may be required in patients with hepatic or renal impairment.

◊ References.

1. Montorsi F, *et al.* Long-term safety and tolerability of tadalafil in the treatment of erectile dysfunction. *Eur Urol* 2004; **45:** 339–44.

Effects on the cardiovascular system. References.

1. Kloner RA, *et al.* Cardiovascular effects of tadalafil. *Am J Cardiol* 2003; **92:** 37M–46M.

Interactions

As for Sildenafil, p.2194.

Antifungals. Priapism occurred in a man who took two separate doses of tadalafil 10 mg, at least one month apart, during *itraconazole* treatment.[1] He was able to take sildenafil during itraconazole treatment without adverse effect. See also Uses and Administration, below, for recommended tadalafil dosage when it is taken with inhibitors of the cytochrome P450 isoenzyme CYP3A4.

1. Galatti L, *et al.* Interaction between tadalafil and itraconazole. *Ann Pharmacother* 2005; **39:** 200.

Nitrates. Phosphodiesterase type-5 inhibitors may potentiate the hypotensive effects of organic nitrates, and are therefore contra-indicated in patients receiving such drugs. An interaction between tadalafil and sublingual *glyceryl trinitrate* was reported to occur when glyceryl trinitrate was given within 24 hours after tadalafil but was no longer detectable at 48 hours.[1] Licensed product information recommends that if nitrate treatment is needed in a life-threatening situation then it should only be given at least 48 hours after the last dose of tadalafil and under close medical supervision.

1. Kloner RA, *et al.* Time course of the interaction between tadalafil and nitrates. *J Am Coll Cardiol* 2003; **42:** 1855–60.

Pharmacokinetics

Tadalafil is well absorbed after an oral dose. Peak plasma concentrations are attained within 2 hours; the rate and extent of absorption are not affected by food.

Tadalafil is widely distributed into tissues and is about 94% bound to plasma proteins. It is metabolised in the liver mainly by the cytochrome P450 isoenzyme CYP3A4. The major metabolite, the methylcatechol glucuronide, is inactive. The mean half-life of tadalafil is about 17.5 hours.

Tadalafil is excreted, mainly as metabolites, in the faeces (61% of the dose), and to a lesser extent the urine (36% of the dose). Clearance may be reduced in the elderly and in patients with renal impairment.

◊ References.

3. Forgue ST, *et al.* Effects of gender, age, diabetes mellitus and renal and hepatic impairment on tadalafil pharmacokinetics. *Br J Clin Pharmacol* 2007; **63:** 24–35.

Uses and Administration

Tadalafil is a phosphodiesterase type-5 inhibitor with actions and uses similar to those of sildenafil (p.2195). It is used in the management of erectile dysfunction (p.2179). Tadalafil is given orally in a usual dose of 10 mg at least 30 minutes before sexual intercourse and may be taken with or without food; the dose may be increased to 20 mg, or decreased to 5 mg, if necessary. Efficacy may persist for up to 36 hours after dosing. Tadalafil should not be taken more than once in 24 hours.

In the UK, for those who respond to tadalafil when taken as needed, and anticipate frequent use (defined as at least twice weekly), a regular daily regimen may be considered suitable. In these patients, the recommended dose is 5 mg once daily, taken at about the same time each day. The dose may be decreased to 2.5 mg once daily based on individual tolerability. In the USA, the recommended starting dose of tadalafil for daily use is 2.5 mg, taken at about the same time each day, which may then be increased to 5 mg, based on tolerability and efficacy. Dosage adjustments are not necessary in elderly patients; for recommendations in hepatic or renal impairment, see below.

Although the use of tadalafil with an alpha blocker is not recommended in the UK, the combination may be used in the USA; in patients stabilised on alpha blocker therapy a starting dose of tadalafil 5 mg may be used. In patients taking potent inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole or ritonavir-boosted HIV-protease inhibitors, the dose of tadalafil when used *as needed* should not exceed 10 mg once every 72 hours; when used on a *regular daily basis*, the dose should not exceed 2.5 mg.

8. Doggrell SA. Comparison of clinical trials with sildenafil, vardenafil and tadalafil in erectile dysfunction. *Expert Opin Pharmacother* 2005; **6:** 75–84.

Administration in hepatic impairment. Exposure to tadalafil in patients with mild to moderate hepatic impairment is comparable to healthy subjects when a dose of 10 mg is used. Regular daily dosing has not been evaluated.

Licensed product information states the following:

- mild to moderate hepatic impairment (Child-Pugh Class A or B): the maximum dose is 10 mg; regular daily dosing has not been evaluated
- severe hepatic impairment (Child-Pugh Class C): insufficient data are available; in the UK, caution is advised, and in the USA use in this group is not recommended

Administration in renal impairment. The clearance of tadalafil is reduced in renal impairment.

In the UK, licensed product information recommends the following:

- mild to moderate renal impairment: no dose adjustment
- severe renal impairment: the maximum dose is 10 mg; regular daily dosing is not recommended in these patients

In the USA, the dose recommendations for tadalafil, when used *as needed*, in patients with renal impairment based on creatinine clearance (CC) are:

- mild (CC 51 to 80 mL/minute): no dose adjustment
- moderate (CC 31 to 50 mL/minute): an initial dose of 5 mg not more than once daily, with a maximum dose of 10 mg in 48 hours
- severe (CC less than 30 mL/minute or on haemodialysis): a maximum dose of 5 mg not more than once in every 72 hours

For patients taking tadalafil on a *regular daily basis*:

- mild (CC 51 to 80 mL/minute): no dose adjustment
- moderate (CC 31 to 50 mL/minute): no dose adjustment
- severe (CC less than 30 mL/minute or on haemodialysis): not recommended

High-altitude disorders. Hypoxic pulmonary hypertension associated with high altitude (p.1168) may respond to tadalafil. A small study[1] has shown some promising results in adults with a history of high-altitude pulmonary oedema.

1. Maggiorini M, *et al.* Both tadalafil and dexamethasone may reduce the incidence of high-altitude pulmonary edema: a randomized trial. *Ann Intern Med* 2006; **145:** 497–506.

Tamsulosin Hydrochloride

(BANM, USAN, rINNM)

Amsulosin Hydrochloride; Hidrocloruro de tamsulosina; LY-253351; Tamsulosiinihydrokloridi; Tamsulosin Hidroklorür; Tamsulosine, chlorhydrate de; Tamsulosinhydroklorid; Tamsulosini hydrochloridum; YM-617; *R*-(−)-YM-12617; YM-12617-1. (−)-(*R*)-5-(2-{[2-(*o*-Ethoxyphenoxy)ethyl]amino}-propyl)-2-methoxybenzenesulfonamide hydrochloride.

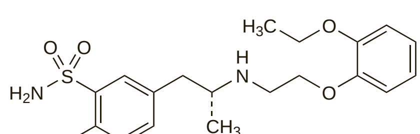
Тамсулозина Гидрохлорид

$C_{20}H_{28}N_2O_5S,HCl = 445.0.$

CAS — 106133-20-4 (tamsulosin); 106463-17-6 (tamsulosin hydrochloride).

ATC — G04CA02.

ATC Vet — QG04CA02.



(tamsulosin)

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.*

Ph. Eur. 6.2 (Tamsulosin Hydrochloride). A white or almost white powder. Slightly soluble in water and anhydrous alcohol; freely soluble in formic acid.

Adverse Effects, Treatment, and Precautions

As for Prazosin Hydrochloride, p.1375. Because tamsulosin is selective for α_1 receptors in the prostate the vasodilator effects may be less frequent. Tamsulosin may cause ejaculation abnormalities. It should be avoided in severe hepatic impairment.

Incidence of adverse effects. A study[1] using prescription event monitoring data for more than 12 000 patients treated with tamsulosin found that dizziness, headache, malaise, and hypotension were the adverse effects most commonly reported.

1. Mann RD, *et al.* The pharmacovigilance of tamsulosin: event data on 12 484 patients. *BJU Int* 2000; **85:** 446–50.

Surgical procedures. In 2005 the manufacturers[1,2] of tamsulosin warned that a syndrome of flaccidity of the iris, progressive miosis, and potential prolapse (intraoperative floppy iris syndrome; IFIS) had been reported in some patients undergoing cataract surgery who were receiving, or had received, alpha blockers. One group of workers[3] had reported that in one series of 741 patients undergoing cataract surgery, 15 of the 16 who developed IFIS had received tamsulosin. An earlier retrospective study of 511 similar patients by the same workers[3] had found IFIS in 10 of the 16 patients with a history of tamsulosin treatment but no cases in any of the other patients, including in 11 patients who had received other alpha blockers. The US manufacturer[2] stated that although most cases had occurred in patients who had been taking alpha blockers concurrently or up to 2 weeks before surgery the benefit of stopping such therapy before cataract surgery has not been established as a few cases had included patients who discontinued alpha blockers up to 9 months before surgery. The manufacturers of tamsulosin recommend that patients being considered for cataract surgery should be questioned to ascertain whether they are taking the drug.[1,2] A literature review[4] found that other alpha blockers, including alfuzosin, doxazosin, and terazosin, have also been associated with IFIS in this patient group; however, IFIS has been most strongly associated with the use of tamsulosin. In the UK, the MHRA[5] has required the inclusion of a warning in the labelling of all alpha blockers advising patients to inform their cataract surgeon about past and current use of these drugs.

Interactions

As for Prazosin Hydrochloride, p.1376.

Pharmacokinetics

Tamsulosin is absorbed from the gastrointestinal tract and is almost completely bioavailable. The extent and rate of absorption are reduced by food. After oral doses of an immediate-release preparation, peak plasma concentrations occur after about 1 hour. Tamsulosin is about 99% bound to plasma proteins. It is metabolised slowly in the liver primarily by the cytochrome P450 isoenzymes CYP2D6 and CYP3A4; it is excreted mainly in the urine as metabolites and some unchanged drug. The plasma elimination half-life has been reported to be between 4 and 5.5 hours.

Some of the pharmacokinetic values cited above may be altered when tamsulosin is given as a modified-release preparation, the form in which it is usually used; for instance, peak plasma concentrations occur about 6 hours after a dose and the apparent elimination half-life may be 10 to 15 hours.

Renal impairment. Plasma-tamsulosin concentrations were reported to be increased in patients with renal impairment when compared with subjects with normal renal function.[1,2] However, plasma concentrations of unbound, pharmacologically active drug were similar in both groups and it was suggested that the raised total plasma concentrations were due to an increase in plasma protein binding.

1. Koiso K, *et al.* Pharmacokinetics of tamsulosin hydrochloride in patients with renal impairment: effects of α -acid glycoprotein. *J Clin Pharmacol* 1996; **36:** 1029–38.
2. Wolzt M, *et al.* Pharmacokinetics of tamsulosin in subjects with normal and varying degrees of impaired renal function: an open-label single-dose and multiple-dose study. *Eur J Clin Pharmacol* 1998; **54:** 367–73.

Uses and Administration

Tamsulosin is an alpha$_1$-adrenoceptor blocker (p.1153) with actions similar to those of prazosin (p.1376); it is reported to be more selective for the alpha$_{1A}$-adrenoceptor subtype, which accounts for about 70% of the α_1 adrenoceptors in the prostate. It is used in benign prostatic hyperplasia (p.2178) to relieve symptoms of urinary obstruction.

In benign prostatic hyperplasia, tamsulosin hydrochloride is given orally in a modified-release formulation, in a dose of 400 micrograms once daily. Licensed US product information states that the dose may be increased after 2 to 4 weeks, if necessary, to 800 micrograms once daily.

◊ Reviews.

3. Lyseng-Williamson KA, *et al.* Tamsulosin: an update of its role in the management of lower urinary tract symptoms. *Drugs* 2002; **62:** 135–67.
4. Wilt TJ, *et al.* Tamsulosin for benign prostatic hyperplasia. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2002 (accessed 29/11/05).

Antidepressant-induced genito-urinary disorders. Tamsulosin was used successfully[1] to treat urinary hesitancy observed in 6 male patients receiving reboxetine. Painful ejaculation associated with reboxetine was also treated successfully[2] in 2 men.

1. Demyttenaere K, *et al.* Tamsulosin as an effective treatment for reboxetine-associated urinary hesitancy. *Int Clin Psychopharmacol* 2001; **16:** 353–5.
2. Demyttenaere K, Huygens R. Painful ejaculation and urinary hesitancy in association with antidepressant therapy: relief with tamsulosin. *Eur Neuropsychopharmacol* 2002; **12:** 337–41.

Prostatitis. Alpha$_1$-adrenoceptor blockers are one of a number of classes of drugs that have been tried for symptomatic relief in men with chronic prostatitis (p.2181). In a 6-week multicentre, double-blind placebo-controlled study involving 58 men with moderate to severe chronic prostatitis/chronic pelvic pain syndrome, tamsulosin 400 micrograms daily produced greater symptomatic relief than placebo;[1] the effect was considered clinically significant for men with severe prostatitis. The benefit appeared to take several weeks to develop, and it was considered possible that longer exposure would produce additional benefit.

1. Nickel JC, *et al.* Treatment of chronic prostatitis/chronic pelvic pain syndrome with tamsulosin: a randomized double blind trial. *J Urol (Baltimore)* 2004; **171:** 1594–7.

Renal calculi. In the conservative management of renal calculi (p.2181) there is increasing interest in the possible use of drug treatment to ease the spontaneous passage of the stone down the ureter. Alpha$_1$-adrenoceptor blockers can decrease smooth muscle spasm in the ureter, reducing obstruction and improving urine flow. In studies[1-5] of patients with uncomplicated lower ureteral stones, tamsulosin has been reported to improve the rate of stone expulsion and expulsion time, and to reduce analgesic requirements. Tamsulosin was generally given orally in a dose of 400 micrograms daily for up to 4 weeks. Comparison groups were treated with various other antispasmodics including benzodiazepines, phloroglucinol, and nifedipine; in most studies patients were also treated with antibacterial prophylaxis, deflazacort, and NSAIDs.

A review[6] found evidence suggesting that adjunctive tamsulosin is safe and effective in enhancing the clearance of renal stones with a larger diameter when used with extracorporeal shock wave lithotripsy. Although evidence regarding ureteral stone clearance is inconclusive, adjunctive tamsulosin has been reported to reduce painful episodes.

Tolterodine Tartrate *(BANM, USAN, rINNM)*

Kabi-2234 (tolterodine); PNU-200583E; Tartrato de tolterodina; Tolterodin Tartrat; Tolterodine L-Tartrate; Toltérodine, Tartrate de; Tolterodini Tartras. (+)-(*R*)-2-{α-[2-(Diisopropylamino)ethyl]benzyl}-*p*-cresol tartrate.

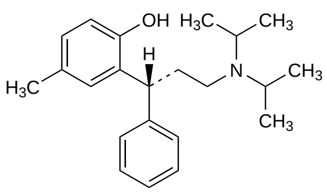
Тольтеродина Тартрат

$C_{22}H_{31}NO,C_4H_6O_6$ = 475.6.

CAS — 124937-51-5 (tolterodine); 124937-52-6 (tolterodine tartrate).

ATC — G04BD07.

ATC Vet — QG04BD07.



(tolterodine)

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. For a report of adverse ocular effects of tolterodine, see Effects on the Eyes under Oxybutynin, p.2190. Tolterodine should be used with caution in patients with hepatic or renal impairment. *Animal* studies have shown that high doses may cause fetal toxicity and it is recommended that tolterodine should be avoided during pregnancy.

Prolongation of the QT interval has occurred in controlled studies using both therapeutic and higher doses of tolterodine, and although changes from baseline did not cross the threshold of concern, the clinical implications are unclear. Licensed product information therefore warns that tolterodine should be used with caution in patients with QT prolongation or relevant risk factors, such as electrolyte disturbances, bradycardia, pre-existing cardiac disease, or the concomitant use of other drugs known to prolong the QT interval. Patients with raised tolterodine concentrations because of drug interactions (see below) would also be at increased risk, particularly poor metabolisers (see Pharmacokinetics, below).

◊ References.

2. Garely AD, Burrows L. Benefit-risk assessment of tolterodine in the treatment of overactive bladder in adults. *Drug Safety* 2004; **27:** 1043–57.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

There is a risk of interactions between tolterodine and drugs that inhibit cytochrome P450 isoenzymes CYP2D6 (but see Antidepressants, below), or CYP3A4. For comment on dosage of tolterodine with potent CYP3A4 inhibitors (such as the macrolide antibacterials erythromycin or clarithromycin, or the azole antifungals ketoconazole, itraconazole, or miconazole), see Uses and Administration, below. Tolterodine can prolong the QT interval and should be used with caution in patients receiving other drugs known to have this effect, particularly class Ia and class III antiarrhythmics.

Anticholinesterases. For mention of an interaction between tolterodine and *donepezil* or *rivastigmine*, see Antimuscarinics, under Donepezil, p.365.

Anticoagulants. For reference to the effect of tolterodine on the activity of *warfarin*, see under Antimuscarinics, p.1429.

Antidepressants. The SSRI *fluoxetine* is a potent inhibitor of the cytochrome P450 isoenzyme CYP2D6 and use with tolterodine has resulted in more than a fourfold increase in the area under the serum concentration-time curve (AUC) of tolterodine, associated with an approximate 20% decrease in the AUC of its 5-hydroxymethyl metabolite.[1] However, since both are active these changes were thought likely to result in little clinical difference, and licensed product information does not recommend a dose adjustment when tolterodine is given with fluoxetine.

1. Brynne N, *et al.* Fluoxetine inhibits the metabolism of tolterodine—pharmacokinetic implications and proposed clinical relevance. *Br J Clin Pharmacol* 1999; **48:** 553–63.

Gastrointestinal drugs. In a study[1] in healthy subjects, a dose of *antacid* was found to speed up the release of tolterodine from a modified-release preparation, probably as a result of the increase in gastric pH. Plasma-tolterodine concentrations were increased, but the half-life and area under the plasma concentration-time curve were not significantly affected. *Omeprazole* was reported to have a similar effect in another study.[2] The possible clinical effect of this change in drug release is unclear.

1. Sathyan G, *et al.* Effect of antacid on the pharmacokinetics of extended-release formulations of tolterodine and oxybutynin. *Clin Pharmacokinet* 2004; **43:** 1059–68.
2. Dmochowski R, *et al.* Effect of the proton pump inhibitor omeprazole on the pharmacokinetics of extended-release formulations of oxybutynin and tolterodine. *J Clin Pharmacol* 2005; **45:** 961–8.

Pharmacokinetics

Peak plasma concentrations of tolterodine occur 1 to 3 hours after an oral dose. It is highly bound to plasma proteins. Tolterodine is mainly metabolised in the liver by the cytochrome P450 isoenzyme CYP2D6 to the active 5-hydroxymethyl derivative (DD-01); in a minority of poor metabolisers tolterodine is metabolised by CYP3A4 isoenzymes to its inactive *N*-dealkylated derivative. The absolute bioavailability of tolterodine is normally about 17%, and the half-life is 2 to 3 hours; these increase in poor metabolisers to an absolute bioavailability of 65% and a half-life of about 10 hours. However, the clinical use of tolterodine is not affected by these differences in metabolism because the exposure to unbound tolterodine in poor metabolisers is similar to the combined exposure to unbound tolterodine and the active 5-hydroxymethyl metabolite in extensive metabolisers. Tolterodine is excreted primarily in the urine with about 17% appearing in the faeces; less than 1% of a dose is excreted as unchanged drug.

Uses and Administration

Tolterodine tartrate is a tertiary antimuscarinic with actions similar to those of atropine (p.1220); it is claimed to have a greater selectivity for the muscarinic receptors of the bladder. Tolterodine is used in the management of urinary frequency, urgency, and incontinence in detrusor instability. Usual oral doses of tolterodine tartrate are 2 mg twice daily; modified-release preparations are given in a usual dose of 4 mg once daily. Doses of 1 mg twice daily (or 2 mg daily as a modified-release preparation) are recommended in patients experiencing troublesome adverse effects. The *BNFC* suggests that a dose of 1 mg daily, increased according to response to a maximum of 2 mg twice daily, may be used in children from 2 years of age. Licensed US product information advises that the dose of tolterodine should not exceed 2 mg daily in patients receiving potent CYP3A4 inhibitors; UK product information recommends against such combinations. See also below for doses in patients with hepatic or renal impairment.

Administration in hepatic or renal impairment. Oral doses of 1 mg of tolterodine tartrate twice daily (or 2 mg daily as a modified-release preparation) are recommended by UK and US licensed product information in patients with hepatic or severe renal impairment.

Urinary incontinence. Tolterodine is used as an alternative to oxybutynin in the treatment of urge incontinence (see p.2180). Tolterodine is said to have fewer adverse effects than oxybutynin, but these may be comparable to modified-release oxybutynin.

Preparations

Proprietary Preparations (details are given in Part 3)

Arg.: Breminal; Detrusitol; Toltem; Urginol; ***Austral.:*** Detrusitol; ***Austria:*** Detrusitol; Detsel; ***Belg.:*** Detrusitol; ***Braz.:*** Detrusitol; ***Canad.:*** Detrol; Unidet; ***Chile:*** Detrusitol; ***Cz.:*** Detrusitol; ***Denm.:*** Detrusitol; ***Fin.:*** Detrusitol; ***Fr.:*** Detrusitol; ***Ger.:*** Detrusitol; ***Gr.:*** Detrusitol; ***Hong Kong:*** Detrusitol; ***Hung.:*** Detrusitol; ***India:*** Detrusitol; Terol; ***Indon.:*** Detrusitol; ***Irl.:*** Detrusitol; ***Israel:*** Detrusitol; ***Ital.:*** Detrusitol; ***Malaysia:*** Detrusitol; ***Mex.:*** Detrusitol; ***Neth.:*** Detrusitol; Detsel†; ***Norw.:*** Detrusitol; ***NZ:*** Detrusitol; ***Pol.:*** Detrusitol; ***Port.:*** Detrusitol; ***Rus.:*** Detrusitol (Детрузитол); ***S.Afr.:*** Detrusitol; ***Singapore:*** Detrusitol; ***Spain:*** Detrusitol; Urotrol; ***Swed.:*** Detrusitol; ***Switz.:*** Detrusitol; ***Thai.:*** Detrusitol; ***Turk.:*** Detrusitol; ***UK:*** Detrusitol; ***USA:*** Detrol; ***Venez.:*** Detrusitol.

Trospium Chloride *(BAN, USAN, rINN)*

Cloruro de trospio; IP-631; Trospii chloridum; Trospio chloridas; Trospium, chlorure de; Trospium-chlorid; Trospiumklorid; Trospiumkloridi; Trospiyum Klorür. 3α-Benziloyloxynortropane-8-spiro-1′-pyrrolidinium chloride.

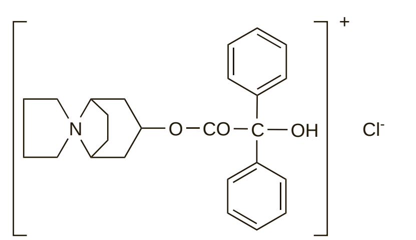
Троспия Хлорид

$C_{25}H_{30}ClNO_3$ = 428.0.

CAS — 10405-02-4.

ATC — G04BD09.

ATC Vet — QG04BD09.



Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Trospium Chloride). A white or almost white, crystalline powder. Very soluble in water; practically insoluble in dichloromethane; freely soluble in methyl alcohol. A 1% solution in water has a pH of 5.0 to 7.0. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219. Trospium should be used with caution in patients with hepatic or renal impairment. *Animal* studies have shown that trospium crosses the placenta and is distributed into breast milk; licensed product information therefore recommends that caution should be observed during pregnancy and breast feeding.

Interactions
As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Pharmacokinetics
After oral doses of trospium chloride, peak plasma concentrations are reached at 4 to 6 hours. The bioavailability of trospium chloride is reduced by the simultaneous intake of food, especially with a high fat content. Plasma protein binding ranges from about 50% to about 80%. Trospium is excreted in the urine mainly by active renal tubular secretion as unchanged drug; about 10% appears as the spiroalcohol metabolite. The plasma half-life has been reported to be between 10 and 20 hours for the immediate-release preparation, and about 35 hours for the modified-release preparation. The mean half-life has been reported to be prolonged twofold in patients with severe renal impairment (creatinine clearance between 8 and 32 mL/minute). Trospium has been reported to cross the placenta and has been detected in the milk of *rats*.

◊ Reviews.

1. Doroshyenko O, *et al.* Clinical pharmacokinetics of trospium chloride. *Clin Pharmacokinet* 2005; **44:** 701–20.

◊ For reference to the bioavailability of trospium chloride after intravesical instillation, see below.

Uses and Administration
Trospium chloride is a quaternary ammonium antimuscarinic with actions similar to those of atropine (p.1220). It is used for the management of urinary frequency, urgency, and incontinence in detrusor instability or detrusor hyperreflexia. It has also been used as an antispasmodic.

The immediate-release preparation is given orally in usual doses of 20 mg twice daily before meals on an empty stomach. Lower doses of 20 mg once daily may be warranted in patients aged 75 years and over. The need for continued treatment should be assessed at regular intervals of 3 to 6 months. A modified-release preparation is also available in some countries; the usual oral dose is 60 mg once daily in the morning, at least one hour before food. For use in patients with hepatic or renal impairment, see below.

Trospium chloride has also been given by slow intravenous injection. An inhaled formulation of trospium chloride for the treatment of chronic obstructive pulmonary disease is also being developed.

Administration in hepatic impairment. Licensed product information for trospium chloride states that maximum plasma concentrations and area under the concentration-time curve were increased in patients with mild (Child-Pugh score 5 to 6) or moderate (Child-Pugh score 7 to 12) hepatic impairment compared with healthy subjects. There is no information regarding the use of trospium chloride in patients with severe hepatic impairment. UK licensed product information advises caution in those with mild to moderate impairment, and advises against treatment in severe hepatic impairment. US licensed product information for both the immediate-release and the modified-release preparations advises caution in those with moderate to severe hepatic impairment. No specific dosage recommendations are given in either the UK or US product information.

Administration in renal impairment. Trospium chloride is mainly eliminated through active tubular secretion. Licensed product information states that increases in maximum plasma concentrations, area under the concentration-time curve, and half-life have been seen in patients with severe renal impairment given the immediate-release preparation; the pharmacokinetics of trospium chloride have not been studied in those with mild or moderate renal impairment.

UK licensed product information for the immediate-release preparation advises caution in those with mild to moderate renal impairment, while allowing for an oral dose of trospium chloride 20 mg once daily, or every alternate day, in those with severe renal impairment, defined as creatinine clearance (CC) of between 10 and 30 mL/minute per $1.73m^2$.

US licensed product information for the immediate-release preparation recommends a dose of 20 mg daily at bedtime for those with severe renal impairment (defined as CC less than 30 mL/minute). The modified-release preparation is not recommended for use in patients with severe renal impairment.

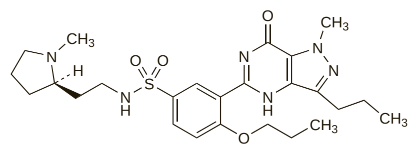
Udenafil *(rINN)*

DA-8159; Udénafil; Udenafilo; Udenafilum. 3-(1-Methyl-7-oxo-3-propyl-4,7-dihydro-1*H*-pyrazolo[4,3-*d*]pyrimidin-5-yl)-*N*-{2-[(2*RS*)-1-methylpyrrolidin-2-yl]ethyl}-4-propoxybenzenesulfonamide.

Уденафил

$C_{25}H_{36}N_6O_4S$ = 516.7.

CAS — 268203-93-6.



Profile
Udenafil is a phosphodiesterase type-5 inhibitor with actions and uses similar to those of sildenafil (p.2195). It is used in the management of erectile dysfunction.

Vardenafil *(rINN)*

Vardénafil; Vardenafilum. 1-{[3-(3,4-Dihydro-5-methyl-4-oxo-7-propylimidazo[5,1-*f*]-*as*-triazin-2-yl)-4-ethoxyphenyl]sulfonyl}-4-ethylpiperazine.

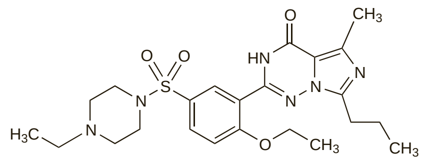
Варденафил

$C_{23}H_{32}N_6O_4S$ = 488.6.

CAS — 224785-90-4.

ATC — G04BE09.

ATC Vet — QG04BE09.



Vardenafil Dihydrochloride *(USAN, rINNM)*

Dihidrocloruro de vardenafil; Vardénafil, Dichlorhydrate de; Vardenafili Dihydrochloridum.

Варденафила Дигидрохлорид

$C_{23}H_{32}N_6O_4S,2HCl$ = 561.5.

CAS — 224789-15-5.

ATC — G04BE09.

ATC Vet — QG04BE09.

Vardenafil Hydrochloride *(USAN, rINNM)*

Bay-38-9456; Hidrocloruro de vardenafil; Vardénafil, Chlorhydrate de; Vardenafil Monohydrochloride; Vardenafili Hydrochloridum.

Варденафила Гидрохлорид

$C_{23}H_{32}N_6O_4S,HCl$ = 525.1.

CAS — 224785-91-5.

ATC — G04BE09.

ATC Vet — QG04BE09.

Adverse Effects and Precautions
As for Sildenafil, p.2193. Photosensitivity has also been reported. Vardenafil may prolong the QT interval and is best avoided in patients with relevant risk factors such as hypokalaemia, congenital QT prolongation, or the use of antiarrhythmics of class Ia or class III. Dosage reductions may be required in patients with hepatic or renal impairment.

Effects on the cardiovascular system. References.

1. Thadani U, *et al.* The effect of vardenafil, a potent and highly selective phosphodiesterase-5 inhibitor for the treatment of erectile dysfunction, on the cardiovascular response to exercise in patients with coronary artery disease. *J Am Coll Cardiol* 2002; **40:** 2006–12.

Interactions
As for Sildenafil, p.2194. The use of vardenafil with potent inhibitors of the cytochrome P450 isoenzyme CYP3A4 (such as HIV-protease inhibitors, some azole antifungals, and macrolide antibacterials) is generally best avoided; if thought to be essential, dosage of vardenafil must be reduced and suggested doses are given below (p.2199). Use with ketoconazole and itraconazole is contra-indicated in men older than 75 years of age. An enhanced hypotensive effect may be seen if vardenafil is taken with nifedipine. Vardenafil may prolong the QT interval and its use with antiarrhythmics of class Ia or class III should be avoided.

Pharmacokinetics
Vardenafil is rapidly absorbed after an oral dose, with a bioavailability of about 15%. Peak plasma concentrations are attained within 30 to 120 minutes; the rate of absorption is reduced when vardenafil is given with a high-fat meal.

Vardenafil is widely distributed into tissues and is about 95% bound to plasma proteins. It is metabolised in the liver primarily by cytochrome P450 isoenzymes CYP3A4 (the major route) as well as CYP3A5 and CYP2C isoforms. The major metabolite produced by desethylation of vardenafil also has some activity. The terminal half-life is about 4 to 5 hours.

Vardenafil is excreted as metabolites mainly in the faeces (91 to 95%), and to a lesser extent in the urine (2 to 6%). Clearance may be reduced in the elderly and in patients with hepatic or severe renal impairment.

◊ References.

2. Gupta M, *et al.* The clinical pharmacokinetics of phosphodiesterase-5 inhibitors for erectile dysfunction. *J Clin Pharmacol* 2005; **45:** 987–1003.

Uses and Administration
Vardenafil is a phosphodiesterase type-5 inhibitor with actions and uses similar to those of sildenafil (p.2195). It is used in the management of erectile dysfunction (p.2179). Vardenafil is given orally as the hydrochloride trihydrate although doses are expressed in terms of

the base; vardenafil hydrochloride trihydrate 11.85 mg is equivalent to about 10 mg of vardenafil.

The usual dose is 10 mg taken about 25 minutes to one hour before sexual intercourse. The dose may be increased or decreased depending on response. The maximum recommended dose is 20 mg, and vardenafil should not be taken more than once in 24 hours. The dose may be taken with or without food, but onset of activity may be delayed if taken with a high-fat meal.

- An initial dose of 5 mg is recommended in elderly patients, which may be increased to 10 mg and then to 20 mg if necessary.
- In patients stabilised on alpha blocker therapy, the dose of vardenafil should be no more than 5 mg daily and it should not be taken within 6 hours of the alpha blocker, although this interval may not be necessary with tamsulosin.
- A maximum daily dose of vardenafil 5 mg is advised in patients taking erythromycin (dose not specified in licensed product information), itraconazole (200 mg daily), or ketoconazole (200 mg daily). A daily dose of 2.5 mg is recommended for those taking clarithromycin (dose not specified in licensed product information), itraconazole (400 mg daily), or ketoconazole (400 mg daily).
- A maximum dose of vardenafil 2.5 mg every 24 hours is recommended in patients taking HIV-protease inhibitors. This dose should be reduced to 2.5 mg every 72 hours in those taking ritonavir-boosted regimens, although this combination may be best avoided (see also Interactions, above).

For doses in hepatic or renal impairment, see below.

Administration in hepatic impairment. An initial dose of 5 mg of vardenafil is recommended by UK licensed product information in patients with mild to moderate hepatic impairment (Child-Pugh category A to B), which may be increased if necessary, according to response and tolerability. The maximum dose recommended in patients with moderate hepatic impairment is 10 mg. Vardenafil has not been evaluated in severe hepatic impairment (Child-Pugh category C).

Administration in renal impairment. In the UK, an initial dose of 5 mg of vardenafil is recommended by licensed product information in patients with a creatinine clearance of less than 30 mL/minute, which may be increased to 10 mg and then to 20 mg if necessary, according to response and tolerability. US licensing information does not consider adjustment to be necessary. The pharmacokinetics of vardenafil have not been studied in patients requiring dialysis.

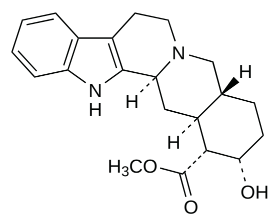
ATC Vet — QG04BE04.



(yohimbine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Yohimbine Hydrochloride). A white or slightly yellowish, crystalline powder. Sparingly soluble in water; practically insoluble in alcohol and in dichloromethane. A 1% solution in water has a pH of 3.5 to 5.5. Store in airtight containers. Protect from light.

USP 31 (Yohimbine Hydrochloride). A white to yellow powder. Slightly soluble in water and in alcohol; soluble in boiling water. Store in airtight containers.

Profile

Yohimbine is the principal alkaloid of the bark of the yohimbe tree, *Pausinystalia yohimbe* (*Corynanthe yohimbi*) (Rubiaceae); it is also found in *Rauwolfia serpentina.* It is an alpha$_2$-adrenoceptor blocker with a short duration of action. It has an antidiuretic effect and produces increases in heart rate and blood pressure. It has been reported to cause CNS effects including anxiety and manic reactions. It has been given orally in the treatment of erectile dysfunction (p.2179) and for its alleged aphrodisiac properties but convincing evidence of such an effect is lacking. It is contra-indicated in renal or hepatic disease.

Adverse effects. A warning about the potential adverse effects, including anxiety, manic reactions, bronchospasm, and a lupus-like syndrome, associated with yohimbine taken in health food products.[1] Interactions with tricyclic antidepressants and with phenothiazines might also occur.

Vaccines Immunoglobulins and Antisera

The agents described in this section are immunological agents used for both active and passive immunisation.

Active immunisation is the exposure of the immune system to antigens in the form of micro-organisms or products of their activity in order to stimulate production of antibodies and acquired cell-mediated responses with a specific protective capacity. It may be a natural process after infection, or an artificial process induced by giving *vaccines*. It is inevitably a slow process dependent upon the rate at which the antibodies can be produced. Although the terms vaccination and immunisation are often used synonymously and interchangeably, *vaccination* simply refers to giving a vaccine whereas *immunisation* implies the development of protective levels of antibodies.

Passive immunisation, which results in immediate short-term protection, may be achieved by giving exogenous antibodies in the form of *antisera* (of animal origin) or *immunoglobulins*.

Antisera

Antisérums; Antisueros; Immunsera.

Антисыворотки

Description

Antisera (immunosera) are sterile preparations containing immunoglobulins obtained from the serum of immunised animals by purification. The term antisera includes antitoxins, which are antibodies that combine with and neutralise specific toxins, and antivenins (antivenoms), which are antitoxins directed against the toxic principle of the venoms of poisonous animals such as certain snakes and arthropods.

