Somidobove (*BAN*) is synthetic bovine growth hormone.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Somatropin). A protein having the structure (191 amino acid residues) of the major component of growth hormone produced by the human pituitary. A white or almost white powder, containing not less than 2.5 units/mg. Store at 2° to 8° in airtight containers.

Ph. Eur. 6.2 (Somatropin Concentrated Solution). A clear or slightly turbid, colourless solution. It may contain buffer salts and other auxiliary substances. Store at −20° in airtight containers. Avoid repeated freezing and thawing.

USP 31 (Somatropin). A protein hormone consisting of 191 amino acid residues, and its structure corresponds to the major component of the growth hormone extracted from human pituitary glands. It is produced as a lyophilised powder or bulk solution by methods based on recombinant DNA technology. The lyophilised powder contains not less than 910 micrograms of somatropin per mg, calculated on the anhydrous basis. The bulk solution contains not less than 910 micrograms of somatropin per mg of total protein.

Store at −25° to −10° in airtight containers.

Units

4.4 units of human growth hormone (somatropin) are contained in 1.75 mg of freeze-dried purified human growth hormone, with 20 mg of glycine, 2 mg of mannitol, 2 mg of lactose, and 2 mg of sodium bicarbonate, in one ampoule of the first International Standard (1987).

The second International Standard for Somatropin (2000), rDNA-derived human growth hormone, has a defined content of 1.95 mg of protein per ampoule, with a specific activity of 3.0 units/mg. One mg of anhydrous Somatropin USP is equivalent to 3.0 USP Somatropin Units. Commercial preparations vary somewhat in the number of units/mg.

Adverse Effects and Precautions

Antibodies to growth hormone have been formed in some patients but these rarely seem to affect growth. There may be redness, itching, lumps, or lipoatrophy at the site of injection. Transient dose-related fluid retention with peripheral oedema and carpal tunnel syndrome has occurred; headache, muscle and joint pain, paraesthesia, and cases of benign intracranial hypertension have been reported. Although growth hormone has diabetogenic effects, high acute dosage has been associated with hypoglycaemia followed by hyperglycaemia. Growth hormone therapy may further increase the risk of ear disorders and otitis media in patients with Turner's syndrome, who are already at increased risk of ear and hearing disorders.

Growth hormone therapy is contra-indicated in patients with active neoplasms or intracranial lesions and should be stopped if evidence of tumour growth develops. Growth hormones should not be used for growth promotion in patients with closed epiphyses. Patients with scoliosis should be monitored during growth hormone therapy because of the risk of progression of scoliosis that can occur with rapid growth. Because of the diabetogenic effect of growth hormone it should be given with care to patients with diabetes mellitus; adjustment of antidiabetic therapy may be necessary. Somatropin is contra-indicated in patients with proliferative or preproliferative diabetic retinopathy. Hypothyroidism may develop during treatment, and may result in suboptimal response. Secondary hypoadrenalism may be unmasked by somatropin treatment, requiring glucocorticoid replacement therapy (see also Interactions, below). Growth hormone should not be used in patients with Prader-Willi syndrome who are severely obese or have severe respiratory impairment (see also below). For the suggestion that growth hormone should not be used to treat acute catabolic states, as in patients with severe burns or who are otherwise critically ill, see Burns, under Uses and Administration, below.

Abuse. Growth hormone has been subject to abuse in sport for its anabolic effects. However, limited study data suggest that although it may increase lean body-mass, it has minimal effect on strength and athletic performance, and may worsen exercise capacity.[1]

Benign intracranial hypertension. Benign intracranial hypertension (pseudotumor cerebri) has been described[1,2] in patients given growth hormone treatment. In an analysis[3] of a post-marketing surveillance database (1985 to 2000) of almost 40 000 children and adolescents who had been treated with growth hormone for various conditions, benign intracranial hypertension was more common than in the general paediatric population. The incidence in new patients starting growth hormone therapy was estimated to be about 30 in 100 000, and it had occurred more frequently in patients with renal failure or Turner's syndrome. Headache and papilloedema were the most common symptom and sign, but these did not occur in all patients, and most cases had an onset of a few months. The condition was effectively managed by stopping growth hormone. A small number of patients were rechallenged after the benign intracranial hypertension had resolved, and most could be treated with doses that were 25 to 50% of the original dose. In a report of another case[4] it was pointed out that diagnosis may be complicated by the not infrequent occurrence of headache in patients receiving growth hormone; these normally resolved spontaneously.

Carcinogenicity. Despite fears to the contrary, studies in children given growth hormone after cranial irradiation for brain tumours or CNS leukaemia have found no evidence that therapy with growth hormone increased the relapse rate.[1-3]

Cases of acute leukaemia have been reported among patients treated with growth hormones. An international workshop convened in 1988 to review known leukaemia cases in patients treated with growth hormones in Europe, North America, Japan, and Australia since 1959 found the observed incidence of leukaemia in growth hormone-treated patients to represent a twofold increase over the expected rate.[4] It was concluded that there may be a small increase in leukaemia incidence associated with growth hormone treatment of growth hormone-deficient patients, but that it was not clear that this was actually attributable to growth hormone. A later study involving 6284 patients treated with growth hormone between 1963 and 1985 in the USA confirmed an increase of about 2.5-fold in the incidence of leukaemia in this population, but noted that many of the patients had other risk factors for leukaemia.[5] It has been suggested that growth hormone deficiency is itself a risk factor for leukaemia and that perhaps this, rather than growth hormone treatment, is related to the increased incidence of leukaemia in these patients.[6] If there is any risk it is relatively small, and in view of the essential nature of growth hormone therapy in growth hormone-deficient children it was considered inappropriate and unwise to withhold it.[4] Further large cohort studies of survivors of childhood cancers[3] or patients treated for idiopathic growth hormone deficiency[7] have found that the use of growth hormone was not associated with an increased risk of leukaemia.

There is some evidence to suggest that growth hormone may increase the risk of solid tumours. The risk of secondary solid tumours was increased in a cohort of childhood cancer survivors, but the authors considered that the risk was probably quite small compared with the benefits of growth hormone therapy in these patients.[3] Another cohort of patients who had been treated for idiopathic growth hormone deficiency showed increased risks in the incidence and mortality of colorectal cancer.[7]

Further reports of malignancies associated with growth hormone therapy include two children with Bloom's syndrome (a rare chromosomal disorder affecting DNA replication), one of whom developed B-cell non-Hodgkin's lymphoma and the other stem-cell leukaemia.[8]

Continued surveillance of patients who have received growth hormone therapy has been encouraged.[9]

Creutzfeldt-Jakob disease. Reports in 1985 of a small number of deaths from Creutzfeldt-Jakob disease in patients under 40 years of age who had received growth hormone extracted from human pituitary glands resulted in the suspension of the distribution of pituitary-derived growth hormone by the licensing authorities in a number of countries, including Australia, Canada, the Netherlands, the UK, and the USA. Preparations of non-pituitary-derived growth hormone are now available that are free from contamination with Creutzfeldt-Jakob agent. However, because of the long incubation period of the disease, cases are still being reported in patients who had received pituitary-derived growth hormone years previously.[1-4]

Effects on carbohydrate metabolism. A retrospective analysis[1] of data from a pharmacoepidemiological survey of children treated with growth hormone found a higher incidence of type 2 diabetes, compared with that found in untreated children. The researchers speculated that growth hormone treatment might precipitate the onset of type 2 diabetes in predisposed patients, and proposed that patients with risk factors for diabetes, including Turner's syndrome, Prader-Willi syndrome, or intrauterine growth retardation, be monitored. Studies of growth hormone have reported rises in serum concentrations of insulin, fasting and postprandial blood-glucose, and glycosylated haemoglobin, although these changes were generally small.[2] It has been noted that these effects appear to regress during treatment, but not always, and in some patients glucose intolerance or diabetes mellitus are not reversible after withdrawal of growth hormone.

Nonketotic hyperglycaemia developed within weeks of beginning growth hormone therapy in a 22-month-old child, leading to convulsions and metabolic acidosis; the patient died despite correction of the hyperglycaemia.[3]

Effects on immune function. Growth hormone is generally considered to interact with the immune system although there is a lack of evidence that this is clinically significant.[1-4] There has been a report of acute renal transplant rejection in 2 children receiving treatment for growth retardation with somatropin.[5] In both children renal function of the transplant was stable for several years before somatropin was started, and growth hormone therapy had continued for some months before rejection occurred. It was suggested that during the first months of growth hormone therapy in transplant recipients, immunosuppressive therapy should be increased and transplant function carefully monitored. However, in subsequent studies[6,7] the use of growth hormone did not affect the incidence of rejection.

Prader-Willi syndrome. One US manufacturer of somatropin has stated that as of April 2003 it was aware of 7 reports of death in children with Prader-Willi syndrome treated with growth hormone.[1] The patients shared one or more of the following risk factors: severe obesity, a history of respiratory impairment or sleep apnoea, or unidentified respiratory infection. It was recommended that patients with Prader-Willi syndrome should be evaluated for upper airway obstruction, before beginning treatment, and if signs of such obstruction, such as snoring, developed during treatment therapy should be suspended. Somatropin was considered contra-indicated in these patients if they were severely obese or had severe respiratory impairment; licensed drug information in the USA had been amended accordingly. Early diagnosis and aggressive treatment of respiratory infections was also recommended. A few cases have been described in the literature.[2-4]

Children with Prader-Willi syndrome appear to have a higher incidence of respiratory problems such as sleep apnoea, hypoventilation, and infections than healthy children.[5] A prospective study[6] of 25 patients reported that sleep-disordered breathing had actually improved in most of them after 6 weeks of growth hormone therapy. However, there was a subgroup of 6 patients in which obstructive sleep apnoea and hypopnoea worsened; 4 of them had developed upper respiratory-tract infections and enlarged tonsils, and 2 had high serum concentrations of insulin-like growth factor I (IGF-I) and enlarged tonsils.

Interactions

High doses of corticosteroids may inhibit the growth promoting effects of growth hormone. Doses of growth hormone may need to be increased in women receiving oral oestrogen replacement therapy, and may require adjustment if the route of oestrogen administration is changed.

Pharmacokinetics

Somatropin is well absorbed after subcutaneous or intramuscular injection with a bioavailability varying from about 60 to 80%; peak serum concentrations may not be achieved for several hours. After intravenous injection it has a half-life of about 20 to 30 minutes but after subcutaneous or intramuscular doses serum concentrations decline with a half-life of 3 to 5 hours, due to more prolonged release from the injection site. It is metabolised in the liver and kidneys and excreted in bile.

Absorption. Studies of the pharmacokinetics of somatropin after transdermal jet injection from 2 devices in healthy subjects suggested that absorption was more rapid and peak serum concentration higher than after conventional subcutaneous injection of the same dose.[1,2] However this did not seem to result in any difference in the total amount absorbed, nor in the biological effect. A third device[3] provided a similar concentration-time profile for somatropin compared with conventional injection in healthy subjects. When studied in children with growth hormone deficiency, however, this device was considered to cause more bleeding, pain, soreness, and bruising at the injection site than a needle-injection pen device.

Uses and Administration

Somatropin is synthetic human growth hormone and somatrem its methionyl analogue.

Growth hormone is an anabolic hormone secreted by the anterior lobe of the pituitary, varying in size and amino-acid sequence between animal species. It promotes growth of skeletal, muscular, and other tissues, stimulates protein anabolism, and affects fat and mineral metabolism. The hormone has a diabetogenic action on carbohydrate metabolism. Secretion is pulsatile and dependent on neural and hormonal influences including a hypothalamic release-inhibiting hormone (see Somatostatin, p.1809), and a hypothalamic releasing hormone (see Somatorelin, p.1808). Sleep, hypoglycaemia, and physical or emotional stress result in increased secretion of growth hormone. The effects of growth hormone on skeletal growth are mediated by the somatomedins (see p.1807).

Somatropin or somatrem is given to children with open epiphyses for the treatment of short stature due to growth hormone deficiency (pituitary dwarfism) following assessment of pituitary function. Somatropin is also used in children with some other forms of growth retardation, such as that associated with Turner's syndrome, Noonan syndrome, SHOX (short stature homeobox-containing gene) deficiency, or chronic renal insufficiency, in short children born small for gestational age, and in idiopathic short stature. In Prader-Willi syndrome, somatropin is given to improve growth and body composition (but see also under Adverse Effects and Precautions, above). In adults, somatropin is given for confirmed growth hormone deficiency. It is also used in the management of wasting or cachexia associated with AIDS. In short bowel syndrome, somatropin is used to increase intestinal absorption of water, electrolytes, and nutrients from specialised nutritional support.

Doses should be individualised for each patient. Manufacturers vary somewhat in their estimates of the number of units/mg for somatropin and although some countries specify labelling in mg, others require labelling in units or both. Somatrem has been given in doses similar to those of somatropin, but is no longer generally available.

In *children with growth hormone deficiency,* the usual daily dose in the UK is 25 to 35 micrograms/kg by subcutaneous injection (0.07 to 0.1 units/kg), or 0.7 to 1 mg/m^2 (2 to 3 units/m^2). Similar doses are used in other countries, by subcutaneous or intramuscular injection, and the total weekly dose may be divided into 3, 6, or 7 doses. A suspension of somatropin for subcutaneous depot injection has also been used, given in a dose of 1.5 mg/kg on the same day of each month. Alternatively, the dose could be given as 750 micrograms/kg twice monthly (for example, on days 1 and 15 of each month).

In *Turner's syndrome* (gonadal dysgenesis), a subcutaneous daily dose of 45 to 50 micrograms/kg (0.14 units/kg), or 1.4 mg/m^2 (4.3 units/m^2), may be used, although higher doses of up to 67 micrograms/kg daily have been licensed for use in the USA. Doses of up to 66 micrograms/kg daily have been used for growth retardation related to *Noonan syndrome*. Daily doses of 45 to 50 micrograms/kg may be used in children with growth retardation due to *chronic renal insufficiency* or *SHOX deficiency.*

In children with growth retardation who were *born small for gestational age*, the licensed daily dose in the UK is 35 micrograms/kg by subcutaneous injection (0.1 units/kg), or 1 mg/m^2 (3 units/m^2). In the USA, the licensed dose is somewhat higher, at 480 micrograms/kg weekly, divided into 6 or 7 doses.

In children with *idiopathic short stature* somatropin is given subcutaneously in a weekly dose of up to 300 to 470 micrograms/kg divided into 6 or 7 doses.

In children with *Prader-Willi syndrome*, a daily dose of about 35 micrograms/kg, or 1 mg/m^2, is given subcutaneously; daily doses should not exceed 2.7 mg.

In *adults with growth hormone deficiency* lower doses are recommended. The initial dose is not more than 6 micrograms/kg (0.018 units/kg) subcutaneously daily. The dose can then be gradually increased according to patient response, to a usual maximum of 12.5 micrograms/kg daily. Alternatively, an initial dose in the range of 150 to 300 micrograms daily (0.45 to 0.9 units) is increased gradually at monthly intervals, based on clinical response, to a maintenance dose of no more than 1 mg daily. Dosage requirements may decline with increasing age. In the UK, it has been recommended that treatment should be re-assessed 9 months after starting therapy.

In the treatment of *HIV-associated wasting or cachexia* somatropin is given in doses of 100 micrograms/kg daily by subcutaneous injection at bedtime, to a maximum of 6 mg daily. A starting dose of 100 micrograms/kg on alternate days may be considered for patients who are at increased risk of adverse effects.

In *short bowel syndrome* somatropin is given subcutaneously in a dose of about 100 micrograms/kg daily (to a maximum of 8 mg daily) for 4 weeks.

Administration in adults. Growth hormone continues to be secreted in adult life, although secretion and activity gradually decline with increasing age, and it appears to play a role in maintaining skeletal and lean body-mass amongst other things. In adults with growth hormone deficiency (usually secondary to pituitary adenoma or its treatment) replacement therapy with growth hormone is reported to decrease body fat and abdominal adiposity, increase lean body-mass, and improve lipid profiles.[1-4] It may also increase bone density,[1,3] but many studies have been uncontrolled and of short duration, and any beneficial effect on bone density appears to be small.[5] Strength and exercise capacity can also be improved, although prolonged growth hormone therapy and physical training may be required to increase muscle performance.[3] Cardiac structure and function can be adversely affected by growth hormone deficiency, and replacement therapy in adults can have a positive effect on some cardiac parameters.[6] There are also some reports of improvements in quality of life;[3] although a study[7] using general standardised psychometric tests found no benefit, another[8] using a questionnaire developed for adults with hypopituitarism reported long-term benefits. Long-term data are not yet available to determine whether growth hormone therapy reduces the mortality rate in this group of patients, but it may provide some protection against myocardial infarction.[9] Guidelines on the use of growth hormone in adults with growth hormone deficiency have been issued.[10-13]

Less well established is the use of growth hormone in otherwise healthy elderly patients. Considerable controversy has attended suggestions that growth hormone therapy may retard or reverse some of the metabolic effects of ageing, and there is some concern that these patients may be at increased risk of adverse effects.[14] Studies[15] have shown that growth hormone can increase lean body-mass and decrease body fat, but functional ability does not necessarily improve and common adverse effects include peripheral oedema, carpal tunnel syndrome, arthralgias, and gynaecomastia.

Burns. In children with severe burns requiring skin grafts, somatropin 200 micrograms/kg daily by intramuscular injection reduced donor-site healing times and hospitalisation times; subcutaneous somatropin 100 micrograms/kg daily was ineffective.[1] There has been some concern that growth hormone therapy might increase hypertrophic scar formation, but a study[2] of somatropin 50 micrograms/kg daily for 1 year after hospital discharge did not find this. Somatropin treatment given during hospitalisation has also been reported to ameliorate burn-induced growth delays in such children; those injured during non-growth-spurt years may benefit most.[3,4] Long-term therapy given for 1 year after wound healing may also improve weight, linear growth, lean body-mass, and bone mineral content.[5] However, the manufacturers have recommended that somatropin should not be used to treat acute catabolic states in critically ill and burn patients, as there is some evidence in adults that mortality may be increased.[6] The management of burns is described on p.1578.

Cachexia and lipodystrophy. Treatment with subcutaneous growth hormone has been reported[1,2] to reverse weight loss and improve body wasting in subjects with HIV disease (p.858). It can have beneficial effects on physical function, body-weight, lean body-mass, and measures of health-related quality of life.[3]

Some benefit has been reported[4-8] with growth hormone therapy in HIV-associated lipodystrophy.

Growth hormone therapy has also been reported to improve metabolic indicators of malnutrition in some[9] but not other[10] studies of patients undergoing haemodialysis.

Cardiovascular disorders. A few small uncontrolled studies have reported improvements in heart failure (p.1165) with the use of growth hormone.[1] A meta-analysis[2] of 12 studies using growth hormone in adults with chronic heart failure, including 8 placebo-controlled studies, also found evidence for improvement in several cardiovascular measures; however, individual results have been mixed and further study of long-term high-dose therapy is needed. A small underpowered study[3] of 6 months of treatment in children with dilated cardiomyopathy found only a trend towards improved cardiac function. Retrospective analysis[4] of a group of childhood cancer survivors found that growth hormone used to treat deficiency had some beneficial effects on anthracycline-induced left ventricular dysfunction, but that these diminished when growth hormone therapy was stopped.

Infertility. Growth hormone appears to sensitise the ovary to stimulation by gonadotrophins and it has been suggested that somatropin may have a role in the management of female infertility. However, studies of somatropin added to gonadotrophin regimens have generally been small, used different treatment protocols and outcome measures, and studied mixed groups of women in terms of the cause of infertility. Studies of women with poor response to ovarian stimulation have shown mixed results, and response may depend on the cause of infertility. Mixed results have also been reported in women with polycystic ovary syndrome. Benefits may be most likely in women with hypogonadotrophic hypogonadism,[1] but there is no additional benefit for women who have a normal ovarian response to gonadotrophins.[1,2] UK guidelines[3] for the treatment of infertility do not recommend its use. Growth hormone has also been tried similarly to enhance spermatogenesis in infertile men unresponsive to conventional therapy, but studies have been small, and despite some encouraging reports[4] others have found no benefit.[5,6]

For a discussion of infertility and the more usual drugs used in its management, see p.2080.

Osteogenesis imperfecta. For reference to possible benefit from growth hormone therapy in patients with osteogenesis imperfecta, see p.1083.

Osteomalacia. As mentioned on p.1084, there has been some interest in the use of growth hormone in children with hypophosphataemic rickets.

Prader-Willi syndrome. Growth hormone treatment may be of benefit in the management of Prader-Willi syndrome (p.2149). It increases growth velocity and improves body composition, by reducing fat mass and increasing muscle mass. However, there is limited information about long-term efficacy, and the effect on growth velocity is reported to wane after 1 to 3 years of therapy. There are also specific contra-indications and precautions relating to the use of growth hormone in these patients (see under Adverse Effects and Precautions, above).

Short bowel syndrome. A combination of growth hormone, glutamine, and dietary modification may improve intestinal absorption of fluid, electrolytes, and other nutrients, and thus reduce parenteral nutrition requirements in patients with short bowel syndrome.[1] However, studies have produced conflicting results, and benefit may depend on a number of factors including the type and length of remaining bowel, the presence or absence of mucosal disease, and the doses of somatropin and glutamine.[2]

Veterinary and agricultural use. Bovine growth hormone or bovine somatotropin (bovine somatotropin; BST) can increase milk yield in dairy cows. There has been considerable debate about both animal welfare and human food safety, and although it is approved in the USA[1] its use is banned in the EU.[2]

Lanreotide *(BAN, rINN)*

Angiopeptin; BIM-23014; BN-52030; DC-13-116; Lanreotid; Lanreotida; Lanréotide; Lanreotidi; Lanreotidum. 3-(2-Naphthyl)-D-alanyl-L-cysteinyl-L-tyrosyl-D-tryptophyl-L-lysyl-L-valyl-L-cysteinyl-L-threoninamide cyclic (2→7)-disulfide.

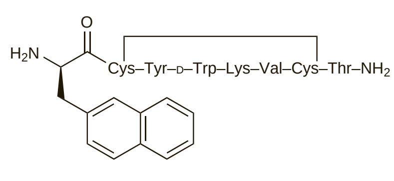
Ланреотид

$C_{54}H_{69}N_{11}O_{10}S_2$ = 1096.3.

CAS — 108736-35-2.

ATC — H01CB03.

ATC Vet — QH01CB03.



Lanreotide Acetate *(BANM, USAN, rINNM)*

Acetato de lanreotida; BIM-23014C; Lanréotide, Acétate de; Lanreotidi Acetas.

Ланреотида Ацетат

$C_{54}H_{69}N_{11}O_{10}S_2,x(C_2H_4O_2)$.

CAS — 127984-74-1.

ATC — H01CB03.

ATC Vet — QH01CB03.

Adverse Effects and Precautions

As for Octreotide Acetate, p.1803.

Interactions

As for Octreotide Acetate, p.1804.

Pharmacokinetics

After intravenous injection lanreotide has a terminal half-life of about 2.5 hours. Lanreotide is available as injectable depot preparations, and after subcutaneous or intramuscular use of these an initial rapid liberation of the drug is followed by more prolonged release with an apparent half-life of about 5 to 30 days. The absolute bioavailability is stated to range from about 50 to 80%, depending on the product.

Uses and Administration

Lanreotide is a somatostatin analogue with similar properties to those of octreotide (p.1804). It is given, as a long-acting depot injection, in the treatment of acromegaly (p.1798) and thyrotrophic adenoma, as well as in the symptomatic management of carcinoid syndrome (p.643).

Lanreotide is given as the acetate, but doses are usually expressed in terms of the base. The usual starting dose is equivalent to lanreotide 30 mg by intramuscular depot injection every 14 days. In acromegaly and carcinoid syndrome, this may be increased if necessary to 30 mg every 7 to 10 days; in thyrotrophic adenoma it may be increased to 30 mg every 10 days. An alternative preparation for acromegaly and carcinoid syndrome, given by deep subcutaneous injection every 28 days, delivers doses equivalent to 60, 90, or 120 mg of lanreotide. In patients with acromegaly who respond to treatment, lanreotide may be gradually reduced to maintenance doses of 120 mg given at intervals of up to 56 days. In those who are not adequately controlled, a maximum dose of 120 mg once every 28 days may be used.

Lanreotide has been tried for the prevention of restenosis in coronary blood vessels following angioplasty (see Reperfusion and Revascularisation Procedures, p.1181).

Administration in hepatic and renal impairment. The clearance of lanreotide, given by intravenous bolus, was significantly reduced in patients with severe chronic renal impairment requiring haemodialysis.[1] However, the authors of this study suggested that considering the wide therapeutic window of lanreotide, depot formulations may be given at the usual initial dose, with further doses adjusted according to response. Clearance of lanreotide was only slightly reduced in patients with moderate to severe hepatic impairment (Child-Pugh category B and C).[2] The UK licensed product information for one depot formulation (*Somatuline Autogel; Ipsen, UK*) given every 28 days recommends that dose adjustment is not necessary in renal or hepatic impairment. Another preparation (*Somatuline LA; Ipsen, UK*) usually given every 14 days suggests that renal and hepatic function should be monitored and the dosage interval adjusted as needed.

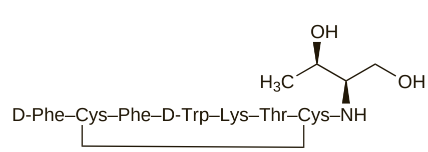
ATC — H01CB02.

ATC Vet — QH01CB02.



(octreotide)

Incompatibility. Apparent loss of insulin has been reported from a total parenteral nutrient solution containing octreotide; there may be an incompatibility.[1] Also the manufacturers had suggested that octreotide might be adsorbed onto plastics. However, a solution containing octreotide 200 micrograms/mL as the acetate was reported to be stable at 5° or −20° for up to 60 days when stored in polypropylene syringes.[2]

1. Rosen GH. Potential incompatibility of insulin and octreotide in total parenteral nutrient solutions. *Am J Hosp Pharm* 1989; **46:** 1128.
2. Ripley RG, *et al.* Stability of octreotide acetate in polypropylene syringes at 5 and −20°C. *Am J Health-Syst Pharm* 1995; **52:** 1910–11.

Adverse Effects and Precautions

There may be a transient local reaction at the site of injection of octreotide. Systemic adverse effects are mainly gastrointestinal and may include anorexia, nausea, vomiting, diarrhoea and steatorrhoea, abdominal discomfort, and flatulence. Use between meals or at bedtime may reduce these gastrointestinal effects. Hypersensitivity reactions and hair loss have been reported rarely.

Gallstones may develop on long-term therapy; there have been isolated reports of hepatic dysfunction and of biliary colic associated with drug withdrawal. Checks should be made for gallstones before prolonged therapy and at 6- to 12-month intervals during treatment. There have also been isolated reports of pancreatitis and of hepatic dysfunction without cholestasis. Hypoglycaemia may occur, especially in patients with insulinomas, but there is also a risk of hyperglycaemia or impaired glucose tolerance. Thyroid function should be monitored during octreotide therapy because of the possibility of hypothyroidism. Pituitary tumours that secrete growth hormone can expand during treatment, causing serious complications; patients should be monitored for signs of tumour expansion, such as visual field defects. Cardiac rhythm should be monitored during intravenous use of octreotide. Doses may need to be adjusted in patients with end-stage renal failure, in whom the clearance of octreotide is reduced.

Effects on the biliary tract. Octreotide has an inhibitory effect on gallbladder motility and bile secretion, accounting for the development of gallstones and biliary colic.[1-5]

Effects on carbohydrate metabolism. Changes in glucose tolerance may occur in patients with acromegaly who are treated with somatostatin analogues. In a study[1] of 90 patients treated with octreotide for 6 months, impaired glucose tolerance or frank diabetes developed in half of the 55 who initially had normal glucose tolerance. There was initial impaired glucose tolerance in 24 patients, which deteriorated in 4, remained stable in 10, and normalised in 10. Of the 11 patients who were diabetic before octreotide treatment, 8 remained diabetic but 1 improved to having impaired glucose tolerance and 2 to being normal. A later study[2] of 24 patients treated with either octreotide or lanreotide also found that glucose tolerance could remain stable, deteriorate, or improve. Overall, however, there was an improvement in insulin resistance but an impairment of insulin secretion, and a deterioration in glucose homoeostasis in nondiabetic patients.

There has been a report of deterioration in glucose tolerance leading to death from diabetic ketoacidosis when octreotide treatment was stopped in a patient with acromegaly and insulin-resistant diabetes mellitus.[3]

The symbol † denotes a preparation no longer actively marketed

Effects on the hair. Diffuse loss of scalp hair has been reported in 4 of 7 women who received octreotide; after withdrawal of octreotide in 3 of the women there was a complete recovery of scalp hair.[1] Other similar cases have also been reported. In one case, diffuse alopecia in a male patient was completely reversed when octreotide was replaced with lanreotide.[2]

2. Lami M-C, *et al.* Hair loss in three patients with acromegaly treated with octreotide. *Br J Dermatol* 2003; **149:** 655–6.

Effects on the liver. Hepatitis occurred in 2 acromegalic patients treated with octreotide 300 micrograms daily subcutaneously.[1,2] In both cases liver enzyme values returned to normal within 1 to 2 months of withdrawing octreotide, and recurred on rechallenge.

2. González-Martín JA, *et al.* Acute liver injury and octreotide. *Am J Gastroenterol* 1996; **91:** 2434–5.

Effects on mental function. A woman with acromegaly developed manic symptoms on 2 separate occasions 2 months after starting treatment with octreotide.[1]

1. Fernández-Real J-M, *et al.* Octreotide-induced manic episodes in a patient with acromegaly. *Ann Intern Med* 2006; **144:** 704.

Effects on the pancreas. There have been reports of pancreatitis associated with octreotide[1-4] and lanreotide.[4] It has been suggested that octreotide-induced pancreatitis may result from spasm of the sphincter of Oddi, resulting in retention of activated pancreatic enzymes due to outflow obstruction.[3]

4. Cannavò S, *et al.* Octreotide and lanreotide treatment in active acromegaly. *J Clin Endocrinol Metab* 1997; **82:** 2376–7.

Pregnancy. There have been reports of women who have received lanreotide[1] or octreotide[2-5] during pregnancy. Most were receiving the drug for the treatment of acromegaly, although there is also a report[5] of octreotide use during pregnancy in a woman treated for nesidioblastosis. In most cases, the somatostatin analogue was stopped early in the pregnancy, but in some cases octreotide was continued to term. No maternal complications or congenital anomalies were described.

Interactions

Octreotide has been associated with alterations in nutrient absorption and there is a theoretical possibility that it may affect the oral absorption of other drugs. Patients receiving insulin or oral hypoglycaemics may require dose adjustments of these drugs if octreotide is also used. The bioavailability of bromocriptine is increased by octreotide. It has been suggested that dosage of beta blockers, calcium-channel blockers, or drugs to control fluid and electrolyte balance may also need to be adjusted.

Ciclosporin. For a reference to octreotide reducing serum concentrations of ciclosporin, see p.1828.

Pharmacokinetics

Octreotide is rapidly absorbed after subcutaneous injection, with peak plasma concentrations reached about 25 to 40 minutes after a dose, and is distributed to body tissues. About 40 to 65% of the octreotide in the circulation is bound to plasma proteins. It is said to exhibit non-linear pharmacokinetics, with reduced clearance at high doses. Octreotide is removed from the body with a plasma elimination half-life of about 1.5 hours; half-life is prolonged in elderly patients, renal impairment, and liver cirrhosis. About a third of a dose is excreted unchanged in the urine. Octreotide diffuses across the placenta.

Uses and Administration

Octreotide is an octapeptide analogue of somatostatin (p.1809) with similar properties but a longer duration of action.

It is used as the acetate in the symptomatic management of carcinoid tumours and other secretory neoplasms such as VIPomas and glucagonomas. Octreotide acetate is also used in the treatment of acromegaly and the prevention of complications after pancreatic surgery, and may be used in the treatment of other disorders including variceal haemorrhage and HIV-associated diarrhoea. It has also been investigated in a variety of other disorders including the dumping syndrome.

In the management of **secretory neoplasms** octreotide acetate is given subcutaneously in an initial dose equivalent to 50 micrograms of octreotide once or twice daily gradually increased, according to response, to up to 600 micrograms daily in 2 to 4 divided doses. Higher doses have been used. If there is no benefit within a week of starting treatment for carcinoid tumour, continued therapy is not recommended.

Where a rapid response is required, the initial dose may be given by the intravenous route. In the UK licensed product information states that it should be diluted not less than 1 in 1 or not more than 1 in 9 in sodium chloride 0.9%, but in the USA product information permits the use of the undiluted solution as an intravenous bolus in emergencies; alternatively the dose may be given by intermittent infusion over 15 to 30 minutes, diluted in 50 to 200 mL of sodium chloride 0.9% or glucose 5%.

Once control has been established maintenance therapy with a depot preparation may be possible; initially 20 mg by intramuscular injection every 4 weeks is suggested. Subcutaneous injection with a rapid-acting preparation should be continued for 2 weeks after the first depot injection to provide symptomatic cover, and may be added to therapy when necessary thereafter. Maintenance doses of the depot preparation may be adjusted after 2 or 3 months to between 10 and 30 mg every 4 weeks, as necessary.

In **acromegaly**, the usual dose is the equivalent of 100 to 200 micrograms of octreotide three times daily by subcutaneous injection. In the USA it is suggested that dosage begin with 50 micrograms three times daily in order to minimise gastrointestinal disturbance. If there is no relevant reduction in growth hormone concentrations and no improvement in clinical symptoms within 3 months of starting treatment, octreotide should be stopped. Once control has been established maintenance therapy with a depot preparation is possible; an initial dose equivalent to 20 mg of octreotide given intramuscularly once every 4 weeks has been recommended for patients with acromegaly, adjusted after 3 months to between 10 and 30 mg every 4 weeks. For patients who are not adequately controlled on 30 mg, the dose may be further increased to 40 mg every 4 weeks. The depot preparation may also be used for short-term treatment before pituitary surgery, but the last dose should be given at least 3 to 4 weeks before surgery to ensure successful endocrine testing for tumour removal 5 to 6 weeks after surgery.

For the prevention of complications after **pancreatic surgery** the equivalent of 100 micrograms of octreotide may be given three times daily by subcutaneous injection of a rapid-acting preparation; treatment is given for 7 consecutive days, beginning at least 1 hour before laparotomy on the day of operation.

In the management of **variceal haemorrhage** in patients with cirrhosis, octreotide is given as a continuous intravenous infusion at a dose equivalent to octreotide 25 micrograms/hour for 48 hours. Doses up to 50 micrograms/hour have been used. Patients at high risk of re-bleeding may continue treatment for up to 5 days. Although not licensed for use in children in the UK, the *BNFC* includes a dose of 1 microgram/kg per hour by continuous intravenous infusion for children from 1 month to 18 years of age; higher doses may be needed initially, to a maximum dose of 50 micrograms/hour, and the dose should be reduced gradually over 24 hours once there is no active bleeding.

HIV-associated diarrhoea may be treated with an initial dose of octreotide 100 micrograms three times daily, given subcutaneously. If the diarrhoea is not controlled after a week, the dose may be increased to 250 micrograms three times daily, but if this is not effective after one week then octreotide therapy should be stopped.

Acromegaly. Although surgery remains the most important method of treatment, octreotide has a useful role in the management of acromegaly (p.1798). It can reduce growth hormone concentrations, normalise IGF-I concentrations, reduce tumour size, and improve signs and symptoms.[1-4] There is also some evidence that it may improve cardiac function, which is usually compromised in these patients.[5-7] Octreotide can be given subcutaneously and this route is generally used initially to determine patient response and tolerance, but it must be given three times daily making it unattractive for long-term use. Intramuscular sustained-release octreotide is effective for maintenance therapy.[4,7,8] There is also increasing interest in the role of octreotide for primary therapy of acromegaly, instead of surgery[8,9] and a recent meta-analysis[10] concluded that tumour shrinkage was greatest when somatostatin analogues were given as primary rather than secondary therapy.

Cardiovascular disorders. There have been reports of benefit from octreotide in patients with postprandial hypotension and orthostatic hypotension (p.1530) associated with autonomic neuropathy.[1-5] Octreotide has also produced cardiac improvement in patients with acromegaly (see above). Promising results have been reported in patients with primary hypertrophic cardiomyopathy.[6,7]

Chylous effusion. Chylous effusion results in accumulation of a milky lymphatic fluid containing raised concentrations of white blood cells, triglycerides, and cholesterol. Chylothorax, when the effusion affects the pleural cavity, is generally a complication of malignancy or chest surgery, or may be idiopathic. Treatment usually involves catheter drainage and dietary modification; surgery is used when these measures fail. Octreotide has been used successfully in a number of cases, given subcutaneously or by continuous infusion, to treat chylothorax;[1-7] there are also reports of octreotide being ineffective.[8] Octreotide has also been used in chyloperitoneum[9-11] and for cervical chylous fistula.[12]

Cushing's syndrome. Cushing's syndrome (p.2344) can be caused by excessive secretion from an ectopic ACTH-secreting tumour. Many of these ectopic tumours express somatostatin receptors and it has been suggested that octreotide may be useful in the diagnosis, and possibly the treatment, of selected patients.[1] However, there are 5 types of somatostatin receptor,[2,3] and responses to octreotide have been variable,[4] even in the same patient.[3,5]

Diabetes mellitus. Although octreotide has been reported to impair glucose tolerance, and even precipitate frank diabetes (see Effects on Carbohydrate Metabolism, under Adverse Effects, above), its variable effects on blood glucose and insulin have led to investigations[1,2] of its ability to induce beta cell rest in patients with diabetes mellitus (p.431) who still have residual insulin secretion. There is also some suggestion that it may be of benefit in the treatment or prevention of diabetic nephropathy[3,4] and retinopathy.[5-7] Benefit has been reported from the use of octreotide in patients with diabetic diarrhoea—see under Gastrointestinal Disorders, below.

Diagnosis and testing. Radiolabelled octreotide or other somatostatin analogues such as pentetreotide and depreotide may be used to visualise various malignant neoplasms which express somatostatin receptors.[1,2] Somatostatin receptor scintigraphy is the most sensitive method for imaging lesions in patients with Zollinger-Ellison syndrome.[3]

Octreotide may also have a role in the diagnosis of Cushing's syndrome, see above.

Eye disorders. There are reports of response to octreotide in 2 patients with bilateral cystoid macular oedema, a refractory form of retinal oedema.[1,2] In 1 case the problem recurred when octreotide was twice withdrawn and each time responded to resumption of octreotide injections.[1]

Gastrointestinal disorders. Somatostatin inhibits gastric and intestinal secretion and the production of various active substances in the gastrointestinal tract. It also reduces splanchnic arterial blood flow and portal and gastric mucosal blood flow. These properties are made use of, usually in the form of octreotide, in the management of a number of gastrointestinal disorders including bleeding, refractory diarrhoea, fistulae, dumping syndrome, and nausea and vomiting secondary to bowel obstruction (see Other Gastrointestinal Disorders, below).

Octreotide is used particularly in the treatment of carcinoid syndrome arising from endocrine tumours (see Carcinoid Tumours, p.643).

BLEEDING. There have been mixed results with octreotide in the treatment of nonvariceal upper gastrointestinal bleeding. Although a large multicentre study[1] showed that octreotide had no benefit compared with placebo in the management of bleeding upper gastrointestinal ulcers, a meta-analysis that included somatostatin and octreotide suggested there might be some benefit.[2] Nevertheless, a later study[3] found that octreotide, given as an adjunct to endoscopic haemostasis using noradrenaline, did not seem to provide any additional benefit, and it is not recommended in the management of nonvariceal bleeding associated with peptic ulcer (p.1702).

Octreotide may be used in the management of variceal haemorrhage (see under Monoethanolamine, p.2346). A systematic review[4] of studies comparing somatostatin or its analogues with either placebo or no drug treatment found that although there was a small benefit in controlling bleeding, it was doubtful whether this benefit was worthwhile, and that deaths were not reduced. There is some evidence that octreotide is as effective as sclerotherapy in the control of acute bleeding.[5] A meta-analysis[6] of studies comparing octreotide with other therapies (including vasopressin, terlipressin, sclerotherapy, or balloon tamponade) for the control of acute variceal bleeding found that octreotide had a similar effect to sclerotherapy in the prevention of rebleeding and was more effective and associated with fewer major complications than vasopressin or terlipressin. However, there was no evidence of mortality benefit associated with octreotide use. Another systematic review[7] also found that sclerotherapy was no better than drug therapy, including octreotide, but associated with more frequent and severe adverse effects. Controlled studies have suggested that combination of octreotide infusion for 5 days with endoscopic ligation[8] or sclerotherapy[9,10] reduces the risk of rebleeding. In another study,[11] sclerotherapy with 48 hours of octreotide infusion was more effective at controlling bleeding than sclerotherapy alone, and octreotide was as effective as sclerotherapy in those with evidence of recent bleeding. However, another study[12] found that octreotide given subcutaneously for up to 29 days after sclerotherapy did not affect the rate of early rebleeding. Octreotide has also produced some benefit (combined with regular sclerotherapy), in the long-term management of patients with cirrhotic portal hypertension.[13]

DIARRHOEA. Octreotide has been tried for its effects on gastrointestinal secretion and intestinal transit time in the management of severe refractory diarrhoea associated with a variety of conditions. A review[1] found that studies were generally small, and that although there appeared to be an overall benefit associated with the use of octreotide, response was influenced by the cause of diarrhoea. There are reports of octreotide controlling diarrhoea associated with amyloidosis,[2-4] diabetes mellitus,[5-11] and bone marrow transplantation.[12,13] Although octreotide was reported to be useful in a case of microvillous atrophy,[14] others have not found it to be effective.[15] There have been reports of benefit in refractory AIDS-associated diarrhoea,[16] and it has been licensed for this use in some countries, but a double-blind, controlled study found octreotide to be no more beneficial than placebo.[17] In patients with the short bowel syndrome and jejunostomies or ileostomies, octreotide may be useful in decreasing faecal mass[18] or jejunal efflux,[19] and increasing small bowel transit time.[20] Octreotide has also been used with some benefit in refractory diarrhoea associated with chemotherapy, particularly with regimens that include fluorouracil[21,22] and irinotecan.[23] In a small series of patients[24] the use of depot octreotide controlled most episodes of diarrhoea, and allowed the continuation of chemotherapy in some cases.

FISTULAE. Octreotide has been used in the management of postoperative small-bowel fistulae. There have been mixed reports, but some have found reduced fistula output,[1,2] with the time to spontaneous fistula closure either reduced[1] or unchanged.[2] Octreotide has also been reported to accelerate healing of pancreatic cutaneous fistulae of various causes,[3] but others[4] have found no benefit from octreotide in preventing pancreatic fistula formation after pancreaticoduodenectomy. A systematic review[5] of controlled trials commented on the variation in trial methods and conflicting results, but concluded that there is probably benefit in giving octreotide preoperatively to prevent complications of pancreatic surgery, and that in established postoperative fistulae it may have a limited role in reducing fistula output and reducing the time to fistula closure. In a series of 5 patients[6] with Crohn's disease who were treated for 8 weeks with high-dose octreotide, enterocutaneous fistulae closed in 4 cases.

OTHER GASTROINTESTINAL DISORDERS. Other gastrointestinal disorders in which octreotide might be useful include dumping syndrome[1,2] (p.1695), reactive (or postprandial) hypoglycaemia,[3] and protein-losing enteropathy associated with intestinal lymphangiectasia.[4,5] Nausea and vomiting secondary to bowel obstruction in patients terminally ill with cancer may also be relieved by octreotide.[6,7] The *BNF* states that in palliative care a dose of 300 to 600 micrograms may be given by subcutaneous infusion over 24 hours to reduce intestinal secretions and vomiting.

Hypercalcaemia. There have been individual reports of hypercalcaemia associated with raised plasma concentrations of parathyroid hormone-related protein (hypercalcaemia of malignancy—p.1083) being successfully controlled with octreotide in patients with malignant pancreatic endocrine tumours[1,2] and adrenal phaeochromocytoma.[3] Octreotide also resolved hypercalcaemia occurring in a patient with VIPoma and vasoactive intestinal peptide concentrations declined.[4] In two patients with a parathyroid hormone-related protein secreting carcinoid tumour, octreotide reduced protein concentrations in both patients[5,6] but controlled hypercalcaemia in only one.[6] Octreotide also normalised calcium concentrations in a patient with hypercalcaemia related to B cell lymphoma.[7] In many of these cases, hypercalcaemia had previously been resistant to treatment with bisphosphonates.

Hyperinsulinism. As well as reactive hypoglycaemia (see under Other Gastrointestinal Disorders, above), octreotide has been used to control inappropriate insulin secretion, both in the short-term and long-term, in children with hypoglycaemia of infancy,[1-4] or nesidioblastosis.[5-7] Although not licensed in the UK for children, the *BNFC* includes a dose of octreotide for persistent hyperinsulinaemic hypoglycaemia unresponsive to diazoxide and glucose. For neonates an initial dose of 2 to 5 micrograms/kg may be given every 6 to 8 hours subcutaneously and adjusted according to response. For children aged from 1 month to 18 years, an initial dose of 1 to 2 micrograms/kg every 4 to 6 hours may be used. Doses up to 7 micrograms/kg every 4 hours may be required in rare cases.

Octreotide has also been used to treat a patient with hyperinsulinaemia induced by quinine.[8,9] For mention of investigations of octreotide for the reverse effect, see Diabetes Mellitus, above.

Malignant neoplasms. See also Carcinoid Syndrome, above. For mention of the use of octreotide to treat nausea and vomiting associated with malignant gastrointestinal obstruction see under Other Gastrointestinal Disorders, above. Octreotide has also proved of benefit in some patients with cancer pain (see Pain, below). An unconventional regimen using octreotide or somatostatin with melatonin, bromocriptine, and a solution of retinoids (the Di Bella regimen) was investigated in patients with a variety of advanced malignancies and found to be ineffective.[1,2]

1. Italian Study Group for the Di Bella Multitherapy Trials. Evaluation of an unconventional cancer treatment (the Di Bella multitherapy): results of phase II trials in Italy. *BMJ* 1999; **318:** 224–8.
2. Buiatti E, *et al.* Results from a historical survey of the survival of cancer patients given Di Bella multitherapy. *Cancer* 1999; **86:** 2143–9.

HEPATOCELLULAR CARCINOMA. In a study in 58 patients with advanced hepatocellular carcinoma (p.667) treatment with octreotide was associated with prolongation of survival compared with no treatment.[1] In a further case report[2] cancer regression occurred in a patient given octreotide, and a study[3] found better survival in patients treated with octreotide and tamoxifen compared with fluorouracil and mitomycin. However, other studies of octreotide in patients with advanced hepatocellular carcinoma failed to demonstrate any benefit.[4,5]

MENINGIOMA. Octreotide has been reported to suppress headaches and visual disturbances associated with meningioma in a small number of patients.[1-3] Doses were generally started at 100 micrograms three times daily subcutaneously, but were increased to 500 micrograms three times daily in some cases because of tolerance. Although it was thought that octreotide may have had a beneficial effect on the meningioma size in one case,[1] others found no evidence of tumour shrinkage.[2,3]

1. Rünzi MW, *et al.* Successful treatment of meningioma with octreotide. *Lancet* 1989; **i:** 1074.
2. García-Luna PP, *et al.* Clinical use of octreotide in unresectable meningiomas: a report of three cases. *J Neurosurg Sci* 1993; **37:** 237–41.
3. Jaffrain-Rea M-L, *et al.* Visual improvement during octreotide therapy in a case of episellar meningioma. *Clin Neurol Neurosurg* 1998; **100:** 40–3.

THYMOMA. A patient with thymoma and pure red cell aplasia, in whom corticosteroids alone failed to control anaemia, had complete remission after treatment with octreotide and prednisone, and subsequently remained well on long-term maintenance therapy with octreotide 500 micrograms twice daily subcutaneously and prednisone 200 micrograms/kg daily.[1] In a study[2] that included 32 patients with thymoma and a positive octreotide scan, octreotide therapy alone (500 micrograms subcutaneously three times daily for up to 1 year) or with prednisone (600 micrograms/kg daily) had modest activity; there were 2 complete and 10 partial responses overall.

1. Palmieri G, *et al.* Successful treatment of a patient with a thymoma and pure red-cell aplasia with octreotide and prednisone. *N Engl J Med* 1997; **336:** 263–5. Correction. *ibid.*; 1039.

Nesidioblastosis. For reference to the use of octreotide in nesidioblastosis, see Hyperinsulinism, above.

Obesity. Hypothalamic obesity can be a complication of hypothalamic damage caused by insults such as head trauma, brain tumours, and cranial surgery or irradiation. Octreotide has improved body-weight, body-mass index, and regulation of insulin secretion in small studies of children with hypothalamic obesity.[1,2] Octreotide is also under investigation in the treatment of Prader-Willi syndrome (p.2149).[3]

1. Lustig RH, *et al.* Hypothalamic obesity caused by cranial insult in children: altered glucose and insulin dynamics and reversal by a somatostatin agonist. *J Pediatr* 1999; **135:** 162–8.
2. Lustig RH, *et al.* Octreotide therapy of pediatric hypothalamic obesity: a double-blind, placebo-controlled trial. *J Clin Endocrinol Metab* 2003; **88:** 2586–92.
3. Haqq AM, *et al.* Circulating ghrelin levels are suppressed by meals and octreotide therapy in children with Prader-Willi syndrome. *J Clin Endocrinol Metab* 2003; **88:** 3573–6.

Pain. Octreotide 120 to 480 micrograms daily was given by continuous intrathecal infusion to 6 patients with cancer pain that had been poorly controlled by opioid analgesics.[1] All patients obtained good pain relief, 3 reporting pain to be totally absent. Sustained decrease in incapacitating bone pain has also been reported in a patient with skeletal metastasis of a gastrinoma who was given subcutaneous octreotide 100 micrograms three times daily.[2] The pain of hypertrophic pulmonary osteoarthropathy (a paraneoplastic syndrome of periostitis, arthropathy, and gynaecomastia seen particularly with squamous cell lung cancer) has also been reported to respond to octreotide.[3] However, a controlled study of octreotide in cancer pain found that it was no better than placebo in most patients.[4] (General guidelines for the management of cancer pain are discussed on p.5.) Octreotide has also been reported to ease headache associated with meningioma (above), and pituitary adenoma (see Acromegaly, above, and Pituitary Adenoma, below).

The use of intrathecal octreotide has also been described[5] in 2 patients with severe intractable non-malignant pain. During 5 years of treatment, octreotide provided a beneficial degree of pain relief and allowed a reduction in opioid dosage. However, the dose of octreotide had to be gradually increased, suggesting tolerance to the analgesic effect; one patient was receiving a daily dose of 648 micrograms.

Pancreatic disorders. Octreotide has been tried in the treatment of acute pancreatitis, but was found to be ineffective.[1] For reference to the use of octreotide in the management of pancreatic endocrine tumours, see under Carcinoid Tumours (p.643); for its use in pancreatic fistulae, see under Gastrointestinal Disorders, above.

1. Uhl W, *et al.* A randomised, double blind, multicentre trial of octreotide in moderate to severe acute pancreatitis. *Gut* 1999; **45:** 97–104.

Pituitary adenoma. Octreotide has a role in the management of pituitary adenomas that cause acromegaly (see above). It has also been used in the management of rare tumours such as thyrotropin-secreting pituitary adenomas, usually when surgery or radiotherapy have failed. Octreotide may reduce concentrations of thyrotropin and normalise thyroid hormones in most patients; tumour shrinkage also occurs in at least a third of cases.[1-4] Octreotide has also been tried in the management of other rare adenomas such as clinically nonfunctioning adenomas, but results have been mixed; in a few cases there has been relief of symptoms such as headache without any change in tumour volume.[5]

Pretibial myxoedema. Pretibial myxoedema (deposition of glycosaminoglycans in the subcutaneous tissue of the shins) is associated with Graves' disease (see Hyperthyroidism, p.2165). There are reports of apparent benefit from the use of octreotide for this condition. In one case,[1,2] octreotide given for 6 months after surgical removal of the myxoedematous tissue may have prevented its recurrence. In another,[3] octreotide injected intralesionally was reported to improve and control the condition. However, in other cases[4] subcutaneous octreotide has been ineffective.

Raised intracranial pressure. For a reference to octreotide being tried in idiopathic intracranial hypertension, see p.1181.

Sulfonylurea overdose. Octreotide has been used in the treatment of severe refractory cases of sulfonylurea-induced hypoglycaemia (see p.461).

Preparations

Proprietary Preparations (details are given in Part 3)

Pegvisomant *(USAN, rINN)*

B2036-PEG; Pegvisomantti; Pegvisomantum. 18-L-Aspartic acid-21-L-asparagine-120-L-lysine-167-L-asparagine-168-L-alanine-171-L-serine-172-L-arginine-174-L-serine-179-L-threonine growth hormone (human), reaction product with polyethylene glycol.

Пэгвизомант

CAS — 218620-50-9.

ATC — H01AX01.

ATC Vet — QH01AX01.

Adverse Effects and Precautions

Adverse effects commonly reported with the use of pegvisomant include gastrointestinal disturbances, elevated liver function tests, flu-like symptoms, fatigue, injection site reactions, arthralgia, myalgia, peripheral oedema, headache, dizziness, somnolence, tremor, sweating, pruritus, rash, sleep disorders, hypercholesterolaemia, weight gain, hyperglycaemia, hunger, and hypertension.

Liver function tests should be measured before starting pegvisomant, then every 4 to 6 weeks for the first 6 months of therapy. In the USA, it is also recommended that further testing take place twice in the next 6 months and then twice in the following year.

Pegvisomant is structurally similar to growth hormone and may cause assays to overestimate growth hormone concentrations.

Effects on the skin. Lipohypertrophy has been described in patients who have consistently injected pegvisomant into the same subcutaneous area.[1,2] The efficacy of pegvisomant was also reduced in one case, but lipohypertrophy resolved and pegvisomant efficacy improved when the patient used the recommended technique of injection site rotation.[2]

1. Maffei P, *et al.* Lipohypertrophy in acromegaly induced by the new growth hormone receptor antagonist pegvisomant. *Ann Intern Med* 2006; **145:** 310–12.
2. Marazuela M, *et al.* Pegvisomant-induced lipohypertrophy: report of a case with histopathology. *Ann Intern Med* 2007; **147:** 741–3.

Interactions

Pegvisomant may increase insulin sensitivity. In patients with diabetes, doses of insulin or oral hypoglycaemics may need to be decreased because of the increased risk of hypoglycaemia. Patients taking opioid analgesics may require higher serum concentrations of pegvisomant to achieve appropriate IGF-I suppression.

Pharmacokinetics

Pegvisomant is absorbed slowly after subcutaneous injection, and peak serum concentrations occur after about 33 to 77 hours. It is slowly eliminated from serum, with a half-life estimated to range from 74 to 172 hours. Renal clearance of pegvisomant is negligible.

Uses and Administration

Pegvisomant is a protein of recombinant DNA origin to which several polyethylene glycol polymers are covalently bound. It is an analogue of human growth hormone that acts as an antagonist at growth hormone receptors, and is used in the treatment of acromegaly (below). A loading dose of 40 or 80 mg is given subcutaneously, followed by 10 mg daily. Further dose adjustments, in increments of 5 mg, are made according to serum concentrations of IGF-I, which should be measured every 4 to 6 weeks. The maintenance dose should not exceed 30 mg daily.

Acromegaly. Pegvisomant may be used in patients with acromegaly (p.1798) who have not responded adequately to surgery, radiotherapy, or somatostatin analogues, or when these therapies are unsuitable or not tolerated. The combination of pegvisomant with a somatostatin analogue is also under investigation in patients whose response to a somatostatin analogue alone is inadequate.

(pralmorelin)

Profile

Pralmorelin is a small synthetic peptide that stimulates the release of growth hormone. It is under investigation in the diagnosis of growth hormone deficiency and for the treatment of growth retardation (p.1798).

Somatomedins ⊗

IGFs; Insulin-like Growth Factors; Somatomedinas; Sulphation Factors.

Description. Somatomedins are a group of polypeptide hormones related to insulin and usually known individually as insulin-like growth factors (IGFs), with molecular weights of about 7000 to 8000. They are synthesised in the liver, kidney, muscle, and other tissues.

Mecasermin *(BAN, USAN, rINN)* ⊗

Mecasermin Rinfabate *(USAN, rINN)* ⊗

Mecasermina rinfabato; Mécasermine Rinfabate; Mecaserminum Rinfabas; rhIGF-I/rhIGFBP-3. A complex of insulin-like growth factor I (human) with insulin-like growth factor-binding protein IGFBP-3 (human).

Мекасермин Ринфабат

CAS — 478166-15-3.

ATC — H01AC05.

ATC Vet — QH01AC05.

Adverse Effects and Precautions

Since the somatomedins are considered to be responsible for many of the actions of growth hormone similar adverse effects (see p.1800) might be expected, and have been seen with mecasermin. Hypoglycaemia is common but symptoms can generally be avoided if mecasermin is given within 20 minutes of food. Tonsillar hypertrophy can develop; patients should be monitored for complications such as snoring, sleep apnoea, and chronic middle ear effusions. Thickening of the soft tissues of the face can also occur. Cardiomegaly and valvulopathy have been reported in a few patients. Although a relationship between cardiac changes and mecasermin therapy has not been confirmed, echocardiogram monitoring has been recommended. Injection site hypertrophy may occur, but can be avoided or resolved by proper rotation of injection sites.

Effects on the eyes. For concerns about an increased risk of retinopathy in diabetic patients receiving mecasermin, see under Diabetes Mellitus, below.

Intravenous administration. Syncope in the absence of hypoglycaemia has been reported in patients given mecasermin by intravenous bolus, accompanied in some cases by convulsions, asystole, bradycardia, hypotension, or dizziness.[1] Reports appear to have ceased since recommendations that mecasermin should not be given intravenously at rates greater than 24 micrograms/kg per hour. Arthralgia, nerve palsies, and hypophosphataemia and dyspnoea have been associated with high-dose intravenous bolus therapy.[2] Mecasermin is now given by subcutaneous injection (see Uses and Administration, below).

1. Malozowski S, Stadel B. Risks and benefits of insulin-like growth factor. *Ann Intern Med* 1994; **121:** 549.
2. Usala A-L. Risks and benefits of insulin-like growth factor. *Ann Intern Med* 1994; **121:** 550.

Pharmacokinetics

After subcutaneous injection, mecasermin has a bioavailability of almost 100% in healthy subjects. In the circulation it is bound to 6 binding proteins, with more than 80% bound to binding protein 3 (IGFBP-3). However, IGFBP-3 is greatly reduced in patients with severe primary IGF-I deficiency, such that there is an increase in the clearance of mecasermin. Mecasermin is metabolised in the liver and the kidney, and has a terminal half-life of about 6 hours in children with severe primary IGF-I deficiency.

After subcutaneous injection of mecasermin rinfabate in children with severe primary IGF-I deficiency, the half-life of free IGF-I is prolonged to about 13 hours and IGFBP-3 has a half-life of about 54 hours.

Uses and Administration

The somatomedins are a group of polypeptide hormones, some of which are involved in mediating the effects of growth hormone in the body. Insulin-like growth factor I (IGF-I) is believed to be responsible for many of the anabolic effects of growth hormone. It is secreted primarily by the liver, regulated principally by growth hormone and insulin secretion; IGF-I may also be secreted in other tissues, where it may exert local hormonal (paracrine) effects. In the circulation, IGF-I is almost completely protein bound; 6 binding proteins have been identified and production of some of these is also under the control of growth hormone. In addition to its anabolic effects IGF-I, which is structurally related to insulin, also has potent hypoglycaemic properties.

IGF-I is available as mecasermin, a product of recombinant DNA technology. It is used in the treatment of growth failure in children with severe primary IGF-I deficiency (such as Laron-type dwarfism, in which an abnormality of the growth hormone receptor results in an inability to secrete endogenous IGF-I—see Growth Retardation, below). It may also be used in children with growth hormone gene deletion who have developed neutralising antibodies to growth hormone. However, it is not recommended for children less than 2 years of age because of a lack of data. The starting dose of mecasermin is 40 to 80 micrograms/kg twice daily by subcutaneous injection. After 1 week, if this dose is tolerated, it may be increased by 40 micrograms/kg per dose to a maximum of 120 micrograms/kg twice daily. Mecasermin should be given within 20 minutes before or after food, to minimise hypoglycaemia. The dose should be reduced if hypoglycaemia occurs with recommended doses despite adequate food intake. If the patient is unable to eat for any reason, the dose of mecasermin should be withheld.

Mecasermin rinfabate is a recombinant protein complex of IGF-I and its most abundant binding protein, insulin-like growth factor binding protein-3 (IGFBP-3). It is under investigation in the management of amyotrophic lateral sclerosis and myotonic muscular dystrophy.

IGF-II (IGF-2) is thought to play an important role in fetal growth, although its function in adults is uncertain. It is closely related in structure to IGF-I, but is not under the control of growth hormone.

Diabetes mellitus. Patients with type 1 diabetes mellitus (p.431) have low circulating levels of insulin-like growth factor I (IGF-I), and there has been considerable interest in the therapeutic potential of mecasermin in these patients.[1] Randomised studies[2,3] have found that mecasermin 40 micrograms/kg once or twice daily by subcutaneous injection improves metabolic control in the short term when added to insulin therapy. Insulin doses can also be reduced in some patients.[3] However, the role of IGF-I in the development of diabetic complications is unclear and there has been some concern about its proliferative effect in diabetic retinopathy.[1] Optic disc swelling and worsening of retinopathy have been reported with higher doses of mecasermin.[3] Mecasermin rinfabate is being studied in an attempt to limit adverse effects such as oedema, jaw pain, headache, Bells' palsy, and retinal oedema.[4]

Mecasermin has also been reported to improve insulin sensitivity and to lower concentrations of insulin, glucose, and C-peptide in patients with syndromes of severe insulin resistance or type 2 diabetes mellitus.[1]

Growth retardation. Mecasermin is used in the treatment of Laron-type dwarfism (growth hormone resistance), a form of growth retardation (p.1798). Doses of 150 to 240 micrograms/kg daily, given subcutaneously, have stimulated linear growth and normalised biochemical abnormalities in these patients.[1] During long-term use, growth hormone and insulin are persistently suppressed, preventing hypoglycaemia and stabilising blood-glucose concentrations. There is also an increase in the production of the insulin-like growth factor binding protein-3, which prolongs the half-life of mecasermin so that a progressive dose reduction is needed to avoid overdosage and adverse effects.[2]

1. Laron Z. The essential role of IGF-I: lessons from the long-term study and treatment of children and adults with Laron syndrome. *J Clin Endocrinol Metab* 1999; **84:** 4397–4404.
2. Laron Z. Laron syndrome (primary growth hormone resistance or insensitivity): the personal experience 1958–2003. *J Clin Endocrinol Metab* 2004; **89:** 1031–44.

Motor neurone disease. Mecasermin is under investigation for the management of amyotrophic lateral sclerosis, a form of motor neurone disease (p.2380). Mecasermin may have modest benefits but there is not enough available evidence to assess conclusively.[1]

$C_{149}H_{246}N_{44}O_{42}S.xC_2H_4O_2.yH_2O$ = 3357.9 (sermorelin).

CAS — 86168-78-7 (sermorelin); 114466-38-5 (sermorelin acetate).

ATC — H01AC04; V04CD03.

ATC Vet — QH01AC04; QV04CD03.

Adverse Effects and Precautions

Facial flushing and pain at the injection site may occur after injection of sermorelin acetate. Headache, nausea and vomiting, dysgeusia, and tightness in the chest have also been reported. Antibodies to somatorelin may develop on repeated use.

Sermorelin should be used with care in patients with epilepsy. Uncontrolled hypothyroidism, obesity, hyperglycaemia, or elevated plasma fatty acids may impair response to sermorelin. Sermorelin should not be used to treat growth retardation in children whose growth hormone response to stimulation tests is inadequate. Treatment should cease once the epiphyses have closed.

Interactions

Drugs that affect the secretion of growth hormone may interfere with the diagnostic efficacy of somatorelin or sermorelin; these include growth hormone itself, somatostatin, insulin, corticosteroids, and cyclo-oxygenase inhibitors such as aspirin and indometacin. Growth hormone concentrations may be raised by clonidine and levodopa. The response to somatorelin or sermorelin may also be reduced by antimuscarinic drugs such as atropine, and by antithyroid drugs such as propylthiouracil.

Uses and Administration

Somatorelin is a peptide, secreted by the hypothalamus, that promotes the release of growth hormone from the anterior pituitary. It exists as 44-, 40-, and 37-amino acid peptides; the 44-amino acid form may possibly be converted to the smaller forms but all are reported to be active, the activity residing in the first 29 amino acid residues. Sermorelin is a synthetic peptide corresponding to the 1–29 amino acid sequence of somatorelin.

Sermorelin acetate is used for the diagnosis of growth hormone deficiency. The usual dose is the equivalent of sermorelin 1 microgram/kg by intravenous injection in the morning after an overnight fast. A normal response to sermorelin indicates that the somatotrophs are functional, but does not exclude growth hormone deficiency due to hypothalamic dysfunction; to establish a diagnosis it must be used with other tests. Somatorelin acetate is used similarly.

Sermorelin has also been used for the treatment of growth hormone deficiency in children; doses equivalent to 30 micrograms/kg, as the acetate, may be given once daily at bedtime by subcutaneous injection.

Sermorelin has also been tried as an adjunct to gonadotrophin therapy in the induction of ovulation and has been investigated in the treatment of HIV-associated wasting.

Diagnostic use. Somatorelin (in its 40- or 44-amino acid forms) has been used in the assessment of growth hormone deficiency.[1-3] It has usually been given as a single intravenous injection in doses of 1 microgram/kg or total doses of up to 200 micrograms. Subsequent normal or exaggerated increases in serum-growth hormone concentrations have occurred in healthy subjects,[1,2] and in patients with hypothalamic tumours[3] or acromegaly,[2] but not in patients with hypopituitarism.[2] A synthetic 29-amino-acid sequence of somatorelin, sermorelin acetate is now available for the diagnosis of growth hormone deficiency. However, it has been suggested that the test is not useful for screening as it does not test the hypothalamic-pituitary axis, and that it should not be used in routine clinical practice.[4] The use of sermorelin with the synthetic hexapeptide growth-hormone-releasing peptide-6 has also been reported.[5,6]

Growth retardation. Sermorelin has been studied in children with growth hormone deficiency (p.1798), usually given in doses of 30 micrograms/kg subcutaneously daily. Although there have been reports of improved growth rates,[1-3] there are limited data directly comparing these with growth hormone. One large study[4] of sermorelin found that, compared with results generally reported for growth hormone therapy, fewer patients responded over a 12-month period and growth responses were poorer.

Соматостатина Ацетат
ATC — H01CB01.
ATC Vet — QH01CB01.

Adverse Effects and Precautions

Abdominal discomfort, flushing, nausea, and bradycardia have been associated with too rapid infusion. Because of the short half-life of somatostatin adverse effects are generally transitory on stopping or reducing the infusion. Giving with parenteral nutrition has been suggested because of the inhibitory effects of somatostatin on intestinal absorption; blood glucose should be monitored since somatostatin may interfere with the secretion of insulin and glucagon.

Effects on the kidneys. Somatostatin has been reported to have an inhibitory effect on renal function[1,2] and severe water retention and hyponatraemia have been reported.[3]

Uses and Administration

Somatostatin is a polypeptide obtained from the hypothalamus or by synthesis. The naturally occurring form has a cyclic structure. Although somatostatin derived from the hypothalamus is a 14-amino-acid peptide, a longer, 28-amino-acid form also exists in some tissues. Somatostatin inhibits the release of growth hormone (p.1799) from the anterior pituitary. It also inhibits the release of thyrotrophin (p.2177) and corticotropin (p.1523) from the pituitary, glucagon and insulin from the pancreas, and appears to have a role in the regulation of duodenal and gastric secretions. In the CNS it appears to play a role in the perception of pain.

It has been tried in a variety of disorders such as upper gastrointestinal haemorrhage including variceal haemorrhage (see under Monoethanolamine, p.2346), insulin resistance, and the management of hormone-secreting tumours and other hypersecretory disorders. However, it has a very short duration of action and several analogues of somatostatin have been produced in an attempt to prolong its activity as well as making its inhibitory effects more specific. Octreotide (p.1803) and lanreotide (p.1803) are such analogues.

Somatostatin is usually given as the acetate. In the treatment of gastrointestinal haemorrhage, such as acute bleeding from oesophageal varices, somatostatin acetate equivalent to somatostatin 250 micrograms has been given by intravenous bolus over 3 to 5 minutes, followed by a continuous infusion of 250 micrograms/hour (about 3.5 micrograms/kg per hour) until the bleeding has stopped, which is usually within 12 to 24 hours. The infusion may then be continued for a further 48 to 72 hours to prevent recurrent bleeding. In some cases, the infusion may be continued to a maximum of 120 hours.

Malignant neoplasms. Somatostatin given with melatonin, bromocriptine, and a solution of retinoids (the Di Bella regimen) was ineffective in the treatment of advanced malignancies (see Malignant Neoplasms, under Uses and Administration of Octreotide, p.1806).

Profile

Vapreotide is a somatostatin analogue similar to octreotide (p.1803). It is under investigation in the management of various disorders, including bleeding oesophageal varices, gastrointestinal and pancreatic fistulas, acromegaly, carcinoid tumours, and for the prevention of postoperative complications following pancreatic surgery.

The compounds described in this chapter are used in diseases considered to have an auto-immune component, and in organ and tissue transplantation. The choice of an immunosuppressant is discussed below.

Choice of Immunosuppressant

Asthma

Immunosuppressant drugs do not play a role in the regular management of asthma (p.1108). In individual patients requiring oral corticosteroids for chronic severe asthma immunosuppressants have however been investigated for their anti-inflammatory and corticosteroid-sparing properties.

Blood disorders

For the use of immunosuppressants in aplastic anaemia, see p.1042.

Diabetes mellitus

For a discussion of diabetes mellitus and its treatment, including the experimental use of immunosuppressants, see p.431. See also Pancreatic Transplantation, below.

Gastrointestinal disorders

Inflammatory bowel disease. A number of immunosuppressants have been tried in inflammatory bowel disease (p.1697), with some success, but the mainstays of drug therapy remain the aminosalicylates and the corticosteroids. Immunosuppressants may be valuable in some circumstances for their corticosteroid-sparing effect and for chronic active disease refractory to other treatments.

Liver disorders

For a discussion of the role of immunosuppressants, and particularly azathioprine, in the management of chronic active hepatitis, see p.1501. For the use of immunosuppressants in primary biliary cirrhosis see under Ursodeoxycholic Acid, p.2408.

Lung disorders

Diffuse parenchymal lung disease. Corticosteroids, usually with azathioprine (or occasionally cyclophosphamide), are the mainstay of treatment for diffuse parenchymal lung disease (p.1502) such as cryptogenic fibrosing alveolitis.

Neurological disorders

Multiple sclerosis. Immunosuppressants have been tried in the treatment of multiple sclerosis (p.892), although in some studies the benefit obtained may have been outweighed by toxicity.

Myasthenia gravis. Patients with myasthenia gravis (p.629) who require immunosuppression are usually treated with corticosteroids. Azathioprine is used mainly in myasthenia gravis for its corticosteroid-sparing effect but may also be of use when corticosteroids are contra-indicated or when response to their use alone is insufficient. Ciclosporin, mycophenolate mofetil, and tacrolimus have been tried similarly.

Ocular disorders

Immunosuppressants have been used with some success in ocular disorders with inflammatory or immunological components. In *scleritis* and *uveitis* (see p.1512 and p.1515) corticosteroids, given topically, intra-ocularly, or systemically are widely used when treatment is needed, but in unresponsive disease, or in patients with unacceptable adverse effects, immunosuppressants such as azathioprine, ciclosporin, or mycophenolate mofetil, may be given. Daclizumab, leflunomide, sirolimus, and tacrolimus have also been tried in uveitis. Immunosuppressants may be valuable in the management of *Behçet's disease*, *rheumatoid arthritis*, or *Wegener's granulomatosis*, (see p.1499, p.11, and p.1515, respectively), including their associated ocular lesions. Ciclosporin or azathioprine have been used with corticosteroids in the management of both ocular and vascular symptoms of *Cogan's syndrome* (p.1502). Ciclosporin has also been used topically in corneal ulceration, see p.1831.

In *Graves' ophthalmopathy* (see under Hyperthyroidism, p.2165), ciclosporin with oral glucocorticoids has been used as an effective alternative treatment.

Organ and tissue transplantation

Although surgical techniques suitable for the removal of organs and tissues from a donor, and their engraftment into a host, have existed for many years, such grafts would not normally survive for long. The host's CD4 T-cells recognise foreign antigens from donor cells. A CD4 cell is then activated by antigen-presenting cells to secrete interleukin-2 and induce T-cell proliferation. Activated T-cells mediate a rejection response, by increasing the activity and function of B-cells, cytotoxic CD8 T-cells, and macrophages, either directly, or by cytokine release. Only from the 1960s with the development of drugs capable of attenuating or suppressing this response, did transplantation start to become a feasible mode of treatment.

The drugs available vary in their mechanisms of action, and are often combined for optimum effect. **Corticosteroids** (glucocorticoids) act at several points in the immune cascade, including antigen recognition and production of lymphokines. The **calcineurin inhibitors** ciclosporin and tacrolimus prevent formation of cytotoxic T-cells by inhibiting calcineurin activation, an important step in the release of interleukin-2 from helper T-cells, while polyclonal or monoclonal **antibodies** such as antilymphocyte immunoglobulins and muromonab-CD3 bind to and deplete T-cell populations. Basiliximab and daclizumab function as **interleukin-2 receptor antagonists**. **Anti-proliferative drugs** such as azathioprine and mycophenolate mofetil act by preventing cell division of lymphocytes. Sirolimus and everolimus are **proliferation signal inhibitors** that inhibit the T-cell response to cytokines.

Immunosuppressant regimens may be divided into those aimed at:

- prevention of rejection in the early period after transplantation
- long-term maintenance prophylaxis
- treatment of acute episodes of rejection.

In haematopoietic stem cell transplantation, where an immunologically competent tissue is transplanted, it is the donor cells which attack host tissues (graft-versus-host disease), and immunosuppression is required for prophylaxis of this condition.

Because of the critical nature of the early stage, when the organ or tissue must recover normal function, and perhaps to permit better long-term tolerance, initial immunosuppressant regimens tend to use higher doses than maintenance therapy. Standard protocols are usually based around ciclosporin or tacrolimus, combined with corticosteroids and an anti-proliferative agent (triple therapy). Where appropriate, a course of monoclonal or polyclonal antibodies is added to the standard regimen for induction (quadruple therapy). This is usually only required in individuals at increased risk of acute rejection, such as children or patients with a previous transplant or pregnancy, multiple blood transfusions, or a poor HLA-matching. However, it also enables delayed introduction of ciclosporin or tacrolimus in patients at risk of nephrotoxicity, and the use of low-dose regimens, allowing for withdrawal of corticosteroids.

No one immunosuppressive regimen has been identified as being superior to others in pregnancy, and although there are known theoretical risks to mother and fetus, successful pregnancies are now common in transplant recipients. The incidence of structural malformation has not been noted to be increased compared with the general population, but newer regimens have yet to be evaluated.

Since immunosuppressant therapy must in most cases be given for the lifetime of the graft, in long-term maintenance the toxicity of the drugs used, and the risks of infection, neoplasia, post-transplant diabetes mellitus, gout, hyperlipidaemia, and osteoporosis, must be considered. Doses and numbers of drugs used tend to be reduced, and in particular there is a tendency to taper or even eliminate the doses of corticosteroids used in maintenance regimens because of the potential sequelae of prolonged corticosteroid use. Post-transplant cardiovascular disease is a leading cause of death and graft loss. The risk varies between types of transplant, and specific recommendations for prophylaxis may differ.

The use of less intensive maintenance regimens must be balanced against the risk of an acute rejection episode, and the likelihood of its responding to therapy. High-dose corticosteroids and polyclonal or monoclonal antibodies often play a role in the rescue therapy of patients with acute rejection episodes, although much depends upon the severity of the reaction, and whether such episodes have occurred previously.

The management of immunosuppression for the transplantation of particular organs is discussed in more detail below. With the use of suitable immunosuppressant regimens long-term graft survival can be obtained after transplantation. Ultimately, however, the complications of chronic rejection are likely to lead to loss of the graft: the induction of specific tolerance to the donor organ remains the goal of much research. In allogeneic haematopoietic stem cell transplantation, where the aim of immunosuppression is prevention of graft-versus-host disease rather than rejection, immunosuppressant therapy can often be tapered off and eventually withdrawn.

Much interest has been aroused by the possibility of organ transplants from *animals*, genetically modified to reduce complement-mediated hyperacute rejection. It is not clear whether such xenotransplantation will require modified immunosuppressive regimens.