Antisera are obtained from healthy animals immunised by injections of the appropriate toxins or toxoids, venins, or suspensions of micro-organisms or other antigens. The specific immunoglobulins may be obtained from the serum by fractional precipitation and enzyme treatment or by other chemical or physical means. A suitable antimicrobial preservative may be added, and is invariably added if the product is issued in multidose containers. The Ph. Eur. 6.2 directs that when antisera contain phenol, the concentration is not more than 0.25%. The antiserum is distributed aseptically into sterile containers, which are sealed so as to exclude micro-organisms. Alternatively they may be supplied as freeze-dried preparations for reconstitution immediately before use.

Adverse Effects and Precautions

Reactions are liable to occur after the injection of any serum of animal origin. Anaphylaxis (type I hypersensitivity reaction, p.561) may occur, with hypotension, dyspnoea, urticaria, and shock, which requires management as a medical emergency (see p.1205).

Serum sickness (type III hypersensitivity reaction, p.561) may also occur, frequently 7 to 10 days after the injection of serum of animal origin.

Before injecting serum, information should be obtained whenever possible as to whether the patient is subject to hypersensitivity disorders or has received serum injections before. Sensitivity testing should be performed before giving antisera. The patient must be kept under observation after giving a full dose of antisera. Adrenaline injection and resuscitation facilities should be available.

Uses and Administration

Antisera have the specific power of neutralising venoms or bacterial toxins, or combining with the bacterium, virus, or other antigen used for their preparation. Most antisera in current use are antitoxins or antivenins. The use of antisera to induce passive immunity has declined; immunoglobulins are preferred. Although antisera are defined as being of animal origin (see above), the term antisera has been used in some countries to describe antitoxins of human origin (immunoglobulins).

Immunoglobulins

Immunglobuline; Inmunoglobulinas.

Иммуноглобулины

Description

Immunoglobulins are produced by B lymphocytes as part of the humoral response to foreign antigens. Immunoglobulins used in clinical practice are preparations containing antibodies, usually prepared from human plasma or serum, and mainly comprise IgG. Normal immunoglobulin, prepared from material from blood donors, contains several antibodies against infectious diseases prevalent in the general population, whereas specific immunoglobulins contain minimum specified levels of one antibody. Antibodies may also be prepared by genetic engineering techniques.

Adverse Effects

Local reactions with pain and tenderness at the site of intramuscular injection may follow the use of immunoglobulins. Hypersensitivity reactions, including, rarely, anaphylactic reactions, have also been reported; such reactions, though, are far less frequent than after the use of antisera of animal origin.

Some immunoglobulins are available as intravenous preparations. Systemic reactions with fever, chills, facial flushing, headache, and nausea may occur, particularly at high rates of infusion.

Precautions

Strenuous efforts are made to screen human donor material used in the preparation of immunoglobulins; the transmission of infections, including hepatitis B and HIV, which has been associated with the use of certain blood products (see p.1056), does not appear to be a problem with the immunoglobulins currently in use.

IgA, present in some immunoglobulin preparations, may give rise to the production of anti-IgA antibodies in patients with IgA deficiencies, with the consequent risk of anaphylactic reactions. For precautions in such patients, see Hypersensitivity under Adverse Effects and Precautions in Normal Immunoglobulins, p.2226.

Interactions

Immunoglobulins may interfere with the ability of live vaccines to induce an immune response and a suitable interval should separate their use (see Vaccines, Interactions, p.2202).

Uses and Administration

Immunoglobulins are used for passive immunisation, thus conferring immediate protection against some infectious diseases. They are preferred to antisera of animal origin as the incidence of adverse reactions is lower.

It is generally important to follow the conferment of passive immunity, which is largely an emergency procedure, by the injection of suitable antigens to produce active immunity.

Vaccines

Vacunas.

Вакцины

Description

Vaccines are traditionally preparations of antigenic materials that are given with the objective of inducing in the recipient active immunity to specific infecting agents or toxins or antigens produced by them. They may contain living or killed micro-organisms, bacterial toxoids, or antigenic material from particular parts of the infecting organism, which may be derived from the organism or produced by recombinant DNA technology. Vaccines may be single-component vaccines or mixed combined vaccines. Vaccines against some non-infectious diseases are being developed.

Storage. All vaccines are sensitive to heat to differing extents, with oral poliomyelitis vaccines and measles vaccines the most heat-sensitive of the commonly used vaccines. Freeze-dried vaccines become much more heat-sensitive once reconstituted. The effect of heat on vaccines is generally irreversible loss of potency, but in some cases heat exposure may also cause the vaccine to become more reactogenic. The system used for storing and distributing vaccines at sufficiently low temperature is called the cold chain, and consists of a series of storage and transport links all designed to keep the vaccine at the correct temperature until it reaches the user. WHO recommends[1] that oral poliomyelitis vaccines be stored at −25 to −15° and that, in general, freeze-dried vaccines should be stored at 2 to 8°.

Some vaccines are also sensitive to excessive cold, notably hepatitis B vaccines and Haemophilus influenzae vaccines, and care should be taken not to store them at too low a temperature.[1]

In addition to temperature sensitivity, some vaccines are also sensitive to strong light, such as BCG vaccines, measles-containing vaccines, and rubella-containing vaccines. These are usually supplied in dark brown glass vials for protection, but further care should be taken to keep them covered.[1]

Further advice concerning vaccine storage is given in the references below.[2-6]

6. Public Health Agency of Canada. National vaccine storage and handling guidelines for immunization providers (2007). Available at: http://www.phac-aspc.gc.ca/publicat/2007/nvshglp-ldemv/index-eng.php (accessed 05/06/08)

Adverse Effects

Injection of a vaccine may be followed by a local reaction, possibly with inflammation and lymphangitis. An induration or sterile abscess may develop at the injection site. Fever, headache, and malaise may start a few hours after injection and last for 1 or 2 days. Hypersensitivity reactions may occur and anaphylaxis has been reported rarely.

Further details, if appropriate, of adverse effects of vaccines may be found in the respective individual monographs.

Anaphylaxis. In a retrospective study[1] in the USA conducted to quantify the risk of anaphylaxis after vaccination of children and adolescents, only 5 cases potentially associated with vaccines were identified from more than 7.5 million doses given. Vaccines implicated were generally given in combination and included the following components: diphtheria and tetanus; diphtheria, tetanus, and pertussis; hepatitis B; Haemophilus influenzae; measles, mumps, and rubella; and oral poliomyelitis. One case followed measles, mumps, and rubella vaccine given alone. It was concluded that vaccine-associated anaphylaxis is a rare event.

1. Bohlke K, *et al.* Risk of anaphylaxis after vaccination of children and adolescents. *Pediatrics* 2003; **112:** 815–20.

Long-term effects. The introduction of routine childhood vaccination has been accompanied by concerns over the safety and possible long term sequelae of some commonly used vaccines. Difficulties have arisen in distinguishing temporal and causal associations and in some cases the perceived dangers of vaccination have impeded uptake. Among the disorders that have been temporally (but generally not causally) associated with childhood vaccination are neurological disorders, sudden infant death syndrome, type 1 diabetes mellitus, and demyelinating disorders. Information on adverse effects associated with specific vaccines can be found under diphtheria, tetanus, and pertussis vaccines (p.2210), hepatitis B vaccines (p.2215), influenza vaccines (p.2218), measles, mumps, and rubella vaccines (p.2223), and pertussis vaccines (p.2230).

Additives or excipients have sometimes been alleged to be the cause of adverse reactions—see below for further details.

Effects of adjuvants. *Aluminium hydroxide* has been used frequently as an adsorbent in vaccines. A review[1] found significantly more erythema and induration with aluminium-containing vaccines than with plain ones. There was, however, no evidence of serious or long-lasting adverse effects that could be attributed to aluminium salts.

Thiomersal has been used as a preservative but because of alleged adverse effects is no longer used as widely as it once was (see Vaccines, under Thiomersal, p.1664 for further details). However, the comment has been made that in developing countries far more benefit will be seen from protecting children with current, inexpensive, domestically-manufactured thiomersal-containing vaccines, than by investing in thiomersal-free alternatives.[2]

Effects on the nervous system. *GUILLAIN-BARRÉ SYNDROME.* Guillain-Barré syndrome (see p.2228) has occasionally been reported after vaccination, although causal relationships have been difficult to evaluate. Such reports have been made after diphtheria and tetanus vaccines (p.2210), haemophilus influenzae vaccines (p.2213), hepatitis A vaccines (p.2214), hepatitis B vaccines (p.2215), a swine influenza vaccine (p.2218), measles, mumps, and rubella vaccines (p.2223), meningococcal vaccines (p.2224), and oral poliomyelitis vaccines (p.2232), although only the association with swine influenza vaccine appears to have been accepted.

Precautions

Most persons can safely receive the majority of vaccines. In a few individuals vaccination is contra-indicated or should be deferred.

All vaccines are contra-indicated in those who have had a previous confirmed anaphylactic reaction to a previous dose of a vaccine containing the same antigens or a confirmed anaphylactic reaction to another component contained in the relevant vaccine (for example, neomycin, polymyxin B, or streptomycin which may be present in trace amounts).

Some vaccines are prepared in egg cultures and are contra-indicated in persons with a confirmed anaphylactic reaction to egg.

Live vaccines are contra-indicated in the following groups of immunosuppressed patients:

- severe primary immunodeficiency
- malignant disease being treated with either chemotherapy or radiotherapy and for at least 6 months after stopping such treatment
- solid organ transplant receiving immunosuppressive therapy
- bone marrow transplant and for at least 12 months after stopping immunosuppressive therapy (or longer if graft-versus-host disease develops)
- all patients receiving high-dose systemic corticosteroids until at least 3 months after stopping treatment; this includes children receiving prednisolone, orally or rectally, at a daily dose (or its equivalent) of 2 mg/kg for at least 1 week or 1 mg/kg for 1 month and adults receiving a daily dose of 40 mg for more than 1 week.
- HIV positive patients with immunosuppression

Vaccination may be delayed in persons who are acutely unwell and in those with evolving neurological conditions (until stabilised). In pregnancy, vaccination should be delayed until after delivery; termination of pregnancy is not recommended if a vaccine is inadvertently given during pregnancy.

If any alcohol or disinfectant is used for cleansing the skin it should be allowed to evaporate before vaccination otherwise inactivation of live vaccines may occur.

Immunocompromised patients. For a discussion of the use of vaccines in HIV-infected and otherwise immunocompromised patients, see under Uses, below.

Premature infants. In the UK, the Royal College of Paediatrics and Child Health[1] and the Department of Health[2] consider that all routine childhood immunisations should be scheduled on the basis of the child's actual date of birth with no allowance being made for prematurity. In the USA, the American Academy of Pediatrics offers similar advice.[3] It is acknowledged that more studies are required into immunisation in prematurity, particularly in infants receiving corticosteroids.[1] There is some evidence that a minority of premature infants may fail to respond adequately to Haemophilus influenzae vaccines and to hepatitis B immunisation.[1]

Interactions

The ability of vaccines to induce an immune response can be influenced by the recent use of other vaccines or immunoglobulins. Live vaccines should either be given simultaneously (but at different sites) or an interval of at least 3 weeks allowed between them. Live vaccines should normally be given at least 3 weeks before or at least 3 months after the use of immunoglobulin. However, travellers should receive appropriate vaccines regardless of these limitations if time is short.

Patients receiving immunosuppressant therapy, including antineoplastics or therapeutic doses of corticosteroids, may also display a reduced response to vaccines and deferral of immunisation is advised, see Precautions, above. For further details on immunisation in immunocompromised patients, see under Uses and Administration, below.

Any agent that is active against the bacterial or viral strain present in the vaccine may interfere with development of a protective immune response but treatment with antibacterials is not a contra-indication to immunisation.

Uses and Administration

Vaccines are used for active immunisation as a prophylactic measure against some infectious diseases. They provide partial or complete protection for months or years. For inactivated vaccines, a slight and rather slow antibody response of primarily immunoglobulin M (IgM) (the primary response) is produced after the first or second dose but, when a further dose is given after a suitable interval, a prompt antibody response follows and high concentrations of IgG occur in the blood (the secondary response). Though the antibody concentration may later fall, a further dose of vaccine promptly restores it. For most live vaccines only one dose is required, although 3 doses of live (oral) poliomyelitis vaccines are needed to achieve complete immunisation. Some inactivated vaccines contain an adjuvant such as aluminium hydroxide or aluminium phosphate to enhance the immune response.

Protection against several infectious diseases may be provided in early life by active immunisation and national schedules for childhood immunisation are regularly reviewed and updated. Schedules for routine immunisation of infants and children are generally designed to fit in with routine health checks and landmark events such as school starting and leaving ages. National immunisation schedules should be consulted for full details of local recommendations.

In the **UK**, the following schedule of vaccination and immunisation is recommended:

- at 2 months of age, the first dose of a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and *Haemophilus influenzae* vaccine (p.2212), together with a first dose of pneumococcal conjugate vaccine (p.2231)
- at 3 months of age, a second dose of a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and *Haemophilus influenzae* vaccine, together with the first dose of meningococcal C conjugate vaccine (p.2224)
- at 4 months of age, a third dose of a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and *Haemophilus influenzae* vaccine, together with a second dose of meningococcal C conjugate vaccine and pneumococcal conjugate vaccine
- at 12 months of age, a fourth dose of *Haemophilus influenzae* vaccine (p.2213) and a third dose of a meningococcal C conjugate vaccine
- at about 13 months, measles, mumps, and rubella vaccine (p.2223) and a third dose of pneumococcal conjugate vaccine
- at 3 years 4 months to 5 years, a reinforcing dose of a combined diphtheria, tetanus, pertussis (acellular component), and poliomyelitis (inactivated) vaccine (p.2211) and a second dose of measles, mumps, and rubella vaccine
- at 12 to 13 years of age, human papillomavirus vaccine (p.2217) will be offered to all girls (starting in September 2008)
- before leaving school (age 13 to 18 years), a reinforcing dose of a low-dose diphtheria, tetanus, and poliomyelitis (inactivated) vaccine (p.2212).

The following schedule is recommended in the **USA**:

- at birth, the first dose of hepatitis B vaccine (p.2215)
- at age 1 to 2 months, a second dose of hepatitis B vaccine, not less than 1 month after the first
- at 2 months, a first dose of diphtheria, tetanus, and pertussis (acellular component) vaccine (p.2210), together with a *Haemophilus influenzae* vaccine (p.2213), a pneumococcal conjugate vaccine (p.2231), a poliomyelitis (inactivated) vaccine (p.2232) and a rotavirus vaccine (p.2236)
- at 4 months, a second dose of diphtheria, tetanus, and pertussis (acellular component) vaccine, together with the second doses of a *Haemophilus influenzae* vaccine, pneumococcal conjugate vaccine, poliomyelitis (inactivated) vaccine, and rotavirus vaccine
- at 6 months, the third dose of *Haemophilus influenzae* vaccine if necessary (depending on the type of vaccine used), a third dose of diphtheria, tetanus, and pertussis (acellular component) vaccine, a third dose of pneumococcal conjugate vaccine and a third dose of rotavirus vaccine
- at 6 to 18 months, the third doses of hepatitis B and poliomyelitis (inactivated) vaccines
- from 6 months to 18 years, annual influenza vaccine in high-risk patients, although influenza vaccine is also recommended in healthy infants aged 6 to 59 months
- from 12 months, 2 doses (at least 6 months apart) of a hepatitis A vaccine (p.2214)
- at 12 to 15 months, a reinforcing dose of *Haemophilus influenzae* vaccine, the first dose of measles, mumps, and rubella vaccine, the first dose of varicella-zoster vaccine (p.2242) and the fourth dose of pneumococcal conjugate vaccine
- at 15 to 18 months, the fourth dose of diphtheria, tetanus, and pertussis (acellular component) vaccine
- at 2 to 18 years, pneumococcal polysaccharide vaccine (in addition to previously administered pneumococcal conjugate vaccine) in certain high-risk groups
- at 2 to 10 years, meningococcal C conjugate vaccine (p.2224) to children with terminal complement deficiencies or asplenia and other high-risk groups; meningococcal polysaccharide vaccine may alternatively be used
- at 4 to 6 years, the fifth dose of diphtheria, tetanus, and pertussis (acellular component) vaccine, the fourth dose of poliomyelitis (inactivated) vaccine, the second dose of measles, mumps, and rubella vaccine, and the second dose of varicella-zoster vaccine

- at age 11 to 12 years, a sixth dose of low-dose diphtheria, tetanus, and pertussis (acellular component) plus a meningococcal C conjugate vaccine in those not previously vaccinated (meningococcal polysaccharide vaccine may alternatively be used); the first dose of human papillomavirus vaccine (p.2217) may be given to girls, the second dose is given 2 months after the first dose and the third dose is given 6 months after the first dose

Immunisation schedules for older children and adults are also produced, along with recommendations for vaccination of high-risk groups, including the immunocompromised and the elderly, and of travellers.

In addition to vaccines directed against bacteria and viruses, advances are being made in producing vaccines against fungi, protozoa, and helminths, and for non-infective diseases including cancer and auto-immune disorders.

Development of novel vaccine formulations and delivery methods is continuing, including transdermal and transmucosal systems. Genetic manipulation of foodstuffs is being investigated with the aim of producing edible vaccines.

EXPANDED PROGRAMME ON IMMUNIZATION. In 1974 the World Health Assembly adopted a resolution creating the Expanded Programme on Immunization (EPI), the aim of which was to provide immunisation against 6 target diseases (diphtheria, measles, pertussis, poliomyelitis, tetanus, and tuberculosis) for all children throughout the world by 1990. More recently, EPI has added hepatitis B, yellow fever, and *Haemophilus influenzae* infection to the list of target diseases. Although the attention of WHO had been focussed mainly on the developing countries, it was emphasised that the programme was not created exclusively for these countries. Besides WHO, many other organisations, including UNICEF, were involved –more recently, much work has been carried out under the auspices of the Global Alliance for Vaccination and Immunisation (GAVI).

Although many cases of the target diseases and many deaths have been prevented, vaccine coverage, especially for measles and neonatal tetanus is still low. It is particularly important to immunise children as early in life as possible and not to withhold vaccines from those with minor illness or malnutrition. Vaccine uptake was around 70% in 1990 compared with less than 5% in 1974. By 2003, all 192 member states of WHO were routinely immunising against diphtheria, measles, pertussis, poliomyelitis, and tetanus before the age of 18 months. Also, 158 member states were routinely immunising against tuberculosis, but routine BCG vaccination has been discontinued in some countries, including the UK, due to low risk and prevalence of disease.

A schedule designed to provide protection at the earliest possible age consisted of: trivalent oral poliomyelitis vaccine together with BCG vaccine at birth; hepatitis B vaccine at birth, 6 weeks, and 14 weeks (where transmission at birth is likely), or at 6, 10, and 14 weeks (where transmission at birth is less likely); trivalent oral poliomyelitis vaccine together with diphtheria, tetanus, and pertussis vaccine and Haemophilus influenzae vaccine at 6, 10, and 14 weeks of age; and measles vaccine and yellow fever vaccine at 9 months of age. Tetanus vaccine is also given to all women of child-bearing age. Also included in the programme in parts of the Far East is Japanese encephalitis vaccine.

Immunisation of immunocompromised patients. Immunocompromised patients may require immunisation against opportunistic infections but immune response to vaccination may be impaired, and there is a risk of disseminated infection with live vaccines (see Precautions, above).

Recommendations for immunisation of HIV-positive individuals have varied, particularly with regard to live vaccines.

In the UK,[1] it is generally recommended that vaccines used for routine immunisation in childhood may be given to HIV-positive persons, providing they are not immunosuppressed, but that BCG and yellow fever vaccines should not be given at all. WHO and UNICEF recommend[2] that for asymptomatic HIV-positive persons routine immunisation should be carried out according to their usual Expanded Programme on Immunization (see above). In addition, an extra dose of measles vaccine should be given at 6 months of age with the standard dose given as soon after 9 months of age as possible.

Some detailed guidance on vaccination of immunocompromised children is provided by the Royal College of Paediatrics and Child Health in the UK[3] and by the Children's HIV Association of UK and Ireland.[4] Guidance on immunisation of HIV-infected adults is provided by the British HIV Association.[5]

Immunisation for travellers. A guide entitled *International Travel and Health* is published annually by WHO.[1] In 2008 the following information regarding certification of vaccination was given.

A *yellow fever* vaccination certificate is now the only one that may be required in international travel. The vaccine used must be approved by WHO and given at a designated centre. Vaccination is strongly recommended for travel outside the urban areas of countries in the yellow fever endemic zone even if these countries have not officially reported the disease and do not require evidence of vaccination on entry. Many countries require a certificate from travellers arriving from infected areas or from countries with infected areas, or who have been in transit through those areas. Some countries require a certificate from all entering travellers including those in transit; although there is no epidemiological justification for this requirement, and it is clearly in excess of the International Health Regulations (WHO recommendations for prevention of the international spread of diseases), travellers may find that it is strictly enforced, particularly for persons going to Asia from Africa or South America. The validity period of international certificates of vaccination against yellow fever is 10 years, beginning 10 days after vaccination.

No country or territory any longer requires a certificate of *cholera* immunisation as the introduction of cholera into any country cannot be prevented by cholera vaccination.

Now that *smallpox* has been eradicated, smallpox vaccination is no longer required by any country.

Apart from vaccinations required by countries for entry to their territory, other vaccinations are either recommended by WHO for general protection against certain diseases or advised in certain circumstances. A vaccination plan should be established, taking into account the traveller's destination, overall state of health and current immune status, the duration and type of travel, and the time available before travel.

Further information for international travellers is also often provided by national authorities including those in the UK[2] and USA.[3]

Infection eradication. Eradication of infectious diseases has proved more difficult than was hoped, and smallpox is the only disease to have been recognised officially as having been eradicated so far. Eradication is defined as the extinction of the pathogen that causes the infectious disease in question, whereas in elimination the disease disappears but the causative agent remains. Of the target diseases of WHO's Expanded Programme on Immunization (see above), many of the factors necessary for elimination are present for each of the diseases, but some are not. *Measles* is so highly communicable a disease that a vaccine efficacy rate of about 95% is probably not high enough even to eliminate, much less eradicate, the disease. However, immunisation campaigns have produced substantial reductions of infection rate in some countries, although repeated vaccination may be necessary. *Pertussis* is also highly infectious and the vaccine is almost certainly not effective enough. *Tetanus* is not eradicable as the causative organism is ubiquitous. However, elimination of neonatal tetanus may be possible although it depends on protection of more than 80% of infants at birth. This depends not only on maternal vaccination but also on delivery practices. For *poliomyelitis*, countries that are efficient at giving vaccines have proved remarkably successful not only in practically eliminating the disease but also in virtually eradicating the organism. *Tuberculosis* is clearly not eradicable at present and *diphtheria* has many features that suggest it cannot be easily eradicated. Prospects for eradicating *congenital rubella syndrome* are more encouraging and the prospects for elimination or eradication of *mumps* are probably similar to those of rubella.

Other factors that may contribute to the failure of vaccination policies in eradicating disease include: concern, often unfounded, over the safety of vaccines and the perpetuation of invalid contra-indications, the use of inappropriate indicators for the effectiveness of vaccines, the suitability of different types of vaccine and of vaccination schedules, difficulties in vaccine supply, and social and behavioural pressures which reduce compliance with vaccination schedules.

Vaccine development. The WHO Initiative for Vaccine Research (IVR) supports and facilitates the development, clinical evaluation, and worldwide access to safe, effective, and affordable vaccines against infectious diseases of public health importance, especially in developing countries. The Global Vaccine Research Forum hosts an annual conference to discuss vaccine research and development issues, and to update research agendas. Information is frequently updated by WHO.[1,2].

AIDS Vaccines

HIV Vaccines; Vacunas del SIDA.

Profile

Many prototype vaccines against AIDS have been or are being developed but the results of clinical studies have generally been disappointing.

◊ Despite the passage of more than two decades since the discovery of HIV, no effective vaccine has been found to either ameliorate the disease or to prevent infection.[1-10] Globally between 40 and 50 million people are infected with HIV, with the overwhelming majority of infections occurring in developing countries which in many cases lack the resources and infrastructure to acquire and deliver costly antiretroviral therapy. A safe, effective, easily administered, and inexpensive AIDS vaccine is therefore desperately required.

There are many reasons why no such vaccine has so far been developed. Firstly, natural infection with HIV does not result in protective immunity; rather, it establishes persistent and lifelong infection and viral clearance and development of resistance to re-infection never occur. This means that there is no model of protective immunity to emulate through vaccination. Various aspects of the biology of the virus have also presented thus far insurmountable problems in vaccine development. The complex structure of the HIV envelope glycoprotein is inherently resistant to antibody attack and the virus has the capacity to evolve quickly in order to evade any neutralising antibody responses mounted by the host. In addition, the selective infection, progressive destruction, and impaired regeneration of CD4+ T helper cells, and the enormous genetic diversity of HIV with its continually evolving geographical distribution and prevalence have proven problematical. Finally, the ability of HIV to evade immune surveillance enables it to establish a state of proviral latency in long-lived CD4+ cells thus providing a persistent, yet immunologically invisible, reservoir of virus infection.

Despite these problems, research has continued[1-9] into developing AIDS vaccines from two distinct perspectives, namely prophylactic vaccines aimed at preventing primary infection and therapeutic vaccines aimed at reducing the rate of disease progression in HIV-infected individuals. Subunit recombinant viral envelope proteins, notably gp120, have been investigated as both prophylactic and therapeutic vaccines, but phase III clinical studies have proved disappointing.[9] In one, involving a bivalent formulation of recombinant gp120 proteins from HIV subtype B, predominant in North America and Europe (AIDSVAX B/B) given to 5009 subjects most of whom were homosexual men, no effect on the rate of HIV infection was found. In a second study in Thailand using AIDSVAX B/E, a related vaccine consisting of recombinant gp120 proteins from HIV subtypes B and E predominant in South-East Asia, no protection against HIV infection was found among 2546 HIV-negative injection drug users. Despite these disappointing results, AIDSVAX B/E is being evaluated in a further study in Thailand as the booster component of a combination immunisation prime-boost regimen that includes an attenuated canarypox vector prime (ALVAC vCP1521). Concerns about the potential success of this trial have, however, been raised by a number of AIDS vaccine researchers and plans for a similar study in the USA have been cancelled due to poor immunogenicity exhibited by the combination during earlier investigations.[9]

While typical HIV neutralising antibody responses are only transiently effective within a given individual and generally not cross-reactive with other isolates, several monoclonal antibodies have been derived from B cells or molecular clones of immunoglobulin genes obtained from HIV-infected persons during the course of natural infection, and exhibit significant neutralisation activity against a wider array of HIV isolates. These monoclonal antibodies act by penetrating gp120 and other viral envelope proteins, thereby preventing CD4 attachment to the virus. Since they have activity against a broader range of isolates and may be produced in relatively large quantities by recombinant technology, passive delivery of a cocktail of monoclonal antibodies is being investigated in *animal* models as a means of prophylaxis.[9] The cost of this approach may, however, potentially prohibit its future use on a wide scale in humans.

Efforts at understanding why it is so difficult to configure immunogens from the HIV envelope that more effectively elicit neutralising antibody responses continue but, in addition, attention has turned to what is termed the cytotoxic T lymphocyte (CTL) hypothesis.[9] This proposes that vaccination of uninfected individuals will not prevent infection but will induce an anti-HIV CTL (CD8+) response. If subsequently infected with HIV these immunised persons would be better able to control viral replication and progress to AIDS much more slowly or perhaps not at all and potentially decrease viral transmission. The validity of this hypothesis is at present uncertain but it has been supported by the observation of low level, yet detectable, HIV-specific CD8+ T cell responses in certain cohorts of highly exposed but uninfected individuals.

Additionally, new vaccine strategies are becoming available which it is thought will probably be able to elicit HIV-specific CTL responses of sufficient magnitude to allow direct testing of the concept in humans. Numerous *animal* studies are underway to assess the safety and immunogenicity of a number of replication-defective recombinant viral vectors (modified vaccinia Ankara strain, vesicular stomatitis virus, Venezuelan equine encephalitis virus, adeno-associated virus, and adenovirus) and also bacterial, yeast, and plasmid DNA vectors, all of which are designed to elicit antiviral CD8+ T cell responses.[9] However, initial analyses from a large study of an adenovirus-based vaccine designed to boost T cell responses (the STEP trial) provoked alarm since results suggested that it did not decrease susceptibility to HIV infection and might have increased it in some cases.[11]

Recombinant plasmid DNA immunogens are also under investigation as potential AIDS vaccines because of their desirable safety profile and ability to express defined and discrete inserted HIV antigens. They are either used singly or as a priming immunogen in prime-boost regimens using different vaccine vectors for sequential immunisation. Initial results in preclinical *animal* studies were encouraging, but results have been disappointing in subsequent phase I human studies.[8]

Within the field of AIDS vaccine research, the decision to advance candidate vaccines from phase I or II to phase III efficacy studies is somewhat complex. At present there are no consistent criteria in place to provide guidance on such decisions and there is a need for a coordinated, objective, and rigorous process for prioritisation in order to facilitate vaccine development. To the same end, alternative designs for phase III studies are being considered, including the use of endpoints such as reduction of viral load or preservation of CD4+ T cell counts for assessing vaccine efficacy rather than prevention of infection as the single primary endpoint. These and other measures may facilitate licensure of vaccines which currently would not occur.

Anthrax Vaccines

Vacunas del carbunco.

ATC — J07AC01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Anthrax Vaccine for Human Use (Adsorbed, Prepared from Culture Filtrates)); Vaccinum Anthracis Adsorbatum ab Colato Culturarum ad Usum Humanum. A preparation of *Bacillus anthracis* antigens precipitated by aluminium potassium sulphate. The antigens are prepared from a sterile culture filtrate produced by a non-encapsulated strain, either avirulent or attenuated, of *B. anthracis*. The main virulence components of *B. anthracis* are the polyglutamic acid capsule and 2 binary anthrax toxins, namely lethal toxin and oedema toxin, formed from the respective combination of protective antigen with either lethal factor or oedema factor. In addition, the vaccine is likely to contain many other *B. anthracis* antigens, including membrane proteins, secreted proteins, cytoplasmic proteins, peptidoglycans, nucleic acids, and carbohydrates. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

An anthrax vaccine that is an alum precipitate of the antigen found in the sterile filtrate of suitable cultures of the Sterne strain of *Bacillus anthracis* is available in the UK for human use. It is used for active immunisation against anthrax (p.163) and is recommended for persons working with potentially infected animals or animal products. It is given in 4 doses, each of 0.5 mL by intramuscular injection. The first 3 doses are separated by intervals of 3 weeks and the fourth dose follows after an interval of 6 months. In the USA, where an anthrax vaccine is also available, 6 doses, each of 0.5 mL, are given subcutaneously, the first 3 at intervals of 2 weeks and the last 3 at intervals of 6 months. Reinforcing doses of 0.5 mL are required each year.

Anti-D Immunoglobulins

Inmunoglobulinas anti-D.

ATC — J06BB01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Human Anti-D Immunoglobulin; Immunoglobulinum Humanum Anti-D; Anti-D (Rh_o) Immunoglobulin BP 2008). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG). It is intended for intramuscular administration. It is obtained from plasma from D-negative donors who have been immunised against the D-antigen. It contains specific antibodies against the erythrocyte D-antigen and may also contain small quantities of other blood group antibodies, such as anti-C, anti-E, anti-A, and anti-B. Normal immunoglobulin may be added. The liquid and freeze-dried preparations should be stored, protected from light, in a colourless, glass container. The freeze-dried preparation should be stored in an airtight container.

Ph. Eur. 6.2 (Human Anti-D Immunoglobulin for Intravenous Administration; Immunoglobulinum Humanum Anti-D ad Usum Intravenosum; Anti-D Immunoglobulin for Intravenous Use BP 2008). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG). It is obtained from plasma from D-negative donors who have been immunised against the D-antigen. It contains specific antibodies against the erythrocyte D-antigen and may also contain small quantities of other blood group antibodies. Human normal immunoglobulin for intravenous administration may be added. Storage requirements are similar to those for Human Anti-D Immunoglobulin, except that the freeze-dried preparation is stored at a temperature not exceeding 25°.

USP 31 (Rh_o (D) Immune Globulin). A sterile solution of globulins derived from human plasma containing antibody to the erythrocyte factor Rh_o (D). It contains 10 to 18% of protein, of which not less than 90% is gamma globulin. It contains glycine as a stabilising agent, and a suitable preservative. It should be stored at 2° to 8°.

Adverse Effects and Precautions

As for immunoglobulins in general, p.2201.

In patients given anti-D immunoglobulin for idiopathic thrombocytopenic purpura (ITP) there have been rare reports of back pain, shaking chills, fever, and discoloured urine; such signs and symptoms may be associated with intravascular haemolysis. Serious and sometimes fatal complications of intravascular haemolysis including anaemia, acute renal insufficiency, or disseminated intravascular coagulation have been rarely reported. Most reported cases of haemolysis occurred within 4 hours of the dose.

For the treatment of ITP, anti-D immunoglobulin is contra-indicated in rhesus-negative or splenectomised patients. Patients with ITP who need a blood transfusion should be given rhesus-negative red blood cells so as not to exacerbate ongoing haemolysis. Those with low initial haemoglobin concentrations (less than 10 g/dL) should be given a reduced dosage of the immunoglobulin to minimise the risk of severe anaemia.

When given for prophylaxis of rhesus sensitisation, anti-D immunoglobulin should not be used in rhesus-positive individuals.

Interactions

As for immunoglobulins in general, p.2201.

Uses and Administration

Anti-D immunoglobulin is used to prevent a rhesus-negative mother actively forming antibodies to fetal rhesus-positive red blood cells that may pass into the maternal circulation during childbirth, abortion, or certain other sensitising events. In subsequent rhesus-positive pregnancies these antibodies could produce haemolytic disease of the newborn (erythroblastosis foetalis). The injection of anti-D immunoglobulin is not effective once the mother has formed anti-D antibodies. Anti-D immunoglobulin is also used in the management of some blood disorders, primarily idiopathic thrombocytopenic purpura.

Anti-D immunoglobulin products are available either for intramuscular use only or for intramuscular or intravenous use. Doses differ for these products and the manufacturer's recommendation should be followed for commercial products.

In the UK, recommendations produced by expert groups relate to the use of a non-proprietary product produced by the National Blood Transfusion Service. They recommend that **postnatal prophylaxis** with anti-D immunoglobulin should always be given to rhesus-negative mothers with no anti-D antibodies in their serum and who have just delivered rhesus-positive infants. It should be given as soon as possible after delivery but may give some protection even if treatment is delayed beyond 72 hours. A dose of 500 units (100 micrograms) by intramuscular injection will clear up to 4 mL of fetal red cells. An additional dose may be required depending on the amount of transplacental bleeding; for bleeds exceeding 4 mL an additional 125 units for each mL of red cells will be required.

For routine **antenatal prophylaxis**, two intramuscular doses of at least 500 units of anti-D immunoglobulin should be given at 28 and 34 weeks' gestation. Postnatal prophylaxis is still necessary.

There is also a risk of sensitisation during pregnancy from spontaneous, induced, or threatened abortion, amniocentesis, or external version. Any rhesus-negative woman at **risk of transplacental haemorrhage** during pregnancy and not known to be sensitised should be given an intramuscular dose of 250 units at up to 20 weeks' gestation and 500 units of anti-D immunoglobulin after 20 weeks' gestation.

Anti-D immunoglobulin is also given to rhesus-negative women of child-bearing potential after the inadvertent **transfusion of Rh-incompatible blood**, or after receiving blood components containing rhesus-positive red cells or organ donations from rhesus-positive donors. The dose is based on the amount of red blood cells transfused; an intramuscular dose up to 125 units/mL of transfused cells may be used.

In the USA, doses of anti-D immunoglobulin have traditionally been higher than in the UK; dosage recommendations are based on a standard dose that is capable of suppressing the immune response to 15 mL of incompatible red blood cells. One-sixth of this dose may be used up to 12 weeks of gestation for sensitising episodes.

For **idiopathic thrombocytopenic purpura**, a usual initial dose of 250 units/kg (50 micrograms/kg) of a licensed anti-D immunoglobulin product is given by intravenous injection; it may be given in two divided doses on separate days if desired. Maintenance doses usually range between 125 to 300 units/kg (25 to 60 micrograms/kg) depending on the clinical response. A reduced initial dose of 125 to 200 units/kg (25 to 40 micrograms/kg) is recommended in patients with pre-existing anaemia (haemoglobin below 10 g/dL).

Haemolytic disease of the newborn. Rhesus (Rh) incompatibility, in particular Rh(D) incompatibility, is a major cause of potentially severe haemolytic disease of the newborn, although other blood group antibodies may also cause the disease. The use of anti-D immunoglobulin to suppress the production of anti-D antibodies in a Rh(D)-negative mother in response to leakage of red blood cells across the placenta from a Rh(D)-positive fetus has produced a major reduction in the incidence of this disorder.

Prophylaxis. Postnatal prophylaxis of Rh(D)-negative mothers after the birth of a Rh(D)-positive infant is well established. In 1971, WHO[1] suggested a standard intramuscular dose of 200 to 300 micrograms but stated that a 100-microgram dose was likely to have a success rate only slightly inferior to that of a 200-microgram dose, thus allowing optimum use to be made of a limited resource. Clinical experience in the UK has confirmed the efficacy of the 100-microgram (500 units) intramuscular dose and this is the amount officially recommended in the UK in such situations.[2,3] Doses do, however, vary considerably in other countries: 200 to 300 micrograms (1000 to 1500 units) is given in the USA and in many European countries, and 125 micrograms (625 units) is used in Australia.

Despite the success of anti-D immunoglobulin prophylaxis, sensitisations have continued to occur. There are several possible reasons for this, the main one being immunisation during pregnancy where there has been no overt sensitising event. Postpartum doses may be omitted due to oversight or loss to follow-up. Assessment of the volume of any transplacental haemorrhage is essential to avoid inadequate dosing. Significantly large feto-maternal haemorrhage is likely to occur after traumatic deliveries including caesarean section, manual removal of the placenta, still-birth or intra-uterine death, abdominal trauma during the third trimester, delivery of twins, or unexplained hydrops fetalis.

The efficacy of postpartum prophylaxis is not in question but opinions differ on the need for prophylaxis during pregnancy. It is generally agreed that prophylaxis is necessary in all non-sensitised Rh(D)-negative women after therapeutic terminations at any stage of pregnancy, including medical termination utilising mifepristone, after ectopic pregnancy, spontaneous complete or incomplete miscarriage after 12 weeks' gestation, or threatened miscarriage after 12 weeks' gestation as evidenced by abnormal bleeding or abdominal pain. Recommendations have been made by the British Committee for Standards in Haematology for the management of these sensitising events.[3]

Prophylaxis should also be given to all non-sensitised Rh(D)-negative women after the following sensitising events during pregnancy: invasive prenatal diagnosis including amniocentesis, chorion villus sampling, or fetal blood sampling; other intra-uterine procedures such as insertion of shunts or embryo reduction; antepartum haemorrhage; external cephalic version of the fetus; closed abdominal injury; or intra-uterine death.[2,3] A dose of 50 micrograms (250 units) is recommended for prophylaxis after these events up to 20 weeks of pregnancy, and at least 100 micrograms (500 units) thereafter.

In the UK routine antenatal prophylaxis at 28 and 34 weeks' gestation is recommended for all Rh(D)-negative women[2-4] and should be given irrespective of whether anti-D prophylaxis had been given for other sensitising events during the same pregnancy or previous pregnancies.[3]

Treatment. In mild cases, the resultant hyperbilirubinaemia can be managed with phototherapy. In severe cases, exchange transfusions may be necessary and intra-uterine transfusions may be considered in pregnancies of less than about 34 weeks' gestation; beyond this, premature delivery is often preferable.[5] Some clinicians have reported treatment failures with intra-uterine transfusions but have found intravenous normal immunoglobulin 400 mg/kg daily for 5 days every 2 to 3 weeks to the mother to be effective. There are several case reports[6,7] of beneficial responses using similar doses, but no benefit was seen in 4 patients receiving 1000 mg/kg once a week.[8] This dose, however, appeared to reduce the severity of the disease in a patient with Kell sensitisation.[8] Reductions in bilirubin concentrations have been reported with intravenous normal immunoglobulin 500 mg/kg as a single dose in newborn infants,[9] and a systematic review[10] found that such treatment reduced the number of infants requiring exchange transfusion and the duration of hospital stay and phototherapy needed. Reports in small numbers of infants[11-15] suggest that epoetins may be of value in controlling anaemia which develops 2 to 8 weeks after birth.

Idiopathic thrombocytopenic purpura. Normal immunoglobulin is used for chronic idiopathic thrombocytopenic purpura (p.1505), and anti-D immunoglobulin has been found to have similar properties. The potential role of anti-D immunoglobulin in the treatment of idiopathic thrombocytopenic purpura has been discussed in several reviews.[1-3] In general, despite many studies showing the clinical efficacy and low toxicity of intravenous anti-D immunoglobulin, its precise role has not been defined for a number of reasons. Firstly, the optimal dose has not been established: doses used have ranged from 12.5 to 25 micrograms/kg daily, given for at least 2 days, in early studies to later more promising single doses of 50 to 75 micrograms/kg. Secondly, no study has shown anti-D immunoglobulin to be as effective as corticosteroid therapy for initial treatment. Furthermore, despite suggestions that anti-D immunoglobulin may be safer and easier to give than normal immunoglobulin, good comparative data is scanty. Clinical studies have, however, shown the safety and efficacy of intravenous anti-D immunoglobulin in Rh(D)-positive, non-splenectomised patients with idiopathic thrombocytopenic purpura.[1] A prospective, randomised clinical study[4] in Rh(D)-positive children with idiopathic thrombocytopenic purpura found that a single intravenous dose of 75 micrograms/kg raised the platelet count more rapidly than a single intravenous dose of 50 micrograms/kg, and was as effective as a single intravenous dose of 800 mg/kg of normal immunoglobulin.

BCG Vaccines

Bacillus Calmette-Guérin Vaccines; Vacunas BCG.

Вакцины БЦЖ

ATC — J07AN01; L03AX03.

Pharmacopoeias. Many pharmacopoeias, including *Br., Eur.* (see p.vii), and *US*, have monographs.

Ph. Eur. 6.2 (BCG Vaccine, Freeze-dried; Vaccinum Tuberculosis (BCG) Cryodesiccatum; Bacillus Calmette-Guérin Vaccine BP 2008). A freeze-dried preparation containing live bacteria obtained from a strain derived from the bacillus of Calmette and Guérin (*Mycobacterium bovis* BCG) whose capacity to protect against tuberculosis has been established. It may contain a stabiliser. The dried vaccine should be stored at 2° to 8° and be protected from direct sunlight.

The BP 2008 states that BCG may be used on the label.

The BP 2008 gives BCG Vaccine as an approved synonym.

BP 2008 (Percutaneous Bacillus Calmette-Guérin Vaccine). A suspension of living cells of an authentic strain of the bacillus of Calmette and Guérin with a higher viable bacterial count than Bacillus Calmette-Guérin Vaccine. It is supplied as a dried vaccine and is reconstituted immediately before use by the addition of a suitable sterile liquid. The dried vaccine should be stored at a temperature below −20° and be protected from light.

The BP 2008 states that Tub/Vac/BCG (Perc) may be used on the label.

The BP 2008 gives Percut. BCG Vaccine as an approved synonym.

USP 31 (BCG Vaccine). A dried living culture of the bacillus Calmette-Guérin strain of *Mycobacterium tuberculosis* var. *bovis*; it is grown from a strain that has been maintained to preserve its capacity for conferring immunity. It contains an amount of viable bacteria such that inoculation, in the recommended dose, of tuberculin-negative persons results in an acceptable tuberculin conversion rate. It contains a suitable stabiliser and no antimicrobial agent. The dried vaccine should be stored in hermetically sealed containers at 2° to 8°. The reconstituted vaccine should be used immediately after preparation and any portion not used within 2 hours should be discarded.

Ph. Eur. 6.2 (BCG for Immunotherapy; BCG ad Immunocurationem). A freeze-dried preparation of live bacteria derived from a culture of the bacillus of Calmette and Guérin (*Mycobacterium bovis* BCG) whose capacity for treatment has been established. It may contain a stabiliser. It is for intravesical use only. The product should be stored at 2° to 8° and be protected from direct sunlight.

USP 31 (BCG Live). A freeze-dried preparation of attenuated live bacteria derived from a culture of Bacillus Calmette-Guérin (*Mycobacterium bovis*, var. BCG) for intravesical use only. It is reconstituted and further diluted aseptically with a sterile diluent before use. A reconstituted dose contains 1.0–19.2 × 10^8 colony-forming units (cfu). It does not contain a preservative.

BCG Live is sensitive to light and must be stored in a glass container, protected from direct light, and at 2° to 8°.

Adverse Effects and Treatment

As for vaccines in general, p.2201.

Serious adverse reactions to BCG vaccines used *for immunisation* against tuberculosis are rare, although the incidence may vary between strains. The normal therapeutic response involves induration and development of a lesion at the injection site, possibly with enlargement of local lymph nodes; this lesion may later ulcerate and heal over some months leaving a scar. In a few patients an exaggerated reaction, usually associated with overdose, inadvertent subcutaneous injection, or use in persons who are already tuberculin positive, may result in an abscess or discharging ulcer, or suppurative lymphadenitis. Nonspecific systemic reactions may include fever and headache. Generalised reactions, possibly due to hypersensitivity, have been reported with a few fatalities. Disseminated BCG infection may occur and has also led to fatalities, particularly in immunocompromised patients. Disseminated BCG complications such as osteitis have been reported with some BCG vaccines. Very rarely, a lupoid type of reaction has occurred, mostly after multiple revaccination.

Intravesical use of BCG in the treatment and prophylaxis of bladder cancer is associated with an inflammatory response; transient dysuria and urinary frequency, sometimes with fever or a flu-like syndrome, and haematuria, are common, especially with repeated treatment (as in maintenance therapy). Rarely bladder contracture and epididymo-orchitis have been reported. As with vaccination, disseminated BCG infection has occurred rarely and may potentially be fatal. Fever lasting more than 24 hours should be investigated, and antimycobacterial therapy given if necessary. Other reported adverse effects have included hypersensitivity reactions such as rashes and arthralgia, and ocular symptoms including uveitis, conjunctivitis, iritis, and keratitis.

◊ Reviews and studies of the adverse effects of BCG vaccines and their management.[1-6] An increased incidence of local effects has followed intradermal injection of high doses of BCG vaccines.[7,8] The incidence of adverse effects may vary between strains; an increase in incidence was reported in Ireland after withdrawal of a vaccine based on the Evans strain and its replacement with a vaccine containing the SSI strain of BCG.[9]

9. Bolger T, *et al.* Complications associated with the bacille Calmette-Guérin vaccination in Ireland. *Arch Dis Child* 2006; **91:** 594–7.

Effects on the bones and joints. The risk of osteitis after BCG vaccination varies from country to country and appears to be linked to the strain of bacillus used.[1]

Osteitis or arthritis has also been reported after intravesicular use of BCG (see below).

1. Milstien JB, Gibson JJ. Quality control of BCG vaccine by WHO: a review of factors that may influence vaccine effectiveness and safety. *Bull WHO* 1990; **68:** 93–108.

Effects on the eyes. Follicular conjunctivitis occurred after accidental contamination of the eye with BCG vaccine.[1] The conjunctivitis responded to topical corticosteroid therapy, but a course of isoniazid was given as a precautionary measure.

For reference to uveitis after intravesical instillation see below.

1. Pollard AJ, George RH. Ocular contamination with BCG vaccine. *Arch Dis Child* 1994; **70:** 71.

Effects on the lymphatic system. Lymphadenitis associated with BCG vaccination has been reviewed.[1] It is the most common adverse effect of BCG vaccination and may develop 2 to 24 weeks after vaccination, with most cases occurring within 6 months. The incidence and severity depend on the dose, vaccine strain, the age at vaccination, and the immunological state of the patient. Suppurative BCG lymphadenitis in the form that develops in 30 to 80% of cases; neonates and immunodeficient patients are associated with an increased risk.

The treatment of BCG lymphadenitis remains controversial. Although antibacterials and antituberculous drugs such as isoniazid and rifampicin have been given, there is little evidence to support their use; the non-suppurative (simple) form regresses spontaneously without treatment while suppurating lymph nodes may be drained by needle aspiration and left to heal.

Intravesicular administration. Intravesicular instillation of BCG can give rise to both localised and systemic adverse effects as a consequence of the immune stimulation required to eradicate cancer cells.[1-3] The most serious effects are due to disseminated infection and include severe sepsis with cardiorespiratory manifestations and a disseminated mycobacterial infection with granulomatous pneumonitis and hepatitis; prompt treatment with antimycobacterials is required.[1,4,5] Fatalities have occurred.[6,7] Other reports include severe haemophagocytic syndromes,[8] uveitis,[9,10] and arthritis and osteitis.[11,12] Epididymo-orchitis has also been reported up to 4 years after intravesicular BCG therapy.[13,14]

Initial findings of a study[15] involving 115 patients indicated that prophylactic use of ofloxacin, a fluoroquinolone with tuberculostatic activity, decreased the incidence of moderate to severe adverse effects associated with intravesical BCG without any significant decrease in recurrence-free survival at 12 months. Ofloxacin was given orally after each BCG instillation; a dose of 200 mg was given 6 hours after the first urination with a second dose about 10 to 12 hours later. Long-term study, however, was still needed to confirm these results.

Precautions

As for vaccines in general, p.2202.

BCG vaccines may be given with other live vaccines, but if they are not given at the same time it is preferable to allow an interval of 4 weeks between each although the period may be reduced to 10 days if absolutely necessary. However, routine primary immunisation in infants, including the use of live poliomyelitis vaccine, need not be delayed. No further vaccination should be given in the arm used for BCG vaccination for at least 3 months because of the risk of lymphadenitis. BCG vaccination should be postponed in patients with fever or generalised skin infection. In patients with eczema, BCG vaccines should be given at a site free from lesions. Because of the possible risk of disseminated infections, BCG vaccines should not be given to immunocompromised patients including those with HIV infection. Infants born to HIV-positive mothers may be vaccinated once HIV infection has been ruled out; vaccination should be considered in infants of unknown status in areas of high tuberculosis prevalence if there are no signs suggestive of HIV infection. Vaccination is contra-indicated in patients taking antimycobacterial therapy, and those with a history of tuberculosis or a positive tuberculin skin test. Neonates in household contact with a known or suspected case of active tuberculosis should not be vaccinated.

The instillation of *intravesical* BCG should be postponed for 7 to 14 days after any trauma to the urinary tract including transurethral resection, biopsy, and trauma caused by catheterisation. Treatment should also be postponed in patients with acute febrile illness, urinary tract infection, or gross haematuria. Use is contra-indicated in patients with active tuberculosis, previous history of systemic reaction to BCG, or treatment with antimycobacterial therapy. As with vaccination, intravesical BCG should be avoided in immunocompromised patients, including those with HIV infection. Because BCG contains live mycobacteria that may be excreted in the urine, patients should be advised on the risk of contamination, and on appropriate infection control procedures to protect family and close contacts.

Immunocompromised patients. Like other live vaccines, BCG vaccine should not be given to immunocompromised patients including those with symptomatic HIV infections and AIDS. An increased risk of disseminated BCG infection has been seen in infants and children with asymptomatic HIV infections,[1,2] leading to high mortality rates of about 80%. WHO Global Advisory Committee on Vaccine Safety therefore no longer recommends BCG vaccination of infants and children with known HIV infection (see Tuberculosis, HIV-infected Patients, below).

Interactions

As for vaccines in general, p.2202.

Theophylline. For a report of increased theophylline half-life and serum concentrations after BCG vaccination, see under Theophylline Hydrate, p.1145.

Uses and Administration

BCG vaccines are used for active immunisation against tuberculosis. A form suitable for immunotherapy is also used locally in the treatment and prophylaxis of carcinoma *in-situ* of the bladder, and the prophylaxis of recurrent early stage bladder papillomas after resection.

For vaccination against **tuberculosis** different strategies may be adopted, depending on the prevalence of the disease in local populations, the prevalence of HIV co-infection, the potential for infant exposure to these diseases, and the existence of infrastructure to diagnose infection and follow-up vaccinated persons. WHO considers that BCG vaccination of adults is not normally recommended, although it may be considered for tuberculin-negative subjects in unavoidable and close contact with drug-resistant tuberculosis. In countries with a high prevalence of tuberculosis, infant immunisation with a single dose of BCG as soon as possible after birth is ideally to be recommended. However, these populations tend to have a high prevalence of HIV infection as well, and BCG vaccination is contra-indicated in HIV-infected subjects. Nonetheless, WHO considers that children without HIV infection will particularly benefit from vaccination in these circumstances, and recommends that immunisation should be carried out in:

- infants born to women of unknown HIV status
- infants without obvious signs of HIV infection born to women known to be HIV-infected
- infants known to be HIV-negative as a result of virological testing

It considers that immunisation should be avoided in infants known to be infected with HIV, or whose HIV status is unknown but who are born to HIV-infected mothers and have signs or symptoms suggestive of HIV infection.

In contrast, a country such as the UK has a relatively low prevalence of tuberculosis, and routine immunisation is no longer carried out. Instead, immunisation is targeted at groups considered to be at increased risk:

- all neonates and infants (0 to 12 months) living in areas where the annual incidence of tuberculosis is greater than 40 cases per 100 000 of the population
- all neonates and infants with a parent or grandparent born in a country where the annual incidence of tuberculosis is greater than 40 cases per 100 000 of the population
- previously unvaccinated children aged 1 to 5 years with a parent or grandparent born in a country where the annual incidence of tuberculosis is greater than 40 cases per 100 000 of the population; such children aged from 6 to 16 years should also be vaccinated if they have been shown to be tuberculin-negative
- previously unvaccinated, tuberculin-negative contacts of persons suffering from active respiratory tuberculosis
- previously unvaccinated, tuberculin-negative immigrants under 16 years of age who were born in, or lived in for at least 3 months, a country where the annual incidence of tuberculosis is greater than 40 cases per 100 000 of the population
- previously unvaccinated, tuberculin-negative persons under 16 years of age intending to stay or work with local people for more than 3 months in a country where the annual incidence of tuberculosis is greater than 40 cases per 100 000 of the population.
- vaccination should be *withheld* in all those known or suspected to be HIV-infected, regardless of clinical status. Where vaccination is indicated, as in infants born to HIV-positive mothers, it should only be given after two appropriately timed negative postnatal tests for HIV infection.

Vaccination is also recommended in the UK for previously unvaccinated, tuberculin-negative persons under 35 years of age in the following groups:

- health care workers or laboratory staff at high risk of infection
- veterinary and other staff who handle animals known to be susceptible to tuberculosis
- staff in any institution where the incidence of tuberculosis is high

In the USA, CDC advises still more selective use, with BCG vaccination restricted essentially to tuberculin-negative children or health workers who are continually exposed to individuals with untreated or drug-resistant tuberculosis.

BCG vaccine is given intradermally (intracutaneously) at the insertion of the deltoid muscle in a dose of 0.1 mL; infants under 12 months of age are given 0.05 mL.

Contacts of patients with active pulmonary tuberculosis may require chemoprophylaxis (see under Tuberculosis, p.196) despite previous vaccination. Neonates and children under 2 years of age should be given chemoprophylaxis and immunised, if appropriate, once the course is completed. An isoniazid-resistant form of the vaccine has been produced for use in patients who have received isoniazid, but its use is not recommended.

For use in immunotherapy of **bladder cancer** several regimens have been tried. A typical induction regimen consists of once-weekly intravesical instillation of a solution containing 1 to 16×10^8 colony forming units of BCG in about 50 mL of preservative-free saline 0.9%, for 6 consecutive weeks. Maintenance regimens vary widely from single doses or short courses (once a week for 3 weeks) at 3- to 6-monthly intervals, to instillation once a month; the period of suggested maintenance also varies from 6 months to 3 years. Some also favour a consolidation regimen of three further instillations, a week apart, carried out 6 weeks after completion of induction. Instillations should be retained in the bladder for 2 hours if possible, and then voided with the patient in a sitting position to minimise the risk of environmental contamination (see also Precautions, above).

Leprosy. BCG vaccination has been shown to protect recipients against leprosy and is considered to be one of the factors responsible for the decrease in the incidence of leprosy. A meta-analysis[1] of studies using BCG vaccine to prevent leprosy found that the average protective effect was 26% for the clinical studies and 61% for the observational (cohort or case-controlled) studies. Protection was better for multibacillary forms rather than paucibacillary forms of leprosy. Age at the time of vaccination was not a predictor of vaccine efficacy, but in the observational studies the protective effect was found to decrease with age. Clinical studies indicated that an additional dose of BCG was more effective than a single dose. For further details concerning the use of BCG vaccines in both the immunoprophylaxis and immunotherapy of leprosy, see Leprosy Vaccines, p.2220.

1. Setia MS, *et al.* The role of BCG in prevention of leprosy: a meta-analysis. *Lancet Infect Dis* 2006; **6:** 162–70.

Malignant neoplasms. Immunotherapy with BCG vaccines has been tried in various malignant disorders and is most successful when given locally. The possibility that BCG vaccination might protect children against malignancies has been discussed.[1]

1. Grange JM, Stanford JL. BCG vaccination and cancer. *Tubercle* 1990; **71:** 61–4.

BLADDER. Immunotherapy with adjuvant intravesical BCG is used in the management of bladder cancers and is the treatment of choice for carcinoma *in situ* (p.659). It does not have a direct toxic effect on tumour cells, but produces a cascade of immune reactions that is reported to reduce tumour recurrence and disease progression. A systematic review[1] indicated that intravesical BCG after transurethral resection (TUR) reduced recurrence of Ta and T1 bladder cancers compared with TUR alone. A systematic review[2] of intravesical therapy concluded that tumour recurrence was significantly reduced with BCG when compared with mitomycin C but only in patients at high risk of recurrence; there was no difference in terms of disease progression or survival. However, another meta-analysis[3] reported intravesical BCG to be better than mitomycin C in the prevention of tumour recurrences, particularly in those on BCG maintenance regime, irrespective of the risk of recurrence.

SKIN. Several studies have reported that BCG vaccine injected into intradermal metastases of melanoma can result in regression of the injected, and sometimes also the uninjected nodules. BCG therapy has been disappointing for visceral metastases. Many anecdotal reports and nonrandomised studies have shown benefit from BCG vaccine as adjuvant therapy, but these results have not been confirmed in large randomised, controlled studies.[1,2] More specific immunological interventions such as therapeutic vaccines are now becoming available for the treatment of melanomas (p.673).

Tuberculosis. Studies from many parts of the world have evaluated the efficacy of BCG vaccine to protect against tuberculosis. Levels of protection have varied from 0 to over 80%.[1] Many explanations for such variability have been proposed: interaction with the immune response to other mycobacterial infections; antigenic, microbiological, or formulation differences between BCG vaccines; differences in the natural history of infection and disease; variations in host genetics or nutrition; or methodological differences between studies.[1,2] It has been noted that in general the efficacy of BCG vaccine in any region is proportional to its distance from the equator and this possibly reflects differences in exposure to environmental mycobacteria.[3] This could be the strongest influence on efficacy,[3] with the implication that BCG may be least effective in areas of the world where the risk of tuberculosis is greatest. BCG also appears to be more effective against systemic (miliary and meningitic tuberculosis) than against pulmonary tuberculosis. It is likely that BCG cannot produce complete protection against infection, and the development of new vaccines is ongoing.[4-6]

National policies of BCG vaccination vary widely. Some countries recommend routine vaccination; in others, such as the UK,[7] and USA[8] routine vaccination is no longer carried out and targeted immunisation aimed at infants and others at increased risk is performed (see Uses and Administration, above). Schedules throughout the world have varied from single vaccination at birth (as recommended by WHO),[9] to single vaccination at age 10 to 14, to repeated vaccination every few years (particularly in eastern Europe). These policy differences appear to be related as much to differences of opinion about the mechanism of action and effectiveness of vaccines as to local differences in the epidemiology of tuberculosis.[1] WHO considers BCG vaccination to be an adjunct to case detection and treatment in the control of tuberculosis,[9,10] and recommends that neither tuberculin skin testing nor repeat vaccination should be used.

HIV-INFECTED PATIENTS. Like other live vaccines, BCG vaccine should not be given to immunocompromised patients, including patients with symptomatic HIV infection or AIDS. WHO[1] states that HIV prevalence is one of the factors that should be considered when determining local policies on BCG vaccination (see Uses and Administration, above), and recommends that infants with known or likely HIV infection should not be vaccinated because of the increased risk in this group (see under Precautions, above). In the UK and USA, BCG vaccination is also not recommended for HIV-positive patients.

Botulism Antitoxins

Antitoxinas botulínicas.

Ботулинические Антитоксины

ATC — J06AA04.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Botulinum Antitoxin; Immunoserum Botulinicum). A sterile preparation containing the specific antitoxic globulins that have the power of neutralising the toxins formed by type A, type B, type E, or any mixture of types A, B, and E, of *Clostridium botulinum*. It contains not less than 500 international units of each of type A and type B and not less than 50 units of type E per mL. It should be stored at 2° to 8° and not be allowed to freeze.

The BP 2008 states that Bot/Ser may be used on the label.

The BP 2008 states that when Mixed Botulinum Antitoxin or Botulinum Antitoxin is prescribed or demanded and the types to be present are not stated, Botulinum Antitoxin prepared from types A, B, and E shall be dispensed or supplied.

USP 31 (Botulism Antitoxin). A sterile solution of the refined and concentrated antitoxic antibodies, chiefly globulins, obtained from the blood of healthy horses that have been immunised against the toxins produced by type A and type B and/or E strains of *Clostridium botulinum*. It contains a suitable antimicrobial agent. It should be stored at 2° to 8° in single-use containers.

◊ NOTE. Some antitoxins used in the UK have not conformed to the requirements of the BP 2008 and Ph. Eur. 6.2 (having a higher phenol content than the pharmacopoeias allow), and thus have been referred to as **botulism antitoxin** rather than botulinum antitoxin.

Adverse Effects and Precautions

As for antisera in general, p.2201.

Uses and Administration

Botulism antitoxins are used in the postexposure prophylaxis and treatment of botulism. Treatment should be given as early as possible in the course of the disease.

Since the type of botulism toxin is seldom known the polyvalent antitoxin is usually given. Sensitivity testing should always be performed before using the antitoxin.

In the UK, equine-derived trivalent antitoxins containing antitoxin types A, B, and E are used. One type contains not less than 500 units/mL of each of the 3 antitoxins. For the treatment of botulism, 20 mL of this antitoxin should be diluted to 100 mL with sodium chloride 0.9% and given by slow intravenous infusion over at least 30 minutes; another 10 mL may be given 2 to 4 hours later if necessary, and further doses at 12- to 24-hour intervals if indicated. Persons who have been exposed to the toxin and in whom symptoms have not developed should be given 20 mL intramuscularly as a prophylactic measure.

A second preparation used for treatment of botulism in the UK contains 750 units/mL of antitoxin type A, 500 units/mL of antitoxin type B, and 50 units/mL of antitoxin type E. Patients are given 250 mL by slow intravenous infusion, followed by a further 250 mL by continuous drip infusion. A further 250 mL may be given 4 to 6 hours later if necessary according to response. Patients with severe intoxication should be given an intralumbar injection of 20 mL, particularly if intravenous treatment has produced no improvement; this procedure may be repeated at 24-hour intervals if required..

In the USA, a human-derived intravenous botulism immunoglobulin (BIG-IV) is available for the treatment of patients under 1 year of age with infant botulism caused by toxin type A or B. The recommended dose of 1 mL/kg (50 mg/kg), given as a single intravenous infusion, provides a protective level of neutralising antibodies for at least 6 months.

Botulism. Botulism[1-3] is caused by the exotoxin of *Clostridium botulinum*, a spore-forming, Gram-positive anaerobe which occurs in soil and mud. There are 3 naturally occurring forms of botulism; *food-borne botulism* caused by ingestion of contaminated foodstuffs, *wound botulism* due to the growth of toxin-releasing organisms in the wound, and *intestinal botulism* (including infant botulism and adult intestinal toxaemia) caused by intestinal colonisation and toxin production. Accidental or intentional exposure to botulinum toxin may result in inhalation botulism (from aerosolisation of botulinum toxin) or iatrogenic botulism (from injection of the toxin). Seven types of *C. botulinum* can be distinguished (types A to G), each producing a different exotoxin; human disease is usually caused by types A, B, and E. The toxin is heat labile, but the spores can survive temperatures of up to 120°.

All forms of botulism produce the same clinical syndrome. Symptoms arise as a result of the toxin blocking the release of acetylcholine at the neuromuscular junction and include symmetrical cranial nerve palsies and descending flaccid paralysis, orthostatic hypotension, dry mouth, and dilated pupils. Gastrointestinal symptoms occur with food-borne or intestinal colonisation botulism. Death is usually from respiratory arrest.

Treatment of botulism is with equine-derived antitoxins and intensive respiratory and supportive therapy. Antitoxins should be given as early as possible as only toxins that are not bound to nerve ending are neutralised; however, antitoxins may still be beneficial if treatment is delayed. Some patients may benefit from drugs, such as fampridine or guanidine, aimed at reversing the neuromuscular blockade.

Infant botulism is of increasing importance, especially in the USA where it is reported to be the most common form of botulism, with honey (see p.1948) reputed to be the most frequent source of infection. In contrast to food-borne botulism, in infant botulism low doses of toxin continue to be released into the gut for some time. Treatment is with intensive supportive care; equine botulism antitoxin used in adults is not generally used for infant botulism because of its serious adverse effects (including serum sickness and anaphylaxis), its short half-life, and the possibility of life-long sensitisation to equine proteins.[4] A human-derived intravenous botulism immunoglobulin (BIG-IV) is available in the USA for the treatment of patients under 1 year of age with infant botulism caused by toxin type A or B. Clinical studies[4] reported that treatment with BIG-IV within 7 days of hospital admission reduced the length of hospital stay and severity of illness in infant botulism type A or B; treatment given within 3 days was more effective than treatment given 4 to 7 days after admission.

Proprietary Preparations (details are given in Part 3)
USA: BabyBIG.

Multi-ingredient: ***Cz.:*** Bosea†.

Bovine Colostrum

Calostro bovino.

Profile

Bovine colostrum has been used similarly to antisera and human immunoglobulin preparations to provide passive immunity against infectious diseases. Hyperimmune bovine colostra have been prepared from cows previously immunised with specific antigens. In particular, these specific hyperimmune bovine colostra have been tried in cryptosporidiosis and in the prevention of rotavirus diarrhoea in infants. They may also have potential for use against *Helicobacter pylori*, *Shigella* spp., and measles.

Brucellosis Vaccines

Vacunas de la brucelosis.

ATC — J07AD01.

Profile

A brucellosis vaccine prepared from an antigenic extract of *Brucella abortus* has been used for active immunisation against brucellosis (p.165) in persons at high risk of contracting the disease.

Campylobacter Jejuni Vaccines

Vacunas contra el Campylobacter jejuni.

Profile

An oral vaccine is under development to provide active immunisation against *Campylobacter jejuni* infection.

Cholera Vaccines

Vacunas del cólera.

ATC — J07AE01; J07AE02.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Cholera Vaccine; Vaccinum Cholerae). A sterile homogeneous suspension of a suitable killed strain or strains of *Vibrio cholerae*. It consists of a mixture of equal parts of vaccines prepared from smooth strains of 2 main serological types, Inaba and Ogawa of the classical biotype with or without the El Tor biotype. A single strain or several strains of each type may be included. All strains must contain, in addition to their type O antigens, the heat-stable O antigen common to the Inaba and Ogawa types. If more than one strain each of Inaba and Ogawa are used they may be selected to contain other O antigens. It contains not less than 8000 million *V. cholerae* per dose, which does not exceed 1 mL. It contains not more than 0.5% of phenol. It should be stored at 2° to 8° and protected from light.

The BP 2008 states that Cholera may be used on the label.

Ph. Eur. 6.2 (Cholera Vaccine, Freeze-dried; Vaccinum Cholerae Cryodesiccatum). Cholera vaccine that is freeze-dried and reconstituted immediately before use by the addition of a suitable sterile liquid. Phenol may not be used in the preparation of the dried vaccine. It should be stored at 2° to 8° and be protected from light.

Ph. Eur. 6.2 (Cholera Vaccine (Inactivated, Oral); Vaccinum Cholerae Perorale Inactivatum). A homogeneous suspension of inactivated suitable strains of *Vibrio cholerae* serogroup O1, representing serotypes and biotypes of epidemic strains. The vaccine may contain the B subunit of cholera toxin (CTB). Just prior to ingestion, one dose of vaccine suspension is mixed with a suitable buffer as stated on the label. Store at 2° to 8 °. Protect from light.

The BP 2008 states that Dried/Cholera may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Slight swelling, erythema, and tenderness occasionally occur at the injection site. Fever and malaise have been reported and general reactions, including anaphylaxis and hypersensitivity reactions, have occurred. Neurological and psychiatric reactions have occasionally occurred.

Gastrointestinal disturbances, headache, dizziness, and respiratory symptoms have followed use of oral cholera vaccine.

Interactions

As for vaccines in general, p.2202.

The oral cholera vaccine available in the UK is acid labile; consequently food should not be consumed for 1 hour before and after use.

Uses and Administration

Injectable inactivated whole-cell cholera vaccines have been used for active immunisation against cholera but are not considered to be very effective and the immunity conferred is short-lived. They have no role in the management of contacts of cases or in controlling the spread of infection.

Oral vaccines containing either live attenuated or inactivated strains are available in some countries and appear to be more effective than parenteral vaccines (see below). In the UK, an oral vaccine containing inactivated strains of *Vibrio cholerae* O1 and recombinant cholera toxin B subunit is available for use in adults and children aged over 2 years who are travelling to areas of risk. The vaccine is given as a suspension, in doses of 3 mL, mixed with sodium hydrogen carbonate solution. Adults and children aged over 6 years are given two doses, and children aged 2 to 6 years three doses, in each case at weekly intervals. Immunisation should be complete at least 1 week prior to potential exposure. Booster doses may be given after 2 years in adults and children over 6 years, or after 6 months in children aged 2 to 6 years, if continuous protection is required. Oral vaccines containing a live attenuated form of the *V. cholerae* strain CVD 103-HgR are available in some countries. They are effective against the O1 serogroup of cholera, but do not afford protection against the O139 serogroup. They may be given to adults and children aged over 2 years who are travelling to areas of risk and are given as a single-dose suspension in sodium hydrogen carbonate solution. Immunisation should be carried out at least 1 week before potential exposure. When necessary revaccination is recommended every 6 months.

The WHO International Health Regulations do not require cholera vaccination for travellers as the introduction of cholera into any country cannot be prevented by cholera vaccination. However, travellers may still be asked for evidence of immunisation at some borders.

Oral cholera vaccines. Since parenteral cholera vaccines are not considered to be very effective, providing at best 50% protection and confer immunity lasting only 3 to 6 months, attention has turned towards oral vaccines that stimulate intestinal immunity.[1] Both killed and live attenuated oral vaccines have been developed, and both types have been shown to be non-toxic and immunogenic.

Killed vaccines contain inactivated whole *Vibrio cholerae* O1 either alone or with B subunit component of cholera toxin. These vaccines typically produce a protective efficacy of about 60 to 70% and both modify established infections and prevent new ones. Although the vaccines are effective in areas where the El Tor biotype predominates, they are more effective against classical strains. Immunity particularly against El Tor may be less sustained in children under 5 years of age than in older children and adults. The main drawback is the need to give two or more doses at 1- to 2-week intervals to achieve a protective effect. The protective effect is rapidly established but diminishes over time and booster doses are necessary to maintain a high level of immunity.

A live attenuated vaccine is now available containing CVD 103-HgR in which the genes encoding the toxic A subunit are deleted by recombinant techniques.[2,3] This vaccine is effective 8 days after a single dose but less so against El Tor than against classical strains. It is not effective against *V. cholorae* O139.

Live oral vaccines effective against El Tor are now being developed,[4,5] and promising responses have also been reported with a live attenuated O139 vaccine.[6]

The efficacy and cost-effectiveness of oral vaccines to control cholera outbreaks in refugee populations is uncertain.