Corneal transplantation. For reference to the use of immunosuppressants to treat graft rejection after corneal transplant see Corneal Graft Rejection, p.1502.

Haematopoietic stem cell transplantation. Haematopoietic stem cell transplantation (HSCT) is used in the treatment of a variety of malignancies, notably leukaemias and lymphomas; to permit the use of very high-dose chemotherapy in the management of some solid tumours (bone marrow rescue); and to treat some other serious disorders affecting the bone marrow, such as aplastic anaemia and the haemoglobinopathies.[1,2]

HSCT may be **autologous**, in which case the patient's own stem cells are harvested or **allogeneic**, where stem cells are harvested from a healthy donor matched as closely as possible for HLA type.[3,4] The haematopoietic stem cells themselves may be derived from:

- bone marrow (classical bone marrow transplantation, BMT)
- peripheral blood (peripheral blood stem cell transplantation, PBSCT)
- umbilical cord blood

PBSCT is convenient as collection does not require hospitalisation or general anaesthesia for the donor, and clinical studies have shown more rapid engraftment of neutrophils and platelets compared with BMT.[2,5-7] However, allogeneic PBSCT appears to increase the risk of graft-versus-host disease[1,2,6-10] (see below). Allogeneic PBSCT was associated with decreased relapse rates and improved disease-free survival but similar overall survival in adults, when compared with BMT.[6] However, in children, allogeneic PBSCT was associated with higher mortality and treatment failure than BMT although relapse rates were similar; advanced disease status and use of colony-stimulating factor were also associated with poorer outcome.[7] Use of umbilical cord blood is associated with slightly delayed engraftment,[2,11-13] and hence, perhaps, an increased risk of fatal infection,[2,11] but a lower risk[2,12,14] of graft-versus-host disease (see below). A meta-analysis[15] confirmed these findings, but found a similar relapse rate, and equivalent survival for cord blood transplantation compared with unrelated BMT. It has mainly been used for transplants in children, since the total number of stem cells in a donation often falls short of the levels deemed necessary for engraftment in an adult.[1,2,5,13] However, cord blood is increasingly used for transplants in adults.[16] Since cell dose correlated with outcome in most studies, strategies have been developed to increase progenitor cell numbers in the cord blood units; techniques include pooled or sequential cord blood transplantation, or expansion of the cord blood cells with cytokines. Combination cord blood and bone marrow transplants, and reduced intensity regimens are under investigation.[16-18]

With autologous HSCT problems of **compatibility** do not arise, but if abnormal cell clones are present in the marrow (as in leukaemia) or stem cells they may be transferred back into the patient and cause disease relapse.[1] Allogeneic HSCT requires immunosuppression for about 6 months[19] to prevent graft-versus-host disease (see below) until a new immunological balance is achieved.

The patient is normally prepared by **conditioning** with total body irradiation, or myeloablative chemotherapy with drugs such as cyclophosphamide or busulfan, or more often both, in order to destroy host bone marrow cells.[5,20] In autologous procedures, harvesting of bone marrow or peripheral blood must be carried out before conditioning. Bone marrow is aspirated from the donor, and infused into the recipient via an indwelling catheter or directly into a peripheral vein. Peripheral blood stem cells are collected by cell separation after mobilisation, which is best achieved by a combination of chemotherapy and granulocyte or granulocyte-macrophage colony-stimulating factor.[1,2,5] Infection is a major cause of morbidity and mortality after transplantation, so prophylactic cover with antimicrobials[2,21,22] and normal immunoglobulins is recommended,[21] although the value of the latter has been questioned.[23] Granulocyte colony-stimulating factors are sometimes used after allogeneic transplants to hasten haematopoietic recovery. While a meta-analysis found no evidence for an increase in risk for acute or chronic graft-versus-host disease,[24] a large study found delayed platelet engraftment, increased graft-versus-host disease, and increased mortality in those given growth factors after allogeneic bone marrow transplants; these effects were not seen in patients given allogeneic PBSCT.[25]

In addition to such supportive care, patients who have received allogeneic transplants require immunosuppressive therapy aimed at the prevention of **graft-versus-host disease** (GVHD). GVHD is usually characterised as *acute* or *chronic* depending on the manifestations, and the time of presentation[1,4,5,10,26-28] (by convention acute disease occurs within a hundred days of transplantation, and chronic disease after this time, although in practice there is considerable overlap).

The organ systems primarily affected are skin, liver, lung, and gastrointestinal tract. Both forms are marked by maculopapular rashes, which in severe disease may progress to bullous lesions and epidermal necrolysis. Liver disease may include cholestatic jaundice (usually in the acute form) and hepatitis; symptoms may need to be distinguished from the veno-occlusive disease (VOD) which sometimes complicates bone marrow transplantation and is due to the pre-transplant conditioning regimen (VOD may respond to treatment with antithrombin III[29] or defibrotide[30,31]). Ursodeoxycholic acid has been found to be of benefit for the prophylaxis of hepatic complications.[32] The main symptom of gastrointestinal GVHD is diarrhoea, often severe and painful. In patients with chronic GVHD other manifestations may include arthritis, mucositis, lung disease, and scleroderma.

Most modern regimens for the prophylaxis of GVHD after allogeneic HSCT are based on ciclosporin. Although GVHD still occurs in many ciclosporin-treated patients, morbidity is much reduced and survival improved. Combination regimens have been tried for prophylaxis, particularly ciclosporin or tacrolimus with methotrexate, but also combinations with other drugs including antilymphocyte immunoglobulins, corticosteroids, mycophenolate mofetil, and sirolimus.[9,19,33] Monoclonal antibodies have been used to produce T-cell depletion or reduce the effects of circulating cytokines.[9,27]

Acute GVHD is usually treated primarily by the addition of corticosteroids (usually methylprednisolone) to the prophylactic regimen until symptoms are controlled, followed by gradual tapering of the dose. Mycophenolate mofetil, antilymphocyte immunoglobulins, interleukin-2 receptor antibodies, etanercept, and infliximab have also been tried.[2,9,19,34-36] PUVA therapy and extracorporeal photopheresis have been used[2,9] and infusion of mesenchymal stem cells is also under investigation.[9,37]

Chronic GVHD has no specific standard therapy; most centres use a combination of corticosteroids and a calcineurin inhibitor (ciclosporin or tacrolimus).[2,10,19,38,39] Drugs that have been tried for salvage therapy include mycophenolate mofetil, sirolimus, daclizumab, thalidomide, pentostatin, etanercept, infliximab, and rituximab.[10,19,35,38] PUVA therapy with extracorporeal photopheresis has also been used, with good response rates,[10,38] and recommendations for use have been published in the UK.[40] Mesenchymal stem cell infusion may be a potential therapy.[10] Octreotide is recommended for the symptomatic treatment of diarrhoea.[41]

Donor T-cells reactive to recipient minor histocompatibility antigens can inhibit the growth of abnormal cells, and may also target aberrantly expressed proteins, provoking a 'graft-versus-tumour' effect, which reduces relapse, both after allogeneic transplantation and among patients in whom GVHD develops.[1] Indeed, many leukaemia patients who relapse after allogeneic transplant can be reinduced into remission by an additional infusion of donor lymphocytes.[2] Consequently, too effective an immunosuppressant regimen may not always be desirable, and leukaemic patients given bone marrow transplants purged of T-cells, which virtually abolishes GVHD, do not have a better survival rate than those given conventional prophylaxis (engraftment too is reduced in the absence of all T-cells). Specific donor marrow T-cell depletion has been investigated as the sole form of GVHD prophylaxis.[42] In a multicentre randomised study, marrow T-cell depletion was found to reduce but not abolish the incidence of acute GVHD, accelerate neutrophil recovery and reduce toxicity compared to transplantation with T-cell replete marrow; however, disease-free survival at 3 years did not differ due to higher rates of relapse in some patients, and a higher incidence of serious infection in T-cell depleted marrow recipients.[43] The observation of graft-versus-malignancy effects has led to the development of low-dose non-myeloablative conditioning regimens (with or without donor lymphocyte infusions) for elderly or more sensitive patients who might have been unable to receive the standard aggressive therapy.[1-3,15,44-48] Safety and efficacy of these reduced-intensity regimens has led to wider application;[1] however, the lower mortality rate may be offset by a higher relapse rate,[1] and poor engraftment.[2]

The combination of irradiation, chemotherapy, and immunosuppression can cause the development of **secondary malignancies** in long-term survivors of HSCT.[1,49-52]

Intracoronary injection of haematopoietic stem cells into the heart is under investigation for cardiac disease,[53] **intramuscular** injection has also been investigated in peripheral vascular disease.[54] There is also interest in HSCT in some auto-immune disorders.[54]

Heart transplantation. Marked improvements have been seen in the outcome of heart transplantation since the introduction of ciclosporin, which has resulted in a reduced incidence and severity of rejection episodes.[1] The 1-year survival rate is about 80%.[1,2]

A common **immunosuppressive regimen** consists of triple therapy with ciclosporin or tacrolimus, azathioprine or mycophenolate, and corticosteroids.[3-6] Some centres also use induction therapy with antilymphocyte immunoglobulins (polyclonal antibodies) or muromonab-CD3.[4,7]

Induction therapy increases the risk of infection and lymphoproliferative disorders, but does delay the first rejection episode and allows transplantation in higher risk groups. It also enables calcineurin inhibitor use to be delayed in patients with initial poor renal function[7] and corticosteroids to be stopped as maintenance therapy in some groups of patients.[8] Muromonab-CD3 may be associated with a higher incidence of adverse reactions than polyclonal antibodies. Sensitisation to muromonab-CD3 is strongly associated with vascular rejection, and this and the dose-related propensity for lymphoproliferative disease with muromonab-CD3 have led to a decline in its use; some consider it should be abandoned in favour of polyclonal preparations.[7,9] The interleukin-2 receptor antibodies basiliximab and daclizumab have also been used for induction therapy.[2,7,10,11] However, daclizumab use has been associated with an increased risk of death due to infection, mostly in patients given additional immunosuppressive treatment with antilymphocyte drugs for early postoperative complications.[11] The interleukin-2 receptor antibodies have not as yet been associated with an additional risk of malignancies.[7] Alemtuzumab is under investigation for induction therapy in heart transplantation.[7,9]

There does not seem to be any great clinical benefit of tacrolimus over ciclosporin in heart transplant patients,[9,12,13] although some have reported reduced rates of histological rejection,[14,15] and there is evidence that patients of Afro-Caribbean origin in particular may be more prone to acute rejection with ciclosporin than with tacrolimus.[16] It has been suggested that tacrolimus be substituted for ciclosporin in those patients suffering persistent rejection, or adverse effects associated with ciclosporin,[17] or with hyperlipidaemia or hypertension.[18] Microemulsifying ciclosporin may be associated with less rejection than the oil-based formulation.[19]

The use of mycophenolate mofetil instead of azathioprine in triple therapy has been shown to reduce mortality and rejection in the first year after heart transplantation,[20] and a retrospective review[21] concluded that the advent of mycophenolate mofetil has contributed to improved survival in cardiac transplant recipients. Although lower mycophenolic acid (MPA) concentrations may be associated with an increased allograft rejection,[22] there appears to be no benefit in monitoring MPA concentrations beyond the first year in heart transplant recipients,[23] and MPA levels may be affected by concomitant immunosuppression, see Immunosuppressants under Interactions of Mycophenolate, p.1837.

Many variations of regimens exist, and different drugs have been substituted or used adjunctively in order to decrease the doses, and thus alleviate the adverse effects associated with calcineurin inhibitors and/or corticosteroids. Substituting cyclophosphamide for azathioprine for 6 weeks after transplantation is reported to reduce the development of anti-muromonab-CD3 antibodies from induction therapy.[24] Substitution of mycophenolate mofetil with intravenous pulse cyclophosphamide for 4 months post-transplantation appeared to decrease the risk of rejection in a small, non-randomised study in sensitised allograft recipients.[25]

Alternative adjunctive therapies are the proliferation signal inhibitors, sirolimus and everolimus,[2,9] which allow for use of lower doses of calcineurin inhibitors, thus preserving renal function; however, long-term data are limited, and there is little experience with these drugs in paediatric patients. Use of sirolimus with ciclosporin and corticosteroids markedly reduced the incidence of acute rejection in a small open-label study.[26] However, the use of sirolimus with mycophenolate mofetil was associated with a higher than expected incidence of acute rejection in cardiac transplant patients switched from calcineurin inhibitors to this combination.[27]

It has been suggested that the high doses of corticosteroids used increase the risk of cardiac adverse events in the longer term, and protocols that wean patients from corticosteroids after 6 months postoperatively have been used,[28,29] without apparent increases in infection or rejection. Corticosteroid avoidance or early withdrawal regimens are feasible in many, if not most, paediatric heart transplant recipients.[9]

In the early post-transplant period, the most significant **causes of morbidity** are infection and rejection episodes.[8,9] Other complications post-transplant include right ventricular failure and cardiac arrhythmias.[30] Co-trimoxazole is used to protect against *Pneumocystis jirovecii* infection, and ganciclovir as prophylaxis against CMV.[3] Rejection is usually treated with corticosteroids, but other drugs have been used for corticosteroid-resistant cases,[8] including antilymphocyte immunoglobulins and muromonab-CD3.[4,29] In repetitive rejection, tacrolimus may be substituted for ciclosporin, and mycophenolate mofetil for azathioprine.[4,5] Adjunctive methotrexate, total lymphoid irradiation and photopheresis have all been tried.[8]

In the late post-transplant period, malignancy and coronary artery disease are the most significant problems.[3,7,8] About 5% of paediatric heart transplant recipients have been reported to develop post-transplant lymphoproliferative disease (PTLD).[2,31] The strongest risk factor for PTLD is the development of primary Epstein-Barr virus infection after transplantation although children who are seropositive for the virus are not necessarily protected from this complication.[2,9] Despite treatment with chemotherapy or a reduction in immunosuppression, PTLD is associated with significant morbidity and mortality; acute rejection may occur in those whose immunosuppression is reduced.[2] Rituximab and cellular immunotherapy are novel therapeutic approaches for PTLD.[9] Cardiac allograft vasculopathy (also termed coronary artery vasculopathy, or chronic rejection) is a major cause of death and prevention of its progression is a major therapeutic goal.[2,3,9,32,33] It is thought to be mainly an immunological response, but can be accelerated by the classical risk factors of dyslipidaemia, obesity, glucose intolerance, and smoking, as well as by postoperative CMV infection, and immunosuppression itself.[3,6,8,34] Long-term use of calcineurin inhibitors is associated with renal dysfunction and also contributes to hypertension and hyperlipidaemia, all of which may exacerbate cardiac allograft vasculopathy.[33] Calcium-channel blockers have been used to decrease the incidence of coronary artery disease, but it has remained a difficult complication to treat.[34] HMG-CoA reductase inhibitors such as pravastatin and simvastatin are recommended[35,36] for the treatment of hyperlipidaemia; pravastatin or atorvastatin have been used in paediatric heart transplant patients.[2] There is evidence that statin therapy substantially improves survival.[37] Fibric acid derivatives may be considered in those patients with hypertriglyceridaemia not controlled by diet alone.[36] Supplementation with antioxidant vitamins such as C or E may reduce the progression of arteriosclerosis after transplantation,[38] and a small study[39] found that omega-3 fatty acids improved blood pressure control in hypertensive transplant recipients. There is some suggestion that sirolimus[26,40] and everolimus[41] may be of benefit in preventing cardiac allograft vasculopathy in adults; data are lacking in paediatric patients.[2,9] Retransplantation for graft failure due to cardiac allograft vasculopathy may be necessary.[33]

Improved surgical techniques and the use of ciclosporin have also made possible successful combined *heart-lung* transplants, although these may require enhanced or modified immunosuppression to prevent obliterative bronchiolitis, a possible manifestation of chronic rejection.[42] Early rejection after transplantation is the most important risk factor for the development of bronchiolitis obliterans syndrome although pathogenesis is unclear.[43] Lung infection,[42] or oxidative stress and lack of glutathione[43] may be factors in the aggravation or onset of bronchiolitis obliterans syndrome.

Donor-specific tolerance, whereby the patient permanently accepts their graft without the need for long-term immunosuppression, while remaining immunocompetent, remains the ultimate goal in cardiac transplantation.[6,9]

Intestinal transplantation. Transplantation of the *small bowel* is becoming more common, especially in children.[1] There are 3 types of intestinal allograft: the isolated intestine, combined liver and intestine, and the multivisceral graft, which can also include the pancreas, stomach, liver, and kidneys.[2-5] Combined liver and small intestine transplants are used for patients dependent on parenteral nutrition and with irreversible intestinal and hepatic failure, while intestine-only transplants tend to be used for intestinal failure in patients with severe progressive complications of parenteral nutrition, such as recurring sepsis and impending loss of central venous access.[1,5-8] Multivisceral transplants are most common in patients with diffuse gastrointestinal motility disorders.[3,4] Transplantation of the *colon* is avoided because of poorer outcomes and increased risk of sepsis.[9] Overall patient and graft survival varies according to the type of intestinal allograft, and between transplant centres, but is increasing, and reported to be about 50% at 5 years post-transplant.[1]

Tacrolimus and tapered corticosteroid doses[1,2,9-13] are the basis of the standard immunosuppressive regimen. In some centres, corticosteroid-free protocols are used, with induction therapy, and tacrolimus alone as maintenance.[5,13] Prostaglandins[8,9] such as alprostadil may also be given to augment mucosal immunosuppression, and improve splanchnic and renal blood flow. Induction therapy with antilymphocyte immunoglobulins or the interleukin-2 receptor antibodies basiliximab and daclizumab is used to prevent rejection.[1,9,11,13-15] Alemtuzumab has also been used.[12,13,15]

Adjunctive immunosuppressants have been added to the maintenance regimen. Azathioprine has been used.[5,11] Sirolimus has also been tried,[1,4,8,9,14] but combining tacrolimus with sirolimus does not have additional benefit over tacrolimus alone.[15] Sirolimus maintenance monotherapy, after induction, is increasingly favoured.[15] Any role for mycophenolate mofetil in intestinal transplantation is questionable,[12,14,16] owing to its gastrointestinal toxicity and poor absorption in intestinal transplant recipients, particularly during rejection.

Substantial morbidity occurs with intestinal transplants and acute rejection, manifested by diarrhoea, fever, and ileus, is common.[1,2,5,9] Initial treatment is with corticosteroids, and most centres increase the dose of tacrolimus as well. Antilymphocyte immunoglobulins or muromonab-CD3 may be used for severe or corticosteroid-unresponsive episodes.[1,2,7,9,13,15] Azathioprine, sirolimus, or mycophenolate mofetil have also been used adjunctively for treatment of rejection,[1,7] although concerns persist about the use of mycophenolate in intestinal transplantation (see above). Chronic rejection, a common cause of late graft dysfunction, is more difficult to treat.[1,9,16] Infliximab has been tried.[17]

Bacterial, viral, and fungal infections are also common post-transplant,[1,2,9,16] and may be confused with rejection.[4,16] Protocols for antimicrobial prophylaxis and treatment are similar to those used for other solid organ transplants. Selective gastrointestinal decontamination with non-absorbable oral antibacterials is usually performed during the first fortnight after transplantation, and during moderate to severe rejection episodes.[10,11] The high level of immunosuppression necessary in intestinal transplantation makes recipients particularly susceptible to post-transplant lymphoproliferative disease associated with Epstein-Barr virus infection.[1,2,4,6,16] Controlling rejection by more potent immunosuppression is difficult because of these complications, so the induction of immune tolerance through adjunctive bone marrow infusion is being investigated.[1,2,12,14] Graft-versus-host disease (see Haematopoietic Stem Cell Transplantation, p.1811) may occur and there may be a recurrence of the original disease.[2]

Kidney transplantation. The transplantation of kidneys is now established as the ultimate therapy for end-stage renal disease. There is no single generally accepted immunosuppressant regimen, and different centres have achieved good results with a variety of strategies.[1] Therapy should be tailored to the individual patient. A number of factors affect the intensity of immunotherapy required, including the donor source (living or cadaveric) and degree of HLA histocompatibility, and the age, race and panel reactive antibody titre of the recipient.[1]

A widely used approach consists of **triple therapy** with a *calcineurin inhibitor* (ciclosporin or tacrolimus), an *anti-proliferative* (azathioprine or mycophenolate mofetil), and a *corticosteroid* (prednisolone).[2,3] Triple therapy is popular because it allows the use of lower doses of nephrotoxic calcineurin inhibitors, and the eventual tapering or even elimination of corticosteroids in some patients.[1]

Many variations of triple therapy regimens have been used.

- Azathioprine has largely been replaced by mycophenolate mofetil, which lowers the incidence of acute rejection and reduces the risk of chronic allograft failure.[4,5] This has been challenged, however, by a study[6] in which mycophenolate mofetil was found to be no better than azathioprine in prevention of acute rejection. The drugs were given with microemulsifying ciclosporin and corticosteroids, and ciclosporin dosage was targeted to plasma trough concentrations. The authors noted that previous studies attesting greater efficacy with mycophenolate mofetil had been carried out using the older standard ciclosporin formulation, and that the possibility of better activity with mycophenolate mofetil could not be excluded in patients in whom target ciclosporin concentrations are not achieved.
- Tacrolimus has been substituted for ciclosporin because it appeared to be more effective in preventing acute rejection than either the older oil-based formulation,[4] or the newer microemulsifying formulation.[7,8] Although it has been suggested that this does not lead to improved survival of either patients or grafts,[9] a systematic review[10] concluded that use of tacrolimus did improve graft survival, with a 44% reduction in graft loss within the first 6 months of transplantation; acute rejection was reduced by almost a third and severe rejection by half. The benefit in graft survival diminished with higher concentrations of tacrolimus. However, although tacrolimus may have a better cardiovascular risk profile than ciclosporin,[7,11,12] patients are two to three times more likely to develop diabetes and to have neurological adverse effects.[10] Choice of calcineurin inhibitor is therefore strongly influenced by adverse effect profiles.[9,13,14]
- There is some evidence of synergism between sirolimus and ciclosporin[15] and *addition* of sirolimus to ciclosporin-based regimens may reduce the incidence of acute rejection.[4,16] Combining sirolimus with tacrolimus instead of ciclosporin may be even more effective.[4] However, sirolimus may augment the nephrotoxicity of both ciclosporin[2] and tacrolimus,[5] and its use with full-dose calcineurin inhibitors has been associated with significantly reduced rates of allograft survival.[17] In an attempt to reduce the chronic allograft nephropathy (see below) associated particularly with calcineurin inhibitors, sirolimus has been given with azathioprine or mycophenolate mofetil, as an *alternative* to ciclosporin-based protocols. Comparable rejection rates and better renal function have been reported, although the use of sirolimus may increase the risk of cardiovascular-related morbidity and mortality, and safety has not been established.

Sequential quadruple therapy, in which antibody-based induction therapy is given postoperatively, in addition to triple therapy,[2,13] is also used. The antibodies are usually stopped once good graft function is achieved.[1] The regimen may improve long-term graft survival in patients with delayed graft function.[18]

Polyclonal lymphocyte-depleting antibodies are associated with a low incidence of rejection but evidence of their benefit in terms of graft survival is lacking; rabbit antilymphocyte immunoglobulin appears to be better than that of equine origin. Use of muromonab-CD3 has declined because of poor tolerability and an increased risk of lymphoproliferative disease.[19] The more specific interleukin-2 receptor antibodies basiliximab and daclizumab are widely used and appear to reduce the incidence of rejection episodes without increased toxicity.[4,5,18-21] Alemtuzumab has also been used, but data for this drug are comparatively limited.[19,22,23]

Some consider the interleukin-2 receptor antibodies to be the first-line choice for induction therapy because of their superior safety profile. While there appears to be no difference between rabbit antilymphocyte immunoglobulins and interleukin-2 receptor antibodies in terms of efficacy, acute rejection in high-risk patients appears to occur less often with rabbit antilymphocyte immunoglobulins, which may be the preferred choice in patients who are highly sensitised or receiving a second transplant.[19] Basiliximab or daclizumab, used as part of a ciclosporin-based regimen, are recommended in the UK as options for induction therapy in children and adolescents undergoing renal transplantation, irrespective of immunological risk.[14]

As immunosuppressant regimens have developed the role of corticosteroids has come to be questioned, mainly because of the adverse effects associated with their prolonged use.[4,9,24,25] Studies indicate that corticosteroid **withdrawal** is feasible in many patients initially given triple therapy,[1,26] although there is debate about the long-term consequences of this for graft survival.[4,25,27,28] Corticosteroid-sparing regimens may increase the risk of acute or chronic rejection, and the benefit associated with them may be limited by the high proportion of patients who need to resume corticosteroid therapy. Nevertheless, such regimens are considered to be feasible, even in the early period after transplantation. Even complete avoidance of corticosteroids may be possible with induction therapy using interleukin-2 receptor antibodies. However, it is crucial to individualise therapy, and caution is advised for high-risk patients, such as African Americans, sensitised, previously transplanted patients, or those with previous acute rejection episodes. Some consider the best approach to rapid corticosteroid withdrawal to be induction therapy (with antilymphocyte immunoglobulins in high-risk patients), calcineurin inhibitors, and mycophenolate mofetil.[25] Protocols that withdraw, minimise, or avoid calcineurin inhibitors have also been investigated.[28-33] Ciclosporin withdrawal is considered by some[30] to be more feasible for patients treated with mycophenolate mofetil than those given azathioprine. However, the most effective regimen in terms of patient and graft survival benefit, and minimisation of rejection and adverse effects, remains to be determined.[28] Data on long-term outcomes are lacking.[28,29,31]

Where an **acute rejection** episode occurs treatment is likely to be with high-dose corticosteroids, or with drugs such as antilymphocyte immunoglobulins, or muromonab-CD3, which are potent and effective reversers of rejection.[1,2,13] European guidelines recommend that the antibody preparations be reserved for corticosteroid-resistant rejection or more severe episodes,[18] but approaches remain varied.[1] Tacrolimus,[4] mycophenolate mofetil,[4] sirolimus,[34] and gusperimus[3,22] have been effective in reversing acute rejection episodes. Ciclosporin and azathioprine are ineffective in treating established rejection. Interleukin-2 receptor antibodies have not been shown to reverse established rejection episodes.[3] There has also been evidence that asymptomatic CMV infection may be associated with episodes of late acute rejection;[35] ganciclovir is reported to improve graft function in such circumstances. However, augmented or rescue immunosuppressive therapy predisposes the patient to infections such as CMV, which may itself mimic late acute rejection, and contribute to chronic rejection.[36]

Severe, recurrent, late episodes of acute rejection are considered to be a major risk factor for the development of **chronic rejection**. Manifested clinically by declining renal function, hypertension, and low-grade proteinuria, the term chronic allograft nephropathy is used.[4] Long-term calcineurin inhibitor treatment and inadequate immunosuppression may contribute to this, but there is some suggestion that the addition of mycophenolate mofetil can delay this process.[4] Protocols using sirolimus, and allowing for the early withdrawal of calcineurin inhibitors have been investigated; improved renal function has been reported, but use of sirolimus may increase the risk of coronary artery disease, and long-term results are lacking.[17,37,38]

Although newer drugs have decreased the incidence of acute rejection, there is only limited evidence that this has improved longer-term **graft survival**.[39-41] The one-year cadaveric graft survival is about 88% and about 60% at 10 years.[42] Recurrence of the original disease or *de novo* renal disease may also cause graft failure.[43] Pentoxifylline[44] and gusperimus[45] may improve graft survival.

Cardiovascular disease is a major cause of **death** in renal transplant patients.[46] Corticosteroids and ciclosporin can impair endothelial function, cause hypertension, and hyperlipidaemia. Sirolimus has also been implicated in hyperlipidaemia.[46] Dyslipidaemia occurs in about 60% of patients after renal transplantation;[12,46] HMG-CoA reductase inhibitors (statins) and dietary modification have been recommended as first-line treatment by some,[12] whereas others[47] recommend drug treatment with various lipid-lowering drugs only if lifestyle changes are insufficient. Modification of the immunosuppressive protocols, as discussed above, may also be effective.[12]

Hyperuricaemia is a common problem among renal transplant recipients;[48] the use of ciclosporin is an independent risk factor for new-onset gout after transplantation.[49] Use of sirolimus is also associated with an increased risk, whereas use of tacrolimus and mycophenolate mofetil carries a lower risk. Hyperuricaemia, besides having direct deleterious effects on the graft, may potentiate chronic renal dysfunction induced by calcineurin inhibitors, and contribute to chronic allograft nephropathy.[48] New-onset gout after transplantation may also be associated with hypertension, cardiovascular disease, and death.[49]

Morbidity and mortality have improved with reductions in cardiac, vascular and infectious complications, but there has been no decrease in death from **malignancy**, and the risk of developing cancer has been estimated to be about 100% by 30 years post-transplant.[50] Compared with the general population, renal transplant recipients have a three- to fivefold higher risk of malignancy; cancers tend to be more aggressive in transplant recipients, and solid organ tumours have a poorer prognosis. The most common malignancies include non-melanoma skin cancers and post-transplant lymphoproliferative disease (PTLD).[51,52] While not all malignancies are a consequence of transplantation or immunosuppressive therapy,[51] both the duration and intensity of immunosuppression have been linked to this increased incidence.[52] Other risk factors include increasing age, male gender,[53] sun exposure, and cigarette smoking.[51]

It is difficult to assess the impact of individual drugs on cancer risk;[51] some studies have found an increased incidence in patients given ciclosporin (compared with azathioprine) or muromonab-CD3.[53] Data are conflicting on the carcinogenic effects of mycophenolate.[51] Proliferation signal inhibitors such as sirolimus and everolimus have been reported to carry less of a risk, possibly as a result of their mode of action.[51-54] Although long-term data are needed, some have suggested that conversion from calcineurin inhibitors to proliferation signal inhibitors should be considered in high-risk patients.[52-54]

Nonmyeloablative conditioning regimens allowing for the development of immunological **tolerance** specific to the donor remain the ultimate goal of renal transplantation.[4,55] There are reports of the development of chimerism and tolerance allowing withdrawal of all immunosuppression in a few patients in whom kidney transplants were combined with haematopoietic stem cell transplantation.[56,57]

Liver transplantation. Marked improvements have occurred in the outcome and reliability of liver transplantation and it is now seen as standard therapy for acute and chronic hepatic failure, regardless of aetiology,[1-3] and some metabolic disorders.[4] The 1-year patient and graft survival rates[2,4,5] are about 90%.

The liver induces some tolerance and liver transplant recipients usually require less immunosuppression than other solid organ transplant patients.[6] **Immunosuppressive regimens** generally combine a calcineurin inhibitor (ciclosporin or tacrolimus) with a corticosteroid and azathioprine or mycophenolate mofetil; such triple therapy prevents acute rejection episodes in the majority of cases.[7-9] Double therapy with ciclosporin or tacrolimus and corticosteroids is also used,[8,10] and monotherapy with a calcineurin inhibitor alone has also been used, allowing for complete corticosteroid withdrawal or avoidance.[10]

A review of corticosteroid-free strategies in liver transplantation concluded that up to 50% of patients can avoid corticosteroids with little modification of their maintenance immunosuppressive regimen; adding mycophenolate mofetil and/or induction therapy with antibodies can increase this percentage, although over-immunosuppression may be a problem. Although data are weak and limited, corticosteroid avoidance is not advised with calcineurin inhibitor monotherapy, nor with calcineurin inhibitors and azathioprine; it may be feasible with tacrolimus and mycophenolate mofetil, or with calcineurin inhibitors and antibodies. Benefits of corticosteroid avoidance are seen in growth rates in children, diabetes mellitus, dyslipidaemia, CMV infection, and possibly other infections.[11] Patients with underlying auto-immune hepatitis or inflammatory bowel disease may be relatively refractory to corticosteroid withdrawal.[12]

Tacrolimus is better than ciclosporin at preventing acute rejection in liver transplantation. It is also marginally better at preventing patient death and graft loss, but it increases the risk of post-transplant diabetes.[13] Studies of different formulations of ciclosporin found a reduced incidence of rejection with the microemulsifying formulation compared with the older oil-based product.[5]

The use of azathioprine in liver transplant patients has been limited due to its possible hepatotoxicity.[10] Mycophenolate mofetil has been used in place of azathioprine, to reduce the dose of the calcineurin inhibitor or corticosteroid used, and possibly prevent rejection.[2,8] Calcineurin inhibitors have been replaced with mycophenolate mofetil in an attempt to improve renal function,[10] although a small study has suggested that this monotherapy carries a high risk of rejection.[14] The long-term efficacy of calcineurin inhibitor minimisation or avoidance has yet to be determined.[15] The role of sirolimus in liver transplantation has yet to be evaluated.[3] There have been reports of efficacy when used with a calcineurin inhibitor,[1,9] which might allow dose reduction[9] or withdrawal of therapy[5] in patients with toxicity from tacrolimus or ciclosporin, but excess mortality, graft loss, and hepatic artery thrombosis has been associated with such use.

Induction therapy with antilymphocyte immunoglobulins or muromonab-CD3 has declined due to the high incidence of infection and lymphoproliferative disease associated with their use, and they are generally reserved for the treatment of corticosteroid-resistant acute rejection.[2,4,8,9] The use of interleukin-2 receptor antibodies, basiliximab, and daclizumab, is increasing;[10] initial studies suggest they decrease the number of rejection episodes.[8,9] It has been suggested that they may be of benefit in those with pre-transplant renal impairment by allowing for delayed introduction or lower doses of calcineurin inhibitors.[16] The use of alemtuzumab has also been investigated.[10,15]

The induction of complete immune **tolerance** remains the ultimate goal in liver transplantation.[10,17,18] It may be feasible to reduce or stop all immunosuppression in long-term stable liver transplant patients.[6,19] The term 'operational tolerance' is used to define stable graft function without features of rejection and without immunosuppressive treatment; 'prope tolerance' refers to stable graft function in patients with minimal immunosuppression.[10,19] Although it is not uncommon for rejection to eventually occur in those withdrawn from immunosuppression, this may be reversed by resumption of therapy, with a small rate of graft loss. Favourable markers for successful withdrawal appear to be at least 2 years of post-transplant follow-up, low incidence of previous rejection episodes, non-auto-immune primary liver disease, and possibly minimal post-transplant immunosuppression.[19]

Most **acute rejection** episodes occur during the first 3 to 6 months of therapy.[12] Early acute rejection does not affect patient or graft survival[6,20,21] and, if mild, may be associated with increased survival.[1] Late acute rejection, occurring after 30 days post-transplant may be related to reduction or withdrawal of immunosuppressive therapy.[22] It has a worse prognosis, with reports of up to half of patients developing graft loss.[21] Corticosteroids are used in the first-line treatment of acute rejection.[11,23] For corticosteroid-resistant rejection, muromonab-CD3 or antilymphocyte immunoglobulins are used, and increasing the dose of tacrolimus, or conversion from ciclosporin to tacrolimus, may also be effective.[2,4,9] Interleukin-2 receptor antibodies may also be used. Mycophenolate mofetil or sirolimus have been added to treat recurrent acute rejection.[23] **Chronic rejection** is almost always preceded by one or more episodes of corticosteroid-resistant acute rejection,[21,22] and although its incidence has decreased[5,21-23] to less than 5%, it remains difficult to treat. Corticosteroids are generally ineffective; conversion from ciclosporin to tacrolimus has been reported to be effective,[21] as has addition of mycophenolate mofetil to tacrolimus, followed by interleukin-2 receptor antibodies, and then sirolimus in non-responsive patients.[23]

The main **complications** encountered with liver transplants are infection in the early post-transplant period, vascular and biliary complications, recurrent disease (particularly viral recurrence), and adverse effects due to immunosuppressants.[4,6,22,23]

Sepsis is an important cause of death in the early post-transplant period.[6,24,25] Patients at increased risk, including those with malnutrition, fulminant liver failure, or renal insufficiency, require particularly cautious immunosuppression and more aggressive antibacterial and antifungal prophylaxis regimens.

Recurrence of hepatitis B infection is common.[26] Although the introduction of hepatitis B immunoglobulins and lamivudine have improved the prospects for these patients, combination antiviral therapy and a modified immunosuppression protocol are usually needed.[3,6,7,20,21] Hepatitis C recurrence is almost universal in infected patients,[11,21,27] with a probable reduction in long-term graft survival.[7,20,21] The use of corticosteroids and muromonab-CD3 appears to be associated with more severe recurrence of hepatitis C. Treatment with interferon alfa plus ribavirin appears promising.[26-28]

Nephrotoxicity from ciclosporin or tacrolimus can be a significant problem after long-term therapy.[29] Long-term renal function is affected by the function in the early post-transplant period, so serum creatinine concentrations at 1 and 3 months are often used to predict toxicity.[7] Cardiovascular complications may follow metabolic abnormalities such as diabetes mellitus, hypertension, hyperlipidaemia, and obesity. Dose reduction or change of the calcineurin inhibitor used, corticosteroid withdrawal, or use of statins could minimise the cardiovascular risk post-transplantation.[30-32] Malignancy may occur after prolonged immunosuppression.[4,20,23]

Lung transplantation. Lung transplantation has become accepted therapy[1-4] for end-stage pulmonary disease such as pulmonary hypertension, cystic fibrosis, emphysema, and pulmonary fibrosis, with a 1-year survival of 70% or more.[2] The rate of death is highest in the first year after transplantation, with infection and primary graft failure the leading causes of early death.[1,5]

Immunosuppressant therapy is usually with a triple therapy regimen of ciclosporin or tacrolimus, azathioprine or mycophenolate mofetil, and a corticosteroid.[1-9] Some centres also use induction therapy with polyclonal or monoclonal antibodies, although its use is controversial. While induction therapy may reduce the incidence and severity of acute rejection, and allow for a delay in calcineurin inhibitor therapy, there is an increased risk of infection and of post-transplant lymphoproliferative disease.[2,3,5,10] Antilymphocyte immunoglobulins and muromonab-CD3 have been used; the interleukin-2 receptor antibodies basiliximab and daclizumab are increasingly used,[1,2,10] although experience with these drugs in lung transplantation is limited.[11] Alemtuzumab is under investigation for induction;[1,2,10,11] preliminary results are promising. Corticosteroids remain a mainstay in lung transplantation,[5,10-12] although corticosteroid-free regimens have been investigated, with promising results, and further study is warranted.[11,12] Sirolimus has been investigated in lung transplantation, but its early use as a primary immunosuppressant is not recommended due to its potent antifibrotic effects;[1,2] sirolimus may also induce pulmonary toxicity.[10] Cases of fatal anastomotic dehiscence have been reported, and concerns about wound healing complications have led to recommendations to only use sirolimus after initial airway bronchial wound healing is completed, or not until at least 3 months after transplant.[10] Everolimus is also under investigation for adjunctive use in lung transplantation.[10,11]

Acute rejection occurs more frequently with lung transplants than with other solid organ transplants;[1,13] from early reports in 60 to 100% of cases, incidence has apparently decreased to about 35% in those receiving induction therapy and about 45% in those without induction therapy,[10] although some centres have reported figures as high as 85%.[13] High doses of intravenous corticosteroids are generally used to control acute episodes of rejection.[3,7,10,13] Corticosteroid-refractory rejection demands further intervention, although no consensus exists. Evidence supports the conversion of ciclosporin to tacrolimus for patients with persistent acute rejection.[10] Other therapies include the use of monoclonal or polyclonal antibodies, plasmapheresis, and total lymphoid irradiation.[10,13] Inhaled ciclosporin has also been used to treat refractory acute rejection.[1,10]

Lung transplant recipients are at high risk of **infection** as a result of impaired pulmonary defence mechanisms, and post-transplant antibacterial prophylaxis is routine.[2]

Patients at risk for CMV should be given ganciclovir.[2,7,12] There is no consensus on standard antifungal prophylaxis after lung transplant, but some centres use oral azole therapy or inhaled amphotericin.[2] Respiratory viruses pose a substantial risk to the lung allograft,[2,4,12] and may contribute to chronic rejection. The main complication encountered in the long term and major cause of late mortality is **chronic rejection** manifesting as bronchiolitis obliterans syndrome (obliterative bronchiolitis).[1,2,7,13] This is characterised by progressive airway obstruction and may be present in up to 40% of patients at 2 years, and in 60 to 70% who survive for 5 years.[7] Young children and living donor lung transplant recipients may have a lower risk for the development of this syndrome.[5] The frequency and severity of acute rejection episodes are the main risk factors for the development of bronchiolitis obliterans, but CMV infection, airway ischaemia and HLA mismatching may also play a part.[1,4,6,7,12-15] There are no proven effective therapies,[4] and the prognosis is poor, with 40% mortality within 3 years of diagnosis.[7] Augmentation of immunosuppression is often tried, but may exacerbate the risk of infection.[4] Some centres change the maintenance regimen, converting ciclosporin to tacrolimus, and azathioprine to mycophenolate mofetil, along with a short course of high-dose corticosteroids.[10,13] Inhaled ciclosporin has also been used, with reports of a trend towards survival benefit.[10] Improvement in pulmonary function has been seen with maintenance azithromycin.[10,13,15] Statins may decrease the risk of developing bronchiolitis obliterans syndrome, and promising results have been reported with the use of total lymphoid irradiation.[13] Re-transplantation may be necessary.[4,13]

Post-transplant lymphoproliferative disorders (PTLD) occur in lung transplant recipients, often in association with a primary Epstein-Barr virus infection.[3,4,12] The incidence is high in paediatric patients, ranging from 13 to 20%. Initial treatment involves a reduction in immunosuppression, or chemotherapy with rituximab.[3,12]

The induction of immune tolerance remains the ultimate goal in lung transplantation.[1,11]

Combined *heart-lung* transplants have also been performed, see under Heart Transplantation, above.

Pancreatic transplantation. Transplantation of the pancreas may be considered in some diabetic patients. In the vast majority of cases, pancreatic grafts have been transplanted together with a kidney (simultaneous pancreas-as-kidney or SPK) in patients with end-stage diabetic nephropathy, which has produced better graft survival than transplanting the pancreas alone.[1-3] However, pancreas transplants after renal allografting (PAK), or solitary pancreatic transplantation (PTA), are becoming more common,[3] and approaching comparable survival rates.[2,4] Advances in surgical and preservation techniques, together with new immunosuppressants, have helped to improve survival.[1] Overall patient survival has been estimated to be about 98% at 1 year, with graft survival of about 78%.[5]

The pancreas is a highly immunogenic organ, so extensive **immunosuppression** is required. Standard treatment often consists of quadruple therapy.[2,6,7] Induction therapy is followed by maintenance therapy with a calcineurin inhibitor (ciclosporin or tacrolimus), corticosteroids, and azathioprine or mycophenolate mofetil.[2,7] Induction therapy reduces rejection rates, and may allow for corticosteroid withdrawal, but patient or graft survival is not altered.[6,7] The use of induction therapy varies between centres,[8] and may be dependent on the type of pancreatic transplant.[9] The interleukin-2 receptor antibodies basiliximab and daclizumab are increasingly favoured. Rabbit antilymphocyte immunoglobulins are also used, but the use of muromonab-CD3 has declined.[7] Alemtuzumab is under investigation.[5]

Tacrolimus is usually preferred to ciclosporin[2-4,6,7,9] as it appears to allow for rapid tapering or even complete withdrawal of corticosteroids, causes less rejection, and may increase graft survival and reduce the risk of pancreatic thrombosis. Mycophenolate mofetil is now preferred to azathioprine,[2,6-9] as it decreases rejection rates, although patient and graft survival rates are comparable.[6,7,9] Early withdrawal of corticosteroids appears to be safe and feasible in pancreatic transplantation,[6,7] without an increase in rejection rates; patients may, however, require slightly higher doses of calcineurin inhibitors, which increases the risk of nephrotoxicity.[7] Although the precise role of sirolimus in pancreatic transplantation has yet to be defined, it may be used with a low-dose calcineurin inhibitor, thus mitigating renal dysfunction,[2] or as a substitute for an antimetabolite,[7,9] or as the chief drug in a calcineurin inhibitor-free maintenance protocol, or for episodes of rejection.[7] Sirolimus used with tacrolimus may allow for rapid withdrawal of corticosteroids.[9]

Episodes of rejection are treated with corticosteroids or antilymphocyte immunoglobulins.[2,7] Conversion to tacrolimus from ciclosporin is used, and for those patients on tacrolimus, sirolimus has been tried.[2]

Pancreatic transplantation facilitates normal carbohydrate metabolism and has the potential to improve patient survival and reduce the incidence of diabetic nephropathy. However, there has been concern over the long-term **complications** of immunosuppression,[10] and whether islet-cell autoantibodies might produce diabetes in the transplanted graft (although this is certainly not inevitable with adequate immunosuppression).[11] The incidence of hyperglycaemia induced by immunosuppressive regimens after transplantation appears to be less in pancreatic transplants than in recipients of other organs.[5] Explanations for the absence of a higher diabetogenic effect of tacrolimus after pancreatic transplantation compared with other solid organ transplants may include a more cautious dose of tacrolimus in diabetic patients, the use of tacrolimus with corticosteroid-free protocols, and the use of pancreatic grafts from young donors who may be more resistant to a diabetogenic effect.[9]

One possible alternative to complete pancreatic transplantation is an **islet-cell** graft. These have rarely been successful,[1] with insulin independence at 1 year[3] only in about 10% of cases. However, the use of carefully prepared islet cells from more than one donor and a modified immunosuppressant protocol[12] has produced greatly improved results. In this 'Edmonton Protocol', corticosteroids were completely avoided because of diabetogenic effects. Induction therapy with daclizumab was used, followed by maintenance with sirolimus and low-dose tacrolimus.[12] Short-term follow-up data indicated that patients with unstable type I diabetes benefited in terms of glucose control from islet transplantation.[13] Reported insulin independence was 80% at 1 year after use of the 'Edmonton protocol'[14] and 10% at 5 years post-transplant.[15] Thus, engrafting an adequate beta-cell mass appears to be the critical factor for transplant success.[8] Insulin independence has been reported with single organs from cadaveric donors.[16] Further study of the 'Edmonton protocol' confirmed that islet-cell transplantation may successfully restore endogenous insulin production and glycaemic stability in patients with type I diabetes mellitus. Insulin independence is gradually lost again in most cases, but persistent islet function without insulin independence confers benefit in terms of glycaemic control, provided the patient can tolerate the immunosuppressive regimen. Islet transplantation may be best for highly selected patients with severe hypoglycaemia or labile type I diabetes mellitus, provided all other attempts to stabilise glycaemic control have been tried. For patients seeking long-term insulin independence, whole pancreas transplantation is a better option at present.[17] See also under Diabetes Mellitus, p.431.

The induction of tolerance,[3,5,10,18] the possibility of neogenesis of beta cells from pancreatic stem or precursor cells,[10,18,19] less toxic immunosuppressive therapy, and enhanced islet engraftment[17] remain focuses of investigation in islet transplantation.

Renal disorders

Corticosteroids and immunosuppressants are commonly used in the treatment of glomerular kidney disease (p.1504).

Rheumatoid arthritis

Disease-modifying antirheumatic drugs (DMARDs) including immunosuppressants may be given to patients with rheumatoid arthritis (p.11) in an attempt to modify the course of the disease. Ciclosporin appears to be effective, but adverse effects have been a problem. The use of low-dose regimens may help to minimise nephrotoxicity. Use of ciclosporin with methotrexate has produced clinical improvement in patients who had only partial responses to methotrexate alone, but some investigators found that a combination of methotrexate, ciclosporin and intra-articular corticosteroids was no more effective than standard DMARD therapy. Tacrolimus is licensed in some countries for use in refractory rheumatoid arthritis.

Azathioprine has been used, with beneficial short-term effects, but is reported to be no more effective than other DMARDs and significantly more toxic; it may however be useful with prednisone in rheumatoid vasculitis. Mycophenolate mofetil may be effective in rheumatoid arthritis, but further studies are needed.

Sarcoidosis

Where drug therapy is required for sarcoidosis (p.1512), corticosteroids are the usual treatment. In patients in whom these are ineffective or poorly tolerated, immunosuppressants have been given, with variable results.

Scleroderma

The term scleroderma has been used for both systemic sclerosis, an uncommon multisystem disease characterised by collagen proliferation and fibrosis throughout the body, and for localised fibrotic changes of the skin (morphea) which rarely progresses to involve other organs. In systemic sclerosis, Raynaud's syndrome secondary to vascular involvement usually precedes skin changes; oedema is followed by thickening and tightening of the skin of hands and face, and sometimes limbs and trunk, before progressing to atrophy and contractures. Cutaneous changes may be limited or take a more aggressive diffuse form. Decreased gastrointestinal motility, dysphagia and gastro-oesophageal reflux, arthritis, muscle weakness, and cardiac involvement may occur. Among the most serious potential symptoms, which may result in death, are pulmonary disease and renal failure with malignant hypertension.[1-7]

Many treatments have been tried for localised scleroderma.[4,5] Symptomatic therapies include emollients and topical and systemic antipruritics. Topical, intralesional, and systemic corticosteroids may be useful, especially in early inflammatory stages. Other treatments include topical and systemic vitamin D analogues, topical tacrolimus, and imiquimod cream. Oral therapies used include ciclosporin, colchicine, hydroxychloroquine, interferon gamma, penicillamine, phenytoin, and methotrexate. Phototherapy with UV light, with or without psoralens, has also been reported to be of benefit.

There is a paucity of adequately controlled studies for systemic scleroderma; no treatment has been clearly shown to affect the progression of the disease, and much management is essentially symptomatic. Immunosuppressants are probably appropriate in the early oedematous stages of diffuse scleroderma.[1,6,8] Antilymphocyte immunoglobulins have been tried as an induction therapy in early stages of the disease.[8] Ciclosporin has been found to be beneficial, both for skin and visceral manifestations, but its use has been limited by nephrotoxicity and hypertension.[1,3,8-10] Tacrolimus has also been tried, though again adverse effects limit its benefit.[8-10] Mycophenolate mofetil has been tried after antilymphocyte immunoglobulins with reports of significant skin improvement.[10] Cyclophosphamide with or without corticosteroids has been shown to improve skin thickening, stabilise pulmonary function, and increase survival, especially in early disease, in a number of studies.[7] Other novel immunosuppressive strategies include bone marrow ablation followed by peripheral blood stem cell transplantation (see Haematopoietic Stem Cell Transplantation, p.1811),[1,3,5,8] photopheresis with a psoralen, and the induction of oral tolerance with native bovine type I collagen.[8] Rituximab is under investigation.[10]

Penicillamine has been widely used as an antifibrotic drug, but with variable effects; usual doses proved to be no more effective than lower doses,[1,8,11] and it is considered by some to be no more effective than placebo.[5] Interferons alfa and gamma have produced variable results;[5,8] the latter is under investigation for pulmonary fibrosis.[3] Some other drugs have been investigated for their antifibrotic properties, including halofuginone, minocycline and relaxin.[8,11] There is some evidence that oxidative stress is involved in the pathogenesis of scleroderma, so antoxidants like probucol may also be useful.[8] Other drugs that have been investigated include potassium aminobenzoate, and thymopentin.

Many patients will require therapy for organ-specific symptoms.

- *Skin* flexibility may be maintained by emollients,[12] and systemic antihistamines can relieve itching, an early feature of diffuse cutaneous scleroderma.[8] Methotrexate has been used with some benefit.[1,3,5,7,8,11]
- Most progress has been made in the management of *vascular* symptoms. ACE inhibitors are considered to be the standard treatment for patients with renal ischaemia,[3,5,6,13] although some 30% of patients will still eventually require renal replacement therapy.[8] For patients who develop pulmonary arterial hypertension the prostaglandins epoprostenol, iloprost, or treprostinil may be given intravenously;[1,3,5,6,8] some have also been investigated subcutaneously[6] or by inhalation.[3,5,6] Sildenafil or bosentan are also used.[3,5-7] There is some evidence that epoprostenol and bosentan may be associated with improved survival as well as symptomatic improvement.[3] Novel therapies for pulmonary arterial hypertension include ambrisentan[7] and sitaxentan.[6,7]

  Treatment of Raynaud's syndrome (see under Vasospastic Arterial Disorders, p.1188) unresponsive to nonpharmacological therapy involves the use of calcium-channel blockers such as nifedipine or diltiazem.[1,3,12] Topical nitrates have been used, and intravenous epoprostenol or iloprost are used in acute attacks.[1,3,6,8] Oral iloprost has been tried with variable results.[6] Bosentan can prevent the development of new digital ulcers but may not speed the healing of existing ones.[3] Calcitonin gene-related peptide is being investigated as an alternative to iloprost.[1] Because elevated levels of serotonin have been found in patients with Raynaud's phenomenon, SSRIs and ketanserin have been used.[1] Atorvastatin[6] and sildenafil[13] have been reported to be helpful. Dietary supplementation with antoxidant vitamins, fish oils, and evening primrose oil has been of anecdotal benefit.[1,8,14] Acetylcysteine has also been reported to be of benefit in Raynaud's syndrome.[6,14]

  Cardiac involvement may be underdiagnosed;[8] ACE inhibitors or digoxin may be used.[1]
- *Lung* fibrosis is usually treated with cyclophosphamide,[1,3,5,8,15] with or without a corticosteroid such as prednisolone. There is no evidence for corticosteroids alone in lung scleroderma, and high dose may precipitate scleroderma renal crisis, leading to irreversible renal failure.[7] As mentioned above, interferon gamma is under investigation.
- In patients with *gastrointestinal* disease, proton pump inhibitors such as omeprazole, sometimes with prokinetic drugs, are extremely effective for oesophageal involvement, and broad spectrum antibacterials are helpful for small bowel bacterial overgrowth.[1,8]

NSAIDs and corticosteroids must be used with care in scleroderma because of the risk of exacerbating renal and other problems.[1,8]

Skin and connective tissue disorders

Immunosuppressants are used in various skin and connective tissue disorders, including Behçet's syndrome (p.1499), eczema (p.1579), pemphigus and pemphigoid (p.1582), polymyositis (p.1510), psoriasis (p.1583), SLE (p.1513), and the various vasculitic syndromes (p.1515). See also Scleroderma, above.

Abetimus Sodium *(USAN, rINNM)*

Abetimus sódico; Abétimus Sodique; LJP-394; Natrii Abetimusum.

Натрий Абетимус

CAS — 169147-32-4.

ATC — L04AA22.

ATC Vet — QL04AA22.

Profile

Abetimus sodium is an immunomodulator that arrests the production of antibodies to double-stranded DNA. It is under investigation for the treatment of lupus nephritis in patients with SLE.

Antilymphocyte Immunoglobulins

Inmunoglobulinas antilinfocitarias.

Иммуноглобулины Антилимфоцитарные

ATC — L04AA03 (antilymphocyte immunoglobulin, horse); L04AA04 (antilymphocyte immunoglobulin, rabbit).

ATC Vet — QL04AA03 (antilymphocyte immunoglobulin, horse); QL04AA04 (antithymocyte immunoglobulin, rabbit).

Description. Antilymphocyte immunoglobulins are polyclonal antibodies to human lymphocytes produced by the purification of sera from appropriately immunised animals. The term antilymphocyte immunoglobulin (ALG; lymphocyte immune globulin) implies a product raised against all lymphocyte subsets. The term antithymocyte immunoglobulin (antithymocyte gammaglobulin; antithymocyte globulin; ATG) implies specificity for T-cells (thymus lymphocytes or thymocytes). However, in practice the nomenclature does not seem to be used consistently, and both terms tend to be used for antibodies raised against T-cells. Nomenclature normally includes an indication of the animal source of the immunoglobulin e.g. antithymocyte immunoglobulin (horse), or antithymocyte immunoglobulin (rabbit).

In addition to the purified immunoglobulins the native sera (antilymphocyte serum and antithymocyte serum, sometimes referred to as lymphocytic antiserum and thymitic antiserum) have also been used as immunosuppressants.

Pharmacopoeias. *Eur.* (see p.vii) includes an anti-T lymphocyte immunoglobulin.

Ph. Eur. 6.2 (Anti-T Lymphocyte Immunoglobulin for Human Use, Animal; Immunoglobulinum Anti-T Lymphocytorum ex Animale ad Usum Humanum). A liquid or freeze-dried preparation containing immunoglobulins, obtained from serum or plasma of animals, mainly rabbits or horses, immunised with human lymphocytic antigens. It has the property of diminishing the number and function of immunocompetent cells, in particular T-lymphocytes. It contains principally immunoglobulin G, and may contain antibodies against other lymphocyte subpopulations and against other cells. It is intended for intravenous administration, after dilution with a suitable diluent where applicable. Protect from light.

Adverse Effects and Precautions

Common adverse reactions to antilymphocyte immunoglobulins include fever, chills, and skin reactions including rash, pruritus, and urticaria, which may be manifestations of hypersensitivity. Infusion reactions suggestive of a cytokine release syndrome can occur, usually with the first dose. To minimise fever and chills, the first dose can be infused over at least 6 hours. Dyspnoea, hypotension, chest, back or flank pain may indicate anaphylaxis, which can occur in up to 1% of patients. Fever, pruritus, rashes, myalgia, and arthralgia may represent serum sickness, especially in patients with aplastic anaemia. Use with other immunosuppressants may reduce the incidence or severity of hypersensitivity but increase the risk of acquired systemic infections, such as CMV or herpes simplex. Enhanced immunosuppression may also increase the incidence of post-transplant lymphoproliferative disease or other malignancies.

Leucopenia and thrombocytopenia are also common. Although usually transient, dosage adjustment may be necessary if they become severe or prolonged, and if unremitting, they may warrant stopping therapy. Other adverse effects include dizziness, malaise, headache, abdominal pain, gastrointestinal disturbances, hypertension, peripheral oedema, asthenia, hyperkalaemia, and tachycardia. Nephrotoxicity has been reported.

Intra-uterine contraceptive devices should be used with caution during immunosuppressive treatment as there is an increased risk of infection. Use of live vaccines should generally be avoided for the same reason. Thrombophlebitis may be avoided by infusion into a vein with a rapid blood flow. To identify those at risk of anaphylaxis, patients should be tested for skin sensitivity before infusion. If there is a locally positive skin reaction, alternative therapy should be considered although hypersensitivity reactions may still occur in patients whose skin test is negative. If there is a systemic reaction, further doses of antilymphocyte immunoglobulins should not be given. Facilities for management of anaphylaxis (see p.1205) should be available during treatment, and the patient should be observed continuously.

Effects on the kidneys. Acute renal failure has been reported after the use of antilymphocyte immunoglobulins.[1,2] Prolonged anuria requiring haemodialysis has occurred.[2]

Uses and Administration

Antilymphocyte immunoglobulins are antibodies, raised in *animals*, which act against lymphocytes, and in particular against T-cells, to produce suppression of cell-mediated immunity.

They may be added to existing immunosuppressant regimens to treat acute rejection episodes in patients who have undergone organ or tissue transplantation. Alternatively, they may be given prophylactically as part of a combination immunosuppressant regimen with several other agents. For discussion of the role of antilymphocyte immunoglobulins in transplantation, see p.1810 *et seq*.

Antilymphocyte immunoglobulins are also used in the treatment of aplastic anaemia (p.1042) in patients unsuitable for bone marrow transplantation, and have been tried in other immunological disorders. They are under investigation for the treatment of myelodysplastic syndromes (p.654).

Different antilymphocyte preparations may vary in their activity, as may different lots of the same preparation. However, daily doses in **transplantation** have usually ranged from 10 to 30 mg/kg of *equine* immunoglobulin, or 1 to 2.5 mg/kg of *rabbit* immunoglobulin. For **aplastic anaemia**, doses of *equine* immunoglobulin range from 10 to 20 mg/kg daily; regimens vary in different countries.

For children's doses, see Administration in Children, below.

Doses of antilymphocyte immunoglobulin are given as a slow intravenous infusion diluted in sodium chloride 0.9%, or other suitable diluent. It has been recommended that the final dilution should contain no more than 1 mg/mL of immunoglobulin and be given over 4 hours or more, via an in-line filter.

Administration in children. Although data in children are limited, licensed product information in the USA states that doses of *equine* immunoglobulin for transplantation in children have ranged from 5 to 25 mg/kg daily. The dose for *rabbit* immunoglobulin is not thought to differ from that for adults, namely 1.5 mg/kg daily, based on limited European studies and US compassionate use.

Organ and tissue transplantation. Antilymphocyte immunoglobulin derived from *rabbits* was found to be more effective than the *equine* product in treating acute rejection and preventing recurrent rejection in adult kidney transplantation (p.1813); patient and graft survival rates and the incidence of infection did not differ significantly.[1] Although unlicensed for induction therapy in the USA, some consider rabbit antilymphocyte immunoglobulin to be safe and effective for such use in adult renal transplantation.[2,3] Rabbit immunoglobulin induction is also considered safe and effective[4,5] in paediatric renal transplant recipients. The incidence of acute rejection was lower in rabbit immunoglobulin recipients than in those given the equine product;[6] however, rates of Epstein-Barr virus (EBV) infection were higher with the rabbit product. Patient and graft survival rates, incidence of chronic rejection, EBV lymphoma, or other infection did not differ significantly between the 2 groups.

In adult renal transplant recipients considered to be at high risk for acute rejection or delayed graft function, induction with rabbit antilymphocyte immunoglobulin reduced the incidence and severity of acute rejection (but not the incidence of delayed graft function) compared with basiliximab induction. Patients receiving antilymphocyte immunoglobulin had a greater incidence of infection but a lower incidence of CMV disease; patient and graft survival were similar in the 2 groups.[7]

Induction therapy with antilymphocyte immunoglobulins has also been shown to be beneficial in other solid organ transplants, with lower rates of rejection reported in liver (p.1815), pancreas (p.1816), kidney-pancreas, heart (p.1812), and heart-lung transplantation. Use in lung transplantation remains controversial due to a higher incidence of CMV infection.[8] Induction protocols differ between institutions.

In haematopoietic stem cell transplant recipients (p.1811), those given rabbit antilymphocyte immunoglobulin prior to a matched unrelated donor (MUD) transplant had comparable outcomes to those given matched related donor (MRD) transplants but no antilymphocyte immunoglobulin; the authors supposed that the use of antilymphocyte immunoglobulin caused MUD recipients to behave clinically like MRD recipients.[9] A review of the use of antilymphocyte immunoglobulins in haematopoietic stem cell transplantation concluded that it significantly reduces the severity and incidence of acute graft-versus-host disease (GVHD) and chronic GVHD. This protective effect is dependent on the dose, the timing of infusion, and the brand used. However, antilymphocyte immunoglobulin induction therapy delays immune reconstitution and there is an increased risk of infection; the use of an antilymphocyte immunoglobulin is a risk factor for EBV reactivation.[10]

Azathioprine *(BAN, USAN, rINN)*

Atsatiopriini; Azathioprin; Azathioprinum; Azatioprin; Azatioprina; Azatioprinas; Azatiopryna; BW-57322; NSC-39084. 6-(1-Methyl-4-nitroimidazol-5-ylthio)purine.

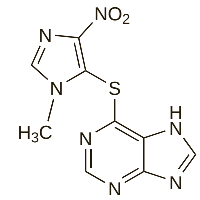
Азатиоприн

$C_9H_7N_7O_2S$ = 277.3.

CAS — 446-86-6.

ATC — L04AX01.

ATC Vet — QL04AX01.



NOTE. The abbreviation AZT, which has sometimes been used for azathioprine, has also been used to denote the antiviral zidovudine.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Azathioprine). A pale yellow powder. Practically insoluble in water and in alcohol; soluble in dilute solutions of alkali hydroxides; sparingly soluble in dilute mineral acids. Protect from light.

USP 31 (Azathioprine). A pale yellow, odourless powder. Insoluble in water; very slightly soluble in alcohol and in chloroform; sparingly soluble in dilute mineral acids; soluble in dilute solutions of alkali hydroxides. Store in airtight containers. Protect from light.

Adverse Effects

Dose-related bone-marrow depression is common with use of azathioprine; this may be manifested as leucopenia or, less often, thrombocytopenia or anaemia, and rarely, as agranulocytosis, pancytopenia, or aplastic anaemia. Myelosuppression is generally reversible, and may occasionally be delayed. Macrocytic, including megaloblastic, anaemia has occurred. Patients with an inherited deficiency of the enzyme thiopurine methyltransferase (TPMT) may be at increased risk of myelotoxicity. Azathioprine has also been associated with the development of liver damage; it has been suggested that cholestatic symptoms may be due to the mercaptopurine moiety. Rarely, delayed and potentially fatal veno-occlusive liver disease has occurred.

Other adverse effects associated with azathioprine include gastrointestinal disturbances, reversible alopecia, and symptoms including rashes, muscle and joint pains, fever, rigors, pneumonitis, pancreatitis, tachycardia, renal dysfunction, and hypotension, some or all of which may represent hypersensitivity reactions. Stevens-Johnson syndrome and toxic epidermal necrolysis have been reported rarely.

Solutions for injection are irritant.

Carcinogenicity. Immunosuppression, including that with azathioprine, may be associated with an increased risk of certain neoplasms such as lymphomas and skin cancers in transplant recipients,[1] in patients with inflammatory bowel disease,[2,3] and in patients with rheumatoid arthritis.[4-6] Partly because of lower doses of immunosuppressants used in inflammatory bowel disease, the risk of lymphoma in these patients appears to be less than that associated with transplant recipients;[7] this risk appears to be far outweighed by the benefits of immunosuppressant therapy in inflammatory bowel disease. Rheumatic diseases may themselves be associated with an increased risk of malignancy that is independent of treatment, but one study[5] concluded that there is a further risk related to the duration of exposure to immunosuppressive drugs, including azathioprine. A recent systematic review[8] of the use of azathioprine for multiple sclerosis concluded that, when the balance between the benefits and harms were considered, azathioprine was a reasonable alternative to interferon beta in patients who frequently relapse and require corticosteroids. Other evidence in the literature suggested that the long-term risk of malignancy may be related to use for longer than 10 years and a cumulative dose above 600 g and the reviewers recommended that this dose should not be exceeded.

Skin cancer may be a particular risk in immunosuppressed patients with a history of high sun exposure.[7] A synergistic clastogenic effect has been noted with azathioprine and long-wave ultraviolet light.

Effects on the blood. Neutropenia in patients receiving mercaptopurine has been reported to correlate negatively with the concentration of the metabolite tioguanine nucleotide in erythrocytes,[1] and it has been suggested that measurement of metabolite concentrations in erythrocytes,[2] or activity of the enzyme thiopurine methyltransferase (TPMT),[3-6] permits prediction of those individuals likely to experience severe bone-marrow toxicity with mercaptopurine and the related drugs tioguanine and azathioprine. However, not all studies have found such correlations,[7] and effects on the bone marrow with this class of drugs are probably multifactorial;[8,9] low activity of other enzymes such as lymphocyte 5-nucleotidase,[10] and other factors, may contribute to toxicity. A review[9] of studies investigating TPMT activity in patients with Crohn's disease concluded that measurement of TPMT activity on starting azathioprine has a role in identifying those at risk of severe myelosuppression. Lower TPMT activities correlate with low neutrophil counts in the initial 4 months of thiopurine therapy; identification of the heterozygote might allow for safer management (see Therapeutic Drug Monitoring, below). However, in those patients established on therapy, TPMT did not predict clinical response or toxicity. Pure red cell aplasia occurs rarely with use of azathioprine; reported cases have all been in renal transplant recipients. In one such case,[11] reduction of the dose and use of erythropoietin was ineffective; however, the patient recovered within weeks of stopping azathioprine.

Effects on the liver. A review[1] of drug-related hepatotoxicity noted that azathioprine has been associated with hepatocanalicular cholestasis, in which the interference with bile flow is combined with hepatocyte damage, and with several hepatic vascular disorders, including focal sinusoidal dilatation, peliosis, and veno-occlusive disease. A later review[2] grouped reported cases into three syndromes: hypersensitivity, idiosyncratic cholestatic reaction, and presumed endothelial cell injury, with the imidazole and 6-mercaptopurine components of azathioprine playing different roles in pathogenesis.

2. Romagnuolo J, *et al.* Cholestatic hepatocellular injury with azathioprine: a case report and review of the mechanisms of hepatotoxicity. *Can J Gastroenterol* 1998; **12:** 479–83.

Hypersensitivity. In 2 of 5 renal transplant recipients with acute allergic reactions associated with azathioprine, the symptoms (interstitial nephritis) were initially mistaken for acute rejection episodes.[1] In another report,[2] shock, fever, and acute renal insufficiency in a patient led to an initial mistaken diagnosis of sepsis, and it was recommended that a hypersensitivity reaction be considered as a cause if any of these symptoms occurred within 4 weeks of azathioprine ingestion. Other reported features of hypersensitivity include malaise, gastrointestinal disturbances, myalgia, arthralgia, fever, headache and raised liver enzymes.[3,4] Skin lesions have been reported, with maculopapular erythema occurring most frequently; purpura, urticaria, and erythema nodosum-like lesions have also been described.[4,5] Skin biopsies often showed features of leucocytoclastic vasculitis.[4] Stevens-Johnson syndrome has also been reported.[5] In some cases, skin patch testing for azathioprine was negative;[3,5] a drug-induced lymphocyte stimulation test (which evaluates the antigen specific reactivity of lymphocytes by measuring the proliferation of peripheral blood lymphocytes exposed to the suspected drug) has been proposed as a sensitive and reliable test for azathioprine hypersensitivity.[5]

Precautions

Regular monitoring of blood counts is required. Patients with renal or hepatic impairment require more frequent monitoring of blood counts and may need reduced doses; liver function tests should be performed in hepatic impairment. Consideration should be given to testing patients for thiopurine methyltransferase (TPMT) activity. Intra-uterine devices should be used with caution during immunosuppressive treatment as there is an increased risk of infection. Use of live vaccines should be avoided for the same reason. Azathioprine should generally be avoided in pregnancy (see below).

For a recommendation that the cumulative dose of azathioprine should not exceed 600 g in patients with multiple sclerosis, see under Carcinogenicity, above.

Breast feeding. Low concentrations of mercaptopurine have been found in human colostrum and breast milk of patients taking azathioprine.[1] Breast feeding by these patients has not been recommended because of the potential risk of immunosuppression in the infant.[1-3] However, there are reports[1,2] of 3 breast-fed infants, whose mothers had been taking doses of 75 or 100 mg of azathioprine daily, in whom no evidence of immunosuppression was found. All 3 had normal blood counts, no increase in infections, and above average growth rate. In one case, the levels of mercaptopurine were determined at 2 days and after 2 weeks of breast feeding,[1] and in the other 2 cases, no levels were determined.[2] In a third report, 31 breast-milk samples were collected from 10 breast-feeding women (taking from 75 to 150 mg azathioprine daily);[3] low concentrations of mercaptopurine were only detected in one case. The neonates were followed for up to 28 days, and showed no signs of immunosuppression, nor were mercaptopurine and tioguanine nucleotides detectable in their red blood cells. The authors concluded that breast feeding should not be withheld in infants of mothers receiving azathioprine. However, they cautioned that there were no data on the effect of thiopurine methyltransferase (TPMT) activity (see Therapeutic Drug Monitoring, below) on metabolite concentrations in breast milk, and expressed concern as to whether a TPMT-deficient infant, unable to inactivate mercaptopurine absorbed into the breast milk, will be exposed to significant blood levels of the drug. In a study of 4 mothers and their infants,[4] all of whom had the wild-type TPMT genotype (with normal TPMT activity), infant exposure to azathioprine through breast milk was undetectable. The authors also cautioned that mothers taking higher doses or those with decreased TPMT activity might transfer more drug to the infant. It has been noted[5] that many breast-fed infants would have already been exposed to potentially much higher concentrations of mercaptopurine *in utero*.

Pregnancy. Azathioprine and/or its metabolites have been found in low concentrations in fetal blood after maternal use of azathioprine.[1] Azathioprine is teratogenic in *animals*, and congenital abnormalities, chromosomal aberrations,[2] fetal growth retardation,[3,4] low birth-weight, and spontaneous abortion have been reported in the offspring of pregnant women taking azathioprine. Neonatal leucopenia and thrombocytopenia have also been reported after maternal exposure.[5] Cohort studies have found an increased risk of congenital abnormalities, perinatal mortality, and preterm births after maternal or paternal exposure to azathioprine.[6,7] However, adverse birth outcomes may be related to the underlying disease rather than use of azathioprine or mercaptopurine,[8] and some consider its use in inactive inflammatory bowel disease to be safe;[9] however, there is suggestion that those with active disease, especially Crohn's disease, may have a higher incidence of spontaneous abortion, premature births, or still-births.[9] Given the nature of the severe chronic conditions for which azathioprine is generally used, stopping therapy in patients who become pregnant may not be necessary or desirable, but it seems prudent to avoid its use where possible during pregnancy.

Interactions

The effects of azathioprine are enhanced by allopurinol and the dose of azathioprine should be reduced to one-third to one-quarter of the usual dose when allopurinol is given. A further dose reduction or alternative therapy should be considered in those patients with low or absent thiopurine methyltransferase (TPMT) activity.

◊ In addition to being affected by allopurinol, azathioprine may itself affect other drugs including the following:

- competitive neuromuscular blockers (antagonism, see under Immunosuppressants on p.1904)
- vaccines (reduced response or generalised infection, see p.2202)
- warfarin (inhibition, see Immunosuppressants p.1431).

Gastrointestinal drugs. For mention of *5-aminosalicylates* inhibiting the metabolism of thiopurines such as azathioprine, and increasing their toxicity, see Mercaptopurine, p.744.

Mercaptopurine. The Institute for Safe Medication Practices in the USA reported a case in which a patient with a history of Crohn's disease was prescribed azathioprine and mercaptopurine by separate practitioners. The patient developed profound myelosuppression, severe sepsis, and died. Many drug information software programs were found to not warn of this possible therapeutic duplication.[1]

1. Institute for Safe Medication Practices. Duplication with azathioprine and mercaptopurine (issued 29 June, 2006). Available at: http://www.ismp.org/Newsletters/acutecare/articles/20060629_3.asp?ptr=y (accessed 15/01/08)

Pharmacokinetics

Azathioprine is well absorbed from the gastrointestinal tract when given orally. After oral or intravenous doses it disappears rapidly from the circulation and is extensively metabolised to mercaptopurine (which is then further metabolised—see p.744). Both azathioprine and mercaptopurine are about 30% bound to plasma proteins. About 10% of a dose of azathioprine is reported to be split between the sulfur and the purine ring to give 1-methyl-4-nitro-5-thioimidazole. The proportion of different metabolites is reported to vary between patients. Metabolites and small amounts of unchanged azathioprine and mercaptopurine are eliminated in the urine. Azathioprine is distributed into breast milk in low concentrations.

Therapeutic drug monitoring. Although plasma concentrations of 6-thiouric acid (the inactive product of mercaptopurine, and hence of azathioprine) can be readily measured in patients who have been receiving azathioprine, they are of little value in therapeutic drug monitoring.[1] The active moieties are the tioguanine nucleotides (6-TGN) formed intracellularly, which appear to have extremely long half-lives,[2] and mean erythrocyte concentrations of which appear to vary considerably between individuals.[2] The formation of other inactive metabolites is catalysed by thiopurine methyltransferase (TPMT) and its activity is genetically determined, with a trimodal distribution in the general population; 0.3% have low activity of TPMT, 11% have intermediate activity, and 89% have normal or high activity. Patients with low or intermediate activity appear to shift metabolism toward production of 6-TGN.

Because excess concentrations of 6-TGN have been associated with leucopenia, it has been suggested[3] that:

- patients with normal or high TPMT activity receive standard doses of azathioprine or mercaptopurine
- those with intermediate TPMT activity have reduced doses
- those with low activity not be treated with either drug

However, these recommendations remain controversial.[4] Haematological toxicity is not always explained by TPMT status, and other factors may be involved[5] (see also Effects on the Blood, above). Some consider that TPMT deficiency is not a contra-indication to thiopurine therapy; an initial dose reduction to 10 to 15% of the standard azathioprine dose has been used in TPMT-deficient patients with inflammatory bowel disease.[5] There are a proportion of patients in whom TPMT activity is very high; these patients appear to respond less well to standard doses, and higher-than-standard doses have been recommended.[6] While recommendations for pre-treatment measurement of TPMT status remain controversial,[4,5] some consider the avoidance of potentially fatal toxicity a compelling argument for TPMT assessment before thiopurine therapy is started.[6] However, TPMT units and normal ranges vary between laboratories depending on the methodology used,[6] and TPMT genotype or phenotype testing is not a surrogate for monitoring of complete blood counts.[4]

Because low concentrations of erythrocyte 6-TGN have been associated with disease relapse in lymphomas and leukaemias, a small study[7] of patients with inflammatory bowel disease attempted to define a therapeutic window of drug efficacy. Without monitoring TPMT genotype, treatment efficacy was found to correlate with erythrocyte 6-TGN levels. It was concluded that patients who remain symptomatic despite apparently therapeutic 6-TGN concentrations should be treated with adjunctive or alternative immunosuppression or surgery. However, a large study[8] did not confirm disease correlation with 6-TGN concentrations, and concluded that therapeutic drug monitoring of 6-TGN may be premature. It was noted that methodological differences, such as assay technique, existed between their study and others. As the role of routine monitoring of 6-TGN remains controversial,[4,9,10] it has been suggested that selective monitoring, such as in those with low or intermediate TPMT activity, be considered.[3] Some consider the measurement of 6-TGN useful to assess treatment compliance, or in cases of malabsorption.[4]

Uses and Administration

Azathioprine is an immunosuppressive antimetabolite with similar actions to those of mercaptopurine (p.744), to which it is converted in the body. Its effects may not be seen for several weeks after a dose. It is given orally, but where this is not feasible it may be given by slow intravenous injection or by infusion as azathioprine sodium. If given by infusion, the required dose should be diluted to a concentration of 0.25 to 2.5 mg/mL in sodium chloride 0.9% or glucose 5%, and infused over 30 to 60 minutes.

Azathioprine is mainly used as an immunosuppressant for the prevention of rejection in **organ and tissue transplantation** (p.1810). The dose for this purpose, given orally or intravenously, varies from 1 to 5 mg/kg daily and depends partly on the regimen used; the higher doses are used initially, adjusted according to clinical response and haematological tolerance.

Azathioprine is also used in **auto-immune diseases** or conditions that are considered to have an auto-immune component, see below. The usual dose of azathioprine, given orally or intravenously, in these conditions is in the range of 1 to 3 mg/kg daily. If no improvement is seen after 12 weeks, therapy may be stopped.

For doses in children, see Administration in Children, below.

Use of azathioprine with a corticosteroid (p.1495) may have a corticosteroid-sparing effect.

Blood counts should be carried out regularly during treatment and azathioprine withdrawn or the dosage reduced at the first indication of bone-marrow depression. Measurement of thiopurine methyltransferase (TPMT) activity may be used to identify patients at risk of haematological toxicity, although this cannot substitute for blood count monitoring.

Administration in children. UK licensed product information for azathioprine allows for the same doses in children as those used in adults (see Uses and Administration, above), both in organ and tissue transplantation and for diseases with an auto-immune component. The *BNFC* recommends that children aged 1 month to 18 years be given a maintenance dose of 1 to 3 mg/kg once daily for suppression of **transplant rejection**; alternatively, the total daily dose may be given in 2 divided doses. Although unlicensed for **severe ulcerative colitis and Crohn's disease**, the *BNFC* states that azathioprine may be given to children aged 2 to 18 years in an oral dose of 2 mg/kg (if necessary up to 3 mg/kg) once daily, reduced according to response to the lowest effective dose; alternatively, the total daily dose may be given in 2 divided doses.

Administration in hepatic or renal impairment. UK licensed product information states that controlled studies have not supported the suggestion that toxicity of azathioprine might be enhanced in the presence of renal impairment. Nevertheless, doses used should be at the lower end of the normal range, and haematological response should be carefully monitored. US licensed product information also recommends low doses, while stating that relatively oliguric patients, especially those with tubular necrosis in the immediate post-cadaveric transplant period, may have delayed clearance of azathioprine and/or its metabolites.

UK licensed product information states that the metabolism of azathioprine may be impaired in patients with hepatic dysfunction; regular blood counts and liver function tests should be performed and the dosage of azathioprine reduced if hepatic or haematological toxicity occurs.

Blood disorders. Immunosuppressants such as azathioprine are occasionally tried in auto-immune haemolytic anaemia (p.1043) refractory to other treatment and may permit reduction of corticosteroid dosage. Similarly in patients with idiopathic thrombocytopenic purpura (p.1505), immunosuppressants may be tried as a last resort. Azathioprine with a corticosteroid has been tried in the rare condition of acquired haemophilia (p.1048).

Cogan's syndrome. Azathioprine has been used with corticosteroids for severe Cogan's syndrome with large-vessel vasculitis (see p.1502).

Connective tissue and muscular disorders. Azathioprine is one of many drugs tried for disease control in Behçet's syndrome[1] (p.1499) and SLE[2] (p.1513). In polymyositis (p.1510), combined therapy with azathioprine and a corticosteroid has been found to be better than a corticosteroid alone for maintenance long-term.[3] However, there is also some evidence that methotrexate may be more effective in refractory polymyositis than azathioprine.[4]

Inflammatory bowel disease. Azathioprine, or its metabolite mercaptopurine, is used to induce remission in chronically active inflammatory bowel disease (p.1697), and to maintain remission, particularly in Crohn's disease.[1-3] They have a useful corticosteroid-sparing effect. Azathioprine may also be useful as a postoperative maintenance treatment in Crohn's disease.[4] In patients with ulcerative colitis, azathioprine may be an effective maintenance therapy for those who are refractory to or intolerant of mesalazine or sulfasalazine; it may also be useful for patients who require repeated courses of corticosteroids.[5]

Continuation of azathioprine therapy beyond 4 years has had conflicting results in terms of relapse rates and flare incidence. A randomised study in patients with Crohn's disease and in clinical remission, having been treated with azathioprine for at least 42 months, found that relapse rates were higher in those patients continued on placebo compared with those continued on azathioprine.[6] In another study of patients with corticosteroid-dependent Crohn's disease, a breakthrough of symptoms during continuous therapy was common, particularly after 48 months on azathioprine.[7] In an analysis of 1176 patients with inflammatory bowel disease, the authors concluded that stopping azathioprine therapy may be considered after 3 to 4 years in Crohn's disease patients in complete remission and without corticosteroid requirements but that continuation appears beneficial in all other Crohn's disease patients and for patients with ulcerative colitis.[8]

The onset of benefit from oral azathioprine may be delayed for several months. One study[9] reported that a more rapid response could be achieved with an intravenous loading dose but a later study failed to confirm this.[10]

Leprosy. For mention of the use of azathioprine as a corticosteroid-sparing agent in the management of type 1 lepra reactions, see p.176.

Liver disorders. Azathioprine has been widely used with corticosteroids to produce and maintain remission of chronic active hepatitis (p.1501); such combination therapy, which also permits a reduction in corticosteroid dosage, is generally thought to be more effective than azathioprine alone. Patients successfully maintained in remission for at least a year on azathioprine with a corticosteroid can subsequently be maintained on azathioprine (at a dose of 2 mg/kg daily) alone.[1] Results in patients with primary biliary cirrhosis (p.2408) have been more equivocal, and initial studies did not indicate much benefit from azathioprine, although a later study did seem to indicate improved survival and disease retardation.[2]

1. Johnson PJ, *et al.* Azathioprine for long-term maintenance of remission in autoimmune hepatitis. *N Engl J Med* 1995; **333:** 958–63.
2. Christensen E, *et al.* Beneficial effect of azathioprine and prediction of prognosis in primary biliary cirrhosis: final results of an international trial. *Gastroenterology* 1985; **89:** 1084–91.

Lung disorders. Although corticosteroids remain the mainstay of treatment for the various forms of diffuse parenchymal lung disease (p.1502) including cryptogenic fibrosing alveolitis (CFA), there is some evidence that combined therapy with azathioprine improves survival in the latter condition,[1] and the British Thoracic Society now recommends that initial treatment of CFA should be with oral prednisolone plus azathioprine 2 to 3 mg/kg daily.[2]

1. Raghu G, *et al.* Azathioprine combined with prednisone in the treatment of idiopathic pulmonary fibrosis: a prospective double-blind, randomized, placebo-controlled clinical trial. *Am Rev Respir Dis* 1991; **144:** 291–6.
2. British Thoracic Society. The diagnosis, assessment and treatment of diffuse parenchymal lung disease in adults. *Thorax* 1999; **54** (suppl 1): S1–S30. Also available at: http://www.brit-thoracic.org.uk/portals/0/Clinical%20Information/DPLD/Guidelines/Parenchymaltext.pdf (accessed 17/07/08)

Neuromuscular disorders. Azathioprine may be used for its corticosteroid-sparing properties in patients who require corticosteroid treatment for myasthenia gravis (p.629). It may also be of use when corticosteroids are contra-indicated or when response to corticosteroids alone is insufficient. Azathioprine is not usually used alone because it may be several months before any beneficial effect is seen. Some studies have also indicated modest benefit from azathioprine in patients with multiple sclerosis (p.892). It has been suggested that the benefits are too slight to justify the toxicity of the required doses, but it has also been pointed out that in terms of relapse reduction azathioprine appears as effective as newer treatments such as interferon beta. For a recommendation that the cumulative dose of azathioprine should not exceed 600 g, see under Carcinogenicity, above.

Ocular disorders. For mention of the use of azathioprine in various disorders characterised by ocular lesions such as scleritis or uveitis, see p.1810.

Polymyalgia rheumatica. Azathioprine may be used for its corticosteroid-sparing properties in patients who require corticosteroid treatment for polymyalgia rheumatica (p.1510) and in whom withdrawal is difficult.

Psoriatic arthritis. Azathioprine may be useful for severe or progressive cases of psoriatic arthritis (see under Spondyloarthropathies, p.13) when the arthritis is not controlled by physical therapy and NSAIDs.

Rheumatoid arthritis. Although azathioprine may be beneficial in rheumatoid arthritis (p.11) in the short-term, its toxicity is significantly more severe than other disease-modifying antirheumatic drugs (DMARDs).[1] It may, however, be useful in patients with severe disease unresponsive to other DMARDs especially in those with extra-articular manifestations such as vasculitis.[2]

1. Suarez-Almazor ME, *et al.* Azathioprine for treating rheumatoid arthritis. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2000 (accessed 15/01/08).
2. Heurkens AHM, *et al.* Prednisone plus azathioprine treatment in patients with rheumatoid arthritis complicated by vasculitis. *Arch Intern Med* 1991; **151:** 2249–54.

Sarcoidosis. Cytotoxic immunosuppressants such as azathioprine have been tried in patients with sarcoidosis (p.1512) who do not respond to or cannot tolerate corticosteroids.

Skin disorders. Like other immunosuppressants, azathioprine has been tried in various refractory skin disorders, notably in pemphigus and pemphigoid[1,2] (see below). Other conditions in which it has been tried include atopic eczema,[3-8] nodular prurigo,[9] chronic actinic dermatitis,[3,6] pyoderma gangrenosum,[4] erythema multiforme,[4,10] pompholyx, and plaque psoriasis,[6] as well as in the skin manifestations of systemic disorders such as dermatomyositis and lupus erythematosus.[2] Guidelines for the use of azathioprine in dermatology have been developed.[1] The recommended dose for azathioprine in dermatological disorders is 1 to 3 mg/kg daily, adjusted according to response. Treatment should be withdrawn if no response is seen within 3 months. Azathioprine should not be used in dermatology patients with very low or absent thiopurine methyltransferase (TPMT) activity (see Therapeutic Drug Monitoring, above), due to the danger of prolonged and severe myelosuppression (see Effects on the Blood, above). If azathioprine is given to patients with low TPMT activity, doses of 0.5 to 1 mg/kg daily should be used, with monitoring for myelosuppression. Patients with normal to high TPMT activity should be started on doses at the higher end of the range of 1 to 3 mg/kg daily; in those who do not respond, and have not experienced adverse effects, doses above this range may be considered for a trial period.

PEMPHIGUS AND PEMPHIGOID. Corticosteroids are the main treatment for blistering in pemphigus and pemphigoid (p.1582). Other immunosuppressants may be added to maintain disease control and allow a reduction in corticosteroid dosage, and azathioprine is commonly used in this way in pemphigus vulgaris.[1] There is limited evidence to suggest that azathioprine may also be effective as monotherapy to induce remission in mild pemphigus.[1] Azathioprine has been used similarly in bullous pemphigoid, but there is some disagreement about its efficacy,[2] and guidelines suggest that it should only be considered if the corticosteroid cannot be reduced to an acceptable dose.[3]

Vasculitic syndromes. Azathioprine has been tried in vasculitic syndromes, including giant cell arteritis (p.1503), microscopic polyangiitis (p.1510), Churg-Strauss syndrome (p.1501), Takayasu's arteritis (p.1514), and Wegener's granulomatosis (p.1515). In general it is most useful in maintenance for its corticosteroid-sparing effect. Cyclophosphamide tends to be preferred where a more aggressive regimen is required, as in some combinations for induction of remission.

Preparations

BP 2008: Azathioprine Tablets;
USP 31: Azathioprine Oral Suspension; Azathioprine Sodium for Injection; Azathioprine Tablets.

Proprietary Preparations (details are given in Part 3)

Basiliximab *(BAN, USAN, rINN)*

Basiliksimab; Basiliksimabi; Basiliximabum; chRFT5; SDZ-CHI-621. Immunoglobulin G1, anti-(human interleukin 2 receptor) (human-mouse monoclonal CHI621 γ1-chain), disulfide with human-mouse monoclonal CHI621 light chain, dimer.

Базиликсимаб

CAS — 179045-86-4.
ATC — L04AC02.
ATC Vet — QL04AC02.

Adverse Effects and Precautions

Severe acute hypersensitivity reactions have occurred rarely with basiliximab. These have included anaphylactoid-type reactions such as rash, urticaria, pruritus, sneezing, hypotension, tachycardia, cardiac failure, wheezing, dyspnoea, bronchospasm, pulmonary oedema, and respiratory failure. Capillary leak syndrome and cytokine release syndrome have been reported. Reactions have been seen both on initial exposure and with subsequent therapy. Patients in whom other immunosuppression was prematurely stopped, after initial therapy with basiliximab, appear to be at increased risk of hypersensitivity reactions. Therapy should be permanently stopped if a severe reaction occurs.

Giving basiliximab as a bolus may cause nausea, vomiting, and local reactions, including pain.

Pharmacokinetics

Basiliximab has a terminal half-life of about 7 days in adults and about 9 days in children.

Uses and Administration

Basiliximab is a chimeric murine/human monoclonal antibody similar to daclizumab (p.1833) that functions as an interleukin-2 receptor antagonist by binding to the alpha chain (CD25 antigen) of the interleukin-2 receptor on the surface of activated T-lymphocytes. It is used in the prevention of acute graft rejection episodes in patients undergoing renal transplantation, and is given as part of an immunosuppressive regimen that includes ciclosporin and corticosteroids; azathioprine or mycophenolate mofetil may also be added to the regimen. Doses are given either as an intravenous bolus, or diluted to a usual concentration of 400 micrograms/mL in sodium chloride 0.9% or glucose 5%, for infusion over 20 to 30 minutes. The recommended dose for adults is 20 mg, given within 2 hours before transplant surgery and repeated once after 4 days. (For children's doses, see Administration in Children, below). The second dose should be withheld if graft loss or a severe hypersensitivity reaction occurs.

Administration in children. Licensed product information recommends the following intravenous doses of basiliximab in children over 1 year of age, for prophylaxis of acute rejection in allogeneic renal transplantation, as part of an immunosuppressive regimen containing ciclosporin and corticosteroids:

- body-weight under 35 kg: 10 mg within 2 hours before transplantation surgery; 10 mg 4 days after surgery
- body-weight 35 kg or more: 20 mg within 2 hours before transplantation surgery; 20 mg 4 days after surgery (same as adults, see Uses and Administration, above)

Doses may be given either as an intravenous bolus, or diluted to a usual concentration of 400 micrograms/mL in sodium chloride 0.9% or glucose 5%, for infusion over 20 to 30 minutes.

Organ and tissue transplantation. Basiliximab is used as induction therapy to reduce the incidence of acute rejection episodes after kidney transplantation (p.1813), including paediatric renal transplant recipients;[1-6] it is usually given as part of an immunosuppressive regimen that includes ciclosporin and corticosteroids. A small study found that basiliximab significantly reduced the occurrence of rejection episodes in those treated with dual therapy (calcineurin inhibitor and corticosteroids) but not in those given triple therapy (including mycophenolate).[7] In a study of paediatric renal transplant recipients, addition of basiliximab to a tacrolimus-based regimen was safe, but did not result in a lower incidence of rejection episodes.[8] There is some suggestion that antilymphocyte immunoglobulins may be more effective than basiliximab in reduction of acute rejection in adult renal transplant patients,[9,10] although some consider basiliximab to offer improved clinical efficacy over antilymphocyte immunoglobulin induction in paediatric patients,[11] and others have commented[12] that graft survival at 12 months has been similar with each drug. Two reviews[13,14] concluded that the use of basiliximab in renal transplantation was safe and effective, with reduced rates of acute rejection, but no long-term benefit in terms of graft survival; basiliximab appears to allow the safe withdrawal of corticosteroids or the use of corticosteroid-free immunosuppressive regimens.

There is a short report suggesting that the use of a single dose is as effective as the standard 2-dose regimen in renal transplantation in terms of the incidence of acute rejection.[15]

Basiliximab has also been investigated in liver transplantation (p.1815). Given with dual therapy to adult patients, it was found to reduce the incidence of acute rejection episodes in the first year when compared with placebo, including patients positive for hepatitis C.[16] Basiliximab with dual therapy also reduced the incidence of acute graft rejection in small paediatric studies.[17,18] In paediatric liver transplantation, corticosteroid-free immunosuppressive regimens using basiliximab and tacrolimus have been associated with significantly lower rejection rates at 1 year than corticosteroid-based regimens.[19,20]

Basiliximab has been investigated for the prevention of rejection in heart,[21,22] lung,[23,24] and pancreatic transplantation (see p.1812). It has been reported to be effective[25] in the treatment of corticosteroid-refractory acute graft-versus-host disease (GVHD; see Haematopoietic Stem Cell Transplantation, p.1811).

Belatacept *(USAN, rINN)*

Bélatacept; Belataceptum; BMS-224818; LEA-29Y.

Белатацепт

CAS — 706808-37-9.

Profile

Belatacept is a derivative of abatacept (p.14). It is a fusion protein and co-stimulation blocker that prevents T-cell activation. Belatacept is under investigation for the management of solid organ transplant rejection.

◊ References.

Biolimus A9

42-*O*-(2-Ethoxyethyl) rapamycin.

$C_{55}H_{87}NO_{14}$ = 986.3.

CAS — 851536-75-9.

Profile

Biolimus A9 is an analogue of sirolimus (p.1841). A biolimus A9-releasing stent has been developed to reduce restenosis after coronary artery stent placement.

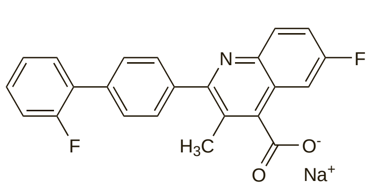
Brequinar Sodium *(USAN, rINNM)*

Brequinar sódico; Bréquinar Sodique; DuP-785; Natrii Brequinarum; NSC-368390. Sodium 6-fluoro-2-(2′-fluoro-4-biphenylyl)-3-methyl-4-quinolinecarboxylate.

Натрий Брехинар

$C_{23}H_{14}F_2NO_2Na$ = 397.3.

CAS — 96187-53-0 (brequinar); 96201-88-6 (brequinar sodium).



Profile

Brequinar sodium is an inhibitor of pyrimidine metabolism with potent immunosuppressant properties that has been investigated for the prevention and treatment of rejection episodes after organ and tissue transplantation and for treating various cancers.

Ciclosporin *(BAN, rINN)*

27-400; Ciclosporina; Ciclosporina A; Ciclosporine; Ciclosporinum; Ciklosporin; Ciklosporinas; Cyclosporin; Cyclosporin A; Cyclosporine *(USAN)*; Cyklosporin; OL-27-400; Siklosporiini; Siklosporin. Cyclo{-[4-(*E*)-but-2-enyl-*N*,4-dimethyl-L-threonyl]-L-homoalanyl-(*N*-methylglycyl)-(*N*-methyl-L-leucyl)-L-valyl-(*N*-methyl-L-leucyl)-L-alanyl-D-alanyl-(*N*-methyl-L-leucyl)-(*N*-methyl-L-leucyl)-(*N*-methyl-L-valyl)-}.

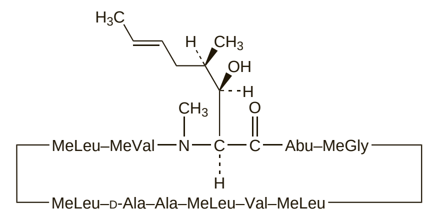
Циклоспорин

$C_{62}H_{111}N_{11}O_{12}$ = 1202.6.

CAS — 59865-13-3.

ATC — L04AD01.

ATC Vet — QL04AD01; QS01XA90.



Cyclosporin A

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Ciclosporin). A substance produced by *Beauveria nivea* (=*Tolypocladium inflatum* Gams) or obtained by any other means. A white or almost white powder; practically insoluble in water; freely soluble in dehydrated alcohol and in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Cyclosporine). A white to almost white powder. Practically insoluble in water; soluble in alcohol, in acetone, in chloroform, in dichloromethane, in ether, and in methyl alcohol; slightly soluble in saturated hydrocarbons. Store in airtight containers. Protect from light.

Incompatibility. The plasticiser diethylhexyl phthalate, which is a possible carcinogen, was leached from PVC containers by ciclosporin preparations containing polyoxyl castor oil.[1] Such preparations should not be given through PVC tubing nor stored in PVC containers. Polysorbate 80, which is an excipient in other ciclosporin preparations, also leached plasticiser from PVC,[1] and similar precautions would apply to preparations so formulated. UK licensed product information further recommends that containers and stoppers be free of silicone oil and fatty substances.

For reported incompatibility between ciclosporin and mycophenolate, see Incompatibility, under Mycophenolate, p.1836.

1. Pearson SD, Trissel LA. Leaching of diethylhexyl phthalate from polyvinyl chloride containers by selected drugs and formulation components. *Am J Hosp Pharm* 1993; **50:** 1405–9.

Stability. Ciclosporin was stable over 72 hours after dilution in glucose 5% or glucose/amino-acid solutions and storage at room temperature in the dark; similar stability was seen after dilution in lipid emulsion, but dilutions in sodium chloride 0.9% were considered to be stable only for 8 hours.[1] In all cases miscibility in the diluent was poor and vigorous shaking was required after addition to produce even distribution of ciclosporin. An extemporaneously compounded paste produced from ciclosporin oral solution (*Sandimmun*) in an oral gel base was found to be stable[2] for at least 31 days in aluminium-lined ointment tubes stored at 2° to 37°.

Adverse Effects and Treatment

Nephrotoxicity, manifesting as raised serum creatinine and urea, is the major adverse effect of ciclosporin. It is related to drug-plasma concentrations and is usually reversible on reduction of the dose. In renal graft recipients episodes of nephrotoxicity may be difficult to distinguish from graft rejection. Interstitial fibrosis may develop during long-term therapy.

Other frequent adverse effects include hypertension, gastrointestinal disturbances, fatigue, hepatotoxicity, hypertrichosis, gum hyperplasia, tremor, headaches, hyperlipidaemias, hyperkalaemia, hypomagnesaemia, hyperuricaemia, paraesthesia, and muscle cramps and myalgia. Less commonly, anaemia, thrombocytopenia, rashes, weight increase, oedema, pancreatitis, myopathy, neuropathy, and hyperglycaemia have been reported. Glomerular capillary thrombosis has occurred, and may progress to graft failure. Encephalopathy, manifest as convulsions, confusion, visual disturbances including blindness, movement disorders, or psychiatric disturbances, has been reported. Optic disc oedema, including papilloedema with possible visual impairment secondary to benign intracranial hypertension, has occurred rarely.

Anaphylactoid reactions have occurred after intravenous use; it has been suggested that these represent a reaction to the polyoxyl castor oil vehicle of the intravenous preparation.

There is an increased incidence of certain malignancies and a predisposition to infection in patients receiving ciclosporin therapy.

Alopecia. Although ciclosporin is more often associated with reports of hypertrichosis, there have been cases of alopecia areata developing in patients given ciclosporin,[1] sometimes with complete hair loss (alopecia universalis).[2,3]

3. Parodi A, *et al.* Alopecia universalis and cyclosporin A. *Br J Dermatol* 1996; **135:** 657.

Carcinogenicity. The use of ciclosporin in **organ transplant** recipients is associated with an increased incidence of malignancy, notably lymphoma,[1] and also skin cancer and Kaposi's sarcoma. The manufacturers have stated that of an estimated 5550 transplant patients who had been treated with ciclosporin by February 1984, lymphoproliferative disorders had been reported in 40; this represented an overall incidence of 0.7%, varying from 0.2 to 8% in different series.[2] In 1991, a report of 12 cases of lymphoproliferative disorders among 132 paediatric liver graft recipients estimated the incidence at about 2.8% per year for the first 6 years after transplantation, giving a cumulative risk of nearly 20% after 7 years.[3] There is evidence that the incidence of malignancy is related to dose,[2,4] and is greater when ciclosporin is used with other potent immunosuppressants.[2] In addition, the incidence of malignancy varies geographically, possibly reflecting environmental triggers and genetic susceptibility.[5]

It has been suggested that these lymphomas represent proliferation of B-cells under the influence of Epstein-Barr virus, a process normally prevented by the T-cells which are specifically inhibited by ciclosporin.[3] The resultant, usually polyclonal, lymphoproliferative tumours appear to regress on prompt excision of the affected tissue and reduction or withdrawal of the immunosuppressant regimen, in most cases without graft loss.[6] However, the need for vigilance and rapid response to these conditions has been stressed, since the responsive polyclonal disorder may evolve into a monoclonal, frankly malignant form; where the presentation is indistinguishable from a classic non-Hodgkins lymphoma the prognosis is much less good.[3] Interestingly, use of lower dose ciclosporin regimens appears to maintain normal elimination of Epstein-Barr virus-infected B-cells by specific T-cells,[7] and may lead to a reduced incidence of malignancy compared with earlier results.[4,7]

The risk of skin cancers in ciclosporin recipients is further increased by the exposure to sunlight.[8] Prophylactic retinoid therapy may prevent skin cancer in patients with renal transplants.[9]

There is no clear evidence that ciclosporin is associated with an increased incidence of malignancy compared with other immunosuppressants, although in one study dysplastic skin lesions were found in 14 of 64 transplant patients receiving ciclosporin compared with 3 of 33 previous similar patients who had received azathioprine.[10] However, such comparisons are difficult, not least because many transplant patients tend to have received multiple immunosuppressant agents. The safety of ciclosporin in **dermatology** patients has been reviewed.[11] Despite reports of lymphomas and other malignancies in dermatology patients treated with ciclosporin, a 5-year cohort study showed no increased risk of lymphoma or internal malignancies. While there was an increased risk of non-melanoma skin cancers, especially squamous cell carcinoma, many patients had been previously exposed to PUVA, methotrexate, or other immunosuppressants. Adjusting for these variables, more than 2 years of cumulative treatment with ciclosporin was estimated to increase the risk of non-melanoma skin cancer by a factor of 3.3 when compared with less than 2 years of cumulative treatment.

Dysmorphic changes. There was pronounced coarsening of facial features in 11 children who were treated with prednisone and ciclosporin for renal transplantation and followed up for more than 6 months.[1] The changes resembled those seen with phenytoin therapy. In a 13-year-old patient given ciclosporin as part of an immunosuppressive regimen after lung transplantation, facial dysmorphism, which developed along with follicular disturbances, later improved upon conversion to tacrolimus.[2] Similarly, lip hypertrophy associated with ciclosporin use in 2 paediatric patients resolved after therapy was changed to tacrolimus.[3] A 58-year-old renal transplant recipient on long-term ciclosporin therapy developed progressive facial changes, including swelling and distortion of the nose (rhinophyma);[4] surgery or physical ablation of excess tissue may provide cosmetic improvement.

Effects on the blood. Erythraemia[1,2] and thrombocytosis[3] have both been reported with ciclosporin treatment, both of which may contribute to **thromboembolic complications.** One retrospective study reported 17 thromboembolic events (pulmonary embolism, renal-vein or deep-vein thrombosis, or haemorrhoidal thrombosis) in 13 of 90 renal allograft recipients treated with ciclosporin and corticosteroids, compared with only 1 episode of superficial thrombophlebitis in 90 similar patients treated with an azathioprine-based regimen.[4] However, other authors dispute that the incidence of thromboembolic events is any greater after ciclosporin than azathioprine,[5-7] and one group found the reverse.[8]

Other effects that have been associated with ciclosporin therapy include cases of the haemolytic-uraemic syndrome,[9] and thrombocytopenia,[10] or leucopenia.[11] Post-transplant thrombotic microangiopathy has also been reported.[12,13] This syndrome can include haemolytic anaemia and thrombocytopenia, and must be distinguished from rejection in renal transplant recipients. In those patients with a history of thrombotic microangiopathy, the risk of recurrence is high, irrespective of ciclosporin treatment.

Effects on the cardiovascular system. The principal cardiovascular adverse effect of ciclosporin is **hypertension.** This may be severe,[1] appears to be dose-related,[1,2] and is particularly common in recipients of cardiac or heart-lung grafts.[3,4] There may be an association with low serum-magnesium concentrations.[5] Mechanisms that may contribute to ciclosporin-induced hypertension include impaired sodium excretion,[6] enhanced sympathetic nervous activity,[3,7] effects on renal prostaglandin metabolism,[2] and direct damage to endothelial cells[8] with release of the potent vasoconstrictor endothelin,[9] all of which may be due to calcineurin inhibition.[10] Thus hypertension may occur independently of nephrotoxicity,[2,7] and may be difficult to treat with conventional antihypertensive regimens.[6] Calcium-channel blockers are the preferred class of antihypertensives for hypertension that develops after transplantation.[1,11] It is important to choose one that does not interact with ciclosporin (see Cardiovascular Drugs under Interactions, below).[1] Beta blockers may also be used. Diuretics are usually avoided.[11] For mention of the ability of calcium-channel blockers to ameliorate the nephrotoxic effects of ciclosporin, see Transplantation, under Diltiazem, p.1267, Nifedipine, p.1356, and Verapamil, p.1424 Occasionally, hypertension may be irreversible.[2,12]

Raynaud's syndrome has been reported with ciclosporin.[13] Conversely, use of ciclosporin has also reportedly caused erythromelalgia, with painful inflammatory vasodilatation of the extremities.[14] For a discussion of possible thromboembolic complications, see Effects on the Blood, above.

Effects on glucose tolerance. Ciclosporin, particularly in high doses, may be associated with reduced insulin production,[1] impaired glucose tolerance,[2] and occasional overt diabetes mellitus,[3,4] although ciclosporin has also been tried, with some apparent benefit, in the treatment of recent-onset diabetes mellitus (for mention of the use of immunosuppressants in diabetes mellitus, see p.431). The incidence of fasting hyperglycaemia has been estimated at about 8% in ciclosporin-treated renal transplant recipients, compared with about 5% in those given an azathioprine-based regimen.[4]

Effects on the kidneys. Ciclosporin nephrotoxicity comprises 2 distinct forms of renal injury.[1,2]

Acute nephrotoxicity is dose-related, and reversible.[1-4] It occurs shortly after starting ciclosporin and often presents as an asymptomatic increase in serum creatinine, which improves quickly on dosage adjustment or drug withdrawal.[2,5] It may be difficult to distinguish ciclosporin nephrotoxicity from acute graft rejection after kidney transplantation.[5] Extremely high intravenous doses of ciclosporin (21 mg/kg per 24 hours for 60 hours) have been associated with fatal acute tubular necrosis;[6] in another patient given an overdose of 30 mg/kg per 24 hours, the error was detected after 18 hours, and the necrosis deemed to be partially reversible.[7]

Acute ciclosporin nephrotoxicity appears to be related to a renal imbalance of vasoconstrictor and vasodilator mediators, leading to intense vasoconstriction within the kidney.[1,2] Stimulation of the renin-angiotensin system,[5] free radical damage,[1,2] and activation of the sympathetic nervous system[1,5] have been suggested to play a role; numerous vasoactive mediators, including prostaglandins, thromboxanes, nitric oxide, and endothelin-1, may be implicated.[2,3] However, studies with therapies affecting vasoactive factors have produced equivocal results.[1-3]

Chronic nephrotoxicity is related to long-term exposure to ciclosporin.[2] It may be difficult to distinguish between chronic ciclosporin nephrotoxicity and chronic allograft rejection or nephropathy.[4,5] There is a decline in glomerular filtration rate, which may be irreversible or only partially reversible in transplant patients;[3] Some cardiac transplant patients given higher doses than those used in renal transplantation have developed end-stage renal failure.[3] One study[8] in paediatric heart transplant patients found that the decline in renal function correlated with early exposure to ciclosporin. However, in non-transplant patients, renal function impairment has been reported to be reversible after stopping ciclosporin.[3,9] Long-term follow-up has not shown progressive loss of renal function in these patients.[3] Chronic nephrotoxicity is also associated with typical irreversible histological changes, such as interstitial fibrosis.[1-3] which may occur as a result of ischaemic damage secondary to the prolonged alterations in intrarenal haemodynamics.[3] The mechanism is not completely understood, and chronic nephrotoxicity can occur independently of acute renal dysfunction, dosage, or ciclosporin blood concentrations.[4]

Drugs tried to *ameliorate* the nephrotoxic effects of ciclosporin in patients who have undergone transplantation include calcium-channel blockers (see Transplantation, under Diltiazem, p.1267, Nifedipine, p.1356, and Verapamil, p.1424), clonidine, codergocrine,[10-12] omega-3 triglycerides,[13] misoprostol and other prostaglandin analogues,[14,15] and cilastatin.[16] Although benefits have been reported with some of these, hydration, careful monitoring of ciclosporin concentrations, and the use where possible of low-dose or intermittent regimens of ciclosporin appear to remain the major means of minimising nephrotoxicity. Calcium-channel blockers are used if hypertension occurs (see Effects on the Cardiovascular System, above).

Effects on lipids. Marked hyperlipidaemia has been associated with ciclosporin therapy, with notable increases reported in low-density lipoprotein cholesterol,[1,2] and triglycerides. An increase in lipoprotein(a) has been reported,[3] but this was disputed.[4-6] Ciclosporin has been reported to have greater effects on lipids than azathioprine[7] or tacrolimus[8] post-transplantation. The use of corticosteroids with ciclosporin appears to have an additive adverse effect on lipids.[9] Lipid regulating drugs are used to decrease hypercholesterolaemia in transplant patients.

Effects on the nervous system. Adverse effects of ciclosporin on the CNS include tremor,[1-4] ataxia,[1-3] confusion[1,2,5] or agitation,[2] mental depression,[3] headache,[2,5] sleep disturbances,[2] lethargy,[1,2,6,7] or coma[2,5-7] (in one case coma persisted for 44 days),[8] convulsions,[2,3,5,9-13] leukoencephalopathy,[2,8,9,13] cortical blindness,[2,9] diplopia,[14] and spasticity or paralysis of the limbs.[1,2] Opsoclonus (an involuntary eye movement disorder) has also been reported.[13] In one reported case of posterior leukoencephalopathy, the patient developed irreversible abulia (impairment of ability to perform voluntary actions or make decisions; reduction in speech, movement, thought, and emotional reaction);[15] the patient initially presented with subtle symptoms of decreased appetite and reduced activity. Convulsions have sometimes been associated with hypertension and fluid retention,[11] but this is by no means always the case.[9,10]

Although neurotoxicity usually manifests within a month of beginning treatment, it may be delayed, and in one case occurred only after 3 years of ciclosporin therapy.[16] Severe CNS toxicity has been stated to vary in incidence from 0.1% in renal transplant patients to about 1.6% in bone marrow transplant recipients.[12] There is some evidence for an association of serious neurological effects with low total serum-cholesterol concentrations,[2] and the use of the intravenous formulation.[2] Neurotoxicity may also be associated with the use of lipid solutions.[17] An association with hypomagnesaemia has also been proposed[3] but may just represent concomitant nephrotoxicity.[18] Convulsions may be more likely or more severe in patients with a familial history of epilepsy,[19] subclinical aluminium overload,[20] or in those also given high-dose corticosteroids.[5,21,22]

The mechanism of toxicity is unknown but may be associated with disturbance of the blood-brain barrier;[10,12,23] it has been suggested that the metabolite M-17, or possibly other metabolites, are responsible for neurotoxicity.[6] Ciclosporin may be selectively toxic for glial cells, and alteration of sympathetic outflow by calcineurin inhibition may also mediate neurotoxicity.[24]

Effects on skeletal muscle. Ciclosporin has occasionally been associated with myopathy.[1-6] The manufacturer noted that 29 cases had been reported by December 1990, which appeared to be divided into cases of toxic or non-specific myopathy or mild sensory motor neuropathy, which were generally dose-related; and rhabdomyolysis, often, but not always, when used with lovastatin or colchicine.[7] Rhabdomyolysis has also been reported when other statins were used with ciclosporin, see Lipid Regulating Drugs, under Interactions, below.

Hyperplasia. Ciclosporin is well known to be associated with the development of gingival hyperplasia or gingival overgrowth: one review[1] has estimated the incidence at about 30% in transplant patients, while noting that reported values in the literature range from about 7 to 70%. A large study[2] found dosage and serum concentration of ciclosporin to be the most significant risk factors in the development of gingival hyperplasia. The presence of dental plaque may exacerbate the response, and good oral hygiene is important in preventing or minimising of gingival overgrowth.[1] Use with nifedipine (which can itself produce hyperplasia) may exacerbate overgrowth;[3] a cohort study[4] of renal transplant recipients found that amlodipine was associated with a greater prevalence of overgrowth than nifedipine. Overgrowth is generally reversible after dosage reduction or withdrawal of ciclosporin; where this is not feasible, surgical excision is recommended.[1] However, improvement or resolution of the overgrowth may also be produced by a course of azithromycin.[5-7] Similar benefit has been reported for metronidazole in some[8,9] but not all patients.[10] There are reports[11,12] of marked improvement in hyperplasia after changing treatment from ciclosporin to tacrolimus, including a case apparently resistant to azithromycin.[13]

Enlargement of the papillae of the tongue[14] and sebaceous gland hyperplasia[15] have also occurred in association with ciclosporin.

Hypersensitivity. Anaphylactoid reactions in 5 of 21 patients given intravenous ciclosporin infusions were found to be associated with improper mixing of the ciclosporin concentrate, which had a polyoxyl castor oil vehicle, with the infusion solution.[1] It was concluded that this had led to an initial bolus of polyoxyl castor oil that had triggered the anaphylactic reactions. Subsequent study indicated that peak concentrations of up to 9 times the intended concentration of ciclosporin and polyoxyl castor oil were present in the first 10 minutes of a poorly mixed infusion.[2] Anaphylactic shock after ingestion of ciclosporin capsules has been reported. The microemulsifying base containing corn oil and polyoxyl 40 hydrogenated castor oil, which is related to the polyoxyl castor oil vehicle used in the intravenous formulation, was considered to be the likely cause.[3]

Hyperuricaemia. Ciclosporin therapy may be associated with marked hyperuricaemia,[1-3] which may lead (mainly in male patients[1]) to episodes of severe gouty arthritis.[1-3] It has been suggested that ciclosporin specifically reduces urate clearance by the kidney independently of its effects on glomerular filtration,[4,5] but this has been disputed.[6] Treatment of ciclosporin-induced gout can be difficult since interactions with NSAIDs may lead to enhanced renal toxicity[5] and patients who are also receiving azathioprine may experience increased bone-marrow toxicity if given allopurinol.[7] Benzbromarone appears to be an alternative[8] for treating hyperuricaemia in renal transplant recipients with a creatinine clearance greater than 25 mL/minute.

Overdosage. Anxiety, diarrhoea, vomiting, and perspiration, with weak and irregular pulse, occurred in a patient accidentally injected with 250 mg (estimated 6.25 mg/kg) of ciclosporin.[1] The patient subsequently developed atrial fibrillation, which was treated with digoxin, and in the next 36 hours showed signs of slight renal insufficiency. Two days later no adverse effects were apparent. Atrial fibrillation also developed in another patient accidentally given 1 g of microemulsifying oral ciclosporin.[2] No adverse renal, hepatic, or neurological effects were seen in a third patient[3] who took 25 g of ciclosporin over 8 days. There was a mild increase in blood pressure and other symptoms included burning sensations in the mouth and the extremities, dysgeusia, facial flushing, and gastrointestinal disturbances. Symptoms resolved within 2 weeks of stopping ciclosporin.

A patient accidentally given intravenous ciclosporin at 30 mg/hour for 13 hours, developed massive intracerebral oedema and brainstem compression and died despite stopping the infusion.[4]

Although ciclosporin is only minimally dialysable, whole blood exchange (therapeutic erythrocytapheresis followed by plasma exchange) has been used in the management of a patient inadvertently given 3.5 g of ciclosporin orally; the overdose was discovered too late for the use of activated charcoal or gastric lavage, and plasma exchange alone was considered unsuitable because of the partitioning of ciclosporin between plasma and erythrocytes. The patient, who had signs of nephrotoxicity and hepatotoxicity, recovered without long-term sequelae.[5]

For reference to tubular necrosis after extremely high intravenous doses of ciclosporin, see under Effects on the Kidneys, above.

Precautions

Regular monitoring of renal and hepatic function, blood pressure, and serum electrolytes (chiefly potassium and magnesium) is required in patients receiving ciclosporin. Serum lipids should also be monitored. Monitoring of plasma ciclosporin concentrations is mandatory in transplant patients. Dosage adjustment is often necessary in patients with renal impairment or other factors affecting plasma ciclosporin concentrations. Care is required in patients with hyperuricaemia, and intravenous formulations should be given cautiously to those who have previously received parenteral drugs formulated in polyoxyl castor oil, or to those with a history of allergic reactions.

Ciclosporin should not be used to treat atopic dermatitis, psoriasis, or rheumatoid arthritis in patients with persistently raised creatinine, uncontrolled hypertension, uncontrolled infections, or malignancy. An exception is patients with treated malignant or pre-malignant lesions of the skin who may receive ciclosporin as a last resort for psoriasis. Psoriatic patients should not be given concomitant ultraviolet irradiation and should avoid excessive sun exposure. Ciclosporin may increase the risk of benign intracranial hypertension.

The commercially available oral formulations of ciclosporin differ in their bioavailability, and patients should not be transferred from one to another without appropriate monitoring. Intra-uterine contraceptive devices should be used with caution during immunosuppressive treatment as there is an increased risk of infection. Immunosuppressants may reduce the response to vaccines and use with live vaccines should generally be avoided as there is a possibility of generalised infection, see below.

Oral formulation. After development of the oral microemulsifying formulation of ciclosporin patients were switched from the old formulation on a 1:1 basis by weight initially, with monitoring of resultant ciclosporin concentrations and subsequent dosage adjustment. Results were generally good, despite some reports of nephrotoxicity or rejection in previously stable grafts,[1-4] and a meta-analysis[5] concluded that of *de novo* transplant recipients, those receiving the microemulsifying formulation had significantly fewer instances of rejection, and, in liver transplant recipients, significantly fewer adverse events.

Breast feeding. The American Academy of Pediatrics considers that ciclosporin may possibly suppress the immune system in a nursing infant.[1] However, a study[2] in the breast-fed infants of 7 women given ciclosporin found that the amounts ingested by the infant produced undetectable blood concentrations. In another case it was estimated that a breast-fed infant received less than 100 micrograms/kg of ciclosporin daily.[3]

Porphyria. Ciclosporin is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*. However, there are reports of patients with acute intermittent porphyria given ciclosporin pre- and post-transplant with no exacerbation of symptoms.[1,2]

2. Warholm C, Wilczek H. Renal transplantation in a case of acute intermittent porphyria. *J Clin Pharmacol* 2003; **43:** 1158–60.

Pregnancy. Ciclosporin has been used successfully in pregnant women. However, in common with other immunosuppressants, fetal growth retardation may be a significant problem.[1-4] Patients with hypertension or graft dysfunction are more likely to have adverse outcomes, so patients should have stable graft function and be on maintenance therapy before considering pregnancy.[1,2] Serum ciclosporin concentrations may fall during pregnancy,[2,3,5] but although frequent monitoring is necessary, the altered immune state of pregnancy may protect against rejection episodes.[5] Ciclosporin should be used at the lowest possible dose to maintain efficacy, and one review[3] has recommended that the daily dose should be kept below 5 mg/kg.

One case of osseous malformation, resulting in hypoplasia of the right leg has been reported in an infant born to a ciclosporin-treated mother.[6]

Interactions

Ciclosporin is extensively metabolised in the liver and plasma-ciclosporin concentrations may be affected by inducers or competitive inhibitors of hepatic enzymes, particularly cytochrome P450 isoenzyme CYP3A4. For example, use of carbamazepine, nevirapine, phenytoin, phenobarbital, rifampicin, St John's wort, and other inducers of hepatic enzymes may lead to lower plasma concentrations of ciclosporin, and increased plasma concentrations have been reported with some antifungals, macrolide antibacterials, HIV-protease inhibitors, the NNRTI delavirdine, some calcium-channel blockers, sex hormones, corticosteroids and grapefruit juice. In transplant patients frequent measurement of plasma ciclosporin and, if necessary, ciclosporin dosage adjustment is required, particularly during the introduction or withdrawal of other drugs.

Concurrent use of statins may increase the risk of myopathy and rhabdomyolysis. Potassium-sparing diuretics should be avoided because of the risk of hyperkalaemia, and patients taking ciclosporin should avoid a high dietary intake of potassium. The risk of gingival hyperplasia may be increased by amlodipine or nifedipine.

During treatment with ciclosporin, vaccination may be less effective, and the use of live vaccines should generally be avoided.

Care should be taken when ciclosporin is given with other nephrotoxic drugs.

Antibacterials. ***AMINOGLYCOSIDES.*** Increased nephrotoxicity has been reported after the use of aminoglycosides with ciclosporin.[1,2] However, a retrospective analysis in 21 patients given ciclosporin for allogeneic bone marrow transplant, in whom aminoglycosides were used if fever and neutropenia developed, showed no greater incidence of nephrotoxicity than in 20 autologous bone marrow recipients who did not receive ciclosporin, suggesting that these drugs can be given together provided careful monitoring is maintained.[3]

CHLORAMPHENICOL. Marked rises in plasma-ciclosporin concentrations have been reported when chloramphenicol was given.[1-3] Ciclosporin trough concentrations should be monitored if these drugs are used together.[3]

MACROLIDES. Markedly raised blood concentrations of ciclosporin have been reported in patients also given *erythromycin*.[1-4] The mechanism involved appears to be a combination of decreased hepatic metabolism of ciclosporin and increased gastrointestinal absorption.[5] Similar elevations of ciclosporin concentrations have been noted after use with other macrolide antibacterials, including *clarithromycin*,[6-8] *josamycin*,[9,10] *midecamycin*,[11] *midecamycin acetate*,[12] and the structurally-related streptogramins, *pristinamycin*[13] and *quinupristin/dalfopristin*.[14] Small increases in ciclosporin concentrations have been seen with *roxithromycin*.[15] Increases in ciclosporin concentrations were attributed to *azithromycin* in 2 patients,[16,17] but a study in 6 patients found no effect.[18] *Spiramycin* does not appear to affect the pharmacokinetics of ciclosporin.[19,20]

PENICILLINS. Decreased plasma-ciclosporin concentrations and effect were seen in a patient given *nafcillin*.[1] Conversely, another study reported increased nephrotoxicity from the use of ciclosporin with nafcillin but no apparent increase in ciclosporin concentrations.[2]

QUINOLONES. A number of reports have indicated that the quinolone *ciprofloxacin* has no effect on the pharmacokinetics of ciclosporin.[1-3] However, there is a report of enhanced nephrotoxicity without a change in ciclosporin concentrations in a patient given ciprofloxacin,[4] and another report showing both enhanced nephrotoxicity and increased ciclosporin concentrations.[5] Furthermore, a small case-control study suggested an increase in transplant rejection with ciprofloxacin.[6] *Norfloxacin* has been reported to decrease clearance and increase blood concentrations of ciclosporin in paediatric patients,[7] probably by inhibition of ciclosporin metabolism. *Levofloxacin* did not alter ciclosporin pharmacokinetics in healthy subjects,[8] but a study in renal transplant patients found that levofloxacin partially inhibited the metabolism of ciclosporin;[9] no adverse effects and no supratherapeutic concentrations of ciclosporin were seen.

RIFAMYCINS. Use with *rifampicin* has been associated with marked decreases in blood-ciclosporin concentrations,[1-5] and has resulted in graft rejection.[1,3] Although it has been assumed that this effect represents induction of the hepatic metabolism of ciclosporin by rifampicin, there is some suggestion that rifampicin may decrease the absorption of ciclosporin or induce intestinal metabolism, resulting in reduced bioavailability.[6] Topical application of *rifamycin* has also been associated with a decrease in blood-ciclosporin concentrations in another patient;[7] ciclosporin concentrations rose immediately after withdrawal of rifamycin, suggesting that the effect was not due to enzyme induction.

STREPTOGRAMINS. Increased plasma concentrations of ciclosporin have occurred after therapy with *pristinamycin* and *quinupristin/dalfopristin* (see Macrolides, above).

SULFONAMIDES. Intravenous, but not oral, therapy with *sulfadimidine* and *trimethoprim* has been associated with falls in ciclosporin concentrations to subtherapeutic values.[1,2] Oral *sulfadiazine* has had a similar effect.[3] Conversely, *trimethoprim* and *co-trimoxazole* can cause rises in serum creatinine, and therefore may contribute to ciclosporin-induced nephrotoxicity.[4,5]

Antidepressants. Giving *fluoxetine* to a patient receiving ciclosporin as part of an immunosuppressant regimen after cardiac transplantation was associated with a subsequent marked increase in ciclosporin trough blood concentrations to about twice their original value, necessitating a reduction in ciclosporin dosage.[1] After withdrawal of fluoxetine, ciclosporin concentrations fell, and dosage had to be increased. However, a study in 13 other patients given ciclosporin with fluoxetine failed to find any evidence of altered ciclosporin concentrations.[2] A nearly tenfold increase in ciclosporin concentration was seen in a cardiac transplant patient after use of *nefazodone*,[3] and there are 2 case reports[4] of ciclosporin toxicity due to interactions with nefazodone and *fluvoxamine* in renal transplant recipients. Ciclosporin concentrations decreased in a 10-year-old African American heart transplant recipient 22 days after starting *bupropion*. Despite an increase in ciclosporin dosage, ciclosporin concentrations decreased even further, necessitating another increase in ciclosporin dose, and withdrawal of bupropion.[5]

ST JOHN'S WORT. Ciclosporin plasma levels are reduced by St John's wort.[1] This has lead to acute rejection episodes in transplant patients,[2] and the two drugs should not be used together.[3]

Antiepileptics. Use with the antiepileptics *carbamazepine*,[1-3] *phenobarbital*,[4] and *phenytoin*,[5] which are all inducers of hepatic cytochrome P450, has been associated with a reduction in blood-ciclosporin concentrations. *Oxcarbazepine* also decreased ciclosporin trough concentrations in a kidney transplant recipient with epilepsy; concentrations were corrected by an increase in ciclosporin dose. The dose of oxcarbazepine also had to be reduced due to hyponatraemia, and ciclosporin concentrations remained stable thereafter.[6] *Valproate* has been successfully used in ciclosporin-treated patients without apparent interaction.[1,2]

Antifungals. The imidazole *ketoconazole* is a potent inhibitor of hepatic cytochrome P450 and markedly increased blood-ciclosporin concentrations have resulted when conventional formulations of the latter were given with the antifungal.[1-4] The interaction has been used, similarly to the calcium-channel blockers (see below), to permit therapeutic blood concentrations of ciclosporin to be achieved at lower doses;[5-8] however, this method may result in considerable variations in ciclosporin pharmacokinetics, and has been criticised on several grounds.[9] It was noted[10] that this improved bioavailability of ciclosporin was not seen when the microemulsifying formulation (see Absorption under Pharmacokinetics, below) was given with ketoconazole, suggesting that bioavailability was already maximal. Increased ciclosporin concentrations have also been reported with *itraconazole*,[11,12] and it has also been suggested[13] that use be made of this interaction, similarly to ketoconazole, to allow for decreased ciclosporin doses. *Voriconazole* also increases exposure to ciclosporin, and ciclosporin concentrations should be closely monitored.[14,15] There is a single report of increased ciclosporin plasma concentrations with use of *miconazole*.[16] However, although such an interaction has also been reported with *fluconazole*,[17,18] a small study has failed to note any significant interaction;[19,20] it has been suggested that an interaction may take place only at high doses of fluconazole,[21] or that sex and ethnicity may play a role.[18]

Increased nephrotoxicity may occur if ciclosporin is used with *amphotericin B*,[22,23] while liposomal amphotericin B has been reported possibly to exacerbate ciclosporin neurotoxicity.[24] There is a report of decreased ciclosporin concentrations in a patient after addition of *griseofulvin* to therapy.[25] Modest decreases have also been seen in ciclosporin concentrations when *terbinafine* was given.[26] *Micafungin* modestly inhibits ciclosporin metabolism; however, in a minority of patients it may cause a significant increase in ciclosporin concentrations.[27]

Antigout drugs. A patient who had been receiving maintenance doses of ciclosporin for some years, with consistent whole-blood trough concentrations of around 130 nanograms/mL at doses of 175 mg twice daily had a rise in ciclosporin concentrations to 410 nanograms/mL after 2 months of treatment with *allopurinol* 200 mg daily.[1] Ciclosporin concentrations returned to their previous levels over several weeks after stopping allopurinol, and rose again on rechallenge. Dosage of ciclosporin was then reduced. For a report of a low dose of allopurinol being added to a ciclosporin-containing immunosuppressive regimen, see Organ and Tissue Transplantation, p.554.

UK licensed product information states that *colchicine* may increase ciclosporin concentrations.

In a report of 120 heart transplant recipients with hyperuricaemia, *sulfinpyrazone* reduced ciclosporin concentrations, and 2 patients needed treatment for acute rejection.[2]

1. Gorrie M, *et al.* Allopurinol interaction with cyclosporin. *BMJ* 1994; **308:** 113.
2. Caforio ALP, *et al.* Sulfinpyrazone reduces cyclosporine levels: a new drug interaction in heart transplant recipients. *J Heart Lung Transplant* 2000; **19:** 1205–8.

Antimalarials. A large rise in serum-ciclosporin concentration was seen on 2 occasions in a renal graft recipient when *chloroquine* was added to his medication for malaria prophylaxis.[1] *Quinine* has been reported to reduce ciclosporin concentrations.[2]

1. Finielz P, *et al.* Interaction between cyclosporin and chloroquine. *Nephron* 1993; **65:** 333.
2. Tan HW, Ch'ng SL. Drug interaction between cyclosporine A and quinine in a renal transplant patient with malaria. *Singapore Med J* 1991; **32:** 189–90.

Antineoplastics. Elevated plasma-ciclosporin concentrations and an increased incidence of nephrotoxic effects and hypertension have been reported in patients receiving ciclosporin for psoriasis who had been previously,[1] or concurrently,[2] treated with *methotrexate*. Conversely, methotrexate has been used effectively with reduced-dose ciclosporin in graft-versus-host disease.[3] Severe renal failure has been reported when standard oral doses of ciclosporin were given after high-dose intravenous *melphalan* (used as a bone marrow conditioning agent before allogeneic bone marrow transplantation).[4] A retrospective analysis of allogeneic haematopoietic stem cell transplant patients taking ciclosporin found that, in those given a conditioning regimen containing *cyclophosphamide*, mean serum-ciclosporin concentrations were reduced; no effect on the incidence of graft-versus-host disease could be established.[5]

UK licensed product information states that *imatinib* may increase ciclosporin concentrations.

Ciclosporin increases plasma-*doxorubicin* concentrations and toxicity (see p.714), and has been used to increase oral absorption of *paclitaxel* (see p.760). For the effects of ciclosporin on the pharmacokinetics of *teniposide* and *etoposide*, see p.778 and p.719, respectively.

Ciclosporin and its analogues have been given with antineoplastics for their ability to inhibit the P-glycoprotein cellular pump responsible for multidrug resistance, thus resulting in raised intracellular concentrations of the other drug.

5. Nagamura F, *et al.* Effect of cyclophosphamide on serum cyclosporine levels at the conditioning of hematopoietic stem cell transplantation. *Bone Marrow Transplant* 2003; **32:** 1051–8.

Antiobesity drugs. A reduction in ciclosporin concentrations to subtherapeutic levels has been reported[1-3] in transplant recipients given *orlistat*. It was postulated[2] that the interaction was a result of reduced absorption of ciclosporin in the presence of orlistat and that at least 2 hours should elapse between doses of these two drugs. However, despite this dosing interval, there has been a further report[3] of subtherapeutic plasma levels of ciclosporin. The patient had had severe diarrhoea, and the subsequent decreased absorption of fats was thought to have decreased the absorption of ciclosporin.

An increase in ciclosporin trough concentrations occurred when a renal transplant patient was given *sibutramine*;[4] both drugs are metabolised by cytochrome P450 isoenzyme 3A4.

3. Barbaro D, *et al.* Obesity in transplant patients: case report showing interference of orlistat with absorption of cyclosporine and review of literature. *Endocr Pract* 2002; **8:** 124–6.
4. Clerbaux G, *et al.* Interaction between sibutramine and cyclosporine. *Am J Transplant* 2003; **3:** 906.

Antivirals. For a report of mutual elevations in the area under the plasma concentration-time curves for ciclosporin and the HIV-protease inhibitor *saquinavir*, see Indinavir, p.883.

Bifendate. In 2 patients given maintenance doses of ciclosporin, trough whole-blood concentrations decreased from 97.7 nanograms/mL to 49.0 nanograms/mL and from 127.5 nanograms/mL to 45.0 nanograms/mL respectively when bifendate was given. Ciclosporin concentrations returned to pretreatment levels over several weeks once bifendate was stopped.[1]

1. Kim YS, *et al.* The effect of diphenyl-dimethyl-dicarboxylate on cyclosporine-A blood level in kidney transplants with chronic hepatitis. *Korean J Intern Med* 1997; **12:** 67–9.

Cardiovascular drugs. *ACE INHIBITORS.* There may be an increased risk of hyperkalaemia when ACE inhibitors are used with ciclosporin. Acute renal failure, associated with use of *enalapril*, has been reported in 2 patients given ciclosporin after renal transplantation.[1] Renal function recovered when the ACE inhibitor was withdrawn.

1. Murray BM, *et al.* Enalapril-associated acute renal failure in renal transplants: possible role of cyclosporine. *Am J Kidney Dis* 1990; **16:** 66–9.

ANTIARRHYTHMICS. Marked rises in serum-ciclosporin concentrations despite reductions in dose have been noted in recipients of organ transplants after treatment with *amiodarone*.[1-3] A rise in serum ciclosporin has similarly been seen in a patient given both ciclosporin and *propafenone*.[4]

4. Spes CH, *et al.* Ciclosporin-propafenone interaction. *Klin Wochenschr* 1990; **68:** 872.

ANTICOAGULANTS. Treatment with *warfarin* for deep-vein thrombosis in a patient maintained on ciclosporin for pure red cell aplasia resulted in a relapse of the latter and a significant fall in ciclosporin blood concentrations.[1] Increase in the ciclosporin dose restored control of the aplasia but resulted in a marked increase in prothrombin activity requiring an increase in warfarin dosage. The results suggest that each drug interferes with the activity of the other. The influence of the patient's other medications (including phenobarbital and folic acid), if any, is unknown, although it has been suggested[2,3] that the phenobarbital had enhanced the metabolism of both drugs. In another report,[2] a patient on long-term warfarin for deep-vein thrombosis was started on ciclosporin for lymphoma relapse, and subsequently required larger doses of warfarin. During use of *acenocoumarol* with ciclosporin, the dose of ciclosporin had to be increased[3] in one patient and both drugs decreased[4] in another. It appears that the interaction between ciclosporin and anticoagulants is unpredictable[3] and dependent on the anticoagulant used.[2]

4. Campistol JM, *et al.* Interaction between ciclosporin A and Sintrom. *Nephron* 1989; **53:** 291–2.

ANTIPLATELET DRUGS. *Ticlopidine* decreased serum-ciclosporin concentrations in isolated cases,[1-3] but a study in 20 heart transplant patients failed to show any interaction between ciclosporin and low-dose ticlopidine.[4] For reports of rhabdomyolysis occurring in patients stabilised on ciclosporin and a statin when *clopidogrel* was added to their treatment, see p.1250.

4. Boissonnat P, *et al.* A drug interaction study between ticlopidine and cyclosporin in heart transplant recipients. *Eur J Clin Pharmacol* 1997; **53:** 39–45.

BETA BLOCKERS. Ciclosporin plasma concentrations increased when *carvedilol* was added to treatment regimens of renal[1] and cardiac[2] transplant patients. Considerable interindividual variation was seen in one study,[1] so it is recommended that ciclosporin concentrations should be monitored carefully if the drugs are used together.

1. Kaijser M, *et al.* Elevation of cyclosporin A blood levels during carvedilol treatment in renal transplant patients. *Clin Transplant* 1997; **11:** 577–81.
2. Bader FM, *et al.* The effect of β-blocker use on cyclosporine level in cardiac transplant recipients. *J Heart Lung Transplant* 2005; **24:** 2144–7.

BOSENTAN. There is a complex interaction between ciclosporin and bosentan. If the drugs are given together reduced ciclosporin concentrations and increased bosentan concentrations may occur; further details are given on p.1235.

CALCIUM-CHANNEL BLOCKERS. The calcium-channel blockers *diltiazem*,[1-3] *lercanidipine*, *nicardipine*,[4,5] and *verapamil*[6,7] have all been associated with increases in ciclosporin blood concentrations. It has been suggested that such an interaction can be used to obtain effective ciclosporin concentrations with lower doses.[8] In addition, there is some evidence of mitigation of ciclosporin-induced nephrotoxicity when calcium-channel blockers are given (see Effects on the Kidneys, above), and they are useful for ciclosporin-induced hypertension (see Effects on the Cardiovascular System, above). However, some caution is required: one report has pointed out that diltiazem does not increase ciclosporin concentrations in all cases,[9] while others have found that use together alters the pattern of ciclosporin metabolites, and that pharmacokinetic changes are greater in female than in male patients.[10] Therefore, some prefer a calcium-channel blocker that does not alter ciclosporin pharmacokinetics for hypertension and renal protection. *Nifedipine* has not been shown to increase blood-ciclosporin concentrations.[6] For a report of increased nifedipine toxicity with ciclosporin see Immunosuppressants, p.1353. Other calcium-channel blockers that do not appear to affect ciclosporin pharmacokinetics include *felodipine*[7,11] and *isradipine*.[7,12] Ciclosporin concentrations have been reported to increase or to remain unchanged with *amlodipine*.[13] Use of amlodipine or nifedipine with ciclosporin may exacerbate the problem of gingival hyperplasia—see Hyperplasia under Adverse Effects, above.

CARDIAC GLYCOSIDES. For reference to the effect of ciclosporin on serum-digoxin concentrations, see under Digoxin, p.1262.

CLONIDINE. Addition of clonidine to the regimen of a 3-year-old child who had developed hypertension after a renal transplant resulted in a marked increase in whole blood ciclosporin concentrations, despite a reduction in ciclosporin dose.[1] Ciclosporin concentrations fell rapidly on withdrawal of clonidine.

1. Gilbert RD, *et al.* Interaction between clonidine and cyclosporine A. *Nephron* 1995; **71:** 105.

DIURETICS. Enhanced nephrotoxicity, without apparent change in ciclosporin blood concentrations, has been seen in individual patients after addition of *metolazone*[1] or *amiloride* with *chlorothiazide*[2] to their regimen. Severe nephrotoxicity, resulting in loss of graft function, has been seen in a renal transplant patient given *mannitol* with ciclosporin;[3] graft function recovered on withdrawal of the diuretic.

LIPID REGULATING DRUGS. A study in 10 renal transplant recipients indicated that use of ciclosporin with *probucol* markedly reduced the whole blood and plasma concentrations of the former in 9 of them, compared with use of ciclosporin alone.[1] *Bezafibrate* has been reported to increase blood concentrations of ciclosporin, with resultant nephrotoxicity.[2] However, other studies with bezafibrate have found a small decrease in ciclosporin concentrations,[3] or no effect,[4,5] despite an increase in serum creatinine in each study. Conflicting effects have also been reported with other fibrates: decreased[6] and unchanged[7] ciclosporin concentrations have occurred with *fenofibrate*, and both a decrease[8] and lack of effect[9] have also occurred with *gemfibrozil*.

In 1 study, *simvastatin* increased the unbound fraction of ciclosporin in the blood, resulting in a modest increase in apparent ciclosporin clearance.[10] In renal transplant recipients, *atorvastatin* increased ciclosporin blood concentrations in 4 out of 10 patients in one study[11] but was deemed to have minimal clinical effect in others.[12,13] Ciclosporin concentrations were unaffected by *cerivastatin*,[11,14] *fluvastatin*,[15] *lovastatin*,[16] and *pravastatin*.[16,17] A literature review concluded that the statins do not interact with ciclosporin to a clinically relevant degree. However, given the narrow therapeutic range of ciclosporin, the increase in systemic exposure to statins, and reports of rhabdomyolysis when used together, the authors advise that ciclosporin levels be monitored when starting statin therapy, and that lower doses of statins be used.[18] For the effects of ciclosporin on plasma levels of statins and reports of rhabdomyolysis, see Immunosuppressants, under Interactions of Simvastatin, p.1393.

Colchicine. Use of ciclosporin with colchicine may result in myopathy or rhabdomyolysis—see Effects on Skeletal Muscle, under Adverse Effects, above. For reports of adverse effects and increased serum-ciclosporin concentrations when given with colchicine, see also p.556.

Corticosteroids. It has been suggested that use of ciclosporin with corticosteroids increases plasma concentrations of both drugs, but not all studies support this—see Immunosuppressants, p.1495.

Gastrointestinal drugs. Giving *cisapride*[1] or *metoclopramide*[2] to renal transplant recipients receiving ciclosporin has been reported to increase peak ciclosporin concentrations and increase the speed of absorption. *Cimetidine*,[3,4] *ranitidine*,[3] or *famotidine*,[4] do not appear to affect ciclosporin pharmacokinetics. A literature review[5] noted that although there are reports of cimetidine influencing peak concentrations of ciclosporin, there is no support for a pharmacokinetic interaction. A pharmacodynamic interaction between ciclosporin and histamine H_2-receptor antagonists, resulting in a potentiation of nephrotoxicity, is also unlikely.

Grapefruit juice. Grapefruit juice increases the bioavailability of oral ciclosporin,[1-4] including the microemulsion formulation,[5] leading to marked increases in blood-ciclosporin concentrations; intravenous ciclosporin is unaffected. The effect appears to be due to inhibition of cytochrome P450 enzymes in the gut wall by substances present in grapefruit juice,[3] resulting in transiently reduced ciclosporin metabolism. Although it has been suggested that the effect might be used similarly to that of calcium-channel blockers or ketoconazole in reducing the required dose of ciclosporin,[2] others have pointed out that grapefruit juice is not standardised and its effects are variable.[6]

Pomelo juice has also reportedly increased ciclosporin bioavailability; pomelo is a citrus fruit closely related to grapefruit.[7]

Hypoglycaemic drugs. Use of *glibenclamide* with ciclosporin in 6 patients was associated with a mean 57% increase in the steady-state plasma concentration of ciclosporin, suggesting that dosage adjustment may be necessary when both drugs are given.[1]

Troglitazone decreased ciclosporin-blood concentrations by 32%, necessitating an increase in ciclosporin dosage.[2]

For the effect of ciclosporin on *repaglinide*, see under Interactions of Repaglinide, p.458.

2. Burgess SJ, *et al.* Effect of troglitazone on cyclosporine whole blood levels. *Transplantation* 1998; **66:** 272–3.

Immunosuppressants. There has been a report of altered ciclosporin requirements in paediatric renal graft patients treated with *basiliximab*,[1] but others have failed to note such an effect,[2] and whether an interaction exists is unclear.

Treatment of acute rejection of kidney grafts in 10 patients using *muromonab-CD3* resulted in increases in mean trough ciclosporin concentrations, despite a reduction in ciclosporin dosage.[3] Once muromonab-CD3 was withdrawn the dosage of ciclosporin had to be increased again to provide adequate concentrations. In a retrospective study[4] of renal transplant recipients given ciclosporin and either muromonab-CD3 or antilymphocyte immunoglobulin, ciclosporin trough concentrations were found to be raised on day 5 postoperatively in the patients receiving muromonab-CD3. Although no differences were found in trough concentrations on days 7 and 10, the doses of ciclosporin had by then been adjusted based on the levels obtained on day 5.

For the effects of ciclosporin on the pharmacokinetics of *everolimus*, *mycophenolate mofetil*, and *sirolimus*, see p.1834, p.1837, and p.1841 respectively.

Tacrolimus inhibits ciclosporin metabolism *in vitro*[5] but did not alter the pharmacokinetics of intravenous ciclosporin in 7 liver transplant patients.[6] However, there is a possibility of increased nephrotoxicity when the drugs are used together, so licensed product information contraindicates such use.

Methoxsalen. In a pharmacokinetic study, a single oral dose of methoxsalen significantly increased the oral bioavailability of ciclosporin.[1]

1. Rheeders M, *et al.* Drug-drug interaction after single oral doses of the furanocoumarin methoxsalen and cyclosporine. *J Clin Pharmacol* 2006; **46:** 768–75.

Methylphenidate. Methylphenidate led to an increase in ciclosporin concentrations in a 10-year-old African American boy, necessitating reduction of the ciclosporin dose.[1] The patient had previously had to stop bupropion because of decreased ciclosporin concentrations.

1. Lewis BR, *et al.* Pharmacokinetic interactions between cyclosporine and bupropion or methylphenidate. *J Child Adolesc Psychopharmacol* 2001; **11:** 193–8.

NSAIDs. Raised serum-ciclosporin trough concentrations, together with small increases in serum creatinine and BUN concentrations, followed the use of *sulindac* in a previously-stabilised renal graft recipient taking an immunosuppressive regimen including ciclosporin.[1] Increased renal impairment was seen when sulindac or *naproxen* were added to ciclosporin therapy in patients with rheumatoid arthritis.[2] Nephrotoxicity, in the absence of significantly raised blood-ciclosporin concentrations, has been reported in other patients given *diclofenac* with ciclosporin.[3] Ciclosporin may also increase plasma-diclofenac concentrations, see p.45. In general, because of the known potential of NSAIDs to adversely affect renal function, careful monitoring of renal function is advised if these drugs are added to ciclosporin therapy or their dosages altered.

3. Branthwaite JP, Nicholls A. Cyclosporin and diclofenac interaction in rheumatoid arthritis. *Lancet* 1991; **337:** 252.

Octreotide. A marked reduction in ciclosporin serum concentrations was seen in 10 diabetic patients with pancreatic transplants when octreotide was also given;[1] it was suggested that if these 2 drugs are used together the oral dosage of ciclosporin needs to be increased on average by 50%.

1. Landgraf R, *et al.* Effect of somatostatin analogue (SMS 201-995) on cyclosporine levels. *Transplantation* 1987; **44:** 724–5.

Quercetin. In a small study in healthy males, pre-treatment with the flavonoid quercetin significantly increased the peak concentration and bioavailability of ciclosporin.[1]

1. Choi JS, *et al.* Effect of quercetin on the pharmacokinetics of oral cyclosporine. *Am J Health-Syst Pharm* 2004; **61:** 2406–9.

Retinoids. After a report of increased whole-blood ciclosporin concentrations and nephrotoxicity in a patient given *etretinate* with ciclosporin, *in-vitro* results indicated that etretinate inhibited hepatic microsomal metabolism of ciclosporin, as did *acitretin* and *isotretinoin*.[1] However, a study failed to find evidence of such an interaction *in vitro*.[2]

Sex hormones. Raised ciclosporin concentrations in blood have been seen when therapy with *danazol*,[1] *methyltestosterone*,[2] or *norethisterone*[1] was given with ciclosporin, and clinical evidence of both nephrotoxicity[1,2] and hepatotoxicity[2] has been seen. Severe hepatotoxicity and raised plasma-ciclosporin trough values also resulted when an oral contraceptive containing *levonorgestrel* and *ethinylestradiol* was taken by a woman receiving ciclosporin;[3] she had taken the same contraceptive before beginning ciclosporin without ill-effects.

Ursodeoxycholic acid. In a heart transplant patient with short bowel syndrome, ursodeoxycholic acid increased the trough concentrations of ciclosporin by enhancing its absorption.[1] In an attempt to determine whether this interaction would aid the attainment of therapeutic ciclosporin concentrations after heart transplantation, a patient with a jejunoileal bypass was given ciclosporin both with and without ursodeoxycholic acid; no difference was noted in the bioavailability of ciclosporin.[2] Small studies in liver transplant recipients found no alteration in ciclosporin pharmacokinetics when given single doses of ursodeoxycholic acid,[3] nor any difference in ciclosporin requirements between patients given ursodeoxycholic acid and those given placebo.[4] Another study in 12 liver transplant patients, 6 of whom had cholestatic liver dysfunction, found that ursodeoxycholic acid increased the rate of absorption of ciclosporin, but that peak concentrations and bioavailability did not change significantly.[5] In a study using microemulsifying ciclosporin in liver transplant recipients, ursodeoxycholic acid reduced the absorption rate and bioavailability of ciclosporin in 9 patients without cholestasis, but increased absorption rate and bioavailability in 3 cholestatic patients.[6] UK licensed product information for the microemulsifying formulation states that ursodeoxycholic acid increases ciclosporin concentrations.

Vaccines. Efficacy of immunoprophylaxis may be expected to be reduced during ciclosporin therapy, and use of live virus vaccines, in particular, is contra-indicated in immunocompromised patients;[1] there has also been concern that vaccine antigens given during ciclosporin therapy might induce tolerance and result in increased rather than decreased susceptibility to diseases.

Vitamins. For reference to increased absorption of ciclosporin when given with a water-soluble macrogol derivative of *vitamin E*, see Absorption, under Pharmacokinetics, below.

Pharmacokinetics

The pharmacokinetics of ciclosporin are variable and difficult to determine. Results vary depending on the assay used, and values obtained by different methods are not strictly comparable.

Absorption of conventional formulations of ciclosporin from the gastrointestinal tract is variable and incomplete. An oral microemulsifying formulation with improved absorption characteristics is available and is more rapidly and completely absorbed, with peak concentrations achieved about 1.5 to 2 hours after a dose.

Ciclosporin is widely distributed throughout the body. Distribution in the blood is concentration-dependent, with between 41 and 58% in erythrocytes and 10 to 20% in leucocytes; the remainder is found in plasma, about 90% protein-bound, mostly to lipoprotein. Because of distribution into blood cells whole blood concentrations are higher than, and not comparable with, plasma concentrations; where peak plasma concentrations are reported to be about 1 nanogram/mL (by specific HPLC assay) for each mg of oral ciclosporin, whole blood concentrations for each mg range from about 1.4 to 2.7 nanograms/mL. Ciclosporin is reported to cross the placenta, and to be distributed into breast milk.

Clearance from the blood is biphasic. The terminal elimination half-life of an oral dose is reported to range from about 5 to 20 hours; clearance in children is more rapid.

Ciclosporin is extensively metabolised in the liver and primarily excreted in faeces via the bile. About 6% of a dose is reported to be excreted in urine, less than 0.1% unchanged.

Absorption. Ingestion of conventional *oral* formulations of ciclosporin with food may increase its bioavailability, although the effect only appears to be significant when the meal is high in fat;[1] ingestion with food and added bile acids may also increase absorption moderately.[2] A micelle-forming macrogol derivative of vitamin E (tocofersolan) has also been reported to markedly increase ciclosporin absorption.[3,4]

Because of the problems of variable oral absorption, an oral microemulsifying formulation has been developed that offers greatly improved and more predictable bioavailability,[5-8] particularly in liver transplant patients with impaired bile flow.[5] It should be noted that the formulation of this product in fact includes a vitamin E compound.

However, a study[9] has suggested that contrary to previous assumptions, conventional formulations of ciclosporin are quite well absorbed, and that the low bioavailability is due to extensive cytochrome-mediated metabolism in the gut wall (see also Metabolism, below). If this were the case, the improved bioavailability seen with the microemulsifying formulation is presumably less to do with improved absorption than with protection from such metabolism.

Very little drug is absorbed after application to the *eye*; ciclosporin accumulates on the ocular surface and cornea, achieving concentrations considered suitable for local immunomodulation. Corneal concentrations are affected by the choice of vehicle, but intra-ocular penetration is low. Little or no ocular metabolism is considered to occur in humans.[10]

Distribution. The distribution characteristics of ciclosporin are clinically important; binding in blood and plasma is of importance in determining immunosuppressive activity after organ transplantation.[1] The unbound concentration of ciclosporin may have a closer association with both renal and cardiac allograft rejection than the total (bound plus unbound) concentration.

Ethnicity and sex. Gender-dependent racial differences in the pharmacokinetics of ciclosporin have been suggested.[1] African American women showed larger clearances of intravenous and oral ciclosporin (microemulsifying formulation) than African American men, and white women. There were no significant differences in clearance between men of different ethnic origin, or between white men and women. Overall bioavailability was also lower in African Americans compared with white subjects. However, other studies[2,3] found no differences in relative bioavailability between races.