Crimean-Congo Haemorrhagic Fever Vaccines

Profile

An inactivated vaccine against Crimean-Congo haemorrhagic fever, derived from *mouse* brains, is used in parts of eastern Europe.

Cytomegalovirus Immunoglobulins

Inmunoglobulinas contra el citomegalovirus.

ATC — J06BB09.

Description. Cytomegalovirus immunoglobulins containing high levels of specific antibody against CMV have been prepared from human plasma.

Adverse Effects and Precautions

As for immunoglobulins in general, p.2201.

Interactions

As for immunoglobulins in general, p.2201.

Uses and Administration

Cytomegalovirus immunoglobulins are used for passive immunisation against CMV infection. They are used prophylactically, especially in patients undergoing certain transplant procedures. In transplants from CMV-seropositive donors into seronegative recipients, prophylactic use of cytomegalovirus immunoglobulin with ganciclovir should also be considered.

In the USA, a cytomegalovirus immunoglobulin G is available for use in recipients of heart, kidney, liver, lung, and pancreas transplants, and for CMV-seronegative recipients of these organs other than kidney from CMV-seropositive donors. The dosage schedule for kidney transplant recipients is 150 mg/kg by intravenous infusion within 72 hours of transplantation, then 100 mg/kg once every 2 weeks for 4 doses, then 50 mg/kg every 4 weeks for 2 doses. The rate of infusion should start at 15 mg/kg per hour increasing gradually to a maximum rate of 60 mg/kg per hour. For recipients of transplants other than kidney, the recommended dosage schedule is 150 mg/kg within 72 hours of transplantation and then once every 2 weeks for 4 further doses, then 100 mg/kg every 4 weeks for 2 doses. In the UK, cytomegalovirus immunoglobulin is available on a named patient basis for prophylaxis in patients receiving immunosuppressive treatment.

The name sevirumab is applied to a χ-chain human monoclonal cytomegalovirus immunoglobulin G1.

Cytomegalovirus Vaccines

Vacunas contra el citomegalovirus.

Profile

Several vaccines for active immunisation against CMV infection are under investigation, including some produced by recombinant technology. A live attenuated cytomegalovirus vaccine containing human CMV Towne strain has been investigated in humans since the late 1970s, particularly for the prevention of CMV infection in renal transplant recipients. However, there have been doubts over its safety.

◊ Several promising candidate vaccines against human CMV infection are under development, of which 5 have been or are being tested in humans.[1] Firstly, attenuated CMV (Towne strain) vaccine has been tried but found to be erratic in efficacy and loses segments of its genetic material; to overcome this a second, more robust, vaccine has been designed consisting of a chimera between the attenuated CMV and wild-type virus. The third vaccine developed, known as ALVAC, consists of a canarypox vector with either a glycoprotein B envelope or a core antigen from CMV pp65, a protein found to be recognised by CD8+ T lymphocytes during naturally acquired infection. Fourthly, a protein sub-unit vaccine consisting of a recombinant envelope glycoprotein has been found to be safe and to induce a neutralising antibody response. Finally, the fifth vaccine developed is a mixture of synthetic peptides incorporating a T helper epitope known as CD8+ cytotoxic T cell epitope and a lipid tail. Currently, the attenuated cytomegalovirus vaccine, the protein sub-unit vaccine, and the recombinant vector vaccine have been or are being tested in CMV-negative subjects, and the chimeric vaccine has been tested in CMV-positive patients as a precursor to testing in CMV-negative persons.[1]

Further vaccine candidates that have been proposed include DNA vaccines and a vaccine based on recombinant technology.[1] Some commentators[2] have suggested that reduction or prevention of cytomegalovirus disease may be a more realistic goal for a vaccine than prevention of infection.

Dengue Fever Vaccines

Vacunas del dengue.

Profile

Live attenuated vaccines under study for active immunisation against dengue fever contain dengue virus types 1, 2, 3, and 4 alone or in various combinations. WHO considers that protection against only one or two dengue viruses might actually increase the risk of more serious disease. The ultimate aim is to produce a vaccine active against all types of dengue virus.

Recombinant vaccines are also under investigation.

Dental Caries Vaccines

Vacunas de la caries dental.

Profile

Dental caries vaccines consisting of purified proteins from *Streptococcus mutans* or *Str. sobrinus* are under investigation. Monoclonal antibodies are also being studied for local passive immunisation.

◊ Several *animal* studies of candidate vaccines for the prevention of dental caries have shown that immunisation with protein antigens from *Streptococcus mutans* or *Str. sobrinus* can induce salivary IgA antibodies which inhibit both sucrose-dependent or sucrose-independent accumulation of these organisms on tooth surfaces. It is thought that candidate vaccines for study in humans could be given by mucosal application since children are already naturally exposed to the antigens involved during the first years of life. Infection with *Str. mutans* normally occurs from the age of about 18 months and the intention is therefore to vaccinate 1-year-old children in order to intercept colonisation. However, progress towards a vaccine for active immunisation against dental caries requires further clinical evaluation. Passive administration of salivary antibodies to *Str. mutans* has also provided some protection in preclinical studies and small scale studies in humans.[1-4]

Diphtheria Antitoxins

Antitoxinas diftéricas.

ATC — J06AA01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria Antitoxin; Immunoserum Diphthericum). A sterile preparation containing the specific antitoxic globulins that have the power of neutralising the toxin formed by *Corynebacterium diphtheriae*. It has a potency of not less than 1000 international units/mL when obtained from horse serum and not less than 500 international units/mL when obtained from other mammals. It should be stored at 2° to 8°, and not be allowed to freeze.

The BP 2008 states that Dip/Ser may be used on the label.

Adverse Effects and Precautions

As for antisera in general, p.2201.

Uses and Administration

Diphtheria antitoxins neutralise the toxin produced by *Corynebacterium diphtheriae* locally at the site of infection and in the circulation.

Diphtheria antitoxin is used for passive immunisation in suspected cases of diphtheria and should be given without waiting for bacteriological confirmation of the infection. An antibacterial is usually given concomitantly (see p.168). Diphtheria antitoxin is generally not used for the prophylaxis of diphtheria because of the risk of provoking a hypersensitivity reaction. Contacts of a diphtheria case should be promptly investigated, given antibacterial prophylaxis and active immunisation with a suitable diphtheria-containing vaccine as appropriate (see below), and kept under observation.

A test dose of diluted diphtheria antitoxin should always be given intradermally to exclude hypersensitivity. In the UK, diphtheria antitoxin is given by intravenous infusion for the treatment of diphtheria of mild to moderate severity in the following recommended doses: for nasal diphtheria, 10 000 to 20 000 units; for tonsillar diphtheria, 15 000 to 25 000 units; for pharyngeal or laryngeal diphtheria, 20 000 to 40 000 units. In cases of combined disease, or when diagnosis is delayed, 40 000 to 60 000 units should be given, and, in severe disease, doses up to 100 000 units used. For most cutaneous infections, diphtheria antitoxin is insufficiently absorbed and is therefore not given; however, if the ulcer is sufficiently large (more than 2 cm^2) and especially if it is membranous, then 20 000 to 40 000 units may be given. Higher doses have been used in some countries.

Preparations

Ph. Eur.: Diphtheria Antitoxin.

Diphtheria Vaccines

Vacunas de la difteria.

ATC — J07AF01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria Vaccine (Adsorbed); Vaccinum Diphtheriae Adsorbatum). A preparation of diphtheria formol toxoid adsorbed on a mineral carrier. The formol toxoid is prepared from the toxin produced by the growth of *Corynebacterium diphtheriae*. The mineral carrier may be hydrated aluminium phosphate or aluminium hydroxide and the resulting mixture is approximately isotonic with blood. The antigenic properties are adversely affected by certain antimicrobial preservatives, particularly those of the phenolic type. It contains not less than 30 international units per dose. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Ph. Eur. 6.2 (Diphtheria Vaccine (Adsorbed, Reduced Antigen Content); Vaccinum Diphtheriae, Antigeniis Minutum, Adsorbatum). It is an adsorbed diphtheria vaccine containing not less than 2 international units per dose.

The BP 2008 states that for a vaccine for use in the UK, the amount of toxoid used is adjusted so that the final vaccine contains not more than 2.0 flocculation equivalents per dose.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Local reactions may occur but are generally not severe in young children; the frequency and severity of reactions is reported to be less in children under 2 years of age than in older children and adults. If diphtheria vaccines or vaccines containing a diphtheria component need to be given to children over the age of 10 years or to adults, vaccines with a reduced content of diphtheria toxoid and intended for adults and adolescents should be used. For further details see Uses and Administration, below.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Diphtheria vaccines are used for active immunisation against diphtheria. The non-adsorbed vaccine has poor immunogenic properties and its effects are enhanced if given as an adsorbed preparation. For primary immunisation combined diphtheria vaccines, usually diphtheria, tetanus, and pertussis vaccines (p.2210) or diphtheria, tetanus, pertussis, poliomyelitis, and haemophilus influenzae vaccines (p.2212), are used. A single-component diphtheria vaccine has sometimes been used, for example in the event of contact with an infected patient or a carrier. For discussion of immunisation schedules, see under Vaccines, p.2202.

Individuals coming into contact with a case of diphtheria or carrier of a toxigenic strain, or those travelling to an endemic or epidemic area should receive a complete primary course or a reinforcing dose according to age and immunisation history; those not previously immunised should receive a primary course of immunisation, and those previously immunised should receive a single reinforcing dose of a diphtheria-containing vaccine. Contacts of a case of diphtheria or carrier of a toxigenic strain should in addition receive a prophylactic course of a suitable antibacterial (see p.168). Individuals at repeated risk of exposure to infection may be offered booster doses every 10 years.

Schick testing (p.2384) to ascertain immune status is no longer considered necessary before giving diphtheria vaccine to adults provided that a low dose is given; antibody testing is used to check immunity in those regularly exposed to diphtheria.

In some countries, booster doses of a diphtheria and tetanus vaccine are recommended every 10 years (see under Diphtheria and Tetanus Vaccines, p.2210).

Conjugation to diphtheria toxoid has been used to increase the immunogenicity of other vaccines (see Haemophilus Influenzae Vaccines, p.2213).

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Aldiana†; ***NZ:*** Di Anatoxal.

Diphtheria and Tetanus Vaccines

Vacunas de la difteria y el tétanos.

ATC — J07AM51.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Diphtheria and Tetanus Vaccine (Adsorbed); Vaccinum Diphtheriae et Tetani Adsorbatum). A preparation of diphtheria formol toxoid and tetanus formol toxoid adsorbed on a mineral carrier. The mineral carrier may be hydrated aluminium phosphate or aluminium hydroxide and the resulting mixture is approximately isotonic with blood. The antigenic properties are adversely affected by certain antimicrobial preservatives particularly those of the phenolic type. It contains not less than 30 international units of diphtheria toxoid and not less than 40 international units of tetanus toxoid per dose. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that DT/Vac/Ads(Child) may be used on the label.

The BP 2008 gives Adsorbed Diphtheria-Tetanus Prophylactic as an approved synonym.

Ph. Eur. 6.2 (Diphtheria and Tetanus Vaccine (Adsorbed, Reduced Antigen(s) Content); Vaccinum Diphtheriae et Tetani, Antigeni-o(-is) Minutum). It is diphtheria and tetanus vaccine (adsorbed) containing not less than 2 units of diphtheria toxoid and not less than 20 units of tetanus toxoid per dose.

The BP 2008 states that for a vaccine for use in the UK, the amount of diphtheria toxoid used is adjusted so that the final vaccine contains not more than 2.0 flocculation equivalents of diphtheria toxoid per dose.

The BP 2008 states that dT may be used on the label.

USP 31 (Diphtheria and Tetanus Toxoids Adsorbed). A sterile suspension prepared by mixing suitable quantities of plain or adsorbed diphtheria toxoid and plain or adsorbed tetanus toxoid and, if plain toxoids are used, an aluminium adsorbing agent. The antigenicity or potency and the proportions of the toxoids are such as to provide an immunising dose of each toxoid in the labelled dose. It should be stored at 2° to 8° and not be allowed to freeze.

USP 31 (Tetanus and Diphtheria Toxoids Adsorbed for Adult Use). A sterile suspension prepared by mixing suitable quantities of adsorbed diphtheria toxoid and adsorbed tetanus toxoid using the same precipitating or adsorbing agent for both toxoids. The antigenicity or potency and the proportions of the toxoids are such as to provide, in the labelled dose, an immunising dose of adsorbed tetanus toxoid and one-tenth of the immunising dose of adsorbed diphtheria toxoid specified for children and not more than 2 Lf of diphtheria toxoid. It should be stored at 2° to 8° and not be allowed to freeze.

Adverse Effects and Precautions

As for vaccines in general, p.2201. See also under Diphtheria Vaccines, above, and Tetanus Vaccines, p.2240. Diphtheria and tetanus vaccines are reported to produce fewer adverse effects than diphtheria, tetanus, and pertussis vaccines (see under Incidence of Adverse Effects, p.2210).

Dose-related effects. A high incidence of adverse effects was reported in teenagers inadvertently given a high-dose diphtheria and tetanus vaccine intended for use in infants.[1] Most reactions were classified as mild or moderately severe, but severe local or systemic reactions occurred in a third of those reporting reactions.

1. Sidebotham PD, Lenton SW. Incidence of adverse reactions after administration of high dose diphtheria with tetanus vaccine to school leavers: retrospective questionnaire study. *BMJ* 1996; **313:** 533–4.

Effects on the nervous system. Encephalopathy more commonly follows vaccination with diphtheria, tetanus, and pertussis vaccine than with diphtheria and tetanus vaccine (p.2210). Several cases of encephalopathy occurred in a small region in Italy in children after immunisation against diphtheria and tetanus,[1] although it was not possible to infer a causal relationship. A case of polyradiculoneuritis has been reported in a patient after the use of a diphtheria-tetanus vaccine and was considered most likely to have been due to the tetanus component.[2]

1. Greco D. Case-control study on encephalopathy associated with diphtheria-tetanus immunization in Campania, Italy. *Bull WHO* 1985; **63:** 919–25.
2. Holliday PL, Bauer RB. Polyradiculoneuritis secondary to immunization with tetanus and diphtheria toxoids. *Arch Neurol* 1983; **40:** 56–7.

GUILLAIN-BARRÉ SYNDROME. Evidence mainly from case reports and uncontrolled studies favoured a causal relationship between vaccination with diphtheria and tetanus vaccines or single-antigen tetanus vaccines and Guillain-Barré syndrome. The data came primarily from immunocompromised patients.[1] However, a later analysis of active surveillance epidemiological studies of Guillain-Barré syndrome and tetanus vaccination history concluded that if an association exists, it must be extremely rare and not of public health significance.[2]

1. Stratton KR, *et al.* Adverse events associated with childhood vaccines other than pertussis and rubella: summary of a report from the Institute of Medicine. *JAMA* 1994; **271:** 1602–5.
2. Tuttle J, *et al.* The risk of Guillain-Barré syndrome after tetanus-toxoid-containing vaccines in adults and children in the United States. *Am J Public Health* 1997; **87:** 2045–8.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Combined adsorbed diphtheria and tetanus vaccines may be used for active immunisation, although vaccines used for primary immunisation usually combine diphtheria, tetanus, and pertussis, and sometimes also Haemophilus influenzae and poliomyelitis. Diphtheria and tetanus vaccines are used in some countries for reinforcing doses after primary immunisation; in the USA they are given to adults every 10 years. For discussion of immunisation schedules, see under Vaccines, p.2202.

The non-adsorbed combined diphtheria and tetanus vaccines have weaker immunogenic properties than adsorbed vaccines and are no longer recommended.

Booster doses. In many countries, booster doses of combined diphtheria and tetanus vaccines are recommended every 10 years, and studies have been conducted to assess whether this is necessary. Since the incidence of clinical diphtheria in many countries in western Europe and North America approaches zero, it had been considered that there was no need for booster doses in adults, despite low antibody titres, so long as the policy of immunisation during infancy was maintained.[1,2] However, after a report[3] of an outbreak of clinical diphtheria in Sweden after a period of many years during which no indigenous cases of diphtheria had occurred and the disease was regarded as being eliminated from the country, the question of immunity in adults and the need for revaccination again arose. In the USA, it was considered[4] that re-immunisation every 10 years with a diphtheria and tetanus combined vaccine was mandatory and that this combined vaccine should be used whenever a tetanus vaccine was indicated as in treating emergency wounds. This policy is also adopted in the UK. Outbreaks of diphtheria in Russia and neighbouring countries[5] have prompted recommendations for booster doses in travellers to these countries.

Diphtheria, Tetanus, and Haemophilus Influenzae Vaccines

Vacunas de la difteria, el tétanos y Haemophilus influenzae.

Profile

Combined adsorbed diphtheria, tetanus, and *Haemophilus influenzae* type b vaccines have been used in some countries for active immunisation of infants. For discussion of immunisation schedules see under Vaccines, p.2202. For concern over the antigenicity of *Haemophilus influenzae* type b vaccine in combined vaccines, see under Haemophilus Influenzae Vaccines, Interactions, p.2213.

Diphtheria, Tetanus, and Hepatitis B Vaccines

ATC — J07CA07.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria, Tetanus, and Hepatitis B (rDNA) Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani et Hepatitidis B (ADNr) Adsorbatum). A combined vaccine composed of diphtheria formol toxoid, tetanus formol toxoid, hepatitis B surface antigen, and a mineral carrier such as aluminium hydroxide or hydrated aluminium phosphate. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Profile

Combined diphtheria, tetanus, and hepatitis B vaccines have been used in some countries for active immunisation.

Preparations

Ph. Eur.: Diphtheria, Tetanus and Hepatitis B (rDNA) Vaccine (Adsorbed).

Proprietary Preparations (details are given in Part 3)
Gr.: Primavax†.

Diphtheria, Tetanus, and Pertussis Vaccines

Vacunas de la difteria, el tétanos y la tos ferina.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria, Tetanus and Pertussis Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani et Pertussis Adsorbatum). A preparation of diphtheria formol toxoid and tetanus formol toxoid on a mineral carrier to which a suspension of killed *Bordetella pertussis* has been added. The mineral carrier may be hydrated aluminium phosphate or aluminium hydroxide and the resulting mixture is approximately isotonic with blood. The antigenic properties are adversely affected by certain antimicrobial preservatives particularly those of the phenolic type. It contains not less than 30 international units of diphtheria toxoid, not less than 40 international units if the test is performed in *guinea-pigs*, or 60 international units if the test is performed in *mice*, of tetanus toxoid, and not less than 4 international units of the pertussis component per dose. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that DTwP may be used on the label.

Ph. Eur. 6.2 (Diphtheria, Tetanus and Pertussis (Acellular, Component) Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani et Pertussis Sine Cellulis ex Elementis Praeparatum Adsorbatum). A combined vaccine composed of diphtheria formol toxoid, tetanus formol toxoid, individually purified antigenic components of *Bordetella pertussis*, and a mineral carrier such as aluminium hydroxide or hydrated aluminium phosphate. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP2008 states that DTaP may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201. See also under Diphtheria Vaccines, p.2209, Pertussis Vaccines, p.2230, and Tetanus Vaccines, p.2240.

The incidence of local reactions and fever is reported to be lower with the current accelerated immunisation schedules than the formerly used schedules spreading primary immunisation over 6 months. Local reactions and pyrexia occur less commonly after acellular pertussis vaccines than whole-cell pertussis vaccines, especially in children older than 6 months.

In infants with a personal or close family history of seizures, precautions should be taken to avoid pyrexia. See under Pertussis Vaccines for further details of precautions and contra-indications in individuals with a history of neurological problems.

Incidence of adverse effects. The incidence of local reactions is lower with diphtheria and tetanus vaccines combined with an acellular pertussis component (acellular DTP) than with a whole-cell pertussis component, and is similar to that after diphtheria and tetanus (DT) vaccines. Such reactions are generally mild and self-limiting. Rarely, high fever, persistent or inconsolable crying (possibly as a reaction to pain), hypotonic-hyporesponsive collapse, or short-lived convulsions (frequently febrile convulsions) may occur, and have been reported after both DT and acellular DTP vaccines with equal frequency. These reactions do not appear to have any long-term consequences. Rare but serious acute neurological complications including encephalopathy and prolonged seizures have been reported after DTP vaccines and have been attributed to the whole-cell pertussis component (see Effects on the Nervous System, p.2230) but the association could be coincidental. Epidemiological studies have shown that such events are exceedingly rare and only occasionally followed by long-term neurological damage. Analysis of these studies has been difficult but authorities in the UK and USA concluded that the evidence was insufficient for a link.

A causal relationship between DTP vaccination and sudden infant death syndrome (SIDS) has not been established and any temporal relationship is likely to be due to chance.[1,2] There is evidence that the risk of SIDS is lower in infants who have been vaccinated.[3]

Immediate anaphylactic reactions have been reported and are regarded as a contra-indication to further use of DTP vaccine. However, the appearance of a rash is not generally regarded as a contra-indication to further doses.

For further details concerning the contra-indications and precautions to be observed for pertussis-containing vaccines, see p.2230.

Interactions

As for vaccines in general, p.2202.

For a report of a diminished immune response to *Haemophilus influenzae* conjugated vaccine when mixed with diphtheria, tetanus, and acellular pertussis vaccine, see Haemophilus Influenzae Vaccines, p.2213.

Uses and Administration

Combined diphtheria, tetanus, and pertussis vaccines are used for active immunisation of children. For discussion of immunisation schedules, see under Vaccines, p.2202.

Combined adsorbed vaccines may be given by deep subcutaneous or intramuscular injection (vaccines with acellular pertussis components are for intramuscular injection only) in usual doses of 0.5 mL. In the USA, a vaccine with an acellular pertussis component is used as part of the recommended schedule for primary immunisation. Three doses are given at intervals of 2 months (the first preferably at 2 months of age), a fourth dose at least 6 months after the third, and a fifth dose at school entry. Another dose of a vaccine specially formulated for use in adults and adolescents is given at 11 to 12 years of age.

Vaccines containing an acellular pertussis component are now preferred to those containing a whole-cell component (see Vaccine Development, p.2231). The non-adsorbed type of combined diphtheria, tetanus, and pertussis vaccines have weaker immunogenic properties than adsorbed vaccines and are no longer recommended.

Preparations

Diphtheria, Tetanus, Pertussis, and Haemophilus Influenzae Vaccines

Vacunas de la difteria, el tétanos, la tos ferina y Haemophilus influenzae.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria, Tetanus, Pertussis (Acellular, Component) and Haemophilus type b Conjugate Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani, Pertussis Sine Cellulis ex Elementis Praeparatum et Haemophili Stirpe b Conjugatum Adsorbatum). A combined vaccine composed of diphtheria formol toxoid, tetanus formol toxoid, individually purified antigenic components of *Bordetella pertussis*, polyribosylribitol phosphate derived from a suitable strain of *Haemophilus influenzae* type b and covalently bound to a carrier protein, and a mineral carrier such as aluminium hydroxide or hydrated aluminium phosphate. The product may be presented with the Haemophilus type b component in a separate container, the contents of which are mixed with the other components immediately before use. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Diphtheria Vaccines, p.2209, Diphtheria, Tetanus, and Pertussis Vaccines, p.2210, Haemophilus Influenzae Vaccines, p.2213, Pertussis Vaccines, p.2230, and Tetanus Vaccines, p.2240.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Combined adsorbed diphtheria, tetanus, whole-cell or acellular pertussis, and *Haemophilus influenzae* type b vaccines are available in some countries for active immunisation of children. For discussion of immunisation schedules, see under Vaccines, p.2202. Some combined vaccines are not licensed for use in primary immunisation regimens because of concerns over the response to the *Haemophilus influenzae* type b component (see under Interactions of Haemophilus Influenzae Vaccines, p.2213).

Preparations

Ph. Eur.: Diphtheria, Tetanus, Pertussis (Acellular, Component) and Haemophilus Type b Conjugate Vaccine (Adsorbed); Diphtheria, Tetanus, Pertussis (Acellular, Component), Poliomyelitis (Inactivated) and Haemophilus Type b Conjugate Vaccine (Adsorbed); Diphtheria, Tetanus, Pertussis, Poliomyelitis (Inactivated) and Haemophilus Type b Conjugate Vaccine (Adsorbed).

Diphtheria, Tetanus, Pertussis, and Poliomyelitis Vaccines

Vacunas de la difteria, el tétanos, la tos ferina y la poliomielitis.

ATC — J07CA02.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Diphtheria, Tetanus, Pertussis (Acellular, Component) and Poliomyelitis (Inactivated) Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani, Pertussis Sine Cellulis ex Elementis Praeparatum et Poliomyelitidis Inactivatum Adsorbatum). A combined vaccine containing diphtheria formol toxoid, tetanus formol toxoid, individually purified antigenic components of *Bordetella pertussis*, suitable strains of human polioviruses type 1, 2, and 3 grown in suitable cell cultures and inactivated by a validated method, and a mineral carrier such as aluminium hydroxide or hydrated aluminium phosphate. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Ph. Eur. 6.2 (Diphtheria, Tetanus, Pertussis and Poliomyelitis (Inactivated) Vaccine (Adsorbed); Vaccinum Diphtheriae, Tetani, Pertussis et Poliomyelitidis Inactivatum Adsorbatum). A combined vaccine containing diphtheria formol toxoid, tetanus formol toxoid, an inactivated suspension of *Bordetella pertussis*, suitable strains of human polioviruses type 1, 2, and 3 grown in suitable cell cultures and inactivated by a validated method, and a mineral carrier such as aluminium hydroxide or hydrated aluminium phosphate. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Ph. Eur. 6.2 (Diphtheria, Tetanus, Pertussis (Acellular, Component) and Poliomyelitis (Inactivated) Vaccine (Adsorbed, Reduced Antigen(s) Content); Vaccinum Diphtheriae, Tetani, Pertussis Sine Cellulis ex Elementis Praeparatum et Poliomyelitidis Inactivatum, Antigeni-o(-is) Minutum, Adsorbatum). A combined vaccine containing diphtheria formol toxoid, tetanus formol toxoid, individually purified antigenic components of *Bordetella pertussis*, suitable strains of human polioviruses type 1, 2, and 3 grown in suitable cell cultures and inactivated by a validated method, and a mineral adsorbent such as aluminium hydroxide or hydrated aluminium phosphate. The amount of diphtheria toxoid per single human dose is reduced compared to vaccines generally used for primary vaccination; the amounts of tetanus toxoid and pertussis components may also be reduced. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Diphtheria Vaccines, p.2209, Diphtheria, Tetanus, and Pertussis Vaccines, p.2210, Pertussis Vaccines, p.2230, and Tetanus Vaccines, p.2240.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

A combined diphtheria, tetanus, pertussis (acellular component), and poliomyelitis (inactivated) vaccine is used for active immunisation. For discussion of immunisation schedules see under Vaccines, p.2202.

In the UK it is used as part of the recommended schedule and is given by intramuscular injection in a single dose of 0.5 mL as a booster at pre-school age (3 years

4 months to 5 years). It is not suitable for primary immunisation.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Diphtheria Vaccines, p.2209, Diphtheria, Tetanus, and Pertussis Vaccines, p.2210, Haemophilus Influenzae Vaccines, p.2213, Pertussis Vaccines, p.2230, and Tetanus Vaccines, p.2240.

Premature neonates. In an observational study[1] of 78 very-low-birth-weight premature neonates given a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and Haemophilus influenzae vaccine before hospital discharge, increased incidences of apnoea, bradycardia, desaturation, or oxygen requirement occurred in 47% overall within 24 to 48 hours of vaccination. All neonates with increased events returned to baseline within 48 to 72 hours and there was no detrimental impact on clinical course. The authors considered that, although monitoring and appropriate intervention were required, delaying vaccination was not warranted, a view in line with UK and USA official recommendations (see p.2202).

1. Pfister RE, *et al.* Safety of DTaP-based combined immunization in very-low-birth-weight premature infants: frequent but mostly benign cardiorespiratory events. *J Pediatr* 2004; **145:** 58–66.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

A combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and Haemophilus influenzae vaccine is used for active immunisation of children. For discussion of immunisation schedules, see under Vaccines, p.2202.

In the UK it is used as part of the recommended schedule for primary immunisation. It is given by intramuscular injection in usual doses of 0.5 mL; three doses are given at intervals of one month, starting preferably at 2 months of age. Although it is not licensed for use after a child's fourth birthday, the national schedule considers it may be used up to the age of 10 years.

Diphtheria, Tetanus, and Poliomyelitis Vaccines

Vacunas de la difteria, el tétanos y la poliomielitis.
ATC — J07CA01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.
Ph. Eur. 6.2 (Diphtheria, Tetanus and Poliomyelitis (Inactivated) Vaccine (Adsorbed, Reduced Antigens(s) Content); Vaccinum Diphtheriae, Tetani et Poliomyelitidis Inactivatum, Antigeni-o(-is) Minutum, Adsorbatum). A combined vaccine containing diphtheria formol toxoid, tetanus formol toxoid, suitable strains of human polioviruses types 1, 2, and 3 grown in suitable cell cultures and inactivated by a validated method, and a mineral adsorbent such as aluminium hydroxide or hydrated aluminium phosphate. The amount of diphtheria toxoid per single human dose is reduced compared to vaccines generally used for primary vaccination; the amount of tetanus toxoid may also be reduced. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Diphtheria Vaccines, p.2209, Diphtheria and Tetanus Vaccines, p.2210, and Tetanus Vaccines, p.2240.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

A combined diphtheria, tetanus, and poliomyelitis (inactivated) vaccine is used for active immunisation. For discussion of immunisation schedules see under Vaccines, p.2202.

In the UK it is used as part of the recommended schedule and is given by intramuscular injection in a single dose (usually 0.5 mL) as a booster at the ages of 13 to 18 years. It is not licensed for primary immunisation.

Preparations

Ph. Eur.: Diphtheria, Tetanus, and Poliomyelitis (Inactivated) Vaccine (Adsorbed, Reduced Antigen(s) Content).

Austria: Revaxis; ***Belg.:*** Revaxis; ***Canad.:*** Td-Polio; ***Fr.:*** DT Polio; Revaxis; Vaccin DTP†; ***Ger.:*** Revaxis; Td-Virelon; ***Gr.:*** Revaxis; ***Hung.:*** Dultavax; ***Irl.:*** Revaxis; ***Ital.:*** Revaxis; ***Neth.:*** Revaxis; ***Port.:*** Revaxis; ***Switz.:*** Revaxis; Td-Virelon; ***UK:*** Revaxis.

Endotoxin Antibodies

Anticuerpos antiendotoxinas.

Profile

Antibodies against the endotoxin of Gram-negative bacteria have been tried as adjunctive therapy for the treatment and prevention of Gram-negative bacteraemia and shock.

Early preparations consisted of antisera prepared from the sera of donors immunised with *Escherichia coli* J5; these were superseded by human and murine IgM monoclonal antibodies. Nebacumab (HA-1A) is a human monoclonal IgM antibody that binds specifically to the lipid A domain of endotoxin. Lipid A in the circulation releases tumour necrosis factor and other cytokines from macrophages and endothelial cells which may ultimately culminate in physiological effects such as multiple organ failure. Despite early promising results of clinical studies the safety of nebacumab in patients without Gram-negative septicaemia was questioned and the product was withdrawn.

A murine monoclonal IgM antibody (edobacomab; E5) has also undergone clinical trials although results have been disappointing.

Epstein-Barr Virus Vaccines

Vacunas del virus de Epstein-Barr.

Profile

Several Epstein-Barr virus vaccines are under investigation for active immunisation against infectious mononucleosis and post-transplant lymphoproliferative disorders.

◊ Epstein-Barr virus is a herpesvirus that is ubiquitous in the adult population. It only causes clinical illness where primary infection occurs in adolescence or adulthood, when it prompts the symptoms of infectious mononucleosis in about 50% of cases. More than 90% of the world's population, however, carry the virus as a lifelong latent infection of B-lymphocytes and, as a result, Epstein-Barr virus can also be associated with malignancies including lymphoproliferative diseases, Burkitt's lymphoma, gastric carcinoma, oral hairy leucoplakia, nasopharyngeal carcinoma, and Hodgkin's disease.

Vaccines against Epstein-Barr virus infection are under investigation[1,2] and the main focus has been towards the development of a vaccine to prevent primary infection or to minimise its consequences, namely infectious mononucleosis and post-transplant lymphoproliferative disease, rather than towards the malignancies associated with the virus which occur in relatively fewer patients. Two main approaches have been adopted, the first of which seeks to exploit the major envelope glycoprotein of the virus, gp340, because of its ability to induce neutralising antibodies. This vaccine may prevent infectious mononucleosis by moderating the initial viral replication and spread during primary infection, thereby curtailing the cytotoxic T-lymphocyte response to lytic antigens that would otherwise invoke the immunological processes responsible for clinical symptoms. The second approach is based on the induction of cytotoxic T-cells specific to Epstein-Barr virus, thereby aiming to reduce the clinical symptoms of infectious mononucleosis rather than to prevent primary infection.

Potential future vaccines for malignancies associated with Epstein-Barr virus are likely to be therapeutic rather than preventative and to exploit the presence of the virus in tumour cells; alternatively they may be focussed on tumour antigens not encoded by Epstein-Barr virus.[1,2]

Escherichia Coli Vaccines

Vacunas de Escherichia coli.

Profile

Vaccines against enterotoxigenic strains of *Escherichia coli* are under investigation. Vaccine candidates include toxoids, inactivated whole bacteria, purified surface antigens, and live oral vaccines.

◊ Infectious diarrhoea remains a major source of morbidity and mortality in the world and a significant proportion is caused by pathogenic strains of *Escherichia coli* While it is considered feasible to develop effective vaccines against *E. coli*, at present there are no such vaccines available. Current approaches against enteropathogenic *E. coli* (EPEC) and enterohaemorrhagic *E. coli* (EHEC) have focussed on three main areas: the EPEC and EHEC proteins involved in colonisation of the intestine, the EHEC O157-specific side-chain of lipopolysaccharides, and the immunogenicity of Shiga toxin produced by the organism. While vaccination against EPEC has to be directed towards susceptible human populations, there are two possible approaches with regard to EHEC, namely vaccination of either humans or the animal reservoir, cattle. Studies of vaccine candidates are ongoing *in vitro*, in *animal* models, and in healthy subjects. For both pathogens, however, the development of vaccines would not in itself serve to eradicate the spread of infections and would need to be accompanied by public health campaigns to increase food hygiene and monitoring of water supplies and facilities.[1]

Enterotoxigenic *E. coli* (ETEC) is a major cause of travellers' diarrhoea. A phase II placebo-controlled study[2] found that a vaccine containing heat-labile enterotoxin from ETEC given as a skin patch (2 patches applied 2 to 3 weeks apart), reduced the risk of moderate to severe travellers' diarrhoea by 75% and severe diarrhoea by 84%. In vaccinated travellers who got diarrhoea, the illness was significantly shorter and milder.

Gas-gangrene Antitoxins

Antitoxinas de la gangrena gaseosa.

ATC — J06AA05.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Gas-gangrene Antitoxin (Novyi); Immunoserum Gangraenicum (Clostridium Novyi)). A sterile preparation containing the specific antitoxic globulins that have the power of neutralising the alpha toxin formed by *Clostridium novyi*. It has a potency of not less than 3750 international units/mL. It should be stored at 2° to 8°, and not be allowed to freeze.

The BP 2008 states that Nov/Ser may be used on the label.

The BP 2008 gives Gas-gangrene Antitoxin (Oedematiens) as an approved synonym.

Ph. Eur. 6.2 (Gas-gangrene Antitoxin (Perfringens); Immunoserum Gangraenicum (Clostridium Perfringens)). A sterile preparation containing the specific antitoxic globulins that have the power of neutralising the alpha toxin formed by *Clostridium perfringens*. It has a potency of not less than 1500 international units/mL. It should be stored at 2° to 8°, and not be allowed to freeze.

The BP 2008 states that Perf/Ser may be used on the label.

Ph. Eur. 6.2 (Gas-gangrene Antitoxin (Septicum); Immunoserum Gangraenicum (Clostridium Septicum)). A sterile preparation containing the specific antitoxic globulins that have the power of neutralising the alpha toxin formed by *Clostridium septicum*. It has a potency of not less than 1500 international units/mL. It should be stored at 2° to 8°, and not be allowed to freeze.

The BP 2008 states that Sep/Ser may be used on the label.

Ph. Eur. 6.2 (Gas-gangrene Antitoxin, Mixed; Immunoserum Gangraenicum Mixtum). It is prepared by mixing Gas-gangrene Antitoxin (Novyi), Gas-gangrene Antitoxin (Perfringens), and Gas-gangrene Antitoxin (Septicum) in appropriate quantities. It has a potency of not less than 1000 international units/mL of Gas-gangrene Antitoxin (Novyi), not less than 1000 international units/mL of Gas-gangrene Antitoxin (Perfringens), and not less than 500 international units/mL of Gas-gangrene Antitoxin (Septicum). It should be stored at 2° to 8°, and not be allowed to freeze.

The BP 2008 states that Gas/Ser may be used on the label.

Profile

Gas-gangrene antitoxins have been used for the treatment of gas gangrene and for prophylaxis in patients at risk after injury. They are now seldom used and have been superseded by antibacterials. Monovalent gas-gangrene antitoxins have been little used in practice owing to the difficulty of rapidly identifying the infecting organism.

Preparations

Ph. Eur.: Gas-gangrene Antitoxin (Novyi); Gas-gangrene Antitoxin (Perfringens); Gas-gangrene Antitoxin (Septicum); Mixed Gas-gangrene Antitoxin.

Proprietary Preparations (details are given in Part 3)

Cz.: Gasea†.

Gonococcal Vaccines

Gonorrhoea Vaccines; Vacunas de la gonorrea.

Profile

Several experimental gonococcal vaccines, produced usually from the surface antigens of *Neisseria gonorrhoeae*, have been investigated.

Haemophilus Influenzae Vaccines

Vacunas de Haemophilus influenzae.

ATC — J07AG01 (B, purified antig. conjugate).

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Haemophilus type b Conjugate Vaccine; Vaccinum Haemophili Stirpe B Conjugatum). A liquid or freeze-dried preparation of a polysaccharide, polyribosylribitol phosphate (PRP), derived from a suitable strain of *Haemophilus influenzae* type b, covalently bound to a carrier protein. The carrier protein, when conjugated to PRP, is capable of inducing a T-cell-dependent B-cell immune response to the polysaccharide. Carrier proteins currently approved are diphtheria toxoid, tetanus toxoid, CRM 197 diphtheria protein, and meningococcal group B outer membrane protein (OMP). It should be stored at 2° to 8° and protected from light.

The BP 2008 states that Hib may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Erythema multiforme and transient cyanosis of the lower limbs have been reported rarely in children receiving haemophilus influenzae-containing vaccines.

Effects on the nervous system. Guillain-Barré syndrome has been reported[1] after vaccination with haemophilus influenzae conjugate vaccines in a small number of infants. In one report, onset of symptoms occurred within 1 week of vaccination of 3 infants with an haemophilus influenzae conjugate vaccine (diphtheria toxoid conjugate). However, a causal relationship has not yet been established.

1. D'Cruz OF, *et al.* Acute inflammatory demyelinating polyradiculoneuropathy (Guillain-Barré syndrome) after immunization with Haemophilus influenzae type b conjugate vaccine. *J Pediatr* 1989; **115:** 743–6.

Interactions

As for vaccines in general, p.2202.

Antineoplastics. Haemophilus influenzae infection occurred in a child who had received antineoplastic therapy despite having completed a primary course of immunisation before the neoplasia was diagnosed.[1] A subsequent booster dose produced an adequate antibody response. Antineoplastic therapy may have impaired the T-cell response to infection.

1. Jenkins DR, *et al.* Childhood neoplasia and Haemophilus influenzae type b vaccine failure. *Lancet* 1996; **348:** 131.

Diphtheria, tetanus, and pertussis vaccines. Some haemophilus influenzae conjugated vaccines may be mixed with diphtheria, tetanus, and pertussis vaccines before administration without adversely affecting the immunogenicity of the components[1,2] although there has also been a report of reduced immunogenicity.[3] Manufacturers may provide further information on compatibility.

1. Miller MA, *et al.* Safety and immunogenicity of PRP-T combined with DTP: excretion of capsular polysaccharide and antibody response in the immediate post-vaccination period. *Pediatrics* 1995; **95:** 522–7.
2. Mulholland EK, *et al.* The use of Haemophilus influenzae type b-tetanus toxoid conjugate vaccine mixed with diphtheria-tetanus-pertussis vaccine in Gambian infants. *Vaccine* 1996; **14:** 905–9.
3. Eskola J, *et al.* Randomised trial of the effect of co-administration with acellular pertussis DTP vaccine on immunogenicity of Haemophilus influenzae type b conjugated vaccine. *Lancet* 1996; **348:** 1688–92.

Uses and Administration

Haemophilus influenzae (Hib) vaccines are used for active immunisation against *Haemophilus influenzae* type b infections. Vaccines are prepared from the capsular polysaccharide of *H. influenzae* type b and immunogenicity, especially in young children, is improved by linking the polysaccharide to a protein carrier to form a conjugate vaccine.

Different proprietary vaccines may be conjugated to differing proteins but are generally regarded as interchangeable.

Haemophilus Influenzae Conjugate Vaccine (Diphtheria Toxoid Conjugate) (PRP-D) consists of the purified capsular polysaccharide of *Haemophilus influenzae* type b covalently linked to diphtheria toxoid.

Haemophilus Influenzae Conjugate Vaccine (Diphtheria CRM_{197} Protein Conjugate) (HbOC) consists of oligosaccharides derived from the purified capsular polysaccharide of *Haemophilus influenzae* type b covalently linked to a non-toxic variant of diphtheria toxin isolated from *Corynebacterium diphtheriae.*

Haemophilus Influenzae Conjugate Vaccine (Meningococcal Protein Conjugate) (PRP-OMP or PRP-OMPC) consists of the purified capsular polysaccharide of *Haemophilus influenzae* type b covalently linked to an outer membrane protein complex of *Neisseria meningitidis* group B.

Haemophilus Influenzae Conjugate Vaccine (Tetanus Toxoid Conjugate) (PRP-T) consists of the purified capsular polysaccharide of *Haemophilus influenzae* type b covalently linked to tetanus toxoid.

For primary immunisation either combined vaccines or single-component Haemophilus influenzae vaccines may be used.

In the UK, a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and Haemophilus influenzae vaccine (p.2212) is used. Children over 1 year of age and under 10 years of age who have not been immunised against *Haemophilus influenza* or have not completed a primary vaccination course of diphtheria, tetanus, pertussis, or polio, should be given 3 doses of a combined diphtheria, tetanus, pertussis (acellular component), poliomyelitis (inactivated), and *Haemophilus influenzae* vaccine. Those who have completed a primary vaccination course of diphtheria, tetanus, pertussis, and polio, should receive a single dose of a combined *Haemophilus influenzae* and meningococcal C conjugate vaccine. Routine use in children older than 10 years or adults is not recommended in the UK, but asplenic children (over 10 years of age) and adults who have not been previously immunised should receive two doses of combined *Haemophilus influenzae* and meningococcal C conjugate vaccine, two months apart.

In the USA, primary immunisation is also carried out in conjunction with diphtheria, tetanus, and pertussis vaccination. If a meningococcal protein conjugate vaccine is used, only 2 doses are given for the primary course. A reinforcing dose using any of the available vaccines is given at 12 to 15 months of age.

Where compatibility has been shown, Hib vaccines may be mixed immediately before use with diphtheria, tetanus, and pertussis vaccines (but see Interactions, above).

Preparations

Haemophilus Influenzae and Hepatitis B Vaccines

Vacunas de Haemophilus influenzae y la hepatitis B.

ATC — J07CA08.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Haemophilus influenzae type b (Hib) conjugate and hepatitis B vaccines are available in some countries for active immunisation as part of the primary immunisation of infants born to HBsAg-negative mothers. In the USA, an Haemophilus influenzae type b conjugate (meningococcal protein conjugate) and hepatitis B (recombinant) vaccine is used. It is given in a schedule of 3 doses, 0.5 mL being given intramuscularly at 2 months, 4 months, and 12 to 15 months of age. Use in infants less than 6 weeks old is not recommended.

Preparations

Proprietary Preparations (details are given in Part 3)
Austral.: Comvax; ***Austria:*** Procomvax; ***Cz.:*** Procomvax; ***Ger.:*** Procomvax†; ***Gr.:*** Procomvax; ***Ital.:*** Procomvax; ***Mex.:*** Comvax; ***Neth.:*** Procomvax; ***NZ:*** Comvax; ***Pol.:*** Procomvax; ***Port.:*** Procomvax; ***USA:*** Comvax.

Haemophilus Influenzae and Meningococcal Vaccines

Profile

A combined Haemophilus influenza type b and meningococcal C conjugate vaccine is available for active immunisation in some countries; in the UK a single dose may be given to children between 1 and 10 years of age who have completed a primary vaccination course of diphtheria, tetanus, pertussis, and polio. Two doses given 2 months apart may be given to asplenic children (over 10 years of age) or adults who have not been previously immunised.

Preparations

Proprietary Preparations (details are given in Part 3)
UK: Menitorix.

Haemophilus Influenzae and Poliomyelitis Vaccines

ATC — J07CA04.

Profile

Combined haemophilus influenzae type b conjugate and inactivated poliomyelitis vaccines have been used in some countries for active immunisation of infants.

Preparations

Proprietary Preparations (details are given in Part 3)
Norw.: Act-HIB Polio†; ***Swed.:*** PolioHib†.

Haemorrhagic Fever with Renal Syndrome Vaccines

HFRS Vaccine; Vaccinum Haemorrhagia Febris cum Renis Sindronum; Vacunas de la fiebre renal epidémica.

Description. A fluid or freeze-dried preparation of a suitable hantavirus grown in the neural tissue of suckling rodents or in cell cultures and inactivated. The fluid vaccine should be stored at 2° to 8° and not allowed to freeze. The freeze-dried form should be stored below 10°.

Profile

Inactivated viral vaccines against haemorrhagic fever with renal syndrome have been investigated and are available in some countries, but there have been problems producing a sufficient and sustained immune response.

Helicobacter Pylori Vaccines

Vacunas de Helicobacter pylori.

Profile

Vaccines against *Helicobacter pylori* are being developed for prophylaxis of peptic ulcer disease and gastric cancer.

◊ Studies in *animals* have shown the feasibility of both prophylactic and therapeutic vaccination against *Helicobacter pylori* infection, but there have been few studies in humans. Encouraging results have been obtained with parenteral, multicomponent, aluminium hydroxide-based vaccines in terms of safety and immunogenicity. In contrast, preliminary results obtained with mucosally delivered single-component vaccines have been disappointing, partly due to the intrinsic difficulty in developing purified proteins that are sufficiently immunogenic following mucosal delivery. Studies are ongoing into the mechanisms by which the host's genetic make-up modifies the inflammatory and immunological response to *H. pylori*.[1-4]

Hepatitis A Immunoglobulins

Inmunoglobulinas contra la hepatitis A.

ATC — J06BB11.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Human Hepatitis A Immunoglobulin; Immunoglobulinum Humanum Hepatitidis A). A liquid or freeze-dried preparation containing human immunoglobulins, mainly immunoglobulin G (IgG). It is obtained from plasma from selected donors having specific antibodies against the hepatitis A virus. Normal immunoglobulin may be added. It contains not less than 600 international units/mL. The liquid preparation should be stored, protected from light, in a sealed, colourless, glass container. The freeze-dried preparation should be stored, protected from light, in a colourless, glass container under vacuum or under an inert gas.

Profile

Immunoglobulins containing high levels of specific antibodies against hepatitis A have been used in some countries for passive immunisation against hepatitis A infection; in the UK, normal immunoglobulin is usually given.

Preparations

Ph. Eur.: Human Hepatitis A Immunoglobulin.

Proprietary Preparations (details are given in Part 3)
Port.: Globuman Hepatite A†.

Hepatitis A Vaccines

Vacunas de la hepatitis A.

ATC — J07BC02.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Hepatitis A Vaccine (Inactivated, Adsorbed); Vaccinum Hepatitidis A Inactivatum Adsorbatum; Inactivated Hepatitis A Vaccine BP 2008). A liquid preparation of a suitable strain of hepatitis A virus grown in cell cultures, inactivated by a validated method, and adsorbed on a mineral carrier. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.
The BP 2008 states that Hep A may be used on the label.

Ph. Eur. 6.2 (Hepatitis A Vaccine (Inactivated, Virosome); Vaccinum Hepatitidis A Inactivatum Virosomale). A liquid preparation of a suitable strain of hepatitis A virus grown in cell cultures and inactivated by a validated method. Virosomes composed of influenza proteins and phospholipids are used as adjuvants. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.
The BP 2008 states that HepA may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

◊ General references.

1. Niu MT, *et al.* Two-year review of hepatitis A vaccine safety: data from the Vaccine Adverse Event Reporting System (VAERS). *Clin Infect Dis* 1998; **26:** 1475–6.

Effects on the blood. WHO has received reports of 5 cases of thrombocytopenia, 3 with purpura, associated with hepatitis A vaccine.[1]

1. Meyboom RHB, *et al.* Thrombocytopenia reported in association with hepatitis B and A vaccines. *Lancet* 1995; **345:** 1638.

Effects on the nervous system. Neurological symptoms resembling encephalitis have followed a third dose of hepatitis A vaccine.[1] Other serious neurological reactions reported in patients given inactivated hepatitis A vaccine include transverse myelitis, Guillain-Barré syndrome, and neuralgic amyotrophy.[2] Such reactions appear to be very rare, and, since other vaccines have often been given simultaneously, may not be directly attributable to hepatitis A vaccine.

2. Committee on Safety of Medicines/Medicines Control Agency. Hepatitis A vaccination (Havrix). *Current Problems* 1994; **20:** 16.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Hepatitis A vaccines are used for active immunisation against hepatitis A infection.

In the UK, the use of an inactivated vaccine is recommended as an alternative to normal immunoglobulin for frequent travellers to areas of high or moderate hepatitis A endemicity or for those staying for more than 3 months in such areas; in some countries a hepatitis A immunoglobulin (p.2214) is available for those making shorter or less frequent journeys. Immunisation is also recommended in haemophiliacs, patients with chronic liver disease, and in those at risk of exposure to hepatitis A by virtue of their occupation, and should be considered in persons whose lifestyle is likely to place them at risk. The vaccine is given intramuscularly, except in haemophiliacs in whom it should be given by deep subcutaneous injection. In the UK, various vaccines are available and the dose (0.5 or 1 mL) depends on the product used and age of the patient. They may be prepared from several inactivated hepatitis A virus strains including CR326F, GBM, HM175, and RG-SB. The primary immunisation schedule for all vaccines consists of a single dose appropriate to the age of the patient and should be followed 6 to 12 months later by a booster dose. Immunity is provided for at least 10 years after these doses.

In the US, immunisation at 12 months of age (with a booster at least 6 months later) is recommended as part of the routine primary immunisation schedule. Post-exposure prophylaxis is recommended in persons who have not previously received a hepatitis A vaccine. Vaccination is also recommended for travellers to countries with intermediate to high hepatitis A endemicity.

Vaccine development. Commercially available hepatitis A vaccines are usually produced from inactivated hepatitis A virus strains propagated in cell culture, commonly of human diploid fibroblast cells. 'Virosome' hepatitis A vaccines consisting of inactivated hepatitis A virus epitopes formulated into liposomes are also becoming available. Live attenuated hepatitis A vaccines have also been developed, although an oral live vaccine does not appear to have yet been produced.

Preparations

Hepatitis B Immunoglobulins

Inmunoglobulinas contra la hepatitis B.

ATC — J06BB04.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Human Hepatitis B Immunoglobulin; Immunoglobulinum Humanum Hepatitidis B). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG). It is obtained from plasma from selected and/or immunised donors having specific antibodies against hepatitis B surface antigen. Normal immunoglobulin may be added. It contains not less than 100 international units/mL. The liquid preparation should be stored, protected from light, in a sealed, colourless, glass container. The freeze-dried preparation should be stored, protected from light, in a colourless, glass container, under vacuum or under an inert gas.

Ph. Eur. 6.2 (Human Hepatitis B Immunoglobulin for Intravenous Administration; Immunoglobulinum Humanum Hepatitidis B ad Usum Intravenosum). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG). It is obtained from plasma from selected and/or immunised donors having antibodies against hepatitis B surface antigen. Human normal immunoglobulin for intravenous administration may be added. It contains not less than 50 international units/mL. Storage requirements are similar to those for Human Hepatitis B Immunoglobulin, except that the freeze-dried preparation is stored at a temperature not exceeding 25°.

USP 31 (Hepatitis B Immune Globulin). A is a sterile solution consisting of globulins derived from the plasma of human donors who have high titres of antibodies against hepatitis B surface antigen. It contains 10 to 18% of protein, of which not less than 80% is monomeric immunoglobulin G. It contains glycine as a stabilising agent, and a suitable preservative. It should be stored at 2° to 8°.

Adverse Effects and Precautions

As for immunoglobulins in general, p.2201.

Preparation strength. For a warning concerning possible lack of equivalence between different preparations of hepatitis B immunoglobulins, see under Uses and Administration, below.

Uses and Administration

Hepatitis B immunoglobulins are used for passive immunisation of persons exposed or possibly exposed to hepatitis B virus, including by sexual contact. They are not appropriate for treatment. Hepatitis B immunoglobulins should always be given in addition to active immunisation with hepatitis B vaccine in at-risk patients exposed to hepatitis B virus.

In the UK, a hepatitis B immunoglobulin containing 100 international units/mL is available for intramuscular use. The dose in adults and children over 10 years of age is a single dose of 500 international units by intramuscular injection given preferably within 48 hours of exposure and not more than 1 week after exposure. Children aged 5 to 9 years may be given 300 international units, and children under 5 years 200 international units. Hepatitis B immunoglobulin should also be given to newborn infants at risk whose mothers are persistent carriers of hepatitis B surface antigen or whose mothers are HBsAg-positive as a result of recent infection. The dose is 200 international units by intramuscular injection preferably at birth, and certainly within 24 hours of birth.

There is now a UK and European standard for a preparation for intravenous use containing not less than 50 international units/mL.

In the USA, a hepatitis B immunoglobulin containing 15 to 18% of protein is available for intramuscular use. The dose for adults is 0.06 mL/kg. A dose of 0.5 mL is given to infants perinatally exposed to hepatitis B; this appears to be a significantly lower dose than that used in the UK. A hepatitis B immunoglobulin is also available for the prevention of hepatitis B recurrence after liver transplantation in patients who are positive for hepatitis B surface antigen. It is given intravenously at a dose of 20 000 international units during surgery and then daily from day 1 to day 7 after transplant surgery, then every 2 weeks from week 2 to week 12, and then monthly from 4 months post-surgery.

Preparation strength. *The content of hepatitis B immunoglobulin may vary between countries and between manufacturers. Care should be taken in interpreting dosage recommendations which are not given in terms of international units.* Products available in the USA have their strength expressed with reference to an FDA standard but are considered to contain the equivalent of at least 200 international units/mL.

Monoclonal antibodies. The name tuvirumab is applied to a human hepatitis B monoclonal antibody. A murine monoclonal antibody has been tried in a few patients with primary antibody deficiency.[1]

1. Lever AML, *et al.* Monoclonal antibody to HBsAg for chronic hepatitis B virus infection with hypogammaglobulinaemia. *Lancet* 1990; **335:** 1529.

Organ and tissue transplantation. Studies[1-5] in patients positive for hepatitis B surface antigen undergoing liver transplantation (p.1815) suggest that long-term passive immunisation with hepatitis B immunoglobulin could reduce hepatitis B reinfection and improve survival in these patients.

Hepatitis B Vaccines

Vacunas de la hepatitis B.
ATC — J07BC01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) have monographs.
Ph. Eur. 6.2 (Hepatitis B Vaccine (rDNA); Vaccinum Hepatitidis B (ADNr)). A preparation of hepatitis B surface antigen, that is obtained by recombinant DNA technology. It should be stored at a temperature of 2° to 8°, not be allowed to freeze, and be protected from light. Under these storage conditions it may be expected to retain its potency for 24 months.
The BP 2008 states that Hep B may be used on the label.

Adverse Effects

As for vaccines in general, p.2201.

In addition, abdominal pain and gastrointestinal disturbance, and musculoskeletal and joint pain and inflammation have been reported after hepatitis B vaccines. There may also be dizziness and sleep disturbance. Cardiovascular effects include occasional hypotension and, rarely, tachycardia. Other rare adverse effects include dysuria, visual disturbances, and earache.

Effects on bones and joints. Reactive arthritis[1-3] and Reiter's syndrome[2] have been reported after hepatitis B vaccination. There have also been isolated reports of rheumatoid arthritis occurring after hepatitis B vaccination[3,4] and a suggestion that hepatitis B vaccination may trigger the onset of underlying SLE.[5] A number of reports of arthralgia have been received by the UK CSM and by the manufacturers of *Engerix B*.[2]

3. Germanaud J, *et al.* A case of severe cytolysis after hepatitis B vaccination. *Am J Med* 1995; **98:** 595.

Effects on the nervous system. In the years 1982 to 1985 the Centers for Disease Control, the FDA, and the manufacturer of plasma-derived hepatitis B vaccine received 41 reports of adverse neurological effects.[1] It was estimated that about 850 000 persons had received the vaccine in this time. Neurological events were convulsions (5 cases), Bell's palsy (10), Guillain-Barré syndrome (9), lumbar radiculopathy (5), brachial plexus neuropathy (3), optic neuritis (5), and transverse myelitis (4). In some analyses Guillain-Barré syndrome was reported significantly more often than expected. However, no conclusive epidemiological association could be made between any neurological adverse effect and the vaccine.

In France, spontaneous reports of multiple sclerosis and central demyelinating disease in patients who had received hepatitis B vaccine led to the suspension by the French authorities of hepatitis B vaccination in schools in 1998. This decision was widely condemned by many authorities including WHO, the US National Multiple Sclerosis Society, and the Viral Hepatitis Prevention Board, and there was a fear that reduced confidence in the vaccine could have a profound effect on uptake. Arguments[2] against a link between hepatitis B vaccine and multiple sclerosis include the lack of correlation between the incidence of hepatitis B infection and demyelinating diseases, data from clinical studies including extensive postmarketing surveillance, and analysis of the French cases which concluded that the incidence of multiple sclerosis amongst vaccine recipients was not higher than would be expected in the population as a whole. A consultative group concluded[3] that, in the light of the evidence, the benefits of hepatitis B vaccination supported current WHO recommendations that all countries should have universal infant and/or adolescent hepatitis B immunisation programmes and that adults at increased risk of infection should also be immunised. More recent studies[4,5] have also indicated no association between hepatitis B vaccine and multiple sclerosis, although one study[6] did suggest a threefold increase in risk.

3. Brightman CAJ, *et al.* Yeast-derived hepatitis B vaccine and yeast sensitivity. *Lancet* 1989; **i:** 903.

Precautions

As for vaccines in general, p.2202.

Reduced immune response. The immune response to hepatitis B vaccine is dependent on both host- and immunisation-related factors.[1] Host-related factors that appear to diminish the response include increasing age, increasing body-weight, smoking,[1,2] and male sex;[3] particular HLA haplotypes may also be associated with poor response.[4] Failure of hepatitis B immunisation in infants could be related to high perinatal maternal viraemia[5] rather than to inherent resistance to the vaccine.

Some studies have found a defective response in chronic alcoholics[6,7] whereas others have not;[8] the degree of liver impairment may be a significant factor. It has been suggested that an increased dose of hepatitis B vaccine may be appropriate in those with a history of alcoholism.[9] Active infection with *Schistosoma mansoni* also appears to decrease the response to hepatitis B vaccination.[10] A diminished response occurs in HIV-positive patients[11-13] and in patients on haemodialysis;[1] an increased dose of hepatitis B vaccine is recommended in these patients. In patients with haemophilia who are not HIV-positive[14] immunity is reported to wane rapidly after vaccination and frequent booster doses may be required. Biological response modifiers such as thymopentin[15] and interferon[16] have been used successfully in some patients on haemodialysis to overcome the immune deficit. Use of interleukin-2 has met with variable success. Granulocyte-macrophage colony-stimulating factor has also been investigated as an adjuvant for hepatitis B vaccination in healthy subjects, patients with chronic renal failure or on haemodialysis, and in HIV-infected patients. Overall, the colony-stimulating factor appears to improve seroconversion rates and antibody titres, but further study is needed.[17]

The immune response to hepatitis B vaccine is affected by the site of intramuscular injection. The deltoid region is recommended for adults and the anterolateral thigh for infants. A diminished response has been associated with injection into the gluteal region (buttock).[1]

A related problem is posed by subjects who become infected with hepatitis B despite mounting an adequate response to immunisation. In one study, evidence of viral replication was detected in 44 of 1590 hepatitis B vaccinees despite development of protective titres of antibody.[18] Acute hepatitis occurred in one patient. Although the infection may have been incubating at the time of vaccination, the virus isolated from the child with acute disease was an escape mutant with a different DNA sequence from that isolated from the mother.

Uses and Administration

Hepatitis B vaccines are used for active immunisation against hepatitis B infection. Two types of vaccine have been available, each containing hepatitis B surface antigen (HBsAg) adsorbed onto aluminium hydroxide or a similar adsorbent. The type of vaccine in which the surface antigen is produced in yeast cells using recombinant DNA techniques is now widely used and there has been considerable interest in further developments to improve immunogenicity. The second type of vaccine, in which the surface antigen is obtained from plasma after purification and inactivation processes is now not generally available.

WHO had recommended that national immunisation policies should include routine hepatitis B immunisation for the whole population by 1997 and this has been implemented in some countries including the USA (see Administration, below). The current recommendations in the UK are for immunisation of persons at high risk of contracting hepatitis B. High-risk groups include:

- health care personnel, laboratory workers, or any other personnel who have direct contact with patients or their body fluids or tissues
- staff and residents of accommodation for those with severe learning difficulties
- patients with chronic liver disease
- patients with chronic renal failure including those requiring haemodialysis
- haemophiliacs and those receiving regular blood transfusions or blood products
- close family contacts or sexual partners of cases or carriers of hepatitis B
- families adopting children from countries with a high prevalence of hepatitis B
- foster carers
- individuals who frequently change sexual partners
- parenteral drug abusers
- inmates of custodial institutions
- some travellers to areas where hepatitis B is endemic
- infants born to women who are persistent carriers of hepatitis B surface antigen or infants born to women who are HBsAg-positive as a result of recent infection

Hepatitis C carriers who are not immunised against hepatitis B should also receive immunisation.

A basic immunisation schedule consists of 3 doses of a hepatitis B vaccine, with the second and third doses 1 and 6 months, respectively, after the first. In the USA, some products may be given in an alternative 2-dose regimen to adolescents with doses given 4 to 6 months apart. Doses should be given intramuscularly, with the deltoid region being the preferred site in adults and older children and the anterolateral thigh the preferred site in neonates, infants, and younger children; the gluteal region (buttock) should not be used as efficacy may be reduced. The subcutaneous route should be used in patients with haemophilia. The dose of the recombinant vaccine depends on the product used. Typical doses for adults are 10 or 20 micrograms and for infants and children 5 or 10 micrograms. Products containing 40 micrograms are available for adult dialysis and predialysis patients who have a reduced immune response to the vaccine. However, *the dose of one recombinant preparation should not be seen as equivalent to the dose of another.*

For pre-exposure prophylaxis in high-risk groups and for postexposure prophylaxis an accelerated schedule should be used. It may also be used where more rapid immunisation, for instance with travellers, is required. This schedule involves giving the third dose 2 months after the initial dose with a further booster at 1 year. In exceptional circumstances in adults travelling to an endemic area who commence their vaccination course within a month of departure, an even more rapid schedule involving injections at 0, 7, and 21 days has been used; when this schedule is used, a booster dose is recommended after 1 year.

For newborn infants at risk combined active and passive immunisation against hepatitis B is recommended. The first dose of vaccine should preferably be given at birth, and certainly within 24 hours of birth. A single dose of hepatitis B immunoglobulin (200 international units) should be given at the same time into a different site. Additionally, in any patient in whom immediate protection is required, combined active and passive immunisation may be considered with a single dose of 500 international units of hepatitis B immunoglobulin being the dose for adults. See under Hepatitis B Immunoglobulins, p.2215, for children's doses.

Administration. The major public health burden of hepatitis B infection in the developing world is due to the consequences of chronic carriage of hepatitis B virus (hepatocellular carcinoma and chronic cirrhosis) rather than acute infection. WHO[1] considered that the most important means of controlling hepatitis B on a global scale and of reducing mortality from its sequelae was mass immunisation of infants. It stated that hepatitis B vaccine should be incorporated into the Expanded Programme on Immunization (EPI) and many countries have since done so. WHO later reiterated this aim[2] stating that hepatitis B vaccine should be integrated into national immunisation programmes in all countries with a hepatitis B carrier prevalence (HBsAg) of 8% or greater by 1995 and in all countries by 1997. WHO's aim was to reduce the incidence of new child carriers of hepatitis B by 80% by 2001. Results from Taiwan, where mass immunisation of infants has been in place since the mid-1980s have shown a marked decline in the number of child carriers under 10 years of age.[3,4] The incidence of hepatocellular carcinoma in children has also been reduced.[5,6]

Opinion has been divided in the UK regarding implementation of universal hepatitis B immunisation,[7-9] with some advising increased emphasis on alternative strategies already in place such as antenatal screening.[7,8]

The optimum vaccination strategy depends on the pattern of hepatitis B viral transmission in a particular country. In hyperendemic regions where most infections are acquired early in life, the vaccine should be given shortly after birth and hepatitis B immunisation integrated into the EPI. Immunisation of all infants should be considered for population groups with chronic hepatitis B virus carrier rates greater than 2% and should be a public health priority where carrier rates are greater than 10%. Countries with a lower carrier rate might opt to immunise all adolescents as an alternative to infant immunisation. Immunisation of individuals at high risk of infection should be continued in addition to routine vaccination schedules[2] and, if hepatitis B is not integrated into infant vaccination schedules, screening pregnant women for HBsAg and immunising the infants of HBsAg-positive mothers should continue.[1]

If use of hepatitis B vaccine is integrated into the EPI, 3 doses should be given intramuscularly, the first dose being given as soon as possible after birth with the first EPI immunisation. The exact timing of these doses will depend on the risk of transmission at birth and the EPI schedule in operation. In the USA, these recommendations have been implemented by immunisation of all infants and of children at any age between 2 and 18 years who have not previously received 3 doses of vaccine. The recommended schedule is for all infants to be given an initial dose of the monovalent hepatitis B vaccine soon after birth; then 2 further doses with the monovalent vaccine or 3 further doses with a combination vaccine containing hepatitis B. Infants of HBsAg-positive mothers should receive hepatitis B vaccine plus hepatitis B immunoglobulin within 12 hours of birth. Infants whose mother's HBsAg status is unknown should receive a hepatitis B vaccine within 12 hours of birth and the maternal blood should be checked at delivery and, if positive for HBsAg, the infant given hepatitis B immunoglobulin as soon as possible (no later than 1 week of age). The second dose is given at 1 to 2 months of age and the final dose at 6 months of age or later. Infants who receive a combination vaccine after the birth dose may be given an additional dose at 4 months of age. Alternatively, some products may be given in a two-dose regimen, with doses given 4 to 6 months apart.

BOOSTER DOSES. There has been considerable interest in the duration of immunity conferred by hepatitis B vaccination and the possible need for booster doses.[1,2]

In the UK it is now recommended that individuals at continuing risk of infection should be offered a *single* booster dose of vaccine, *once only*, about 5 years after primary immunisation. Boosters are also recommended if contamination of eyes, mouth, or fresh cuts on skin with blood from a HBsAg-positive person occurs, unless they are known to have protective concentrations of antibody.

Postexposure prophylaxis. A combination of passive immunisation with a hepatitis B immunoglobulin and active immunisation with a hepatitis B vaccine is generally recommended for postexposure prophylaxis against hepatitis B.

One group of patients who should be given postexposure prophylaxis are infants born to mothers who are persistent carriers of hepatitis B surface antigen (HBsAg). The risk is particularly high if the mother has detectable hepatitis B e antigen (HBeAg) or hepatitis B virus DNA or absence of detectable antibody to hepatitis Be antigen (anti-HBe). Postexposure prophylaxis is also recommended in the UK for persons accidentally inoculated, or who contaminate the eye or mouth or breaks to the skin with blood from a known HBsAg-positive person, as well as in sexual contacts (and sometimes close family contacts) of sufferers from acute hepatitis B and who are seen within a week of the onset of jaundice in the contact.

In the UK, the recommended schedule for postexposure prophylaxis is the first dose of vaccine given preferably within 48 hours of exposure and no later than one week after exposure, or, for neonates exposed to hepatitis B at birth, no later than 24 hours after birth, with a single dose of hepatitis B immunoglobulin given simultaneously at a separate site. The second and third doses of vaccine are given 1 and 2 months after the first dose, with a booster dose at 12 months. Health care workers who have been successfully immunised should be given a booster dose after subsequent contamination with blood from an infected person, unless they are known to have adequate antibody concentration.

Hepatitis A and B Vaccines

Vacunas de las hepatitis A y B.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Hepatitis A (Inactivated) and Hepatitis B (rDNA) Vaccine (Adsorbed); Vaccinum Hepatitidis A Inactivatum et Hepatitidis B (ADNr) Adsorbatum; Hepatitis A (Inactivated) and Hepatitis B (rDNA) Vaccine BP 2008). A suspension consisting of a suitable strain of hepatitis A virus, grown in cell cultures and inactivated by a validated method, and of hepatitis B surface antigen obtained by recombinant DNA technology; the antigens are adsorbed on a mineral carrier, such as aluminium hydroxide or hydrated aluminium phosphate. It should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that HepA/HepB may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Hepatitis A Vaccines, p.2214, and Hepatitis B Vaccines, p.2215.

Uses and Administration

Combined hepatitis A and B vaccines are used for active immunisation against hepatitis A and hepatitis B.

A hepatitis A and B vaccine (*Twinrix, GSK*) is available containing not less than 720 ELISA units of inactivated hepatitis A virus and not less than 20 micrograms of recombinant hepatitis B surface antigen (HBsAg) protein in 1 mL. For primary immunisation, three doses of 1 mL are given by intramuscular injection, with the second and third doses 1 and 6 months after the first. For children up to the age of 16 years a 0.5-mL dose is given.

Alternatively, in exceptional circumstances when travel is anticipated within one month or more after the first dose but when insufficient time is available for the standard course, adults may be given an accelerated schedule. In the UK, this consists of three doses at 0, 7 and 21 days. In the US the recommended schedule consists of doses at 0, 7, and 21 to 30 days plus a dose at 12 months.

Booster doses may be given as appropriate with the monovalent component vaccines since protection against hepatitis A and B declines at different rates, or a booster dose of the combined vaccine may be given after 5 years in adults or 4 years in children. A booster is recommended 1 year after the accelerated schedule.

In the UK a similar vaccine (*Ambirix, GSK*) is licensed for primary immunisation in a 2-dose schedule for children aged 1 to 15 years; the second dose is given between 6 and 12 months after the first.

Hepatitis A and Typhoid Vaccines

Vacunas de la hepatitis A y fiebre tifoidea.

ATC — J07CA10.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Uses and Administration

Combined hepatitis A and typhoid vaccines are used for active immunisation. They contain either inactivated HM175 or GBM hepatitis A virus strains together with the Vi capsular polysaccharide from *Salmonella typhi* Ty 2 strain. Adults and adolescents over 15 years of age may be given a dose of 1 mL by intramuscular injection, at least 2 weeks prior to risk of exposure to typhoid and hepatitis A. A booster dose may be given after 6 to 12 months to provide long-term protection.

Herpes Simplex Vaccines

Vacunas del herpes simple.

Profile

Several types of vaccines against herpes simplex virus types 1 and 2 have been developed. They have been tried both in oral and genital herpes infections. They are also being studied for the prevention of infection in sexual partners of patients with genital herpes.