Differences in hepatic cytochrome P450 isoenzyme CYP3A and intestinal P-glycoprotein activity may account for interindividual variability in ciclosporin disposition, and it has been speculated that polymorphic CYP3A5 expression might contribute to interracial differences.[4] However, most studies[5,6] have found little or no association between CYP3A4 or CYP3A5 genotype and ciclosporin pharmacokinetics, although one study found that patients with a CYP3A4 variant allele had a small but significantly higher oral clearance of ciclosporin.[7] However, black and Asian transplant recipients were found to have a reduced oral clearance in this study, independent of their CYP3A genotype, and in apparent contradiction to the literature. The authors commented that most of the studies had been conducted with the older oil-based products, and use of the microemulsifying formulation had not been associated with significant differences in ciclosporin pharmacokinetics between ethnic groups.[7] Genotyping of transplant recipients was considered unlikely to be of use in optimising ciclosporin dosage in clinical practice.[6,7]

Metabolism. *In vitro*[1] and *in vivo*[2-4] evidence indicates that the low oral bioavailability of ciclosporin is due to first-pass metabolism in the gastrointestinal tract rather than the liver.

Therapeutic drug monitoring. Considerable debate has attended the necessity for therapeutic monitoring of ciclosporin concentrations and also on the questions of which assay methods to use and whether to measure drug concentrations in whole blood or plasma.

Before the introduction of specific monoclonal radio-immunoassay the high performance liquid chromatography (HPLC) assay for ciclosporin had the advantage of being specific for the parent compound, and some suggested it to be the method of choice.[1,2] However, it is a more complex procedure, is not universally available, and is slower to perform than radio-immunoassay.[1,3-5] Specific monoclonal radio-immunoassays are now widely available; a comparative study of specific and non-specific radio-immunoassays, HPLC, and polyclonal fluorescence polarisation immunoassay (FPIA) found that the specific assays, used on whole blood samples, gave the best correlation with clinical events.[6]

Because the distribution of ciclosporin between blood cells and plasma is temperature-dependent,[7] plasma concentrations may be twice as high at 37° as at 21°. The temperature at which samples are stored and processed may therefore considerably influence results. In consequence, measurement of drug concentrations in whole blood is to be preferred.[1,3,4,8] However, many, particularly early, clinical studies have given plasma or serum concentrations, which makes comparison of literature data difficult. This problem is compounded by a considerable degree of variation between laboratories,[9,10] even when the same technique is used,[10] and by circadian variations in ciclosporin metabolism which mean that samples should be taken at the same time of day.[11] Since ciclosporin concentrations appear to be generally higher in the morning than the evening, some have suggested that the morning might be the best time for therapeutic drug monitoring.[12]

Because of the variability in results caused by difficulties in monitoring it has proved difficult to determine precisely the ciclosporin concentrations associated with therapeutic benefit and toxicity,[1,3-5] and it has been suggested that measurement of the therapeutic concentrations is unnecessary (provided the patient's clinical condition and renal function are monitored) when low-dose ciclosporin is being given (for example, in psoriasis).[13] However, others consider that it is always critical that ciclosporin blood trough concentrations are regularly measured,[14] in addition to other monitoring. A study in paediatric haematopoietic stem cell transplant recipients found a significant relationship between ciclosporin blood trough concentrations and the severity of acute graft-versus-host disease (GVHD); with lower trough concentrations, GVHD was more severe during the early post-transplantation period.[15] It has been suggested[16] that trough ciclosporin concentrations (C_0), measured by a specific method in whole blood, should not be less than 150 nanograms/mL during the first month after renal transplantation, although lower concentrations are subsequently acceptable; trough concentrations of 250 to 300 nanograms/mL are recommended in the 3 months after liver transplantation.

Other methods of monitoring ciclosporin therapy include monitoring the area under the concentration-time curve (AUC), limited sampling strategies, and Bayesian forecasting.[14,17-21] However, these methods also have limitations, often requiring several samples at inconvenient times for the patient, and can involve complex calculations.

Maximum calcineurin inhibition occurs in the first 1 to 2 hours after ciclosporin dosing, and it was hypothesised that AUC in the first 4 hours after a dose, or the blood concentration at 2 hours after a dose (C_2) might better predict immunosuppressive efficacy than trough concentrations (C_0) or AUC over 12 hours.[22] A large study[23] in liver transplant recipients found that measuring C_2 was superior to C_0 monitoring, resulting in a reduction of the incidence and severity of rejection. It was pointed out that these results could not necessarily be extrapolated to different transplant groups and that analysis when sampling high ciclosporin concentrations needed to be extremely accurate.[24] Data from lung transplant recipients found measurements of C_0 but not C_2 or C_6 to be associated with the risk of acute lung allograft rejection.[25] However, there was some suggestion that C_2 predicted rejection better than C_0 in renal[26] and heart[27] transplant recipients also. In paediatric renal transplant recipients,[22] C_2 monitoring was found to be a better predictor of ciclosporin exposure during the absorption phase than C_0.

An international consensus group considered C_2 to be the best time-point predictor of exposure to ciclosporin during the first 4 hours postdose.[28] This was based on data from studies in adult renal, liver, heart, and lung transplant recipients, as well as in paediatric renal and liver transplant patients; patients had received microemulsifying ciclosporin. C_2 monitoring was also able to identify high, intermediate, or low absorbers of ciclosporin. Additional monitoring beyond the C_2 time point was considered necessary in low absorbers to identify true low absorbers from slow absorbers. Target C_2 concentrations at various times post-transplantation were recommended for adult renal and liver transplant patients receiving ciclosporin microemulsion.

For adult renal transplant recipients:

- 1 month post-transplant: C_2 1.5 to 2 micrograms/mL (this should be achieved by days 3 to 5 after transplantation to maximise clinical benefit);
- 2 months post-transplant: C_2 1.5 micrograms/mL;
- 3 months post-transplant: C_2 1.3 micrograms/mL;
- 4 to 6 months post-transplant: C_2 1.1 micrograms/mL;
- 7 to 12 months post-transplant: C_2 0.9 micrograms/mL;
- 12 months post-transplant or more: C_2 0.8 micrograms/mL

For adult liver transplant recipients:

- 0 to 6 months post-transplant: C_2 1 micrograms/mL (initially achieved by days 3 to 5 after transplantation to maximise clinical benefit);
- 6 to 12 months post-transplant: C_2 0.8 micrograms/mL;
- more than 12 months post-transplant: C_2 0.6 micrograms/mL

Data on long-term clinical benefit of monitoring in terms of rejection prophylaxis and overall safety profile were lacking, and target levels were not established for other transplant groups. A 15-minute 'window of opportunity' before and after the 2-hour time point was considered to provide an acceptable (10%) margin of error, during which time the C_2 sample could be taken.[28] Findings from a 3-year prospective study of C_2 monitoring in stable renal transplant recipients suggested that this method offered clinical benefits in terms of control of hypertension and dyslipidaemia, and protection against chronic renal allograft dysfunction.[29] Australasian guidelines[30] stated that definitive target ciclosporin C_2 concentrations in various organ types or times post-transplant remained to be finalised, and that further evidence supporting C_2 monitoring was needed before C_0 monitoring could be definitively replaced. They recommended that samples clearly indicate which sampling time had been used, that concentrations be preferably reported in units of micrograms/litre, and that each report state the assay method used for analysis. Monitoring practices based on one formulation should not be applied to another formulation unless there was clear evidence of bioequivalence in patients. A subsequent study of C_2 monitoring in heart transplant patients[31] found that higher C_2 concentrations were associated with less episodes of acute cellular rejection. However, in renal transplant patients,[32,33] C_2 concentrations did not predict rejection. A multicentred, retrospective French study[34] determined that, in renal transplant patients monitored on C_0, most patients had C_2 concentrations below the target ranges recommended by the international consensus group; the authors suggested that lower C_2 ranges might be targeted in the early- and long-term post-transplantation periods for those given interleukin-2 receptor antibodies, and that optimal therapeutic windows for ciclosporin monitoring based on C_2 needed more definition. A review of limited sampling strategies in liver transplant patients[35] concluded that, while C_2 monitoring might be better than C_0 monitoring to improve acute rejection rate in the early post-transplantation period, the evidence was not strong, and that further well-designed studies were needed. A review of ciclosporin monitoring after allogeneic stem cell transplantation[36] acknowledged that C_2 monitoring might be preferable to trough concentration monitoring in these patients, but also stated that optimal strategies remained to be defined and that randomised studies were needed.

There has been concern that differences in blood ciclosporin results from various assay systems would necessitate assay-specific target ranges for monitoring. Most transplant centres have developed target ciclosporin ranges that reflect the methodology in use. A study[37] of 5 different assay methods, including radio-immunoassay, HPLC, and FPIA, found that when measuring C_0, this would indeed be the case, but that with C_2 monitoring, differences in the results from the various assay methods were not statistically significant, and were unlikely to be of clinical significance. Different proportions of parent ciclosporin and metabolites were thought to be the reason for this disparity at the two time points. The authors considered that a single target therapeutic range could be adopted when monitoring C_2 concentrations, regardless of the assay method used.

Uses and Administration

Ciclosporin is a powerful immunosuppressant that appears to act specifically on lymphocytes, mainly helper T-cells. It forms a complex with the receptor protein cyclophilin; this complex binds to and inhibits the activation of calcineurin, an important step in the production of lymphokines, including interleukin-2, and results in a depression of cell-mediated immune response. Unlike cytotoxic immunosuppressants such as cyclophosphamide it has little effect on bone marrow.

Ciclosporin is used, usually with corticosteroids (and often with other immunosuppressants), in organ and tissue transplantation for the prophylaxis of graft rejection, or in the management of graft rejection in patients previously treated with other immunosuppressants. It is also used in severe forms of atopic dermatitis, psoriasis, or rheumatoid arthritis, usually when conventional therapy is ineffective or inappropriate, and is used in nephrotic syndrome.

Ciclosporin has been tried in other diseases considered to have an auto-immune component, as indicated by the cross-references given below; they include aplastic anaemia, asthma, Behçet's syndrome, chronic active hepatitis, multiple sclerosis, myasthenia gravis, sarcoidosis, scleritis or uveitis, scleroderma, and various skin disorders.

Ciclosporin is given orally as liquid-filled capsules or as an oily solution, which may be diluted with milk or fruit juice (not grapefruit) immediately before use to improve palatability. Microemulsifying formulations with improved bioavailability are available in a number of countries. When changing between preparations, the initial dose of the new formulation should be the same (mg for mg), and should subsequently be adjusted as necessary based on blood-ciclosporin concentrations, serum creatinine, and blood pressure monitoring. The daily dose of ciclosporin is taken in 2 divided doses, although the conventional formulation is sometimes given as a single daily dose.

In **organ transplantation** the usual initial oral dose of ciclosporin is 10 to 15 mg/kg daily, beginning 4 to 12 hours before transplantation, and continued for 1 to 2 weeks; lower initial doses may be given with other immunosuppressants (e.g. with corticosteroids or as part of 'triple' or 'quadruple' therapy). Dosage may subsequently be reduced gradually to a daily maintenance dose of 2 to 6 mg/kg.

Kidney function and blood pressure should be monitored regularly, as well as blood concentrations of ciclosporin (see Therapeutic Drug Monitoring, above), and dosage should be adjusted as necessary. Hepatic function should also be monitored.

Ciclosporin may also be given intravenously, at one-third of the oral dose, in patients in whom oral dosage is not feasible. It is given by slow intravenous infusion over 2 to 6 hours, the 5% concentrate being diluted 1:20 to 1:100 in sodium chloride 0.9% or glucose 5%, to give a 0.05 to 0.25% solution of ciclosporin. Because of the risk of anaphylactoid reactions, which have been attributed to the polyoxyl castor oil vehicle, patients should be transferred to oral therapy as soon as possible.

For the prevention of graft rejection in **bone marrow transplantation**, and prevention and treatment of graft-versus-host disease, an initial dose of 3 to 5 mg/kg daily by the intravenous route is recommended, starting the day before transplantation and continuing for up to 2 weeks until maintenance by mouth, in doses of 12.5 mg/kg daily can be instituted. If oral treatment is used to begin therapy the recommended dose is 12.5 to 15 mg/kg daily followed by 12.5 mg/kg daily for maintenance. The maintenance dose is continued for at least 3 to 6 months, then gradually reduced until ciclosporin is withdrawn altogether; this may take up to a year after transplantation.

Ciclosporin given by inhalation is under investigation for the prevention and treatment of graft rejection after lung transplantation in some countries.

A silicone matrix ocular implant that provides sustained release of ciclosporin (LX-201) is under investigation for the prevention of rejection in corneal transplantation.

In the treatment of **psoriasis**, ciclosporin may be given in usual initial oral doses of 2.5 mg/kg daily (a maximum of 5 mg/kg daily is recommended in the UK and 4 mg/kg daily in the USA), in 2 divided doses, reduced once remission is achieved to the lowest effective maintenance dose. Treatment should be stopped if there is insufficient response to the maximum dose within 6 weeks. A similar dosage range may be given for a maximum of 8 weeks in the treatment of severe **atopic dermatitis**.

In **rheumatoid arthritis** oral ciclosporin may be given in initial daily doses of 2.5 mg/kg, divided into two doses, for a period of 6 or 8 weeks. If the clinical effect is insufficient dosage may then be gradually increased to a maximum of 4 mg/kg daily; if there is no response after 3 to 4 months, treatment should be stopped.

For **nephrotic syndrome** secondary to glomerular kidney disease (minimal change nephropathy, focal glomerulosclerosis, or membranous nephropathy) dosage of ciclosporin depends on age and renal function. To induce remission in patients with normal renal function 5 mg/kg daily may be given to adults, in 2 divided doses orally. In patients with renal impairment the initial dose should not exceed 2.5 mg/kg daily. Treatment may be stopped if there is no response after 3 months (or 6 months in patients with membranous nephropathy). In patients who do respond, maintenance doses should be gradually reduced to the minimum effective value.

For doses in children, see Administration in Children, below.

Eye drops containing ciclosporin 0.05% are used in the management of **dry eye** associated with ocular inflammation. A topical emulsion of ciclosporin is under investigation for the treatment of vernal keratoconjunctivitis, a severe form of chronic allergic conjunctivitis.

Ciclosporin can inhibit the P-glycoprotein cellular pump responsible for multidrug resistance, and has been given with antineoplastics to raise their intracellular concentrations. Nonimmunosuppressive ciclosporin analogues such as valspodar (p.2410) are also being investigated for their ability to reverse multidrug resistance.

Administration. It has been suggested that calculating doses in mg/kg may not be the best way to achieve the desired blood concentrations of ciclosporin.[1] (See also Therapeutic Drug Monitoring, above) Retrospective study of 1071 renal transplant recipients indicated that blood ciclosporin concentrations were not significantly correlated with patient weight, the best prediction of trough blood concentration being given by the formula:

$$\text{Blood concentration (nanograms/mL)} = \text{dose in mg/day} \times (1.34 + 0.00011 \times \text{days after transplant} - 0.0049 \times \text{height in cm})$$

This formula appeared useful in predicting blood concentrations in prospective studies; from the seventh day after transplantation target trough concentrations could be expected to be about 0.3 times the daily ciclosporin dose in mg.

1. Bock HA, *et al.* Weight-independent dosing of cyclosporine—an alternative to the mg/kg doctrine. *Transplantation* 1994; **57:** 1484–9.

INHALATION. Aerosolised ciclosporin given by inhalation has proved effective[1,2] in the management of acute graft rejection in lung transplantation (p.1815). Doses were up to 300 mg daily via a nebuliser, in either propylene glycol or ethanol solvents.[3] Pulmonary delivery of ciclosporin has been reviewed.[3,4] A positive association between deposited aerosolised ciclosporin dose and improvement in lung function was found in 15 subjects treated over 2 years postoperatively.[5] In a case-control study,[6] aerosolised ciclosporin improved survival among lung transplant recipients with bronchiolitis obliterans. In a randomised controlled study, inhaled ciclosporin given prophylactically did not improve the rate of acute rejection, but it did improve chronic rejection-free survival and overall survival.[7]

A dry powder formulation of ciclosporin for inhalation use has been developed in order to overcome problems of local irritation with propylene glycol; feasibility and efficacy studies with this new formulation are needed.[8]

OCULAR. Topical ciclosporin, in strengths ranging from 0.05 to 2% has been shown to be effective[1,2] in the treatment of various ocular surface disorders, particularly dry eye (see below) and atopic keratoconjunctivitis. It has also been used for corneal ulcers, glaucoma (see below), as adjunctive therapy in corneal allograft rejection, and for the ocular manifestations of graft-versus-host disease.

A silicone matrix ocular implant that provides sustained release of ciclosporin (LX-201) is under investigation for the prevention of rejection in corneal transplantation.

ORAL. The microemulsifying formulation of ciclosporin has been reviewed.[1,2] For discussion of the potential problems involved in converting from conventional to microemulsion oral formulations see under Precautions, above.

1. Noble S, Markham A. Cyclosporin: a review of the pharmacokinetic properties, clinical efficacy and tolerability of a microemulsion-based formulation (Neoral). *Drugs* 1995; **50:** 924–41.
2. Dunn CJ, *et al.* Cyclosporin: an updated review of the pharmacokinetic properties, clinical efficacy and tolerability of a microemulsion-based formulation (Neoral) in organ transplantation. *Drugs* 2001; **61:** 1957–2016.

Administration in children. UK licensed product information states that, while experience with ciclosporin in children is limited, **transplant** patients from 3 months of age have received the drug at the same doses recommended for adults (see Uses and Administration, above). However, at doses above the recommended range, children seem to be more susceptible to fluid retention, convulsions, and hypertension. These effects respond to dose reduction.

In contrast, US licensed product information states that, while data in children are lacking, transplant recipients as young as 6 months and 1 year have received the standard formulation and microemulsifying formulation, respectively, with no unusual adverse effects, and that children have generally required and tolerated higher doses of the standard formulation than those used in adults.

The *BNFC* advises to consult local treatment protocols for details of use in organ transplantation.

For the treatment of **psoriasis** and **atopic dermatitis** doses recommended by the *BNFC* for children from 1 month of age are the same as for adults (see Uses and Administration, above).

In the treatment of **nephrotic syndrome** UK licensed product information states that children may be given 6 mg/kg daily by mouth, in 2 divided doses, if renal function is normal. The dose should not exceed 2.5 mg/kg daily in patients with impaired renal function. The *BNFC* specifies use from 1 month of age.

Although ciclosporin is not licensed in the UK for use in **ulcerative colitis**, the *BNFC* recommends the following initial doses in refractory disease in children, which are then adjusted according to ciclosporin blood concentrations and response:

- orally in those aged 2 to 18 years: 2 mg/kg twice daily (maximum 5 mg/kg twice daily)
- by intravenous infusion in those aged 3 to 18 years: 0.5 to 1 mg/kg twice daily

Aplastic anaemia. Ciclosporin, usually combined with antilymphocyte immunoglobulin, is used in patients with aplastic anaemia when bone marrow transplantation is unsuitable (see p.1042).

Asthma. Ciclosporin is being considered as a potential treatment for some cases of refractory asthma (p.1108). A controlled study[1] in patients with chronic severe asthma requiring long-standing oral corticosteroid treatment found that addition of ciclosporin in an initial dose of 5 mg/kg daily to their regimen resulted in significant improvement in lung function and a reduced frequency of disease exacerbation, compared with placebo. The results were interesting because of the improvement in what had been considered 'irreversible' airflow obstruction. A subsequent study[2] from the same centre involving 39 patients with severe corticosteroid-dependent asthma found that low-dose ciclosporin by mouth (an initial dose of 5 mg/kg daily) permitted a reduction in the daily dosage of prednisolone, from a median of 10 to 3.5 mg daily. However, a systematic review[3] considered that, given the adverse effects of ciclosporin, any clinical benefit was debatable.

1. Alexander AG, *et al.* Trial of cyclosporin in corticosteroid-dependent chronic severe asthma. *Lancet* 1992; **339:** 324–8.
2. Lock SH, *et al.* Double-blind, placebo-controlled study of cyclosporin A as a corticosteroid-sparing agent in corticosteroid-dependent asthma. *Am J Respir Crit Care Med* 1996; **153:** 509–14.
3. Evans DJ, *et al.* Cyclosporin as an oral corticosteroid sparing agent in stable asthma. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2000 (accessed 15/01/08).

Behçet's syndrome. Ciclosporin has been tried in Behçet's syndrome, see p.1499.

Cogan's syndrome. Ciclosporin has been used with corticosteroids for severe Cogan's syndrome with large-vessel vasculitis (see p.1502).

Corneal ulcer. Ciclosporin 1% eye drops, with lamellar keratoplasty, proved effective in treating Mooren's ulcer, a possibly auto-immune corneal disease that is difficult to manage and can lead to blindness.[1] Treatment with topical ciclosporin alone may also be useful[2] in patients with sterile corneal ulcers associated with rheumatoid disease.

1. Chen J, *et al.* Mooren's ulcer in China: a study of clinical characteristics and treatment. *Br J Ophthalmol* 2000; **84:** 1244–9.
2. Gottsch JD, Akpek EK. Topical cyclosporin stimulates neovascularization in resolving sterile rheumatoid central corneal ulcers. *Trans Am Ophthalmol Soc* 2000; **98:** 81–90.

Dermatomyositis. Ciclosporin may be of benefit in refractory dermatomyositis, see Polymyositis and Dermatomyositis, below.

Diabetes mellitus. Immunosuppressants have been used in attempts to prolong the so called 'honeymoon period' in recently diagnosed diabetics (p.431). Ciclosporin has apparently produced modest benefits in such a context,[1-3] but its overall value remains to be determined.

1. Bougneres PF, *et al.* Factors associated with early remission of type 1 diabetes in children treated with cyclosporine. *N Engl J Med* 1988; **318:** 663–70.

3. Carel JC, *et al.* Cyclosporine delays but does not prevent clinical onset in glucose intolerant pre-type 1 diabetic children. *J Autoimmun* 1996; **9:** 739–45.

Diffuse parenchymal lung disease. There are reports of benefit from the use of ciclosporin in diffuse parenchymal lung disease (p.1502), although data are too limited to support its use.

Dry eye. Topical ciclosporin has been found to be beneficial[1,2] for keratoconjunctivitis sicca (dry eye—see p.2140). Further studies[3,4] found ciclosporin 0.05% and 0.1% to be the most appropriate formulations since no additional benefit was found with higher concentrations[3] and both were significantly better than placebo.[4]

Topical ciclosporin has also been reported to be beneficial for patients with dry eyes secondary to graft-versus-host disease.[5]

Eczema. Ciclosporin is effective in atopic eczema (atopic dermatitis),[1-3] where it is used as adjunctive therapy (see p.1579). It is generally reserved for short-term treatment (up to 8 weeks) in patients with severe disease unresponsive to all conventional therapies, although reports have described long-term use in adult patients.[4] It has also been suggested[5] that long-term remission is possible, even in those treated with short courses. Ciclosporin has been used for both short courses[6,7] and continuous therapy in children.[8] A systematic review and meta-analysis[9] that incorporated most of these studies concluded that the mean clinical improvement in disease severity after 6 to 8 weeks of ciclosporin treatment is about 55%; however, the true benefit may be somewhat lower due to publication bias. Higher initial doses of 4 to 5 mg/kg led to a more rapid response, and the mean benefit after 2 weeks at this dose was about 40%. In a small, open, crossover study,[10] the microemulsifying form was considered equivalent or superior in tolerability and efficacy when compared with the conventional formulation. Responses have also been reported in severe eczematisation associated with Darier's disease[11] (p.1578).

Glaucoma. Topical ciclosporin has produced some encouraging results[1] when used as an adjunct to reduce formation of scar tissue and improve outcome of glaucoma filtering surgery. It has been suggested[2] that topical ciclosporin 0.5% may be substituted for topical corticosteroids in the treatment of postkeratoplasty glaucoma.

2. Perry HD, *et al.* Topical cyclosporin A in the management of postkeratoplasty glaucoma. *Cornea* 1997; **16:** 284–8.

Glomerular kidney disease. Ciclosporin has been tried in a number of forms of glomerular kidney disease (p.1504) but use has been cautious because of fears about nephrotoxicity. Nonetheless, responses have been seen in patients with corticosteroid-resistant minimal change nephropathy,[1,2] focal glomerulosclerosis,[1-3] and membranous nephropathy.[4-6]

6. Goumenos DS. What have we learned from the use of ciclosporin A in the treatment of nephrotic patients with idiopathic membranous nephropathy? *Expert Opin Pharmacother* 2008; **9:** 1695–1704.

Hepatitis. In chronic active hepatitis (p.1501), some evidence suggests that ciclosporin may offer an alternative therapy in patients with severe auto-immune (non-viral) disease where corticosteroids alone or with azathioprine do not suffice.

Histiocytic syndromes. As mentioned in the discussion on p.650 ciclosporin has been tried in patients with advanced Langerhans-cell histiocytosis.

Inflammatory bowel disease. Ciclosporin has been tried with variable success as a second-line drug in inflammatory bowel disease (p.1697). Intravenous high-dose ciclosporin has shown some efficacy in refractory ulcerative colitis,[1] and a review[2] concluded that intravenous ciclosporin should be offered to selected patients as an alternative to surgery. Treatment should be started at 2 mg/kg daily, as it appears to be as effective as 4 mg/kg daily. A systematic review,[3] which included only 2 studies, concluded that short-term ciclosporin may be used where surgery is the only option, but that this is not based on strong evidence.

Benefit from ciclosporin in Crohn's disease is less clear. A systematic review[4] concluded that low dose (5 mg/kg daily) oral ciclosporin is not effective for induction of remission in Crohn's disease. While some studies suggest that higher oral doses or intravenous ciclosporin might be beneficial, these are not considered to be useful alternatives for long-term management due to the risk of nephrotoxicity and the availability of other proven therapy.

Leprosy. For mention of the use of ciclosporin in the management of type 1 lepra reactions in patients with leprosy, see p.176.

Lichen planus. Lichen planus is a skin disorder generally controlled with corticosteroids (see p.1580), although ciclosporin has also been used. Ciclosporin has been given successfully in relatively low doses (3 to 5 mg/kg by mouth) to produce remission of severe lichen planus,[1] but such therapy may be associated with the development of hypertension and impairment of renal function. Use of topical ciclosporin for oral lichen planus has been tried, but results have been variable.[2-8] One such study failed to note any benefit long-term from either ciclosporin mouthwash or corticosteroid oral paste.[7]

Lupus nephritis. Ciclosporin has been investigated for SLE (p.1513), particularly lupus nephritis. Significant reductions in proteinuria have been reported,[1-6] although controlled studies are needed.

1. Fu LW, *et al.* Clinical efficacy of cyclosporin A Neoral in the treatment of paediatric lupus nephritis with heavy proteinuria. *Br J Rheumatol* 1998; **37:** 217–21.

Multiple sclerosis. As noted on p.892, immunosuppressants, including ciclosporin, have produced modest benefit in patients with multiple sclerosis. However, it has been concluded that the scanty benefits of therapy are outweighed by the toxicity of the doses required.

Muscular dystrophies. A study in 15 boys with Duchenne muscular dystrophy (p.1507) given ciclosporin 5 mg/kg daily by mouth in divided doses, adjusted according to trough serum concentrations of ciclosporin, found that muscular force generation was improved during treatment, but declined again once treatment ceased.[1] The clinical significance, if any, of this effect remains to be established.

1. Sharma KR, *et al.* Cyclosporine increases muscular force generation in Duchenne muscular dystrophy. *Neurology* 1993; **43:** 527–32.

Myasthenia gravis. Ciclosporin may be of use as an alternative to azathioprine in the management of myasthenia gravis (p.629) for its corticosteroid-sparing effect[1] or when patients are intolerant of or unresponsive to corticosteroids and azathioprine.[2-4] It appears to be of similar efficacy to azathioprine[5] with a more rapid effect but serious adverse effects such as nephrotoxicity may limit its use.

Organ and tissue transplantation. Ciclosporin has greatly improved the prospects for successful organ and tissue transplantation, and is a mainstay of regimens used to prevent rejection of solid organ grafts as well as being used for the prevention of graft-versus-host disease in bone marrow transplantation. For more detailed discussion of organ and tissue transplantation and the role of ciclosporin, see p.1810. Ciclosporin has also occasionally been used for corneal graft rejection (p.1502) in high-risk patients, where corticosteroids alone are insufficient. An ocular implant that provides sustained release of ciclosporin (LX-201) is under investigation for the prevention of rejection in corneal transplantation. Inhaled ciclosporin is under investigation in lung transplantation, see p.1815 and under Administration, above.

A few selected references to the use of ciclosporin in transplantation are given below.

Pemphigus. Although pemphigus is usually treated with corticosteroids (see p.1582), ciclosporin has also been tried in a few patients with pemphigus vulgaris, with variable results.[1-3] A small, randomised study[4] found that use of corticosteroids with ciclosporin had no advantage over corticosteroids alone.

Polymyositis and dermatomyositis. Ciclosporin may be of benefit[1] in refractory polymyositis and dermatomyositis (see p.1510).

1. Qushmaq KA, *et al.* Cyclosporin A in the treatment of refractory adult polymyositis/dermatomyositis: population based experience in 6 patients and literature review. *J Rheumatol* 2000; **27:** 2855–9.

Primary biliary cirrhosis. In primary biliary cirrhosis (p.2408) some benefit has been reported with ciclosporin, but there are problems with toxicity. A systematic review[1] concluded that, despite improvements in pruritus and liver biochemical variables, ciclosporin did not delay the progression of the disease, and that its use outside of clinical studies could not be recommended.

1. Gong Y, *et al.* Cyclosporin A for primary biliary cirrhosis. Available in The Cochrane Database of Systematic Reviews; Issue 3. Chichester: John Wiley; 2007 (accessed 15/01/08).

Psoriasis. Ciclosporin is used to induce remission or prevent relapse in severe refractory psoriasis (p.1583). Response to ciclosporin has been reported for virtually all the clinical manifestations of the disease,[1] including pustular psoriasis of pregnancy.[2-4] Benefit has also been reported in children with severe refractory psoriasis,[1,5] although exposure should be limited in view of the potential for cumulative toxicity.

Doses of 2.5 to 5 mg/kg daily given for up to 12 weeks produced marked improvement in the majority of patients with severe plaque psoriasis.[6] This intermittent therapy allows for a lower cumulative dose of ciclosporin and in turn decreases the risk of nephrotoxicity or hypertension.[7] Recommendations have been made in the UK for the use of ciclosporin in the management of psoriasis;[8] for those with severe stable disease, an initial starting dose of 2.5 mg/kg daily is suggested, with dose increases of 0.5 to 1 mg/kg daily made at intervals of 2 to 4 weeks, according to clinical response, and up to a maximum of 5 mg/kg daily. Treatment is given for about 12 weeks, and use of adjunctive topical therapy is recommended. Ciclosporin should be stopped once remission is achieved, and restarted at the previous effective dose if the patient relapses. In acute flares of the disease, ciclosporin may be started at higher doses (maximum 5 mg/kg daily) and titrated down as symptoms improve. The patient's renal function and blood pressure should be monitored before and during treatment. In a minority of patients requiring long-term continuous therapy, the duration of treatment should be limited to a maximum of 2 years, and an annual assessment of the patient's glomerular filtration rate is recommended. In most studies, maintenance doses were less than 3.5 mg/kg daily.

Reviews[1,9] have concluded that patients on short-term ciclosporin therapy for psoriasis do not require routine therapeutic drug monitoring (see above). However, some consider that monitoring of trough concentrations is necessary in those treated with greater than 3 mg/kg daily, or in those at risk of renal impairment.[9] Monitoring may also be useful when compliance is questionable, or drug interactions are suspected.[1]

Rheumatoid arthritis. Various disease-modifying antirheumatic drugs (DMARDs) are used in rheumatoid arthritis (p.11) in an attempt to modify the disease process. Ciclosporin has produced responses in active disease,[1-4] and there is some evidence that it can slow radiological progression of disease[4] as well as providing symptomatic relief; a systematic review[5] has concluded it has an important clinical benefit in the short-term (up to one year) treatment of progressive disease. There has been some concern about associated nephrotoxicity,[1] but the use of low-dose regimens may help to minimise this.

Ciclosporin has also been combined with other DMARDs. Use with methotrexate has reportedly produced responses in patients unresponsive to methotrexate alone,[6] but some investigators found that a combination of methotrexate, ciclosporin and intra-articular corticosteroids was no more effective than standard DMARD therapy.[7] Others consider that ciclosporin monotherapy is of limited benefit, but that combination therapy with methotrexate is one of the best options to control aggressive disease.[8]

International consensus recommendations for the use of ciclosporin in rheumatoid arthritis[9] suggest that it may be considered in patients who are candidates for DMARDs and who do not have risk factors such as malignancy, uncontrolled hypertension, renal dysfunction, cytopenias, or marked disorder of liver function. They recommend a starting dose of between 2.5 and 3 mg/kg daily, increased if necessary after 4 to 8 weeks, in increments of 0.5 or 1 mg/kg at 1 to 2 month intervals, up to a maximum of 5 mg/kg daily, particular care being taken at doses over 4 mg/kg daily. Once the patient's disease has been stable for at least 3 months the daily dose should be decreased monthly or bimonthly in decrements of 0.5 mg/kg to the lowest effective dose. If it is only partially effective after 3 months at the maximum tolerable dose another medication should be considered instead or in addition; if there is no response to the maximum tolerable dose after 3 months, ciclosporin should be stopped. Patients should be carefully monitored before and during therapy.

Ciclosporin has been shown to have a corticosteroid-sparing effect and control the fever of juvenile idiopathic arthritis.[10] In patients with refractory juvenile idiopathic arthritis, adding ciclosporin to methotrexate therapy has been reported to elicit significant clinical improvement.[11]

11. Ravelli A, *et al.* Combination therapy with methotrexate and cyclosporine A in juvenile idiopathic arthritis. *Clin Exp Rheumatol* 2002; **20:** 569–72.

Sarcoidosis. Corticosteroids are the usual therapy for symptomatic sarcoidosis (p.1512), and other agents are very much second-line; ciclosporin is one of a number of immunosuppressants that have been tried with variable results.

Scleritis. Ciclosporin is used alone or with corticosteroids in the treatment of scleritis (see p.1512).

Scleroderma. There are a few reports of responses to ciclosporin in patients with scleroderma (p.1817).

Toxic epidermal necrolysis. Ciclosporin, given either enterally[1] or intravenously,[2] has been reported to be of benefit in toxic epidermal necrolysis.

1. Arévalo JM, *et al.* Treatment of toxic epidermal necrolysis with cyclosporin A. *J Trauma* 2000; **48:** 473–8.
2. Hashim N, *et al.* Early cyclosporine treatment of incipient toxic epidermal necrolysis induced by concomitant use of lamotrigine and sodium valproate. *Acta Derm Venereol* 2004; **84:** 90–1.

Uveitis. Ciclosporin is used in uveitis, see p.1515.

Vasculitic syndromes. For the use of ciclosporin in Takayasu's arteritis and Wegener's granulomatosis, see p.1514 and p.1515, respectively.

Preparations

USP 31: Cyclosporine Capsules; Cyclosporine Injection; Cyclosporine Oral Solution.

Daclizumab *(BAN, USAN, rINN)*

Dacliximab; Daclizumabum; Daklitsumabi; Daklizumab; Humanised Anti-Tac Antibody; Ro-24-7375. Immunoglobulin G 1, (human-mouse monoclonal 1H4 γ-chain, anti-human interleukin 2 receptor), disulfide with human-mouse monoclonal clone 1H4 light chain, dimer.

Даклизумаб

CAS — 152923-56-3.

ATC — L04AC01.

ATC Vet — QL04AC01.

Adverse Effects and Precautions

Severe acute hypersensitivity reactions have occurred rarely with daclizumab. These have included anaphylactoid-type reactions such as rash, urticaria, pruritus, hypotension, hypoxia, tachycardia, cardiac arrest, wheezing, dyspnoea, bronchospasm, pulmonary oedema, peripheral oedema, laryngeal oedema, and respiratory failure. Injection site reactions have also been reported. Reactions have been seen both on initial exposure and with subsequent therapy. Therapy should be permanently stopped if a severe reaction occurs.

Effects on mortality. Increased mortality was reported in cardiac transplant recipients given an immunosuppressive regimen of daclizumab with ciclosporin, mycophenolate mofetil, and corticosteroids. Some deaths were associated with severe infection and use with antilymphocyte immunoglobulins.[1,2]

1. Roche, USA. 2003 safety alert: Zenapax (daclizumab). Available at: http://www.fda.gov/medwatch/SAFETY/2003/zenapax.htm (accessed 15/01/08)
2. Hershberger RE, *et al.* Daclizumab to prevent rejection after cardiac transplantation. *N Engl J Med* 2005; **352:** 2705–13.

Pharmacokinetics

The recommended regimen of daclizumab (see below) should result in serum concentrations sufficient to saturate interleukin-2 receptors for about 90 days post-transplantation in adult patients, and 120 days in paediatric patients. The terminal elimination half-life of daclizumab has ranged from 11 to 38 days.

Uses and Administration

Daclizumab is a humanised monoclonal murine antibody that functions as an interleukin-2 receptor antagonist by binding to the alpha chain (CD25 antigen, Tac subunit) of the interleukin-2 receptor on the surface of activated T-lymphocytes. It is used in the prevention of acute graft rejection after kidney transplantation as part of an immunosuppressive regimen that includes ciclosporin and corticosteroids. It is given in a dose of 1 mg/kg intravenously over 15 minutes within 24 hours before surgery and repeated at intervals of 2 weeks for a total of 5 doses. The required dose is diluted in 50 mL of sodium chloride 0.9%, and may be infused either centrally or peripherally. Daclizumab is also under investigation for its immunosuppressant properties in other forms of transplantation (see below) and in various diseases with an auto-immune component.

Administration in children. The dose for daclizumab in children aged 1 year and over is the same as in adults (see Uses and Administration, above).

Multiple sclerosis. Daclizumab has been tried[1-4] in patients with relapsing-remitting or secondary progressive multiple sclerosis; benefit has been reported.

1. Bielekova B, *et al.* Humanized anti-CD25 (daclizumab) inhibits disease activity in multiple sclerosis patients failing to respond to interferon β. *Proc Natl Acad Sci U S A* 2004; **101:** 8705–8.
2. Rose JW, *et al.* Treatment of multiple sclerosis with an anti-interleukin-2 receptor monoclonal antibody. *Ann Neurol* 2004; **56:** 864–7.

4. Martin R. Humanized anti-CD25 antibody treatment with daclizumab in multiple sclerosis. *Neurodegener Dis* 2008; **5:** 23–6.

Ocular disorders. There have been reports of benefit with daclizumab in ocular inflammatory disorders[1] including scleritis, ocular cicatricial pemphigoid, and uveitis, all of which had been resistant to conventional therapy.

1. Papaliodis GN, *et al.* Treatment of ocular inflammatory disorders with daclizumab. *Ophthalmology* 2003; **110:** 786–9.

Organ and tissue transplantation. Daclizumab is used as induction therapy to reduce the incidence of acute rejection episodes after kidney transplantation (p.1813);[1-4] it is usually given as part of an immunosuppressive regimen that includes a calcineurin inhibitor and corticosteroids.

There are reports of successful corticosteroid withdrawal and corticosteroid-free regimens using daclizumab.[5] An attempt at using daclizumab to avoid use of ciclosporin after renal transplantation was unsuccessful, with a high rate of overall acute rejection in the daclizumab group.[6]

Daclizumab has also been investigated for the prevention of acute rejection after heart,[7] liver,[8,9] and lung[10] transplantation (see p.1812) but increased mortality has followed its use in patients receiving heart grafts[11] (see also under Adverse Effects and Precautions, above).

Daclizumab has also been tried in the management of acute graft-versus-host disease (GVHD; see Haematopoietic Stem Cell Transplantation, p.1811). While some consider it a viable alternative for corticosteroid-refractory acute GVHD,[12] others found that when daclizumab was used with corticosteroids to treat acute GVHD, this combination had a significantly deleterious effect on patient survival.[13]

Controlled studies that directly compare 2 doses of daclizumab with the standard 5-dose regimen in kidney transplantation are lacking; despite this, many centres use a 2-dose regimen.[14] In a small, retrospective analysis[15] of simultaneous kidney-pancreas transplant recipients (p.1816), patients receiving 1 to 3 doses of daclizumab in addition to triple therapy had a significantly higher incidence of rejection than those receiving 4 to 5 doses. There was no difference in patient or graft survival. A larger multicentre study[16,17] found that simultaneous kidney-pancreas recipients given daclizumab 2 mg/kg every 14 days for 2 doses had a similar incidence of rejection to those given the standard 5-dose regimen; mean time to onset of rejection was delayed in the 2-dose regimen but there was no beneficial effect of daclizumab on graft survival at 3 years. A small comparative study[18] in heart transplant recipients found 2 doses of daclizumab to be at least as effective as the 5-dose regimen; no significant differences were observed for mortality. A novel 3-dose regimen has been investigated in liver transplantation.[19]

Everolimus *(USAN, rINN)*

Évérolimus; Everolimús; Everolimusum; NVP-RAD-001; RAD-001; SDZ-RAD; SDZ-RAD-666. (3*S*,6*R*,7*E*,9*R*,10*R*,12*R*,14*S*,15*E*,17*E*,19*E*,21*S*,23*S*,26*R*,27*R*,34a*S*)-9,10,12,13,14,21,22,23,24,25,26,27,32,33,34,34a-Hexadecahydro-9,27-dihydroxy-3-{(1*R*)-2-[(1*S*,3*R*,4*R*)-4-(2-hydroxyethoxy)-3-methoxycyclohexyl]-1-methylethyl}-10,21-dimethoxy-6,8,12,14,20,26-hexamethyl-23,27-epoxy-3*H*-pyrido[2,1-c][1,4]oxaazacyclohentriacontine-1,5,11,28,29(4*H*,6*H*,31*H*)-pentone.

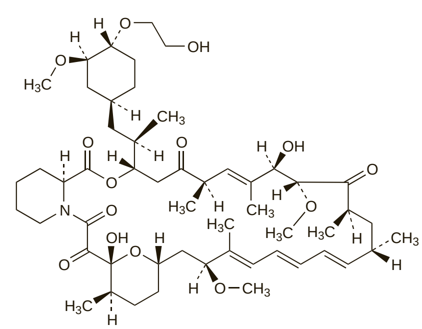
Эверолимус

$C_{53}H_{83}NO_{14}$ = 958.2.

CAS — 159351-69-6.

ATC — L04AA18.

ATC Vet — QL04AA18.



Adverse Effects

Leucopenia, thrombocytopenia, and anaemia occur commonly with everolimus. Haemolysis has been reported rarely. Other common adverse effects include hypercholesterolaemia, hyperlipidaemia, hypertriglyceridaemia, hypertension, lymphocele, venous thromboembolism, and gastrointestinal upsets. Pneumonia, pneumonitis, hepatitis, jaundice, renal tubular necrosis, and pyelonephritis may occur. Acne and oedema occur frequently; rashes and myalgia occur rarely.

Effects on the lungs. Pulmonary toxicity is a well-known adverse effect in patients given sirolimus (p.1841) and similar toxicity has occurred[1] in patients given everolimus.

1. Expósito V, *et al.* Everolimus-related pulmonary toxicity in heart transplant recipients. *J Heart Lung Transplant* 2008; **27:** 797–800.

Interactions

Everolimus is metabolised in the liver and to some extent in the gastrointestinal wall; plasma concentrations may be affected by inducers or competitive inhibitors of P-glycoprotein, or hepatic enzymes, particularly cytochrome P450 isoenzyme CYP3A4. Use with live vaccines should be avoided.

◊ References.

1. Kovarik JM, *et al.* Everolimus drug interactions: application of a classification system for clinical decision making. *Biopharm Drug Dispos* 2006; **27:** 421–6.

Immunosuppressants. The bioavailability of everolimus was significantly increased when given with *ciclosporin*,[1] and dose adjustment of everolimus may be necessary if the ciclosporin dose is altered (see Administration, below).

In contrast, results from a small study implied that *tacrolimus* appeared to have a minimal effect on everolimus blood concentrations, and the dose of everolimus, when used with tacrolimus, may need to be higher than that given with ciclosporin in order to achieve therapeutic everolimus blood concentrations.[2]

1. Kovarik JM, *et al.* Differential influence of two cyclosporine formulations on everolimus pharmacokinetics: a clinically relevant pharmacokinetic interaction. *J Clin Pharmacol* 2002; **42:** 95–9.
2. Kovarik JM, *et al.* Differential pharmacokinetic interaction of tacrolimus and cyclosporine on everolimus. *Transplant Proc* 2006; **38:** 3456–8.

Ketoconazole. In a pharmacokinetic study in 12 healthy subjects,[1] ketoconazole increased the maximum concentration of everolimus by an average of 3.9-fold; area under the concentration-time curve was also increased by about 15-fold. The half-life of everolimus was significantly prolonged, and its clearance reduced. Since ketoconazole inhibits both cytochrome P450 isoenzyme CYP3A4 and P-glycoprotein, the authors supposed that both pathways might have contributed to this interaction. The interaction was deemed to be clinically relevant and they advised against use of these 2 drugs together.

1. Kovarik JM, *et al.* Blood concentrations of everolimus are markedly increased by ketoconazole. *J Clin Pharmacol* 2005; **45:** 514–18.

Rifampicin. In a pharmacokinetic study,[1] rifampicin increased the clearance of everolimus, decreasing exposure to everolimus by about 63%. Licensed product information recommends against the combined use of these drugs.

1. Kovarik JM, *et al.* Effect of rifampin on apparent clearance of everolimus. *Ann Pharmacother* 2002; **36:** 981–5.

Verapamil. Verapamil increased the bioavailability of everolimus; the half-life of everolimus was essentially unchanged. The dose of everolimus should be reduced when these two drugs are given together, but the amount should be determined by blood concentrations and clinical monitoring. Verapamil concentrations may also be affected by everolimus, but the mechanism is unclear; any dose adjustment of verapamil should be guided by blood pressure monitoring.[1]

1. Kovarik JM, *et al.* Pharmacokinetic interaction between verapamil and everolimus in healthy subjects. *Br J Clin Pharmacol* 2005; **60:** 434–7.

Pharmacokinetics

Peak plasma concentrations of everolimus occur about 1 to 2 hours after an oral dose. Plasma protein binding is about 74%. Everolimus is metabolised in the liver and to some extent in the gastrointestinal wall; most metabolites are excreted in the faeces with small amounts found in urine.

2. Kirchner GI, *et al.* Clinical pharmacokinetics of everolimus. *Clin Pharmacokinet* 2004; **43:** 83–95.

Therapeutic drug monitoring. Licensed product information recommends routine monitoring of whole blood everolimus concentrations. Patients with trough levels of 3 nanograms/mL or greater have been found to have a lower incidence of acute rejection in both renal and cardiac transplantation; an upper limit of 8 nanograms/mL is recommended. Monitoring is considered especially important in those with hepatic impairment (see under Uses, below) and if ciclosporin formulation or dosage is changed (see Administration, below).

Uses and Administration

Everolimus is a derivative of sirolimus (p.1841). It is used as a proliferation signal inhibitor in the prevention of graft rejection episodes in patients undergoing renal or cardiac transplantation as part of an immunosuppressive regimen that includes ciclosporin (microemulsifying) and corticosteroids. The recommended adult oral dose is 750 micrograms twice daily, begun as soon as possible after transplantation, and given at the same time as ciclosporin (see Administration, below). Doses of everolimus should be reduced in patients with hepatic impairment, see below.

Everolimus is also under investigation for the treatment of renal cell carcinoma.

Everolimus-releasing stents have been developed to reduce restenosis after coronary artery stent placement.

Administration. Everolimus is given with ciclosporin and corticosteroids. Ciclosporin exposure reduction is recommended 1 month after transplantation. Because ciclosporin interacts with everolimus, and the dose adjustments of ciclosporin will affect exposure to everolimus, licensed product information for everolimus recommends that levels of both drugs be monitored to minimise the risk of graft rejection. Before dose reduction of ciclosporin, everolimus whole blood concentrations should be at least 3 nanograms/mL (see Therapeutic Drug Monitoring, above, and under Ciclosporin, p.1829).

In renal transplantation, ciclosporin doses should be adjusted to the following target ciclosporin concentration ranges, as measured 2 hours after the dose of ciclosporin:

- weeks 0-4: 1000 to 1400 nanograms/mL
- weeks 5-8: 700 to 900 nanograms/mL
- weeks 9-12: 550 to 650 nanograms/mL
- weeks 13-52: 350 to 450 nanograms/mL

In cardiac transplantation, ciclosporin levels are adjusted according to ciclosporin blood trough levels.

Administration in hepatic impairment. The clearance of everolimus was significantly reduced in patients with moderate hepatic impairment.[1] Product information states that the dose should be reduced by 50% in mild to moderate hepatic impairment (Child-Pugh class A or B) with further titration of the dose based on therapeutic drug monitoring (see under Pharmacokinetics, above). Everolimus has not been studied in severe hepatic impairment.

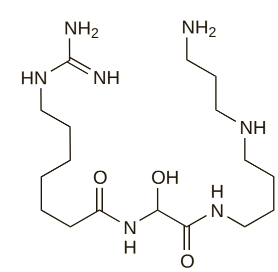
Гусперимуса Гидрохлорид

$C_{17}H_{37}N_7O_3,3HCl = 496.9.$

CAS — 104317-84-2 (gusperimus); 89149-10-0 (gusperimus); 85468-01-5 (gusperimus hydrochloride).

ATC — L04AA19.

ATC Vet — QL04AA19.



(gusperimus)

Profile

Gusperimus is a guanidine derivative that inhibits both cell-mediated and antibody-mediated immunity. It is used in the treatment of renal graft rejection, and has been investigated in the management of graft-versus-host disease and Wegener's granulomatosis. For mention of its role in reversing acute graft rejection in kidney transplantation, see p.1813.

Gusperimus is used as the hydrochloride. A dose of 3 to 5 mg/kg of gusperimus hydrochloride given daily for 7 days, by intravenous infusion over 3 hours, has been suggested in the treatment of acute renal graft rejection. Treatment may be continued for a further 3 days if required.

Adverse effects reported with gusperimus include bone-marrow depression, numbness of face and extremities, headache, gastrointestinal disturbances, alterations in liver enzyme values, and facial flushing. Rapid injection should be avoided as an acute increase in plasma concentration may produce respiratory depression.

Inolimomab *(rINN)*

BT-563; Inolimomabum. Immunoglobulin G1, anti-(human interleukin 2 receptor α-chain) (mouse monoclonal B-B10 γ1-chain), disulfide with mouse monoclonal B-B10 κ-chain, dimer.

Инолимомаб

CAS — 152981-31-2.

Profile

Inolimomab is a murine/human monoclonal antibody similar to daclizumab (p.1833) that acts as an interleukin-2 receptor antagonist at the alpha chain (CD25) of the interleukin-2 receptor on the surface of activated T-lymphocytes. It is under investigation for the treatment of graft-versus-host disease after organ transplantation (p.1810).

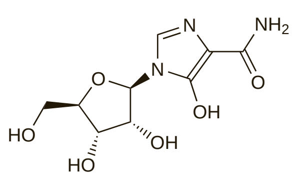
HE-69; Mizoribina; Mizoribinum. 5-Hydroxy-1-β-D-ribofuranosylimidazole-4-carboxamide.

Мизорибин

$C_9H_{13}N_3O_6$ = 259.2.

CAS — 50924-49-7.



Profile

Mizoribine is an oral immunosuppressant that is used for the management of rejection in kidney transplantation, for nephrotic syndrome associated with primary glomerular disease, for lupus nephritis, and for rheumatoid arthritis.

Adverse effects include myelosuppression, hyperuricaemia, gastrointestinal disturbances, and hypersensitivity reactions. Stevens-Johnson syndrome has also been reported.

◊ Although oral doses of mizoribine of 1 to 3 mg/kg daily have been recommended in renal transplantation, higher doses (above 5 mg/kg daily) have been widely used. Similarly, an oral dose of 50 mg three times daily has been recommended for patients with nephrotic syndrome associated with primary glomerular disease or lupus nephritis, and in rheumatoid arthritis, but high-dose regimens have been investigated.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Bredinin.

Muromonab-CD3 *(USAN, rINN)*

Muromonabum-CD3; OKT3.

Муромонаб-CD3

ATC — L04AA02.

ATC Vet — QL04AA02.

Description. A murine monoclonal antibody comprising a purified IgG_{2a} immunoglobulin with a heavy chain having a molecular weight of about 50 000 daltons and a light chain with a molecular weight of about 25 000 daltons.

Pharmacopoeias. In *Chin.*

Adverse Effects, Treatment, and Precautions

An acute cytokine release syndrome occurs in most patients, typically 30 to 60 minutes after the first few doses of muromonab-CD3 (although it may occur later). Frequency and severity tend to decrease with successive doses, while prophylactic corticosteroids may reduce initial adverse reactions (see Uses and Administration, below). The syndrome ranges from a more frequently reported, mild, self-limiting, flu-like illness to a less common, severe, and life-threatening, shock-like reaction, which may include serious cardiovascular and CNS manifestations. Typical clinical manifestations of the cytokine release syndrome include high fever, chills or rigors, headache, tremor, gastrointestinal disturbances, myalgia, and generalised weakness. Rash and pruritus may also occur. Cardiorespiratory findings may include apnoea, dyspnoea, bronchospasm or wheezing, tachypnoea, respiratory arrest or failure, acute respiratory distress syndrome, angina, myocardial infarction, chest pain or tightness, tachycardia, hypertension, hypotension, cardiac failure, pulmonary oedema, hypoxaemia, and arrhythmias. Reversible impairment of renal function may also be associated with the syndrome.

Other reported effects of muromonab-CD3 include encephalopathy, cerebral oedema, and a syndrome resembling aseptic meningitis, with headache, fever, stiff neck, and photophobia; seizures have also occurred. Hypersensitivity reactions, including fatal anaphylaxis, have been reported and may be difficult to distinguish from the cytokine release syndrome.

As with other potent immunosuppressants, treatment with muromonab-CD3 may increase the risk of serious infections and the development of certain malignancies. Intra-uterine devices should be used with caution during immunosuppressive therapy as there is an increased risk of infection. Use of live vaccines should be avoided for the same reason.

Muromonab-CD3 should not be given to patients with uncontrolled hypertension, or in patients hypersensitive to products of murine origin. It should be avoided in patients with a history of seizures. Because fluid overload is associated with an increased risk of pulmonary oedema due to the cytokine release syndrome, muromonab-CD3 is contra-indicated in patients who have undergone a more than 3% weight gain in the week preceding therapy, or who have radiographic evidence of fluid overloading. Repeated courses of muromonab-CD3 may be less effective because of the development of antibodies to the drug. Paediatric patients may be at increased risk of serious adverse effects following muromonab-CD3 therapy.

Effects on the blood. *THROMBOEMBOLISM.* Intragraft thromboses developed in 9 of 93 consecutive kidney transplant recipients given high-dose muromonab-CD3 (10 mg daily) as part of their immunosuppressive regimen.[1] In one patient the thrombosis was in the renal artery, and in 3 in the renal vein; the remainder had thromboses in the glomerular capillaries and thrombotic microangiopathy similar to that of haemolytic-uraemic syndrome. The authors suggested that muromonab-CD3 has procoagulant effects, perhaps mediated by released tumour necrosis factor; these effects had also been seen in 3 patients receiving muromonab-CD3 at conventional doses (5 mg daily). Another group[2] has also reported an apparently increased incidence of acute vascular thrombosis in patients given muromonab-CD3 at conventional doses, but in the experience of others,[3] despite evidence of activation of coagulation by the drug, treatment of acute rejection with 5 mg daily was not associated with thromboembolic complications. US licensed product information states that the relationship to dose remains unclear, but that the relative risk appears to be greater with doses above the recommended dose.

3. Raasveld MHM, *et al.* Thromboembolic complications and dose of monoclonal OKT3 antibody. *Lancet* 1992; **339:** 1363–4.

Effects on the ears. Bilateral sensorineural hearing loss has occurred after muromonab-CD3 therapy. In one case series, 5 out of 7 patients were affected, showing a mean hearing loss of 18 decibels.[1] Tinnitus may also occur.[1,2] Although symptoms are generally reversible,[1,2] one patient still showed a deficit in hearing after 6 months.[3]

3. Michals M, *et al.* Hearing loss associated with muromonab-CD3 therapy. *Clin Pharm* 1988; **7:** 867–8.

Effects on the nervous system. Generalised seizures were reported in 2 uraemic kidney-graft recipients given muromonab-CD3.[1] Delayed graft function may result in the accumulation of uraemic toxins which combine with cytokines released by the immunosuppressant to produce the effects on the CNS. Seizures and encephalopathy were reported in siblings given muromonab-CD3 after renal transplantation, and appeared to predispose one of them to develop ciclosporin neurotoxicity.[2] A neurological syndrome characterised by akinetic mutism, blepharospasm, anomic aphasia, and delirium, occurred in a heart transplant patient given muromonab-CD3; symptoms resolved after stopping therapy.[3]

The manufacturers have warned that children treated with muromonab-CD3 may be at increased risk of nervous system complications, notably cerebral oedema that may result in fatal cerebral herniation. Since 1986, and as of May 2004, 9 cases of cerebral oedema had been reported worldwide in children, resulting in 6 deaths. Cerebral herniation had occurred within a few hours to 1 day after injection. Signs include the sudden appearance of severe headache, seizures, impaired mental function, drowsiness and lethargy, and coma.[4]

Pharmacokinetics

Therapeutic drug monitoring. US licensed product information states that serum concentrations of muromonab-CD3 are measurable using an enzyme-linked immunosorbent assay (ELISA). Studies in organ transplant recipients found that patients less than 10 years of age had higher concentrations than patients aged 10 to 50 years. Subsequent clinical experience has shown that serum concentrations of muromonab-CD3 greater than or equal to 800 nanograms/mL block the function of T-cells. Reduced T-cell clearance or low plasma concentrations of muromonab-CD3 provide a basis for adjusting muromonab dosage or stopping therapy.

In adults, periodic monitoring to ensure plasma muromonab-CD3 concentrations of 800 nanograms/mL or greater, or CD3-positive cells less than 25 cells/mm^3 is recommended. Paediatric patients are known to have higher CD3 lymphocyte counts than adults, and often require increased doses of muromonab-CD3 to achieve similar depletion of CD3-positive cells and therapeutic serum concentrations; both T-cell clearance and plasma muromonab-CD3 should be monitored daily in children.

Uses and Administration

Muromonab-CD3 is a murine monoclonal antibody to the T3 (CD3) antigen of human T-lymphocytes, which is essential to antigen recognition and response; the antibody thus specifically blocks T-cell generation and function, to exert an immunosuppressant effect without affecting the bone marrow.

It is used in the treatment of acute allograft rejection in organ transplant recipients, in doses of 5 mg daily by intravenous injection for 10 to 14 days. For children's doses, see Administration in Children, below. The dose of any other immunosuppressant therapy may need to be reduced. Patients should be monitored closely after the first few doses of muromonab-CD3 because of the risk of cytokine release syndrome and hypersensitivity reactions. The first dose may be preceded by intravenous methylprednisolone sodium succinate, in a dose of 8 mg/kg, 1 to 4 hours before muromonab-CD3. Paracetamol and antihistamines may also be given with muromonab-CD3 to reduce early reactions.

Muromonab-CD3 has also been given experimentally as part of regimens for the prophylaxis of graft rejection. For further details of the use of muromonab-CD3 in the treatment and prophylaxis of graft rejection see Organ and Tissue Transplantation, p.1810, *et seq.*

Administration in children. The initial recommended doses in children given muromonab-CD3 for acute allograft rejection are as follows:

- those weighing 30 kg or less: 2.5 mg daily
- those weighing more than 30 kg: 5 mg daily

Doses are given by intravenous injection for 10 to 14 days.

Paediatric patients are known to have higher CD3 lymphocyte counts than adults, and often require doses to be titrated upwards. The initial dose may be subsequently adjusted in 2.5 mg increments to achieve T-cell clearance (CD3-positive cells less than 25 cells/mm^3) and ensure therapeutic serum concentrations of muromonab-CD3 (of 800 nanograms/mL or greater, see Therapeutic Drug Monitoring, above).

Mycophenolate

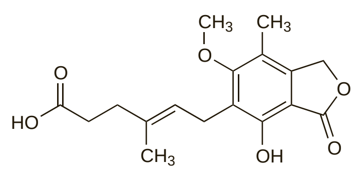
ATC — L04AA06.
ATC Vet — QL04AA06.

Mycophenolic Acid *(BAN, USAN, rINN)*

Acide Mycophénolique; Ácido micofenólico; Acidum Mycophenolicum; Lilly-68618; MPA; NSC-129185. (*E*)-6-(4-Hydroxy-6-methoxy-7-methyl-3-oxo-5-phthalanyl)-4-methyl-4-hexenoic acid.

Микофеноловая Кислота

$C_{17}H_{20}O_6$ = 320.3.
CAS — 24280-93-1.
ATC — L04AA06.
ATC Vet — QL04AA06.



Mycophenolate Mofetil *(BANM, USAN, rINNM)*

Micofenolato de mofetilo; Mikofenolat Mofetil; Mikofenolato mofetilis; Mofetilis Mycophenolas; Mofetil-mykofenolát; Mycophenolas Mofetil; Mycophenolas Mofetilum; Mycophenolas-mofetil; Mycophénolate mofétil; Mycophénolate, Mofétil de; Mycophenolate Morpholinoethyl; Mykofenolaattimofetiili; Mykofenolatmofetil; RS-61443. 2-Morpholinoethyl (*E*)-6-(4-hydroxy-6-methoxy-7-methyl-3-oxo-5-phthalanyl)-4-methyl-4-hexenoate.

Микофеноловаяа Мофетил

$C_{23}H_{31}NO_7$ = 433.5.
CAS — 115007-34-6.
ATC — L04AA06.
ATC Vet — QL04AA06.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Mycophenolate Mofetil). A white or almost white, crystalline powder. M.p. about 96°. Practically insoluble in water; sparingly soluble in dehydrated alcohol; freely soluble in acetone. Protect from light.

USP 31 (Mycophenolate Mofetil). A white or almost white, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol; soluble in methyl alcohol; freely soluble in acetone. Store in airtight containers.

Mycophenolate Mofetil Hydrochloride *(BANM, USAN, rINNM)*

Hidrocloruro del micofenolato de mofetilo; Mycophénolate, Mofétil Chlorhydrate de; Mycophenolati Mofetili Hydrochloridum; RS-61443-190. 2-Morpholinoethyl (*E*)-6-(4-hydroxy-6-methoxy-7-methyl-3-oxo-5-phthalanyl)-4-methyl-4-hexenoate hydrochloride.

Микофеноловой Мофетила Гидрохлорид

$C_{23}H_{31}NO_7,HCl$ = 470.0.
CAS — 116680-01-4.
ATC — L04AA06.
ATC Vet — QL04AA06.

Incompatibility. Solutions of mycophenolate mofetil hydrochloride were found to be physically compatible and chemically stable with solutions containing clinically relevant concentrations of cefepime, dopamine, noradrenaline, tacrolimus, and vancomycin, for up to 4 hours of simulated Y-site administration. However, combining ciclosporin and mycophenolate resulted in effervescence and chemical instability.[1]

1. Cochran BG, *et al.* Physical compatibility and chemical stability of mycophenolate mofetil during simulated Y-site administration with commonly coadministered drugs. *Am J Health-Syst Pharm* 2007; **64:** 1410–14.

Stability. UK and US licensed product information states that, after reconstitution of *mycophenolate mofetil oral suspension,* it may be stored at room temperature (15° to 30°) or in a refrigerator (2° to 8°) for up to 60 days; it should not be frozen.

UK licensed product information for *mycophenolate mofetil hydrochloride solution for infusion* states that the infusion should be started within 3 hours of reconstitution and dilution; solutions may be kept at room temperature (15° to 30°). A study found that solutions of mycophenolate mofetil hydrochloride in concentrations equivalent to mycophenolate mofetil 1, 5, or 10 mg/mL were stable for 7 days when stored at 4° or 25° in PVC infusion bags.[1] However, it was noted that a progressive discoloration occurred in bags unprotected from light and stored at 25°; further study was required to determine the source of the discoloration.

1. Certain E, *et al.* Stability of i.v. mycophenolate mofetil in 5% dextrose injection in polyvinyl chloride infusion bags. *Am J Health-Syst Pharm* 2002; **59:** 2434–9.

Mycophenolate Sodium *(BANM, USAN, rINNM)*

ERL-080; Micofenolato sódico; Mycophénolate de Sodium; Natrii Mycophenolas. Sodium 4(*E*)-6-(4-hydroxy-6-methoxy-7-methyl-3-oxo-1,3-dihydroisobenzofuran-5-yl)-4-methylhex-4-enoate.

Натрий Микофеноловая

$C_{17}H_{19}NaO_6$ = 342.3.
CAS — 37415-62-6.
ATC — L04AA06.
ATC Vet — QL04AA06.

Adverse Effects, Treatment, and Precautions

Mycophenolate is associated with gastrointestinal disturbances, particularly diarrhoea and vomiting; gastrointestinal haemorrhage and perforation have occurred. Leucopenia may develop; as with other immunosuppressants there is an increased risk of infection and certain malignancies in patients receiving mycophenolate mofetil (see below). To minimise any risk of skin cancer, exposure to sunlight or ultraviolet light should be limited. Thrombocytopenia and anaemia are also common; there have been reports of aplastic anaemia and bone-marrow depression, sometimes fatal. Regular full blood counts are recommended during therapy, and treatment may need to be stopped if severe neutropenia develops. Other reported adverse effects include asthenia, fever, pain, headache, renal impairment, hypertension or hypotension, hyperglycaemia, disturbances of electrolytes and blood lipids, peripheral oedema, pleural effusion, dyspnoea, cough, acne, rash, alopecia, dizziness, insomnia or somnolence, paraesthesia, and tremor. Agitation, depression, anxiety, tachycardia, and arthralgia are also common. Abnormal hepatic function tests have also been reported. Hypersensitivity reactions, including angioedema and anaphylaxis, have occurred. Pancreatitis and hepatitis have been reported. There are rare reports of interstitial lung disorders, including fatal pulmonary fibrosis. Other less common adverse effects include renal tubular necrosis, haematuria, conjunctivitis, blurred vision, and impotence. Cases of progressive multifocal leukoencephalopathy (PML), sometimes fatal, have also been reported. Mycophenolate is teratogenic in *animals*; malformations, especially of the external ear, and other facial abnormalities, have been reported in infants after maternal exposure to mycophenolate (see below).

Mycophenolate should be given with care to patients with severe renal impairment or active disorders of the gastrointestinal tract. Intra-uterine devices should be used with caution in those given immunosuppressive treatment as there is an increased risk of infection. Live vaccines should be avoided in these patients for the same reason.

Mycophenolate mofetil and mycophenolate sodium should not be indiscriminately interchanged or substituted because of their differing pharmacokinetic profiles.

Effects on the gastrointestinal tract. The adverse effects of mycophenolate mofetil on the gastrointestinal tract appeared to be mostly of an irritative nature and included diarrhoea, abdominal pain, nausea and vomiting, anorexia, dyspepsia, and occasionally gastrointestinal haemorrhage or perforation.[1] Paediatric patients tended to have a higher incidence of adverse gastrointestinal events than adults. There was some evidence that adverse effects were related to peak plasma concentrations of the drug.

A review comparing the adverse effect profile of enteric-coated mycophenolate sodium with that of mycophenolate mofetil found a similar incidence of gastrointestinal adverse effects with the two formulations. It was noted that the pathophysiology of the gastrointestinal disturbances seen with mycophenolate is complex and not fully understood. An increased incidence of diarrhoea has been seen with higher mycophenolic acid (MPA) concentrations, possibly due to a direct effect of MPA on intestinal enterocytes, caused by its inhibitory effect on inosine monophosphate dehydrogenase. While exposure to MPA may be higher with the enteric-coated formulation, studies have not shown an appreciable increase in gastrointestinal adverse effects with mycophenolate sodium; the enteric coating might have diminished the direct effect of MPA on enterocytes in the upper gastrointestinal tract.[2] Two studies found that gastrointestinal adverse effects decreased after patients were switched from mycophenolate mofetil to enteric-coated mycophenolate sodium.[3,4]

2. Behrend M, Braun F. Enteric-coated mycophenolate sodium: tolerability profile compared with mycophenolate mofetil. *Drugs* 2005; **65:** 1037–50.
3. Calvo N, *et al.* Renal transplant patients with gastrointestinal intolerability to mycophenolate mofetil: conversion to enteric-coated mycophenolate sodium. *Transplant Proc* 2006; **38:** 2396–7.
4. Boswell A, *et al.* Conversion from mycophenolate mofetil to enteric-coated mycophenolate sodium in patients with gastrointestinal side effects: case studies. *Prog Transplant* 2006; **16:** 138–40.

Handling. The UK licensed product information for film-coated gastro-resistant tablets of mycophenolate sodium (*Myfortic, Novartis*) warns that if it is necessary to crush the tablets, inhalation of the powder or direct contact of the powder with the skin or mucous membranes should be avoided.

Infection. The use of mycophenolate mofetil was not found to increase the risk of CMV infection in 2 small studies.[1,2] However, it did appear to be associated with an increased frequency[1] and severity[2] of CMV disease (defined as CMV infection plus evidence of viral syndrome). The number of organs affected in patients with CMV disease was also higher in those treated with mycophenolate mofetil.[2]

A retrospective study[3] found that the use of a protocol containing mycophenolate mofetil and tacrolimus was an independent risk factor for the development of CMV disease, but that the dose of mycophenolate mofetil was not. The authors interpreted this to mean that either the combination of mycophenolate mofetil and tacrolimus had an overall stronger immunosuppressive effect than other regimens, or that this protocol bore a specific risk for the development of CMV disease. The pharmacokinetics of mycophenolic acid (MPA), a metabolite of mycophenolate mofetil, and its interaction with tacrolimus, must be considered, with further studies taking MPA levels into account (see Immunosuppressants, under Interactions, below).

In contrast to these findings, another retrospective study[4] found that, although no patient developed CMV disease, the use of mycophenolate mofetil was an independent risk factor for the development of CMV infection in those patients initially seropositive for the CMV antigen.

In a study comparing the adverse effects of mycophenolate mofetil and enteric-coated mycophenolate sodium in renal transplant patients, the overall incidence of infections was similar. However, patients receiving mycophenolate sodium had significantly fewer serious infections. The incidence of CMV infection was very low and similar in both groups.[5]

In February 2008 the manufacturer in agreement with the EMEA warned[6] that isolated cases of progressive multifocal leukoencephalopathy (PML), sometimes fatal, had been reported in patients receiving mycophenolate mofetil (*CellCept, Roche*) for transplant rejection or SLE; a diagnosis of PML should be considered in patients who develop neurological symptoms while receiving mycophenolate mofetil. It was also recommended that consideration should be given to reducing the total immunosuppression in patients who develop PML but with a reminder that such a reduction may place the graft at risk in transplant patients.

6. Roche, UK. Reports of progressive multifocal leukoencephalopathy (PML) in CellCept (mycophenolate mofetil) treated patients (issued 18th February 2008). Available at: http://www.mhra.gov.uk/home/idcplg?IdcService=GET_FILE&dDocName=CON014106&RevisionSelectionMethod=Latest (accessed 19/05/08)

Pregnancy. There have been reports of spontaneous abortions and structural malformations in infants born to women taking mycophenolate. The manufacturers of mycophenolate mofetil (*Roche, USA*) have warned that use of the drug during pregnancy is associated with an increased risk of first trimester pregnancy loss and an increased risk of congenital malformations, especially external ear and other facial abnormalities including cleft lip and palate, and anomalies of the distal limbs, heart, oesophagus, and kidney.[1] Women of child-bearing potential should have a negative pregnancy test within 1 week of starting mycophenolate therapy. Women taking mycophenolate should use effective contraception, from at least 4 weeks before starting therapy, and until 6 weeks after stopping mycophenolate.

1. Roche, USA. Important changes in the CellCept (mycophenolate mofetil) prescribing information—use of CellCept is associated with increased pregnancy loss and congenital malformations/change from pregnancy category C to pregnancy category D (issued October 2007). Available at: http://www.fda.gov/Medwatch/SAFETY/2007/CellCept_dearhcpoct07.pdf (accessed 18/02/08)

Interactions

Mycophenolate may compete with other drugs that undergo active renal tubular secretion, resulting in increased concentrations of either drug. Antacids, polycarbophil calcium, sevelamer, or colestyramine may reduce absorption of mycophenolate. Rifampicin decreases exposure to mycophenolate (in patients not also taking ciclosporin); mycophenolic acid (MPA) concentrations should be monitored when rifampicin and mycophenolate are used together. See above for precautions about use with live vaccines.

Antacids. Although giving mycophenolate mofetil with an antacid mixture (aluminium and magnesium hydroxides) or food both resulted in reductions in peak plasma concentrations of mycophenolic acid (MPA), the differences were small compared with interindividual variation, and were considered unlikely to be clinically significant.[1]

UK licensed product information for mycophenolate sodium states that, although magnesium- or aluminium-containing antacids decrease MPA exposure and peak plasma concentrations, they may be used intermittently for the treatment of occasional dyspepsia; chronic use of antacids is not recommended.

Antibacterials. A selective bowel decontamination regimen of *tobramycin*, *cefuroxime*, and the antifungal *nystatin*, apparently inhibited the enterohepatic recycling of mycophenolic acid (MPA), thereby reducing the bioavailability of mycophenolate in liver transplant recipients.[1] *Norfloxacin*, *metronidazole*, or a combination of the two, reduced exposure to MPA and mycophenolic acid glucuronide (see Metabolism, below) when given to healthy subjects receiving mycophenolate mofetil. The effect of the antibacterials appeared to be additive.[2] Rapid reductions in MPA concentrations were seen after renal transplant patients stabilised on mycophenolate were given either *ciprofloxacin* or *amoxicillin with clavulanic acid*; MPA concentrations recovered to baseline within 3 days of stopping antibacterial therapy, and the effect was seen to wane with continued dosage of antibacterials for 14 days.[3] *Rifampicin* markedly reduced exposure to MPA in a heart-lung transplant recipient, possibly through induction of mycophenolate glucuronidation.[4] A study in renal transplant recipients given rifampicin confirmed this reduction in MPA exposure, concluding that the mechanism was induction of glucuronidation and inhibition of enterohepatic circulation.[5]

Immunosuppressants. Stopping *ciclosporin* therapy in renal transplant recipients was found to increase serum concentrations of mycophenolic acid (MPA),[1,2] leading to the hypothesis that ciclosporin inhibits the enterohepatic circulation of MPA. In contrast,[3,4] *tacrolimus* therapy increased serum concentrations of MPA, apparently by inhibiting conversion to mycophenolic acid glucuronide (MPAG). While the studies have been criticised,[5] it has been pointed out that an interaction cannot be excluded.[6] An increased incidence of CMV disease has been reported in renal transplant recipients given a triple therapy regimen containing tacrolimus and mycophenolate mofetil.[7] Based on a study[8] in children it has been recommended that mycophenolate mofetil be given in initial doses of 600 mg/m² twice daily with ciclosporin but 300 mg/m² twice daily with tacrolimus; 500 mg/m² twice daily was suggested if no calcineurin inhibitor was given. It is also recommended that dose adjustments are made using therapeutic drug monitoring. However, a pharmacokinetic study[9] showed that changes in MPA exposure with tacrolimus varied with the dose of mycophenolate mofetil used and that this effect was not adequately reflected by MPA trough concentrations (see Therapeutic Drug Monitoring, below). Another study found marked interindividual variability in MPA and MPAG pharmacokinetics when patients were given ciclosporin microemulsion or tacrolimus in the early stages after renal transplantation. This variability was greater in those given ciclosporin than in those given tacrolimus, and mean total MPA concentrations were about half that of patients in the tacrolimus group.[10] A randomised crossover study compared the effect of ciclosporin microemulsion or tacrolimus on the pharmacokinetics of MPA when each of these were given with enteric-coated mycophenolate sodium to stable renal transplant recipients.[11] In comparison with use with ciclosporin, giving mycophenolate sodium with tacrolimus resulted in a moderate increase in the total exposure of MPA and decreased maximum concentrations and total exposure to the metabolites MPAG and the acyl glucuronide. The results were not statistically significant, and the authors suggested that on this basis, doses of mycophenolate sodium need not be adjusted when converting stable renal transplant patients from one calcineurin inhibitor to the other. However, they recommended that mycophenolate sodium dose adjustments should be based on both the pharmacokinetic data and the clinical situation.

UK licensed product information has stated that ciclosporin reduces MPA exposure, and may decrease MPA concentrations when these two drugs are given together. The exact extent of the decrease is not known for mycophenolate sodium, but may be about 20%, extrapolated from data for mycophenolate mofetil. However, since efficacy studies used this combination, no dose adjustment of mycophenolate is considered necessary. If concomitant ciclosporin therapy is interrupted or stopped, an increase in MPA of about 30% is to be expected, and dosage should be re-evaluated depending on the immunosuppressive regimen. While not commenting on dose adjustment when used with tacrolimus, UK licensed product information for mycophenolate sodium stated that stable renal transplant patients showed increased MPA exposure and decreased MPAG when tacrolimus was substituted for ciclosporin.