◊ Herpes simplex virus types 1 and 2 are widespread in populations throughout the world. Herpes simplex virus type 2 causes lifelong infection with significant morbidity. Even with the availability of effective antiviral therapy, the increasing burden of herpes simplex virus infection makes it a suitable candidate for vaccine development. The incidence of neonatal herpes infections has also increased and this risk would also be addressed by development of appropriate vaccines. An additional benefit would be a reduced risk of acquiring HIV infection.

Vaccines for herpes simplex were first studied in the 1920s and many different types of vaccine have undergone evaluation. They have included auto-inoculation of live herpes simplex virus, whole inactivated vaccines, attenuated live virus vaccines, modified live virus subunit vaccines, cell culture-derived subunit vaccines, recombinant glycoprotein subunit vaccines, disabled infectious single cycle (DISC) vaccines, and nucleic acid (DNA) vaccines.[1,2]

Prophylactic vaccines against HSV-2 could be beneficial if they either shift the threshold of infection i.e. increase the titre of virus necessary to cause infection, or if they prevent clinical disease itself. An attenuated live virus vaccine based on modified HSV-1 has been tested in clinical studies but was poorly tolerated at the doses required to elicit an immune response. Prophylactic vaccines including subunit vaccines encoding virus glycoproteins and delivered with adjuvants have shown some benefits.[1,2]

To date, no randomised clinical studies have demonstrated useful benefit from therapeutic vaccines for HSV-1 or HSV-2. A therapeutic vaccine should prevent recurrences or at least minimise their severity or duration. Heat killed, whole virus vaccines from HSV-1 (Lupidon H) and HSV-2 (Lupidon G), and inactivated subunit vaccines have been studied but have generally produced disappointing results.[1,2] Recombinant glycoprotein vaccines have also been tested but again results have been disappointing.[1,2]

Human Papillomavirus Vaccines

HPV Vaccines; Human Papilloma Virus Vaccines; Vacunas del virus del papiloma humano.

ATC — J07BM01.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Breast feeding. In mothers given the quadrivalent recombinant human papillomavirus vaccine or placebo during clinical studies, the rates of adverse reactions in the mother and in the breast-fed infant, as well as vaccine immunogenicity, were comparable in the 2 groups. Based on apparently the same data the UK licensed product information states that the vaccine can be given to breast-feeding women whereas the US information recommends caution.

Pregnancy. Although specific studies of the quadrivalent recombinant human papillomavirus vaccine in pregnant women have not been conducted, some women during clinical development did receive the vaccine in pregnancy. Overall, the proportions of pregnancies with an adverse outcome were comparable in those who received the vaccine and those who received placebo. It is, nevertheless, recommended that vaccination should be postponed until after completion of pregnancy.

Uses and Administration

A quadrivalent recombinant human papillomavirus (HPV) vaccine, prepared from purified virus-like particles of the capsid protein L1, is used to prevent genital warts, cervical cancer, and other pre-cancerous lesions caused by HPV types 6, 11, 16, and 18.

It is given in three doses of 0.5 mL intramuscularly. The first dose may be given at any time to girls and women between 9 and 26 years of age; the second dose is given 2 months later, and the third dose 6 months after the first dose.

A similar recombinant HPV vaccine, prepared from a mixture of L1 capsid proteins of HPV types 16 and 18 and containing an adjuvant AS04, is licensed in some countries for the prevention of cervical cancer and high grade cervical intraepithelial neoplasia (grades 2 and 3). It is given intramuscularly in 3 doses of 0.5 mL to girls and women between 10 and 25 years of age. The first dose may be given at any age in the approved range; the second dose is given 1 month later, and the third dose 6 months after the first dose.

Further vaccines are under investigation for the treatment or prophylaxis of genital warts and several malignant neoplasms.

Vaccine development. There are more than 100 known human papillomavirus (HPV) genotypes; at least 13 of these can cause cervical cancer and are also associated with other anogenital cancers and cancers of the head and neck. Genotypes 16 and

18 cause about 70% of all cervical cancers, while genotypes 6 and 11 can cause genital warts. HPV is highly transmissible with risk of infection being highest soon after sexual activity begins. Asymptomatic and transient infection occurs in most people at some time in their life. However, the fact that more than 99% of cases of cervical cancer diagnosed are associated with the presence of sexually transmitted human papillomavirus DNA has prompted the possibility of vaccine development.

Viral recombinant proteins are being studied as antigenic components of both prophylactic and therapeutic vaccines.[1-8] Prophylactic vaccine candidates are based on the recombinant capsid proteins L1 and L2 which self-assemble into virus-like particles which induce antibodies that in turn neutralise the infecting virus. Therapeutic vaccines are based on the viral oncogenic proteins E6 and E7 and are designed to induce cell-mediated immune responses to eliminate infected cells. Prophylactic vaccines based on the recombinant capsid protein LI are licensed in several countries, while other prophylactic vaccines are in phase III and further therapeutic vaccine candidates are undergoing phase II evaluation. There is also some preliminary study being conducted into the possibility of a 'chimeric' vaccine combining both prophylactic and therapeutic components, but the immunogenicity and efficacy of such vaccines remains to be established.

For it to be claimed justifiably that a prophylactic vaccine prevents cervical cancer, it is necessary to demonstrate that such a vaccine not only prevents infection but also prevents cancer itself, or at least a defined precursor of disease. Since any placebo-controlled study defining established cancer as an end-point would clearly be unethical, an appropriate compromise is to use the appearance of high-grade dysplasia or pre-cancerous lesions as an end-point, this being regarded as a direct precursor to cervical cancer requiring treatment. However, true pre-cancerous lesions of this kind are relatively unusual in current practice and therefore phase III studies require tens of thousands of subjects in order to establish this efficacy.[3]

Guidance and technical information on HPV, HPV-related diseases, and HPV vaccines has been produced by WHO.[9] They consider HPV vaccines to be highly effective among females not exposed to HPV vaccine genotypes at the time of their first vaccination and that the target group for vaccination will probably be preadolescent girls (about 9 to 12 years of age). Guidelines for the use of HPV vaccine for the prevention of cervical cancer have been developed in the USA by the CDC,[10] the American Cancer Society[11] and the American Academy of Pediatrics.[12] These authorities recommend routine vaccination for all girls 11 to 12 years of age, although girls as young as 9 years of age may be vaccinated at the discretion of their doctor. Catch-up vaccinations may be given to older girls and young women who have not received or completed a vaccine course. In the UK the Joint Committee on Vaccination and Immunisation[13] recommends routine vaccination of all girls 12 to 13 years of age. Catch-up vaccination is recommended for girls under 18 years of age.

Influenza Vaccines

Vacunas de la gripe.

Противогриппозные Вакцины

ATC — J07BB01; J07BB02.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Influenza Vaccine (Whole Virion, Inactivated); Vaccinum Influenzae Inactivatum ex Viris Integris Praeparatum). A sterile aqueous suspension of a suitable strain or strains of influenza virus types A and B, either individually or mixed, grown individually in embryonated hen eggs and inactivated so that they retain their antigenic properties. The stated amount of haemagglutinin antigen for each strain present is usually 15 micrograms per dose. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu may be used on the label.

The BP 2008 directs that when Inactivated Influenza Vaccine or Influenza Vaccine is prescribed or demanded and the form is not stated, Influenza Vaccine (Whole Virion, Inactivated), Influenza Vaccine (Split Virion, Inactivated), or Influenza Vaccine (Surface Antigen, Inactivated) may be dispensed or supplied.

Ph. Eur. 6.2 (Influenza Vaccine (Split Virion, Inactivated); Vaccinum Influenzae Inactivatum ex Virorum Fragmentis Praeparatum). A sterile aqueous suspension of a suitable strain or strains of influenza virus types A and B, either individually or mixed, grown individually in embryonated hen eggs and inactivated so that the integrity of the virus particles has been disrupted without diminishing their antigenic properties. The stated amount of haemagglutinin antigen for each strain present is usually 15 micrograms per dose. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu may be used on the label.

The BP 2008 directs that when Inactivated Influenza Vaccine or Influenza Vaccine is prescribed or demanded and the form is not stated, Influenza Vaccine (Whole Virion, Inactivated), Influenza Vaccine (Split Virion, Inactivated), or Influenza Vaccine (Surface Antigen, Inactivated) may be dispensed or supplied.

Ph. Eur. 6.2 (Influenza Vaccine (Surface Antigen, Inactivated); Vaccinum Influenzae Inactivatum ex Corticis Antigeniis Praeparatum). A sterile suspension consisting predominantly of haemagglutinin and neuraminidase antigens of a suitable strain or strains of influenza virus types A and B either individually or mixed, grown individually in embryonated hen eggs and inactivated so that they retain their antigenic properties. The stated amount of haemagglutinin antigen for each strain is usually 15 micrograms per dose. It may contain an adjuvant. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu or Flu(adj) may be used on the label as appropriate.

The BP 2008 directs that when Inactivated Influenza Vaccine or Influenza Vaccine is prescribed or demanded and the form is not stated, Influenza Vaccine (Whole Virion, Inactivated), Influenza Vaccine (Split Virion, Inactivated), or Influenza Vaccine (Surface Antigen, Inactivated) may be dispensed or supplied.

Ph. Eur. 6.2 (Influenza Vaccine (Surface Antigen, Inactivated, Virosome); Vaccinum Influenzae Inactivatum ex Corticis Antigeniis Praeparatum Virosomale). A sterile aqueous suspension consisting predominantly of haemagglutinin and neuraminidase antigens of a suitable strain or strains of influenza virus types A and B either individually or mixed, grown individually in embryonated hen eggs and inactivated so that they retain their antigenic properties and reconstituted to virosomes with phospholipids and without reducing the antigenic properties of the antigens. The stated amount of haemagglutinin antigen for each strain is 15 micrograms per dose. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu may be used on the label.

Ph. Eur. 6.2 (Influenza Vaccine (Whole Virion, Inactivated, Prepared in Cell Cultures); Vaccinum Influenzae Inactivatum ex Cellulis Virisque Integris Praeparatum). A sterile aqueous suspension of a suitable strain or strains of influenza virus types A and B, either individually or mixed, grown individually in cell cultures (diploid or continuous cell lines of mammalian origin) and inactivated so that they retain their antigenic properties. It may contain an adjuvant. The stated amount of haemagglutinin antigen for each strain present is usually 15 micrograms per dose. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu or Flu (adj) may be used on the label as appropriate.

Ph. Eur. 6.2 (Influenza Vaccine (Surface Antigen, Inactivated, Prepared in Cell Cultures); Vaccinum Influenzae Inactivatum ex Cellulis Corticisque Antigeniis Praeparatum). A sterile aqueous suspension of a suitable strain or strains of influenza virus types A and B, either individually or mixed, grown individually in cell cultures (diploid or continuous cell lines of mammalian origin) and inactivated so that they retain their antigenic properties. It may contain an adjuvant. The stated amount of haemagglutinin antigen for each strain present is usually 15 micrograms per dose. Suitable strains of influenza virus are those recommended by WHO. An antimicrobial preservative may be added. The vaccine should be stored at 2° to 8°, not be allowed to freeze, and be protected from light.

The BP 2008 states that Flu or Flu (adj) may be used on the label as appropriate.

USP 31 (Influenza Virus Vaccine). A sterile aqueous suspension of suitably inactivated influenza virus types A and B, either individually or combined, or virus subunits prepared from the extra-embryonic fluid of virus-infected chick embryos. Suitable strains of influenza virus are those designated by the US Government's Expert Committee on Influenza and recommended by the Surgeon General of the US Public Health Service. It may contain a suitable antimicrobial agent. It should be stored at 2° to 8° and not be allowed to freeze.

Nomenclature of strains. The strain designation for influenza virus types A, B, and C contains: a description of the antigenic specificity of the nucleoprotein antigen (types A, B, or C) (an internal antigen, the matrix antigen, has also been described); the host of origin (if not man, including, if appropriate, the inanimate source); the geographical origin; the strain number; and the year of isolation; e.g. A/lake water/Wisconsin/1/79. For type A viruses the antigenic description follows (in parentheses) including the antigenic character of the haemagglutinin (e.g. H1) and the antigenic character of the neuraminidase (e.g. N1). There is no provision for describing subtypes of B and C viruses. Recombination between viruses within a type is readily accomplished; the letter R should be added after the strain description to indicate the recombinant nature of the virus, e.g. A/Hong Kong/1/68(H3N2)R. In addition the strain of origin of the H and N antigens of antigenic hybrid recombinant A and B viruses should be given, e.g. A/BEL/42(H1)—Singapore/1/57(N2)R.[1]

Adverse Effects

As for vaccines in general, p.2201.

Local and systemic reactions may occur but are usually mild. Fever and malaise sometimes occur and severe febrile reactions have been reported particularly on giving whole-virion vaccine to children, although this type of vaccine is seldom used now. Flu-like symptoms may follow the use of intranasal vaccines.

Various neurological syndromes have been temporally associated with use of influenza vaccine, the most notable report being of the Guillain-Barré syndrome occurring after vaccination with inactivated swine influenza vaccine in 1976 (see below).

Effects on the eyes. For a discussion of bilateral eye redness, occurring as part of an oculorespiratory syndrome following influenza vaccination, see below.

Effects on the nervous system. ***BELL'S PALSY.*** Between October 2000 and April 2001, the Swiss Drug Monitoring Centre and the University of Zurich received 46 reports of Bell's palsy occurring in patients who had used an inactivated intranasal influenza vaccine (*Nasalflu*). The manufacturers suspended distribution of the vaccine and, after a subsequent study[1] suggested a strong association between the vaccine and the development of Bell's palsy, it was withdrawn from clinical use.

1. Mutsch M, *et al.* Use of the inactivated intranasal influenza vaccine and the risk of Bell's palsy in Switzerland. *N Engl J Med* 2004; **350:** 896–903.

GUILLAIN-BARRÉ SYNDROME. In 1976 a limited outbreak of influenza in the USA caused by a virus closely resembling the swine influenza virus led to the use of a killed swine influenza virus vaccine.[1] After about 45 million doses of the vaccine had been given the vaccination programme ceased because there was some evidence of a temporal association between vaccination and the onset of a paralytic polyneuropathy of the Guillain-Barré type. An epidemiologic and clinical evaluation of these cases suggested a definite link between vaccination and the onset of the syndrome with extensive paralysis but no association with the onset of limited motor lesions.

Surveillance systems have since investigated any possible link with the development of Guillain-Barré syndrome. The Immunization Safety Review Committee in the USA[2] concluded in 2004 that the evidence was inadequate to either accept or reject a causal relationship with non-swine influenza vaccines used after 1976. This review had inspected reports submitted from 1990 to 2003 to VAERS (Vaccine Adverse Events Reporting System in the USA) but considered that such case reports were uninformative with respect to causality, although they were useful for hypothesis generation. One suggestion made by workers monitoring the VAERS data[3] was the question as to whether *Campylobacter* infection could be involved. Influenza vaccines have traditionally been made in chicken eggs. *Campylobacter* is endemic in chickens and a known cause of Guillain-Barré syndrome.

3. Haber P, *et al.* Guillain-Barré syndrome following influenza vaccination. *JAMA* 2004; **292:** 2478–81.

MULTIPLE SCLEROSIS. Analysis[1] indicated that there was no association between the use in the USA during 1976 of influenza vaccines containing a swine virus component and the development of multiple sclerosis. Later analysis by the Immunization Safety Review Committee in the USA[2] concluded in 2004 that the evidence favoured rejection of a causal relationship between influenza vaccines used in various years (including the swine vaccines of 1976) and relapse of multiple sclerosis but that the evidence was inadequate to either accept or reject a causal relationship with incident multiple sclerosis.

Effects on the respiratory tract. For a discussion of respiratory symptoms, occurring as part of an oculorespiratory syndrome following influenza vaccination, see below.

Henoch-Schönlein purpura. Influenza vaccination has been associated with both development[1] and exacerbation[2] of Henoch-Schönlein purpura.

Oculorespiratory syndrome. During 2000 to 2001, an increased incidence of ocular and respiratory effects was reported in Canada in 960 patients, 96% of whom had received a specific split virion influenza vaccine (*Fluviral S/F*).[1] Symptoms included bilateral redness of the eyes and facial oedema with coughing, wheezing, tightness of the chest, breathing difficulty, or sore throat and were collectively termed oculorespiratory syndrome.[1,2] It was postulated that the syndrome might be due to numerous microaggregates of unsplit viruses present in the vaccine. A study[3] using an improved formulation of the vaccine found that oculorespiratory symptoms still occurred in 6.3% of recipients and that, since the improved formulation was otherwise minimally reactogenic, such symptoms might be associated with influenza vaccines in general. A subsequent study[4] of influenza vaccination among persons previously afflicted by oculorespiratory syndrome was halted early owing to a 33% rate of recurrence of symptoms within 24 hours. The authors concluded that previously afflicted patients should be warned of the risk of recurrence but that episodes of recurrence were usually mild and well tolerated.[4]

Precautions

As for vaccines in general, p.2202.

Whole-virion influenza vaccine is not recommended for use in children because of the increased risk of febrile reactions. Split-virion and surface-antigen vaccines are, however, suitable for children and infants and are widely used in mass immunisation campaigns.

Influenza vaccines should not be given to individuals with a known hypersensitivity to egg products.

Vaccination should be postponed in patients with active infection or acute febrile illness.

Asthma. There have been reports of exacerbations of asthma after influenza vaccination,[1,2] but reviews[3,4] have concluded that evidence of a causal relationship is lacking and that any risk of exacerbation which might exist is outweighed by the risk of influenza itself. Chronic respiratory disease, including asthma, is an indication for influenza vaccination in both the UK and USA. A systematic review has supported the use of inactivated vaccines for patients with chronic obstructive pulmonary disease.[5] A further systematic review, however, has concluded that, while there is no significant increase in asthma exacerbations immediately after vaccination (at least with inactivated influenza vaccination), uncertainty remains about the degree of protection that vaccination affords against asthma exacerbations after influenza infection.[6]

Diagnostic tests. False-positive screening enzyme-linked immunosorbent assays (ELISAs) for antibodies to HIV-1, HTLV-1 and hepatitis C virus were reported in blood donors who had recently received influenza vaccine.[1] The reaction was attributed to cross-reactivity of the test kit in use at the time with non-specific IgM.

1. Anonymous. False-positive serologic tests for human T-cell lymphotropic virus type 1 among blood donors following influenza vaccination, 1992. *JAMA* 1993; **269:** 2076 and 2078.

Interactions

◊ For the effect of influenza vaccination on some other drugs see under Phenobarbital Sodium, p.494, Phenytoin Sodium, p.500, Theophylline Hydrate, p.1145, and Warfarin Sodium, p.1432.

Uses and Administration

Influenza vaccines are used for active immunisation against influenza.

Three types of the influenza virus occur, namely types A, B, and C, and the formulation and composition of influenza vaccines is constantly reviewed with changes made to accommodate the antigenic shifts and drifts of the influenza virus. Recommendations concerning the antigenic nature of influenza vaccines are made annually by WHO. Currently, influenza vaccines are mainly of the inactivated type and are available as split-virion vaccines or as various surface-antigen vaccines (including virosomal products); whole-virion vaccines are now seldom used. In the USA, a live attenuated influenza vaccine against influenza virus types A and B is available.

Influenza vaccination is recommended for persons considered to be at special risk, particularly the elderly, those with chronic heart disease, chronic respiratory disease including asthma (see above), chronic hepatic or renal disease, diabetes mellitus, and patients who are immunosuppressed. Vaccination is also recommended for residents, particularly elderly persons and children, in closed institutions. Medical personnel and other persons at risk from infection through contact with infected patients should also receive vaccination. Vaccination usually produces immunity after about 14 days, lasting for about 6 months to 1 year. Injections are therefore scheduled annually so that the period of maximum immunity coincides with the usual period of influenza infection. In the UK and USA, they are generally given between September and early November.

Influenza vaccines are given in the UK by deep subcutaneous injection or intramuscular injection. The preferred site for injection is the deltoid muscle in adults and older children and, in infants and young children, the anterolateral aspect of the thigh. The recommended dose is 0.5 mL for adults and children aged over 3 years. In children aged 6 months to 3 years, doses of 0.25 or 0.5 mL have been used. Children should be given a second dose at least 4 weeks after the first if receiving the vaccine for the first time.

The live attenuated influenza vaccine available in the USA is given intranasally, in a dose of 0.2 mL (0.1 mL in each nostril) in adults (up to 49 years of age) and children aged over 9 years and in children aged 2 to 8 years who have received it previously. Children aged 2 to 8 years who have not previously received the vaccine are given a repeat dose after at least 30 days.

Commercially available influenza vaccines are not effective against avian influenza virus H5N1; however, such a vaccine has been developed in the USA (see below).

◊ Reviews.

2. Jefferson T, *et al*. Vaccines for preventing influenza in healthy children. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2008 (accessed 09/06/08).

Administration. Haemagglutinin on the surface of the influenza virus allows the virus to attach to the host cells, and antibody against it is the main form of immunity to influenza. Antibody to neuraminidase on the virus surface and cell-mediated immunity may be important as well. Adults with previous exposure to the relevant subtype usually get a fourfold or greater increase in haemagglutinin antibody after vaccination with 20 to 30 micrograms of haemagglutinin [equivalent to about one 0.5-mL dose], but in some cases most of the new antibody is against the original strain rather than the variant in the vaccine. Children and unprimed adults need 2 injections of a much larger dose of haemagglutinin (60 micrograms or more) for an adequate antibody response. The level of antibody falls by about 75% over 8 months after split-virus vaccine and by 50% over 6 months after whole-virus vaccine. Because of this decrease in antibody level, and antigenic drift, immunisation against influenza is required each year. After 1 or 2 doses of killed vaccine, clinical infection rates are reduced by 60 to 80% in children and young adults. Vaccination reduces clinical infection by only about 30% in elderly patients in institutions, but serious illness and death are probably cut by about 70%. The effectiveness of vaccination has varied widely in different studies, probably because of differences in previous exposure to the influenza subtype, vaccine dose, interval between vaccination and challenge, and matching of vaccine and challenge antigens.

Avian influenza vaccine. Since 1997, infection of humans with avian influenza virus H5N1 has been reported and is associated with high mortality. Although the current H5N1 influenza strains appear not to be transmissible from human to human, it is of major concern that further mutations or mixing with human influenza strains could convert H5N1 to a strain that would spread from human to human and cause a serious pandemic. Candidate avian influenza vaccines have been investigated and *Sanofi Pasteur, USA* has developed a vaccine. Although the vaccine will not be commercially available, it has been licensed by the FDA and will be included in the National Stockpile in the USA for use in the event that the H5N1 virus develops the ability to become readily transmissible from human to human.[1]

Japanese Encephalitis Vaccines

Vacunas de la encefalitis japonesa.

ATC — J07BA02.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Hypersensitivity reactions including urticaria, angioedema, hypotension, and dyspnoea have been reported mainly in travellers from non-endemic areas. In May 2005 the Japanese government suspended routine vaccination with mouse brain-derived vaccine in response to a report of acute disseminated encephalomyelitis after vaccination; however, a causal link has not been established.

Persons with unstable neurological conditions, including convulsions in the past year, may be at higher risk of adverse events. It is suggested that vaccine should not be given to those who are recovering from acute disseminated encephalomyelitis or to those with Guillain-Barré syndrome, multiple sclerosis, or other demyelinating disorders.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Two types of inactivated Japanese encephalitis (JE) vaccine containing either the Nakayama or the Beijing-1 strain of the virus and grown in mouse-brain tissue are generally used for active immunisation against encephalitis due to JE virus. The Nakayama strain vaccine produced in Japan was widely available internationally, but production has been stopped. Another inactivated JE vaccine is made in China from the Beijing-3 strain of JE virus and grown in Syrian hamster kidney-cell cultures. This vaccine has been replaced in the Chinese vaccination programme by a live, attenuated JE virus (strain SA 14-14-2) vaccine that is also produced on primary hamster cells. JE vaccines are widely used in China, Japan and other parts of Asia where JE is endemic and may form part of the WHO Expanded Programme on Immunization. Vaccination is recommended for visitors to rural areas of South East Asia and the Far East where infection is endemic and where the visit is to be for more than one month; it is also recommended for shorter visits in individuals likely to be at exceptional risk.

In the UK adults and children over 3 years who are non-immune travellers are usually given 3 doses each of 1 mL of the inactivated mouse-brain vaccine subcutaneously at 0, 7 to 14, and 28 to 30 days; full immunity will take up to one month to develop. A two-dose schedule with doses given 7 to 14 days apart may provide short-term immunity but is less effective; in the USA, an abbreviated dosage schedule with doses at 0, 7, and 14 days is suggested if time is not available for the standard schedule. Children under 3 years of age may be given 3 doses of 0.5 mL; in the USA, the vaccine is not recommended for children under 1 year. Reinforcing doses may be needed but the interval at which they are given varies with the vaccine preparation.

In areas where JE is endemic, primary immunisation with inactivated vaccines has been given according to a different schedule. Although the ages and schedule of subsequent boosters varies in different countries, the same schedule is used for primary immunisation. The first dose is given at age 6 months to 3 years according to the country, but in all cases is followed by a second dose 1 to 4 weeks later and then a third after 1 year. Live attenuated Japanese encephalitis vaccines are also used, in single or 2-dose schedules (see below), in some countries in the Far East where disease is endemic.

◊ Inactivated Japanese encephalitis vaccines have been widely used in Asia for some years. In Japan, the incidence of the disease has decreased since the introduction of nationwide vaccination in the mid-1960s.

A live attenuated vaccine, SA14-14-2, is widely used in China and is replacing the use of inactivated vaccine. Studies[1,2] with the live attenuated vaccine showed that 2 doses given a year apart were 97% effective in an endemic region of rural China. Similar results were obtained when the interval between doses was reduced to 1 to 3 months. A further case-control study[3] in Nepal found that single-dose administration was more than 99% effective.

Other vaccines are under development including recombinant DNA and chimeric vaccines. Recombinant vaccines delivered using poxvirus vectors were also investigated but research appears to have been halted.[4,5]

Jellyfish Venom Antisera

Antisuero contra el veneno de la medusa; Jellyfish Antivenins; Jellyfish Antivenoms.

Adverse Effects and Precautions

As for antisera in general, p.2201.

Uses and Administration

An antiserum for use in the management of severe stings by the box jellyfish or sea wasp *Chironex fleckeri* is available in Australia. The preparation contains the specific antitoxic globulins that neutralise the venom of *Chironex fleckeri* and is prepared from the serum of sheep immunised with the venom of the box jellyfish.

Box jellyfish antivenom is usually given by the intravenous route in a dose of 20 000 units. Alternatively, 60 000 units may be injected intramuscularly.

Jellyfish stings. Many stings caused by the box jellyfish *Chironex fleckeri* are of little consequence and can be managed by simple first aid measures; however, some can be rapidly fatal so immediate assessment is vital.[1] Fragments of tentacle adhering to the skin should be inactivated by the application of vinegar or 3 to 10% acetic acid solution. Cardiopulmonary resuscitation may be necessary in severe cases. The antiserum can be effective if given quickly and in adequate dosage,[2,3] although use is mainly reserved for those with cardiorespiratory instability, severe pain refractory to opioid analgesics, or at risk of significant scarring.[1,3] Some experimental evidence suggested that verapamil might be useful for treatment of the cardiotoxic effects of the venom and allow more time for the antiserum to exert its action,[1,4] but is now considered to be contraindicated.[3] Some have suggested that the *Chironex fleckeri* antiserum may be effective for severe envenomation by related species.[3,5]

Irukandji syndrome consists of several hypercatecholaminergic symptoms (such as generalised pain, distress, hypertension, cardiomyopathy, and pulmonary oedema) arising from envenomation with the small box jellyfish *Carukia barnesi*.[1,6] Treatment is essentially symptomatic and supportive. The *Chironex fleckeri* antivenom is not effective.[3,5] Acetic acid may also be helpful for stings by related species (see p.2244).

Leishmaniasis Vaccines

Vacunas de la leishmaniasis.

Profile

Vaccines containing *Leishmania* spp. are under investigation in an attempt to prevent cutaneous leishmaniasis.

◊ The inoculation of an infective strain of a *Leishmania* sp. into the skin, a technique known as leishmanisation, has been used to protect against cutaneous leishmaniasis (p.824). Although the technique has been standardised it is not generally recommended since large, slow-healing lesions have occurred in some patients. There is currently no effective vaccine for any form of leishmaniasis. First-generation vaccines containing killed leishmanial promastigotes, with or without BCG as an adjuvant, have been developed and tested in humans. These have conferred some protection against cutaneous disease but it has waned relatively quickly in some cases. They have not been found to confer protection against visceral leishmaniasis. New studies are ongoing investigating the use of alum as an adjuvant. There is also further investigation into second-generation vaccines using different approaches such as the use of surface antigens (gp63 and lipophosphoglycan), promastigote antigen from *L. amazonensis*, enzyme receptor (LACK), Th1-driving adjuvant such as interleukin-12, oligodeoxynucleotides with leishmanial antigens, or recombinant leishmanial antigen (TSA, LmSTI-1), all of which have conferred some protection in *mice*. A glycoprotein-enriched *L. donovani* promastigote vaccine (*Leishmune*®) is available for prophylactic veterinary use in Brazil. DNA constructs encoding gp63 and LACK have also conferred protection against *L. major* in *mice*. A chimeric vaccine has also been developed combining three leishmanial antigens (LeIF, LmSTI-1, and TSA) in monophosphoryl lipid A adjuvant but had, at best, mixed results in trials in *dogs*. Attenuated vaccines prepared by gene deletion have shown promise in *mice*. The saliva of sandflies (the vector) seems to enhance infectivity, and vaccines against salivary or gut antigens of the insect have also been investigated.

Leprosy Vaccines

Vacunas de la lepra.

Profile

Vaccines against leprosy including those using *Mycobacterium leprae*, as well as other mycobacteria, are under investigation. A killed vaccine has been developed in India for use as an adjunct to standard multidrug therapy in the treatment of leprosy. Although studies of new vaccines are continuing, BCG vaccine (p.2207) also appears to be effective.

◊ Leprosy vaccines are being studied both to prevent infection with *M. leprae* (immunoprophylaxis) and to prevent disease in infected individuals (immunotherapeutic). Attempts to develop a vaccine against leprosy are based on the assumption that induction of a cell-mediated immune response to *Mycobacterium leprae* will lead to protection against the bacillus. Several vaccines have been studied and include BCG, BCG plus heat-killed *M. leprae*, heat-killed *Mycobacterium w*, and ICRC (Indian Cancer Research Centre) bacillus. The fortuitous finding that BCG vaccine, which is inexpensive and widely available, is effective against leprosy has important implications for leprosy control. Considerable **immunoprophylaxis** against leprosy is afforded by BCG vaccination (see p.2207), and a study in Malawi showed that repeated vaccination provided additional protection.[1] However, the addition of killed *M. leprae* did not produce any further improvement, confirming preliminary results of a study in Venezuela.[2] However, in a report of their sixth meeting,[3] the WHO Technical Advisory Group on the Elimination of Leprosy reported superior vaccine efficacy for BCG plus heat-killed *M. leprae* than with BCG alone in a prophylactic leprosy vaccine study in south India. The study was begun in 1991 and involved 171 400 subjects who received either BCG alone, BCG plus heat-killed *M. leprae*, *Mycobacterium w*, ICRC bacillus, or placebo. Three surveys of the results have since been conducted by way of follow-up; the preliminary findings of the latest of these surveys revealed that the overall efficacy rates for the vaccines were 22% for BCG alone, 67% for BCG plus heat-killed *M.leprae*, 41% for *Mycobacterium w*, and 51% for ICRC bacillus. Within these results, the findings specifically for efficacy in contacts of patients with leprosy were 11% for BCG alone, 88% for BCG plus heat-killed *M. leprae*, 87% for *Mycobacterium w*, and 11% for ICRC bacillus. Further studies are being conducted in Brazil regarding the use of BCG for booster doses in schoolchildren, and also for its use in household contacts.

Beneficial responses have been reported[4-10] from the **immunotherapeutic** use of *Mycobacterium w* vaccine with standard multidrug therapy (p.176) although a small increase in Type 1 lepra reactions has been observed.[9-11] A similar, and possibly identical, vaccine based on the ICRC bacillus has also been evaluated.[12,13] Immunotherapy with BCG and heat killed *M.leprae* has produced beneficial responses when given as an adjunct to chemotherapy.[14] WHO has suggested that the immunotherapeutic use of vaccines may ultimately prove to be more clinically relevant than the immunoprophylactic use,[12] and high compliance with immunotherapy appears to be attainable.[15]

Preparations

Proprietary Preparations (details are given in Part 3)
India: Immuvac.

Leptospirosis Vaccines

Leptospira Vaccines; Vacunas de la leptospirosis.

Profile

Leptospirosis vaccines prepared from killed *Leptospira interrogans* are available in some countries. They are used for active immunisation against leptospirosis icterohaemorrhagica (spirochaetal jaundice; Weil's disease) in persons at high risk of contracting the disease.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Spirolept; ***Switz.:*** Spirolept.

Lyme Disease Vaccines

Vacunas de la enfermedad de Lyme.

Profile

Vaccines based on recombinant outer surface proteins of *Borrelia burgdorferi* were developed and used in some countries for active immunisation against Lyme disease in persons at risk of contracting the disease.

Lyme arthritis refractory to treatment with antibacterials has occurred rarely as an immune reaction to vaccine-derived outer surface proteins of *Borrelia burgdorferi*.

Malaria Vaccines

Vacunas del paludismo.

Profile

Malaria vaccines acting against the sporozoite, asexual, and sexual stages of the *Plasmodium falciparum* life cycle are under investigation, as well as multicomponent vaccines consisting of combined antigens from various stages.

Vaccine development. Chemoprophylaxis of malaria is becoming increasingly problematical (see p.594), resulting in the increased desirability of effective malaria vaccines, several of which have been, or are being, studied clinically. The various approaches to malaria vaccine development have been extensively reviewed.[1-15] Malaria vaccines can be categorised into 4 main groups:

- vaccines against pre-erythrocytic forms of the parasite, specifically the sporozoite and liver stages of infection. A sporozoite vaccine could prevent infection either via an antibody response to block invasion of liver cells or via a cell-mediated response to destroy infected liver cells by preventing release of parasites into the bloodstream. The most advanced of these vaccines are derived from the circumsporozoite antigen present on the sporozoite and the main vaccine candidate of this type is RTS,S/AS02A. This vaccine is comprised of the antigenic C-terminus of the circumsporozoite gene from *Plasmodium falciparum* fused to hepatitis B surface antigen and encouraging results in early studies in endemic African areas have been reported.[16] The US military is also investigating the possibility of DNA vaccines for malaria, including a liver-stage DNA candidate encoding the circumsporozoite (CS) protein of *P. falciparum*; however, this vaccine has so far failed to induce antigen-specific antibodies. A multiple-antigen version of this DNA vaccine, known as MuStDo5, encoding 5 different liver-stage antigens including CS is also under investigation. Some workers are investigating the prospect of priming with a DNA vaccine and boosting with recombinant antigen or viral vectors. There is also some development of vaccines that focus on the intracellular liver stage of the parasite, since some antigens expressed by sporozoites or merozoites can also be expressed by liver stage parasites
- vaccines against asexual erythrocytic stages, directed at the merozoite form of the parasite. These vaccines would be expected to reduce the severity and the duration of disease by decreasing the blood-parasite density; this effect correlates with reduced symptoms and risk of death. The most advanced asexual vaccine candidate is merozoite surface protein 1 (MSP-1), which forms part of a complex thought to be involved in erythrocyte invasion; antibodies to MSP-1 have been shown to block parasite entry to erythrocytes *in vitro*. Recombinant MSP-1 has also been shown to protect against lethal parasite challenge in *animal* studies. Several other merozoite surface proteins are also under development (MSP-2, 3, 4, 5, 8, and 9). A vaccine comprising MSP-1 and MSP-2 in combination with *P. falciparum* ring-infected erythrocyte (RESA) has recently shown a 62% reduction in parasite density in children in a study in Papua New Guinea. Two further promising asexual erythrocytic stage vaccine candidates are the apical membrane antigen-1 (AMA-1) and erythrocyte-binding antigen-175 (EBA-175)
- transmission-blocking vaccines to raise antibodies in humans against the gamete stage of the parasite present in the mosquito gut; these antibodies would then be taken up by the biting mosquito from in the blood and block further parasite development in the mosquito, thus rendering it non-infectious. Blocking transmission in this way could reduce infectivity of mosquitoes in that they would carry fewer parasites, and could extend the useful life of a pre-erythrocytic or erythrocytic vaccine by preventing transmission of antibody-resistant mutants. The most advanced candidate vaccines of this type contain the *P. falciparum* surface protein antigens Pfs-25 and Pfs-28 or the *P. vivax* homologues Pvs-25 and Pvs-28. Recombinant forms of these antigens are currently being investigated. Other similar sexual stage vaccines under development include Pfs-48/45 and Pfs-230
- vaccines against the toxins produced by the parasite that contribute to the disease itself. The glycosylphosphatidyl inositol (GPI) anchor, which binds several of the parasite's antigens to the erythrocyte membrane, has been shown to be highly toxic in *mouse* models, but has potential for disease attenuation if it can be detoxified and rendered safe.