Pharmacokinetic analyses found that use of *sirolimus* with mycophenolate led to greater MPA exposure,[12,13] but lower MPAG exposure,[14] when compared with ciclosporin plus mycophenolate. Therapeutic drug monitoring of MPA is recommended in transplant recipients given both mycophenolate and sirolimus;[12,13] guidelines are needed when switching patients from ciclosporin to sirolimus, since the same dose of mycophenolate mofetil would lead on average to a 50% increase in MPA exposure in patients receiving sirolimus compared with ciclosporin.[13]

Iron. Absorption of mycophenolate mofetil after oral doses was markedly reduced by iron preparations in a study in 7 healthy subjects:[1] mean peak serum concentrations of mycophenolic acid were reduced from 20.1 to 1.3 micrograms/mL. However, in contrast, a study in 16 healthy subjects found no interaction between iron supplements and mycophenolate mofetil,[2] and 2 studies in renal transplant patients found no significant effect of oral iron supplements on the absorption of mycophenolate mofetil.[3,4]

Pharmacokinetics

Mycophenolate mofetil is rapidly and extensively absorbed from the gastrointestinal tract; enteric-coated mycophenolate sodium is also extensively absorbed. Mycophenolate undergoes presystemic metabolism to active mycophenolic acid (MPA). MPA undergoes enterohepatic recirculation and secondary increases in plasma MPA concentrations are seen; these have been reported at between 6 to 12 hours after a dose of mycophenolate mofetil, and at between 6 to 8 hours after a dose of mycophenolate sodium. MPA is metabolised by glucuronidation to the inactive mycophenolic acid glucuronide. The majority of a dose of mycophenolate is excreted in the urine as this glucuronide, with negligible amounts of MPA; about 6% of a dose is recovered in faeces. MPA is 97% bound to plasma albumin. The mean half-life of MPA after oral and intravenous doses of mycophenolate mofetil has been reported to be 17.9 hours and 16.6 hours, respectively; an MPA half-life of about 12 hours has been reported for mycophenolate sodium.

Bioavailability. A study in renal transplant patients found single doses of mycophenolate sodium 640 mg and 720 mg to be bioequivalent to mycophenolate mofetil 1 g. The 720-mg dose most closely approximated the mycophenolic acid (MPA) exposure of the mycophenolate mofetil dose.[1] The authors noted that since the study was conducted in patients given ciclosporin, bioequivalence of MPA exposure between these two formulations could not be assumed for patients receiving other immunosuppressants. A meta-analysis of 3 studies in stable renal transplant recipients concluded that mycophenolate mofetil and enteric-coated mycophenolate sodium give equivalent mycophenolate exposure in these patients.[2]

Metabolism. Mycophenolate mofetil is rapidly de-esterified in the body to active mycophenolic acid (MPA), which is subsequently converted to inactive mycophenolic acid glucuronide (MPAG) in the gastrointestinal tract, liver and possibly kidney. This conversion to MPAG is considered to be the most important and rate limiting step.[1] MPA undergoes enterohepatic circulation, with MPAG formed in the liver being excreted into bile and converted back to MPA in the gastrointestinal tract. A further metabolite, the acyl glucuronide, has been shown to be active *in vitro*, inhibiting human inosine monophosphate dehydrogenase,[1,2] and may have implications in therapeutic drug monitoring (see below). MPA is extensively bound to albumin in patients with normal renal and hepatic function, but this binding may be affected in transplant patients by several factors such as hypoalbuminaemia, hyperbilirubinaemia, and uraemia. Accumulation of MPAG leads to an increase in unbound MPA, and a subsequent increase in MPA clearance.[2]

A crossover study to compare the metabolism of mycophenolate mofetil with mycophenolate sodium[3] found that the onset of MPA absorption was delayed with mycophenolate sodium, consistent with its enteric-coated formulation. However, MPA exposure was considered to be bioequivalent, and MPA metabolism did not differ significantly between the two formulations. MPAG was confirmed as being the principal metabolite of MPA, and the authors considered that acyl glucuronide exposure was of a sufficient magnitude to potentially contribute to immunosuppression and toxicity.

Therapeutic drug monitoring. Mycophenolic acid (MPA) concentration appears to correlate with efficacy and toxicity.[1] Patients with low MPA concentrations may be at increased risk of transplant rejection,[2-5] or graft-versus-host disease,[5] and there is some evidence that a high MPA concentration correlates with increased adverse effects.[4,6] Fixed doses of mycophenolate mofetil have been reported to lead to variable MPA exposure,[7,8] and other immunosuppressants can affect MPA concentrations, see under Interactions, above. Therapeutic drug monitoring of mycophenolate mofetil is therefore considered necessary.[1]

Assay procedures to measure MPA concentrations include high performance liquid chromatography (HPLC) and an enzyme-multiplied immunoassay technique (EMIT). However, the acyl glucuronide metabolite of MPA (see Metabolism, above) may cross-react with the latter method, leading to higher measured concentrations than with HPLC.[8,9] This overestimation of MPA exposure using EMIT was reported to be about 24 to 35%, with the greatest bias seen in kidney recipients early after transplantation. However, in paediatric renal transplant patients, EMIT showed comparable diagnostic efficacy to HPLC, and is an acceptable assay for MPA in this population.[8] Another suggested approach is to measure inosine monophosphate dehydrogenase activity directly, (see Metabolism, above) but this has produced variable results.[10]

A review[9] concluded that while some studies show a correlation between MPA trough concentration (C_o) and acute allograft rejection, MPA area under the concentration-time curve (AUC) is predictive of the risk for rejection, and that both have limitations. An abbreviated AUC involving more practical blood sampling regimens may be more appropriate, and a trough concentration between 1 and 3.5 mg/litre has been proposed. For paediatric transplant recipients, a predose trough concentration, as measured by EMIT assay, of between 1.6 and 3.5 mg/litre has been recommended.[11] However, it has been pointed out[12] that the therapeutic range may be different at different time points after transplantation, and among different patient populations; concomitant drugs may also influence this range. The following target concentrations have been recommended for transplant patients taking mycophenolate mofetil:[13]

- MPA AUC 30 to 60 mg × hours/litre as determined by HPLC in the first 30 days post-transplantation
- for renal transplant recipients on a ciclosporin-based regimen, MPA C_0 greater than or equal to 1.3 mg/litre, as measured by HPLC
- for renal transplant recipients on a tacrolimus-based regimen, MPA C_0 greater than or equal to 1.9 mg/litre, as measured by HPLC
- for cardiac transplant recipients, MPA C_0 greater than or equal to 2 mg/litre, as measured by EMIT, or 1.2 to 3.5 mg/litre as measured by HPLC
- for liver transplant recipients, target concentrations could not be definitively recommended; similar targets to renal transplantation were suggested until more data are available

Some have stated that the contribution of MPA trough level monitoring during mycophenolate mofetil therapy is unproven, given the lack of data in paediatric renal transplant patients, and in cardiac and liver transplantation, and that adherence to recommended target ranges for MPA cannot ensure an improved clinical outcome.[14]

It has also been pointed out that, because of differing pharmacokinetic profiles, algorithms developed for mycophenolate mofetil cannot be used for patients treated with mycophenolate sodium.[15]

Measurements of unbound MPA concentrations may be of benefit in patients with renal or hepatic impairment, as factors such as hypoalbuminaemia and renal dysfunction affect the binding of MPA.[9] In liver transplant patients, plasma protein binding of MPA increased as albumin concentration increased and as bilirubin concentration decreased, leading to decreased unbound fraction of MPA, and contributing to large intra- and interindividual pharmacokinetic variability.[16] A population pharmacokinetic study considered the complexity in determining MPA pharmacokinetics to be underestimated.[17] Bayesian forecasting using only 3 samples has been reported to accurately predict MPA exposure.[18,19]

A study in 6 patients with psoriasis concluded that MPA trough concentrations (measured by EMIT) did not predict efficacy or toxicity, but instead were useful to evaluate compliance.[20]

For the view that MPA trough concentrations may not adequately reflect exposure in patients also receiving tacrolimus, see Interactions, Immunosuppressants, above.

Uses and Administration

Mycophenolic acid is an immunosuppressant derived from *Penicillium stoloniferum*. It is a reversible inhibitor of inosine monophosphate dehydrogenase and thus inhibits purine synthesis, with potent cytostatic effects on both T- and B-lymphocytes. It is given with other immunosuppressants, for the prevention of graft rejection, and has also been tried in diseases with an autoimmune or immune-mediated inflammatory component.

It has been used mainly as the morpholinoethyl derivative, mycophenolate mofetil, or its hydrochloride salt; doses of both are expressed as mycophenolate mofetil. 1.08 g of mycophenolate mofetil hydrochloride is equivalent to about 1 g of mycophenolate mofetil. An enteric-coated formulation of mycophenolate sodium (the sodium salt of mycophenolic acid) is also available in some countries. Doses are expressed in terms of the acid; mycophenolate sodium 769 mg is equivalent to about 720 mg of mycophenolic acid.

In patients to whom oral therapy cannot initially be given, mycophenolate mofetil may be given for up to 14 days by intravenous infusion. Infusions are given as the hydrochloride salt. It is dissolved in glucose 5% to a final concentration equivalent to mycophenolate mofetil 6 mg/mL, and given over 2 hours through either a central or peripheral vein.

In the prophylaxis of acute **renal** graft rejection in adults, the conventional formulation of mycophenolate mofetil is given orally in doses of 1 g twice daily, usually within 72 hours of transplantation; the equivalent dose may be given by intravenous infusion, but is usually started within 24 hours after transplantation.

The enteric-coated formulation of mycophenolate sodium is also given for the prophylaxis of acute renal graft rejection to adults in a dose equivalent to mycophenolic acid 720 mg twice daily; the two formulations cannot be indiscriminately interchanged or substituted.

In the prophylaxis of **cardiac** graft rejection in adults, mycophenolate mofetil 1.5 g twice daily is given by mouth, within 5 days after transplantation, or by intravenous infusion at an equivalent dose.

For use in the prophylaxis of rejection in **hepatic** transplantation in adults, the equivalent of mycophenolate mofetil 1 g twice daily is given by intravenous infusion for the first 4 days after transplantation, with subsequent conversion to 1.5 g twice daily by mouth as soon as it can be tolerated.

For doses of mycophenolate used for organ transplantation in children see Administration in Children, below.

Patients should undergo regular blood counts; if neutropenia develops consideration should be given to interrupting mycophenolate treatment, reducing the dose, or stopping therapy.

Administration in children. Oral mycophenolate mofetil is licensed from the age of 2 years in the UK, and from 3 months of age in the USA. For prevention of **renal** graft rejection in patients up to 18 years of age, the recommended oral dose of mycophenolate mofetil is 600 mg/m^2 twice daily, up to a maximum of 1 g twice daily. Patients with a body-surface of 1.25 to 1.5 m^2 may be given 750 mg twice daily, whereas those with a body-surface of greater than 1.5 m^2 may be given the same dose as adults (see Uses and Administration, above). In the UK, the *BNFC* allows for use from 1 month to 18 years at 600 mg/m^2 twice daily orally or by infusion when used with ciclosporin and corticosteroids, but recommends 300 mg/m^2 twice daily when used with tacrolimus and corticosteroids; the maximum in both cases is 2 g daily.

UK licensed product information states that no data are available for paediatric cardiac and hepatic transplant patients. However, for prophylaxis of rejection in **hepatic** transplantation, the *BNFC* recommends mycophenolate mofetil 10 mg/kg twice daily, orally or by intravenous infusion, for children aged from 1 month to 18 years. This may be increased to 20 mg/kg twice daily, to a maximum of 2 g daily. The dose is the same whether used with either ciclosporin and corticosteroids, or tacrolimus and corticosteroids.

Administration in hepatic or renal impairment. Licensed product information in the UK and USA states that no dose adjustments of mycophenolate mofetil are needed for renal transplant recipients with severe *hepatic* parenchymal disease. However, it is not known whether dose adjustments are necessary for those with hepatic disease of differing aetiology. No data are available for cardiac transplant patients with severe hepatic parenchymal disease. UK licensed product information states that no dose adjustments are needed for mycophenolate sodium in renal transplant patients with hepatic impairment.

US licensed product information states that exposure to mycophenolic acid (MPA) is increased in patients with chronic *renal* impairment. Although mean MPA concentrations in patients with delayed renal graft function were comparable to those transplant patients without delayed renal graft function, there is a potential for a transient increase in MPA concentrations if renal graft function is delayed. However, dose adjustment does not appear to be necessary in these patients. UK licensed product information states that in renal transplant patients with severe chronic renal impairment (GFR less than 25 mL/minute per 1.73 m^2), oral or intravenous doses of mycophenolate mofetil above 1 g twice daily should be avoided outside the immediate post-transplantation period; the daily dose of mycophenolate sodium in these patients should not exceed 1.44 g. No dose adjustments of mycophenolate are needed in those with delayed renal graft function. No data are available for cardiac or hepatic transplant recipients with severe chronic renal impairment.

Chronic active hepatitis. Mycophenolate mofetil may be of benefit in patients with auto-immune hepatitis (p.1501) who are intolerant of or unresponsive to azathioprine or other standard therapy.[1-3]

1. Richardson PD, *et al.* Mycophenolate mofetil for maintenance of remission in autoimmune hepatitis in patients resistant to or intolerant of azathioprine. *J Hepatol* 2000; **33:** 371–5.
2. Devlin SM, *et al.* Mycophenolate mofetil for the treatment of autoimmune hepatitis in patients refractory to standard therapy. *Can J Gastroenterol* 2004; **18:** 321–6.
3. Inductivo-Yu I, *et al.* Mycophenolate mofetil in autoimmune hepatitis patients not responsive or intolerant to standard immunosuppressive therapy. *Clin Gastroenterol Hepatol* 2007; **5:** 799–802.

Eczema. Mycophenolate mofetil (typically 1 to 3 g daily by mouth) has been reported[1-3] to be safe and effective in the treatment of moderate-to-severe, refractory eczema (p.1579).

1. Neuber K, *et al.* Treatment of atopic eczema with oral mycophenolate mofetil. *Br J Dermatol* 2000; **143:** 385–91.
2. Grundmann-Kollmann M, *et al.* Mycophenolate mofetil is effective in the treatment of atopic dermatitis. *Arch Dermatol* 2001; **137:** 870–3.
3. Heller M, *et al.* Mycophenolate mofetil for severe childhood atopic dermatitis: experience in 14 patients. *Br J Dermatol* 2007; **157:** 127–32.

Eye disorders. Retrospective evaluations of treatment outcomes in patients with chronic inflammatory eye disease treated with mycophenolate mofetil found that it was effective in controlling inflammation and had a useful corticosteroid-sparing effect.[1,2] Mycophenolate mofetil, used either alone or adjunctively, has been reported[3-7] to be of benefit in refractory uveitis (p.1515). Oral doses of 600 mg/m^2 twice daily or 1 g twice daily have been used in children; the latter dose has also been used in adults with uveitis. There was some suggestion mycophenolate might be less effective in those patients initially unresponsive to azathioprine.[5]

Glomerular kidney disease. Mycophenolate mofetil, in usual oral doses of 1 to 2 g daily, has been reported[1-3] to be of benefit in various forms of glomerular kidney disease (p.1504); in childhood nephrotic syndrome, it was reported to have a significant corticosteroid-sparing effect, reduce relapse rates,[4] and benefit renal function.[5]

Inflammatory bowel disease. Mycophenolate mofetil has been investigated as an alternative to azathioprine in Crohn's disease (see Inflammatory Bowel Disease, p.1697). A randomised study in 70 patients compared therapy with corticosteroids plus mycophenolate mofetil or azathioprine in patients with moderate or severe Crohn's disease. The authors concluded that the mycophenolate regimen produced a clinical response earlier than the azathioprine regimen, and that mycophenolate should be considered in patients allergic or unresponsive to azathioprine or mercaptopurine.[1] However, it has been suggested[2] that the study may have been too short to draw definite conclusions, given the known delayed therapeutic effect of azathioprine. A beneficial effect for 5 out of 6 patients with severe Crohn's disease was reported[3] after 3 months of therapy with oral mycophenolate mofetil 1 g twice daily, but this effect was not sustained beyond 6 months.[4] Others have also noted relapse or lack of response to be relatively common;[5,6] while mycophenolate may have a role in those who cannot tolerate, or are refractory to, azathioprine, the latter remains the immunosuppressant of choice due to its greater ability to prevent flare-ups.[2]

Multiple sclerosis. In a small open-label study, 5 out of 7 patients with multiple sclerosis (p.892) benefited from mycophenolate mofetil; 3 of these patients reported improved movement.[1] A retrospective review[2] of mycophenolate mofetil treatment (given either adjunctively or as monotherapy) in 79 patients, reported subjective improvements in 12 patients given adjunctive therapy.

Organ and tissue transplantation. Mycophenolate mofetil is used for the prophylaxis of graft rejection in kidney (p.1813), heart (p.1812), and liver transplantation (p.1815), and has also been used after transplantation of the lung (p.1815), pancreas (p.1816), and intestines (p.1813). It has been used as an alternative to, or replacement for, azathioprine, and may result in fewer rejections. However, in a small study of heart transplant recipients switched from standard immunosuppressive therapy with a calcineurin inhibitor, mycophenolate mofetil, and corticosteroids, to sirolimus with mycophenolate mofetil, there was an increased incidence of acute rejection; target sirolimus and mycophenolate concentrations may have been insufficient to maintain adequate immunosuppression. It has also been tried for the prophylaxis of graft-versus-host disease after bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p.1811).

A few selected references to the use of mycophenolate mofetil in transplantation are given below.

Pemphigus and pemphigoid. Mycophenolate mofetil has been used successfully in the treatment of pemphigus and pemphigoid (p.1582), both with prednisolone[1-3] and alone.[4] In a randomised, non-blinded study,[5] adjuvant mycophenolate mofetil was found to be as effective as adjuvant azathioprine; corticosteroid-sparing effects were similar and there was a trend towards fewer adverse effects with mycophenolate.

Polymyositis and dermatomyositis. Mycophenolate mofetil has been reported to be of benefit in refractory cases of polymyositis and dermatomyositis (p.1510), allowing for tapering of corticosteroid doses.[1-3] Despite benefit in 6 out of 10 patients in another study,[4] 3 patients developed opportunistic infection, which was fatal in 1 case. While acknowledging that other factors may have had a role in this, the authors advised caution in the use of mycophenolate in dermatomyositis.

Rheumatoid arthritis. Mycophenolate mofetil has been tried in rheumatoid arthritis (p.11); reports suggest it may effectively suppress synovial inflammation.[1]

1. McMurray RW, Harisdangkul V. Mycophenolate mofetil: selective T cell inhibition. *Am J Med Sci* 2002; **323:** 194–6.

Sarcoidosis. Mycophenolate mofetil has been used as an adjunct in the successful treatment of patients with mucocutaneous sarcoidosis (p.1512)[1] and neurosarcoidosis.[2] It was reported to have a significant corticosteroid-sparing effect in an adolescent with renal involvement,[3] and was effective in a case of severe, relapsing, corticosteroid-dependent gastrointestinal sarcoidosis.[4]

1. Kouba DJ, *et al.* Mycophenolate mofetil may serve as a steroid-sparing agent for sarcoidosis. *Br J Dermatol* 2003; **148:** 147–8.

Systemic lupus erythematosus. Mycophenolate mofetil by mouth plus prednisolone, given for 12 months, was found to be as effective as oral cyclophosphamide plus prednisolone, for 6 months, followed by azathioprine plus prednisolone for 6 months,[1] in the treatment of Chinese patients with diffuse proliferative *lupus nephritis* (see Systemic Lupus Erythematosus, p.1513). However, some[2,3] have cautioned about generalising these findings to other patients since mycophenolate was compared with oral and not intravenous pulsed cyclophosphamide, which is considered the standard of care in those with diffuse proliferative disease. Patients with poorer prognoses were also considered to have been excluded or underrepresented in the study, and follow-up was short. However, in a 24-week unblinded study[4] oral mycophenolate mofetil was more effective in inducing complete remission than intermittent intravenous cyclophosphamide when used as induction therapy for active lupus nephritis and appeared to be better tolerated. Also, there have been reports of benefit with mycophenolate mofetil in patients with various forms of refractory lupus nephritis, including proliferative disease and membranous nephropathy,[5-7] and some consider it a good therapeutic alternative.[8,9] A review[10] concluded that limited data support induction with cyclophosphamide followed by maintenance with azathioprine or mycophenolate; in selected patients induction with mycophenolate is a reasonable alternative. Meta-analyses concluded that daily oral mycophenolate mofetil, in average or median doses of 1 to 2 g, was more effective than pulsed intravenous or oral cyclophosphamide,[11] and that mycophenolate reduced the risk of failure to induce remission during induction therapy when compared with cyclophosphamide.[12] However, the role of racial and ethnic differences in lupus remain poorly understood, and enrolment of varying ethnic populations in studies can significantly affect results of therapy.[13] Furthermore, it has been pointed out that subjects in studies included in one meta-analysis had relatively preserved renal function, and results cannot be generalised to patients with moderate to severe renal impairment and rapidly progressive glomerulonephritis.[14] While acknowledging data of mycophenolate use in children are limited, another review[15] concluded that from data in adults, mycophenolate is an acceptable alternative to intravenous cyclophosphamide in the induction phase for newly diagnosed patients with mild to moderate nephritis and intact renal function; it may also be suitable if there is concern about a patient's future fertility. However, the optimal dose and length of induction treatment with mycophenolate are still unknown.

Mycophenolate mofetil has been used to control extra-renal manifestations of SLE,[16,17] although it was ineffective in a small number of patients with severe refractory cutaneous disease.[18] Oral mycophenolate sodium 1.44 g daily has been reported to be effective in the treatment of patients with subacute cutaneous lupus erythematosus resistant to standard therapy.[19]

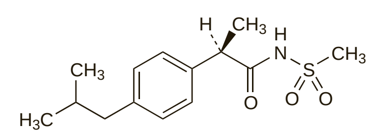
Reparixin *(USAN, rINN)*

DF-1681Y; Reparixina; Réparixine; Reparixinum; Repertaxin. (2*R*)-2-[4-(2-Methylpropyl)phenyl]-*N*-methylsulfonylpropanamide.

Репариксин

$C_{14}H_{21}NO_3S$ = 283.4.

CAS — 266359-83-5.



Reparixin Lysine *(rINNM)*

Reparixin L-Lysine; Reparixina lisina; Réparixine Lysine; Reparixinum Lysinum; Repertaxin L-Lysine. Reparixin compound with L-lysine (1:1); .

Репариксин Лизин

$C_{14}H_{21}NO_3S,C_6H_{14}N_2O_2$; = 429.6.

CAS — 266359-93-7.

Profile

Reparixin is an inhibitor of interleukin-8. Reparixin and reparixin lysine are under investigation for the prevention of delayed graft function in organ transplantation.

Sirolimus (BAN, USAN, rINN)

AY-22989; AY-022989; NSC-226080; Rapamycin; Sirolimús; Sirolimusum; Sirolimuusi; Wy-090217. (3S,6R,7E,9R,10R,12R,14S,15E,17E,19E,21S,23S,26R,27R,34aS)-9,10,12,13,14,21,22,23,24,25,26,27,32,33,34,34a-Hexadecahydro-9,27-dihydroxy-3-{(1R)-2-[(1S,3R,4R)-4-hydroxy-3-methoxycyclohexyl]-1-methylethyl}-10,21-dimethoxy-6,8,12,14,20,26-hexamethyl-23,27-epoxy-3H-pyrido[2,1-c][1,4]oxaazacyclohentriacontine-1,5,11,28,29-(4H,6H,31H)-pentone.

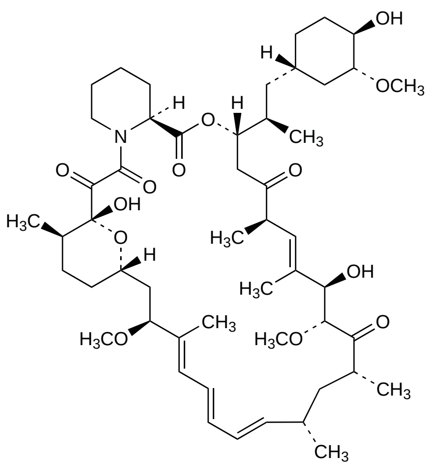
Сиролимус

$C_{51}H_{79}NO_{13}$ = 914.2.

CAS — 53123-88-9.

ATC — L04AA10.

ATC Vet — QL04AA10.



Adverse Effects and Precautions

The most frequent adverse effects of sirolimus include peripheral oedema, lymphocele, hypokalaemia, hypophosphataemia, hyperlipidaemia, hypercholesterolaemia, hyperglycaemia, tachycardia, venous thromboembolism, gastrointestinal disturbances, stomatitis, arthralgia, epistaxis, acne, rash, and bone necrosis. Anaemia, thrombocytopenia, neutropenia or leucopenia are common, especially at higher doses. Infections, including urinary-tract infections, pyelonephritis, CMV, Epstein-Barr virus, herpes zoster, and pneumocystis pneumonia, are also common, and antimicrobial prophylaxis for pneumonia is recommended for the first year after transplantation.

Thrombotic thrombocytopenic purpura and the haemolytic-uraemic syndrome may occur, as may hypersensitivity, including anaphylactic reactions, angioedema, exfoliative dermatitis, and hypersensitivity vasculitis. There are reports of fluid accumulation, including lymphoedema, pleural effusions, and pericardial effusions. Pulmonary embolism, pulmonary haemorrhage, and pancreatitis may occur rarely. Renal impairment, proteinuria, or nephrotic syndrome may develop; renal function should be monitored, especially when given with ciclosporin. In patients with delayed graft function, sirolimus may delay recovery of renal function. There are reports of hepatotoxicity, and rarely, fatal hepatic necrosis. Excess mortality, graft loss, and hepatic artery thrombosis has been associated with the use of sirolimus in immunosuppressive regimens in liver transplant recipients and therefore use in such patients is not recommended. Interstitial lung disease has been reported, including some fatalities, although other cases resolved on stopping or reducing the dose of sirolimus. Abnormal wound healing after transplant surgery has been reported with the use of sirolimus, especially in those with a BMI greater than 30 kg/m^2; bronchial anastomotic dehiscence, including some fatal cases, has occurred in lung transplant recipients and use in the latter is not recommended. There is an increased risk of lymphoma and other malignancies with immunosuppression, and to minimise any risk of skin cancer, exposure to sunlight or ultraviolet light should be limited.

Sirolimus may have adverse effects on sperm parameters; azoospermia and infertility have been reported. These effects are usually reversible on stopping sirolimus.

Immunosuppressants may reduce the response to vaccines, and the use of live vaccines should be avoided. Intra-uterine devices should be used with caution during immunosuppressive therapy, as there is an increased risk of infection.

Hypersensitivity reactions and subacute thrombosis have occurred with use of the sirolimus-eluting stent; fatalities have been reported.

Effects on the kidneys. There are a number of reports of proteinuria and renal dysfunction associated with sirolimus. A review[1] concluded that the vast majority of evidence suggested that proteinuria was mediated by glomerular haemodynamic mechanisms due to withdrawal of other immunosuppressants in kidneys with chronic glomerular injury, as in those transplant patients with chronic allograft dysfunction. Whether sirolimus directly causes proteinuria and/or mediates direct glomerular toxicity remains to be resolved and further studies are needed.

1. Rangan GK. Sirolimus-associated proteinuria and renal dysfunction. *Drug Safety* 2006; **29:** 1153–61.

Effects on the lungs. Pulmonary toxicity, including interstitial pneumonitis,[1-7] and alveolar haemorrhage,[5,8,9] has been reported in association with sirolimus. There was some suggestion in one series that the incidence of interstitial pneumonitis might be higher in patients who switched from calcineurin inhibitors to sirolimus than in those who were started on sirolimus after transplantation.[6] Possible risk factors include giving a loading dose, late use of sirolimus compared with initial therapy, and higher sirolimus dose and trough concentrations; additional risk factors include allograft dysfunction, hypervolaemia, and male gender.[7] Acute respiratory distress has been reported in a 1-year-old heart transplant recipient 3 days after starting sirolimus.[10] Pulmonary alveolar proteinosis has also been reported in a renal transplant patient 2 years after starting sirolimus; symptoms resolved markedly upon stopping sirolimus.[11]

Similar toxicity has occurred with everolimus (p.1833).

Effects on the nervous system. Posterior reversible encephalopathy syndrome (a neurotoxic condition involving oedema of the white matter in the posterior parts of the brain and characterised by headache, confusion, and visual disturbances) has been reported after use of sirolimus.[1,2]

1. Bodkin CL, Eidelman BH. Sirolimus-induced posterior reversible encephalopathy. *Neurology* 2007; **68:** 2039–40.
2. Moskowitz A, *et al.* Posterior reversible encephalopathy syndrome due to sirolimus. *Bone Marrow Transplant* 2007; **39:** 653–4.

Thrombosis. There was an apparent clustering of reports of subacute thrombosis associated with the use of the sirolimus-eluting stent soon after its marketing approval in 2003.[1] However, subsequent studies[2] and additional data from 2063 patients[3] suggest that use of the sirolimus-eluting stent is not associated with an excess risk of subacute thrombosis compared with bare-metal stents.

Interactions

Inhibitors of the cytochrome P450 isoenzyme CYP3A4, such as ketoconazole, HIV-protease inhibitors, the NNRTI delavirdine, and diltiazem may increase plasma concentrations of sirolimus. Conversely, inducers of this isoenzyme, such as nevirapine and rifampicin, may reduce plasma concentrations of sirolimus. Use of sirolimus with strong inhibitors or inducers of CYP3A4 and/or P-glycoprotein is not recommended. Grapefruit juice should not be taken with sirolimus. Ciclosporin can affect the rate and extent of sirolimus absorption and it is recommended that these drugs be given 4 hours apart. Use of sirolimus with a calcineurin inhibitor may also increase the risk of calcineurin inhibitor-induced haemolytic uraemic syndrome, thrombotic thrombocytopenic purpura, or thrombotic microangiopathy. Use of sirolimus with an ACE inhibitor may increase the risk of developing angioedema. See above for precautions about use with live vaccines.

Immunosuppressants. Concentrations of sirolimus, and area under the concentration-time curve were significantly higher when sirolimus and *ciclosporin* were given together than when the 2 drugs were given 4 hours apart,[1,2] and a synergistic effect has been suggested.[3] This effect may allow for lower doses[4] or early withdrawal[5] of ciclosporin, resulting in improved renal function and less nephrotoxicity. However, for the risk of increased thrombotic reactions see above.

Sirolimus may decrease blood concentrations of *tacrolimus*.

Pharmacokinetics

Sirolimus is rapidly absorbed after doses of the oral solution, with a time to peak concentration of about 2 hours. Absorption is variably affected by food, especially high-fat meals. Sirolimus is extensively bound to plasma proteins. It is metabolised by the cytochrome P450 isoenzyme CYP3A4. Metabolism occurs by demethylation or hydroxylation, and the majority of a dose is excreted via the faeces, with only about 2% excreted in the urine. In healthy subjects, the bioavailability of a single dose of the tablet formulation is about 27% higher than the oral solution, bioavailability of which is only about 14%. However, this difference is less marked in renal transplant recipients, and when switching between formulations, licensed product information recommends giving the same dose, with trough concentrations verified 1 to 2 weeks later. The terminal half-life in stable renal transplant patients after multiple oral doses has been reported to be about 62 hours; the half-life in men was reported to be significantly longer than in women (about 72 hours compared with about 61 hours).

◊ References.

Genetic factors. Renal transplant recipients with at least one CYP3A5*1 allele had lower exposure to sirolimus than those patients homozygous for CYP3A5*3, and patients with CYP3A5*1/*1 and *1/*3 genotypes required significantly higher sirolimus daily dosage to achieve the same blood concentrations at steady state as the *3/*3 genotypes.[1] Determination of this cytochrome P450 isoenzyme polymorphism could be useful for individualising doses of sirolimus.

Therapeutic drug monitoring. The immunosuppressive efficacy and the occurrence and severity of adverse effects of sirolimus correlate with blood concentrations.[1] There is also a good correlation between sirolimus trough concentrations and the area under the concentration-time curve (AUC); the trough concentration is therefore a useful surrogate marker for sirolimus exposure.[2] When sirolimus is used with ciclosporin, whole blood trough concentrations of sirolimus between 4 and 12 nanograms/mL are associated with protection from acute rejection episodes and adverse events. Black patients may require higher doses of sirolimus to achieve a similar exposure to non-black patients; trough concentrations in the higher end of the range are recommended to reduce the risk of rejection.[3] When ciclosporin therapy is stopped, a target trough concentration of sirolimus of about 12 to 20 nanograms/mL is recommended (see also Uses and Administration, below).

Daily monitoring of sirolimus is not necessary due to the relatively long half-life of the drug (about 60 hours). Furthermore, sirolimus concentrations are variable early after transplantation due to physiological changes from surgery and concurrent dose adjustments in other immunosuppressants. The first sample should be taken about 4 days or more after the initial loading dose, and then weekly for the first month and every 2 weeks for the second month.[3] Monitoring is also necessary after changes in the dose of sirolimus or ciclosporin, or of their relative timing.[2,3]

After the first 2 months of dose titration, routine therapeutic drug monitoring is not considered necessary in all patients, although it is considered warranted in patients receiving concurrent CYP3A4 and/or P-glycoprotein inducers or inhibitors. Monitoring may also be needed in those at high risk of rejection, those displaying signs of toxicity, or those in whom compliance is a problem.[3] Patients with liver disease, hyperlipidaemia, or leucopenia should also have their sirolimus blood concentrations determined,[2] and concentrations in children should be monitored.[3] Licensed product information states that the recommended 24-hour trough concentrations for sirolimus are based on chromatographic assay methods, and that these values are not interchangeable with immunoassay methods.

Bayesian forecasting has also been proposed as an accurate predictor of sirolimus pharmacokinetics.[4,5]

Uses and Administration

Sirolimus is a macrolide compound obtained from *Streptomyces hygroscopicus* and has potent immunosuppressant properties. Sirolimus binds to a protein (FK binding protein-12; FKBP-12; FKPB-12) and this complex inhibits the activation of the mammalian target of rapamycin (mTOR), a key regulatory kinase for cell cycle progression thus suppressing cytokine-driven T-cell proliferation.

Sirolimus is used for the prevention of graft rejection in kidney transplantation (p.1813), and is being investigated for induction of remission in some auto-immune diseases. Sirolimus-releasing stents have been developed to reduce restenosis after coronary artery stent placement. They are also used in the treatment of severe claudication and critical limb ischaemia of infrapopliteal lesions (which is the most severe form of arterial disease in the leg).

For prevention of graft rejection, sirolimus is given with ciclosporin and corticosteroids as soon as possible after transplantation. A loading dose of 6 mg is given orally, followed by a maintenance dose of 2 mg daily, 4 hours after ciclosporin. In patients 13 years of age or more who weigh less than 40 kg a loading dose of 3 mg/m^2, followed by initial maintenance doses of 1 mg/m^2 daily, is recommended. It is recommended that the dose of sirolimus should be adjusted to obtain whole blood trough concentrations of 4 to 12 nanograms/mL (by chromatographic assay), and the doses of ciclosporin and corticosteroids gradually reduced. After 2 to 3 months, ciclosporin should be gradually stopped over 4 to 8 weeks, and the dose of sirolimus adjusted to obtain trough concentrations of about 12 to 20 nanograms/mL. In the USA, ciclosporin may be continued for up to 4 months; sirolimus trough concentrations of 16 to 24 nanograms/mL have been recommended for the first year after transplantation; thereafter, the concentrations should be 12 to 20 nanograms/mL. In patients at high immunological risk (defined as black [Afro-Caribbean] patients and/or repeat renal transplant patients), sirolimus may be used with ciclosporin and corticosteroids for the first year after transplantation. The recommended loading dose is 15 mg, followed by an initial maintenance dose of 5 mg daily; adjustments thereafter are made on the basis of whole blood trough concentrations. In patients in whom ciclosporin withdrawal is unsuccessful or cannot be attempted, sirolimus should not be used for more than 3 months after transplantation.

Sirolimus has been shown to possess antifungal and antineoplastic properties. It is under investigation for gene regulation in gene therapy.

Administration. A study in renal transplant recipients judged the tablet and oral solution formulations of sirolimus to be therapeutically equivalent.[1] Licensed product information states that while 2 mg of oral solution has been shown to be clinically equivalent to 2 mg of the oral tablet formulation, and the two are hence interchangeable, it is not known whether higher doses of the oral solution are clinically equivalent to the same doses as tablets. When switching patients between formulations, it is recommended to give the same dose and verify the sirolimus trough concentrations 1 to 2 weeks later; verification of trough concentrations is also recommended when switching between different tablet strengths.

Administration in children. Sirolimus is not licensed for use in children under 13 years of age. For doses in children aged 13 years or older, and weighing under 40 kg, see Uses and Administration, above. In the UK, the *BNFC* recommends local treatment protocols be consulted for details of doses to be used in children; official guidance from NICE recommends that sirolimus be used as a component of immunosuppressive regimens in children and adolescents only if intolerance necessitates the withdrawal of a calcineurin inhibitor.[1]

Administration in hepatic impairment. Exposure to sirolimus and half-life are both increased in patients with mild to moderate hepatic impairment (Child-Pugh category A or B). UK licensed product information states that in patients with hepatic impairment, it is not necessary to modify the loading dose of sirolimus, but whole blood trough concentrations should be closely monitored in these patients. US licensed product information states that the maintenance dose should be reduced by about one-third in patients with mild to moderate hepatic impairment.

A study[1] involving 9 patients with severe hepatic impairment (Child-Pugh category C) indicated that an initial dosage reduction of about 60% followed by therapeutic drug monitoring might be suitable in these patients. For patients with severe hepatic impairment UK and US licensed product information state that the maintenance dose should be reduced by about one half.

1. Zimmerman JJ, *et al.* Pharmacokinetics of sirolimus (rapamycin) in subjects with severe hepatic impairment. *J Clin Pharmacol* 2008; **48:** 285–92.

Kaposi's sarcoma. Transplant recipients are susceptible to the development of Kaposi's sarcoma (p.675) as a result of long-term immunosuppressive therapy. In 15 renal transplant recipients with biopsy-proven Kaposi's sarcoma, therapy with ciclosporin and mycophenolate was stopped, and sirolimus started. After 1 month, cutaneous lesions had regressed in 12 patients and after 6 months biopsy specimens were negative for Kaposi's sarcoma.[1] While stopping ciclosporin or mycophenolate has led to remission of Kaposi's sarcoma,[2] sirolimus may have an antineoplastic action independent of its immunosuppressive effect.[1] In renal transplant recipients, those who received sirolimus-based therapy after ciclosporin withdrawal at month 3 had a reduced incidence of both skin and non-skin (including Kaposi's sarcoma) malignancies at 5 years after transplantation, compared with those who continued with sirolimus and ciclosporin therapy.[3]

Lymphangioleiomyomatosis. Improvements in left lung function have been noted in a patient with lymphangioleiomyomatosis treated with sirolimus after transplantation of the right lung.[1] For mention of the use of medroxyprogesterone in this rare disease, see Respiratory Disorders, p.2114.

1. Egan JJ, *et al.* Sirolimus for lymphangioleiomyomatosis lesions. *N Engl J Med* 2008; **358:** 1963–4.

Organ and tissue transplantation. Sirolimus is used for the prophylaxis of graft rejection in kidney transplantation (p.1813), initially as an adjunct to calcineurin inhibitor-based regimens. It is increasingly used for corticosteroid or calcineurin inhibitor withdrawal, although long-term data are lacking, and the safety of ciclosporin withdrawal in high-risk patients has not been adequately studied and is not recommended. Sirolimus has been investigated for liver (p.1815), heart (p.1812), pancreas (p.1816), and lung (p.1815) transplantation, although safety has not been established. In *de novo* renal transplant patients, there was an increased risk of rejection in those given sirolimus and mycophenolate and corticosteroids with an interleukin-2 receptor antibody, compared with those not given an interleukin-2 receptor antibody. In a small study of heart transplant recipients switched from standard immunosuppressive therapy with a calcineurin inhibitor, mycophenolate mofetil, and corticosteroids, to sirolimus with mycophenolate mofetil, there was an increased incidence of acute rejection; target sirolimus and mycophenolate concentrations may have been insufficient to maintain adequate immunosuppression.

Reperfusion and revascularisation procedures. Restenosis is a particular problem after percutaneous coronary revascularisation procedures (p.1181) and various drugs have been tried for its prevention. Coronary stents that elute sirolimus effectively reduce restenosis[1-8] and have been widely used. There is some suggestion that sirolimus-eluting stents may be superior to paclitaxel-eluting stents in terms of clinical outcome and rates of restenosis,[9-12] although not all studies have noted differences.[13] The risk of late stent thrombosis may be increased with drug eluting stents,[14] although the evidence is controversial,[15] and their role in complex interventions is not yet established.[16,17] Oral sirolimus may also be effective in preventing restenosis.[18-21]

Tacrolimus *(BAN, USAN, rINN)*

FK-506; FR-900506; Tacrolimús; Tacrolimusum; Takrolimus; Takrolimuusi; Tsukubaenolide. (−)-(3*S*,4*R*,5*S*,8*R*,9*E*,12*S*,14*S*,15*R*,16*S*,18*R*,19*R*,26a*S*)-8-Allyl-5,6,8,11,12,13,14,15,16,17,18,19,24,25,26,26a-hexadecahydro-5,19-dihydroxy-3-{(*E*)-2-[(1*R*,3*R*,4*R*)-4-hydroxy-3-methoxycyclohexyl]-1-methylvinyl}-14,16,-dimethoxy-4,10,12,18-tetramethyl-15,19-epoxy-3*H*-pyrido[2,1-c][1,4]oxaazacyclotricosine-1,7,20,21(4*H*,23*H*)-tetrone monohydrate.

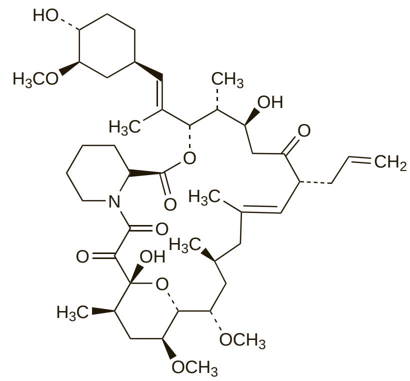
Такролимус

$C_{44}H_{69}NO_{12},H_2O$ = 822.0.

CAS — 104987-11-3 (anhydrous tacrolimus); 109581-93-3 (tacrolimus monohydrate).

ATC — D11AX14; L04AD02.

ATC Vet — QD11AX14; QL04AD02.



Adverse Effects, Treatment, and Precautions

The most common adverse effects after **systemic** use of tacrolimus include tremor, headache, paraesthesias, nausea and diarrhoea, hypertension, insomnia, and impaired renal function. Disturbances of serum electrolytes, notably hyperkalaemia, and hyperglycaemic conditions, including diabetes mellitus, occur frequently. Hyperlipidaemia, hypercholesterolaemia, and hypertriglyceridaemia are common. Anaemia, leucopenia, and thrombocytopenia also occur commonly. Other common adverse effects include mood changes, anxiety, confusion, dizziness, tinnitus, visual disturbances, peripheral neuropathies, and convulsions; constipation, dyspepsia, gastrointestinal perforation and ulceration, and gastrointestinal haemorrhage; dyspnoea, parenchymal lung disorders, pleural effusions, pharyngitis, cough, nasal congestion and inflammation; alopecia, acne, skin rashes, and pruritus; and arthralgia, muscle cramps, asthenia, febrile disorders, oedema, and liver dysfunction. Tachycardia is common; ventricular arrhythmias, cardiac arrest, heart failure, palpitations, and ECG changes are less frequent. Cardiomyopathies, including ventricular hypertrophy have also been reported; most cases have been reversible, and occurring primarily in children with tacrolimus blood concentrations much higher than the recommended maximum levels. Coagulation disorders, neutropenia, and pancytopenia have occurred, as have asthma, acute respiratory distress syndrome, hypoproteinaemia, deep limb venous thrombosis, paralytic ileus, acute and chronic pancreatitis, and haemolytic uraemic syndrome. Coma, CNS haemorrhage, encephalopathy, amnesia, and speech and language abnormalities have also been reported. There are rare reports of thrombotic thrombocytopenic purpura, hypoprothrombinaemia, and hirsutism. Toxic epidermal necrolysis, Stevens Johnson syndrome, hepatic artery thrombosis, and veno-occlusive liver disease have occurred rarely.

Tacrolimus injection is formulated with polyoxyl castor oil: anaphylactoid reactions have occurred, and appropriate means for their management should be available in patients given the injection. Use of tacrolimus should be avoided in patients hypersensitive to macrolides.

Dosage reduction may be necessary in patients with hepatic impairment. Care is also required in patients with pre-existing renal impairment, and dosage reduction may prove advisable in such patients. Monitoring of blood concentrations of tacrolimus is recommended in all patients, especially during episodes of diarrhoea as concentrations may be significantly affected. Renal and hepatic function, blood pressure, serum glucose electrolytes, haematological and cardiac function, as well as neurological and visual status, coagulation values, and plasma protein should be monitored regularly. As with other immunosuppressants, patients receiving tacrolimus are at increased risk of infection and malignancy. Intra-uterine devices should be used with caution during immunosuppressive therapy as there is an increased risk of infection. Use of live vaccines should be avoided for the same reason. Tacrolimus may affect visual or neurological function, and patients so affected should not drive or operate dangerous machinery.

Topical tacrolimus has been associated with local irritation and skin disorders including an increased incidence of herpes simplex and zoster infections; headache and 'flu-like' symptoms have also been reported. Facial flushing and skin irritation has been reported after consumption of alcohol. Exposure of the skin to sunlight should be minimised and the use of artificial sources of ultraviolet light avoided. Carcinogenicity studies in *animals* have reported an increase in the incidence of lymphoma and skin cancers associated with topical tacrolimus and rare cases of skin malignancy and lymphoma have been reported in patients (see also below).

Skin infections should be treated before starting therapy with topical tacrolimus. It should not be used in immunocompromised patients or those with conditions that might increase systemic absorption of tacrolimus. It must also not be applied to pre-malignant or malignant skin conditions; some malignant skin conditions may mimic eczema.

Breast feeding. Tacrolimus is distributed into breast milk. Tacrolimus concentrations were measured in milk from a liver transplant recipient on a dose of 100 micrograms/kg daily. The authors estimated that the infant would ingest only 0.06% (0.06 micrograms/kg daily) of the mother's weight-adjusted dose. No adverse effects were noted in the infant at 2.5 months of age.[1]

Licensed product information recommends that women should avoid breast feeding while taking tacrolimus.

1. French AE, *et al.* Milk transfer and neonatal safety of tacrolimus. *Ann Pharmacother* 2003; **37:** 815–18.

Carcinogenicity. The systemic use of tacrolimus increases the risk of malignancy.

Carcinogenicity studies in *animals* have also reported an increase in the incidence of malignancies associated with the topical calcineurin inhibitors, tacrolimus and pimecrolimus. As of December 2004 the FDA had received reports of 19 cases of lymphoma or cutaneous tumours associated with topical tacrolimus, of which 4 cases were a recurrence or aggravation of a pre-existing malignancy, and 3 other cases were confounded by other possible risk factors. At this same date, the FDA had also received reports of 10 cases of malignancy in patients treated with topical pimecrolimus, including 6 cutaneous tumours. Although the potential for systemic immunosuppression from topical use was unknown and the role of the drug in these cases was uncertain, the FDA recommended that topical calcineurin inhibitors should only be used as a second-line drug for short-term and intermittent treatment of eczema, and that they should not be used in immunocompromised patients or in children younger than 2 years of age.[1,2] Similar warnings have been issued in the European Union.[3] However, there has been some debate about the risk of malignancy associated with the topical use of these drugs, and a number of groups[4-6] have examined the evidence used by the FDA. They found that after topical application in humans the serum concentrations of these drugs were usually low or undetectable, that there was no evidence of systemic immunosuppression as measured by response to childhood immunisation and delayed hypersensitivity, no evidence of an increase in malignancy in clinical studies or compared with the general population, and that none of the reported lymphoma cases resembled the usual presentation and histology seen with systemic immunosuppression-associated lymphoma. They concluded that based on available data the risk of cancer from topical calcineurin inhibitors was theoretical and unknown. A review[7] of skin cancer risk found that there was no conclusive evidence from *rodent* studies to suggest that topical calcineurin inhibitors were associated with an increase in skin cancers, or a potentiation of UV-associated immunosuppression and carcinogenicity. There was also no evidence of an increased risk of skin cancer in human studies. In general, there seems to be agreement that long-term data are still needed to determine the carcinogenic risk, if there is any, from topical tacrolimus and pimecrolimus. Until long-term safety data are available some[8] consider that it would be prudent if topical calcineurin inhibitors were:

- not used in children under 2 years of age
- not used continuously for more than 6 weeks, with an application-free period of up to 2 weeks
- avoided in immunocompromised patients
- avoided in patients with neoplasia
- avoided in those with skin disorders liable to lead to increased systemic absorption

Patients should also be encouraged to use a broad-spectrum sunscreen daily on all sunlight-exposed skin.

Effects on the blood. Severe anaemia due to selective depression of erythropoiesis in a patient given tacrolimus resolved when tacrolimus was replaced with ciclosporin.[1] More generalised bone marrow suppression,[2] post-transplant thrombotic microangiopathy,[3] and red cell aplasia[4] have also been reported. Hypoplasia occurring in a liver transplant recipient,[5] was characterised by a slow but complete recovery after substituting tacrolimus with ciclosporin.

Effects on carbohydrate metabolism. The development of diabetes mellitus after solid organ transplantation is common,[1,2] which may be attributed to the diabetogenic effects of immunosuppressive drugs. Incidence has appeared to be increased in both adult[3] and paediatric[4] renal transplant recipients given tacrolimus. However, a retrospective review[2] found no significant difference in incidence between patients receiving tacrolimus or ciclosporin but found instead a correlation between the absence of an antiproliferative agent and the development of diabetes. A retrospective study of liver transplant recipients found that, although those given tacrolimus had a greater incidence of diabetes mellitus, hepatitis C infection was the only factor predictive of its development.[1] In contrast, a meta-analysis[5] found the incidence of new-onset diabetes mellitus (NODM) to be significantly higher among patients receiving tacrolimus compared with those receiving ciclosporin after solid organ transplantation. An observational study[6] confirmed this finding, and found it to be unrelated to corticosteroid dosage, although relatively high doses of corticosteroids were used across the study. A retrospective study[7] found tacrolimus to be significantly more diabetogenic than ciclosporin, even when corticosteroid dosing was lower with tacrolimus. An analysis of data for 8839 patients[8] found the risk of NODM to be greatest with high tacrolimus doses, but the increased risk versus ciclosporin was sustained even with lower tacrolimus doses. Higher corticosteroid doses potentiated the diabetogenic effect of tacrolimus, but even the lowest dosage group for tacrolimus and corticosteroids had higher rates of NODM than all ciclosporin groups; there was no association between corticosteroid dose and NODM for any dosage of ciclosporin. In a small, retrospective study,[9] conversion from tacrolimus to ciclosporin resulted in marked improvement of glucose metabolism, and even reversal of diabetes mellitus in a significant proportion of patients.

Effects on the cardiovascular system. Hypertrophic cardiomyopathy, and in some cases heart failure, has been described in paediatric patients receiving tacrolimus after organ grafting (small bowel or liver).[1] Symptoms largely resolved on stopping or reducing dosage. A similar case had been found *post mortem* in an adult,[2] and the UK CSM[3] was aware of 29 reported cases worldwide as of July 1995. Echocardiographic monitoring of patients receiving tacrolimus has been recommended, with dose reduction or withdrawal in those who developed hypertrophic changes.[3] However, echocardiographic abnormalities may be quite common after orthotopic liver transplantation in adults, with no obvious relationship to the use of tacrolimus,[4] and a retrospective analysis concluded that tacrolimus is not a risk factor for hypertrophic cardiomyopathy in adult transplant recipients.[5]

Severe hypertension was documented in 5 out of 10 paediatric patients who received intravenous tacrolimus after renal transplant surgery. All patients responded to intravenous labetalol. By contrast none of 11 children who received ciclosporin at the same institution developed hypertension.[6] However, a review[7] concluded that tacrolimus causes less hypertension than ciclosporin, resulting in a better cardiovascular risk profile in renal transplant recipients, and possibly ultimately prolonging graft survival.

Effects on the kidneys. A comparison in patients who had undergone liver transplantation suggested that nephrotoxicity was more of a problem in those receiving tacrolimus than in those given a ciclosporin-based regimen.[1] In particular intravenous tacrolimus during the first week after transplantation was associated with acute renal failure in 4 of 20 patients. Furthermore, on follow-up for 1 year, GFR was somewhat lower in the tacrolimus-treated group. A small study compared GFR and effective renal plasma flow (ERPF), at various stages after transplantation, in renal and liver transplant recipients given tacrolimus.[2] In renal transplant patients, the GFR, although lower than normal, was increased after transplant, and remained stable over 3 months. ERPF, however, was significantly lower at 3 months. In liver transplant recipients, despite being lower than normal, GFR and ERPF were unchanged at 1 year post-transplant.

2. Agarwala S, *et al.* Evaluation of renal function in transplant patients on tacrolimus therapy. *J Clin Pharmacol* 2002; **42:** 798–805.

Effects on the nervous system. Although many of the symptoms of neurotoxicity induced by tacrolimus are similar to those of ciclosporin (p.1824), some symptoms such as headaches, tremor, and sleep disturbances, appear to be more prevalent with tacrolimus, and the incidence of tacrolimus-induced neurotoxicity appears to be higher in liver transplant recipients.[1]

Severe peripheral neuropathy together with signs of cerebral dysfunction has been reported in 2 patients receiving tacrolimus.[2] Among other central effects, tacrolimus has also been associated with speech disorders, including severe dysarthria and mutism in 1 patient;[3] some degree of speech dysfunction, in the form of an apparent Norwegian accent, appeared to be permanent in this case.

Encephalopathy, sometimes occurring within the reversible posterior leukoencephalopathy syndrome (RPLS), has been reported with use of tacrolimus.[4-8] Presenting symptoms included acute severe headache, seizures, cortical blindness, disorientation, and hypertension.

Miller Fisher syndrome, a variant of Guillain-Barré syndrome, has been attributed to tacrolimus use in a liver transplant recipient.[9] Clinical manifestations included ataxia, ophthalmoplegia, and areflexia.

9. Kaushik P, *et al.* Miller Fisher variant of Guillain-Barré syndrome requiring a cardiac pacemaker in a patient on tacrolimus after liver transplantation. *Ann Pharmacother* 2005; **39:** 1124–7.

Effects on skeletal muscle. Severe acute rhabdomyolysis, leading to fatal acute renal failure, developed in an 18-month-old child given tacrolimus after bone marrow transplantation.[1] Seizures, severe rhabdomyolysis, and acute renal failure were reported in a renal transplant patient taking tacrolimus and a monoclonal antibody.[2]

1. Hibi S, *et al.* Severe rhabdomyolysis associated with tacrolimus. *Lancet* 1995; **346:** 702.
2. Fontana I, *et al.* Severe rhabdomyolysis and acute renal failure in a kidney transplant patient treated with tacrolimus and chimaeric CD25 monoclonal antibody. *Transplant Proc* 2004; **36:** 711–2.

Effects on the skin. Three children developed lentigines (small pigmented macules) while receiving long-term (9 months to 4 years) treatment with topical tacrolimus 0.1% for eczema. The lesions developed primarily in the areas where tacrolimus had been applied. Despite withdrawal of tacrolimus, the lentigines still persisted at review 6 to 18 months later. The authors noted that use of tacrolimus was outside the product's licensed indications, and that the clinical implications of their findings remained uncertain.[1]

1. Hickey JR, *et al.* Does topical tacrolimus induce lentigines in children with atopic dermatitis? A report of three cases. *Br J Dermatol* 2005; **152:** 152–4.

Hepatitis. For the suggestion that dosage requirements of tacrolimus may be reduced in children with hepatitis C see Administration, below.

Infection. For a report of an increased incidence of CMV disease in renal transplant recipients given a regimen combining tacrolimus and mycophenolate mofetil see under Interactions, p.1837.

Overdosage. A report[1] of 12 cases of acute overdose with tacrolimus described overdoses of up to 30 times the prescribed dose. Three patients were asymptomatic, while 7 showed mild transient renal and hepatic impairment, nausea, and mild hand tremors. One patient suffered renal failure, histoplasmosis, and sepsis 48 hours after admission for the overdose. The outcome was unknown in one patient. All 8 symptomatic patients recovered when tacrolimus concentrations returned to normal. No specific treatment regimen has been recommended, but patients have been treated with gastric lavage, oral activated charcoal, and phenytoin. The latter is used both to prevent seizures and to enhance tacrolimus metabolism by stimulation of cytochrome P450. Patients should be closely monitored for known signs and symptoms of tacrolimus toxicity. In a further series of 5 cases,[2] acute ingestion of tacrolimus was reported to be well tolerated, and adequately managed with conservative treatment.

2. Mrvos R, *et al.* Tacrolimus (FK 506) overdose: a report of five cases. *J Toxicol Clin Toxicol* 1997; **35:** 395–9.

Porphyria. Data are limited on the use of tacrolimus in patients with porphyria. There has been a report of a patient with acute intermittent porphyria given tacrolimus for 5 days before renal transplantation, and maintenance tacrolimus post-transplantation, without exacerbation of symptoms.[1]

1. Barone GW, *et al.* The tolerability of newer immunosuppressive medications in a patient with acute intermittent porphyria. *J Clin Pharmacol* 2001; **41:** 113–5.

Pregnancy. Tacrolimus crosses the placenta. Licensed product information states that, although *systemic* tacrolimus has shown abortifacient and teratogenic properties in *animal* studies, limited data in humans show no evidence of an increased risk of adverse effects on the course and outcome of pregnancy compared with other immunosuppressants. However, use of tacrolimus has been associated with neonatal hyperkalaemia, which appears to normalise spontaneously, and neonatal renal dysfunction; the neonate should be monitored for potential adverse effects.

There are no adequate data from the use of *topical* tacrolimus in pregnancy.

Interactions

Increased nephrotoxicity may result if tacrolimus is given with other potentially nephrotoxic drugs: use with ciclosporin should be avoided for this reason. Similarly, concurrent use with neurotoxic drugs should be avoided. High potassium intake or potassium-sparing diuretics should also be avoided in patients receiving tacrolimus.

Tacrolimus is metabolised by the cytochrome P450 isoenzyme CYP3A4, and drugs that inhibit this enzyme system, such as azole antifungals, bromocriptine, calcium-channel blockers, cimetidine, some corticosteroids, ciclosporin, danazol, HIV-protease inhibitors, the NNRTI delavirdine, macrolide antibacterials, and metoclopramide, may produce increased blood concentrations of tacrolimus. The metabolism of tacrolimus may also be inhibited by grapefruit juice and they should not be taken together. Equally, inducers of this enzyme system (such as carbamazepine, nevirapine, phenobarbital, phenytoin, rifampicin, and St John's wort) may reduce blood concentrations of tacrolimus. Sirolimus can also decrease blood concentrations of tacrolimus. For a warning concerning the use of live vaccines in patients receiving immunosuppressants see Adverse Effects and Precautions, above.

Facial flushing or skin irritation may occur if alcohol is consumed by patients using topical tacrolimus.

◊ The cytochrome P450 isoenzyme subfamily CYP3A, and P-glycoprotein, are involved in the pharmacokinetic pathways of tacrolimus.[1] Drugs known to interact with these systems will probably affect tacrolimus concentrations, primarily by influencing oral bioavailability rather than clearance.[2] A study[3] *in vitro* found that metabolism of tacrolimus by CYP3A in human liver microsomes was inhibited by bromocriptine, corticosterone, dexamethasone, ergotamine, erythromycin, ethinylestradiol, josamycin, ketoconazole, miconazole, midazolam, nifedipine, omeprazole, tamoxifen, troleandomycin, and verapamil. No effect on tacrolimus metabolism was seen with aspirin, amphotericin B, captopril, cefotaxime, ciprofloxacin, diclofenac, diltiazem, doxycycline, furosemide, glibenclamide, imipramine, lidocaine, paracetamol, prednisolone, progesterone, ranitidine, sulfamethoxazole, trimethoprim, or vancomycin.

3. Christians U, *et al.* Identification of drugs inhibiting the in vitro metabolism of tacrolimus by human liver microsomes. *Br J Clin Pharmacol* 1996; **41:** 187–90.

Antibacterials. Increased concentrations of tacrolimus in plasma have been reported with *erythromycin*;[1] the interaction was accompanied by some evidence of nephrotoxicity. A similar interaction has been reported between tacrolimus and *clarithromycin*.[2,3] For reference to the effects of macrolides on tacrolimus metabolism *in vitro* see above.

Treatment with *rifampicin* has been found to substantially decrease tacrolimus concentrations.[4,5] A pharmacokinetic study found that rifampicin induces metabolism of tacrolimus in both the liver and intestine, probably by induction of the cytochrome P450 isoenzyme subfamily CYP3A and P-glycoprotein.[6] Both *metronidazole*[7,8] and *chloramphenicol*[9,10] increased the blood concentrations of tacrolimus. This is probably due to inhibition of metabolism, and dosage reduction of the immunosuppressant may be necessary when either drug is given with tacrolimus. A pharmacokinetic study[11] found that *levofloxacin* partially inhibited the metabolism of tacrolimus, and recommended that drug concentrations be monitored when these 2 drugs are used together.

Plasma concentrations of tacrolimus are also increased by *quinupristin/dalfopristin*.

Antidepressants. Tacrolimus trough concentrations reduced sharply in a patient who took *St John's wort*, and returned to previous levels on stopping the St John's wort.[1] St John's wort induces cytochrome P450 isoenzyme CYP3A4, enhancing the metabolism of tacrolimus. A pharmacokinetic study[2] confirmed this, finding an increase in tacrolimus clearance; the authors concluded that potential consequences of this interaction in transplant recipients are rejection and graft loss.

Antiepileptics. For the effect of tacrolimus on *phenytoin*, see Immunosuppressants in Phenytoin, p.500.

Antifungals. Elevated plasma-tacrolimus concentrations have been reported in patients given *clotrimazole*,[1] *fluconazole*,[2] or *voriconazole*[3]; a reduction in the dose of tacrolimus was likely to be necessary if it were given with an azole antifungal. A study involving tacrolimus and *ketoconazole* suggested that an increase in the oral bioavailability of tacrolimus from a mean of 14 to 30% when given with the azole was probably due to decreased cytochrome P450 isoenzyme CYP3A4 metabolism in the gut wall, or improved absorption due to inhibition of P-glycoprotein mediated efflux, rather than an effect on hepatic metabolism.[4] Similarly, a 50% reduction in tacrolimus dosage was found to be necessary when the drug was given with *itraconazole*.[5] It has been suggested that the interaction could be exploited to reduce the cost of immunosuppressant regimens.[6] In another study of itraconazole with tacrolimus,[7] 1 patient required a 20% increase in the dose of tacrolimus, 3 patients required no dose adjustment, and 5 patients required tacrolimus dose reductions, ranging from 20 to 76.5%. The authors concluded that the magnitude of the dose reduction is dependent on the initial tacrolimus serum concentration and the final target concentration.

Antivirals. Ten- to fiftyfold reductions in tacrolimus dosage were necessary to maintain therapeutic tacrolimus trough concentrations, in 6 HIV-positive liver transplant recipients receiving tacrolimus-based immunosuppressive therapy, when antiretroviral therapy including an HIV-protease inhibitor was started postoperatively.[1] This effect was more pronounced with *nelfinavir* than *indinavir.* In contrast, 4 HIV-positive kidney transplant recipients received antiretroviral therapy without protease inhibitors, and required only conventional doses of tacrolimus. The authors caution that some protease inhibitors can act as both inducers and inhibitors of the cytochrome P450 isoenzyme CYP3A4. While the inhibitory effect appears to predominate when given with tacrolimus, if the protease inhibitor is withdrawn suddenly the CYP3A4 system may remain induced, and a sudden decrease in tacrolimus concentration may occur; this had occurred in one case. For this reason, they concluded that great caution and frequent tacrolimus monitoring are necessary when protease inhibitors are introduced or withdrawn in transplant recipients receiving tacrolimus.

Dramatic increases in tacrolimus blood concentrations have been reported after addition of *lopinavir/ritonavir* in HIV-positive liver transplant recipients.[2-4] Some patients did not need further tacrolimus for up to 3 weeks, even with normal hepatic function; with hepatic dysfunction, 1 mg of tacrolimus provided a therapeutic concentration for up to 5 weeks, and in one patient the tacrolimus concentration increased for the next few days with the introduction of lopinavir/ritonavir without any additional dose of tacrolimus. The authors recommended a pre-emptive decrease in tacrolimus dose by at least 50% one day before starting therapy with lopinavir/ritonavir, and withholding tacrolimus for the next few days; therapy should then be guided by therapeutic drug monitoring of tacrolimus blood concentrations.[3] The usual dose of tacrolimus while a patient is on lopinavir/ritonavir is expected to be about 0.5 to 1 mg weekly.[2,3] In contrast, *efavirenz* did not appreciably affect tacrolimus pharmacokinetics.[4]

Calcium-channel blockers. Dosage requirements for tacrolimus were substantially reduced in 22 liver graft recipients who also received *nifedipine*, compared with 28 patients given tacrolimus alone, in a 1-year retrospective study.[1]

Tacrolimus toxicity has been reported in a liver transplant patient shortly after starting *diltiazem*.[2]

2. Hebert MF, Lam AY. Diltiazem increases tacrolimus concentrations. *Ann Pharmacother* 1999; **33:** 680–2.

Danazol. Nephrotoxicity and tremors associated with elevated concentrations of tacrolimus developed in a patient given danazol with the immunosuppressant.[1] The effect might have been due to inhibition of the metabolism of tacrolimus.

1. Shapiro R, *et al.* FK 506 interaction with danazol. *Lancet* 1993; **341:** 1344–5.

Deoxyschizandrin. Mean blood concentrations of tacrolimus in 12 healthy subjects rose from 22.2 to 66.4 nanograms/mL after they had received 13 days of treatment with SchE (*Hezheng Pharmaceutical Company, China*), an extract of *Schisandra sphenanthera* containing amongst other ingredients deoxyschizandrin.[1] During the study the area under the concentration-time curve (AUC) of tacrolimus also rose by 164.2% while oral clearance fell by 49%. It was suggested that constituents of *Schisandra sphenanthera* may act as inhibitors of the cytochrome P450 isoenzyme CYP3A4 and/or P-glycoprotein.

1. Xin H-W, *et al.* Effects of *Schisandra sphenanthera* extract on the pharmacokinetics of tacrolimus in healthy volunteers. *Br J Clin Pharmacol* 2007; **64:** 469–75.

Gastrointestinal drugs. In 2 renal transplant recipients, tacrolimus trough concentrations increased markedly after introduction of *lansoprazole* and returned to normal after it was stopped.[1,2] One of the patients was later given *rabeprazole* with no effect on tacrolimus concentration.[2] The same effects were apparent in a study of healthy subjects,[3] with lansoprazole increasing the concentration and decreasing the clearance of tacrolimus, but the degree of interaction was found to depend, at least partly, upon the genetic status of the patients. The authors supposed that certain ethnic groups might be at higher risk for this interaction. In contrast, rabeprazole appears less affected by genotypic status, and had minimal effect on tacrolimus pharmacokinetics; the authors considered it a safer proton pump inhibitor than lansoprazole for those with cytochrome P450 isoenzyme CYP2C19 gene mutation who were receiving tacrolimus. An *in-vitro* study suggested that omeprazole inhibited the metabolism of tacrolimus.[4] Despite a study reporting no clinically relevant interaction between omeprazole and tacrolimus in renal transplant recipients,[5] increased tacrolimus concentrations were reported when a paediatric liver transplant patient was started on omeprazole.[6]

Immunosuppressants. *Sirolimus* may decrease blood concentrations of tacrolimus; in stable renal transplant recipients given both drugs, mean exposure and trough concentrations of tacrolimus decreased by about 30% relative to tacrolimus alone. Tacrolimus may inhibit *ciclosporin* metabolism *in vitro*, with the possibility of increased nephrotoxicity (see under Ciclosporin, p.1828). Tacrolimus may also increase concentrations of mycophenolic acid, a metabolite of *mycophenolate mofetil* (see under Mycophenolate Mofetil, p.1837), and the risk of infection may be increased if used together.

Pharmacokinetics

Absorption of tacrolimus after oral doses is reported to be erratic. Oral bioavailability varies very widely; the mean value is in the range of 20 to 25%. The rate and extent of absorption of tacrolimus is decreased by the presence of food, with the effect most pronounced after a high-fat meal. There is little or no systemic exposure to tacrolimus after topical use (but see Absorption, below). After intravenous doses it is widely distributed to the tissues; it is extensively bound to erythrocytes in the blood, and variations in red cell binding account for much of the variability in pharmacokinetics. The portion in plasma is about 99% bound to plasma proteins. Tacrolimus is extensively metabolised in the liver, principally by cytochrome P450 isoenzyme CYP3A4, and excreted, primarily in bile, almost entirely as metabolites. Considerable metabolism also occurs in the intestinal wall. Whole-blood elimination half-life has been reported to average 43 hours in healthy subjects, and to range from about 12 to 16 hours in transplant patients.

Absorption. A single topical application of a 0.1% tacrolimus ointment to an infant for the treatment of chronic dermatitis, resulted in high serum-tacrolimus concentrations (24 nanograms/mL). Tacrolimus levels decreased over 7 days, after which another smaller, single application of 0.03% tacrolimus ointment again resulted in high serum concentrations. The authors cautioned against its use in young children and diseases with decreased skin barrier function.[1] In another report,[2] elevated blood tacrolimus concentrations were seen after application of 0.1% tacrolimus ointment to a large area of the body of a patient with erythroderma; again, caution in conditions where the skin barrier is disrupted was advised.

2. Teshima D, *et al.* Increased topical tacrolimus absorption in generalized leukemic erythroderma. *Ann Pharmacother* 2003; **37:** 1444–7.

Bioavailability. Bioavailability of tacrolimus appears to be influenced by the type and timing of meals. Food, particularly high-fat meals, significantly reduced bioavailability, compared with the fasting state.[1] Ingestion of tacrolimus up to 1.5 hours after a meal also considerably reduced absorption.[2] UK licensed product information states that tacrolimus should be taken on an empty stomach, or at least 1 hour before or 2 to 3 hours after a meal, to achieve maximal absorption. Gastrointestinal metabolism of tacrolimus is thought to be extensive, significantly affecting its bioavailability,[3] and differences in this metabolism may account for apparent differences in availability according to ethnic origin.[4]

Genetic factors. Renal transplant recipients homozygous for CYP3A5*3 required lower doses to reach target trough concentrations of tacrolimus compared with CYP3A5*1 allele carriers;[1] the latter group can be expected to have a tacrolimus clearance 25 to 45% greater than that of homozygotes.[2] Determination of the cytochrome P450 isoenzyme genotype before transplantation may identify patients at risk for underimmunosuppression or toxicity.

Therapeutic drug monitoring. There is a good correlation between tacrolimus trough concentrations and systemic exposure, and analysis at other time points is not considered to offer any advantage.[1] However, since tacrolimus concentrations appear to be generally higher in the morning than the evening, some have suggested that the morning might be the best time for therapeutic drug monitoring.[2]

Microparticle enzyme immunoassay (MEIA) and enzyme-linked immunosorbent assay (ELISA) have both been used to measure tacrolimus whole blood concentrations. A study[3] of liver transplant recipients found that increasing trough tacrolimus concentrations, as measured by the ELISA, correlated with decreasing risk of acute rejection, but increasing risk of nephrotoxicity. The authors suggested a trough blood concentration of less than 15 nanograms/mL to minimise nephrotoxicity. While several studies have shown that adverse effects are more closely correlated with tacrolimus concentrations than with dose, the correlation between concentrations and allograft rejection has not been established. There is some suggestion that measuring the unbound concentration of tacrolimus may be a better correlate for rejection than whole blood concentrations.[4]

Licensed product information states that blood trough concentrations of tacrolimus should be monitored during the post-transplantation period; blood should be drawn about 12 hours after dosing, just before the next dose. Samples which are not analysed immediately should be stored at room temperature or in a refrigerator and assayed within 7 days; if samples are to be kept longer they may be frozen at –20° for up to 12 months. The frequency of monitoring is based on clinical need; about twice-weekly during the early post-transplant period is recommended, followed by periodic monitoring during maintenance therapy. Trough concentrations should also be monitored after dose adjustment, although it may take several days before changes become apparent. Monitoring is also recommended after changes in the immunosuppressive regimen, or when other drugs are given which may alter tacrolimus blood concentrations. The majority of patients can be successfully managed if blood concentrations are maintained below 20 nanograms/mL. In practice, in the early post-transplant period, whole blood trough concentrations have generally been in the range of 5 to 20 nanograms/mL in liver transplant recipients, and 10 to 20 nanograms/mL in kidney and heart transplant recipients. During maintenance therapy, blood concentrations have generally been between 5 to 15 nanograms/mL in liver, kidney, and heart transplant patients.

Bayesian forecasting has also been used.[5]

UK licensed product information states that the relationship between tacrolimus trough concentrations and systemic exposure is similar for the standard formulation (*Prograf, Astellas*) and the prolonged-release formulation (*Advagraf, Astellas*).

Uses and Administration

Tacrolimus is a potent macrolide (macrolactam) immunosuppressant derived from *Streptomyces tsukubaensis*, and has actions similar to those of ciclosporin (see p.1830). Tacrolimus binds to an intracellular protein, FKBP-12, and then forms a complex with calcium, calmodulin, and calcineurin, which inhibits the activity of calcineurin. This interferes with the production of lymphokines such as interleukin-2 and inhibits T-lymphocyte activation, resulting in immunosuppression.

Tacrolimus is used to prevent or manage rejection in patients receiving organ transplants, as indicated by the cross-references given in Organ and Tissue Transplantation, below. Tacrolimus has been tried in a few patients with refractory auto-immune or immune-mediated disorders; in some countries it is licensed for use in myasthenia gravis, in rheumatoid arthritis that is unresponsive to conventional therapy, and in lupus nephritis where corticosteroids are ineffective or contra-indicated. Tacrolimus is also applied topically in the management of moderate to severe atopic eczema. Tacrolimus-releasing stents have been developed to reduce restenosis after coronary artery stent placement.

UK licensed product information recommends that oral tacrolimus should be taken on an empty stomach or at least 1 hour before or 2 to 3 hours after a meal, to achieve maximum absorption.

For **transplantation**, in adult patients in the UK, the initial ***oral*** daily doses, to be given in 2 divided doses, are:

- *liver* transplantation: 100 to 200 micrograms/kg, starting about 12 hours after completion of surgery
- *kidney* transplantation: 200 to 300 micrograms/kg, starting within 24 hours of completion of surgery
- *heart* transplantation: 75 micrograms/kg, after antibody induction, and within 5 days of completion of surgery, and when the patient is stable

  Alternatively, tacrolimus has been given orally within 12 hours of transplantation, in patients without other organ dysfunction, at an initial oral dose of 2 to 4 mg daily, with mycophenolate mofetil and corticosteroids, or with sirolimus and corticosteroids

If the patient's condition does not permit oral use, therapy may be started ***intravenously***, by continuous 24-hour infusion; suggested initial adult daily doses are:

- *liver* transplantation: 10 to 50 micrograms/kg
- *kidney* transplantation: 50 to 100 micrograms/kg
- *heart* transplantation: 10 to 20 micrograms/kg

For rejection therapy, increased tacrolimus doses, supplemental corticosteroid therapy, and short courses of monoclonal or polyclonal antibodies have been used. For conversion to tacrolimus from another immunosuppressant, in liver and kidney transplant recipients treatment should begin with the initial oral dose recommended for primary immunosuppression. For heart transplant patients converted to tacrolimus, an initial oral dose of 150 micrograms/kg daily, in 2 divided doses, is recommended. UK dose recommendations for rejection therapy in other allografts are based on limited data. The following initial ***oral*** daily doses of tacrolimus have been used:

- *lung* transplantation: 100 to 150 micrograms/kg
- *pancreatic* transplantation: 200 micrograms/kg
- *intestinal* transplantation: 300 micrograms/kg

In the USA, the following initial ***oral*** daily doses, given in 2 divided doses, are recommended for adult patients:

- *liver* transplantation: 100 to 150 micrograms/kg, starting about 6 hours after transplantation
- *kidney* transplantation: 200 micrograms/kg, starting within 24 hours of transplantation, but delayed if necessary until renal function has recovered
- *heart* transplantation: 75 micrograms/kg, starting no sooner than 6 hours after transplantation

For most transplant patients, initial oral therapy is recommended. If ***intravenous*** tacrolimus therapy is needed, the recommended starting daily doses, to be given as a continuous infusion, are:

- *liver* transplantation: 30 to 50 micrograms/kg
- *kidney* transplantation: 30 to 50 micrograms/kg
- *heart* transplantation: 10 micrograms/kg

Tacrolimus doses are usually reduced in the post-transplant period; in some cases other immunosuppressant therapy can be stopped, leading to tacrolimus monotherapy or tacrolimus-based dual therapy. Maintenance dosage should be adjusted according to whole-blood trough concentrations in individual patients: it is suggested that most patients can be satisfactorily maintained at whole-blood concentrations below 20 nanograms/mL. (see Therapeutic Drug Monitoring, above)

Prolonged-release capsules of tacrolimus are also available in some countries for the prevention of rejection in adult liver or kidney transplantation, and the treatment of allograft rejection. Patients maintained on the twice-daily standard formulation are converted to once daily prolonged-release capsules at the same total daily dose; the prolonged-release formulation should be given in the morning, and tacrolimus trough concentrations should be monitored to maintain similar systemic exposure.

For doses used in paediatric transplant recipients, see Administration in Children, below.

For the treatment of **atopic eczema**, where conventional therapies are ineffective or unsuitable, tacrolimus may be applied twice daily as a 0.03 or 0.1% ointment; an attempt should be made to use the lower strength or reduce the frequency of application when possible. Either strength may be used in adults; for treatment in children, see Administration in Children, below. Treatment should be continued only until resolution of signs and symptoms. UK licensed product information recommends that if no signs of improvement are seen after 2 weeks of treatment, further treatment options should be considered; in the USA, if clinical manifestations do not improve within 6 weeks, diagnosis of atopic eczema should be confirmed through re-examination.

Administration. The mean dose of tacrolimus required to produce a standard trough concentration of 10 to 15 nanograms/mL was reported to be 96% higher in 7 black renal graft recipients than in 20 such patients of white or Asian descent.[1] (For mention of the effect of ethnicity on the bioavailability of tacrolimus see under Pharmacokinetics, above.)

Children generally require relatively higher doses than adults to achieve the same blood concentrations (see Administration in Children, below). There is limited evidence that children with hepatitis C required on average one-third of the dose of tacrolimus needed by children without the virus.[2]

Administration in children. For **transplantation** in paediatric patients in the UK, tacrolimus is given in the following initial **oral** daily doses, in 2 divided doses:

- *liver* transplantation: 300 micrograms/kg, starting about 12 hours after completion of surgery
- *kidney* transplantation: 300 micrograms/kg, starting within 24 hours of completion of surgery; a lower dose of 200 micrograms/kg has been used in adolescents to prevent very high trough concentrations
- *heart* transplantation, *after antibody induction*: 100 to 300 micrograms/kg

If the patient's condition does not allow for oral use, therapy may be started ***intravenously***, by continuous 24-hour infusion; intravenous therapy may be given for up to 7 days, but should be converted to oral therapy as soon as clinically possible. Suggested daily doses are:

- *liver* transplantation: 50 micrograms/kg
- *kidney* transplantation: 75 to 100 micrograms/kg

For *heart* transplantation *without antibody induction*, patients may be started on intravenous doses of 30 to 50 micrograms/kg daily, as a continuous 24-hour infusion. The first oral dose should be started 8 to 12 hours after stopping intravenous infusion, at a dose of 300 micrograms/kg daily, given in 2 divided doses.

For rejection therapy after *liver* and *kidney* transplantation, treatment is as for adults (see Uses and Administration, above). For paediatric *heart* transplant patients converted to tacrolimus, an initial oral dose of 200 to 300 micrograms/kg daily, in 2 divided doses, is recommended.

In the USA, the following ***oral*** daily doses, given in 2 divided doses, are recommended for children:

- *liver* transplantation: 150 to 200 micrograms/kg, starting about 6 hours after transplantation

Intravenous doses are as for adults (see Uses and Administration, above).

Doses are adjusted according to whole-blood trough concentrations (see Therapeutic Drug Monitoring, above); children generally require doses per kg 1⁄ to 2 times higher than adults to achieve the same concentrations.

For the treatment of **atopic eczema**, where conventional therapies are ineffective or unsuitable, the following treatment schedules have been recommended in children:

- 2 to 16 years: apply 0.03% ointment thinly twice daily, for up to 3 weeks, then reduce to once daily until lesion clears. The 0.1% ointment is not licensed for use in children under 16, although it has been used (see Eczema, below).

  For reference to the development of lentigines in children given long-term treatment with the higher strength preparation see Effects on the Skin under Adverse Effects, above
- 16 years and older: as for adults (see Uses and Administration, above)

Treatment duration is as for adults (see Uses and Administration, above).

Eczema. Topical tacrolimus has been found to be safe and effective[1-3] for short-term use in the treatment of moderate to severe atopic eczema (p.1579). In adult patients, the efficacy of 0.1% tacrolimus ointment was similar to that of 0.1% hydrocortisone butyrate ointment in one study[4] and more effective than a combination of 0.1% hydrocortisone butyrate ointment (applied to the trunk and extremities) and 1% hydrocortisone acetate ointment (applied to the head and neck) in another study.[5] In paediatric patients 2 to 15 years of age,[6,7] both 0.03 and 0.1% tacrolimus were significantly more effective than 1% hydrocortisone acetate ointment. In 18 of 19 patients with facial atopic eczema resistant to 0.03% tacrolimus ointment,[8] there was significant improvement upon application of a 0.03% lotion formulation, and 6 patients were positive to a patch test for white petrolatum, an ingredient of the commercial ointment. A meta-analysis concluded that topical tacrolimus 0.1% was as effective as potent topical corticosteroids and more effective than mild topical corticosteroids for the treatment of eczema; however, tacrolimus was significantly more likely to cause skin burning than corticosteroids.[9]

Results from a small, open-label study suggest that long-term intermittent use of tacrolimus ointment may reverse the skin atrophy induced by topical corticosteroids.[10] In another study,[11] adult and paediatric patients (2 to 15 years of age) with atopic eczema were treated continuously or intermittently with tacrolimus 0.1% ointment for up to 4 years; almost 60% of patients were evaluated for at least 2 years and about 38% for at least 3 years. The majority of patients received tacrolimus monotherapy, although some used topical corticosteroids at some point. There was no indication of an increased risk of adverse effects with the long-term use of tacrolimus, nor was there an indication of an increased risk for any cutaneous infection with increased duration of exposure to tacrolimus. In general, however, long-term use of topical tacrolimus should be avoided because of concerns about potential carcinogenicity (see under Adverse Effects, above).

Encephalitis. Compared with historical untreated controls, 7 patients with Rasmussen encephalitis (a progressive neurological disorder thought to have an auto-immune origin) had a superior outcome in terms of neurological function and progression rate of cerebral hemiatrophy after treatment with tacrolimus, but no better seizure outcome.[1] The control patients had more severe disease, but since only 1 patient on tacrolimus showed a cognitive decline, and none became eligible for hemispherectomy, the authors concluded prospective studies would be useful.

1. Bien CG, *et al.* An open study of tacrolimus therapy in Rasmussen encephalitis. *Neurology* 2004; **62:** 2106–9.

Glomerular kidney disease. Tacrolimus has been reported[1-5] to be effective in inducing remission in patients with glomerular kidney disease (p.1504); it has been used as monotherapy from first presentation, as well as in patients refractory to standard therapy, and in those with corticosteroid-dependent disease. However, a small, longitudinal study[6] in children with severe corticosteroid-dependent nephrotic syndrome given tacrolimus after inadequate response to ciclosporin, reported no better management of disease with tacrolimus, although it was beneficial for some children.

Hepatitis. In auto-immune chronic active hepatitis (p.1501), some evidence suggests that tacrolimus may offer an alternative therapy when corticosteroids alone or with azathioprine do not suffice.

Ichthyosis. For mention of the use of tacrolimus in ichthyosis see p.1580.

Inflammatory bowel disease. There are reports of response to tacrolimus in patients with inflammatory bowel disease (IBD; p.1697). Tacrolimus has been given orally,[1-4] intravenously,[1] or topically,[5,6] in the treatment of ulcerative colitis[1,3,4] and Crohn's disease,[1-3,5,6] refractory to standard therapy. A systematic review[7] of 23 reports of tacrolimus use in 286 patients concluded that oral tacrolimus was a reasonable and effective alternative for fistulising Crohn's disease, although the evidence base was poor and comparative studies with infliximab were needed. Tacrolimus was also a possible alternative in IBD cases unresponsive to corticosteroids. Intravenous use was not deemed to confer any advantage over oral dosage; topical tacrolimus might be an option in certain cases.

Myasthenia gravis. Tacrolimus has been reported to be effective in the management of myasthenia gravis (p.629) in patients resistant to conventional therapy, or for whom standard therapy is contra-indicated.[1,2] In an open-label study, 79 patients with myasthenia gravis, who had undergone thymectomy and were on high doses of prednisone and ciclosporin, were switched from ciclosporin to tacrolimus. Initial doses of tacrolimus were 0.1 mg/kg daily, given in 2 divided doses. Dosage was subsequently adjusted to achieve plasma concentrations between 7 and 8 nanograms/mL; tacrolimus doses of 6 to 10 mg daily were needed. After 1 year doses were reduced to achieve concentrations of about 6 nanograms/mL. Doses of prednisone were reduced, and finally withdrawn in all but 2 patients; 73 patients received tacrolimus for more than 3 years. All patients were able to resume normal daily activities.[3] Tacrolimus is licensed for use for myasthenia gravis in some countries, in a usual dose of 3 mg once daily by mouth. Tacrolimus (initial daily dose 3 mg orally) was also reported to reduce corticosteroid dosage in another small study; treatment was continued long-term and efficacy was maintained for up to 3 years.[4] There is some suggestion that tacrolimus may be more effective in thymomatous myasthenia gravis than in non-thymomatous disease.[5]

Tacrolimus has also been used as first-line adjunctive therapy with prednisolone; it was reported to decrease the daily prednisolone dose, and the need for plasmapheresis and high-dose intravenous methylprednisolone.[6]

Ocular disorders. For mention of the use of tacrolimus in various disorders characterised by ocular lesions such as uveitis, see p.1810.

Organ and tissue transplantation. Tacrolimus has been used both for primary immunosuppression and for the control of graft rejection. Much of the initial experience with the drug was for liver grafts, (p.1815), but it is also used in the transplantation of heart (p.1812), kidney (p.1813), lung (p.1815), pancreas (p.1816), and intestines (p.1813). It has also been tried for the prophylaxis of graft-versus-host disease after bone marrow transplantation (see Haematopoietic Stem Cell Transplantation, p.1811).

4. Brune A, *et al.* Tacrolimus ointment is effective for psoriasis on the face and intertriginous areas in pediatric patients. *Pediatr Dermatol* 2007; **24:** 76–80.

Pyoderma gangrenosum. There are reports of response to tacrolimus, given orally,[1-3] or topically,[4-9] or both,[10,11] in patients with pyoderma gangrenosum (p.1583). A small study[12] found topical tacrolimus 0.3% in carmellose sodium paste to be more effective than clobetasol propionate 0.05% for peristomal pyoderma gangrenosum.

Systemic absorption, resulting in tacrolimus blood concentrations equivalent to oral dosing, has been reported in patients with pyoderma gangrenosum in whom tacrolimus was applied directly onto ulcerated areas;[13,14] therapeutic drug monitoring has been suggested for patients treated with topical tacrolimus over large skin areas or with impaired skin barriers.

Rheumatoid arthritis. In a small, open-label study[1] of 12 patients with rheumatoid arthritis (p.11) refractory to other disease-modifying antirheumatic drugs including ciclosporin, 7 had significant response to tacrolimus after treatment for 6 months, with 4 of these patients maintaining this response after 2 years of therapy. In a larger controlled study,[2] tacrolimus improved disease activity in patients with rheumatoid arthritis resistant to methotrexate. Similarly, an open-label multicentre study involving 80 patients with active disease inadequately responsive to methotrexate alone, addition of tacrolimus 3 mg daily by mouth to methotrexate therapy produced a clinical improvement in about half. The regimen was considered to be generally well tolerated.[3] Tacrolimus in an oral dose of 3 mg once daily has been licensed for use in refractory rheumatoid arthritis in some countries; elderly patients may be given 1.5 mg once daily.[4,5]

Scleroderma. There are reports of response to tacrolimus in patients with scleroderma (p.1817).

Skin disorders. Topical tacrolimus has been used to treat various skin disorders. Aside from its licensed use in eczema (above), and use in psoriasis and pyoderma gangrenosum (see above), there are reports of benefit in granuloma annulare,[1,2] lichen sclerosus,[3] lichen striatus,[4] pityriasis alba,[5] pityriasis lichenoides,[6] seborrhoeic dermatitis,[7] as well as the skin manifestations of angiolymphoid hyperplasia,[8] pruritus due to primary biliary cirrhosis,[9] and facial cutaneous lupus erythematosus.[10]

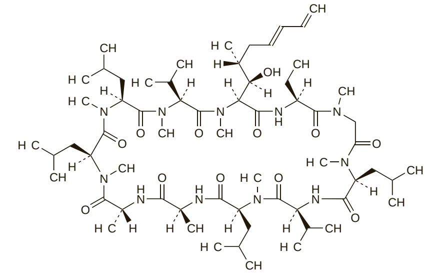
Voclosporin *(USAN, rINN)*

ISA-247; ISATX-247; LX-211; R-1524; Voclosporina; Voclosporine; Voclosporinum. Cyclo{L-alanyl-D-alanyl-N-methyl-L-leucyl-N-methyl-L-leucyl-N-methyl-L-valyl-[(2S,3R,4R,6E)-3-hydroxy-4-methyl-2-(methylamino)nona-6,8-dienoyl]-(2S)-2-aminobutanoyl-N-methylglycyl-N-methyl-L-leucyl-L-valyl-N-methyl-L-leucyl}.

Воклоспорин

$C_{63}H_{111}N_{11}O_{12}$ = 1214.6.

CAS — 515814-01-4.



Profile

Voclosporin is an analogue of ciclosporin (p.1822) that is under investigation for the treatment of uveitis, psoriasis, and for the prevention of rejection in organ transplantation.

Local Anaesthetics

Local anaesthetics produce reversible loss of function or sensation by preventing or diminishing the conduction of nerve impulses near to the site of their application or injection. Because their mode of action is to decrease permeability of the nerve cell membrane to sodium ions, they also have a membrane stabilising effect.

Most clinically useful local anaesthetics have the same general chemical configuration of an amine portion joined to an aromatic residue by an ester or amide link. The type of linkage is important in determining the properties of the drug.

For a classification of local anaesthetics, see Table 1, below.

Table 1. Classification of local anaesthetics.

Amide type	Ester type
Articaine	*Esters of benzoic acid*
Bupivacaine	Amylocaine
Cinchocaine	Cocaine
Ethyl parapiperidinoacetylaminobenzoate	Propanocaine
Etidocaine	*Esters of meta-aminobenzoic acid*
Levobupivacaine	Proxymetacaine
Lidocaine	
Mepivacaine	*Esters of para-aminobenzoic acid*
Oxetacaine	Benzocaine
Prilocaine	Butacaine
Ropivacaine	Butoxycaine
Tolycaine	Butyl aminobenzoate
Trimecaine	Chloroprocaine
Miscellaneous	Oxybuprocaine
Diperodon	Parethoxycaine
Dyclonine	Procaine
Ethyl chloride	Propoxycaine
Ketocaine	Tetracaine
Myrtecaine	Tricaine
Octacaine	
Pramocaine	
Propipocaine	
Quinisocaine	

Adverse Effects

Adverse effects apparent after local anaesthesia may be caused by the anaesthetic or errors in technique, or may be the result of blockade of the sympathetic nervous system. Local anaesthetics may produce systemic adverse effects as a result of raised plasma concentrations that occur when the rate of uptake into the circulation exceeds the rate of breakdown, for example, after

- accidental intravascular injection
- excessive or too rapid doses
- absorption of large amounts through mucous membranes or damaged skin
- absorption of large amounts from inflamed or highly vascular areas

The systemic toxicity of local anaesthetics mainly involves the CNS and the cardiovascular system. Excitation of the CNS may be manifested by restlessness, excitement, nervousness, paraesthesias, dizziness, tinnitus, blurred vision, nausea and vomiting, muscle twitching and tremors, and convulsions. Numbness of the tongue and perioral region, and lightheadedness followed by sedation may appear as early signs of systemic toxicity. Excitation when it occurs may be transient and followed by depression with drowsiness, respiratory failure, and coma. There may be effects on the cardiovascular system with myocardial depression and peripheral vasodilatation resulting in hypotension and bradycardia; arrhythmias and cardiac arrest may occur. Hypotension often accompanies spinal and epidural anaesthesia; inappropriate positioning of the patient may be a contributory factor for women in labour.

Hypersensitivity reactions are rare and generally limited to local anaesthetics of the ester type. There appears to be no cross-sensitivity between ester- and amide-type local anaesthetics. Idiosyncrasy to local anaesthetics has been reported. Hypersensitivity reactions to preservatives in local anaesthetic preparations have also occurred.

Some local anaesthetics cause methaemoglobinaemia.

Fetal intoxication has occurred after the use of local anaesthetics in labour, either as a result of transplacental diffusion or after accidental injection of the fetus.

Prolonged use of topical anaesthetics in the eye causes corneal damage.

Adverse effects may also be caused by vasoconstrictors given with the anaesthetic.

Adverse effects of central block. Central nerve block (see under Local Anaesthetic Techniques, below), comprising spinal or epidural block, is very widely used and certain adverse effects are particularly associated with the technique. Systemic effects (see Adverse Effects, above) are more likely with epidural than with spinal block, because of the larger doses used.

Total spinal anaesthesia from extreme spread of a block or accidental penetration of the dura during an epidural block produces unconsciousness, hypotension, and respiratory arrest. Less extensive spread to the cervical region is usually associated with nausea, agitation, and hypotension.

Hypotension (associated with venodilatation and decreased cardiac output secondary to sympathetic block) is the **cardiovascular** effect most often associated with the technique, and may be especially problematic in pregnancy. Other cardiovascular complications may include bradycardia or heart block; cardiac arrest has also been reported unexpectedly after spinal anaesthesia.

Post-dural puncture headache (see under Treatment of Adverse Effects, below) is probably the most common **neurological complication** related to these procedures and may be accompanied by tinnitus or photophobia. Headache after spinal block may rarely be caused by meningitis. Backache is a frequent postoperative complication of epidural, spinal, or general anaesthesia. Cranial nerve lesions and reversible loss of hearing in the low frequency range, usually affecting both ears, have been reported rarely following spinal block. Neurological complications associated with these blocks may also rarely include paraplegia caused by arachnoiditis, or trauma or compression of the spinal cord after development of a haematoma or abscess. Transient radicular irritation involving the lower back, buttocks, and thighs may develop within 24 hours of spinal block; recovery is usually within 1 week. Cauda equina syndrome, the symptoms of which include urinary retention, loss of perineal sensation, loss of sexual function, and faecal incontinence, is also a rare complication which can present many months after spinal block. There is some evidence that, although still rare, the incidence of neurotoxic complications after spinal anaesthesia is greater with lidocaine than with other commonly used local anaesthetics such as bupivacaine and tetracaine. The incidence of persistent lumbosacral neuropathy may be as high as 1 in 200 after continuous spinal anaesthesia with lidocaine.

Perioperative shivering has been associated with epidural block.

Effects on the ears. Symptoms such as vertigo, nausea, and nystagmus, which have been reported after the use of local anaesthetics in the external[1] or middle ear,[2] may result from penetration of the local anaesthetic into the inner ear. For reference to hearing disturbances associated with spinal block, see under Adverse Effects of Central Block, above.

Effects on wound healing. A review of the literature[1] found evidence that local infiltration of local anaesthetics can have detrimental effects on the first two stages of wound healing. The size of the effect on mature wound strength remains to be determined.

1. Brower MC, Johnson ME. Adverse effects of local anesthetic infiltration on wound healing. *Reg Anesth Pain Med* 2003; **28:** 233–40.

Hypersensitivity. Local anaesthetics may provoke types I and IV hypersensitivity reactions. Type I reactions (e.g. anaphylaxis) to local anaesthetics are generally rare. They occur more often with the ester-type than with the amide-type drugs, probably because of the metabolism of the former to para-aminobenzoic acid (PABA). Nevertheless, severe or fatal reactions have been associated not only with ester-type local anaesthetics such as tetracaine[1] and procaine[2] but also with the amide-type local anaesthetics lidocaine[3-7] and prilocaine.[3] Intolerance may also have been the cause of death in a patient who received mepivacaine for paracervical anaesthesia.[8] Hypotension during dental anaesthesia is usually a vasovagal response unrelated to the type of local anaesthetic used and may be prevented by the use of diazepam. Patients sensitised by topical application may then develop anaphylactic reactions when treated systemically.[9] The use of drugs such as benzocaine or tetracaine in lozenges or throat sprays may also sensitise patients.[10]

Some patients diagnosed as being hypersensitive to local anaesthetics may have reacted to preservatives in the preparations.[11] Cross-hypersensitivity reactions may also occur between some ester-type local anaesthetics and topical preparations, such as sunscreens, that contain PABA or related compounds.[12]

Skin testing may be of benefit in patients who will require future local anaesthesia and when a patient's history does not rule out a possible allergic reaction. However, testing itself can cause severe or anaphylactic reactions.[9,13]

Type IV reactions (i.e. delayed reactions) to local anaesthetics have also been reported, albeit rarely.[14-17]

For reports of the incidence of allergy to local anaesthetics determined by patch testing, see under individual monographs.

Methaemoglobinaemia. Methaemoglobinaemia has been reported with several local anaesthetics including tetracaine,[1] benzocaine,[1-5] and lidocaine[1,6] but is more commonly associated with the use of prilocaine.[7-10] It may occur after local injection or topical use. It has been suggested that the effect is due to the presence of an aniline group in the structure or, in the case of lidocaine and prilocaine, metabolism to an aniline-like structure. Methaemoglobinaemia may result from the use of usual doses as well as exposure to toxic concentrations of local anaesthetic;[1,9] with prilocaine doses of 8 mg/kg or more [above recommended maxima] usually produce symptoms.[11]

Methaemoglobinaemia has occurred after the topical application of a eutectic preparation of prilocaine and lidocaine.[8,10] Although increases in methaemoglobin concentrations are generally small after the use of this mixture in infants[12,13] and children,[14] some infants may be particularly susceptible to induced methaemoglobinaemia during the first 3 months of life probably due to their limited enzyme capacity.[12] The *BNF* states that eutectic prilocaine/lidocaine cream may be used under specialist supervision in infants over 1 month of age, and in some other countries the cream is also licensed for limited use in neonates (see also Surface Anaesthesia under Lidocaine, p.1866). However, UK licensed product information does not recommend its use in children under 1 year old.

Use with drugs such as sulfonamides[8] or antimalarials[11] may predispose to methaemoglobinaemia. Patients with haemoglobinopathies or G6PD deficiency may also be at greater risk.[1]

Pregnancy. As mentioned under Adverse Effects of Central Block, above, hypotension may be particularly problematic for patients receiving epidural or spinal block for analgesia during labour. In addition it has been suggested that patients receiving epidural analgesia during labour may have an increased risk of pyrexia, which can lead to fetal compromise.[1]

The use of paracervical block has fallen out of favour because of serious adverse effects on the fetus.

1. Fusi L, *et al.* Maternal pyrexia associated with the use of epidural analgesia in labour. *Lancet* 1989; **i:** 1250–2.

Treatment of Adverse Effects

At the first signs of local anaesthetic toxicity from parenteral dosage, the injection should be stopped; in some cases it may also be possible to apply a tourniquet to limit further systemic absorption. Subsequent management, regardless of the route, is supportive. If systemic reactions develop, steps should be taken to maintain the circulation and respiration and to control convulsions. A patent airway must be established and oxygen given, together with assisted ventilation if necessary. The circulation should be maintained with infusions of intravenous fluids. Vasopressors have been suggested in the treatment of marked hypotension although their use is accompanied by a risk of CNS excitation. Ephedrine is preferred for the management of hypotension associated with spinal or epidural block, particularly in pregnancy. Vasopressors should not be given to patients receiving oxytocic drugs. Convulsions may be controlled with intravenous benzodiazepines such as diazepam although these drugs may also depress respiration and the circulation. Intravenous phenobarbital is used for persistent convulsions.

Methaemoglobinaemia may be treated with intravenous methylthioninium chloride.

Post-dural puncture headache. Headache after puncture of the dura mater during procedures such as lumbar puncture or central nerve blocks is thought to be caused by subsequent leakage of CSF. The incidence of such post-dural puncture headache is significantly reduced by the use of small, blunt needles which produce a smaller hole in the dura and separate its fibres rather than cutting them.

When treatment is necessary conservative therapy such as analgesics and hydration will relieve symptoms in the majority of patients with mild post-dural puncture headache within 1 to 2 days. Bed rest does not reduce the incidence but once headache develops the patient may feel some relief when recumbent. If the headache persists for a further 24 hours measures such as epidural saline or dextran 40 or the use of intravenous caffeine and sodium benzoate may be effective; oral caffeine has also been shown to be of benefit. However, perhaps the most widely favoured measure, despite a lack of good evidence, is the epidural injection of autologous blood to form a blood patch over the dural puncture. There have been anecdotal reports of success using corticotropin or tetracosactide but such reports of relief with sumatriptan were not confirmed by a controlled study.

Precautions

As with any drug local anaesthetics are contra-indicated in patients with known hypersensitivity. However, it might be possible to avoid reactions by using a local anaesthetic of the alternative chemical type. Facilities for resuscitation should be available when local anaesthetics are given parenterally.

Local anaesthetics should not be used in patients with complete heart block. They should be given cautiously to the elderly, to the debilitated, to children, and to patients with epilepsy, impaired cardiac conduction or respiratory function, shock, or hepatic impairment; patients with myasthenia gravis are particularly susceptible to the effects of local anaesthetics. Ester-type local anaesthetics are contra-indicated in patients with low plasma-cholinesterase concentrations. Techniques such as epidural or spinal block should not be used in patients with cerebrospinal diseases, cardiogenic or hypovolaemic shock, or altered coagulation status. Because of the risk of transmitting infection into the CNS these techniques should not be employed where there is pyogenic infection of the skin at or adjacent to the injection site.

Because of the risk of systemic adverse effects when local anaesthetics are absorbed too rapidly, they should not be injected into or applied to inflamed or infected tissues or to damaged skin or mucosa. For similar reasons, the rate of injection should not be too rapid and great care must be taken to avoid inadvertent intravascular injection. The risk of adverse effects from the uptake of local anaesthetics into the circulation may be reduced by the inclusion of adrenaline to produce vasoconstriction, but the lowest effective concentration of adrenaline should be used. Solutions containing adrenaline should not, however, be used for producing anaesthesia in appendages such as digits, because the profound ischaemia that follows may lead to gangrene. Mepivacaine and prilocaine tend to produce less vasodilatation at low concentrations than other local anaesthetics and may be useful where the addition of vasoconstrictors is contra-indicated (but see also under Action, below).

When used in the mouth or throat, local anaesthetics may impair swallowing and increase the risk of aspiration. Patients who have received local anaesthetics for procedures such as laryngoscopy or tracheoscopy should be cautioned not to eat or drink for at least 3 to 4 hours after the anaesthetic.

The cornea may be damaged by prolonged topical application of local anaesthetics, particularly cocaine. Patients should be warned not to rub or touch the eye while anaesthesia persists and the anaesthetised eye should be protected from dust and bacterial contamination.

Local anaesthetics may be ototoxic and should not be instilled into the middle ear.

The application of local anaesthetics to the skin for prolonged periods or to extensive areas should be avoided.

Precautions for central block. Epidural or spinal block may rarely result in paraplegia caused by an induced haematoma or abscess, and have thus been considered unsuitable in patients with pre-existing neurological disease, infection at the puncture site, or blood disorders, or in those receiving aspirin or full-dose anticoagulant therapy. Such therapy may be stopped at an appropriate time before surgery if central block is planned. It is necessary to balance the risk of withholding anticoagulation against the risk of bleeding in the individual patient. Epidural or spinal block in patients given low-dose anticoagulant therapy to prevent postoperative deep-vein thrombosis is still controversial. For further discussion and recommendations see Spinal Anaesthesia, p.1303.

A study in the USA[1] involving 891 patients found that low-dose aspirin during pregnancy did not increase the risk of bleeding complications during epidural anaesthesia compared with placebo; it was considered that the recommendation to stop aspirin 7 to 10 days before delivery was unjustified.

1. Sibai BM, *et al.* Low-dose aspirin in correlation between bleeding time and maternal-neonatal bleeding complications. *Am J Obstet Gynecol* 1995; **172:** 1553–7.

Tachyphylaxis. The effect of successive epidural injections of 2% solutions of lidocaine, mepivacaine, or prilocaine was reduced by 25 to 30% with each injection when the interval between the disappearance of analgesia and re-injection was more than 10 minutes but anaesthesia was augmented if this interval was less than 10 minutes.[1] Such tachyphylaxis, associated with the prolonged epidural use of all local anaesthetics, has also been reviewed.[2]

2. Mogensen T. Tachyphylaxis to epidural local anaesthetics. *Dan Med Bull* 1995; **42:** 141–6.

Test dose. A test dose is recommended in epidural block to check for accidental intravenous or intrathecal injection but negative results should be treated with caution.[1] Accidental intravenous placement of the needle is notoriously more difficult to detect than inadvertent subarachnoid placement. Adrenaline has been added to the test solution to aid detection of intravenous injection but is considered by some to be of little value.[2,3]

Interactions

The metabolism of ester-type local anaesthetics may be inhibited by anticholinesterases, increasing the risk of systemic toxicity.

Ester derivatives such as tetracaine, benzocaine, or procaine that are hydrolysed to para-aminobenzoic acid may antagonise the activity of aminosalicylic acid or sulfonamides. Ester-type local anaesthetics such as procaine and cocaine that are hydrolysed by plasma cholinesterase may competitively enhance the neuromuscular blocking activity of suxamethonium; the amide local anaesthetic, lidocaine may have a similar effect.

There is an increased risk of myocardial depression when amide-type local anaesthetics such as bupivacaine, levobupivacaine, lidocaine, or ropivacaine are given with antiarrhythmics.

If local anaesthetics containing adrenaline are given for epidural or paracervical block during labour the use of an oxytocic drug post partum may lead to severe hypertension. Although there is no clinical evidence of dangerous interactions between adrenaline-containing local anaesthetics and MAOIs or tricyclic antidepressants, great care should nevertheless be taken to avoid inadvertent intravenous doses of the local anaesthetic preparation.

For further details of interactions between local anaesthetics and other drugs, see under individual monographs.

Pharmacokinetics

Most local anaesthetics are readily absorbed through mucous membranes, and through damaged skin. Local anaesthetics are weak bases and at tissue pH can diffuse through connective tissue and cellular membranes to reach the nerve fibre where ionisation can occur.

Anaesthetics of the ester type are hydrolysed by esterases in the plasma and, to a lesser extent, in the liver. The effect of spinal anaesthetics lasts until the drug is taken up into the blood circulation since there is little esterase in the spinal fluid.

Amide-type anaesthetics are metabolised in the liver and, in some cases, the kidneys. While there is little protein binding with most ester-type anaesthetics, the amide types are considerably bound.

Uses and Administration

Local anaesthetics act by preventing the generation and transmission of impulses along nerve fibres and at nerve endings; depolarisation and ion-exchange are inhibited. The effects are reversible. They are used for the local relief of painful conditions, and to prevent pain and discomfort of various medical and surgical procedure (see below). In general, loss of pain (analgesia) occurs before loss of sensory and autonomic function (anaesthesia) and loss of motor function (paralysis), but this may depend on the drug used and the site into which it is given.

Local anaesthetics vary in their potency and speed of onset and duration of action. The anaesthetic must penetrate the lipoprotein nerve sheath in its unionised form before it can act and therefore drugs with high lipid-solubility tend to have a greater potency and duration of action and a faster onset than drugs with low lipid-solubility. The most protein-bound drugs tend to have the longest duration of action.

The potency of local anaesthetics is traditionally compared against that of procaine, which is low; chloroprocaine, lidocaine, mepivacaine, and prilocaine are similar or somewhat more potent; etidocaine is of intermediate potency, bupivacaine and ropivacaine highly potent, and tetracaine extremely potent.

Speed of onset and duration of action also depend on the technique used (see Local Anaesthetic Techniques, below), the type of block, and the site of administration.

The speed of onset and duration of action of local anaesthetics may be increased by the addition of a vasoconstrictor, which has the effect of reducing the uptake of the local anaesthetic into the circulation from the injection site. Solutions containing adrenaline 1 in 200 000 are generally advocated, although higher concentrations such as 1 in 80 000 may be used in dentistry where the total dose is small. The total amount of adrenaline injected should not exceed 500 micrograms although the amount of adrenaline absorbed varies considerably with the site of injection; some consider that the maximum dose should be 200 micrograms. Other vasoconstrictors including noradrenaline are also used, but the 2002 *Dental Practitioners' Formulary* in the UK considered that noradrenaline should not be used since it presented no advantages and when given at relatively high concentrations had occasionally been associated with severe hypertensive episodes. Vasoconstrictors should not be used when producing a nerve block in an appendage such as a digit, as gangrene may occur. Vasoconstrictors have been added to injections for spinal block, but their use is not recommended because of the danger of reducing the blood supply to the spinal cord.

Local anaesthetics are generally given as acidic solutions of the water-soluble hydrochloride salts; alkalinisation of these solutions or formulation as a carbonated base may increase the speed of onset (see pH of solutions, below).

The dosage of individual local anaesthetics depends on the injection site and the procedure used. The smallest effective dose and the lowest effective concentration should be used. Smaller doses are usually needed in the elderly, in children, in debilitated patients, and in cardiac disease. Doses should also be reduced in the presence of hepatic disease. Meticulous attention to technique is essential particularly in nerve block and spinal procedures. Injections for central nerve blocks, such as epidural (including caudal block) and spinal block should not contain preservatives.

Action. The intrinsic vasoactivity of a local anaesthetic can influence its rate of removal from the site of action and therefore its duration of action. Ester-type local anaesthetics such as tetracaine and procaine are more likely to produce vasodilatation than amide-type local anaesthetics such as cinchocaine, lidocaine, mepivacaine, and prilocaine after intradermal doses.[1] However, cocaine differs from other ester-type local anaesthetics in that it produces vasoconstriction. The amide-type local anaesthetics can produce vasoconstriction but, apart from prilocaine, their vasoconstrictor activity has generally been found to decline with increasing concentration,[1,2] and, in a study, lidocaine and bupivacaine produced more vasodilatation than vasoconstriction at the higher concentrations tested.[2] Mepivacaine has produced greater and more consistent vasoconstriction than lidocaine, cinchocaine, or prilocaine after intradermal injection[1] but this greater vasoactivity is not always evident.[3]

Administration. Systemic toxic effects of local anaesthetics are related to blood concentrations and, as absorption varies considerably according to the site of injection, it has been suggested[1,2] that recommendation of a single maximum dose without regard to the site of the procedure is meaningless. If a plasma-lidocaine concentration of 5 micrograms/mL were required for toxicity then this would be achieved by injection of 300 mg in the intercostal area, 500 mg epidurally, 600 mg in the region of the brachial plexus, or 1000 mg subcutaneously. The reduction of peak concentrations obtained by the addition of adrenaline was also dependent on the site of injection. Furthermore, most cases of severe toxicity did not result from overdosage but from inadvertent intravascular injection or too rapid injection.

CARBONATED SOLUTIONS. The use of carbonated solutions of local anaesthetics instead of the usual hydrochloride salts has been discussed in several reviews.[1-3] Although some early studies indicated that carbonated solutions of bupivacaine, lidocaine, or prilocaine produced earlier onset of anaesthesia and improved the quality of epidural or brachial plexus blocks not all subsequent studies have confirmed these results. A method for preparing carbonated solutions has been published[4] but proprietary preparations of such solutions of bupivacaine or lidocaine may be available in some countries.

PH OF SOLUTIONS. The pain associated with infiltration of local anaesthetics can be reduced by buffering the solution to physiological pH with sodium bicarbonate.[1,2] Although buffering itself does not appear to compromise the efficacy of anaesthesia,[2] alkalinisation of the solution may reduce the solubility of the local anaesthetic and cause precipitation.[2-4] To enhance stability local anaesthetic solutions are usually prepared at an acidic pH and it is therefore recommended that if solutions are buffered they should be used immediately.[2] (Solutions containing adrenaline require an acidic pH.)

Similar pH adjustments of solutions for intravenous regional anaesthesia have been reported to reduce the amount of local venous irritation and thrombophlebitis[5] and to increase the speed of onset and the duration of the block.[6] However, it has been noted that at alkaline pH lidocaine can lower surface tension, thereby altering drop size and potentially resulting in a decreased dose if such solutions are infused via a drop counting device rather than a volume pump.[7] Alkalinisation of a solution used for epidural block for caesarean section has been reported to result in a more rapid onset of action and denser block.[8]

Alkalinisation has also been used to hasten the onset of peripheral nerve block[9] by increasing the proportion of the lipid-soluble nonionised free base but the effect in epidural block has been inconsistent.[10,11]

Anorectal disorders. See under Surface Anaesthesia, below.

Cough. Drugs such as lidocaine or bupivacaine have been given by inhalation in severe intractable cough (p.1547), including cough caused by malignant neoplasms.[1-4] Cough suppression is produced by an indirect peripheral action on sensory receptors, but as all protective pulmonary reflexes may be lost and bronchospasm may be induced, nebulised local anaesthetics should be used in controlled circumstances only; there may also be temporary loss of the swallowing reflex.

Intravenous lidocaine has also been tried for the prevention of fentanyl-induced cough.[5-7]

Endoscopy. Local anaesthetics such as lidocaine are sometimes used before endoscopy to improve patient comfort and facilitate passage of the endoscope. As mentioned in the discussion on drugs used in endoscopy (see p.956) some consider that the use of local anaesthetics for procedures such as gastrointestinal endoscopy should probably be reserved for those patients who prefer not to be sedated as their use in addition to premedication with opioids or benzodiazepines appears to serve little purpose.

Mouth ulceration. For the role of local anaesthetics in the management of mouth ulceration, see p.1700.

Pain. Pain and its general management are discussed on p.2. Local anaesthetics are used in a variety of situations for the management of pain. They are usually given by local injection or applied topically but are sometimes used intravenously in techniques such as intravenous regional anaesthesia, which involves the continuous infusion of local anaesthetics such as lidocaine to produce general analgesia. However, the technique is potentially dangerous and seldom employed.

NERVE BLOCKS. Nerve blocks produce analgesia by interrupting the nervous transmission of pain signals either by temporary inhibition of conduction or by destruction of the nerve. Nerve blocks may be used alone or with analgesics in the management of acute or chronic pain associated with a well-defined anatomical site, especially when the pain is unresponsive to or not adequately controlled by conventional therapy. The route of administration and method used depend on the site to be blocked but may include peripheral nerve block, autonomic nerve blocks such as sympathetic nerve blocks and coeliac plexus block, and central nerve blocks such as epidural (including caudal) and spinal block. **Local anaesthetics** are used when a temporary effect is required. **Neurolytics** such as phenol or alcohol or freezing of the nerve (cryoanalgesia) produce more prolonged block, but even so the effects may last no more than a few months, and the variable and non-selective neural damage produced correlates poorly with pain relief; some consider the risk of complications to outweigh the benefits obtained.[1]

The use of nerve blocks in the *management of cancer* (p.5) has declined following the refinement of the use of conventional analgesics. Some consider that their value may be limited to patients with a life expectancy of 3 months or less[2] and that the main benefit of nerve blocks in cancer is to produce maximum pain relief rapidly. However, others consider that chemical and thermal neurolysis can provide long-term control of severe cancer pain without a substantial incidence of adverse effects.[3] Neurolytic blocks may be of particular value in cancer pain syndromes involving the viscera or the torso, but are rarely applicable in the management of extremity pain.[4] Neuropathic pain is rarely helped by somatic neural block and may even be aggravated,[1] but block of the splanchnic nerves or coeliac plexus with alcohol or phenol is reputed to be effective in relieving severe intractable pain caused by cancer of the pancreas, stomach, small intestine, gallbladder, or other abdominal viscera, especially when the cancer has not spread to the parietal peritoneum.[5]

Similar neurolytic blocks preceded by a local anaesthetic have also been used in patients with *severe intractable pain* of chronic pancreatitis, postcholecystectomy syndrome, or other chronic abdominal visceral diseases unrelieved by medical or surgical therapy.

Central nerve blocks using local anaesthetics with or without **opioids** are used for the *management of acute pain* such as labour pain (p.7) and postoperative pain (p.4) including that in children (p.3); they are also sometimes used for cancer pain.[1,6]

Sympathetic nerve blocks using repeated injections of local anaesthetics or neurolytics have been used for sympathetically maintained pain. Intravenous regional sympathetic block is an alternative when a single limb is involved;[1] guanethidine is one of the drugs that has been used.[7]

Injections of local anaesthetics with or without **corticosteroids** are often used for blocks of localised painful joints. Nerve blocks are also used to block localised painful trigger areas[8] such as postoperative or post-traumatic neuroma formation and for focal muscle pain.

For the role of nerve blocks in the management of low back pain, see p.7.

Postherpetic neuralgia. For the role of local anaesthetics in the management of postherpetic neuralgia, see p.9.

Premature ejaculation. A cream containing lidocaine 2.5% and prilocaine 2.5% has been applied topically to the penis for a desensitising effect in the management of premature ejaculation (p.2181). The cream is usually applied to the penis and covered with a condom for a period of time, then washed off before sexual intercourse. It has been reported to increase intravaginal ejaculatory latency time compared with a placebo cream,[1] and a study[2] of different application times found 20 minutes to be the optimum. Longer application times were associated with erection loss because of numbness of the penis, and delayed ejaculation. Decreased vaginal sensitivity in female partners, from residual anaesthetic, has also been reported.[1]

Soft-tissue rheumatism. For the adjunctive use of local anaesthetics in the management of soft-tissue rheumatism, see p.13.

Spasticity. The management of spasticity (p.1887) involves physiotherapy and the use of antispastic drugs. Other approaches to treatment include nerve blocks with local anaesthetics; these can improve spasticity but should generally only be used when further muscle relaxation would not increase disability.

Stuttering. Local anaesthetics have been tried in the treatment of stuttering (p.1001).

Local Anaesthetic Techniques

Local anaesthetics are used in several techniques. In order of increasing level of anaesthesia they are: surface or topical anaesthesia; infiltration anaesthesia; and regional nerve block, including peripheral nerve block, sympathetic nerve block, and central nerve block which includes epidural and spinal (intrathecal or subarachnoid) block. Local anaesthetics may also be given intravenously for regional anaesthesia in the extremities.

Infiltration anaesthesia

Infiltration anaesthesia is produced by injection of a local anaesthetic such as lidocaine or bupivacaine directly into and around the field of operation without attempting to identify individual nerves. The drug used should not be absorbed too rapidly otherwise the anaesthesia will wear off too quickly for practical use; some local anaesthetics require the addition of a vasoconstrictor in low concentrations, which can increase the duration of infiltration anaesthesia and reduce peak plasma concentrations of the local anaesthetic. Infiltration anaesthesia is extensively used in dentistry.

Anaesthesia of small areas by infiltration techniques requires a relatively large amount of local anaesthetic, which is not a problem for minor surgery but would be for more extensive areas that required anaesthesia. The amount of local anaesthetic used can be reduced and the duration of anaesthesia increased by blocking specific nerves that innervate the area. This may be carried out at several levels. In *field block* anaesthesia subcutaneous injection of a local anaesthetic close to the nerves around the area to be anaesthetised blocks sensory nerve paths. This is a form of infiltration anaesthesia, but the technique requires less drug for a given area to be anaesthetised.

Intravenous regional anaesthesia

Intravenous regional anaesthesia (Bier's block) involves injection of a dilute solution of local anaesthetic into a suitable limb vein after exsanguination and application of a tourniquet, in order to produce anaesthesia distal to it. Arterial flow must remain occluded for at least 20 minutes after injection and adrenaline should not be used. Intravenous regional anaesthesia may be used for short procedures where postoperative pain is not marked, such as manipulation of fractures and minor surgical procedures to the limbs. Although a safe procedure when performed correctly, complications have arisen; there have been fatalities associated with the use of bupivacaine, and prilocaine is the drug of choice. Facilities for resuscitation should be available.

Regional nerve block

Regional nerve block anaesthesia involves specific blocks at the levels of major nerves or spinal roots, and may include peripheral nerve block, sympathetic nerve block, and central nerve block including epidural and spinal block. For a discussion of the use of nerve blocks in the management of pain, see Nerve Blocks, above.

Central nerve block. Central nerve block includes epidural and spinal block.

Epidural block (also referred to as *extradural* or *peridural block*) is widely used to provide analgesia or anaesthesia in surgical and obstetric procedures. It involves injecting a local anaesthetic such as lidocaine, bupivacaine, or ropivacaine, alone or with a small dose of an opioid analgesic into the epidural space in the lumbar, sacral (*caudal block*), thoracic, or cervical regions. Introduction of a cannula into the epidural space enables prolonged analgesia or anaesthesia (epidural anaesthesia) to be provided through the use of 'top-up' doses or continuous infusion of the drugs. A vasoconstrictor is sometimes added to reduce systemic exposure to the local anaesthetic. A test dose at the intended injection site is recommended before starting epidural anaesthesia to ensure that the main dose is not accidentally injected intravascularly or into the subarachnoid space.

Spinal block (also referred to as *subarachnoid* or *intrathecal block*) is produced by injecting a solution of a suitable drug such as bupivacaine within the spinal subarachnoid space, causing temporary paralysis of the nerves with which it comes into contact. It may be used, for example, to produce spinal anaesthesia in surgical procedures on the lower body. Vasoconstrictors have been added to prolong the duration of the block but the effect is not always clinically useful and there is a danger of restricting the blood supply to the spinal cord; therefore this practice is not recommended. The somatic level at which anaesthesia occurs depends on many factors including the specific gravity or baricity of the anaesthetic solution used and the positioning of the patient.

For the adverse effects of and precautions for central block, see above.

Peripheral nerve block. Peripheral nerve block anaesthesia involves injection into or around a peripheral nerve or plexus supplying the part to be anaesthetised; motor fibres may be blocked as well as sensory fibres. *Brachial plexus block* is widely used for procedures involving the arm; lower limb blocks are less simple although *sciatic* and *femoral blocks* may be combined to permit surgery below the knee. Other peripheral nerve blocks such as those for the head and neck, or *intercostal* or *paravertebral blocks* for local anaesthesia of the trunk, are mostly highly specialised techniques. Lidocaine, prilocaine, bupivacaine, or ropivacaine have all been widely used for peripheral nerve blocks. Adrenaline is often added as a vasoconstrictor.

Pudendal block (usually with prilocaine) may be useful in obstetrics before forceps delivery, but as mentioned under Labour Pain on p.7, the technique of *paracervical local anaesthetic block* has largely fallen out of favour because of the high incidence of serious adverse effects on the fetus.

Sympathetic nerve block. Sympathetic nerve block such as *stellate ganglion blockade* and *lumbar sympathectomy* is used in the management of a range of painful conditions and vascular diseases (see under Complex Regional Pain Syndrome on p.6). Temporary block is obtained using local anaesthetics such as lidocaine or bupivacaine but permanent block may be produced with use of neurolytic agents such as phenol (see Pain, p.1657) or alcohol (see Pain, p.1627).

Surface anaesthesia

Surface or topical anaesthesia blocks the sensory nerve endings in the skin or mucous membranes. Many local anaesthetics are effective surface anaesthetics, a notable exception being procaine. Penetration of intact skin by most local anaesthetics is poor whereas absorption through mucous membranes may be rapid. However, reliable percutaneous anaesthesia can be achieved by application of a eutectic mixture of lidocaine and prilocaine to intact skin (see under Surface Anaesthesia in Lidocaine, p.1866). Eutectic mixtures may be of value in providing surface anaesthesia for a number of minor medical or surgical procedures. Tetracaine also provides reliable percutaneous anaesthesia. Other methods of dermal delivery of local anaesthetics include a transdermal patch of lidocaine (either alone or with tetracaine), an iontophoretic drug delivery system incorporating lidocaine and adrenaline. Anaesthesia of the skin and subcutaneous tissues is also discussed under Infiltration Anaesthesia, above.

There are a number of special uses of topical anaesthesia including anaesthetising the cornea during ophthalmological procedures and the throat and larynx before intubation and bronchoscopy. Absorption from the respiratory tract is rapid and care is essential to avoid giving a toxic dose. Great care is also necessary when using local anaesthetics to anaesthetise the urethra; if trauma has occurred, rapid absorption of the drug may occur and give rise to serious adverse effects.

Local anaesthetics have been included in topical preparations to relieve the pain of haemorrhoids (p.1697) but good evidence of their efficacy is lacking. Similar uses include pain relief in pruritus ani and anal fissure. Excessive application of local anaesthetics to the rectal mucosa should be avoided as absorption can occur; use for periods of no longer than a few days is recommended to prevent sensitisation of the anal skin. Local anaesthetics are sometimes included in topical preparations for the relief of pruritus (p.1582). However, they are only marginally effective and can very occasionally cause sensitisation. The use of local anaesthetics in rubefacient and topical analgesic preparations is mentioned on p.5.

Amylocaine Hydrochloride *(BANM)*

Amilocaína, hidrocloruro de; Amyleinii Chloridum; Amylocain. Hydrochlor.; Chlorhydrate d'Amyléine. 1-(Dimethylaminomethyl)-1-methylpropyl benzoate hydrochloride.

$C_{14}H_{21}NO_2,HCl = 271.8.$

CAS — 532-59-2 (amylocaine hydrochloride); 644-26-8 (amylocaine hydrochloride).

Profile

Amylocaine, a benzoic acid ester, is a local anaesthetic (p.1850) used mainly as the hydrochloride in a range of preparations for application to the skin or mucous membranes. It has also been used in preparations for the relief of painful anorectal conditions and has been included in oral mixtures for the relief of coughs.

Preparations

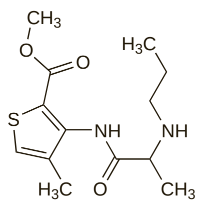
Артикаина Гидрохлорид

$C_{13}H_{20}N_2O_3S,HCl = 320.8.$

CAS — 23964-58-1 (articaine); 23964-57-0 (articaine hydrochloride).

ATC — N01BB08.

ATC Vet — QN01BB08.



(articaine)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Articaine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in alcohol. A 1% solution in water has a pH of 4.2 to 5.2. Protect from light.

Profile

Articaine hydrochloride is an amide local anaesthetic (p.1850). It has been used as a 1 or 2% solution with or without adrenaline for infiltration and regional anaesthesia. A 4% solution of articaine hydrochloride with adrenaline is used similarly in dentistry. A hyperbaric solution of articaine hydrochloride with glucose has been used for spinal block.

Porphyria. Articaine hydrochloride is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of benzocaine:

Coco snow.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Benzocaine). Colourless crystals or a white or almost white, crystalline powder. M.p. 89° to 92°. Very slightly soluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Benzocaine). Small, white crystals or a white odourless crystalline powder. M.p. 88° to 92°. Soluble 1 in 2500 of water, 1 in 5 of alcohol, 1 in 2 of chloroform, 1 in 4 of ether, and 1 in 30 to 50 of almond oil or olive oil; dissolves in dilute acids.

Adverse Effects and Treatment

As for Local Anaesthetics in general, p.1850.

Abuse. Benzocaine has been used as an adulterant or 'cutting' agent in the preparation of cocaine for illicit use and adverse effects such as methaemoglobinaemia have been seen after cocaine overdosage as a result of the benzocaine content.[1]

1. McKinney CD, *et al.* Benzocaine-adultered street cocaine in association with methemoglobinemia. *Clin Chem* 1992; **38:** 596–7.

Hypersensitivity. The incidence of positive reactions in patients patch tested with benzocaine has ranged from 3.3 to 5.9%.[1,2] Patch testing with benzocaine has been recommended by The International Contact Dermatitis Research Group as an indicator of contact hypersensitivity to local anaesthetics. However, it was found that of 40 patients who had had positive reactions to benzocaine with tetracaine and cinchocaine, 21 were not allergic to benzocaine alone.[3]

Precautions

As for Local Anaesthetics in general, p.1851.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Pharmacokinetics

See under Local Anaesthetics, p.1852.

Uses and Administration

Benzocaine, a para-aminobenzoic acid ester, is a local anaesthetic used for surface anaesthesia (p.1853); it has low potency and low systemic toxicity. It is used, often with other drugs such as analgesics, antiseptics, antibacterials, antifungals, and antipruritics, for the temporary local relief of pain associated with dental conditions, oropharyngeal disorders, haemorrhoids, anal pruritus, and ear pain.

Lozenges containing benzocaine in usual doses of up to 10 mg are used for the relief of sore throat. Gels, pastes, solutions, and sprays containing benzocaine in concentrations of up to 20% have been used for surface anaesthesia of the mouth and throat.

Benzocaine is used in ear drops, creams, ointments, lotions, solutions, sprays, gels, and suppositories in concentrations up to 20% for topical analgesia and anaesthesia.

Benzocaine has also been used as the hydrochloride.

Obesity. It has been reported[1] that despite the inclusion of benzocaine in some over-the-counter appetite suppressants there is no good evidence of its value in obesity (p.2149).

Bupivacaine Hydrochloride

(BANM, USAN, rINNM)

AH-2250; Bupivacaïne, chlorhydrate de; Bupivacaini hydrochloridum; Bupivacaini Hydrochloridum Monohydricum; Bupivakaiinihydrokloridi; Bupivakain Hidroklorür; Bupivakain-hidroklorid; Bupivakain-hydrochlorid monohydrát; Bupivakainhydroklorid; Bupivakaino hidrochloridas; Bupiwakainy chlorowodorek; Hidrocloruro de bupivacaína; LAC-43; Win-11318. (±)-(1-Butyl-2-piperidyl)formo-2′,6′-xylidide hydrochloride monohydrate.

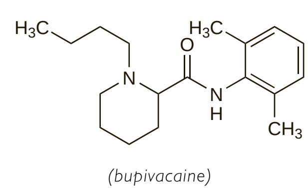
Бупивакаина Гидрохлорид

$C_{18}H_{28}N_2O,HCl,H_2O = 342.9.$

CAS — 2180-92-9 (bupivacaine); 18010-40-7 (anhydrous bupivacaine hydrochloride); 14252-80-3 (bupivacaine hydrochloride monohydrate).

ATC — N01BB01.

ATC Vet — QN01BB01.



(bupivacaine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.,* and *US.*

Ph. Eur. 6.2 (Bupivacaine Hydrochloride). A white or almost white, crystalline powder or colourless crystals. Soluble in water; freely soluble in alcohol. Protect from light.

USP 31 (Bupivacaine Hydrochloride). A white, odourless, crystalline powder. Freely soluble in water and in alcohol; slightly soluble in acetone and in chloroform. A 1% solution in water has a pH of 4.5 to 6.0.

Stability of solutions. For a discussion of the effect that pH has on the stability of local anaesthetic solutions and the pain associated with their injection, see p.1852.

For reference to the stability of admixtures of bupivacaine and fentanyl in solution, with or without adrenaline, see under Fentanyl, p.56.

Adverse Effects and Treatment

As for Local Anaesthetics in general, p.1850.

Bupivacaine appears to be more cardiotoxic than other local anaesthetics. Cardiac arrest due to bupivacaine can be resistant to electrical defibrillation and a successful outcome may require prolonged resuscitative efforts.

◊ For reference to the toxic threshold for bupivacaine plasma concentrations, see Absorption under Pharmacokinetics, below.

Effects on the cardiovascular system. Bupivacaine[1,2] and etidocaine[2] appear to be more cardiotoxic than most other commonly used local anaesthetics and marked cardiovascular depression may occur at plasma concentrations only slightly above those for CNS toxicity.[2] Fatalities have occurred. Simultaneous seizures and cardiovascular collapse may develop rapidly on inadvertent intravascular injection and even prompt oxygenation and blood pressure support might not prevent cardiac arrest.[2] Ventricular fibrillation which is very resistant to normal methods of defibrillation may develop. Since lidocaine and the other local anaesthetics have additive effects on the CNS bretylium may be preferable to lidocaine for the treatment of induced arrhythmias.[1] Seizures and life-threatening ventricular fibrillation have also been reported after systemic absorption of bupivacaine solutions in an adolescent patient undergoing wound debridement.[3] Fatal cardiotoxicity has occurred after the use of bupivacaine in intravenous regional anaesthesia, possibly due to leakage past the tourniquet, and the use of bupivacaine in this technique should be avoided.[1] Fatalities have also been associated with the use of 0.75% solutions for epidural anaesthesia in obstetric patients and this strength is no longer recommended for obstetric anaesthesia. See also Labour Pain under Uses and Administration, below.

1. Anonymous. Cardiotoxicity of local anaesthetic drugs. *Lancet* 1986; **ii:** 1192–4.
2. Albright GA. Cardiac arrest following regional anesthesia with etidocaine or bupivacaine. *Anesthesiology* 1979; **51:** 285–7.
3. Yan AC, Newman RD. Bupivacaine-induced seizures and ventricular fibrillation in a 13-year-old girl undergoing wound debridement. *Pediatr Emerg Care* 1998; **14:** 354–5.

Effects on the eyes. Bilateral retinal haemorrhages developed in a 47-year-old woman[1] after receiving a caudal block with bupivacaine 0.5%. The haemorrhages cleared and her usual vision returned by 3 months.

1. Ling C, *et al.* Bilateral retinal haemorrhages following epidural injection. *Br J Ophthalmol* 1993; **77:** 316–17.

Prolonged block. Use of bupivacaine in regional anaesthesia may result in prolonged block.[1,2]

1. Pathy GV, Rosen M. Prolonged block with recovery after extradural analgesia for labour. *Br J Anaesth* 1975; **47:** 520–2.
2. Brockway MS, *et al.* Prolonged brachial plexus block with 0.42% bupivacaine. *Br J Anaesth* 1989; **63:** 604–5.

Precautions

As for Local Anaesthetics in general, p.1851.

Bupivacaine is contra-indicated for use in intravenous regional anaesthesia (Bier's block) and for paracervical block in obstetrics. The 0.75% solution is contra-indicated for epidural block in obstetrics.

Renal impairment. Spinal block was more rapid in onset and of shorter duration in patients with chronic renal failure given 3 mL of bupivacaine 0.75% than in control patients.[1]

1. Orko R, *et al*. Subarachnoid anaesthesia with 0.75% bupivacaine in patients with chronic renal failure. *Br J Anaesth* 1986; **58:** 605–9.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Antiarrhythmics. There is an increased risk of myocardial depression when bupivacaine and antiarrhythmics are given together.

Beta blockers. *Propranolol* reduced the clearance of bupivacaine by 35% in 6 healthy subjects.[1] There is a risk of increased bupivacaine toxicity if these drugs are used together.

1. Bowdle TA, *et al.* Propranolol reduces bupivacaine clearance. *Anesthesiology* 1987; **66:** 36–8.

Calcium-channel blockers. There is a theoretical risk that the adverse effects of bupivacaine on the heart might be enhanced in patients taking calcium-channel blockers, but evidence of a clinical problem is lacking.

Histamine H_2-antagonists. Studies of the effect of H_2-antagonists on the pharmacokinetics of bupivacaine have yielded variable results. While a group of workers[1] found that pretreatment with *cimetidine* decreased the clearance of bupivacaine, others have failed to find any significant pharmacokinetic effects.[2,3] Similarly, pretreatment with *ranitidine* has either increased plasma concentrations of bupivacaine[4] or had no significant effect.[3]

1. Noble DW, *et al.* Effects of H-2 antagonists on the elimination of bupivacaine. *Br J Anaesth* 1987; **59:** 735–7.
2. Pihlajamäki KK. Lack of effect of cimetidine on the pharmacokinetics of bupivacaine in healthy subjects. *Br J Clin Pharmacol* 1988; **26:** 403–6.
3. Flynn RJ, *et al.* Does pretreatment with cimetidine and ranitidine affect the disposition of bupivacaine? *Br J Anaesth* 1989; **62:** 87–91.
4. Wilson CM. Plasma bupivacaine concentrations associated with extradural anaesthesia for caesarean section: influence of pretreatment with ranitidine. *Br J Anaesth* 1986; **58:** 1330P–1331P.

Local anaesthetics. For reference to the effect of bupivacaine on the protein binding of *lidocaine* and *mepivacaine*, see p.1864 and p.1866, respectively.

Pharmacokinetics

Bupivacaine is about 95% bound to plasma proteins. Reported half-lives are from 1.5 to 5.5 hours in adults and about 8 hours in neonates. It is metabolised in the liver and is excreted in the urine mainly as metabolites with only 5 to 6% as unchanged drug.

Bupivacaine is distributed into breast milk in small quantities. It crosses the placenta but the ratio of fetal concentrations to maternal concentrations is relatively low. Bupivacaine also diffuses into the CSF.

See also under Local Anaesthetics, p.1852.

Absorption. The toxic threshold for bupivacaine plasma concentrations is considered by some[1] to lie in the range of 2 to 4 micrograms/mL and in the UK the maximum single recommended dose for anhydrous bupivacaine hydrochloride is 150 mg (equivalent to about 2 mg/kg). Giving bupivacaine for *regional anaesthesia* of the head and neck in a mean total dose of 3.4 mg/kg has produced mean peak plasma concentrations of 3.56 micrograms/mL (with adrenaline) and 4.95 micrograms/mL (without adrenaline), without producing toxicity.[2] Similarly, *intrapleural* bupivacaine 0.5% in a dose of 2.5 mg/kg has produced mean peak plasma concentrations of 2.57 and 3.22 micrograms/mL (with or without adrenaline, respectively) without producing toxicity.[3] A further study[4] in which a 72-hour interpleural infusion of bupivacaine hydrochloride with adrenaline was given to cholecystectomy patients showed appreciable interpatient variability in steady-state plasma drug concentrations (range 1.3 to 3.2 micrograms/mL; mean 2.1 micrograms/mL); no patient suffered any adverse effects. Bilateral *intercostal* nerve blocks using bupivacaine 2 mg/kg have also produced concentrations within the presumed toxic range without adverse effects but the use of adrenaline with this block did not reliably reduce peak plasma-bupivacaine concentrations.[5]

Stellate ganglion block with bupivacaine 0.25% has produced a mean peak plasma concentration of 0.34 and 0.47 micrograms/mL after doses of 10 or 20 mL, respectively.[6] Giving bupivacaine 0.5% in a dose of 3 mg/kg with or without adrenaline for *sciatic* and *femoral nerve block* produced mean peak plasma concentrations below 0.8 micrograms/mL.[7]

Intra-articular bupivacaine is rapidly absorbed from the synovial membrane of the knee during arthroscopy but plasma concentrations did not exceed 0.35 micrograms/mL after controlled pressure-irrigation with isotonic solutions containing up to 200 mg.[8] Although a group of workers found that the maximum plasma concentrations of bupivacaine after intra-articular injection of 30 mL of a 0.5% solution for arthroscopy was 0.875 micrograms/mL they suggested that adrenaline should probably be added to minimise absorption.[9]

Pregnancy. Bupivacaine crosses the placenta to a lesser degree than lidocaine or mepivacaine following maternal injection. Values of 0.2 to 0.4 have been reported[1,2] for the ratio of fetal to maternal concentrations for bupivacaine compared with values of 0.5 to 0.7 quoted[2,3] for lidocaine and mepivacaine. The greater degree of protein-binding of bupivacaine compared with these other drugs not only limits the amount of bupivacaine available to cross the placenta but also reduces the relative amount of free drug in the fetal circulation[2] (see also under Protein Binding, below). Addition of adrenaline to the injection does not appear to affect the placental transfer rate of bupivacaine.[4] Measurement of a beta-phase half-life of 25 hours in the neonate compared with 1.25 hours in mothers suggests that the neonate is less able to metabolise bupivacaine.[5]

Protein binding. The two major binding proteins for bupivacaine in the blood are α_1-acid glycoprotein, the influence of which is predominant at low concentrations, and albumin, which plays the major role at high concentrations. Reduction in pH from 7.4 to 7.0 decreases the affinity of the α_1-acid glycoprotein for bupivacaine but has no effect on albumin affinity.[1] Binding of bupivacaine is reduced during pregnancy but it is considered that the increase in free bupivacaine concentrations is unlikely to cause a clinically significant increase in the risk of CNS or cardiovascular toxicity.[2]

As fetal plasma contains little α_1-acid glycoprotein the binding capacity for bupivacaine is reduced and this may contribute to the difference between maternal and fetal plasma concentration at delivery[3] (see also under Pregnancy, above).

Ageing, uncomplicated by disease, does not affect the protein binding of bupivacaine.[4]

Uses and Administration

Bupivacaine hydrochloride is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It has a slow onset and a long duration of action. The speed of onset and duration of action are increased by the addition of a vasoconstrictor, and absorption into the circulation from the site of injection is reduced. Slow accumulation occurs with repeated doses. It is used mainly for infiltration anaesthesia and regional nerve blocks, particularly epidural block, but is contra-indicated for obstetric paracervical block and for use in intravenous regional anaesthesia (Bier's block). The 0.75% solution is contra-indicated for epidural block in obstetrics. (Local anaesthetic techniques are discussed on p.1853.)

Bupivacaine is a racemic mixture but the *S*(−)-isomer levobupivacaine (see p.1862) is also used. The carbonated solution of bupivacaine is also available for injection in some countries (see p.1852).

In recommended doses bupivacaine produces complete sensory blockade but the concentration of bupivacaine solution used affects the extent of motor blockade achieved. A 0.25% solution generally produces incomplete motor block, a 0.5% solution will usually produce motor block and some muscle relaxation, and complete motor block and muscle relaxation can be achieved with a 0.75% solution.

The dosage of bupivacaine used depends on the site of injection and the procedure used, as well as the status of the patient. Bupivacaine is given as the hydrochloride monohydrate salt although doses are expressed in terms of the anhydrous hydrochloride; bupivacaine hydrochloride monohydrate 10.55 mg is equivalent to about 10 mg anhydrous bupivacaine hydrochloride. In the UK the suggested general **maximum single dose** of bupivacaine hydrochloride is 150 mg with or without adrenaline followed if necessary by doses of up to 50 mg every 2 hours. In the USA the recommended maximum single dose is 175 mg of the plain preparation or 225 mg when given with adrenaline; doses may be repeated at intervals of not less than 3 hours but the total daily dose should not exceed 400 mg. The dose should be reduced in the elderly, in children, in debilitated patients, and in cardiac or hepatic disease.

A test dose of bupivacaine, preferably with adrenaline, should be given before starting epidural block to detect inadvertent intravascular injection. Subsequent doses should be given in small increments.

Solutions with or without adrenaline may be used for most **local anaesthetic techniques** and procedures apart from dental infiltration, when adrenaline is added to the solution (see below).

- For *infiltration anaesthesia* bupivacaine hydrochloride is typically used as a 0.25% solution in doses up to the recommended maximum (see above). When a longer duration of anaesthesia is required, as in dental or surgical procedures of the maxillary and mandibular area, a 0.5% solution with adrenaline 1 in 200 000 has been used but a total dose of 90 mg (18 mL) should not be exceeded over a single dental sitting.
- For *peripheral nerve block* the usual dose is 12.5 mg (5 mL) as a 0.25% solution or 25 mg (5 mL) as a 0.5% solution, although doses up to the recommended maximum single dose (see above) may also be given. A 0.75% solution has been used for *retrobulbar block* in ophthalmic surgery in a dose of 15 to 30 mg (2 to 4 mL).
- For *sympathetic nerve block* 50 to 125 mg (20 to 50 mL) as a 0.25% solution is recommended.
- For *lumbar epidural block* in surgery a 0.25% solution of bupivacaine hydrochloride may be used in a dose of 25 to 50 mg (10 to 20 mL) or as a 0.5% solution in a dose of 50 to 100 mg (10 to 20 mL). A 0.75% solution is also used for induction of lumbar epidural block in non-obstetric surgery in a single dose of 75 to 150 mg (10 to 20 mL). For *caudal block* in surgery 37.5 to 75 mg (15 to 30 mL) as a 0.25% solution or 75 to 150 mg (15 to 30 mL) as a 0.5% solution may be used. In the management of **acute pain** bupivacaine may be given as an epidural bolus or by continuous infusion. For analgesia during *labour*, doses of 15 to 30 mg (6 to 12 mL) as a 0.25% solution or 30 to 60 mg (6 to 12 mL) as a 0.5% solution have been recommended as a bolus for lumbar block. Alternatively, when given as an infusion, a dose of 10 to 15 mg (10 to 15 mL) per hour as a 0.1% solution or 10 to 15 mg (8 to 12 mL) per hour as a 0.125% solution has been recommended for lumbar block. Bupivacaine may also be given as a bolus caudal injection for labour pain; doses of 25 to 50 mg (10 to 20 mL) as a 0.25% solution or 50 to 100 mg (10 to 20 mL) as a 0.5% solution are recommended. For *postoperative pain* bupivacaine may be given as an epidural infusion in doses of 4 to 15 mg (4 to 15 mL) per hour as a 0.1% solution or 5 to 15 mg (4 to 12 mL) per hour as a 0.125% solution.
- Hyperbaric solutions of bupivacaine hydrochloride without adrenaline may be used for *spinal block*. Preparations containing 0.5% are available and are given in doses of 10 to 20 mg (2 to 4 mL).

Action. Addition of potassium chloride 0.2 mmol to 40 mL of bupivacaine 0.25% solution resulted in a more rapid onset of sensory loss than the same dose of plain bupivacaine in patients undergoing brachial plexus block for forearm or hand surgery.[1]

Hyaluronidase did not increase the speed of onset of brachial plexus block produced by bupivacaine 0.5%, with or without adrenaline, but did reduce the duration of anaesthesia.[2]

Bupivacaine encapsulated in liposomes can prolong postsurgical analgesic action without motor block.[3,4]

For a comparison of the vasoactivity of bupivacaine and some other local anaesthetics, see p.1852.

Administration in children. Bupivacaine 0.25% injected intra-operatively up to a maximum dose of 1.5 mg/kg with adrenaline has been used in infants for the control of postoperative pain due to pyloromyotomy and appears to attenuate some of the cardiac and respiratory effects associated with the use of general anaesthesia alone.[1] Doses of 2.5 mg of bupivacaine for each year of age, as a 0.5% solution, have been used for ilio-inguinal nerve block in children undergoing herniotomy.[2] A study[3] in infants undergoing abdominal surgery found that an epidural infusion of bupivacaine produced comparable analgesia to an intravenous infusion of morphine. It was considered that bupivacaine might be preferable to morphine in neonates and young infants who are particularly prone to respiratory depression, but older children might require additional sedation or analgesia to prevent postoperative restlessness.

Labour pain. For a discussion of the management of labour pain, including mention of the use of local anaesthetics, see p.7.

Early experience in nearly 1000 patients suggested that 8 mL of a 0.5% solution of bupivacaine with adrenaline was the optimum dose for epidural block during labour;[1] pain relief lasted for about 2 hours. Decreasing the concentration of the final dose to 0.25% reduced the persistence of sensory and motor nerve block after delivery. Others[2] found that bupivacaine 0.375% was the most suitable concentration for epidural analgesia when using a regimen of regular 'top-up' doses of 0.5 mg/kg about every 90 minutes. However, the use of low doses of bupivacaine 0.25% for epidural analgesia in primiparous women was associated with a lower incidence of forceps delivery and oxytocin augmentation.[3] Although an even lower concentration of bupivacaine (0.0625%) used with sufentanil[4] produced analgesia similar to that with 0.125% bupivacaine used alone, the duration of the second stage of labour and the incidence of instrumental and surgical delivery were not reduced. Similar results were obtained using bupivacaine 0.0625% with diamorphine 0.005%; in addition pruritus and drowsiness produced by diamorphine were considered to be troublesome in many patients.[5] However, a large UK study[6,7] compared a traditional epidural regimen using 10 mL boluses of bupivacaine 0.25% given up to every hour, with two lower-dose regimens using bupivacaine 0.1% with fentanyl 2 micrograms/mL, and found the lower dose techniques were at least as effective and were associated with a lower incidence of instrumental delivery.

Combined spinal-epidural blocks, in which an initial intrathecal injection of bupivacaine or bupivacaine with an opioid is given before starting the epidural, are also used,[6-9] and have been found to give excellent results,[7] although they may have no advantages over a low-dose epidural technique.[10]

Intrathecal injections containing bupivacaine have also been given alone[11,12] for the management of labour pain but the use of this route alone is usually associated with anaesthesia and management of postoperative pain in caesarean section. Bupivacaine has also been tried with lidocaine for epidural anaesthesia in caesarean section in order to reduce the dose of bupivacaine and minimise cardiotoxicity.[13]

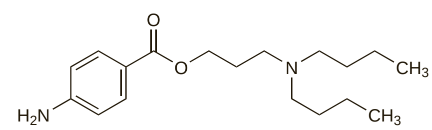
Butacaine Sulfate *(rINNM)*

Butacain. Sulph.; Butacaïne, Sulfate de; Butacaine Sulphate *(BANM)*; Butacaini Sulfas; Sulfato de butacaína. 3-Dibutylaminopropyl 4-aminobenzoate sulphate.

Бутакаина Сульфат

$(C_{18}H_{30}N_2O_2)_2,H_2SO_4 = 711.0.$

CAS — 149-16-6 (butacaine); 149-15-5 (butacaine sulfate).



(butacaine)

Profile

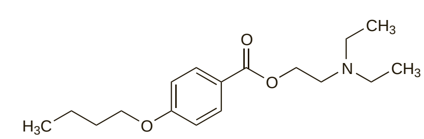
Butacaine, a para-aminobenzoic acid ester, is a local anaesthetic (p.1850) used for surface anaesthesia. It has been used topically, as the sulfate, in solutions for dental pain and in ear and nasal drops.

Butoxycaine Hydrochloride

Butoxicaína, hidrocloruro de; Butoxycaini Hydrochloridum. 2-Diethylaminoethyl-(*p*-butoxybenzoate) hydrochloride.

$C_{17}H_{27}NO_3,HCl = 329.9.$

CAS — 3772-43-8 (butoxycaine); 2350-32-5 (butoxycaine hydrochloride).



(butoxycaine)

Profile

Butoxycaine, a para-aminobenzoic acid ester, is a local anaesthetic (p.1850) that has been used as the base or hydrochloride for surface anaesthesia.

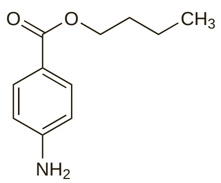
Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Ger.:*** Bismolan†.

Butyl Aminobenzoate

Butamben (*USAN*); Butilaminobenzoato; Butoforme. Butyl 4-aminobenzoate.
$C_{11}H_{15}NO_2$ = 193.2.
CAS — 94-25-7.



Pharmacopoeias. In *Fr.* and *US.*
USP 31 (Butamben). A white, odourless, crystalline powder. M.p. 57° to 59°. Soluble 1 in 7000 of water; soluble in alcohol, in ether, in chloroform, in fixed oils, and in dilute acids. It slowly hydrolyses when boiled with water.

Butyl Aminobenzoate Picrate

Abbott-34842; Butamben Picrate (*USAN*); Butilaminobenzoato, picrato de.
$(C_{11}H_{15}NO_2)_2,C_6H_3N_3O_7$ = 615.6.
CAS — 577-48-0.

Profile

Butyl aminobenzoate, a para-aminobenzoic acid ester, is a local anaesthetic (p.1850) that has been used for surface anaesthesia of the skin and mucous membranes. It has also been used for relief of pain and pruritus associated with anorectal disorders. A suspension of butyl aminobenzoate 5 or 10% has been given epidurally.

Butyl aminobenzoate picrate has been applied to the skin as an ointment.

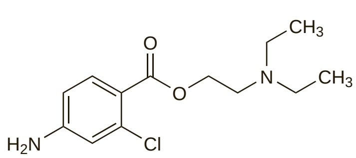
ATC — N01BA04.
ATC Vet — QN01BA04.



(chloroprocaine)

Pharmacopoeias. In *US.*
USP 31 (Chloroprocaine Hydrochloride). A white odourless crystalline powder. Soluble 1 in 20 of water and 1 in 100 of alcohol; very slightly soluble in chloroform; practically insoluble in ether. Solutions are acid to litmus.

pH of solutions. For a discussion of the effect that pH has on the stability of local anaesthetic solutions and the pain associated with their injection, see p.1852.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850. Chloroprocaine is said to be unsuitable for intravenous regional anaesthesia (Bier's block) because of a high incidence of thrombophlebitis associated with such use. It is also contra-indicated in spinal anaesthesia due to potential neurotoxicity.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Pharmacokinetics

Chloroprocaine is hydrolysed rapidly in the circulation by plasma cholinesterase. It has a half-life of 19 to 26 seconds in adults. It is excreted in the urine mainly as metabolites.