A multi-antigen, multistage combination vaccine is thought to be the best approach to effective vaccination against malaria. One such vaccine, SPf66, a synthetic preparation of three antigens from the asexual phase of the parasite in the blood linked by a sporozoite antigen has been studied but little or no evidence for its protective efficacy has been found.[3] Another multicomponent vaccine, NYVAC-Pf7, using a recombinant vaccinia viral vector that expresses 7 proteins from different stages of malarial infection, has also been studied,[17] but results have been disappointing. A further multicomponent vaccine, CDC/NIIMALVAC-1 has provided encouraging preliminary results in *animals* and *in vitro*.[18]

Measles Immunoglobulins

Inmunoglobulinas contra el sarampión.
ATC — J06BB14.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.

Ph. Eur. 6.2 (Human Measles Immunoglobulin; Immunoglobulinum Humanum Morbillicum). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG). It is obtained from plasma containing specific antibodies against the measles virus. Normal immunoglobulin may be added. It contains not less than 50 international units/mL. Both the liquid and freeze-dried preparations should be stored, protected from light, in a colourless, glass container. The freeze-dried preparation should be stored under vacuum or under an inert gas.

Adverse Effects and Precautions

As for immunoglobulins in general, p.2201.

Interactions

As for immunoglobulins in general, p.2201.

Uses and Administration

Measles immunoglobulins may be used for passive immunisation against measles. They have been used to prevent or modify measles in susceptible persons who have been exposed to infection; in the UK, normal immunoglobulin is usually given.

Preparations

Ph. Eur.: Human Measles Immunoglobulin.

Measles Vaccines

Vacunas del sarampión.
ATC — J07BD01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Measles Vaccine (Live); Vaccinum Morbillorum Vivum). A freeze-dried preparation of a suitable live attenuated strain of measles virus grown in cultures of chick-embryo cells or human diploid cells. It is prepared immediately before use by reconstitution from the dried vaccine. The virus concentration is not less than 3.0 log $CCID_{50}$ per dose. The dried vaccine should be stored at 2° to 8° and be protected from light.

The BP 2008 states that Measles may be used on the label.

USP 31 (Measles Virus Vaccine Live). A bacterially sterile preparation of a suitable live strain of measles virus grown in cultures of chick-embryo cells. It contains not less than the equivalent of 1×10^3 $TCID_{50}$ in each immunising dose, and may contain suitable antimicrobial agents. It should be stored at 2° to 8° and be protected from light.

Adverse Effects

As for vaccines in general, p.2201.

Fever and skin rashes may occur after measles vaccines. The fever generally starts about 1 week after the injection, lasts for about 2 or 3 days, and has sometimes been accompanied by convulsions. More serious effects reported rarely include encephalitis and thrombocytopenia.

◊ Reviews.

1. Duclos P, Ward BJ. Measles vaccines: a review of adverse events. *Drug Safety* 1998; **19:** 435–54.

Incidence of adverse effects. Some brief comments made by the Advisory Committee on Immunization Practices in the USA on adverse effects of standard measles vaccines.[1] An excellent safety record of measles vaccines has been indicated by the experience gained through the use of more than 240 million doses up to 1993. Fever with a temperature of 39.4° or more may develop in 5 to 15% of vaccinees beginning 5-12 days after vaccination and usually lasts several days. Transient rashes have been reported in about 5% of vaccinees. CNS disorders, including encephalitis and encephalopathy, have been reported with a frequency of less than one case per million doses given. The incidence of encephalitis or encephalopathy after vaccination is lower than the incidence rate of encephalitis of unknown origin suggesting that such events after vaccination may be only temporally related to, rather than due to, vaccination.

1. Immunization Practices Advisory Committee. Update: vaccine side effects, adverse reactions, contraindications, and precautions. *MMWR* 1996; **45** (RR 12): 1–35.

Atypical measles. The atypical-measles syndrome has occurred in persons vaccinated against measles and later exposed to the natural infection. The syndrome has been characterised by high fever and atypical rash; abdominal pain has been common and pneumonia almost universal.[1] Although atypical measles has occurred particularly in patients given killed vaccine[1] (no longer used) it has been reported in recipients of live measles vaccines.[2,3]

Measles occurring in patients previously vaccinated with live measles vaccines may be mild and go unrecognised. However, secondary vaccine failure does not appear to be a major problem (see Immunisation Schedules under Uses, below).

3. Henderson JAM, Hammond DI. Delayed diagnosis in atypical measles syndrome. *Can Med Assoc J* 1985; **133:** 211–13.

Effects on hearing. There have been individual case reports of sensorineural hearing loss after measles vaccination.[1,2] Similar reports have been made after vaccination with measles and rubella vaccines (p.2223) and measles, mumps, and rubella vaccines (p.2223).

1. Watson JG. Bilateral hearing loss in a 3-year-old girl following measles immunisation at the age of 15 months. *Int J Pediatr Otorhinolaryngol* 1990; **19:** 189–90.
2. Jayarajan V, Sedler PA. Hearing loss following measles vaccination. *J Infect* 1995; **30:** 184–5.

Effects on the nervous system. *GUILLAIN-BARRÉ SYNDROME.* No association was found between measles vaccination and Guillain-Barré syndrome in an analysis of 2296 cases.[1]

1. da Silveira CM, *et al.* Measles vaccination and Guillain-Barré syndrome. *Lancet* 1997; **349:** 14–16.

OPTIC NEURITIS. For a report of optic neuritis in 2 children after being given measles and rubella vaccine, see under Adverse Effects of Measles and Rubella Vaccines, p.2223.

SUBACUTE SCLEROSING PANENCEPHALITIS. Subacute sclerosing panencephalitis (SSPE) is a rare complication of measles infection (p.860) and has been reported in children who have received measles vaccine but have no history of clinical disease. Nevertheless mass measles vaccination has been effective in reducing the incidence of SSPE in both developing and industrialised countries,[1,2] and the risks of remaining unimmunised are considered to be greater than those arising from immunisation.

Effects on the skin. Stevens-Johnson syndrome was associated with measles vaccination in a 10-month-old infant.[1]

1. Hazir T, *et al.* Stevens-Johnson syndrome following measles vaccination. *J Pakistan Med Assoc* 1997; **47:** 264–5.

High-titre vaccines and mortality. After reports of excess mortality in children, especially among girls, who received high-titre Edmonston-Zagreb (EZ) measles vaccine,[1] WHO reversed its recommendation for the use of this vaccine in its Expanded Programme on Immunization in developing countries.[2,3] Subsequent study[4] of children who had received high-titre EZ vaccine showed adverse effects on the nutritional status in either sex, confirming a generally deleterious effect of the vaccine. Others, however, have argued that the problems associated with the use of EZ vaccine have been exaggerated.[5,6] A review[6] pointed out that excess mortality was not seen in all studies, and concluded that the problem was unlikely to be due to the vaccine itself.

Precautions

As for vaccines in general, p.2202.

Measles vaccines are not generally recommended for children below the age of 1 year in whom maternal antibodies might prevent a response, but they have been given to younger infants when the risk of measles is particularly high (see Immunisation Schedules, under Uses, below, for further discussion).

Hypersensitivity. For discussion of precautions to be taken on giving measles vaccines to children allergic to egg, see Measles, Mumps, and Rubella Vaccines, p.2223.

Immunocompromised patients. For a discussion of the use of live vaccines in immunocompromised patients including those with HIV infection, see Precautions on p.2202.

As with other live vaccines, measles vaccine is generally not recommended for use in patients with impaired immunity, although combined measles, mumps, and rubella vaccine may be given to HIV-positive individuals unless they have severe immunosuppression or other contra-indications. WHO and UNICEF[1] recommend that children with suspected or confirmed HIV infection should receive a dose of measles vaccine at 6 months of age in addition to the scheduled dose at 9 months. Immunocompromised patients who come into contact with measles should be given normal immunoglobulin. Specific measles immunoglobulins (p.2221) have been used in some countries. Although measles vaccines have been given to immunocompromised patients without causing adverse effects[2] there have been some reports of severe reactions; disseminated measles infection was reported in a child with severe congenital immunodeficiency,[3] and fatal giant-cell pneumonitis was reported in an adult with AIDS.[4]

4. Angel JB, *et al.* Vaccine-associated measles pneumonitis in an adult with AIDS. *Ann Intern Med* 1998; **129:** 104–6.

Inflammatory bowel disease. Measles vaccination has been suggested as a possible factor in the development of inflammatory bowel disease.[1] However a case-control study involving 140 patients with inflammatory bowel disease provided no support for this hypothesis,[2] and measles virus has not been detected in biopsy specimens from patients with inflammatory bowel disease.[3] Later reviews[4-6] concluded that there is no evidence of any association between measles-containing vaccines and inflammatory bowel disease. A suggested link between measles vaccine-associated inflammatory bowel disease and autism is now refuted (see p.2223).

Interactions

As for vaccines in general, p.2202

Vitamin A. Supplementation with vitamin A (see Deficiency States, p.1973) is now included as part of WHO's Expanded Programme on Immunization. There has been conflicting evidence of the effects of such supplementation on the response to measles vaccination. One study[1] reported a reduced immune response if vaccination occurs at 6 months (before the age at which measles vaccination is usually given in the EPI) while others[2,3] generally found no significant change in seroconversion or immune response in children vaccinated at 9 months (the age at which vaccination is generally started).

3. Cherian T, *et al.* Effect of Vitamin A supplementation on the immune response to measles vaccination. *Vaccine* 2003; **23:** 2418–20.

Uses and Administration

Measles vaccines are used for active immunisation against measles. Measles strains currently used in vaccines are usually the more attenuated Enders' attenuated Edmonston strain or the Schwarz strain. A high-potency measles vaccine prepared from the Edmonston-Zagreb strain of measles virus was formerly used but was stopped because of evidence of increased mortality (see High-titre Vaccines and Mortality, under Adverse Effects, above).

For primary immunisation a combined measles, mumps, and rubella vaccine (p.2223) is usually used. For discussion of immunisation schedules, see below.

Measles vaccines are not generally recommended for children below the age of 1 year in whom maternal antibodies might prevent a response. However, they have been given to infants at 6 to 9 months of age in developing countries and in the USA in certain circumstances (such as during measles outbreaks) (see also Immunisation Schedules, below).

Single-antigen measles vaccines have also been used for prophylaxis after exposure to measles provided they are given within 72 hours of contact.

Administration. Several alternative routes of administration of measles vaccines have been investigated in an attempt to overcome some of the disadvantages of subcutaneous or intramuscular injection.[1] Aerosol administration has produced good responses in children over 9 months of age, although this route was not so effective in younger children.[2,3] Aerosol administration could be potentially useful for mass immunisation campaigns, a suggestion confirmed in a randomised study.[4]

Oral vaccines against measles, produced in edible plants, are under investigation.[5,6]

Work is currently underway to develop oral and/or nasal vaccines that will be suitable in infants less than 9 months of age, a time when they are vulnerable due to waning maternal antibodies.

Immunisation schedules. In the developed world measles vaccine (usually as measles, mumps, and rubella vaccine) is usually given in the second year of life. As a result of concern that measles vaccine would not elicit an appropriate immune response in young infants due to the persistence of maternal antibodies in circulation, vaccination has generally not been attempted in children under 12 months old. However, infants born to vaccinated mothers tend to have lower levels of maternal antibodies and are susceptible to measles infection at under 12 months of age; vaccination has been shown to be effective at 6 to 9 months of age in such children,[1-3] although antibody titres were lower in infants vaccinated at 6 months of age than in those vaccinated later.[1,4]

In the UK and USA, routine vaccination is given at between 12 and 15 months, with a second dose given at between 4 and 6 years (see the immunisation schedules summarised under Vaccines, p.2202). Similar schedules are used in other countries. There is evidence that these 2-dose strategies will produce high levels of immunity in the community. During an outbreak of measles, vaccination may be given as early as 6 months of age;[5] revaccination is recommended in any child who is vaccinated before their first birthday. Vaccine may be given to non-immune persons of any age considered to be at risk of infection even if their immune status is uncertain.

EXPANDED PROGRAMME ON IMMUNIZATION. Measles remains a leading cause of death among young children, despite the availability of a safe and effective vaccine for the past 40 years. WHO estimated 454 000 people, the majority of them children, died from measles and measles complications in 2004.

In the developed world measles vaccine (usually as measles, mumps, and rubella vaccine) is usually given in the second year of life. If given earlier, passively-acquired maternal antibodies against measles may interfere with development of protective immunity.

In the developing world, protection given by maternal antibodies is often rapidly lost and in hyperendemic areas, such as urban and peri-urban areas, clinical measles may occur in children as young as 5 to 6 months of age. Immunisation against measles is part of WHO's Expanded Programme on Immunization. The first dose of measles vaccine is given to children at the age of 9 months or shortly thereafter. A 'second opportunity' for immunisation is provided to all children (either through routine immunisation campaigns or by targeted supplementary activities depending on local need). This assures measles immunity in children who failed to receive a previous dose of measles vaccine, as well as in those who were vaccinated but failed to develop immunity following vaccination (about 10 to 15% of those children vaccinated at 9 months of age).

Immunisation for travellers. WHO recommends that all travellers from the age of 6 months who have not been immunised should be offered measles vaccine. Infants who are travelling to areas where measles is endemic and who receive the first dose of measles vaccine between the ages of 6 to 8 months should also receive the scheduled primary immunisation doses later.[1]

It is generally recommended that individuals with at least a moderate degree of immune deficiency should receive measles vaccine even when travelling to areas with a low risk of contracting the disease.[1]

Measles and Rubella Vaccines

Vacunas del sarampión y la rubéola.
ATC — J07BD53.

Pharmacopoeias. Many pharmacopoeias, including *US*, have monographs.
USP 31 (Measles and Rubella Virus Vaccine Live). Bacterially sterile preparation of suitable live strains of measles virus and live rubella virus. It may contain suitable antimicrobial agents. Each labelled dose provides an immunising dose of each component. It should be stored at 2° to 8° and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Measles Vaccines, p.2221, and Rubella Vaccines, p.2236.

Incidence of adverse effects. Eight million children aged between 5 and 16 years were immunised with a measles and rubella vaccine in 1994 in the UK. By October 1995 the UK CSM had received reports on 2735 suspected adverse reactions most of which were minor and self-limiting.[1] Serious suspected reactions were rare and generally the number of reported cases was consistent with the background frequency of the particular disorder.

Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON2015633&RevisionSelectionMethod=LatestReleased (accessed 25/05/06)

Effects on hearing. Profound, irreversible sensorineural deafness was reported in a 27-year-old woman after administration of a measles and rubella vaccine.[1] Sensorineural deafness has also been reported after use of measles, mumps, and rubella vaccine (below), and monovalent measles vaccine (p.2221).

Measles, Mumps, and Rubella Vaccines

Vacunas del sarampión, la parotiditis y la rubéola.
ATC — J07BD52.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.
Ph. Eur. 6.2 (Measles, Mumps and Rubella Vaccine (Live); Vaccinum Morbillorum, Parotitidis et Rubellae Vivum). A freeze-dried preparation containing suitable live attenuated strains of measles virus, mumps virus (*Paramyxovirus parotitidis*), and rubella virus. The vaccine is prepared immediately before use by reconstitution from the dried vaccine. It contains in each dose not less than 3.0 log $CCID_{50}$ of infective measles virus, not less than 3.7 log $CCID_{50}$ of infective mumps virus, and not less than 3.0 log $CCID_{50}$ of infective rubella virus. The dried vaccine should be stored at 2° to 8° and be protected from light.
The BP 2008 states that MMR may be used on the label.
USP 31 (Measles, Mumps, and Rubella Virus Vaccine Live). A bacterially sterile preparation of suitable live strains of measles virus, mumps virus, and rubella virus. It may contain suitable antimicrobial agents. Each labelled dose provides an immunising dose of each component. It should be stored at 2° to 8° and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

See also under Measles Vaccines, p.2221, Mumps Vaccines, p.2225, and Rubella Vaccines, p.2236.

Events due to the measles component usually occur 6 to 11 days after vaccination and those due to the mumps and rubella components after 2 to 3 weeks but may occur up to 6 weeks after vaccination.

Adverse effects tend to be less frequent after the second dose of vaccine than after the first dose.

Measles, mumps, and rubella vaccines should not be given to individuals with a confirmed anaphylactic reaction to any antibacterial such as neomycin or kanamycin, that may be used in the manufacturing process.

Recommendations on vaccination in persons with egg allergy are discussed under Hypersensitivity, below.

Incidence of adverse effects. A double-blind placebo-controlled crossover study[1] in 581 pairs of twins showed that the frequency of adverse effects from the use of measles, mumps and rubella (MMR) vaccine was between 0.5 and 4.0%, indicating that adverse reactions are much less common than was previously thought. A study in the USA[2] showed that children given the vaccine at age 4 to 6 years had fewer adverse effects than those given it at 10 to 12 years. A later study[3] based on family reported symptoms was unable to detect any vaccine-related adverse effects when the second dose of MMR vaccine was given at either 4 to 6 years or 10 to 12 years. Vaccine-related adverse effects after the first dose of MMR vaccine were reported in about 17% in those vaccinated between the age of 12 and 20 months.

A further study[4] that assessed the effect of almost 3 million doses of vaccines in 1.8 million individuals revealed that 173 potentially serious reactions were claimed to have been caused by vaccination. There were 77 neurologic, 73 allergic, and 22 miscellaneous reactions recorded, and 1 death reported. However, 45% of the reactions were probably caused by some other factor. It was therefore concluded that serious events caused by MMR vaccine are rare and are greatly outweighed by the risks of the natural diseases.

4. Patja A, *et al.* Serious adverse events after measles-mumps-rubella vaccination during a fourteen-year prospective follow-up. *Pediatr Infect Dis J* 2000; **19:** 1127–34.

Effects on the blood. Thrombocytopenia occurs rarely in children receiving measles, mumps, and rubella vaccine and usually resolves spontaneously. The rubella component is considered to be the most likely cause. An increased incidence of thrombocytopenia after the second dose of the vaccine has been reported in children who developed thrombocytopenia after the first dose.[1] A study[2] by the UK Public Health Laboratory Service has suggested a link between measles, mumps, and rubella vaccine and the occurrence of idiopathic thrombocytopenic purpura, with an absolute risk of 1 in 22 300 of occurrence within 6 weeks of the first dose of the vaccine, and 2 out of every 3 cases attributable to it. Children with idiopathic thrombocytopenic purpura before receiving measles, mumps, and rubella vaccine experienced no vaccine-associated recurrences. A further study[3] of children aged 13 to 24 months and diagnosed with idiopathic thrombocytopenic purpura for the first time between January 1988 and December 1999 similarly found the attributable risk of developing it within 6 weeks of receiving the vaccine to be about 1 in 25 000. As a consequence of these findings, the UK CSM has recommended[4] that children developing idiopathic thrombocytopenic purpura within 6 weeks of vaccination with measles, mumps, and rubella vaccine, or any of its components, should have serological testing before their second dose is due; if this suggests that full immunity is not established, then a second dose should be given.

3. Black C, *et al.* MMR vaccine and idiopathic thrombocytopaenic purpura. *Br J Clin Pharmacol* 2003; **55:** 107–11.
4. Committee on Safety of Medicines/Medicines Control Agency. MMR vaccine and idiopathic thrombocytopenic purpura. *Current Problems* 2001; **27:** 15. Also available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON007456&RevisionSelectionMethod=LatestReleased (accessed 24/05/06)

Effects on the bones and joints. Arthralgia and arthritis occurring in patients given mumps, measles, and rubella vaccines have generally been attributed to the rubella component.[1] However, arthritis has been reported in an infant after vaccination with measles and mumps vaccine.[2]

1. Benjamin CM, *et al.* Joint and limb symptoms in children after immunisation with measles, mumps, and rubella vaccine. *BMJ* 1992; **304:** 1075–8.
2. Nussinovitch M, *et al.* Arthritis after mumps and measles vaccination. *Arch Dis Child* 1995; **72:** 348–9.

Effects on hearing. Nine cases of sensorineural hearing loss after measles, mumps, and rubella vaccine were reported to the UK CSM between 1988 and 1993.[1] Of these, 3 cases were judged not to have been associated with the vaccine. In the remaining 6, the mumps virus component was considered to be the most likely cause of deafness if the vaccine was to blame, but the risk was considered to be small compared with the risks of natural infection. However, sensorineural deafness has also been reported after measles and rubella vaccine (see above) and monovalent measles vaccine (see p.2221).

1. Stewart BJA, Prabhu PU. Reports of sensorineural deafness after measles, mumps, and rubella immunisation. *Arch Dis Child* 1993; **69:** 153–4.

Effects on the nervous system. Although there have been case reports[1] linking Guillain-Barré syndrome with measles, mumps, and rubella vaccine, a retrospective study[2] that involved 189 patients with the syndrome and about 630 000 recipients of the vaccine could not find a causal association.

Prolonged tonic-clonic seizures were associated with prolonged hemiparesis in a 16-month-old girl 6 days after measles, mumps, and rubella vaccination.[3] There was evidence of transient encephalopathy. However, a causal relationship between measles-containing vaccines and encephalitis is generally considered to be unlikely. Other reported neurological effects after vaccination include gait disturbances,[4,5] and transverse myelitis.[6] However, a retrospective study[7] found no evidence for a causal association between vaccination and acute ataxia and the development of gait disturbances and suggested the original reports represented chance occurrence.

For discussion of meningitis and encephalitis occurring after measles, mumps, and rubella vaccination, see under Adverse Effects of Mumps Vaccines, p.2225.

7. Miller E, *et al.* No evidence of an association between MMR vaccine and gait disturbance. *Arch Dis Child* 2005; **90:** 292–6.

Hypersensitivity. Since the measles and mumps components of measles, mumps, and rubella vaccines are grown in cell cultures of chick embryos the vaccine was formerly contra-indicated in individuals with a history of anaphylactic reactions to egg. In both the UK and USA, serious reactions to egg including anaphylaxis are no longer regarded as absolute contra-indications to vaccination although specialist advice should be obtained and vaccination performed only under controlled conditions. It is generally agreed that the vaccine can be given safely to children with less severe reactions to eggs.

A confirmed anaphylactic reaction to gelatin, kanamycin, or neomycin is a contra-indication to measles, mumps, and rubella vaccines.

Inflammatory bowel disease and autism. A controversial report[1] in 1998 linked measles, mumps, and rubella vaccination with the development of inflammatory bowel disease and behavioural abnormalities including autism. However, there is now overwhelming evidence from studies and analyses that the vaccine does not cause autism.[2-11] Similarly, the link between measles-containing vaccines and inflammatory bowel disease has not been substantiated (see under Precautions for Measles Vaccines, p.2222).

Interactions

As for vaccines in general, p.2202.

See also under Measles Vaccines, p.2222.

Uses and Administration

Measles, mumps, and rubella vaccines are used for active immunisation against measles, mumps, and rubella. They are used for primary immunisation in children 12 months of age or older and to protect susceptible contacts during an outbreak of measles. For discussion of immunisation schedules, see under Vaccines, p.2202.

In the UK, it is recommended that all children receive two doses of 0.5 mL of a measles, mumps, and rubella vaccine by intramuscular injection (or subcutaneously if there is a bleeding disorder). These are usually given shortly after the first birthday and before school entry, but may be given at any age if routine vaccination has been omitted, allowing 3 months between doses. The combined vaccine may also be used for prophylaxis after exposure to measles provided it is given within 72 hours of contact. However, it is not considered to be effective for postexposure prophylaxis against either mumps or rubella. If the vaccine is given before 12 months of age, re-immunisation will be necessary starting at between 12 and 15 months with a further dose according to national schedules.

Similar schedules are used in the USA.

Measles, Mumps, Rubella, and Varicella-Zoster Vaccines

ATC — J07BD54.

Profile

Measles, mumps, rubella, and varicella-zoster vaccines are used for active immunisation against measles, mumps, rubella and varicella (chickenpox).

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Priorix-Tetra; ProQuad; ***NZ:*** Priorix-Tetra; ***Port.:*** Priorix-Tetra; ProQuad; ***USA:*** ProQuad.

Meningococcal Vaccines

Vacunas de polisacáridos meningocócicos.
ATC — J07AH01; J07AH02; J07AH03; J07AH04; J07AH05; J07AH06; J07AH07.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii), have monographs.
Ph. Eur. 6.2 (Meningococcal Polysaccharide Vaccine; Vaccinum Meningitidis Cerebrospinalis). It consists of one or more purified capsular polysaccharides obtained from one or more suitable strains of *Neisseria meningitidis* group A, group C, group Y, and group W135; it may contain a single type of polysaccharide or any mixture of the types. It is prepared immediately before use by reconstitution from the stabilised freeze-dried vaccine with a suitable sterile liquid. The freeze-dried vaccine should be stored at 2° to 8° and be protected from light.
The BP 2008 states that Men plus the relevant antigen may be used on the label (for example MenAC).
Ph. Eur. 6.2 (Meningococcal Group C Conjugate Vaccine; Vaccinum Meningococcale Classis C Coniugatum). A liquid or freeze-dried preparation of purified capsular polysaccharide derived from a suitable strain of *Neisseria meningitidis* group C covalently linked to a carrier protein. The vaccine may contain an adjuvant. The freeze-dried vaccine should be stored at 2° to 8° and be protected from light.
The BP 2008 states that MenC(conj) may be used on the label.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Immunity to the unconjugated serogroup C polysaccharide in meningococcal vaccines may be insufficient to confer adequate protection against infection in infants under about 2 years of age.

Effects on the nervous system. From June 2005 to September 2006, 17 cases of Guillain-Barré syndrome were reported to the Vaccine Adverse Event Reporting System (VAERS) after use of a tetravalent (A, C, W135, and Y) meningococcal conjugate vaccine (Menactra). Whether the cases were caused by the vaccine or were coincidental was unknown.[1,2] The CDC recommends that persons with a history of Guillain-Barré syndrome should not be vaccinated with the tetravalent meningococcal conjugate vaccine.[2]

1. CDC. Guillain-Barré syndrome among recipients of Menactra meningococcal conjugate vaccine - United States, June-July 2005. *MMWR* 2005; **54:** 1023–5.
2. CDC. Update: Guillain-Barré syndrome among recipients of Menactra meningococcal conjugate vaccine— United States, June 2005-September 2006. *MMWR* 2006; **55:** 1120–4. Correction. *ibid.*; 1177.

Pregnancy and the neonate. A study[1] in 157 Asian women given a tetravalent polysaccharide vaccine in the third trimester of pregnancy found that immunisation was safe for both mothers and infants. Infants were provided with significantly increased levels of IgG for 2 to 3 months and of oral IgA for 6 months from breast feeding.

1. Shahid NS, *et al.* Placental and breast transfer of antibodies after maternal immunization with polysaccharide meningococcal vaccine: a randomized, controlled evaluation. *Vaccine* 2002; **20:** 2404–9.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Meningococcal vaccines are used for active immunisation against *Neisseria meningitidis* infections, which include meningitis and septicaemia. They are preparations of purified polysaccharide antigens from *N. meningitidis* and may be monovalent, containing the antigen of only one serotype of *N. meningitidis* or polyvalent, containing antigens of two or more serotypes. Conjugation of the polysaccharide to a carrier such as diphtheria CRM_{197} protein or to tetanus toxoid protein increases the immunogenicity.

In the UK, primary immunisation is recommended during infancy whereas in the USA routine immunisation is recommended during adolescence or for those at increased risk for meningococcal disease from 2 to 10 years of age. In the UK, a conjugate meningococcal C vaccine is used and is generally given by intramuscular injection with the subcutaneous route reserved for patients with haemophilia or thrombocytopenia. Infants, starting at 2 months of age, are given 3 doses of 0.5 mL at monthly intervals. If primary immunisation is delayed until 5 months of age then 2 doses, one month apart, are sufficient; children over 1 year of age and adults should be given a single dose only. In the USA, routine immunisation with a single dose, given intramuscularly, of a conjugate tetravalent vaccine from groups A, C, Y, and W135 is performed at 11 to 18 years of age if not previously vaccinated. For discussion of immunisation schedules see under Vaccines, p.2202.

Asplenic persons or those who have terminal complement component deficiencies are at higher than normal risk of acquiring meningococcal infection and therefore they should be immunised. Either a conjugate meningococcal C vaccine or a tetravalent vaccine (A, C, Y, and W135, unconjugated or conjugated) may be used depending on availability.

Meningococcal vaccines are also indicated in persons travelling to countries where the risk of infection is high. They should receive a tetravalent meningococcal polysaccharide vaccine (either unconjugated or conjugated) rather than the group C conjugate vaccine, and should be immunised even if they have already received the latter. Vaccination is indicated particularly for visits of 1 month or more and for those backpacking or living or working with local residents. Vaccination is a visa requirement for Hajj pilgrims to Saudi Arabia.

Meningococcal vaccines may be given as an adjunct to chemoprophylaxis in contacts of persons with meningitis (see p.178).

A meningococcal group B vaccine has been developed in New Zealand and contains outer membrane vesicles from *N. meningitidis* group B strain NZ 98/254. It is given for primary immunisation against the New Zealand strain (P1.7-b,4* PorA protein) of group B meningococcal disease. Adults and children over 6 months old are given three doses of 0.5 mL at intervals of 6 weeks intramuscularly; infants less than 6 months old should be given 4 doses, at 6 weeks, 3 months, 5 months, and 10 months of age. Vaccines against other group B meningococci are under investigation (see below).

◊ Reviews.

1. Ruggeberg J, Heath PT. Safety and efficacy of meningococcal group C conjugate vaccines. *Expert Opin Drug Saf* 2003; **2:** 7–19.

Vaccine development. Despite the established use of vaccines against meningococcal groups A, C, W135, and Y, about 60 to 80% of meningococcal infections (p.179) in the UK and the USA are caused by *Neisseria meningitidis* of group B serotype. Unfortunately the purified group B polysaccharide is only poorly immunogenic, even after conjugation with proteins but several avenues of research are being followed in the development of an effective vaccine. These include vaccines based on other outer membrane proteins contained in outer membrane vesicles, in particular the most important outer membrane proteins, PorA, and on lipopolysaccharide derivatives. More recently, group B meningococcal vaccine based on PorA has been developed in New Zealand (see above) and is available for primary immunisation against the New Zealand strain specifically, and has resulted in a marked reduction in incidence in that country. Recombinant technology has been used in the Netherlands to develop both a monovalent PorA vaccine and a hexavalent vaccine containing 6 PorA proteins, including that of the New Zealand strain. Results obtained with the New Zealand PorA antigen in the hexavalent formulation have been poor, but it has been shown to stimulate a satisfactory immune response in infants or small children in the monovalent form. The successful sequencing of the meningococcal genome has allowed discovery of several new proteins and raised potential for the development of new candidate vaccines, including novel surface-located vaccine candidates which are currently in preclinical evaluation.

An intranasal meningococcal group B vaccine is also under development.

Mumps Immunoglobulins

Inmunoglobulinas contra la parotiditis.

ATC — J06BB15.

Profile

Preparations containing antibodies against mumps virus have been used in some countries for passive immunisation against mumps.

Mumps Vaccines

Vacunas de la parotiditis.

ATC — J07BE01.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Mumps Vaccine (Live); Vaccinum Parotitidis Vivum). A freeze-dried preparation containing a suitable live attenuated strain of mumps virus (*Paramyxovirus parotitidis*) grown in cultures of human diploid cells or chick-embryo cells or the amniotic cavity of chick embryos. It is prepared immediately before use by reconstitution from the dried vaccine. The cell-culture medium may contain the lowest effective concentration of a suitable antibacterial. The virus concentration is not less than 3.7 log $CCID_{50}$ per dose. The dried vaccine should be stored at 2° to 8° and be protected from light.

The BP 2008 states that Mumps may be used on the label.

USP 31 (Mumps Virus Vaccine Live). A bacterially sterile preparation of a suitable strain of mumps virus grown in cultures of chick-embryo cells. It contains not less than the equivalent of 5×10^3 $TCID_{50}$ in each immunising dose. It may contain suitable antimicrobial agents. It should be stored at 2° to 8° and be protected from light.

Adverse Effects and Precautions

As for vaccines in general, p.2201.

Parotid swelling may occur. Unilateral nerve deafness, aseptic meningitis, and encephalitis have occurred rarely (see below for further discussion).

Mumps vaccines are not generally recommended for children below the age of 1 year in whom maternal antibodies might prevent a response.

Effects on hearing. For a report of sensorineural hearing loss following measles, mumps, and rubella vaccination, see p.2223.

Effects on the nervous system. There have been a few reports of neurological reactions including meningitis and encephalitis after vaccination with measles, mumps, and rubella vaccines. These reactions have been attributed to the mumps component. However, it has not been possible to isolate the virus from the CSF in every case and identify it as either the vaccine strain or a wild-type strain. Meningitis develops up to 35 days after immunisation, is mild, and sequelae are rare.[1,2] One study[3] found the incidence of virus-positive post-immunisation meningitis from the Urabe strain of mumps vaccine to be about 1 in 11 000 immunised children, with the incidence following Jeryl Lynn mumps vaccine being much lower. This result was supported by the incidence of about 1 in 4000 in another study,[4] making it less likely that this was a chance result, and much higher than the estimates of up to 1 in 1 million reported previously.[5] Subsequent research[6] identified the Urabe vaccine strain in CSF samples from all of 20 children with post-vaccination meningitis in the UK, and no isolates of the Jeryl Lynn strain in patients with meningitis among 80 samples tested. Thus, vaccines containing the Urabe strain, including combined measles, mumps, and rubella vaccines are no longer used in the UK and some other countries.[7] A relatively high incidence of meningitis of about 1 in 1000 has also occurred after use of a measles and mumps vaccine prepared from the Leningrad-3 strain of mumps virus.[8,9]

Encephalitis has been associated with mumps vaccination less frequently than meningitis, but may be more serious.[1] The Advisory Committee on Immunization Practices in the USA has reported that the incidence of encephalitis within 30 days of receiving a mumps-containing vaccine is 0.4 per one million doses.[10] This is no higher than the observed background incidence for CNS dysfunction in the general population.

In considering the above data it should be remembered that mumps is the most common cause of meningoencephalitis in children under 15 years of age in the UK and an important cause of permanent sensorineural deafness in childhood.[1] Meningitis after natural mumps infection is estimated to occur in 1 in 400 cases, an incidence that is very considerably above any reported with vaccination.

10. Immunization Practices Advisory Committee. Mumps prevention. *MMWR* 1989; **38:** 388–400.

Interactions

As for vaccines in general, p.2202.

Uses and Administration

Mumps vaccines are used for active immunisation against mumps.

For primary immunisation a combined measles, mumps, and rubella vaccine (p.2223) is usually used. For discussion of immunisation schedules, see under Vaccines, p.2202.

Many different attenuated strains of mumps virus have been used in vaccines and those commonly used have included Jeryl Lynn, Urabe, Leningrad-3 (and adapted L-Zagreb), and Rubini strains. Efficacy seems to be broadly similar for these strains with the exception of Rubini which is reported to be less effective than Jeryl Lynn or Urabe.

A vaccine prepared from the Jeryl Lynn (B level) strain of mumps virus is available in the USA, and may be given in a dose of 0.5 mL by subcutaneous injection although combined vaccines are usually preferred.

Mycobacterium Vaccae Vaccines

SRL-172; Vacunas de Mycobacterium vaccae.

Profile

Vaccines containing *Mycobacterium vaccae* are under investigation for the prevention and immunotherapy of tuberculosis and other mycobacterial infections. They are also being studied for therapeutic use in asthma, eczema, psoriasis, and some malignant neoplasms.