See also under Local Anaesthetics, p.1852.

Uses and Administration

Chloroprocaine, a para-aminobenzoic acid ester, is a local anaesthetic with actions and uses similar to those described on p.1852. It has properties similar to those of procaine (p.1869). It has a rapid onset (6 to 12 minutes) and short duration (one hour) of action.

Chloroprocaine is used as the hydrochloride for infiltration, peripheral nerve block, and central nerve block including lumbar and caudal epidural blocks. It may be given, if necessary, with adrenaline 1 in 200 000 to delay absorption and reduce toxicity. Chloroprocaine is not an effective surface anaesthetic. It should not be used for spinal anaesthesia. (Local anaesthetic techniques are discussed on p.1853.)

The dosage of chloroprocaine used depends on the site of injection and the procedure used. In adults the **maximum single dose** of chloroprocaine hydrochloride without adrenaline should not exceed 800 mg; when given with adrenaline 1 in 200 000 the maximum single dose should not exceed 1 g. A test dose of chloroprocaine, preferably with adrenaline, should be given before starting epidural block to detect inadvertent intravascular injection. Doses for various procedures include:

- *mandibular nerve block*: 40 to 60 mg (2 to 3 mL) as a 2% solution
- *infra-orbital nerve block*: 10 to 20 mg (0.5 to 1 mL) as a 2% solution
- *brachial plexus block*: 600 to 800 mg (30 to 40 mL) as a 2% solution
- *digital nerve block*: 30 to 40 mg (3 to 4 mL) as a 1% solution without adrenaline
- in obstetrics a dose of 200 mg (10 mL) per side as a 2% solution is suggested for *pudendal block* and for a *paracervical block* a 1% solution in a dose of 30 mg (3 mL) at each of 4 sites
- *lumbar epidural block*: 40 to 50 mg (2 to 2.5 mL) as a 2% solution or 60 to 75 mg (2 to 2.5 mL) as a 3% solution for each segment to be anaesthetised, the usual total dose being 300 to 750 mg with smaller repeat doses being given at intervals of 40 to 50 minutes
- *caudal block*: 300 to 500 mg (15 to 25 mL) as a 2% solution or 450 to 750 mg (15 to 25 mL) as a 3% solution may be given and repeated at intervals of 40 to 60 minutes

Dosages should be reduced in children, elderly or debilitated patients, and those with cardiac or liver disease. For children concentrations of 0.5 to 1% are suggested for infiltration and 1 to 1.5% for nerve block procedures.

Preparations

USP 31: Chloroprocaine Hydrochloride Injection.

ATC Vet — QC05AD04; QD04AB02; QN01BB06; QS01HA06.

NOTE. This compound was originally marketed under the name Percaine, but accidents occurred owing to the confusion of this name with procaine.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Cinchocaine Hydrochloride). A white or almost white, crystalline powder or colourless crystals; it is hygroscopic. It agglomerates very easily. Very soluble in water; freely soluble in alcohol, in acetone, and in dichloromethane. A 2% solution in water has a pH of 5.0 to 6.0. Store in airtight containers. Protect from light.
USP 31 (Dibucaine Hydrochloride). Colourless or white to off-white crystals or white to off-white, crystalline powder. It is odourless, somewhat hygroscopic, and darkens on exposure to light. Freely soluble in water, in alcohol, in acetone, and in chloroform. Its solutions have a pH of about 5.5. Store in airtight containers. Protect from light.

Profile

Cinchocaine is an amide local anaesthetic (p.1850) that is now generally only used for surface anaesthesia. It is one of the most potent and toxic of the long-acting local anaesthetics and its parenteral use was restricted to spinal anaesthesia.

For surface anaesthesia cinchocaine has been used, as the base or hydrochloride, in creams and ointments containing up to 1% and in suppositories for the temporary relief of pain and itching associated with skin and anorectal conditions. Cinchocaine benzoate has also been used topically.

Action. For a comparison of the vasoactivity of cinchocaine and some other local anaesthetics, see p.1852.

Plasma cholinesterase deficiency. For mention of the use of cinchocaine in the determination of plasma cholinesterase activity, see under Precautions of Suxamethonium Chloride, p.1911.

Coca ⊗

Coca Leaves; Hoja de Coca.

Profile

Coca is the dried leaves of *Erythroxylum coca* (Bolivian or Huanuco leaf) or of *E. truxillense* (Peruvian or Truxillo leaf) (Erythroxylaceae), indigenous to Bolivia and Peru and cultivated in Colombia and Indonesia.

Coca leaves contain about 0.7 to 1.5% of total alkaloids, of which cocaine, cinnamyl-cocaine, and α-truxilline are the most important.

Coca was formerly used for its stimulant action and for the relief of gastric pain, nausea, and vomiting, but it has no place in modern medicine. The practice of coca leaf chewing still continues in South America.

Cocaine *(BAN)* ⊗

Cocaína; Cocainum; Kokaiini; Kokain; Methyl Benzoylecgonine. (1*R*,2*R*,3*S*,5*S*)-2-(Methoxycarbonyl)tropan-3-yl benzoate.

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Cocaine). It may be obtained from the leaves of *Erythroxylum coca* and other spp. of *Erythroxylum*, or by synthesis. Colourless crystals or a white, crystalline powder. It is slightly volatile. M.p. 96° to 98°. Practically insoluble in water; freely soluble in alcohol and in ether; very soluble in chloroform; soluble in arachis oil; slightly soluble in liquid paraffin.

USP 31 (Cocaine). Colourless to white crystals or white, crystalline powder. M.p. 96° to 98°. Soluble 1 in 600 of water, 1 in 7 of alcohol, 1 in 1 of chloroform, 1 in 3.5 of ether, 1 in 12 of olive oil, and 1 in 80 to 100 of liquid paraffin. A saturated solution in water is alkaline to litmus. Protect from light.

Cocaine Hydrochloride *(BANM)* ⊗

Chloridrato de Cocaína; Cocaína, hidrocloruro de; Cocaïne, chlorhydrate de; Cocaine Hydrochlor.; Cocaini hydrochloridum; Cocainium Chloratum; Kokaiinihydrokloridi; Kokain-hidroklorid; Kokain-hydrochlorid; Kokainhydroklorid; Kokaino hidrochloridas; Kokainy chlorowodorek.

$C_{17}H_{21}NO_4$,HCl = 339.8.

CAS — 53-21-4.

ATC — N01BC01; R02AD03; S01HA01; S02DA02.

ATC Vet — QN01BC01; QR02AD03; QS01HA01; QS02DA02.

NOTE. CCN is a code approved by the BP 2008 for use on single unit doses of eye drops containing cocaine hydrochloride where the individual containers may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, *US*, and *Viet.*

Ph. Eur. 6.2 (Cocaine Hydrochloride). Colourless crystals or a white or almost white crystalline powder. M.p. about 197° with decomposition. Very soluble in water; freely soluble in alcohol. Protect from moisture and light.

USP 31 (Cocaine Hydrochloride). Colourless crystals or white, crystalline powder. Soluble 1 in 0.5 of water, 1 in 3.5 of alcohol, and 1 in 15 of chloroform; soluble in glycerol; insoluble in ether. Protect from light.

Stability in solutions. ***ALKALIS.*** Solutions of cocaine hydrochloride are adversely affected by alkalis.

PHENOL. A stability study[1] was conducted in response to queries over conflicting data on the incompatibility of cocaine hydrochloride solutions and phenol. Some pharmacists had reported that cocaine hydrochloride eye drops preserved with phenol had shown no sign of physical incompatibility. The BPC 1973 states that cocaine hydrochloride is incompatible with phenol but suggests that cocaine hydrochloride solutions may be preserved with chlorocresol. The study found that there was no sign of physical incompatibility in aqueous solutions containing cocaine hydrochloride 5% and phenol 0.5% stored for a year at temperatures of 0° to 37° but there was a fall in pH, greatest at the higher temperatures, which was suggestive of chemical change. It was recommended that such solutions should be stored in a cool place.

1. *PSGB Lab Report P/75/14* 1975.

Adverse Effects

Because the therapeutic use of cocaine is now very restricted many reports of adverse effects occur in the context of abuse. However, both systemic and local effects have followed its use as a surface anaesthetic. Although some effects are similar to those of other local anaesthetics (p.1850), cocaine differs in that it acts as a potent indirect-acting sympathomimetic. It stimulates the CNS causing agitation, dilated pupils, tachycardia, hypertension, hallucinations, hypertonia, and hyperreflexia. Convulsions, coma, and metabolic acidosis may develop. Symptoms of CNS stimulation and sympathetic overactivity are very marked in overdosage with cocaine. A single oral dose of 1 g may be fatal, but some persons have a cocaine idiosyncrasy and severe toxicity may occur after doses of only 10 mg intravenously. Systemic absorption of small doses may slow the heart, but with increasing doses tachycardia, hypertension, and ventricular fibrillation occur.

High concentrations of cocaine should not be used topically as, in addition to risks of systemic toxicity after absorption, lasting local damage may occur.

Topical application of cocaine to the cornea can cause corneal damage with clouding, pitting, sloughing, and occasionally ulceration. Topical application to the nose or mouth has been reported to cause loss of smell and taste respectively.

Prolonged use of cocaine by nasal inhalation may cause mucosal damage or perforation of the nasal septum.

Abuse. Cocaine abuse and its effects have been discussed in a number of reviews.[1-6]

Cocaine abuse was once only in the form of chewing of coca leaves containing small amounts of cocaine, but processing of the leaves has led to abuse with a variety of more dangerous preparations containing higher concentrations of cocaine.[7] Coca paste, produced by maceration of the leaves with petrol and sulfuric acid, contains about 40 to 90% of cocaine sulfate and is smoked with tobacco or cannabis. Treatment of coca paste with hydrochloric acid produces cocaine hydrochloride, which is abused by intravenous injection, either alone or with diamorphine, or by sniffing to achieve nasal absorption. Alkaloidal cocaine (cocaine base; 'freebase'), which is abused by smoking, is produced by treating cocaine hydrochloride with alkali, followed either by heating (to form 'crack' cocaine) or by extracting the base from ether or another organic solvent. The route by which cocaine is taken determines the rate and extent of its absorption, and hence the abuse potential, although once absorbed, the pharmacokinetics are independent of route. Intravenous cocaine hydrochloride and smoked cocaine base have a greater potential for abuse than intranasal cocaine hydrochloride because of their greater rapidity and intensity of effects.

The psychological effects of cocaine abuse may be described by a cycle of initial euphoria followed by dysphoria and finally schizophreniform psychosis.[7,8] Euphoria may be accompanied by other symptoms of stimulation such as sexual arousal, anorexia, insomnia, hyperexcitability, loquacity, and grandiosity, and users may appear manic. After a short time these feelings are replaced by symptoms of dysphoria including considerable anxiety, fear, depression, apathy, irritability, and suspiciousness. Dysphoria may be ameliorated by repeated use, so the user develops the need to take the drug continuously to feel relatively well, but repeated use appears to diminish the intensity of the effects.[7] During euphoria and dysphoria users may experience a wide range of physical symptoms including palpitations, headache, dizziness, gastrointestinal effects, hyperhidrosis, tremors, tachycardia, hypertension, fever, and myoclonic jerks. Seizures can also occur after repeated use. In chronic abusers psychological deterioration may eventually occur, resulting in loss of mental function, compulsive disorders, suicidal ideation, psychopathic disorders, and ultimately a psychosis resembling acute paranoid schizophrenia similar to that seen with amfetamines.[7,8] Symptoms may include paranoia, stereotyped behaviour, delusions, loss of impulse control, violence, and visual, olfactory, auditory, gustatory, and tactile hallucinations. Overdosage can result in death due to status epilepticus, hyperthermia, ventricular tachycardia, and cardiac or respiratory arrest.[7]

For further details of the adverse effects of cocaine abuse, including effects due to use during pregnancy, see below.

ADULTERATION. For a report of methaemoglobinaemia as a result of the ingestion of cocaine adulterated with benzocaine, see Abuse under Adverse Effects of Benzocaine, p.1854.

BREAST FEEDING. The American Academy of Pediatrics[1] has stated that, when used as a drug of abuse by breast-feeding mothers, cocaine has caused signs of intoxication in the infant, notably diarrhoea, vomiting, irritability, seizures, and tremulousness.

Acute intoxication has been reported in a breast-fed child whose mother was using cocaine intranasally.[2]

Effects on the cardiovascular system. There appears to be no relationship between underlying heart disease and the risk of cocaine-induced cardiac effects and cardiac events can occur regardless of the route of abuse.[1] Cardiovascular toxicity due to cocaine may be related to individual sensitivity and therefore may not be predictable or dose dependent.[2] Patients with plasma cholinesterase deficiency are particularly at risk for sudden death.[3] Other risk factors for cardiovascular disease, such as cigarette smoking or pre-existing atherosclerosis, may exacerbate the cardiac toxicity of cocaine.[4-6] Cocaine blocks reuptake of catecholamines at adrenergic nerve endings and thus produces sympathetic stimulation of the cardiovascular system. Accumulation of catecholamines predisposes the myocardium to arrhythmias,[7] and sinus tachycardia, supraventricular or ventricular tachyarrhythmias, myocarditis, and sudden arrhythmic death may occur.[7-9] Severe hypertension can lead to cerebrovascular accidents and stroke has occurred even in young adults without other predisposing conditions.[10,11] However, the exact mechanism of cocaine-induced stroke remains unclear and other implicated effects include vasospasm, cerebral vasculitis, enhanced platelet aggregation, and cardioembolism.[12] Aortic dissection and rupture of the aorta have also occurred.[6] Up to 25% of emergency admissions to US urban hospitals with nontraumatic chest pain have detectable amounts of cocaine or its metabolites in their urine, but only a minority of these have myocardial infarction,[6] as chest pain without signs of myocardial infarction also commonly occurs.[8] Asymptomatic myocardial ischaemia manifesting as episodes of ST segment elevation has also been reported during withdrawal of cocaine.[13] The mechanism for these changes is probably multifactional, including increased myocardial oxygen demand, coronary vasoconstriction, and enhanced platelet aggregation and thrombus formation.[6,14] The immediate vasoconstrictor effect of cocaine may be followed by delayed or recurrent vasoconstriction due to its active metabolites, benzoylecgonine and ethyl methyl ecgonine.[6]

Vasoconstriction may also produce ischaemia in the fingers, toes, spinal cord,[8] spleen,[15] and intestines.[16] Renal ischaemia and infarction may also occur.[17,18] Other reported cardiovascular effects include dilated cardiomyopathy and premature atherosclerosis.[6]

Effects on the CNS. Severe CNS depression with deep coma has been seen in a few cocaine abusers after prolonged binges.[1]

1. Roberts JR, Greenberg MI. Cocaine washout syndrome. *Ann Intern Med* 2000; **132:** 679–80.

Effects on the kidneys. For reference to renal failure following rhabdomyolysis associated with cocaine abuse, see under Effects on the Muscles, below. There has been a report[1] of acute renal failure occurring in a 16-year-old girl secondary to cocaine abuse but without evidence of rhabdomyolysis.

For reference to renal ischaemia and infarction due to cocaine abuse, see under Effects on the Cardiovascular System, above.

1. Leblanc M, *et al.* Cocaine-induced acute renal failure without rhabdomyolysis. *Ann Intern Med* 1994; **121:** 721–2.

Effects on the lungs. Smoking the free base has resulted in pulmonary complications not encountered with other methods of abuse for cocaine. Associated adverse effects have included pulmonary oedema, hypersensitivity pneumonitis, pulmonary haemorrhage, obliterative bronchiolitis, abnormalities of pulmonary function, pneumomediastinum, and pneumothorax.[1] Severe or life-threatening exacerbations of asthma have also been reported.[2]

Pregnancy. The effects of cocaine abuse during pregnancy have been reviewed.[1-4] Women who abuse cocaine during pregnancy appear to have an increased risk of spontaneous abortion,[5] abruptio placentae[6,7] and associated still-births,[8] premature labour,[9-11] and other birth complications.[9-11] These effects may be due to vasoconstriction by cocaine increasing maternal blood pressure and reducing placental blood flow.[12] Uterine rupture[13] during pregnancy and rupture of ectopic pregnancies[14] have also been associated with cocaine. Neonates born to mothers abusing cocaine have an increased risk of intra-uterine growth retardation and may have lower birth-weight, smaller head size, and shorter length.[6,8-10,15-17] Cocaine is possibly teratogenic and congenital abnormalities associated with abuse include cardiovascular abnormalities,[9,18,19] limb reduction defects,[20] intestinal atresia or infarction,[20] skull defects,[8] and genito-urinary tract anomalies.[21] Neurobehavioural impairment[22] and signs of transient CNS irritability[23] may also occur. Some workers[24,25] have found effects on cognition and motor delays while others have found effects on arousal and attention regulation rather than cognitive processes.[26] Cocaine can increase neonatal cerebral blood flow[27] and cerebral infarction and associated seizures have occurred in neonates whose mothers took cocaine near to the onset of labour.[28] Evidence on the risk of intraventricular haemorrhage is conflicting.[7,24]

Treatment of Adverse Effects

As for Local Anaesthetics in general, p.1851.

Cocaine overdosage. In the emergency management of overdosage with cocaine the general aims are to establish adequate ventilation and support the circulation. If oral ingestion of a large amount is suspected the stomach should be emptied and activated charcoal given.[1] A tourniquet may be applied to limit absorption if the drug was injected. Patients who have swallowed packages containing cocaine for the purpose of smuggling, may be given laxatives but surgical intervention may be required if signs of toxicity appear.[2]

Sedation with intravenous diazepam may be sufficient to manage the symptoms of cocaine overdose. Sedation with benzodiazepines may also be appropriate initial therapy for hypertension or tachyarrhythmias since the excessive sympathetic tone is largely centrally mediated.[3] Severe life-threatening arrhythmias may require treatment with intravenous propranolol although, following a report of paradoxical hypertension presumably due to unopposed α-adrenergic stimulation, a beta blocker with both α- and β-adrenergic effects such as labetalol is preferred by some if hypertension is also present;[2,4] sodium nitroprusside[3,4] or phentolamine[3,5] may also be used. Although labetalol can reduce the hypertension it does not alleviate cocaine-induced coronary vasoconstriction;[6] it has therefore been suggested that glyceryl trinitrate would be preferable for patients with cocaine-induced chest pain.[5,6] Chest pain may also be treated with aspirin. Calcium-channel blockers such as verapamil may also be of use as an antagonist for coronary artery vasoconstriction induced by cocaine.[5] There is concern about the use of lidocaine for the treatment of cocaine-induced arrhythmias as lidocaine may enhance toxicity.[5] Diazepam should be used to manage seizures[1,4] but if they cannot be controlled phenytoin can be used as an adjunct.[1] Hyperthermia should be treated with physical cooling but the use of dantrolene may also be necessary.[1] Control of anxiety and agitation with benzodiazepines when combined with rapid cooling may also have the effect of decreasing heat production in hyperthermic patients.[3] Metabolic acidosis should be monitored and treated where necessary.[1,4] Short-acting barbiturates or benzodiazepines may be used for dysphoric agitation but drugs that lower the seizure threshold or aggravate hyperthermia such as phenothiazines or haloperidol should be avoided.[1]

Cocaine withdrawal syndrome. Cocaine can produce psychological dependence but does not produce a major physical withdrawal syndrome. The management of cocaine abuse and dependence has been reviewed.[1-3] There is no advantage to gradual withdrawal and it is best for the patient to stop the drug abruptly.[1,4] The three major psychiatric complications associated with cocaine withdrawal are dysphoric agitation, severe depression, and psychotic symptoms.[1] Such complications are initially managed with psychosocial treatments. However patients with more severe dependence or those who fail to respond to psychosocial treatments should be considered for drug therapies. Dysphoric agitation is best treated with diazepam; propranolol may also be used in more persistent cases. Depressive symptoms during the acute post-cocaine phase are usually transient and require no treatment other than close observation. Desipramine has been used with equivocal results; it appears to be of most benefit in patients who have antecedent or consequent symptoms of severe depression.[3] Trazodone and imipramine have also been tried but had more adverse effects than desipramine.[3] Furthermore, a systematic review has concluded that there was no evidence to support the use of antidepressants[5] in the treatment of cocaine dependence. Antipsychotics such as chlorpromazine, haloperidol, and promazine have been used to manage patients with psychotic symptoms associated with cocaine dependence.[1]

Several drugs have been tried in the maintenance of abstinence from cocaine.[1] Lithium may be useful in patients with bipolar disorder or cyclothymic personality. Methylphenidate may be helpful in patients with attention deficit disorders but has potential for abuse itself. Phenothiazine derivatives have been tried in the control of impulsive behaviour and to decrease cocaine craving, although adverse effects may limit their acceptability. Carbamazepine has been reported to suppress the craving for cocaine although this has not been supported by subsequent studies.[3] Buprenorphine has been investigated to suppress cocaine and opioid use in patients dependent on both drugs.[3] Anxiolytics or antidepressants are considered unlikely to be of benefit in maintaining abstinence.[3] MAOIs such as phenelzine have been used in a manner analogous to the use of disulfiram in alcohol abuse to provoke unpleasant reactions if patients relapse.[6] Disulfiram itself has also been tried with some success (see below).

There is evidence to suggest that cocaine use affects the dopaminergic modulation of CNS function, and several drugs that interact with the dopamine system have been tried in the treatment of cocaine abuse and dependence.[3,7] For most drugs the results have been disappointing or equivocal although disulfiram and selegiline may warrant further investigation.[7]

Precautions

As for Local Anaesthetics in general, p.1851.

Since some patients have a marked sensitivity to cocaine, giving a test dose before use on mucous membranes has been suggested. Cocaine should not be applied to damaged mucosa because of the risk of systemic toxicity from enhanced absorption. Ophthalmic preparations of cocaine should not be applied to the eyes for prolonged periods as damage to the cornea may occur not only from the local action of cocaine, but also from loss of the protective eyelid reflexes. As with other mydriatics, there is also a risk of cocaine precipitating angle-closure glaucoma in patients predisposed to the condition. Patients receiving cocaine for surface anaesthesia should be monitored for possible cardiovascular effects. Cocaine should be used with great caution in patients with hypertension, cardiovascular disease, or thyrotoxicosis. It is not recommended for use during pregnancy or breast feeding.

Abuse. Cocaine is subject to abuse. See under Adverse Effects, above.

Gilles de la Tourette's syndrome. Gilles de la Tourette's syndrome, which had been well controlled for 10 years by haloperidol, was precipitated in a 27-year-old man after intranasal use of cocaine on one occasion.[1]

1. Mesulam M-M. Cocaine and Tourette's syndrome. *N Engl J Med* 1986; **315:** 398.

Myasthenia gravis. Report of a patient in whom cocaine abuse first unmasked and then exacerbated myasthenia gravis.[1]

1. Berciano J, *et al.* Myasthenia gravis unmasked by cocaine abuse. *N Engl J Med* 1991; **325:** 892.

Porphyria. Cocaine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Cocaine and adrenaline enhance each other's sympathomimetic effects and should preferably not be used together. Caution is needed if cocaine is used with other drugs that may also potentiate the action of catecholamines such as guanethidine or MAOIs.

Adrenaline. In a report[1] of 3 cases of arrhythmias associated with the use of a paste containing cocaine 25% and adrenaline 0.18% for local anaesthesia of the nasal mucosa, the amount of cocaine applied to the nasal mucosa ranged from about 2.5 to 4.5 mg/kg. The maximum recommended dose of cocaine alone in healthy adults is 1.5 mg/kg.

1. Nicholson KEA, Rogers JEG. Cocaine and adrenaline paste: a fatal combination? *BMJ* 1995; **311:** 250–1.

Alcohol. In the presence of alcohol, cocaine is metabolised to its ethyl homologue cocaethylene.[1] Cocaethylene appears to have the same stimulant effects as cocaine but it has a longer half-life and *animal* studies suggest that it is more toxic than the parent drug. However, a review of the literature concluded that the use of cocaine with alcohol did not cause more cardiovascular problems than expected from the additive effects of each drug.[2]

1. Randall T. Cocaine, alcohol mix in body to form even longer lasting, more lethal drug. *JAMA* 1992; **267:** 1043–4.
2. Pennings EJM, *et al.* Effects of concurrent use of alcohol and cocaine. *Addiction* 2002; **97:** 773–83.

Beta blockers. *Propranolol* potentiated cocaine-induced coronary vasoconstriction after intranasal dosage of cocaine in a placebo-controlled study.[1] Because of a possible risk of paradoxical hypertension associated with the use of propranolol to manage arrhythmias associated with cocaine overdosage some prefer the use of labetalol for this indication (see under Treatment of Adverse Effects, above).

1. Lange RA, *et al.* Potentiation of cocaine-induced coronary vasoconstriction by beta-adrenergic blockade. *Ann Intern Med* 1990; **112:** 897–903.

Haloperidol. For the effect of haloperidol in cocaine abusers, see under Chlorpromazine, p.974.

Pharmacokinetics

Cocaine may be slowly absorbed from some sites because of the vasoconstriction it produces, but absorption occurs from all sites of application, including mucous membranes and the gastrointestinal tract, and may be enhanced when there is inflammation. Cocaine is rapidly absorbed when smoked.

Cocaine is rapidly metabolised by plasma esterases and hepatic esterases to ecgonine methyl ester. Benzoylecgonine, another major metabolite of cocaine, may be produced by spontaneous hydrolysis. Cocaine is also demethylated to the active metabolite norcocaine which is not excreted but undergoes further metabolism. There is considerable interindividual variation in the plasma half-life of cocaine possibly due to differences in esterase activity.

Cocaine and its metabolites are excreted in the urine, about 10% appearing as unchanged drug; they may be detectable in urine for several days or even weeks after use. Cocaine crosses the blood-brain barrier and accumulates within the CNS. It does not appear to undergo rapid metabolism within the brain and concentrations in the CNS after acute intoxication may greatly exceed those in plasma.

Cocaine crosses the placenta and the presence of its metabolites in neonatal hair has been used to indicate intra-uterine exposure. Cocaine is distributed into breast milk.

See also under Local Anaesthetics, p.1852.

Absorption. Cocaine is rapidly absorbed from the pulmonary vasculature when smoked and the speed of onset of its effects is similar to that obtained after intravenous injection.[1] Absorption from mucous membranes is delayed by vasoconstriction and peak plasma concentrations of up to 474 nanograms/mL have been obtained 15 to 120 minutes after application of doses of 1.5 to 2 mg/kg to the nasal mucosa as a 10% cocaine hydrochloride solution;[2,3] cocaine may still be detectable in the nose several hours later and this may result in prolonged systemic absorption.[2] In a study it was estimated that only 5% of the total dose of cocaine hydrochloride used prior to nasal surgery was absorbed from the nasal mucosa following application of 500 mg of cocaine hydrochloride as a 25% paste with adrenaline or 200 mg as a 10% solution with adrenaline (Moffett's solution) and blood concentrations were well below those associated with toxicity[4] (but see also Adrenaline, under Interactions, above). Peak serum concentrations of cocaine have been obtained after 50 to 90 minutes after oral use and are similar to those obtained after nasal application.[3]

Uses and Administration

Cocaine, a benzoic acid ester, is a local anaesthetic with actions and uses similar to those described on p.1852. It is used as a surface anaesthetic but, because of systemic adverse effects and its abuse potential, its use is now almost entirely restricted to surgery of the ear, nose, and throat. It has been largely replaced by other drugs in ophthalmology because of its corneal toxicity, although it may still be useful in removal or debridement of the corneal epithelium. Cocaine also blocks the uptake of catecholamines at adrenergic nerve endings and potentiates the action of catecholamines. Its sympathomimetic actions cause tachycardia, peripheral vasoconstriction, a rise in blood pressure, and mydriasis. The use of cocaine with sympathomimetics such as adrenaline increases the risk of cardiac arrhythmias. Despite this hazard some use this combination in otolaryngology to improve the operative field and reduce absorption.

When applied to mucous membranes, surface anaesthesia develops rapidly and persists for 30 minutes or longer depending on the concentration of cocaine used, the dose, and on the vascularity of the tissue.

Cocaine hydrochloride is used in aqueous solutions; cocaine hydrochloride 1.12 g is equivalent to about 1 g of cocaine. Solutions containing up to 4% have been used in ophthalmology (but precautions for ophthalmic use should be considered, see above).

Solutions containing up to 10% of cocaine are applied to the nasal mucosa in otolaryngological procedures. Pastes containing up to 25% of cocaine have also been applied.

In order to avoid systemic effects, the usual maximum total dose recommended for application to the nasal mucosa in healthy adults is 1.5 mg/kg. It should be used only by those skilled in the precautions needed to minimise absorption and the consequent risk of arrhythmias.

Cocaine was used with diamorphine or morphine for the relief of severe pain, especially in terminal illness, but this use is now obsolete.

Cocaine solutions should *never* be given by injection; other local anaesthetics are equally effective and much safer.

(dyclonine)

Pharmacopoeias. In *US.*

USP 31 (Dyclonine Hydrochloride). White crystals or white crystalline powder, with a slight odour. Soluble 1 in 60 of water, 1 in 24 of alcohol, and 1 in 2.3 of chloroform; soluble in acetone; practically insoluble in ether and in hexane. A 1% solution in water has a pH of 4.0 to 7.0. Store in airtight containers. Protect from light.

Profile

Dyclonine hydrochloride is a local anaesthetic (p.1850) used topically for surface anaesthesia of the skin and mucous membranes. Lozenges containing up to 3 mg and throat sprays containing 0.1% of dyclonine hydrochloride have been used for the temporary relief of pain associated with sore throats or mouth irritation; a 1% gel has also been used. A concentration of 0.75% has been used on the skin. It may cause irritation at the site of application.

Ethyl Chloride

Aethylium Chloratum; Chlorethyl; Cloruro de etilo; Ethyli Chloridum; Ethylis Chloridum; Etylklorid; Etylu chlorek; Etyylikloridi; Hydrochloric Ether; Monochlorethane. Chloroethane.

$C_2H_5Cl = 64.51.$
CAS — 75-00-3.
ATC — N01BX01.
ATC Vet — QN01BX01.

Pharmacopoeias. In *Pol.* and *US.*

USP 31 (Ethyl Chloride). A colourless, mobile, very volatile liquid at low temperatures or under pressure, with a characteristic ethereal odour. B.p. 12° to 13°. Slightly soluble in water; freely soluble in alcohol and in ether. Store in airtight containers, preferably hermetically sealed.

Stability. Ethyl chloride is highly flammable and mixtures of the gas with 5 to 15% of air are explosive.

Adverse Effects and Precautions

As for Chloroform, p.1781.

Cutaneous sensitisation can occur rarely. Thawing of frozen tissue following surgery may be painful and prolonged spraying onto the skin can cause chemical frostbite. Freezing may also distort the histological structure of biopsy specimens. Ethyl chloride should not be applied to broken skin or mucous membranes.

Uses and Administration

Owing to its low boiling-point and the intense cold produced by evaporation, ethyl chloride has been used as a local anaesthetic in minor surgery but such use is not generally recommended. It has also been used topically for the relief of pain and to test the effectiveness of regional anaesthesia. Ethyl chloride was formerly used as an inhalational anaesthetic but has no place in modern anaesthetic practice.

CAS — 36637-19-1.
ATC — N01BB07.
ATC Vet — QN01BB07.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Effects on the cardiovascular system. For a discussion of the cardiotoxicity of etidocaine, see under the Adverse Effects of Bupivacaine Hydrochloride, p.1855.

Porphyria. Etidocaine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Pharmacokinetics

Etidocaine is rapidly absorbed into the circulation after parenteral injection and is about 95% bound to plasma proteins. It crosses the placenta but the ratio of fetal to maternal concentrations is relatively low. It also diffuses across the blood-brain barrier. Etidocaine is metabolised in the liver and its numerous metabolites are excreted in the urine; less than 10% of the drug is excreted unchanged. The plasma elimination half-life of etidocaine is 2 to 3 hours in adults.

See also under Local Anaesthetics, p.1852.

Pregnancy. After maternal injection etidocaine rapidly crosses the placenta[1] but the degree of transfer is less than for other local anaesthetics including bupivacaine.[2] The ratio of fetal to maternal concentrations of etidocaine varies but values up to about 0.35 are usual.[1,2] Some metabolites appear to be transferred to a greater degree than the parent compound[1]. Etidocaine is highly protein bound but the fraction of unbound drug in plasma increases in pregnant women during delivery.[1] Protein binding of etidocaine is also reduced in fetal plasma.[3] Although neonates are able to metabolise etidocaine it appears that they are less able to do so than adults; a mean elimination half-life of 6.42 hours has been reported in neonates.[3]

2. Poppers PJ. Evaluation of local anaesthetic agents for regional anaesthesia in obstetrics. *Br J Anaesth* 1975; **47:** 322–7.
3. Morgan D, *et al.* Pharmacokinetics and metabolism of the anilide local anaesthetics in neonates: 11: etidocaine. *Eur J Clin Pharmacol* 1978; **13:** 365–71.

Uses and Administration

Etidocaine hydrochloride is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It has a rapid onset and a long duration of action. Etidocaine has been used for infiltration anaesthesia, peripheral nerve block, and epidural block, usually with adrenaline 1 in 200 000. (Local anaesthetic techniques are discussed on p.1853.)

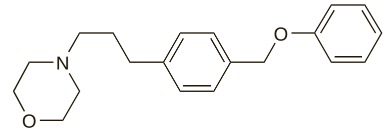
CAS — 17692-39-6 (fomocaine); 56583-43-8 (fomocaine hydrochloride).



(fomocaine)

Profile

Fomocaine is a local anaesthetic that has been included, as the hydrochloride, in mixed products intended for use in infected skin conditions.

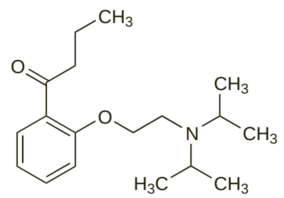
Ketocaine Hydrochloride *(rINNM)*

Chetocaina Cloridrata; Hidrocloruro de ketocaína; Kétocaïne, Chlorhydrate de; Ketocaini Hydrochloridum. 2′-(2-Di-isopropylaminoethoxy)butyrophenone hydrochloride.

Кетокаина Гидрохлорид

$C_{18}H_{29}NO_2,HCl = 327.9.$

CAS — 1092-46-2 (ketocaine); 1092-47-3 (ketocaine hydrochloride).



(ketocaine)

Profile

Ketocaine hydrochloride is a local anaesthetic (p.1850) that has been used as a surface anaesthetic in suppositories or ointments for anorectal disorders.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Ital.:*** Proctolyn.

Levobupivacaine *(BAN, rINN)*

S(−)-Bupivacaine; Levobupivacaína; Lévobupivacaïne; Levobupivacainum; Levobupivakaiini; Levobupivakain. (S)-1-Butyl-2-piperidylformo-2′,6′-xylidide.

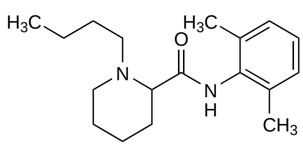
Левобупивакаин

$C_{18}H_{28}N_2O = 288.4.$

CAS — 27262-47-1.

ATC — N01BB10.

ATC Vet — QN01BB10.



Levobupivacaine Hydrochloride

(BANM, USAN, rINNM)

Hidrocloruro de levobupivacaína; Lévobupivacaïne, Chlorhydrate de; Levobupivacaini Hydrochloridum; Levobupivakain Hidroklorür.

Левобупивакаина Гидрохлорид

$C_{18}H_{28}N_2O,HCl = 324.9.$

CAS — 27262-48-2.

ATC — N01BB10.

ATC Vet — QN01BB10.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Levobupivacaine is contra-indicated for use in intravenous regional anaesthesia (Bier's block) and for paracervical block in obstetrics. The 0.75% solution is also contra-indicated for epidural block in obstetrics.

Effects on the cardiovascular system. It has been suggested[1] that levobupivacaine may have a lower risk of causing cardiotoxicity than bupivacaine (for the effects of bupivacaine on the cardiovascular system see p.1855).

1. Mather LE, Chang DH. Cardiotoxicity with modern local anaesthetics: is there a safer choice? *Drugs* 2001; **61:** 333–42.

Interactions

For interactions associated with local anaesthetics, see p.1851. Plasma concentrations of levobupivacaine may be reduced by enzyme-inducing drugs such as rifampicin. Levobupivacaine is metabolised by the cytochrome P450 isoenzymes CYP3A4 and CYP1A2 and there is a theoretical possibility that substrates for or inhibitors of these isoenzymes may adversely alter plasma concentrations of levobupivacaine.

Pharmacokinetics

The pharmacokinetics of levobupivacaine are similar to those of the racemic form, bupivacaine (p.1855). Levobupivacaine is at least 97% bound to plasma proteins. After intravenous doses the mean half-life is about 80 minutes. Levobupivacaine is extensively metabolised and excreted as its metabolites mainly in the urine, with smaller amounts appearing in the faeces. 3-Hydroxylevobupivacaine is a major metabolite and its formation is mediated by the cytochrome P450 isoenzyme CYP1A2; the isoenzyme CYP3A4 is also involved in the metabolism of levobupivacaine.

Uses and Administration

Levobupivacaine is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It is the S-enantiomer of bupivacaine (p.1854). Levobupivacaine is given as the hydrochloride for infiltration anaesthesia and regional nerve blocks including epidural block; however it is contra-indicated for obstetric paracervical block and for use in intravenous regional anaesthesia (Bier's block). The 0.75% solution is also contra-indicated for epidural blocks in obstetrics. (Local anaesthetic techniques are discussed on p.1853.)

Levobupivacaine hydrochloride is available in solutions containing the equivalent of 0.25 to 0.75% of levobupivacaine. The dosage depends on the site of injection and the procedure used as well as the status of the patient. The recommended **maximum single dose** is 150 mg. The total daily dose should not exceed 400 mg. A test dose of a suitable local anaesthetic, preferably with adrenaline, should be given before commencing epidural block with levobupivacaine to detect inadvertent intravascular injection. Subsequent doses of levobupivacaine should be given in small increments. Levobupivacaine should be given in reduced doses to elderly, debilitated, or acutely ill patients.

- For **surgical anaesthesia** doses of levobupivacaine for *epidural block* are 50 to 100 mg (10 to 20 mL) as a 0.5% solution, or 75 to 150 mg (10 to 20 mL) as a 0.75% solution; for caesarean section, doses are 75 to 150 mg (15 to 30 mL) as a 0.5% solution. The dose for *spinal block* is 15 mg (3 mL) as a 0.5% solution.
- For *peripheral nerve blocks*, doses are 2.5 to 150 mg as a 0.25 or 0.5% solution; a volume of 40 mL should not be exceeded. Alternatively doses for peripheral block have been expressed on the basis of body-weight: 1 to 2 mg/kg (0.4 mL/kg) as a 0.25 or 0.5% solution.
- For *infiltration anaesthesia* up to 150 mg (60 mL) as a 0.25% solution may be used. For peribulbar block in *ophthalmic* procedures 37.5 to 112.5 mg (5 to 15 mL) as a 0.75% solution may be given. For ilioinguinal or iliohypogastric blocks in **children** under 12 years, doses of levobupivacaine are 0.625 to 2.5 mg/kg (0.25 to 0.5 mL/kg) as a 0.25 or 0.5% solution.
- In the management of **acute pain** levobupivacaine may be given as an epidural bolus or by continuous infusion. For pain relief during *labour* 15 to 50 mg (6 to 20 mL) as a 0.25% solution is given as a bolus. Alternatively, a 0.125% solution may be given as an infusion in a dose of 5 to 12.5 mg (4 to 10 mL) per hour, or a 0.0625% solution may be given in a dose of 5 to 12.5 mg (8 to 20 mL) per hour. For *postoperative pain* 10 to 25 mg (4 to 10 mL) per hour as a 0.25% solution, 12.5 to 18.75 mg (10 to 15 mL) per hour as a 0.125% solution, or 12.5 to 18.75 mg (20 to 30 mL) per hour as a 0.0625% solution may be given as an epidural infusion.

In some countries such as the UK, licensed product information recommends that a lower concentration such as the 0.125% solution should be used if other analgesics are also given for pain relief; in other countries product information has specifically stated that the 0.125% solution should only be used for adjunctive therapy with fentanyl or clonidine. When necessary, dilutions should be made with sodium chloride 0.9%.

◊ Reviews

1. Foster RH, Markham A. Levobupivacaine: a review of its pharmacology and use as a local anaesthetic. *Drugs* 2000; **59:** 551–79.

Action. A comparison[1] of epidural bupivacaine with levobupivacaine in women in labour found that levobupivacaine had 98% of the potency of the racemate, a clinically insignificant difference. However it was pointed out that whereas the concentration of bupivacaine solutions was expressed in terms of the hydrochloride, solutions of levobupivacaine had their strength expressed in terms of the free base. When calculations were made in terms of molar equivalents levobupivacaine appeared to be 13% less potent than racemic bupivacaine. The difference in expression should be borne in mind when evaluating comparative studies.

NOTE. LIDFLN is a code approved by the BP 2008 for use on single unit doses of eye drops containing lidocaine hydrochloride and fluorescein sodium where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Lidocaine Hydrochloride). A white, or almost white, crystalline powder. M.p. 74° to 79°. Very soluble in water; freely soluble in alcohol. A 0.5% solution in water has a pH of 4.0 to 5.5. Protect from light.

USP 31 (Lidocaine Hydrochloride). A white, odourless, crystalline powder. M.p. 74° to 79°. Very soluble in water and in alcohol; soluble in chloroform; insoluble in ether.

Incompatibility. Lidocaine hydrochloride has been reported to be incompatible in solution with amphotericin B,[1] sulfadiazine sodium,[2] methohexital sodium,[2] cefazolin sodium,[3] or phenytoin sodium.[4]

Acid stable drugs such as adrenaline hydrochloride, noradrenaline acid tartrate, or isoprenaline may begin to deteriorate within several hours of admixture with lidocaine hydrochloride as lidocaine solutions may raise the pH of the final solution above the maximum pH for their stability. Such extemporaneous mixtures should be used promptly after preparation.[5]

4. Kirschenbaum HL, *et al.* Stability and compatibility of lidocaine hydrochloride with selected large-volume parenterals and drug additives. *Am J Hosp Pharm* 1982; **39:** 1013–15.
5. Parker EA. Xylocaine hydrochloride 2% injection. *Am J Hosp Pharm* 1971; **28:** 805.

pH of solutions. For the effect pH has on the surface tension and administration of lidocaine solutions by infusion, see under Administration in Uses and Administration, p.1852. For its effect on the stability of local anaesthetic solutions and the pain associated with their injection, see p.1852.

Stability. Although there was no decrease in the lidocaine content of lidocaine hydrochloride and adrenaline injection during transport and storage under tropical conditions, the content of adrenaline fell to almost zero in some samples after several months; supply of the injection as a dry powder and separate solvent should be considered for the tropics.[1]

The lidocaine content of buffered cardioplegic solutions has been reported[2] to decrease when stored in PVC containers at ambient temperature, but not when stored at 4°. This loss appeared to result from pH-dependent sorption of lidocaine onto the plastic and did not occur when lidocaine solutions were stored in glass bottles.

1. Abu-Reid IO, *et al.* Stability of drugs in the tropics: a study in Sudan. *Int Pharm J* 1990; **4:** 6–10.
2. Lackner TE, *et al.* Lidocaine stability in cardioplegic solution stored in glass bottles and polyvinyl chloride bags. *Am J Hosp Pharm* 1983; **40:** 97–101.

Adverse Effects and Treatment

As for Local Anaesthetics in general, p.1850.

Effects on the CNS. Suspected psychotic reactions have been reported in 6 patients given intravenous lidocaine for the treatment of cardiac disorders.[1] In another case,[2] 2 patients developed signs of cerebral ataxia after topical use of lidocaine for endoscopy.

When compared with other local anaesthetics, lidocaine may be associated with an increased risk of neurotoxic complications when used for spinal anaesthesia, (see under Adverse Effects of Central Block, p.1850).

1. Turner WM. Lidocaine and psychotic reactions. *Ann Intern Med* 1982; **97:** 149–50.
2. Perney P, *et al.* Transitory ataxia related to topically administered lidocaine. *Ann Pharmacother* 2004; **38:** 828–30.

Effects on the skin. Erythema and pigmentation of the upper lip in a child after local dental infiltration of lidocaine was attributed to a type of fixed drug eruption.[1] Erythema may also occur after topical use of some lidocaine formulations, such as transdermal patches, while transient blanching of the skin is frequent after application of eutectic lidocaine/prilocaine mixtures to the skin.[2]

True hypersensitivity reactions, including dermatitis, are rare (see also p.1850) but can occur.[3]

1. Curley RK, *et al.* An unusual cutaneous reaction to lignocaine. *Br Dent J* 1987; **162:** 113–14.
2. Villada G, *et al.* Local blanching after epicutaneous application of EMLA cream: a double-blind randomized study among 50 healthy volunteers. *Dermatologica* 1990; **181:** 38–40.
3. Bircher AJ, *et al.* Delayed-type hypersensitivity to subcutaneous lidocaine with tolerance to articaine: confirmation by in vivo and in vitro tests. *Contact Dermatitis* 1996; **34:** 387–9.

Overdosage. The most serious effects of lidocaine intoxication are on the CNS and cardiovascular system and overdosage can result in severe hypotension, asystole, bradycardia, apnoea, seizures, coma, cardiac arrest, respiratory arrest, and death. Intoxication with lidocaine is relatively common and can occur as a result of acute overdosage after poor control of intravenous maintenance infusions or accidental injection of concentrated solutions. However, it more commonly results from inadvertent intravascular dosage during regional anaesthesia, or from too rapid injection of antiarrhythmic doses, particularly in patients with circulatory insufficiency, or when clearance is reduced due to heart failure, liver disease, old age, or through interaction with other drugs.[1] Seizures have also been reported after excessive doses given subcutaneously.[2] Although the bioavailability of lidocaine is low it may be sufficient to result in significant toxicity when swallowed[1] and there have been reports of CNS effects, seizures, and death in children[3-7] and adults[8-10] after the ingestion of topical solutions and after the use of viscous preparations in the mouth. Death has also ensued after gargling with a 4% lidocaine solution.[11] Lidocaine is absorbed from mucous membranes and serious toxicity has been reported after urethral[12] or rectal[13] instillation of lidocaine preparations.

Pregnancy. Serious adverse effects of epidural anaesthesia are rare but lidocaine may have transient effects on the neonatal auditory system.[1]

1. Bozynski MEA, *et al.* Effect of prenatal lignocaine on auditory brain stem evoked response. *Arch Dis Child* 1989; **64:** 934–8.

Precautions

As for Local Anaesthetics in general, p.1851.

In general lidocaine should not be given to patients with hypovolaemia, heart block or other conduction disturbances, and should be used with caution in patients with congestive heart failure, bradycardia, or respiratory depression. Lidocaine is metabolised in the liver and must be given with caution to patients with hepatic impairment. The plasma half-life of lidocaine may be prolonged in conditions that reduce hepatic blood flow such as cardiac and circulatory failure. Metabolites of lidocaine may accumulate in patients with renal impairment.

The intramuscular injection of lidocaine may increase creatine phosphokinase concentrations that can interfere with the diagnosis of acute myocardial infarction.

Breast feeding. No adverse effects have been seen in breast-fed infants whose mothers were receiving lidocaine, and the American Academy of Pediatrics[1] considers that it is therefore usually compatible with breast feeding.

1. American Academy of Pediatrics. The transfer of drugs and other chemicals into human milk. *Pediatrics* 2001; **108:** 776–89. Correction. *ibid.*; 1029. Also available at: http://aappolicy.aappublications.org/cgi/content/full/pediatrics%3b108/3/776 (accessed 02/06/04)

Cerebrovascular disorders. Lidocaine 5 mg/kg by intravenous infusion over 30 minutes was associated with a 12% reduction in cerebral blood flow in healthy subjects although this returned to normal within 60 minutes.[1] Cerebral blood flow in patients with diabetes was lower than in healthy subjects, but was unaffected by lidocaine infusion, indicating reduced cerebrovascular reactivity.

1. Kastrup J, *et al.* Intravenous lidocaine and cerebral blood flow: impaired microvascular reactivity in diabetic patients. *J Clin Pharmacol* 1990; **30:** 318–23.

Porphyria. Lidocaine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Renal impairment. The pharmacokinetics of lidocaine and its metabolite monoethylglycinexylidide appear to be unaffected in patients with renal failure except that accumulation of the metabolite glycinexylidide may occur during infusions of 12 hours or more.[1] Data to predict the amount of lidocaine and glycinexylidide removed during haemodialysis have been provided.[2,3] Lidocaine does not appear to be removed during haemofiltration.[4]

Smoking. The effects of smoking on lidocaine therapy are unclear. Studies in a limited number of patients have found reduced systemic bioavailability suggestive of induction of drug-metabolising activity[1] and an inconsistent effect on protein binding.[2,3]

Interactions

For interactions associated with local anaesthetics, see p.1851.

The clearance of lidocaine may be reduced by propranolol and cimetidine (see below). The cardiac depressant effects of lidocaine are additive with those of beta blockers and of other antiarrhythmics. Additive cardiac effects may also occur when lidocaine is given with intravenous phenytoin; however, the long-term use of phenytoin and other enzyme-inducers may increase dosage requirements of lidocaine (see Antiepileptics, below). Hypokalaemia produced by acetazolamide, loop diuretics, and thiazides antagonises the effect of lidocaine.

Antiarrhythmics. Lidocaine toxicity, arising from the use of an oral preparation containing lidocaine, has been reported[1] in a patient who was receiving *mexiletine*. There are individual reports of seizures or heart failure and cardiac arrest in patients who received intravenous lidocaine with *ajmaline*,[2] *amiodarone*,[3,4] or *tocainide*.[5] Delirium has been reported in a patient who received lidocaine with *procainamide*.[6]

6. Ilyas M, *et al.* Delirium induced by a combination of anti-arrhythmic drugs. *Lancet* 1969; **ii:** 1368–9.

Antiepileptics. Studies in healthy subjects and patients with epilepsy[1,2] suggest that long-term use of drugs such as *phenytoin* or *barbiturates* may increase dosage requirements for lidocaine due to induction of drug-metabolising microsomal enzymes. Phenytoin can also increase plasma concentrations of α_1-acid glycoprotein and thereby reduce the free fraction of lidocaine in plasma.[3]

The cardiac depressant effects of lidocaine may be dangerously enhanced by intravenous phenytoin.[4]

Beta blockers. Significant increases in plasma-lidocaine concentrations have occurred with *propranolol*,[1-4] owing to a reduction in the clearance of lidocaine from plasma. A similar interaction has occurred with *nadolol*[3] and *metoprolol*,[2] although in another study[5] metoprolol did not alter the pharmacokinetics of lidocaine. The hepatic metabolism of lidocaine may be reduced as a result of a fall in hepatic blood flow associated with reduced cardiac output or it may be caused by direct inhibition of hepatic microsomal enzymes.[6] Significant impairment of lidocaine clearance would therefore be most likely to occur with those drugs that lack intrinsic sympathomimetic activity and have a greater effect on cardiac output or with the more lipid-soluble drugs that have greater effects on microsomal oxygenases. The reduction in clearance produced by propranolol seems to be mainly by direct inhibition of metabolism rather than by lowering of hepatic blood flow.[4]

H_2-antagonists. There have been numerous studies[1-4] of the interaction between *cimetidine* and lidocaine but differences between the studies make interpretation of the overall clinical significance of the results difficult. Cimetidine appears to reduce the hepatic metabolism of lidocaine; it may also reduce its clearance by decreasing hepatic blood flow. Significant increases in plasma-lidocaine concentrations have been reported. Changes in protein binding are not generally important but patients with myocardial infarction who have increased levels of α_1-acid glycoprotein may be partially protected from increases in concentrations of free lidocaine.[5] Since it is not possible to identify those patients at risk all patients receiving both drugs should be closely monitored for signs of toxicity. The use of other H_2-antagonists may be preferable. In studies in healthy subjects *ranitidine* either had no effect on lidocaine kinetics[6] or produced changes consistent with small reductions in hepatic blood flow.[7]

7. Robson RA, *et al.* The effect of ranitidine on the disposition of lignocaine. *Br J Clin Pharmacol* 1985; **20:** 170–3.

Local anaesthetics. Although a number of drugs were shown to reduce the amount of lidocaine bound to α_1-acid glycoprotein only the displacement produced by *bupivacaine* was considered to be of possible clinical significance.[1]

There is concern about the use of lidocaine to treat *cocaine*-induced arrhythmias as lidocaine may enhance toxicity.[2]

Neuromuscular blockers. The possible interaction between neuromuscular blockers and antiarrhythmics including lidocaine is discussed under Atracurium, p.1903.

Oral contraceptives. For mention of the effect of oral contraceptives on the protein binding of lidocaine, see under Protein Binding in Pharmacokinetics, below.

Pharmacokinetics

Lidocaine is readily absorbed from the gastrointestinal tract, from mucous membranes, and through damaged skin. Absorption through intact skin is poor. It is rapidly absorbed from injection sites including muscle.

After an intravenous dose lidocaine is rapidly and widely distributed into highly perfused tissues followed by redistribution into skeletal muscle and adipose tissue. Lidocaine is bound to plasma proteins, including α_1-acid glycoprotein (AAG). The extent of binding is variable but is about 66%. Plasma protein binding of lidocaine depends in part on the concentrations of both lidocaine and AAG. Any alteration in the concentration of AAG can greatly affect plasma concentrations of lidocaine (see under Protein Binding, below).

Plasma concentrations decline rapidly after an intravenous dose with an initial half-life of less than 30 minutes; the elimination half-life is 1 to 2 hours but may be prolonged if infusions are given for longer than 24 hours or if hepatic blood flow is reduced.

Lidocaine is largely metabolised in the liver and any alteration in liver function or hepatic blood flow can have a significant effect on its pharmacokinetics and dosage requirements. First-pass metabolism is extensive and bioavailability is about 35% after oral doses. Metabolism in the liver is rapid and about 90% of a given dose is dealkylated to form monoethylglycinexylidide and glycinexylidide. Both of these metabolites may contribute to the therapeutic and toxic effects of lidocaine and since their half-lives are longer than that of lidocaine, accumulation, particularly of glycinexylidide, may occur during prolonged infusions. Further metabolism occurs and metabolites are excreted in the urine with less than 10% of unchanged lidocaine. Reduced clearance of lidocaine has been found in patients with heart failure, alcoholic liver disease, or chronic or viral hepatitis. Drugs that alter hepatic blood flow or induce drug-metabolising microsomal enzymes can also affect the clearance of lidocaine (see Interactions, above). Renal impairment does not affect the clearance of lidocaine but accumulation of its active metabolites can occur.

Lidocaine crosses the placenta and blood-brain barrier; it is distributed into breast milk.

See also under Local Anaesthetics, p.1852.

Absorption. SURFACE APPLICATION. Serum-lidocaine concentrations were usually so low as to be unmeasurable in patients who gargled and expectorated 15 mL (300 mg) of a 2% viscous solution before endoscopy[1] and mean peak serum concentrations of lidocaine were below those associated with toxicity following endotracheal application of 100 mg of lidocaine by spray.[2] The relative bioavailability of lidocaine has been found to be higher when applied to the upper respiratory tract than after administration to the lower respiratory tract.[3] Acceptably low plasma-lidocaine concentrations were noted with the following regimen used before bronchoscopy: a 4% lidocaine solution gargled for 30 seconds, a 2% solution sprayed onto the oropharynx, a 2% jelly applied to the oropharynx and nasal passages, and a 1% solution injected through a bronchoscope.[4] However, a fatality has been reported following the use of lidocaine as a gargle (see Overdosage, above); the absorption of intranasal lidocaine can also be highly variable.[5] For bronchoscopy, inhalation of lidocaine from a nebuliser rather than a direct spray may result in lower peak serum concentrations.[6]

Absorption of lidocaine is generally poor through intact skin. However, there is some evidence that absorption may be greater after application to the skin of preterm infants.[7]

Protein binding. Lidocaine is markedly bound to α_1-acid glycoprotein (AAG), a plasma protein which is increased after trauma, surgery, burns, myocardial infarction, in chronic inflammatory disorders such as Crohn's disease, and in cancer. Protein binding may therefore be greatly increased in these conditions and reduced in neonates, the nephrotic syndrome, and in liver disease when AAG concentrations are lower than normal. This can result in an eightfold variation in the free fraction of lidocaine between these conditions.[1] Measurement of free drug concentrations may be a better guide to dosage requirements than measurement of total plasma concentrations.[2] AAG concentrations may also be reduced by oestrogens[3] leading to a higher free fraction of lidocaine in women than in men and the free fraction is further increased during pregnancy and in women taking oral contraceptives.[3,4] Protein binding may also be affected by other concomitant drug therapy or smoking (for further details, see Antiepileptics under Interactions, above and Precautions, Smoking, above).

Uses and Administration

Lidocaine is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It is used for infiltration anaesthesia and regional nerve blocks. It has a rapid onset of action and anaesthesia is obtained within a few minutes; it has an intermediate duration of action. The speed of onset and duration of action of lidocaine are increased by the addition of a vasoconstrictor and absorption into the circulation from the site of injection is reduced. It is generally given as the hydrochloride. Lidocaine hydrochloride monohydrate 1.23 g or anhydrous lidocaine hydrochloride 1.16 g are both equivalent to about 1 g of lidocaine. A carbonated solution of lidocaine is also available in some countries for injection (see p.1852). Lidocaine is also a useful surface anaesthetic but it may be rapidly and extensively absorbed following topical application to mucous membranes, and systemic effects may occur. Hyaluronidase (p.2321) has been added to preparations of lidocaine used for surface and infiltration anaesthesia but may enhance systemic absorption. (Local anaesthetic techniques are discussed on p.1853.)

Lidocaine is included in some injections, such as depot corticosteroids, to prevent pain, itching, and other local irritation. Lidocaine sodium has also been included in intramuscular injections of some antibacterials to reduce the pain on injection.

Lidocaine is also a class Ib antiarrhythmic used in the treatment of ventricular arrhythmias, especially after myocardial infarction. It has been given by intravenous infusion in the treatment of refractory status epilepticus.

USE IN LOCAL ANAESTHESIA.

The dose of lidocaine hydrochloride used for local anaesthesia depends on the site of injection and the procedure used. Specific licensed doses for individual procedures are not always available in the UK, although US product information often includes them (see below). When given with adrenaline, the suggested general **maximum single dose** of lidocaine hydrochloride is 500 mg; without adrenaline, the recommended maximum single dose in the UK is 200 mg and in the USA, 300 mg, except for spinal anaesthesia (see below). Lidocaine hydrochloride solutions containing adrenaline 1 in 200 000 are used for infiltration anaesthesia and nerve blocks including epidural block; higher concentrations of adrenaline are seldom necessary, except in dentistry, where solutions of lidocaine hydrochloride with adrenaline 1 in 80 000 are widely used. Doses should be reduced in children, the elderly, and in debilitated patients. A test dose, preferably with adrenaline, should be given before starting epidural block to detect inadvertent intravascular or subarachnoid dosage.

The following doses have been recommended for individual **local anaesthetic procedures** in the USA:

- For percutaneous *infiltration anaesthesia*, 5 to 300 mg (1 to 60 mL of a 0.5% solution, or 0.5 to 30 mL of a 1% solution).
- The dosage in *peripheral nerve block* depends on the route. For brachial plexus block 225 to 300 mg (15 to 20 mL) as a 1.5% solution is used; for intercostal nerve block 30 mg (3 mL) is given as a 1% solution; for paracervical block a 1% solution is used in a dose of 100 mg (10 mL) on each side, repeated not more frequently than every 90 minutes; for paravertebral block a 1% solution may be used in doses of 30 to 50 mg (3 to 5 mL); a 1% solution is recommended for pudendal block in doses of 100 mg (10 mL) on each side; for retrobulbar block a 4% solution may be used in doses of 120 to 200 mg (3 to 5 mL).
- For *sympathetic nerve block* a 1% solution is recommended; doses are 50 mg (5 mL) for cervical block and 50 to 100 mg (5 to 10 mL) for lumbar block.
- For *epidural anaesthesia* 2 to 3 mL of solution is needed for each dermatome to be anaesthetised but usual total doses and recommended concentrations are: lumbar epidural 250 to 300 mg (25 to 30 mL) as a 1% solution for analgesia and 225 to 300 mg (15 to 20 mL) as a 1.5% solution or 200 to 300 mg (10 to 15 mL) as a 2% solution for anaesthesia, and for thoracic epidural a 1% solution may be used at doses of 200 to 300 mg (20 to 30 mL). In obstetric caudal analgesia up to 300 mg (30 mL) is used as a 0.5% or 1% solution and in surgical caudal analgesia a 1.5% solution may be used in doses of 225 to 300 mg (15 to 20 mL). For continuous epidural anaesthesia, the maximum doses should not be repeated more frequently than every 90 minutes.

- A hyperbaric solution of 1.5% or 5% lidocaine hydrochloride in glucose 7.5% solution is available for *spinal anaesthesia*; adrenaline should not be used. Doses of up to 50 mg (1 mL) as a 5% solution and 9 to 15 mg (0.6 to 1 mL) as a 1.5% solution have been used during labour for a normal vaginal delivery. Up to 75 mg (1.5 mL) as the 5% solution has been used for caesarean section and 75 to 100 mg (1.5 to 2 mL) for other surgical procedures.
- For *intravenous regional anaesthesia* a 0.5% solution without adrenaline has been used in doses of 50 to 300 mg (10 to 60 mL); a maximum dose of 4 mg/kg has been recommended for adults.

Lidocaine may be used in a variety of formulations for **surface anaesthesia**.

- Lidocaine ointment is used for *anaesthesia of skin and mucous membranes* with a maximum recommended total dose of 20 g of 5% ointment (equivalent to 1 g of lidocaine base) in 24 hours.
- Gels are used for *anaesthesia of the urinary tract* and the dose used varies in different countries. The manufacturers in the UK have suggested the following doses given as a 2% gel: in females 60 to 100 mg of lidocaine hydrochloride inserted into the urethra several minutes before examination; in males 200 mg instilled initially followed by 60 to 100 mg. A 1% gel may also be used. The doses used in the USA are similar: in females 60 to 100 mg of lidocaine hydrochloride as a 2% gel is inserted into the urethra several minutes before examination; in males 100 to 200 mg is used before catheterisation and 600 mg before sounding or cystoscopy.

  A gel may also be applied for the treatment of *major aphthae* in immunocompromised patients; a dose of 20 to 30 mg (2 to 3 mL) as a 1% gel or 40 to 60 mg (2 to 3 mL) as a 2% gel is used. A maximum volume of up to 15 mL is recommended within 24 hours.
- Topical solutions are used for *surface anaesthesia of mucous membranes of the mouth, throat, and upper gastrointestinal tract*. For painful conditions of the mouth and throat a 2% solution may be used: 300 mg (15 mL) may be rinsed and ejected or, for pharyngeal pain, the solution is gargled and swallowed if necessary; it should not be used more frequently than every 3 hours. The recommended maximum daily dose in the USA for topical oral solutions is 2.4 g. Doses of 40 to 300 mg as a 4% solution (1 to 7.5 mL) are used before bronchoscopy, bronchography, laryngoscopy, oesophagoscopy, endotracheal intubation, and biopsy in the mouth and throat. Lidocaine in a strength of 10% has also been used as a spray for application to mucous membranes for the prevention of pain during various procedures including use in otorhinolaryngology, dentistry, introduction of instruments into the respiratory and gastrointestinal tracts, and in obstetrics. The dose depends on the extent of the site to be anaesthetised; 10 to 50 mg is generally sufficient for dentistry and otorhinolaryngology; for other procedures, the maximum dose in a 24-hour period is 200 mg. For laryngotracheal anaesthesia 160 mg of lidocaine hydrochloride as a 4% solution is sprayed or instilled as a single dose into the lumen of the larynx and trachea.
- Lidocaine is used *rectally* as suppositories, sprays, ointments, and creams in the treatment of haemorrhoids and other painful perianal conditions.
- *Eye drops* containing lidocaine hydrochloride 4% with fluorescein are used in tonometry.
- A *eutectic mixture* containing lidocaine base 2.5% and prilocaine base 2.5% is applied as a cream under an occlusive dressing to produce *surface anaesthesia of the skin* before procedures requiring needle puncture, surgical treatment of localised lesions, and split skin grafting; it has been used similarly, but without an occlusive dressing, before removal of genital warts (see also under Surface Anaesthesia, below).
- Other methods of dermal delivery include a *transdermal patch* of lidocaine 5% for the treatment of pain associated with postherpetic neuralgia, and an *iontophoretic drug delivery system* incorporating lidocaine and adrenaline. A transdermal patch containing lidocaine 70 mg with tetracaine 70 mg is also available for surface anaesthesia, as is an *intradermal injection system* delivering lidocaine hydrochloride 500 micrograms.

USE IN ARRHYTHMIAS.

For the treatment of **ventricular arrhythmias** lidocaine is given *intravenously* as the hydrochloride. It may be used in advanced cardiac life support for cardiac arrest due to ventricular fibrillation and pulseless ventricular tachycardia when direct current shocks (together with adrenaline) have failed to restore a normal rhythm. For adults, a usual dose of 1 to 1.5 mg/kg can be given and repeated as necessary to a maximum total dose of 3 mg/kg. The *endotracheal* route has been employed when intravenous access cannot be obtained, although doses should probably be larger than those employed intravenously; the precise endotracheal dose has not yet been established, however.

Lidocaine is also used in other ventricular arrhythmias in which the patient is in a more stable condition. In these circumstances lidocaine hydrochloride is usually given as a loading dose followed by an infusion. Usual doses are 50 to 100 mg or 1 to 1.5 mg/kg as a direct *intravenous injection* at a rate of 25 to 50 mg/minute. If no effect is seen within 5 to 10 minutes of this loading dose, it may be repeated once or twice to a maximum dose of 200 to 300 mg in 1 hour. A *continuous intravenous infusion* is usually commenced after loading, at a dose of 1 to 4 mg/minute. It is rarely necessary to continue this infusion for longer than 24 hours, but in the event that a longer infusion is required, the dose may need to be reduced to avoid potential toxicity resulting from an increase in the half-life. Dosage may need to be reduced in the elderly and in patients with heart failure or liver disorders.

In emergency situations, lidocaine hydrochloride has also been given for arrhythmias by *intramuscular* injection into the deltoid muscle in a dose of 300 mg, repeated if necessary after 60 to 90 minutes.

Action. For a comparison of the vasoactivity of lidocaine and some other local anaesthetics, see p.1852.

Burns. Lidocaine given intravenously has been reported to have produced pain relief in a few patients with second-degree burns.[1]

1. Jönsson A, *et al.* Inhibition of burn pain by intravenous lignocaine infusion. *Lancet* 1991; **338:** 151–2.

Cardiac arrhythmias. Lidocaine is classified as a class Ib antiarrhythmic drug (p.1153) and may be used in the treatment of ventricular arrhythmias, including those associated with cardiac arrest and myocardial infarction, although other drugs are usually preferred (see Cardiac Arrhythmias, p.1160). It is usually given intravenously (see above). Lidocaine may also be used during advanced cardiac life support (p.1156).

Lidocaine has been considered for the *prophylaxis* of ventricular fibrillation in patients with proven or suspected myocardial infarction. However, while some studies have identified a protective effect of lidocaine,[1,2] in others it was not shown to reduce mortality and might even have increased it,[3,4] and thus is no longer generally recommended.

It has been suggested that the increased mortality sometimes seen with lidocaine might be associated with the duration of treatment; a study[5] found that patients who received a bolus dose of lidocaine followed by a 40-hour continuous infusion for prophylaxis of ventricular arrhythmias experienced more episodes of heart failure than patients who received the bolus dose followed by an 8-hour infusion.

Hiccup. For the management of intractable hiccups see under Chlorpromazine, p.976. Lidocaine is one of a large number of drugs that has been tried in the treatment of hiccups without strong evidence of their efficacy. It has been given intravenously, or in the form of a 2% viscous solution taken by mouth. Nebulised lidocaine has also been tried.[1]

1. Neeno TA, Rosenow EC. Intractable hiccups: consider nebulized lidocaine. *Chest* 1996; **110:** 1129–30.

Intubation. Lidocaine has produced conflicting results when used to attenuate the pressor response and rise in intra-ocular pressure induced by procedures such as tracheal intubation.[1-5] For an overall discussion of this problem, see under Anaesthesia, p.1900.

1. Tam S, *et al.* Attenuation of circulatory responses to endotracheal intubation using intravenous lidocaine: a determination of the optimal time of injection. *Can Anaesth Soc J* 1985; **32:** S65.

Migraine and cluster headache. Despite periodic interest, lidocaine has so far failed to find an accepted role in the management of migraine (p.616) or cluster headache (p.616). Lidocaine has been tried for the emergency parenteral treatment of migraine, but in a comparative study with dihydroergotamine or chlorpromazine it was found to be less effective than either.[1] While some workers have found that intranasal instillation of lidocaine has produced rapid relief of headache in some patients with acute migraine (though early relapse was common)[2] others have found it to be ineffective.[3] It has also been reported to be effective in aborting individual attacks of headache during cluster periods in patients with cluster headache.[4,5] However, most patients do not appear to obtain complete pain relief.

Neuropathic pain syndromes. Lidocaine may be useful in the management of some types of neuropathic pain syndromes (p.8). The pain of *postherpetic neuralgia* has been significantly reduced by the application of lidocaine 5% transdermal patches[1-3] although a systematic review[4] found insufficient evidence to recommend its use as first-line therapy; intravenous lidocaine[5] and a eutectic mixture of lidocaine and prilocaine (see Surface Anaesthesia below) have also been of benefit. Other syndromes where intravenous lidocaine therapy has been tried include *diabetic neuropathy*[6] and *central neuropathic pain* associated with stroke or spinal cord injury.[7]

Pleurodesis. Lidocaine has been instilled intrapleurally as a 1% solution in doses of up to 300 mg to relieve the severe chest pain associated with the use of tetracycline for pleurodesis.[1-3] While the larger doses were significantly more effective[2] toxic plasma concentrations were less likely to occur if a dose of 3 mg/kg or less was used.[3]

Status epilepticus. Lidocaine hydrochloride may be used to control status epilepticus (p.469) resistant to more conventional treatment, particularly in those with respiratory disease. It has a rapid onset of action but its effect is short-lived and continuous infusion may be necessary.[1] It should also be noted that doses producing high plasma concentrations of lidocaine can result in CNS toxicity including seizures.[1] Recurrence of seizures associated with the withdrawal of prolonged lidocaine therapy may be due to its accumulated metabolites exerting an excitatory effect on the nervous system when the inhibitory effect of lidocaine is being reduced.[2]

Lidocaine was used instead of diazepam for 42 episodes of status epilepticus in 36 patients who either had limited pulmonary reserve or who had not responded to intravenous diazepam.[3] Lidocaine 1.5 to 2 mg/kg (usually a dose of 100 mg) was given as a single intravenous dose over 2 minutes. This dose was repeated once if there was no positive response to the first dose (11 episodes) or if the seizures recurred (19 episodes). Subsequently a continuous infusion of lidocaine at a rate of 3 to 4 mg/kg per hour was given in the 7 episodes that recurred after the second dose; 5 of these showed a positive response. The 11 episodes not responding to the first dose did not respond to the second dose or to a continuous infusion. In a retrospective analysis[4] of 37 children with status epilepticus, lidocaine was effective in only 19 of 53 episodes; however, in a few cases it was effective where other drugs had failed, and those patients who responded did so rapidly (within 5 minutes of being given the drug).

Surface anaesthesia. ***EUTECTIC MIXTURES.*** A cream containing lidocaine 2.5% and prilocaine 2.5% as a eutectic mixture can produce local anaesthesia when applied topically to intact skin. It appears to be of value in minor medical or surgical procedures in *adults* and *children*,[1-3] such as venepuncture, intravenous or arterial cannulation, retrobulbar injections, lumbar puncture, curettage of molluscum contagiosum lesions, genital wart removal, split skin grafting, laser treatment, extracorporeal shock wave therapy, separation of preputial adhesions, and circumcision. It has also been tried as an anaesthetic for the ear drum in preparation for otological procedures such as myringotomy and grommet insertion but is potentially ototoxic and should not be used in the presence of a perforation. Postherpetic neuralgia (p.9) has also been treated with some success.[4,5]

The eutectic cream is usually applied to skin under an occlusive dressing for at least 60 minutes although it has been suggested that for children aged 1 to 5 years 30 minutes may be sufficient.[6] The manufacturers suggest a maximum application time of 5 hours. The onset and duration of the effect may be affected by the site of application.[2] When used for the removal of genital warts an occlusive dressing is not necessary and the application time recommended by the manufacturer is 5 to 10 minutes. The level of anaesthesia begins to decline after 10 to 15 minutes when applied to the genital mucosa and any procedure should be started immediately.

Eutectic mixtures of lidocaine and prilocaine have also been used in *neonates* to reduce the pain of puncture procedures[7] and for circumcision,[8,9] and appear to be safe and efficacious. There has been concern that excessive absorption (particularly of prilocaine) might lead to methaemoglobinaemia (see p.1850), and UK licensing information recommends that the eutectic cream not be used in children less than 1 year old. However, there seems to be little evidence of this, and the *BNF* considers that it may be used under specialist supervision in infants over 1 month of age. Similarly, in other countries, including the USA, the cream is licensed for use in neonates provided that their gestational age is at least 37 weeks, and that methaemoglobin values are monitored in those aged 3 months or less; it should not be used in infants under 1 year who are receiving methaemoglobin-inducing drugs.

Systemic absorption of both drugs from the eutectic cream appears to be minimal across intact skin[6] even after prolonged or extensive use.[10] However, it should not be used on wounds or mucous membranes (except for genital warts in adults) and should not be used for atopic dermatitis. It should not be applied to or near the eyes because it causes corneal irritation, and it should not be instilled in the middle ear. It should be used with caution in patients with anaemia or congenital or acquired methaemoglobinaemia. Transient paleness, redness, and oedema may occur following application.

Some studies suggest that a topical gel formulation of tetracaine 4% can produce longer and more rapid anaesthesia than the above lidocaine with prilocaine cream (see Surface Anaesthesia, under Uses and Administration of Tetracaine, p.1872). It has also been suggested[11] that topical tetracaine may have practical advantages over the eutectic mixture of lidocaine and prilocaine, which has to be applied for at least one hour, and causes vasoconstriction at the site of application which can make venepuncture difficult.

Tinnitus. Tinnitus is the perception of a noise that arises or appears to arise within the head.

Objective tinnitus may be audible to others and arises from lesions outside the auditory system. Subjective tinnitus (tinnitus aurium) originates from sites within the auditory system and is perceived only by the patient. A simple and remediable cause of tinnitus can be impacted ear wax. Tinnitus is often associated with head injury, vertigo, and hearing loss, including age-related and noise-induced hearing loss. It may also be a symptom of an underlying disorder such as Ménière's disease, may be associated with anxiety or depressive disorders, or may be a manifestation of drug toxicity (for example with aspirin or quinine). In such cases, treatment of the underlying disorder or removal of the offending drug can resolve the tinnitus.

Treatment of tinnitus is difficult although reassurance and counselling are often effective in helping patients to tolerate their condition. Maskers or, if the tinnitus is associated with hearing loss, hearing aids are also used; surgery is rarely indicated. Intravenous lidocaine has proven to be effective in reducing or eliminating tinnitus but the effect only lasts for a few hours and is, therefore, impractical for most patients. Efforts to find an effective oral analogue of lidocaine have not, so far, been successful. Other drugs that have been tried include benzodiazepines such as alprazolam and clonazepam, the antiepileptics carbamazepine and phenytoin, tricyclic antidepressants, and the loop diuretic furosemide, but adverse effects limit their use. Ginkgo biloba has been tried but there are doubts about its value.

Mepivacaine Hydrochloride

(BANM, rINNM)

Hidrocloruro de mepivacaína; Mépivacaïne, chlorhydrate de; Mepivacaini Chloridum; Mepivacaini hydrochloridum; Mepivakainihydrokloridi; Mepivakain-hidroklori d; Mepivakain-hydrochlorid; Mepivakainhydroklorid; Mepivakaino hidrochloridas. (1-Methyl-2-piperidyl)formo-2′,6′-xylidide hydrochloride.

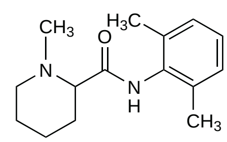
Мепивакаина Гидрохлорид

$C_{15}H_{22}N_2O,HCl = 282.8.$

CAS — 96-88-8 (mepivacaine); 22801-44-1 ((±)-mepivacaine); 1722-62-9 (mepivacaine hydrochloride).

ATC — N01BB03.

ATC Vet — QN01BB03.