Asthma. Heat-killed *Mycobacterium vaccae* is a potent down-regulator of T-helper 2 cytokines which play a central role in asthma. In a double-blind, randomised, placebo-controlled study[1] in 24 asthmatic men, a bronchial allergen challenge was given 2 weeks before and 3 weeks after a single intradermal injection of *Mycobacterium vaccae* vaccine. The maximum fall in FEV_1 during the allergic response to the latter challenge was reduced by a mean of 34%, but this was not statistically significant compared with placebo.

1. Camporota L, *et al.* The effects of Mycobacterium vaccae on allergen-induced airway responses in atopic asthma. *Eur Respir J* 2003; **21:** 287–93.

Eczema. In a double-blind, randomised, placebo-controlled study[1] in 41 children aged 5 to 18 years with moderate to severe atopic dermatitis, an intradermal injection of *Mycobacterium vaccae* vaccine resulted in a 48% reduction in the surface area of the skin affected after 3 months compared with 4% in those given placebo. In a later study[2] in 56 children aged 2 to 6 years, these results could not be replicated because the reduction in affected area was not found to be significantly different from placebo.

1. Arkwright PD, David TJ. Intradermal administration of a killed Mycobacterium vaccae suspension (SRL 172) is associated with improvement in atopic dermatitis in children with moderate-to-severe disease. *J Allergy Clin Immunol* 2001; **107:** 531–4.
2. Arkwright PD, David TJ. Effect of Mycobacterium vaccae on atopic dermatitis in children of different ages. *Br J Dermatol* 2003; **149:** 1029–34.

Malignant neoplasms. *Mycobacterium vaccae* vaccines have been used with limited success as adjunctive therapy in the management of a variety of cancers, notably prostate cancer, malignant melanoma, and non-small-cell lung cancer. In a preliminary study[1] 28 patients with inoperable non-small-cell lung cancer and mesothelioma were randomised to receive chemotherapy either with or without adjunctive intradermal injection of a heat-killed *Mycobacterium vaccae* vaccine (SRL-172). A trend towards improved response rate was found in those patients receiving combined therapy, together with improved median survival and 1-year survival rates; some patients given combined therapy were subsequently able to receive curative surgery or radical radiotherapy. A similar subsequent phase III study[2] in 419 patients found a significant improvement in patient quality of life after combined therapy, but the improvements in survival-time could not be replicated. Secondary analyses of these results[3] suggested an improvement in survival time for patients with adenocarcinoma, but not for those with squamous cell carcinoma. There is also some evidence of beneficial effect in patients with metastatic renal cell carcinoma.[4]

Psoriasis. Preliminary studies have shown that heat-killed *Mycobacterium vaccae* vaccines may induce periods of remission when given intradermally. An open-label study[1] in 24 patients given 2 intradermal injections into lesion-free deltoid skin at a 3-week interval found, 12 weeks after starting treatment: marked improvement (14 patients), moderate improvement (2), no change (6), and worsening of symptoms (2). By 24 weeks, 11 of 22 patients continued to show a greater than 50% improvement and of these 5 had complete clearance of skin lesions lasting for 6 months or more. In another study,[2] a more potent heat-killed, delipidated, deglycolipidated vaccine was given similarly to 20 patients with moderate to severe psoriasis; after 12 weeks, 13 of the 20 patients showed a marked improvement, 3 were unchanged, 3 had worsened, and 1 withdrawn due to an exfoliative flare. At 24 weeks, 13 of 19 patients continued to show a greater than 50% improvement, and in some this lasted for 6 months or more. A double-blind, randomised, placebo-controlled study[3] with the latter vaccine in 36 patients with psoriatic arthritis found no improvement in psoriatic lesions compared with placebo, although there did appear to be some improvement in pain experienced.

Normal Immunoglobulins

Inmunoglobulinas inespecíficas.

ATC — J06BA01; J06BA02.

Pharmacopoeias. Many pharmacopoeias, including *Eur.* (see p.vii) and *US*, have monographs.

Ph. Eur. 6.2 (Human Normal Immunoglobulin; Immunoglobulinum Humanum Normale). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG) antibodies, of normal subjects. Other proteins may be present; it contains not less than 10% and not more than 18% of total protein. It is intended for intramuscular or subcutaneous injection. It is obtained from the pooled plasma collected from at least 1000 donors who must be healthy, must not have been treated with substances of human pituitary origin, and as far as can be ascertained be free from detectable agents of infection transmissible by transfusion of blood or blood components. No antibacterial is added to the plasma used. It is prepared as a stabilised solution and passed through a bacteria-retentive filter. Multidose, but not single dose, preparations contain an antimicrobial preservative. The pH of a solution in sodium chloride 0.9% containing 1% of protein is 5.0 to 7.2. The liquid preparation should be stored, protected from light, in a sealed, colourless, glass container. The freeze-dried preparation should be stored, protected from light, in an airtight, colourless, glass container.

Ph. Eur. 6.2 (Human Normal Immunoglobulin for Intravenous Administration; Immunoglobulinum Humanum Normale ad Usum Intravenosum). A liquid or freeze-dried preparation containing immunoglobulins, mainly immunoglobulin G (IgG); other proteins may be present and the total protein content is not less than 3%. It contains IgG antibodies of normal subjects; the standard does not apply to products intentionally prepared to contain fragments or chemically modified IgG. It is prepared as a stabilised solution and passed through a bacteria-retentive filter. It does not contain an antimicrobial preservative. The pH of a solution in sodium chloride 0.9% containing 1% of protein is 4.0 to 7.4. Storage requirements are similar to those for Human Normal Immunoglobulin, except that the freeze-dried preparation is stored in an airtight container at a temperature not exceeding 25°.

USP 31 (Immune Globulin). A sterile solution of globulins that contains many antibodies normally present in human adult blood. It is prepared from pooled material (approximately equal quantities of blood, plasma, serum, or placentas) from not fewer than 1000 donors. It contains 15 to 18% of protein, of which not less than 90% is gamma globulin. It is intended for intramuscular injection. It contains glycine as a stabiliser, and a suitable preservative. It contains antibodies against diphtheria, measles, and poliomyelitis. It should be stored at 2° to 8°.

Adverse Effects and Precautions

As for immunoglobulins in general, p.2201. Intravenous immunoglobulin preparations should be used with caution in patients with renal impairment. Immunoglobulin products containing sucrose may be associated with an increased risk of inducing acute renal failure (see Effects on the Kidneys, below).

Antibody titres for some common pathogens can vary widely not only between products from different manufacturers, but also from lot to lot. Formulations of intravenous immunoglobulins should therefore not be regarded as equivalent.

Effects on the blood. Adverse effects on the blood have occasionally been reported after intravenous use of normal immunoglobulin to increase the platelet count in patients with idiopathic thrombocytopenic purpura and in the management of other auto-immune diseases. Reduced platelet adhesiveness with multiple subcutaneous haematomas occurred in one patient.[1] Thrombotic events have occurred after intravenous use,[2-4] particularly in elderly subjects (sometimes fatal) suggesting that a rising platelet count during normal immunoglobulin treatment may represent a risk in patients with severe atherosclerotic disease.[2] However, a review of 34 patients over 60 years of age treated with normal immunoglobulin could not confirm the association.[5]

Haemolytic reactions, including a case of haemolytic disease of the newborn, have sometimes been noted[6,7] and passive transfer of anti-A, anti-B, or anti-D antibodies or active immunisation by blood group substances from normal immunoglobulin preparations has been implicated. It has been suggested[7] that blood phenotyping be carried out before treatment with normal immunoglobulin is started.

Transient neutropenia has occurred after use of normal immunoglobulin in patients with thrombocytopenic purpura, but the clinical significance of this effect has been disputed.[8-10]

Effects on the kidneys. There have been occasional case reports of renal failure or impairment associated with the use of intravenous normal immunoglobulin.[1,2] The incidence of renal failure appears to be greatest with immunoglobulin products containing sucrose.[1,3] The FDA in the USA had issued a warning alerting physicians to the potential risks of acute renal failure associated with intravenous use of normal immunoglobulin products, particularly those containing sucrose.[4]

Effects on the nervous system. Aseptic meningitis has been reported after intravenous use of normal immunoglobulin.[1-5]

Migraine, associated with intravenous immunoglobulin therapy in a patient on 2 occasions, did not recur after prophylaxis with propranolol was started.[6]

Hemiplegia has been reported in a 4-year-old child given intravenous immunoglobulin for immune thrombocytopenic purpura.[7]

Effects on the skin. Diffuse alopecia has been reported[1] in 3 women within 1 to 4 weeks of treatment with intravenous normal immunoglobulin. There have been reports[2,3] of severe and extensive eczema in elderly patients up to 3 weeks after receiving normal immunoglobulin intravenously. There has also been a report of cutaneous vasculitic rash on the face of a woman receiving intravenous normal immunoglobulin.[4] Severe cutaneous vasculitis has been reported in a patient who received intravenous normal immunoglobulin for type II mixed cryoglobulinaemia.[5] An erythematous eruption occurred on the hands and feet of a patient 3 days after completing a 5-day treatment course of normal immunoglobulin for chronic inflammatory demyelinating polyneuropathy;[6] the lesions resolved 2 to 3 weeks after completion of therapy. A similar eruption had occurred following normal immunoglobulin therapy in 5 previous occasions.

For mention of a patient with AIDS who developed erythema characteristic of fifth disease following intravenous normal immunoglobulin, see Infection, below.

Hypersensitivity. Hypersensitivity reactions may occasionally occur after intramuscular or intravenous use of normal immunoglobulins particularly in hypogammaglobulinaemic or agammaglobulinaemic patients. Both immediate and late[1] reactions have occurred.

The IgA content of normal immunoglobulins can result in the development of IgE and IgG anti-IgA antibodies in immunodeficient patients with IgA deficiency. It has been suggested by some[2] that the IgE anti-IgA antibodies are responsible for anaphylaxis although others have disagreed.[3] Two patients who had reactions to conventional normal immunoglobulin preparations tolerated preparations with a low content of IgA.[2] Some manufacturers of normal immunoglobulin preparations recommend that they should not be used in patients with selective IgA deficiencies who have known antibody against IgA.

The IgE content of some preparations has also been suggested as a cause of hypersensitivity reactions[4] although this has been disputed.[5] Complement-activating IgG aggregates may also be involved although the anticomplementary activity of the products does not appear to be related to the incidence of adverse effects.[5]

Infection. An association between use of certain intravenous immunoglobulin preparations and hepatitis C infections led to changes in manufacturing procedures and withdrawal of the affected products from the market.[1-3]

In addition, there has been a report[4] of a patient with AIDS who developed fifth disease (erythema infectiosum) after intravenous normal immunoglobulin treatment for infection with parvovirus. Paradoxically, there has also been a report[5] of life-threatening parvovirus B19 infection, resulting in pure red-cell aplasia and aggravation of hepatitis and fulminant disease, from the use of normal immunoglobulin to treat a patient with existing hepatic dysfunction caused by coxsackie B4 virus infection.

Interactions

Normal immunoglobulin may interfere with the immune response to live viral vaccines. Such vaccines should therefore be given at least 3 weeks before, or 3 months after, normal immunoglobulin. This does not apply to yellow fever vaccine for immunoglobulins prepared in the UK, nor for booster doses of oral poliomyelitis vaccines. Where such an interval is impractical for immunisation preceding foreign travel it may have to be ignored.

Poliomyelitis vaccine. For a study indicating that normal immunoglobulin has no effect on the antibody response to oral poliomyelitis vaccine, see p.2233.

Uses and Administration

Normal immunoglobulin is available as two distinct preparations and formulations. One type of injection (Human Normal Immunoglobulin (Ph. Eur. 6.2) and Immune Globulin (USP 31)) generally containing 16% of protein is used for passive immunisation, and sometimes also for primary antibody deficiencies, and should only be given intramuscularly. The second type of preparation is formulated for intravenous use (Human Normal Immunoglobulin for Intravenous Administration (Ph. Eur. 6.2)) and is used in disorders such as primary antibody deficiencies and idiopathic thrombocytopenic purpura; solutions generally contain about 3 to 6% of protein, although some may contain up to 12%.

Doses of normal immunoglobulin often appear confusing, being expressed variously in terms of weight (protein or immunoglobulin G content) or in terms of volume to be given, and the two do not always appear to correspond. It should be remembered that there may be differences between intravenous preparations of normal immunoglobulin including differing IgA content and IgG subclass distribution.

Normal immunoglobulin, being derived from the pooled plasma of blood donors, contains antibodies to bacteria and viruses currently prevalent in the general population; in the UK, and also in some other countries, typical antibodies present include those against hepatitis A, measles, mumps, rubella, and varicella. Normal immunoglobulin therefore may be used to provide passive immunisation against such diseases.

Normal immunoglobulin may be used to control outbreaks of **hepatitis A**, the recommended intramuscular dose for close contacts being 250 mg in those under 10 years of age and 500 mg in older children and adults. It may also be used for prophylaxis against hepatitis A in immunocompromised patients if their response to hepatitis A vaccine is unlikely to be adequate.

Normal immunoglobulin may be used to prevent or possibly modify an attack of **measles** in children and adults at special risk (such as those who are immunocompromised) but should be given as soon as possible after contact with measles. In the UK recommended doses, given intramuscularly, for the prevention of an attack are 250 mg for those under 1 year of age, 500 mg for those aged 1 to 2 years, and 750 mg for those aged 3 years and over; to modify an attack, recommended doses are 100 mg for those under 1 year of age and 250 mg for older children.

Normal immunoglobulin does not prevent **rubella** infection and is not recommended for the protection of pregnant women exposed to rubella; it should only be considered where termination of pregnancy is unacceptable. The dose is 750 mg by intramuscular injection.

Normal immunoglobulin may be used in the management of patients with **primary antibody deficiencies** such as congenital agammaglobulinaemia, hypogammaglobulinaemia, or **immunocompromised patients** including those with immunodeficiency syndromes; the immunoglobulin is given to provide protection against infectious diseases that such patients may suffer. The intramuscular preparation has been used but the intravenous route is usually preferred as it is less painful for the doses required. Alternatively, the subcutaneous route may be used. For intravenous infusion the dose, expressed in terms of weight (protein or immunoglobulin G content), is usually 400 to 800 mg/kg initially, then 200 mg/kg every 3 weeks adjusted as necessary according to trough-immunoglobulin concentrations; the maintenance dose is usually 200 to 800 mg/kg per month. In patients with secondary immunodeficiency syndromes, doses of 200 to 400 mg/kg every 3 to 4 weeks have been recommended. Other dosage regimens have been used. Subcutaneous doses are 200 to 500 mg/kg as an initial loading dose (divided over several days), followed by maintenance doses at repeated intervals to achieve a cumulative monthly dose of 400 to 800 mg/kg. When infused intravenously, normal immunoglobulin should always be given very carefully and slowly with gradual increases in the rate of infusion.

For prophylaxis of infection after **bone marrow transplantation**, normal immunoglobulin is given intravenously in a dose of 500 mg/kg weekly, adjusted according to response.

Intravenous infusion of normal immunoglobulin is also used to raise the platelet count in patients with **idiopathic thrombocytopenic purpura**. Doses of 400 mg/kg are given daily for 2 to 5 consecutive days. Alternatively, a dose of 800 to 1000 mg/kg may be given on day 1 and repeated on day 3 if necessary. Further doses may be given as necessary.

For **Kawasaki disease**, normal immunoglobulin (used with aspirin) is given intravenously in a dose of 1.6 to 2 g/kg in divided doses over 2 to 5 days, or 2 g/kg given as a single dose. Similar doses of intravenous normal immunoglobulin have been tried in a range of disorders believed to have an auto-immune origin. The precise mode of action of normal immunoglobulin in such disorders is unknown.

For the treatment of **Guillain-Barré syndrome**, normal immunoglobulin is given intravenously in a dose of 400 mg/kg for 5 consecutive days, repeated every 4 weeks if required.

Administration. Oral dosage with normal immunoglobulins has been proposed to reduce the incidence and severity of gastrointestinal infections, particularly in patients with defective immune systems including neonates. Although the main immunoglobulin secreted into the gastrointestinal tract in subjects with a normal immune system is IgA, which is not present in large quantities in commercial normal immunoglobulins, beneficial responses, especially in viral infections, have been reported after oral use. Systematic reviews have not, however, supported routine use of oral immunoglobulin for the prevention or treatment of gastrointestinal infections.[1-3] Preparations of immunoglobulin A are available in some countries and have been tried, mainly in bacterial gastrointestinal infections.[4,5]

Blood disorders. Intravenous normal immunoglobulins are used in the treatment of symptomatic severe acute and chronic idiopathic thrombocytopenic purpura (p.1505). Other blood disorders in which normal immunoglobulins have been tried include agranulocytosis[1] and haemolytic disease of the newborn (p.2204), haemolytic anaemias (p.1043), red cell aplasia caused by parvovirus B19 infections (see under Passive Immunisation, below), thrombotic thrombocytopenic purpura and haemolytic-uraemic syndrome (see Thrombotic Microangiopathies p.1076), and thrombocytopenia with a variety of causes.[2-10]

Epilepsy. Normal immunoglobulins have sometimes been of benefit[1-3] in the treatment of children with intractable epilepsy, including Lennox-Gastaut syndrome or West's syndrome, but a review of the literature found that few well controlled studies had been conducted,[4] and a Canadian evidence-based guideline recommended against its use.[5] Although a positive trend in favour of intravenous immunoglobulin therapy for refractory epilepsy was noted in one double-blind controlled study[6] involving 61 patients, the results were not considered to be statistically significant.

Hypogammaglobulinaemia. See under Primary Antibody Deficiency, below.

Immunocompromised patients. Immunodeficiency states may arise from primary disorders of the immune system, or, more commonly, they are secondary to immunosuppressive therapy, HIV infection, or haematological malignancies. Premature neonates may have deficits in their immune systems due to their immaturity; placental transfer of maternal antibodies usually occurs after about 32 weeks of gestation. Such patients and neonates may be deficient in gammaglobulins and they could potentially benefit from the use of normal immunoglobulins to address their increased susceptibility to infection. For information on the use of immunoglobulins in specific conditions, see the following sections and under Neonatal Infection, below.

BONE MARROW TRANSPLANTATION. Normal immunoglobulin is used in patients undergoing allogeneic bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p.1811) with the aim of decreasing the incidence of bacterial and of symptomatic CMV infection, and that of graft-versus-host disease. Prophylaxis and treatment of CMV infection and prophylaxis of graft-versus-host disease are the indications with most clinical support, although there have been few prospective, randomised, controlled studies and these have had small or heterogeneous populations and varying end-points.[1] Overall survival[2] or overall incidence of CMV infection[2,3] has not decreased. A combination of normal immunoglobulin and ganciclovir appears to improve the outcome of CMV pneumonia subsequent to bone marrow transplantation.[4] However, no patients treated with normal immunoglobulin alone survived and ganciclovir monotherapy may be equally effective, thus casting some doubt on the effectiveness of normal immunoglobulin.[1] Cytomegalovirus immunoglobulins (p.2208) may be more appropriate for the specific prophylaxis and treatment of CMV infections.

Intravenous immunoglobulin therapy has been found to be ineffective in preventing infections in patients receiving autologous bone marrow transplants[5] and may have contributed to an increased incidence of fatal hepatic veno-occlusive disease.

Normal immunoglobulin has been associated with a reduced frequency of acute graft-versus-host disease,[2] possibly as a result of a direct immunomodulatory effect, but this has only been found in one study, and there are no studies showing efficacy of normal immunoglobulin in chronic graft-versus-host disease.[1] Furthermore, there is some suggestion that extended use of normal immunoglobulin for graft-versus-host disease prevention may impair recovery of humoral immunity.[1] Overall, the role of normal immunoglobulin for graft-versus-host disease has yet to be clearly defined.

MALIGNANCIES. Hypogammaglobulinaemia and the effects of treatment may increase the susceptibility to infection of patients with *chronic lymphocytic leukaemia*.[1] In a study[2] of 81 patients with chronic lymphocytic leukaemia considered to be at an increased risk of infection, intravenous normal immunoglobulin 400 mg/kg given every 3 weeks for one year reduced the incidence of bacterial infection compared with saline placebo. The incidence of viral and fungal infections was not affected. A study in 34 patients[3] suggested that a dose of normal immunoglobulin 250 mg/kg per month was adequate for routine prophylaxis in most patients. Beneficial effects on infection rates have been reported in patients with *multiple myeloma* receiving normal immunoglobulins.[4]

PRIMARY ANTIBODY DEFICIENCY. There are 3 major forms of primary antibody deficiency: X-linked agammaglobulinaemia (XLA, Bruton's agammaglobulinaemia), common variable immunodeficiency (CVID) which includes IgG subclass and specific antibody deficiencies, and selective IgA deficiency. The disease is characterised by a wide range of infective complications as well as auto-immune disorders. Management is by replacement therapy with normal immunoglobulin accompanied by appropriate antimicrobial therapy for breakthrough infections.[1-4] Immunisation against infection is of no value and is contra-indicated for live viral vaccines.

Normal immunoglobulin was traditionally given by the intramuscular route. However, the maximum dose that could be reasonably given by this route was 25 mg/kg weekly, and it was therefore only satisfactory for patients with mild disease.[5] The introduction of intravenous preparations of normal immunoglobulin allowed high doses to be used in those with severe disease. This route should therefore be used for all patients with XLA and for patients with CVID who have more than mild disease.[1] The use of intravenous normal immunoglobulin in IgG subclass deficiency, with or without IgA deficiency, or in specific antibody deficiency is successful, though less well established. The dose and frequency of administration of intravenous normal immunoglobulin is variable and should be adjusted to prevent breakthrough infection. Most patients require 200 to 600 mg/kg every 2 or 3 weeks to maintain optimum protection.[5] In one study,[6] doses of between 260 and 1120 mg/kg every 3 weeks were necessary to maintain residual serum IgG concentrations above 500 mg/dL. These doses were found to be effective in reducing the incidence of severe acute bacterial infections and pulmonary insufficiency in children with XLA. Surgical procedures should be covered with additional normal immunoglobulin and appropriate prophylactic antibacterials. Home treatment with intravenous normal immunoglobulin has been used successfully in several countries in both adults and children.[5,7-10] Adverse reactions have been few and generally mild.[5,8,9] They are most likely to occur during the first infusion and during intercurrent illness, and may be precipitated by a high infusion rate.[10] Long-term treatment of children with antibody deficiencies with intravenous normal immunoglobulin has been shown to lead to normal growth and similar rates of infection to those found in non-immunodeficient children.[11]

Immunoglobulin replacement can alternatively be given by subcutaneous infusion as an alternative to intravenous therapy.[2,4,12,13] The intraventricular route has been of benefit in some patients with echovirus encephalitis.[5,14]

Kawasaki disease. Kawasaki disease, also known as mucocutaneous lymph node syndrome of childhood, occurs mainly in children under 5 years of age. It is epidemic and endemic worldwide but is a particular problem in Japan. Kawasaki disease presents with high fever which persists for at least 5 days and may be followed by bilateral conjunctivitis, changes in the oropharyngeal mucosa, signs of vasculitis in the extremities, rash, and cervical lymphadenopathy. The major complications of Kawasaki disease are cardiac effects including coronary artery aneurysm, aortic or mitral incompetence, myocarditis, and pericarditis with effusion. The cause of the disease is unknown, although an infective aetiology has been suggested. Early diagnosis, expert cardiac assessment, and immediate treatment are essential for improved outcome.

Treatment aims to reduce inflammation, particularly in the coronary arterial wall and myocardium, and therefore prevent the development of cardiac complications. Long-term antiplatelet treatment is given as necessary to prevent coronary thrombosis.

Initial treatment is with aspirin and normal immunoglobulin.[1,2] Despite the anti-inflammatory and antiplatelet properties of aspirin it does not appear to lower the incidence of coronary abnormalities in Kawasaki disease when used alone; however, high-dose aspirin and normal immunoglobulin appear to possess an additive anti-inflammatory effect when used together and a decreased incidence of coronary-artery abnormalities has been found after such a combination as compared with aspirin alone. Treatment should begin if possible within 10, and preferably within 7, days of the onset of illness. Treatment before day 5 appears to offer no advantage in preventing cardiac sequelae than treating from days 5 to 7, but it may be associated with an increased need for re-treatment with normal immunoglobulin. Treatment should be given to children presenting after the tenth day of illness if they have either persistent unexplained fever or aneurysms with ongoing systemic inflammation.[2]

Normal immunoglobulin has been given by intravenous infusion in divided doses over 2 to 5 days, but high-dose administration as a single dose is now recommended; a meta-analysis[3] and a systematic review[4] have concluded that single-dose therapy is associated with a lower incidence of coronary abnormalities after 30 days than multiple-dose treatment. The optimum dosage and duration of treatment with aspirin is not yet established, but the usual practice is to use an anti-inflammatory regimen until the fever has settled and then to convert to an antithrombotic regimen. A few patients fail to respond to treatment with aspirin and normal immunoglobulin. A small study[5] suggested that re-treatment with normal immunoglobulin may be considered for those with persistent or recurring fever.

The use of corticosteroids remains controversial.[1] They have been given in some centres[6] but since the introduction of immunoglobulin therapy they have not been routinely used as there is a risk that they may exacerbate coronary artery aneurysms. Nevertheless, their use has received renewed attention; randomised studies comparing the adjunctive use of corticosteroids with standard therapy alone have suggested they may be of benefit.[7,8] Alternative suggested drugs for patients refractory to normal immunoglobulin include ulinastatin,[9] which has been used for adjunctive therapy in Japan, but its effectiveness remains currently unproven. Abciximab has been used to treat patients with large coronary aneurysms; in one study,[10] patients given abciximab in addition to standard therapy showed a greater regression in aneurysm diameter. Other treatments under investigation include infliximab[11] in patients unresponsive to initial normal immunoglobulin and the use of cyclophosphamide with corticosteroids in particularly refractory cases.[2]

Long-term management. Aspirin should be continued for 6 to 8 weeks after the onset of illness and then stopped if there are no coronary abnormalities.[1,2] Some practitioners use aspirin and dipyridamole as antithrombotic therapy although it is not known whether this provides benefit over aspirin alone. Dipyridamole may be used as an alternative antithrombotic agent for patients who cannot tolerate aspirin. Aspirin is usually continued for at least one year if coronary abnormalities are present and should be continued indefinitely if coronary aneurysms persist. Anticoagulation with warfarin or heparin in addition to aspirin may be necessary in some patients such as those with giant or multiple aneurysms.

Kidney disorders. Treatment with normal immunoglobulin has been of benefit in some patients with haemolytic-uraemic syndrome and in those with lupus nephritis (see under Musculoskeletal and Nerve Disorders, below). For mention of the use of normal immunoglobulin in IgA nephropathy, see Glomerular Kidney Disease, p.1504.

Musculoskeletal and nerve disorders. High-dose intravenous normal immunoglobulin has been tried with some benefit in various disorders of the nerves, muscles, joints, and connective tissues which may have an auto-immune basis.[1] These include multiple sclerosis,[2-4] chronic inflammatory demyelinating polyneuropathy,[5,6] polymyositis and dermatomyositis,[7-12] myasthenia gravis,[13-17] stiff-man syndrome,[18-22] chronic systemic juvenile arthritis,[23-25] SLE[26] including lupus nephritis,[27] Guillain-Barré syndrome (see below), and motor neurone disease (see also below). Guidelines issued by an expert committee in Canada[28] included recommendations on the use and dose of normal immunoglobulin for acute disseminated encephalomyelitis, chronic inflammatory demyelinating polyneuropathy, dermatomyositis and polymyositis, Guillain-Barré syndrome, Lambert-Eaton myasthenic syndrome and myasthenia gravis, multifocal motor neuropathy, multiple sclerosis, opsoclonus-myoclonus, neuropsychiatric disorders associated with streptococcal infections in children, short-term management of Rasmussen's encephalitis, and stiff man syndrome.

GUILLAIN-BARRÉ SYNDROME. Guillain-Barré syndrome[1] (acute idiopathic inflammatory polyneuropathy; acute idiopathic demyelinating neuropathy; acute infectious polyneuropathy) may follow an infection or, more rarely, immunisation, but very often no predisposing factor can be identified. An association with infection with *Campylobacter jejuni* has been suggested,[2] but the syndrome is also commonly associated with infection with CMV, Epstein-Barr virus, and *Mycoplasma pneumoniae*.[1] Reversible demyelination results in pain and progressive flaccid paralysis. An auto-immune aetiology seems likely. Severely affected patients require cardiovascular monitoring and respiratory support if respiratory muscles are affected or autonomic instability is present. Corticosteroids have been given but are generally considered to be of little value[3] (see Polyneuropathies, p.1511). Plasma exchange (see p.1076) is effective if given early,[4] but is not universally available and is not suitable for all patients. A systematic review[5] has concluded that use of normal immunoglobulins is at least as effective as plasma exchange, but that there is no advantage from combining the two forms of treatment. Deterioration has also been noted in some patients after immunoglobulin therapy,[6,7] although one study[8] found that the incidence of relapse was greater after plasma exchange than after normal immunoglobulin.

MOTOR NEURONE DISEASE. Several studies and a systematic review have shown normal immunoglobulins to be of benefit in the treatment of multifocal motor neuropathy, a form of motor neurone disease (p.2380) associated with anti-GM_1 antibody formation.[1-7] In most patients, however, improvement has to be maintained with periodic infusion and some become less responsive to therapy over time, requiring higher doses. A retrospective study[8] of 10 patients with multifocal motor neuropathy treated with normal immunoglobulins showed that while the initial response could be maintained for several years, efficacy decreased during prolonged treatment even when doses were progressively adjusted. During the first few years of therapy, increased dosage restored the effectiveness of normal immunoglobulins, but was found to be less able to do so later in follow up.

Neonatal disorders. ***HAEMOLYTIC DISEASE OF THE NEWBORN.*** For a discussion of haemolytic disease of the newborn and its management, including the use of intravenous immunoglobulin as an alternative to exchange transfusions in affected pregnancies, see p.2204.

NEONATAL INFECTION. Sepsis is a serious problem in premature infants despite appropriate antimicrobial therapy. Preterm infants are born with low serum-immunoglobulin concentrations which decrease over the next several weeks of life. There is also a deficiency of antibodies to specific organisms such as group B streptococci, *Staphylococcus epidermidis*, and *Escherichia coli*.

Some, but not all, studies suggest that prophylactic use of intravenous normal immunoglobulin in premature infants shortly after birth can decrease the incidence of septicaemia.[1] Aspects of the methodology of these studies have, however, been criticised[2] and a systematic review[3] concluded that prophylactic use of intravenous immunoglobulin for prevention of infection in preterm or low birth-weight neonates was of at best marginal benefit only, and of no benefit in preventing sepsis, and did not recommend routine use. Some benefit has been seen after use of intravenous immunoglobulin to treat infants with suspected sepsis[1] and it may improve the response to antibacterials,[4] although a further systematic review[5] found insufficient evidence to support routine use in infants with suspected, or subsequently proved, neonatal infection.

The optimum dosage of intravenous immunoglobulin is not established. A prophylactic dose of 500 mg/kg on admission repeated every 1 to 2 weeks has been suggested for units where infection is common in very low birth-weight infants.[1] Others have suggested adjusting the dose to maintain a specified serum-immunoglobulin concentration. Alternatively, normal immunoglobulin could be given only to infants with immunoglobulin concentrations below a certain level, or be reserved for immediate use in those who become ill with suspected sepsis.[1]

Normal immunoglobulin cannot protect against all types of infection. Normal immunoglobulin preparations from different manufacturers may have, for a specific pathogen, differing levels of specific antibody and differing levels of functional activity or there may be lot-to-lot variability in functional activity for normal immunoglobulin from a specific manufacturer. Such variability, resulting in low concentrations of functional antibodies in the 4 batches of immunoglobulins used in the National Institute of Child Health Study,[6] was held responsible for the lack of demonstrable effectiveness of immunoglobulins in that study, one of the largest to date.

Neuropsychiatric disorders. Benefit has been demonstrated from plasma exchange or intravenous immunoglobulin in children with exacerbations of obsessive-compulsive disorder or tic disorders including Tourette's syndrome associated with streptococcal infection.[1] These results suggested that these disorders may respond to immunomodulatory therapy in a subgroup of patients with paediatric auto-immune neuropsychiatric disorders associated with streptococcal infections (PANDAS), believed to be due to cross-reaction of antistreptococcal antibodies with neural tissue. In a double-blind, placebo-controlled study[2] of the use of normal immunoglobulins in 30 patients with tic disorders, despite initial improvement compared with placebo over 8 weeks no significant differences were found in the severity of obsessions and compulsions beyond this time.

Passive immunisation. ***CMV INFECTION.*** See Bone Marrow Transplantation, under Immunocompromised Patients, above.

HEPATITIS C. In a randomised, placebo-controlled study[1] in seronegative sexual partners of patients positive for antibody to hepatitis C, normal immunoglobulin given intramuscularly every 2 months was found to significantly reduce the incidence of subsequent seroconversion. One of 450 subjects who received normal immunoglobulin became seropositive during follow-up compared with 6 of 449 who had received placebo.

PARVOVIRUS B19 INFECTION. Persistent infection with human parvovirus B19 can cause red cell aplasia with resultant anaemia, particularly in immunocompromised patients. Normal immunoglobulins contain antibodies able to neutralise parvovirus B19 and have been used in various groups of infected patients.[1] Resolution of anaemia and clearance of parvovirus B19 from the circulation have been reported after use of normal immunoglobulin in a patient who had had red cell aplasia for 10 years.[2] Normal immunoglobulin was given by intravenous infusion in a dose of 400 mg/kg daily for 10 days and then periodically for several months. Successful treatment of anaemia due to parvovirus B19-induced red cell aplasia with plasmapheresis and intravenous immunoglobulin has been described in a liver transplant recipient.[3] Efficacy has also been found in recipients of other solid-organ transplants including heart, kidney, and lung.[1] Clearance of parvovirus B19 from the circulation has been reported in patients who also have AIDS, but the presence of concomitant opportunistic infections may prevent resolution of the anaemia.[4,5]

Normal immunoglobulin given to patients with parvovirus B19-associated chronic fatigue syndrome has also resulted in clearance of the virus from the circulation and resolution of symptoms.[6,7]

Beneficial responses to intravenous immunoglobulin have also been reported in a few patients with parvovirus B19 infections associated with vasculitic syndromes.[8,9]

TOXIC SHOCK SYNDROME. For a discussion of toxic shock syndrome and its treatment, including reference to clinical improvement after administration of intravenous normal immunoglobulins, see p.196.

Pregnancy. Fetal loss has been attributed in some cases to the presence of antiphospholipid antibodies (lupus anticoagulant and anticardiolipin) in the mother. Successful pregnancy outcome has been reported after use of intravenous normal immunoglobulin during pregnancy to a few such women.[1]

Skin disorders. Normal immunoglobulins have been tried in a few patients with blistering skin diseases.[1-3] The usual treatment for pemphigus and pemphigoid is with systemic corticosteroids; normal immunoglobulins in high doses have produced generally transient improvement when used alone,[4] although corticosteroid-sparing effects have been reported.[5,6] There have been case reports of patients with severe epidermolysis bullosa acquisita responding to therapy with high-dose intravenous immunoglobulins.[7,8] Studies have been conducted into the use of high-dose normal immunoglobulin for the treatment of other blistering conditions including Stevens-Johnson syndrome and toxic epidermal necrolysis.[9] One retrospective analysis[10] of 48 consecutive cases of toxic epidermal necrolysis found a beneficial effect with survival in 42 patients. In contrast, a prospective open study[11] in 34 consecutive patients admitted to hospital with Stevens-Johnson syndrome or toxic epidermal necrolysis suggested that normal immunoglobulin might actually be associated with an increase in mortality. Further retrospective analyses, however, did find a reduction in mortality in 16 consecutive patients admitted with toxic epidermal necrolysis[12] and in 7 children with Stevens-Johnson syndrome.[13] Normal immunoglobulin has also produced benefit in patients with pyoderma gangrenosum.[14-17]

Clinical benefit was noted in 9 of 10 patients with auto-immune chronic urticaria who were given a 5-day course of intravenous immunoglobulins, 2 of whom had prolonged remission over 3 years of follow-up.[18] Benefit has also occurred after intravenous immunoglobulin therapy for atopic dermatitis[19] and psoriasis.[20]