(mepivacaine)

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Mepivacaine Hydrochloride). A white or almost white crystalline powder. Freely soluble in water and in alcohol; very slightly soluble in dichloromethane. A 2% solution in water has a pH of 4.0 to 5.0.

USP 31 (Mepivacaine Hydrochloride). A white, odourless, crystalline solid. Freely soluble in water and in methyl alcohol; very slightly soluble in chloroform; practically insoluble in ether. A 2% solution in water has a pH of about 4.5.

pH of solutions. For a discussion of the effect that pH has on the stability of local anaesthetic solutions and the pain associated with their injection, see p.1852.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Porphyria. Mepivacaine is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Local anaesthetics. Studies *in vitro* showed that *bupivacaine* dramatically reduced the binding of mepivacaine to α-1-acid glycoprotein.[1]

1. Hartrick CT, *et al.* Influence of bupivacaine on mepivacaine protein binding. *Clin Pharmacol Ther* 1984; **36:** 546–50.

Pharmacokinetics

Mepivacaine is about 78% bound to plasma proteins. The plasma half-life has been reported to be about 2 to 3 hours in adults and about 9 hours in neonates. It is rapidly metabolised in the liver and less than 10% of a dose is reported to be excreted unchanged in the urine. Over 50% of a dose is excreted as metabolites into the bile but these probably undergo enterohepatic circulation as only small amounts appear in the faeces. Several metabolites are also excreted via the kidneys and include glucuronide conjugates of hydroxy compounds and an *N*-demethylated compound, 2′,6′-pipecoloxylidide. Mepivacaine crosses the placenta.

See also under Local Anaesthetics, p.1852.

Pregnancy. There is considerable transfer of mepivacaine across the placenta after maternal doses and the ratio of fetal to maternal concentrations[1] is about 0.7. Although neonates have a very limited capacity to metabolise mepivacaine it appears they are able to eliminate the drug.[2]

1. Lurie AO, Weiss JB. Blood concentration of mepivacaine and lidocaine in mother and baby after epidural anesthesia. *Am J Obstet Gynecol* 1970; **106:** 850–6.
2. Meffin P, *et al*. Clearance and metabolism of mepivacaine in the human neonate. *Clin Pharmacol Ther* 1973; **14:** 218–25.

Uses and Administration

Mepivacaine hydrochloride is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It is mainly used for infiltration anaesthesia, peripheral nerve block, and epidural block. (Local anaesthetic techniques are discussed on p.1853.) Mepivacaine has a rapid onset and an intermediate duration of action. The speed of onset and duration of action are increased by the addition of a vasoconstrictor and absorption into the circulation from the site of injection is reduced.

The dosage of mepivacaine hydrochloride varies with the site of injection and the type of **local anaesthetic procedure**. In adults, the **maximum single dose** of mepivacaine hydrochloride should not generally exceed 400 mg and the total dose in 24 hours should not exceed 1 g. Doses should be reduced in the elderly, in debilitated patients, and in those with cardiac or hepatic impairment. Concentrations of less than 2% should be used in children under 3 years or weighing less than about 14 kg (30 pounds); the dose in children should not exceed 5 to 6 mg/kg.

- For *infiltration anaesthesia* up to 400 mg as a 1% (40 mL) or 0.5% (80 mL) solution is used. For *dental infiltration and nerve block* a 2% solution with a vasoconstrictor or a 3% plain solution is used. For anaesthesia at a single site in the jaw a dose of 36 mg (1.8 mL) as a 2% solution or 54 mg (1.8 mL) as a 3% solution is used. For anaesthesia of the entire oral cavity 180 mg (9 mL) as a 2% solution or 270 mg (9 mL) as a 3% solution is used. Some recommend that no more than 400 mg should be given at a single dental sitting.
- For *peripheral nerve blocks*, namely *cervical, brachial plexus, intercostal,* and *pudendal blocks*, 1 or 2% solutions may be used in doses of 50 to 400 mg (5 to 40 mL) as a 1% solution, or 100 to 400 mg (5 to 20 mL) as a 2% solution. For pudendal block half of the dose is injected on each side. For *paracervical block* a dose of up to 100 mg (10 mL) as a 1% solution on each side has been suggested allowing an interval of 5 minutes between sides. This may be repeated at an interval of not less than 90 minutes, and for a combined paracervical and pudendal block up to 150 mg (15 mL) as a 1% solution is injected on each side. For therapeutic nerve block in the management of pain 10 to 50 mg (1 to 5 mL) as a 1% solution or 20 to 100 mg (1 to 5 mL) as a 2% solution may be given.
- For *epidural block* usual doses are: 150 to 300 mg (15 to 30 mL) as a 1% solution, 150 to 375 mg (10 to 25 mL) as a 1.5% solution, or 200 to 400 mg (10 to 20 mL) as a 2% solution. Hyperbaric solutions of mepivacaine hydrochloride without adrenaline have also been used for *spinal block*.

Mepivacaine has been included in the intramuscular injections of other drugs to minimise the pain produced at the injection site.

Mepivacaine has also been used as a surface anaesthetic but other local anaesthetics such as lidocaine are more effective.

Action. For a comparison of the vasoactivity of mepivacaine and some other local anaesthetics, see p.1852.

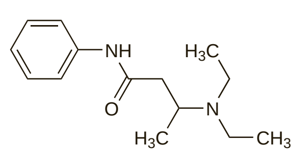
Hidrocloruro de octacaína; Octacaïne, Chlorhydrate d'; Octacaini Hydrochloridum. 3-Diethylaminobutyranilide hydrochloride.

Октакаина Гидрохлорид

$C_{14}H_{22}N_2O,HCl$ = 270.8.

CAS — 13912-77-1 (octacaine); 59727-70-7 (octacaine hydrochloride).



(octacaine)

Profile

Octacaine hydrochloride is a local anaesthetic (p.1850) that has been used for surface anaesthesia.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Switz.:*** Batramycine†.

Oxetacaine *(BAN, rINN)*

Oksetakaiini; Oksetakain; Oxetacaína; Oxétacaïne; Oxetacainum; Oxetakain; Oxethazaine *(USAN)*; Wy-806. 2,2′-(2-Hydroxyethylimino)bis[*N*-(αα-dimethylphenethyl)-*N*-methylacetamide].

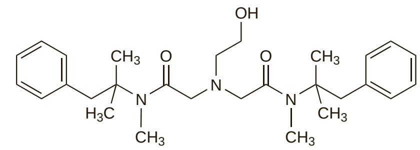
Оксетакаин

$C_{28}H_{41}N_3O_3$ = 467.6.

CAS — 126-27-2 (oxetacaine); 13930-31-9 (oxetacaine hydrochloride).

ATC — C05AD06.

ATC Vet — QC05AD06.



Pharmacopoeias. In *Br.* and *Jpn.*

BP 2008 (Oxetacaine). A white or almost white powder. Practically insoluble in water; freely soluble in methyl alcohol; very soluble in chloroform; soluble in ethyl acetate.

Profile

Oxetacaine is an amide anaesthetic (p.1850) that is stated to have a prolonged action. It is administered orally with antacids for the symptomatic relief of gastro-oesophageal reflux disease (p.1696). It has also been used as the hydrochloride in ointments and suppositories for the relief of pain associated with haemorrhoids.

Oxybuprocaine Hydrochloride

(BANM, rINNM)

Benoxinate Hydrochloride; Hidrocloruro de oxibuprocaína; Oksibuprokaiinihydrokloridi; Oksibuprokain Hidroklorür; Oksibuprokaino hidrochloridas; Oxibuprokain-hidroklorid; Oxibuprokainhydroklorid; Oxybuprocaïne, chlorhydrate d'; Oxybuprocaini hydrochloridum; Oxybuprokain hydrochlorid. 2-Diethylaminoethyl 4-amino-3-butoxybenzoate hydrochloride.

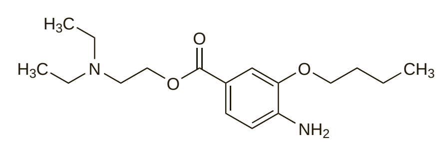
Оксибупрокаина Гидрохлорид

$C_{17}H_{28}N_2O_3,HCl$ = 344.9.

CAS — 99-43-4 (oxybuprocaine); 5987-82-6 (oxybuprocaine hydrochloride).

ATC — D04AB03; S01HA02.

ATC Vet — QD04AB03; QS01HA02.



(oxybuprocaine)

NOTE. OXB, formerly BNX, is a code approved by the BP 2008 for use on single unit doses of eye drops containing oxybuprocaine hydrochloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Oxybuprocaine Hydrochloride). A white or almost white, crystalline powder or colourless crystals. It exhibits polymorphism. Very soluble in water; freely soluble in alcohol. A 10% solution in water has a pH of 4.5 to 6.0. Protect from light.

USP 31 (Benoxinate Hydrochloride). White or slightly off-white, crystals or crystalline powder, odourless or with a slight characteristic odour. Soluble 1 in 0.8 of water, 1 in 2.6 of alcohol, and 1 in 2.5 of chloroform; insoluble in ether. A 1% solution in water has a pH of 5.0 to 6.0.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Effects on the eyes. Fibrinous iritis and moderate corneal swelling occurred in 2 patients after the use of a 0.4% or 1% solution of oxybuprocaine hydrochloride for topical anaesthesia of the eye for minor surgery.[1] The effects may have been due to inadvertent entry of the drug into the anterior chamber of the eye.

1. Haddad R. Fibrinous iritis due to oxybuprocaine. *Br J Ophthalmol* 1989; **73:** 76–7.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Uses and Administration

Oxybuprocaine, a para-aminobenzoic acid ester, is a local anaesthetic with actions and uses similar to those described on p.1852. It is used for surface anaesthesia (p.1853) and is reported to be less irritant than tetracaine when applied to the conjunctiva in therapeutic concentrations.

Oxybuprocaine is used as the hydrochloride in a 0.4% solution in short ophthalmological procedures. One drop instilled into the conjunctival sac anaesthetises the surface of the eye sufficiently to allow tonometry after 60 seconds and a further drop after 90 seconds provides adequate anaesthesia for the fitting of contact lenses. Three drops at 90-second intervals produces sufficient anaesthesia after 5 minutes for removal of a foreign body from the corneal epithelium, or for incision of a Meibomian cyst through the conjunctiva. The sensitivity of the cornea is normal again after about 1 hour.

A 1% solution of oxybuprocaine hydrochloride is used for surface anaesthesia of the ear, nose, and throat.

Preparations

BP 2008: Oxybuprocaine Eye Drops;
USP 31: Benoxinate Hydrochloride Ophthalmic Solution; Fluorescein Sodium and Benoxinate Hydrochloride Ophthalmic Solution.

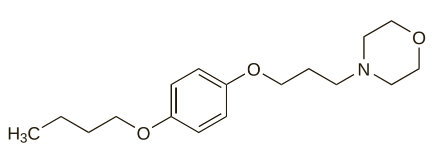
$C_{17}H_{27}NO_3,HCl = 329.9.$

CAS — 140-65-8 (pramocaine); 637-58-1 (pramocaine hydrochloride).
ATC — C05AD07; D04AB07.
ATC Vet — QC05AD07; QD04AB07.



(pramocaine)

Pharmacopoeias. In *US.*

USP 31 (Pramoxine Hydrochloride). A white or almost white crystalline powder; it may have a faint aromatic odour. Freely soluble in water and in alcohol; soluble 1 in 35 of chloroform; very slightly soluble in ether. A 1% solution in water has a pH of about 4.5. Store in airtight containers.

Profile

Pramocaine hydrochloride is a local anaesthetic (p.1850) used for surface anaesthesia. It is used alone or with corticosteroids and other drugs, usually in a concentration of 1%, in a wide range of formulations for the relief of pain and itching associated with minor skin conditions and anorectal disorders. Initial burning or stinging may occur following topical application. It should not be used for the nose or eyes. The base has been used similarly.

Preparations

USP 31: Neomycin and Polymyxin B Sulfates and Pramoxine Hydrochloride Cream; Pramoxine Hydrochloride Cream; Pramoxine Hydrochloride Jelly.

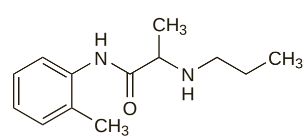
Prilocaine *(BAN, USAN, rINN)*

Prilocaína; Prilocaïne; Prilocainum; Prilokaiini; Prilokain; Prilokainas. 2-Propylaminopropiono-*o*-toluidide.

Прилокаин

$C_{13}H_{20}N_2O = 220.3.$

CAS — 721-50-6.
ATC — N01BB04.
ATC Vet — QN01BB04.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Prilocaine). A white or almost white, crystalline powder. M.p. 36° to 39°. Slightly soluble in water; very soluble in alcohol and in acetone.

USP 31 (Prilocaine). A white or almost white powder or crystal aggregates. M.p. 36° to 39°. Slightly soluble in water; very soluble in alcohol and in acetone. Store at a temperature below 25°.

Eutectic mixture. Prilocaine forms a mixture with lidocaine that has a melting-point lower than that of either ingredient. This eutectic mixture is used in the preparation of topical dosage forms.

Prilocaine Hydrochloride *(BANM, USAN, rINNM)*

Astra-1512; Hidrocloruro de prilocaína; L-67; Prilocaïne, chlorhydrate de; Prilocaini hydrochloridum; Prilokaiinihydrokloridi; Prilokain Hidroklorür; Prilokain hydrochlorid; Prilokain-hidroklorid; Prilokainhydroklorid; Prilokaino hidrochloridas; Propitocaine Hydrochloride.

Прилокаина Гидрохлорид

$C_{13}H_{20}N_2O,HCl = 256.8.$

CAS — 721-50-6 (prilocaine); 1786-81-8 (prilocaine hydrochloride).
ATC — N01BB04.
ATC Vet — QN01BB04.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Prilocaine Hydrochloride). A white or almost white, crystalline powder or colourless crystals. M.p. 168° to 171°. Freely soluble in water and in alcohol; very slightly soluble in acetone.

USP 31 (Prilocaine Hydrochloride). A white odourless crystalline powder. M.p. 166° to 169°. Soluble 1 in 3.5 of water, 1 in 4.2 of alcohol, and 1 in 175 of chloroform; very slightly soluble in acetone; practically insoluble in ether.

pH of solutions. For a discussion of the effect that pH has on the stability of local anaesthetic solutions and the pain associated with their injection, see p.1852.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Prilocaine has relatively modest toxicity compared with most amide-type local anaesthetics. However, dose-related methaemoglobinaemia and cyanosis, attributed to the metabolite *o*-toluidine, appear to occur more frequently with prilocaine than with other local anaesthetics (see Methaemoglobinaemia, p.1850). Symptoms usually occur when doses of prilocaine hydrochloride exceed about 8 mg/kg but the very young may be more susceptible. Methaemoglobinaemia has been observed in neonates whose mothers received prilocaine shortly before delivery and it has also been reported after prolonged topical application of a prilocaine/lidocaine eutectic mixture in children. (See under Surface Anaesthesia in Lidocaine, p.1866 for precautions to be observed with such a eutectic mixture.) Methaemoglobinaemia may be treated by giving oxygen followed, if necessary, by an injection of methylthioninium chloride.

Prilocaine is contra-indicated for paracervical block in obstetrics.

Prilocaine should be avoided in patients with anaemia, congenital or acquired methaemoglobinaemia, cardiac or ventilatory failure, or hypoxia.

Effects on the CNS. For reference to the prilocaine serum concentrations associated with CNS toxicity, see Absorption under Pharmacokinetics, below.

Porphyria. Prilocaine has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Methaemoglobinaemia may occur at lower doses of prilocaine in patients receiving therapy with other drugs known to cause such conditions (e.g. sulfonamides such as sulfamethoxazole in co-trimoxazole).

Neuromuscular blockers. For a possible interaction between *mivacurium* and prilocaine, see under Atracurium, p.1904.

Pharmacokinetics

Prilocaine is reported to be 55% bound to plasma proteins. It is rapidly metabolised mainly in the liver and also in the kidneys and is excreted in the urine mainly as metabolites. One of the principal metabolites excreted in the urine is *o*-toluidine, which is believed to cause the methaemoglobinaemia observed after large doses. Prilocaine crosses the placenta and during prolonged epidural anaesthesia may produce methaemoglobinaemia in the fetus. It is distributed into breast milk.

See also under Local Anaesthetics, p.1852.

Absorption. Peak serum concentrations of prilocaine hydrochloride attained after the use of 8.5 mL of a 1% solution for retrobulbar and facial nerve block were well below the concentration of 20 micrograms/mL associated with CNS toxicity due to prilocaine.[1]

1. Goggin M, *et al.* Serum concentrations of prilocaine following retrobulbar block. *Br J Anaesth* 1990; **64:** 107–9.

Uses and Administration

Prilocaine is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It has a similar anaesthetic potency to lidocaine. However, it has a slower onset of action, less vasodilator activity, and a slightly longer duration of action; it is also less toxic. Prilocaine hydrochloride is used for infiltration anaesthesia and nerve blocks in solutions of 0.5%, 1%, and 2%. A 1% solution is also used for epidural analgesia and a 2% solution is used for epidural anaesthesia; for intravenous regional anaesthesia 0.5% solutions are used. A 3% solution with the vasoconstrictor felypressin (p.2302) or a 4% solution without are used for dental procedures. A 4% solution with adrenaline 1 in 200 000 is also used for dentistry in some countries. Carbonated solutions of prilocaine have also been tried in some countries in epidural and brachial plexus nerve blocks (see under Administration, p.1852). Prilocaine is used for surface anaesthesia in a eutectic mixture with lidocaine. (Local anaesthetic techniques are discussed on p.1853.)

The dosage used in various **local anaesthetic procedures** varies with the site of injection and the procedure used. The recommended **maximum single dose** in adults for prilocaine hydrochloride is 400 mg if used alone, or 300 mg if used with felypressin. Doses should be reduced in elderly or debilitated patients. The dose for children over 6 months of age is up to 5 mg/kg. For *dental infiltration* or *dental nerve blocks*, the usual adult dose of prilocaine hydrochloride without felypressin is 40 to 80 mg (1 to 2 mL) as a 4% solution; children under 10 years generally require about 40 mg (1 mL). Similar doses of the 4% solution with adrenaline (1:200 000) may be used for most routine dental procedures. The usual adult dose of prilocaine hydrochloride with felypressin 0.03 international units/mL is 30 to 150 mg (1 to 5 mL) as a 3% solution; children under 10 years generally require 30 to 60 mg (1 to 2 mL).

A eutectic mixture of prilocaine base 2.5% and lidocaine base 2.5% (see Surface Anaesthesia, under Lidocaine, p.1866) is applied as a cream under an occlusive dressing to produce *surface anaesthesia* of the skin before procedures requiring needle puncture, surgical treatment of localised lesions, and split skin grafting; it has been used similarly, but without an occlusive dressing, before removal of genital warts.

Action. For a comparison of the vasoactivity of prilocaine and some other local anaesthetics, see p.1852.

Infiltration anaesthesia. Addition of felypressin at a concentration of 0.03 international units/mL to prilocaine 3% injection did not reduce plasma concentrations of prilocaine after infiltration of a 60-mg dose into the upper premolar region.[1]

1. Cannell H, Whelpton R. Systemic uptake of prilocaine after injection of various formulations of the drug. *Br Dent J* 1986; **160:** 47–9.

Procaine Hydrochloride *(BANM, rINNM)*

Allocaine; Ethocaine Hydrochloride; Hidrocloruro de procaína; Novocainum; Procaïne, chlorhydrate de; Procaini hydrochloridum; Procainii Chloridum; Procainium Chloride; Prokaiinihydrokloridi; Prokain Hidroklorür; Prokain-hidroklorid; Prokain-hydrochlorid; Prokainhydroklorid; Prokaino hidrochloridas; Prokainy chlorowodorek; Syncaine. 2-Diethylaminoethyl 4-aminobenzoate hydrochloride.

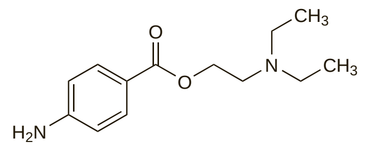
Прокаина Гидрохлорид

$C_{13}H_{20}N_2O_2,HCl = 272.8.$

CAS — 59-46-1 (procaine); 51-05-8 (procaine hydrochloride).

ATC — C05AD05; N01BA02; S01HA05.

ATC Vet — QC05AD05; QN01BA02; QS01HA05.



(procaine)

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Procaine Hydrochloride). A white or almost white crystalline powder or colourless crystals. Very soluble in water; soluble in alcohol. A 2% solution in water has a pH of 5.0 to 6.5. Protect from light.

USP 31 (Procaine Hydrochloride). Odourless, small, white crystals or white, crystalline powder. Soluble 1 in 1 of water and 1 in 15 of alcohol; slightly soluble in chloroform; practically insoluble in ether.

Incompatibility. Procaine hydrochloride has been reported to be incompatible with aminophylline, barbiturates, magnesium sulfate, phenytoin sodium, sodium bicarbonate, and amphotericin B.

Stability of solutions. Degradation of procaine in a cardioplegic solution containing magnesium, sodium, potassium, and calcium salts was found to be temperature dependent.[1] At a storage temperature of 6° the shelf-life of the solution was 5 weeks and this was increased to 9 weeks when the storage temperature was −10°. Using carbon dioxide instead of nitrogen in the head space did not affect stability of procaine.

1. Synave R, *et al*. Stability of procaine hydrochloride in a cardioplegic solution containing bicarbonate. *J Clin Hosp Pharm* 1985; **10:** 385–8.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Effects on the cardiovascular system. Severe hypotension leading to cardiac arrest and death developed in a patient following the infusion of 600 mg of procaine for malignant hyperthermia.[1]

1. MacLachlan D, Forrest AL. Procaine and malignant hyperthermia. *Lancet* 1974; **i:** 355.

Hypersensitivity. Of 600 persons with dermatitis or eczema submitted to patch testing with 2% aqueous solution of procaine hydrochloride, 4.8% gave a positive reaction.[1]

For reports of hypersensitivity including anaphylactic reactions associated with procaine and other local anaesthetics, see under Adverse Effects of Local Anaesthetics, p.1850.

3. Lee SL. Procaine anesthesia after procainamide-induced systemic erythematosus. *JAMA* 1977; **238:** 2201.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Diuretics. Use with *acetazolamide* extends the plasma half-life of procaine.[1]

1. Calvo R, *et al*. Effects of disease and acetazolamide on procaine hydrolysis by red blood cell enzymes. *Clin Pharmacol Ther* 1980; **27:** 179–83.

Pharmacokinetics

Procaine is poorly absorbed from mucous membranes and is usually given parenterally. It is rapidly hydrolysed by plasma cholinesterase to para-aminobenzoic acid and diethylaminoethanol; some may also be metabolised in the liver. Only about 6% is bound to plasma proteins. About 80% of the para-aminobenzoic acid is excreted unchanged or conjugated in the urine. About 30% of the diethylaminoethanol is excreted in the urine, the remainder being metabolised in the liver.

See also under Local Anaesthetics, p.1852.

Uses and Administration

Procaine hydrochloride, a para-aminobenzoic acid ester, is a local anaesthetic with actions and uses similar to those described on p.1852. Because of its poor penetration of intact mucous membranes, procaine is ineffective for surface application and has been chiefly used by injection, although in general it has been replaced by lidocaine and other local anaesthetics. It has a slow onset of action and a short duration of action. It has vasodilator activity and therefore a vasoconstrictor may be added to delay absorption and increase the duration of action. Procaine has mainly been used for infiltration anaesthesia, peripheral nerve blocks, and spinal block. (Local anaesthetic techniques are discussed on p.1853.) It has also been used in cardioplegic solutions to protect the myocardium during cardiac surgery.

For *infiltration anaesthesia* 0.25 or 0.5% solutions of procaine hydrochloride have been used in doses of 350 to 600 mg.

For *peripheral nerve block* a usual dose of 500 mg of procaine hydrochloride has been given as a 0.5% (100 mL), 1% (50 mL), or 2% (25 mL) solution. Doses up to 1 g have been used. For infiltration and peripheral nerve block adrenaline has been added to solutions, in general to give a final concentration of 1 in 200 000 to 1 in 100 000.

Procaine hydrochloride has been used with propoxycaine in dentistry.

Procaine forms poorly soluble salts or conjugates with some drugs, for example penicillin, and is used to prolong their action after injection. It may also reduce the pain of injection.

Procaine-*N*-glucoside hydrochloride has been included in a preparation for gastrointestinal disorders, and procaine ascorbate has been included in a multivitamin preparation.

Action. For a comparison of the vasoactivity of procaine and some other local anaesthetics, see p.1852.

Preparations

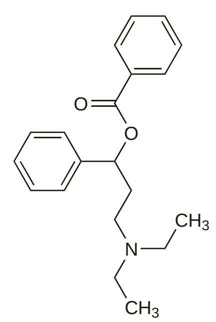
Propanocaine Hydrochloride *(rINNM)*

467D$_3$; Hidrocloruro de propanocaína; Propanocaïne, Chlorhydrate de; Propanocaini Hydrochloridum. 3-Diethylamino-1-phenylpropyl benzoate hydrochloride.

Пропанокаина Гидрохлорид

$C_{20}H_{25}NO_2,HCl = 347.9.$

CAS — 493-76-5 (propanocaine); 1679-79-4 (propanocaine hydrochloride).



(propanocaine)

Profile

Propanocaine hydrochloride, a benzoic acid ester, is a local anaesthetic (p.1850) that has been used topically for surface anaesthesia.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Spain:*** Detraine.

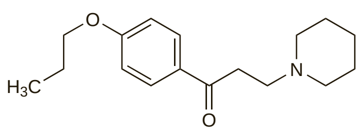
Propipocaine *(rINN)*

Propipocaína; Propipocaïne; Propipocainum; Propoxypiperocaine. 3-Piperidino-4′-propoxypropiophenone.

Пропипокаин

$C_{17}H_{25}NO_2$ = 275.4.

CAS — 3670-68-6.



Profile

Propipocaine is a local anaesthetic (p.1850) that has been used for surface anaesthesia.

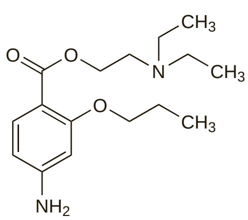
Propoxycaine Hydrochloride *(rINNM)*

Hidrocloruro de propoxicaína; Propoxycaïne, Chlorhydrate de; Propoxycaini Hydrochloridum; Propoxycainium Chloride. 2-Diethylaminoethyl 4-amino-2-propoxybenzoate hydrochloride.

Пропоксикаина Гидрохлорид

$C_{16}H_{26}N_2O_3$,HCl = 330.9.

CAS — 86-43-1 (propoxycaine); 550-83-4 (propoxycaine hydrochloride).



(propoxycaine)

Pharmacopoeias. In *US.*

USP 31 (Propoxycaine Hydrochloride). A white odourless crystalline solid. It discolours on prolonged exposure to light and air. Soluble 1 in 2 of water, 1 in 10 of alcohol, and 1 in 80 of ether; practically insoluble in acetone and in chloroform. A 2% solution in water has a pH of about 5.4. Protect from light.

Profile

Propoxycaine hydrochloride, a para-aminobenzoic acid ester, is a local anaesthetic (p.1850). It has been used with procaine hydrochloride and a vasoconstrictor for infiltration anaesthesia and nerve block in dental procedures. Propoxycaine has a more rapid onset and a longer duration of action than that of procaine.

Preparations

USP 31: Propoxycaine and Procaine Hydrochlorides and Levonordefrin Injection; Propoxycaine and Procaine Hydrochlorides and Norepinephrine Bitartrate Injection.

Proxymetacaine Hydrochloride

(BANM, rINNM)

Hidrocloruro de proximetacaína; Proksimetakain Hidroklorür; Proparacaine Hydrochloride; Proparakain Hidroklorür; Proxymétacaïne, Chlorhydrate de; Proxymetacaini Hydrochloridum. 2-Diethylaminoethyl 3-amino-4-propoxybenzoate hydrochloride.

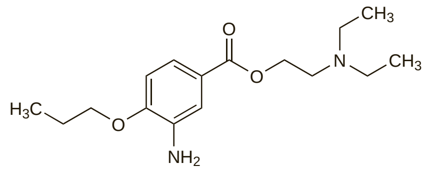
Проксиметакаина Гидрохлорид

$C_{16}H_{26}N_2O_3$,HCl = 330.9.

CAS — 499-67-2 (proxymetacaine); 5875-06-9 (proxymetacaine hydrochloride).

ATC — S01HA04.

ATC Vet — QS01HA04.



(proxymetacaine)

NOTE. PROX is a code approved by the BP 2008 for use on single unit doses of eye drops containing proxymetacaine hydrochloride where the individual container may be too small to bear all the appropriate labelling information. PROXFLN is a similar code approved for eye drops containing proxymetacaine hydrochloride and fluorescein sodium.

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Proxymetacaine Hydrochloride). A white or almost white, odourless or almost odourless, crystalline powder. Soluble in water and in chloroform; very soluble in dehydrated alcohol; practically insoluble in ether. A 1% solution in water has a pH of 5.7 to 6.4. Protect from light.

USP 31 (Proparacaine Hydrochloride). A white to off-white, or faintly buff-coloured, odourless, crystalline powder. Soluble in water, in warm alcohol, and in methyl alcohol; insoluble in ether and in benzene.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

A severe immediate-type corneal reaction to proxymetacaine may rarely occur. Allergic contact dermatitis has also been reported.

Effects on the skin. Exacerbation of Stevens-Johnson syndrome has been reported[1] in a woman after ophthalmic anaesthesia with proxymetacaine hydrochloride.

1. Ward B, *et al.* Dermatologic reaction in Stevens-Johnson syndrome after ophthalmic anesthesia with proparacaine hydrochloride. *Am J Ophthalmol* 1978; **86:** 133–5.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Pharmacokinetics

See under Local Anaesthetics, p.1852.

Uses and Administration

Proxymetacaine hydrochloride, a meta-aminobenzoic acid ester, is a local anaesthetic with actions and uses similar to those described on p.1852. It is used for surface anaesthesia (p.1853) in ophthalmology in a concentration of 0.5%. Proxymetacaine is of similar potency to tetracaine in equal concentrations and induces anaesthesia within about 20 seconds. The duration of action may be 15 minutes or longer. Instillation of 1 or 2 drops permits tonometry after 30 seconds. For removal of foreign bodies or sutures from the cornea 1 or 2 drops are instilled every 5 to 10 minutes for up to 3 applications, or 1 or 2 drops are instilled 2 to 3 minutes before the procedure. For deeper anaesthesia such as needed for cataract extraction 1 drop is instilled every 5 to 10 minutes to a total of 5 to 7 applications.

Trigeminal neuralgia. There have been anecdotal reports that proxymetacaine eye drops relieved trigeminal neuralgia (p.9) refractory to carbamazepine.[1,2] However, a controlled study failed to demonstrate any benefit.[3]

1. Zavon MR, Fichte CM. Trigeminal neuralgia relieved by ophthalmic anesthetic. *JAMA* 1991; **265:** 2807.
2. Zavon MR, Fichte CM. Trigeminal neuralgia relieved by optical anesthesia. *JAMA* 1991; **266:** 1649.

Quinisocaine Hydrochloride *(BANM, rINNM)*

Chinisocainum Hydrochloride; Dimethisoquin Hydrochloride *(USAN)*; Dimethisoquinium Chloride; Hidrocloruro de quinisocaína; Quinisocaïne, Chlorhydrate de; Quinisocaini Hydrochloridum. 2-(3-Butyl-1-isoquinolyloxy)-*NN*-dimethylethylamine hydrochloride.

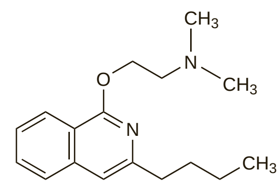
Хинизокаина Гидрохлорид

$C_{17}H_{24}N_2O$,HCl = 308.8.

CAS — 86-80-6 (quinisocaine); 2773-92-4 (quinisocaine hydrochloride).

ATC — D04AB05.

ATC Vet — QD04AB05.



(quinisocaine)

Profile

Quinisocaine hydrochloride is a local anaesthetic (p.1850) that has been used as a surface anaesthetic in the form of an ointment or cream in a concentration of 0.5% for the relief of pruritus, anogenital or anorectal irritation, and minor skin conditions. It has also been used as suppositories.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Quotane; ***Ger.:*** Haenal; Isochinol†; ***Switz.:*** Isochinol.

Multi-ingredient: ***Fr.:*** Rectoquotane.

Ropivacaine Hydrochloride

(BANM, rINNM)

AL-281; Hidrocloruro de ropivacaína; Ropivacaïne, chlorhydrate de; Ropivacaini hydrochloridum; Ropivakaiinihydrokloridi; Ropivakain Hidroklorür; Ropivakainhydroklorid. (*S*)-2′,6′-Dimethyl-1-propylpiperidine-2-carboxanilide hydrochloride monohydrate.

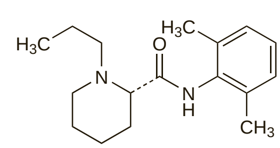
Ропивакаина Гидрохлорид

$C_{17}H_{26}N_2O$,HCl,H_2O = 328.9.

CAS — 84057-95-4 (ropivacaine); 98717-15-8 (anhydrous ropivacaine hydrochloride); 132112-35-7 (ropivacaine hydrochloride monohydrate).

ATC — N01BB09.

ATC Vet — QN01BB09.



(ropivacaine)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Ropivacaine Hydrochloride Monohydrate). A white or almost white, crystalline powder. Soluble in water and in alcohol; slightly soluble in dichloromethane. pH of a 2% solution in water is 4.5 to 6.0.

USP 31 (Ropivacaine Hydrochloride). A white crystalline powder. Soluble in water. A 1% solution in water has a pH of 4.5 to 6.0.

Adverse Effects, Treatment, and Precautions

As for Local Anaesthetics in general, p.1850.

Ropivacaine is contra-indicated for use in intravenous regional anaesthesia (Bier's block) and for paracervical block in obstetrics.

Effects on the cardiovascular system. Ropivacaine is structurally related to bupivacaine, but data from extensive *animal* studies suggest that ropivacaine may be less cardiotoxic than bupivacaine.[1] Results from a study[2] in 12 healthy male volunteers support these data; at doses producing CNS symptoms cardiovascular changes, such as depression of conduction and diastolic function, were less pronounced with ropivacaine than with bupivacaine.

1. Cederholm I. Preliminary risk-benefit analysis of ropivacaine in labour and following surgery. *Drug Safety* 1997; **16:** 391–402.
2. Knudsen K, *et al.* Central nervous and cardiovascular effects of i.v. infusions of ropivacaine, bupivacaine and placebo in volunteers. *Br J Anaesth* 1997; **78:** 507–14.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Giving ropivacaine with general anaesthetics, opioid analgesics, or drugs structurally related to amide-type local anaesthetics (e.g. certain antiarrhythmics) may result in potentiation of adverse effects.

The metabolism of ropivacaine is mediated by the cytochrome P450 isoenzyme CYP1A2 and the potential exists for interactions between ropivacaine and other drugs that inhibit or act as a substrate for this isoenzyme. Prolonged use of ropivacaine should be avoided in patients treated with potent CYP1A2 inhibitors, such as fluvoxamine. Plasma concentrations of ropivacaine may be reduced by enzyme-inducing drugs such as rifampicin.

Pharmacokinetics

Ropivacaine is about 94% bound to plasma proteins. The terminal elimination half-life has been reported to be 1.8 hours. It is extensively metabolised in the liver, predominantly by aromatic hydroxylation which is mediated by the cytochrome P450 isoenzyme CYP1A2; the isoenzyme CYP3A4 plays a minor role in the metabolism of ropivacaine. The metabolites are excreted mainly in the urine; about 1% of a dose is excreted as unchanged drug. Some metabolites also have a local anaesthetic effect but less than that of ropivacaine. Ropivacaine crosses the placenta.

See also under Local Anaesthetics, p.1852.

Uses and Administration

Ropivacaine hydrochloride is a local anaesthetic of the amide type with actions and uses similar to those described on p.1852. It is a long-acting local anaesthetic, although onset and duration of action are dependent upon the site of injection; the presence of a vasoconstrictor such as adrenaline has no effect. Ropivacaine is used for epidural block, peripheral nerve block, and infiltration anaesthesia and field block, but is contra-indicated for obstetric paracervical block and for use in intravenous regional anaesthesia (Bier's block). (Local anaesthetic techniques are discussed on p.1853.) At high doses ropivacaine produces surgical anaesthesia, whereas at lower doses it is used for the management of acute pain such as labour pain (p.7) and in postoperative analgesia (p.4).

Like bupivacaine (p.1854), ropivacaine has a differential blocking effect on nerve fibres and, at the lowest concentration used, there is good differentiation between sensory and motor block. The onset and duration of sensory block produced by ropivacaine is generally similar to that obtained with bupivacaine but the motor block is often slower in onset, shorter in duration, and less intense.

Ropivacaine hydrochloride is given in concentrations of 0.2 to 1%. The dosage depends on the site of injection and the procedure used, as well as the status of the patient. The dose of ropivacaine should be reduced in the elderly, and in acutely ill or debilitated patients. A test dose of lidocaine with adrenaline should be given before starting epidural block with ropivacaine to detect inadvertent intravascular administration.

- For **surgical anaesthesia**, doses of ropivacaine hydrochloride for *lumbar epidural block* are 75 to 150 mg (15 to 30 mL) as a 0.5% solution, or 112.5 to 187.5 mg (15 to 25 mL) as a 0.75% solution, or 150 to 200 mg (15 to 20 mL) as a 1% solution; for caesarean section, doses are 100 to 150 mg (20 to 30 mL) as a 0.5% solution or 112.5 to 150 mg (15 to 20 mL) as a 0.75% solution. Doses for *thoracic epidural block* to establish a block for postoperative pain relief are 25 to 75 mg (5 to 15 mL) as a 0.5% solution or 37.5 to 112.5 mg (5 to 15 mL) as a 0.75% solution; the actual dose used depends on the level of the injection.
- For *peripheral nerve block* of major nerves such as the brachial plexus, typical doses are 175 to 250 mg (35 to 50 mL) as a 0.5% solution; 225 to 300 mg (30 to 40 mL) as a 0.75% solution has also been recommended for brachial plexus block.
- For *infiltration anaesthesia* and *field block* up to 200 mg (40 mL) as a 0.5% solution or up to 225 mg (30 mL) as a 0.75% solution may be used.
- In the management of **acute pain** ropivacaine hydrochloride is used as a 0.2% solution for epidural block (0.5% solutions may be used for infiltration). Doses for *lumbar epidural block* are 20 to 40 mg (10 to 20 mL) as an initial bolus followed by 20 to 30 mg (10 to 15 mL) at intervals of not less than 30 minutes. Alternatively, 12 to 20 mg (6 to 10 mL) per hour may be given as a continuous epidural infusion; if additional pain relief is required, doses of up to 28 mg (14 mL) per hour may be given. Doses for *thoracic epidural block* are 12 to 28 mg (6 to 14 mL) per hour as a continuous infusion.
- For *infiltration anaesthesia* doses are 2 to 200 mg (1 to 100 mL) as a 0.2% solution or 5 to 200 mg (1 to 40 mL) as a 0.5% solution.
- In neonates, infants, and children aged up to 12 years, ropivacaine hydrochloride may be used for the management of peri- and postoperative pain. A 0.2% solution is given in a dose of 2 mg/kg (1 mL/kg) to achieve a *caudal epidural block.*

NOTE. TET is a code approved by the BP 2008 for use on single unit doses of eye drops containing tetracaine hydrochloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn, US,* and *Viet.*

Ph. Eur. 6.2 (Tetracaine Hydrochloride). A white or almost white, slightly hygroscopic, polymorphic, crystalline powder. Freely soluble in water; soluble in alcohol. A 1% solution in water has a pH of 4.5 to 6.5. Store in airtight containers. Protect from light.

USP 31 (Tetracaine Hydrochloride). A fine, white, odourless, hygroscopic, polymorphic, crystalline powder. Very soluble in water; soluble in alcohol; insoluble in ether and in benzene. Its solutions are neutral to litmus. Store in airtight containers. Protect from light.

Adverse Effects and Treatment

As for Local Anaesthetics in general, p.1850.

Tetracaine has high systemic toxicity. Absorption of tetracaine from mucous membranes is rapid and adverse reactions can occur abruptly without the appearance of prodromal signs or convulsions; fatalities have occurred.

A stinging sensation may occur when tetracaine is used in the eye. Mild erythema at the site of application is frequently seen with topical use; slight oedema or pruritus occur less commonly. Blistering of the skin may occur.

Urethral stricture. There has been a report[1] of a sudden increase in the incidence of urethral stricture after transurethral surgery, which may have been due to an increase in the concentration of tetracaine hydrochloride in the lubricant gel from 0.1 to 3%.

1. Pansadoro V. Role of local anaesthetics in urethral strictures after transurethral surgery. *Lancet* 1990; **336:** 64.

Precautions

As for Local Anaesthetics in general, p.1851.

Tetracaine should not be applied to inflamed, traumatised, or highly vascular surfaces. It should not be used to provide anaesthesia for bronchoscopy or cystoscopy, as lidocaine is a safer alternative.

Interactions

For interactions associated with local anaesthetics, see p.1851.

Pharmacokinetics

See under Local Anaesthetics, p.1852. Tetracaine is reported to be about 15% bioavailable after application of a 4% gel to intact skin, with a mean absorption and elimination half-life of about 75 minutes.

Uses and Administration

Tetracaine, a para-aminobenzoic acid ester, is a potent local anaesthetic with actions and uses similar to those described on p.1852. It is used for surface anaesthesia and spinal block; its use in other local anaesthetic techniques is restricted by its systemic toxicity.

Tetracaine is generally used as the hydrochloride in solutions and creams, and as the base in gels or ointments.

For *anaesthesia of the eye*, solutions containing 0.5 to 1% tetracaine hydrochloride have been used; ointments have also been used. Instillation of a 0.5% solution produces anaesthesia within 25 seconds that lasts for 15 minutes or longer and is suitable for use before minor surgical procedures.

For *topical anaesthesia*, a 4% gel is used as a *percutaneous local anaesthetic* before *venepuncture or venous cannulation*. The gel is applied to the centre of the area to be anaesthetised and covered with an occlusive dressing. Gel and dressing are removed after 30 minutes for venepuncture and after 45 minutes for venous cannulation. A single application generally provides anaesthesia for 4 to 6 hours. This method is not suitable for premature infants or those less than 1 month of age. A transdermal patch containing tetracaine 70 mg with lidocaine 70 mg is available for surface anaesthesia of intact skin in connection with *needle puncture* and in cases of *superficial surgical procedures*. A cream or an ointment has been used for painful conditions of the *anus or rectum*.

Tetracaine hydrochloride has also been used in the *mouth* in sprays and lozenges.

Tetracaine hydrochloride has also been used for *spinal block* usually as a 0.5% solution.

Action. For a comparison of the vasoactivity of tetracaine with some other local anaesthetics, see p.1852.

Spinal block. A study[1] in 40 patients indicated that for patients undergoing caesarean section with spinal anaesthesia (see Central Nerve Block, p.1853) doses of 12 or 14 mg of tetracaine provided better intraoperative analgesia than doses of 8 or 10 mg without leading to excessive spread of the block.

1. Hirabayashi Y, *et al.* Visceral pain during Caesarean section: effect of varying dose of spinal amethocaine. *Br J Anaesth* 1995; **75:** 266–8.

Surface anaesthesia. A topical gel formulation of tetracaine 4% appears to provide more rapid and prolonged surface anaesthesia (see p.1853) than a eutectic mixture of lidocaine and prilocaine.[1,2] In a double-blind placebo-controlled study[3] the tetracaine gel formulation was significantly better than the eutectic mixture in reducing pain caused by laser treatment of portwine stains. Similar findings were also seen in a comparative study[4] and a systematic review[5] in children requiring venous cannulation, although others have questioned the efficacy of tetracaine gel in peripheral insertion of a central catheter.[6] The same formulation appears to be effective when incorporated into a transdermal patch.[7] Patches containing a mixture of lidocaine and tetracaine have also been tried[8,9] and are licensed in some countries for surface anaesthesia of intact skin in connection with needle puncture and in cases of superficial surgical procedures.

There have been reports of seizures and death in children after the use of a mixture of tetracaine, adrenaline, and cocaine on mucosal surfaces;[10] application of preparations of tetracaine to highly vascular surfaces is contra-indicated. A gel containing a mixture of lidocaine, adrenaline, and tetracaine has been found to be an effective alternative to the cocaine-containing preparation.[11]

Tetracaine has also been incorporated into a mucosa-adhesive polymer film to relieve the pain of oral lesions resulting from radiation and antineoplastic therapy.[12] Liposome-encapsulated tetracaine has also been shown to provide adequate surface anaesthesia.[13]

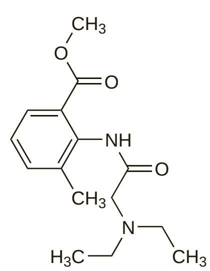
Tolycaine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de tolicaína; Tolycaïne, Chlorhydrate de; Tolycaini Hydrochloridum. Methyl 2-(2-diethylaminoacetamido)-*m*-toluate hydrochloride.

Толикаина Гидрохлорид

$C_{15}H_{22}N_2O_3$,HCl = 314.8.
CAS — 3686-58-6 (tolycaine); 7210-92-6 (tolycaine hydrochloride).



(tolycaine)

Profile

Tolycaine hydrochloride is an amide local anaesthetic (p.1850) included in some preparations to reduce the pain of injection.

Preparations

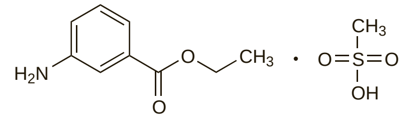
Proprietary Preparations (details are given in Part 3)

Used as an adjunct in: ***Ger.:*** Tardocillin.

Tricaine Mesilate

Metacaine Mesylate; Tricaína, mesilato de; Tricaine Mesylate; TS-222. Ethyl 3-aminobenzoate methanesulphonate.

$C_{10}H_{15}NO_5S$ = 261.3.
CAS — 886-86-2.
ATC Vet — QN01AX93.



Profile

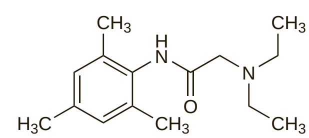
Tricaine mesilate is a derivative of an isomer of benzocaine (see p.1854) and although it has been used as a local anaesthetic in human medicine it is now mainly used as an anaesthetic and tranquilliser for fish and other cold-blooded animals.

Trimecaine Hydrochloride *(rINNM)*

Hidrocloruro de trimecaína; Trimécaïne, Chlorhydrate de; Trimecaini Hydrochloridum; Trimecainium Chloratum; Trimekainhydrochlorid. 2-Diethylamino-2′,4′,6′-trimethylacetanilide hydrochloride.

Тримекаина Гидрохлорид

$C_{15}H_{24}N_2O$,HCl = 284.8.
CAS — 616-68-2 (trimecaine); 1027-14-1 (trimecaine hydrochloride).



(trimecaine)

Profile

Trimecaine hydrochloride is an amide local anaesthetic (p.1850) included in some preparations to reduce the pain of injection.

Preparations

Proprietary Preparations (details are given in Part 3)

Cz.: Mesocain.

Multi-ingredient: ***Cz.:*** Mesocain; Septonex Plus; ***Rus.:*** Levosin (Левосин); Simetrid (Симетрид).

Used as an adjunct in: ***Austria:*** Ketazon†.

Miotics Mydriatics and Antiglaucoma Drugs

Glaucoma and ocular hypertension, p.1873
Mydriasis and cycloplegia, p.1874
Reversal of mydriasis, p.1874
Strabismus, p.1874

Included in this chapter are a variety of drugs used in the eye to alter accommodation and produce mydriasis or cycloplegia, or in the treatment of glaucoma. Some drugs used for these purposes, or in other ocular disorders, but with other primary uses, may be found elsewhere in *Martindale*.

Glaucoma and ocular hypertension

Intra-ocular pressure rises when there is an imbalance between production and drainage of aqueous humour in the eye. Aqueous humour is secreted by the ciliary body and flows into the posterior chamber of the eye. It then passes through the pupil into the anterior chamber from where about 75% drains from the eye through the trabecular meshwork into Schlemm's canal and then into the episcleral veins. The remainder is removed by the uveoscleral route, passing through the ciliary muscle and finally into the episcleral tissues.

The term **ocular hypertension** is used to describe intra-ocular pressure above an upper normal value of 21 mmHg when there are no signs of optic nerve damage. The term **glaucoma** is used to describe a group of conditions characterised by cupping (excavation) of the optic disc and damage of the optic nerve leading to gradual but irreversible visual loss; glaucoma is one of the most common causes of blindness.

Raised intra-ocular pressure is an important risk factor for glaucoma, and as it is the only one that can be altered, current therapy for glaucoma is directed at lowering it. The aim is not just to reduce intra-ocular pressure to a normal value but to a level at which damage to the optic nerve ceases.[1-5] Some patients may have raised intra-ocular pressure for many years without evidence of glaucoma. Whether these patients would receive long-term benefit from a reduction in intra-ocular pressure has been a matter of debate. However, recent randomised trials[6,7] have shown that topical ocular hypotensive treatment was effective in preventing or delaying the onset of open-angle glaucoma in patients with raised intra-ocular pressure. In addition, another study[8,9] has found that lowering intra-ocular pressure slows the progression of glaucoma. A meta-analysis[10] has also confirmed that lowering intra-ocular pressure reduces the risk of visual field loss in the long term in patients with ocular hypertension or newly diagnosed glaucoma. Similarly, a systematic review[11] concluded that topically lowering intra-ocular pressure had a protective effect on the visual field. Some[12] consider that only high-risk patients with raised intra-ocular pressure should be treated; such risk factors include thin central corneal thickness measurement, large cup-to-disc ratio, older age, intra-ocular pressure fluctuation, and a family history of blindness. In practice, many ophthalmologists consider that therapy is indicated if the intra-ocular pressure is higher than 30 mmHg. Glaucoma can also occur and progress in patients with an intra-ocular pressure within the normal range (normal tension glaucoma).

Raised intra-ocular pressure associated with glaucoma is usually due to reduced outflow of aqueous humour from the eye. Glaucoma is described as open-angle or angle-closure depending on the mechanism of the obstruction of drainage and may be acute or chronic. Glaucoma may also be referred to as primary or secondary. **Primary glaucoma** is usually associated with a direct disturbance of outflow whereas **secondary glaucoma** develops as a consequence of a number of diseases or of trauma.

The most common form of glaucoma is **chronic open-angle glaucoma** (simple glaucoma; wide-angle glaucoma), which is due to blockage in drainage through the trabecular meshwork. Intra-ocular pressure increases gradually, and the condition is usually asymptomatic until well advanced and severe damage has occurred. Usually, both eyes are affected. Risk factors include old age, diabetes, Afro-Caribbean race, a family history of glaucoma, and myopia. A '**steroid glaucoma**' may be produced, after a few weeks of treatment with eye drops containing corticosteroids, in patients predisposed to open-angle glaucoma; the risk with systemic corticosteroids appears to be less.

In contrast, **angle-closure glaucoma** (closed-angle glaucoma; narrow-angle glaucoma) usually occurs as an acute emergency. Patients present with a painful red eye, sweating, and nausea and vomiting as a result of a rapid rise in intra-ocular pressure. This can result from blockage of the flow of aqueous humour into the anterior chamber. The resulting rise in intra-ocular pressure bows the iris against the trabecular meshwork, restricting outflow and thereby further raising intra-ocular pressure. It usually occurs in patients with hypermetropia who have a shallow anterior chamber and a narrow filtration angle. The use of mydriatics in such patients is generally considered to be contra-indicated on the grounds that dilatation of the pupil could precipitate an acute attack of angle-closure glaucoma, but see Glaucoma, under Tropicamide, p.1886.

ANTIGLAUCOMA DRUGS.

Drugs used in the treatment of glaucoma[1,3-5,13-15] lower intra-ocular pressure by a variety of mechanisms and their effects are often additive. Most are used topically although a few are given by systemic routes.

- ***Beta blockers*** inhibit beta receptors in the ciliary epithelium and thereby reduce the secretion of aqueous humour. They have traditionally been the drugs of first choice for initial and maintenance treatment of open-angle and other chronic glaucomas and of ocular hypertension; other drugs are used with them when further reductions in intra-ocular pressure are required. Advantages over miotics (below) include a lack of effect on pupil size and accommodation; in addition they can be given once or twice daily which may improve compliance. They are also better tolerated than miotics but can produce systemic effects, and their safety, particularly in the elderly, has been questioned.[16,17] Cardioselective beta blockers may cause fewer pulmonary adverse effects, such as bronchoconstriction, than non-selective beta blockers. Studies suggest that individual topical beta blockers are probably equally effective in reducing intra-ocular pressure but if a non-selective beta blocker is used an additional reduction in pressure may not be obtained with adrenaline (see below). However, a meta-analysis has suggested that timolol may be more effective than betaxolol.[18]
- Topical ***prostaglandin analogues*** or ***prostamides***, such as latanoprost, bimatoprost, and travoprost, lower intra-ocular pressure by increasing uveoscleral outflow. They are increasingly a first choice, alone or as adjuncts, in the treatment of ocular hypertension or open-angle glaucoma. A meta-analysis of the effectiveness of common antiglaucoma drugs found bimatoprost, travoprost, and latanoprost to be the most effective in lowering intra-ocular pressure.[18] They are given once daily and appear to be well-tolerated. They do not affect pupil size or accommodation, but may cause a potentially irreversible increase in brown pigmentation of the iris; the long-term significance of this effect is unknown. Unoprostone, which needs to be used twice daily, appears to be less effective than the other prostaglandin analogues.[19]
- ***Parasympathomimetic miotics*** help trabecular drainage by constricting the pupil and pulling open the trabecular meshwork. However, this can cause blurred vision and browache, especially in younger patients, and the small pupil may cause problems if central vision is already limited. Parasympathomimetic miotics also reduce uveoscleral outflow and this can cause a paradoxical increase in intra-ocular pressure in patients with a recessed anterior angle. They should not be used in the presence of inflammation as adhesions may form between the pupil and the lens (posterior synechiae). Topical miotics were once the mainstay of glaucoma treatment but their ocular adverse effects and multiple dosing regimens have limited their use. Pilocarpine is the most frequently used and is indicated in the treatment of open-angle glaucoma and other chronic glaucomas. It is often added to treatment with other drugs when further reductions in intra-ocular pressure are required. Carbachol is sometimes used when resistance or intolerance to pilocarpine develops. Physostigmine is more potent than pilocarpine but is poorly tolerated and is rarely used now; it was used with pilocarpine but rarely alone. Stronger or longer-acting anticholinesterase miotics such as ecothiopate can cause pupillary block and induce angle-closure glaucoma. They are usually only used in patients refractory to other antiglaucoma treatment or in those in whom the lens of the eye has been removed (aphakic patients). Pilocarpine is also used in the emergency treatment of angle-closure glaucoma before surgery or laser therapy.
- ***Carbonic anhydrase inhibitors*** such as acetazolamide reduce production of aqueous humour by a mechanism independent of their diuretic action. They are used as part of the emergency treatment of angle-closure glaucoma to produce a rapid reduction in intra-ocular pressure before surgery or laser therapy. Systemic doses may also be added to treatment in open-angle glaucoma and other chronic glaucomas in patients refractory to standard treatment but many patients are unable to tolerate prolonged therapy. Topical carbonic anhydrase inhibitors, such as dorzolamide or brinzolamide, have a lower potential to produce adverse effects. They are used similarly to other topical drugs either alone or as an adjunct in patients resistant to or intolerant of first-line drugs.
- Topical ***alpha$_2$-adrenoceptor agonists*** such as apraclonidine and brimonidine lower intra-ocular pressure by reducing production of aqueous humour. Apraclonidine is used alone or as an adjunct to other drugs in the control of intra-ocular pressure associated with ocular surgery or in the short-term to delay laser treatment or surgery for patients with glaucoma not adequately controlled with other drugs; tachyphylaxis and ocular irritation limit its long-term use. Brimonidine is used similarly. Clonidine has also been used in some countries.
- Other topical ***sympathomimetics*** such as dipivefrine increase outflow of aqueous humour through the trabecular meshwork and the uveoscleral route and may also reduce its rate of production. They are used in open-angle glaucoma and other chronic glaucomas usually when further reductions in intra-ocular pressure are required in patients receiving beta blockers (but may not produce an additive effect if used with a non-selective beta blocker).[20] As they produce pupillary dilatation they can induce an acute attack if used in angle-closure glaucoma. Adrenaline can cause eye irritation and produce systemic effects; it is now rarely used. Dipivefrine is converted into adrenaline by corneal esterases and ocular adverse effects are usually less than with adrenaline itself although, again, it is rarely used. Guanethidine, an adrenergic neurone blocker, reduces aqueous humour secretion and is used either alone or in combination to enhance and prolong the effect of adrenaline; prolonged use can cause fibrosis and corneal changes.
- ***Osmotic diuretics*** reduce vitreous volume and can produce a marked reduction in intra-ocular pressure. They are used in the short-term management of glaucoma when a rapid reduction in intra-ocular pressure is required before surgery. Mannitol and urea are both given intravenously and have a faster onset than glycerol or isosorbide given orally.
- Several ***other drugs*** are used topically in glaucoma and ocular hypertension. The alpha-adrenergic antagonist dapiprazole is used in some countries.

DIAGNOSIS OF GLAUCOMA.

Open-angle glaucoma is asymptomatic in its early stages and the use of screening methods for detecting early disease is of great importance.[21] Measurement of intra-ocular pressure alone is a poor diagnostic tool and direct examination of the optic nerve together with visual field examination and intra-ocular pressure tonometry is considered to be more reliable.[1,3-5] Provocative tests such as placing the patient prone in a dark room are sometimes used to identify eyes suffering from or at risk of *angle-closure glaucoma*. Short-acting mydriatics have also been used but are not without risk. Long-term follow-up of patients whose treatment had been determined by the use of a provocative test using phenylephrine with pilocarpine has suggested that this test is neither sensitive nor specific.[22]

TREATMENT OF GLAUCOMA.

Open-angle glaucoma is frequently treated first with a topical beta blocker or, increasingly, a prostaglandin analogue. It may be necessary to combine these drugs or add others such as a topical alpha$_2$-adrenoceptor agonist or a

The symbol † denotes a preparation no longer actively marketed

topical carbonic anhydrase inhibitor to control intra-ocular pressure. Miotics are usually reserved for third-line use. It has been suggested that each type of drug should be tried alone first before resorting to combination therapy.

If further reduction of intra-ocular pressure is required a systemic carbonic anhydrase inhibitor may be used but long-term treatment is poorly tolerated. If this is unsuccessful, surgery (trabeculectomy) or laser treatment (trabeculoplasty) is usually indicated. Laser treatment appears to be as effective as topical drug therapy[23] although its effects may be short-lived.[24] It has been suggested that it might be of use in the initial treatment of older patients who cannot use eye drops or when surgery needs to be postponed or is contra-indicated.[1] Some also recommend that laser treatment is tried before a miotic or an oral carbonic anhydrase inhibitor, because of the potential adverse effects associated with these drugs.[5] Early studies in the UK suggested that surgery was superior to drug or laser treatment in reducing intra-ocular pressure and preserving vision;[24] however, a later study[25] showed no difference in the progression of visual field loss in patients with newly diagnosed glaucoma after the initial use of surgery or drug treatment. A recent systematic review has also found that in early mild open-angle glaucoma progression of the disease over 5 years was no different if first treatment was with medication or trabeculectomy but trabeculectomy was associated with more eye discomfort, an increased risk of cataract, and reduction in visual acuity.[26] The early use of surgery was often advocated in Europe, especially in younger patients, although it is now rarely used as the primary form of treatment, even in the UK.[4]

It is essential to start treatment for an *acute attack of angle-closure glaucoma* within 24 to 48 hours. If treatment is delayed adhesions may form between the iris and the cornea (peripheral anterior synechiae) and the trabecular meshwork may be damaged. *Chronic angle-closure glaucoma* may then develop with permanently raised intra-ocular pressure which ultimately leads to total loss of vision (absolute glaucoma). The initial treatment aims to produce a rapid reduction in intra-ocular pressure. A miotic such as pilocarpine is used topically to constrict the pupil while a carbonic anhydrase inhibitor such as acetazolamide is given orally or by intravenous injection. Osmotic diuretics such as mannitol or urea given intravenously or glycerol or isosorbide given orally may also be used. When intra-ocular pressure has been reduced sufficiently, laser therapy or surgery is performed on both eyes to increase drainage of aqueous humour. If further topical treatment is required after surgery, treatment is usually as for open-angle glaucoma. Beta blockers, with or without adrenaline, are preferred to pilocarpine as there is a risk of posterior synechiae forming when pilocarpine is used.

Glaucoma filtering surgery such as trabeculectomy can be highly effective in reducing intra-ocular pressure, but in some groups of patients, such as children, Afro-Caribbeans, or those who have had previous ocular surgery, there is a high failure rate, usually due to formation of scar tissue.[27] The scar formation is associated with proliferation of fibroblasts; subconjunctival injection of antiproliferative drugs such as fluorouracil has been shown to reduce the failure rate of surgery but at a cost of increased epithelial toxicity and conjunctival wound leaks.[27] A study group[28] reporting on the long-term follow-up of patients treated with fluorouracil recommended that fluorouracil should still be used in the surgical management of glaucoma in patients with a history of ocular surgery, but in view of the increased incidence of late-onset conjunctival wound leaks at the dosage they employed, suggested caution in its use in eyes with good prognoses. Single intraoperative doses of mitomycin have been applied topically as an alternative to the regimen of multiple injections required with fluorouracil. Rates of success comparable with those for fluorouracil have been achieved but there is a risk of adverse effects that could affect vision;[29] long-term safety of antiproliferative drugs remains to be determined.

Postoperative ocular hypertension may occur after surgery on the anterior chamber of the eye or procedures such as trabeculoplasty. Acetylcholine or carbachol instilled directly into the anterior chamber of the eye (intracameral instillation) are used intra-operatively to reduce early postoperative rises in intra-ocular pressure in procedures such as cataract extraction. The short action of acetylcholine can be an advantage as prolonged miosis is associated with severe postoperative pain. However, some consider carbachol to be the more effective drug;[30,31] standard antiglaucoma drugs including beta blockers, pilocarpine, apraclonidine, and carbonic anhydrase inhibitors have also been used for prophylaxis of postoperative ocular hypertension.

Mydriasis and cycloplegia

Drugs that dilate the pupil (mydriatics) and paralyse accommodation (cycloplegics) are used topically in the examination of the eye and other ophthalmic procedures. They are also used in the management of inflammatory conditions of the eye to treat or prevent the formation of adhesions between the lens and the iris (see Uveitis, p.1515) and in strabismus (below).

Mydriasis requires either paralysis of the pupillary constrictor muscles, which can be achieved with antimuscarinics, or stimulation of the dilator muscles, as produced by sympathomimetics. Cycloplegia results from paralysis of the ciliary muscles (antimuscarinics, but not sympathomimetics, have this effect).

Antimuscarinics used in ophthalmology vary in onset and duration of action. *Atropine* can take up to 40 minutes or more to produce mydriasis, which persists for at least 7 days; it takes 1 to 3 hours to produce cycloplegia and 6 to 12 days for recovery of accommodation. *Hyoscine* has a shorter duration of action than atropine, although the effects may still persist for 3 to 7 days. For ophthalmic procedures, antimuscarinics such as *homatropine*, *cyclopentolate*, or *tropicamide*, with a more rapid onset and shorter duration of action than atropine, may be preferable. Recovery occurs up to 6 hours after tropicamide, and up to 24 hours after cyclopentolate; after homatropine it may take up to 3 days. Cycloplegia with homatropine may be incomplete, and particularly for young children (who are often resistant to the action of homatropine) cyclopentolate or atropine may be preferred.

The most common topical sympathomimetic is *phenylephrine*, but *hydroxyamfetamine* is also used in some countries. They are often used with an antimuscarinic to enhance mydriasis, especially in patients who might respond poorly to antimuscarinics alone, such as those with dark irides or diabetes, or those who are receiving prolonged miotic therapy. *Adrenaline* has been used for maintenance of mydriasis during ophthalmic surgery.

The local anaesthetic *cocaine* also has an independent mydriatic effect but because of concern over corneal toxicity it is now little used in ophthalmology.

Miosis (pupil constriction) resistant to conventional mydriatics often develops during ocular surgery, possibly due to the release of prostaglandins and other substances associated with trauma. *NSAIDs* are prostaglandin synthetase inhibitors and have been tried before ocular surgery to prevent or reduce intra-operative miosis. They do not possess intrinsic mydriatic properties.

Reversal of mydriasis

Topical miotics (mydriolytics) are sometimes used to reverse the effects of mydriatics after surgery or ophthalmoscopic examination but do not appear to be in routine clinical use. *Pilocarpine* can counteract the mydriatic effect of topical sympathomimetics, such as phenylephrine and hydroxyamfetamine, but is ineffective against mydriasis produced by antimuscarinics, such as homatropine, and may impair vision further when used with tropicamide. Furthermore, there is also the risk that pilocarpine might precipitate angle-closure glaucoma in susceptible patents. *Dapiprazole* appears to be safer than pilocarpine when used to reverse sympathomimetic-induced mydriasis and is effective to some degree against tropicamide-induced mydriasis. It also appears to enhance recovery of accommodation after the use of cycloplegics.

The rate of reversal of mydriasis is generally slower in patients with dark irides than in those with lighter irides.

Strabismus

Strabismus, sometimes referred to as a squint or cast, is a lack of coordination of the visual axes of the eyes so that the eyes are usually either turned towards (convergent strabismus; esotropia) or away (divergent strabismus; exotropia) from each other. It can arise from a physical defect of the attachment of the extra-ocular muscles to the eye or from paralysis, spasms, or overactivity affecting the extra-ocular muscles of one of the eyes. In young children strabismus or other conditions that prevent a clear image being formed on the retina can result in visual impairment (amblyopia) in the affected eye if not treated.

Treatment for strabismus often consists of eye exercises, and methods to force preferential use of the affected eye by restricting vision through the healthy eye. This is accomplished either by using an eye patch or by penalisation with glasses or the cycloplegic drug *atropine*. However, as prolonged use of atropine eye drops may be required there is a risk of systemic toxicity. Surgery may sometimes be necessary. Extra-ocular injection of *botulinum A toxin* has been used to weaken an overactive extra-ocular eye muscle as an aid to eye realignment; repeated injections may be required. Long-acting parasympathomimetic miotics such as *demecarium*, *dyflos*, and *ecothiopate* have been used in the diagnosis and management of convergent strabismus due to excessive accommodation. Centrally-acting drugs such as *levodopa* and *citicoline* have also been investigated. With any form of treatment care has to be taken not to induce amblyopia in the healthy eye.

Profile

Aceclidine hydrochloride is a parasympathomimetic miotic (see Pilocarpine, p.1884) that is a cholinergic agonist. It has been used in eye drops to lower intra-ocular pressure in patients with glaucoma.

Use. Aceclidine has been tried for the management of disturbances of night vision after laser refractive surgery.[1]

CAS — 1424-27-7.
ATC — S01EC01.
ATC Vet — QS01EC01.

Stability. Solutions of acetazolamide sodium in glucose 5% and sodium chloride 0.9% were stable for 5 days at 25° with a loss of potency of less than 7.2%.[1] At 5° the loss of potency in both solutions was less than 6% after 44 days of storage. Small reductions in pH were recorded, possibly due to the formation of acetic acid during the decomposition of acetazolamide. At –10° the loss in potency after 44 days of storage was less than 3% in both solutions. Results were similar in samples thawed in tap water and in a microwave oven.

An oral suspension of acetazolamide 25 mg/mL prepared from tablets with the aid of sorbitol solution 70% was stable for at least 79 days at 5°, 22°, and 30°. It was recommended that the formulation be maintained at pH 4 to 5 and stored in amber glass bottles.[2]

Adverse Effects

Common adverse effects of acetazolamide are malaise, fatigue, depression, excitement, headache, weight loss, and gastrointestinal disturbances. Drowsiness and paraesthesia involving numbness and tingling of the face and extremities are also common with high doses in particular. Diuresis can be troublesome, but generally abates after a few days of continuous therapy. Acidosis may develop during treatment and is generally mild but severe metabolic acidosis has occasionally been reported, especially in elderly or diabetic patients or those with renal impairment. Electrolyte imbalances including hyponatraemia and hypokalaemia may occasionally occur; hypokalaemia is generally transient and rarely clinically significant.

Blood dyscrasias occur rarely and may include aplastic anaemia, agranulocytosis, leucopenia, thrombocytopenia, and thrombocytopenic purpura. Acetazolamide can give rise to crystalluria, renal calculi, and renal colic; renal lesions, possibly due to a hypersensitivity reaction, have also been reported.

Other adverse reactions include allergic skin reactions, fever, thirst, dizziness, ataxia, irritability, confusion, reduced libido, haematuria, glycosuria, renal failure, abnormal liver function tests, loss of appetite, alterations in taste, transient myopia, and tinnitus and hearing disturbances. Rare reactions include photosensitivity, hepatitis or cholestatic jaundice, flaccid paralysis, and convulsions.

Intramuscular injections are painful owing to the alkalinity of the solution.

Effects on the blood. Severe, often fatal, blood dyscrasias have been reported in patients taking acetazolamide. By 1989, the National Registry of Drug-Induced Ocular Side Effects in the USA[1] had received reports of haematological reactions possibly due to carbonic anhydrase inhibitors in 139 patients, of which 50 cases (36%) were fatal. Most deaths were due to aplastic anaemia. Over half the reactions occurred during the first 6 months of therapy. The value of periodic blood analysis in patients taking carbonic anhydrase inhibitors for prolonged periods has been debated[2-7] but is advised by licensed product information. The US National Registry has recommended[8] that initial and 6-monthly blood analysis should be undertaken.

Effects on electrolyte balance. Acetazolamide has been reported to cause symptomatic metabolic acidosis in the elderly, in diabetic patients, and in those with renal impairment.[1-6] Raised plasma-acetazolamide concentrations have been reported in elderly patients, probably attributable to reduced renal function, and in 6 of 9 glaucoma patients this was associated with hyperchloraemic metabolic acidosis.[7] A single-dose study[8] in 4 elderly patients found that reduced acetazolamide clearance correlated with renal function. Urea and electrolyte concentrations should be measured before and during treatment with acetazolamide, particularly in the elderly and in other patients, such as diabetics, who may have renal impairment.

Effects on endocrine function. Hirsutism occurred in a 2½-year-old girl after treatment for 16 months with acetazolamide for congenital glaucoma.[1] There was no evidence of virilisation.

1. Weiss IS. Hirsutism after chronic administration of acetazolamide. *Am J Ophthalmol* 1974; **78:** 327–8.

Effects on the kidneys. Large reductions in glomerular filtration rate occurred during treatment with carbonic anhydrase inhibitors in 3 type 1 diabetics with nephropathy and glaucoma.[1] Kidney function improved when the drug was withdrawn.

1. Skøtt P, *et al.* Effect of carbonic anhydrase inhibitors on glomerular filtration rate in diabetic nephropathy. *BMJ* 1987; **294:** 549.

Effects on the liver. For a report of liver damage associated with use of acetazolamide, see Hypersensitivity, below.

Effects on the skin. Rashes, including severe skin reactions such as erythema multiforme, Stevens-Johnson syndrome, and toxic epidermal necrolysis, have been reported during acetazolamide therapy; the fact that acetazolamide is a sulfonamide-derivative has been suggested as a cause for these reactions. Photosensitivity has also been noted rarely.

Severe exacerbation of rosacea occurred in a patient taking acetazolamide for glaucoma; the rosacea improved on withdrawal of acetazolamide and relapsed again on its reintroduction.[1]

1. Shah P, *et al.* Severe exacerbation of rosacea by oral acetazolamide. *Br J Dermatol* 1993; **129:** 647–8.

Extravasation. Extravasation was reported in a patient after intravenous acetazolamide and led to severe ulceration requiring surgery to repair the skin defect.[1] It was recommended that 1 to 2 mL of sodium citrate 3.8% should be injected subcutaneously near the site of extravasation in order to neutralise the alkaline effects of the acetazolamide injection.

1. Callear A, Kirkby G. Extravasation of acetazolamide. *Br J Ophthalmol* 1994; **78:** 731.

Hypersensitivity. A 54-year-old man with glaucoma who was treated with acetazolamide 500 mg daily for 26 days developed a generalised erythematous rash and became delirious, dehydrated, markedly jaundiced, with peripheral circulatory failure, and died from cholestatic jaundice with hepatic coma and anuria.[1] Drug-induced hypersensitivity and hepatitis due to acetazolamide was suspected.

Anaphylaxis has also been reported[2] after a single oral dose in a patient who had not previously received acetazolamide. However, the patient was hypersensitive to sulfonamides and the reaction may have been caused by cross-sensitivity.

1. Kristinsson A. Fatal reaction to acetazolamide. *Br J Ophthalmol* 1967; **51:** 348–9.
2. Tzanakis N, *et al.* Anaphylactic shock after a single oral intake of acetazolamide. *Br J Ophthalmol* 1998; **82:** 588.

Precautions

Acetazolamide is contra-indicated in the presence of sodium or potassium depletion, in hyperchloraemic acidosis, in conditions such as Addison's disease and adrenocortical insufficiency, and in marked hepatic or renal impairment. Encephalopathy may be precipitated in patients with hepatic dysfunction. It should not be used in chronic angle-closure glaucoma since it may mask deterioration of the condition. Since acetazolamide is a sulfonamide derivative, it should not be used in patients with a history of sulfonamide hypersensitivity.

Acetazolamide should be given with care to patients likely to develop acidosis or with diabetes mellitus; severe metabolic acidosis may occur in the elderly, and in patients with renal impairment, pulmonary obstruction, or emphysema. Acetazolamide may increase the risk of hyperglycaemia in diabetic patients.

Periodic monitoring of plasma electrolytes and blood count is recommended during long-term therapy and patients should be cautioned to report any unusual skin rashes. Acetazolamide is teratogenic in *animals*.

Some adverse effects such as drowsiness and myopia may affect a patient's ability to perform skilled tasks including driving.

Breast feeding. Acetazolamide has been detected in breast milk.[1] However, there have been no reports of adverse effects in breast-fed infants whose mothers were receiving acetazolamide and the American Academy of Pediatrics considers[2] that it is therefore usually compatible with breast feeding.

Diabetes mellitus. For a brief discussion of metabolic acidosis in patients with diabetes, see Effects on Electrolyte Balance, above.

For a report of deterioration in renal function in patients with diabetic nephropathy who were given carbonic anhydrase inhibitors, see Effects on the Kidneys, above.

The elderly. A retrospective review[1] of 222 patients with glaucoma indicated that those aged 40 years or less tolerated treatment with carbonic anhydrase inhibitors much better than older patients. A single-dose study[2] of acetazolamide in 4 elderly subjects indicated that the capacity to clear acetazolamide from plasma correlated with creatinine clearance and was thus reduced in the elderly. They also had reduced plasma protein binding and the combination of these factors predisposed the elderly to enhanced accumulation of acetazolamide in erythrocytes.

Plasma-acetazolamide concentrations exceeded the **therapeutic range** (5 to 10 micrograms/mL) in 9 of 12 elderly patients receiving acetazolamide for glaucoma or metabolic alkalosis.[3] Hyperchloraemic metabolic acidosis was detected in 6 of 9 glaucoma patients. The excessive plasma concentrations were attributed to age-related reductions in renal function. It was suggested that elderly patients may require reduced doses of acetazolamide.

For reports of symptomatic metabolic acidosis associated with use of acetazolamide in the elderly, see Effects on Electrolyte Balance, above.

1. Shrader CE, *et al*. Relationship of patient age and tolerance to carbonic anhydrase inhibitors. *Am J Ophthalmol* 1983; **96:** 730–3.
2. Chapron DJ, *et al*. Influence of advanced age on the disposition of acetazolamide. *Br J Clin Pharmacol* 1985; **19:** 363–71.
3. Chapron DJ, *et al*. Acetazolamide blood concentrations are excessive in the elderly: propensity for acidosis and relationship to renal function. *J Clin Pharmacol* 1989; **29:** 348–53.

Interference with laboratory estimations. Acetazolamide interfered with an HPLC method of assay for theophylline[1] resulting in an unnecessary dose reduction and worsening apnoea in an infant. Other workers[2] pointed out that the interference depended on the solvent used in the extraction, and presented evidence to suggest that acetazolamide may not interfere with other assay methods for theophylline.

1. Mecrow IK, Goldie BP. Acetazolamide interferes with theophylline assay. *Lancet* 1987; **i:** 558.
2. Kelsey HC, *et al*. Interference by acetazolamide in theophylline assay depends on the method. *Lancet* 1987; **ii:** 403.

Renal impairment. For a brief discussion of metabolic acidosis in patients with renal impairment, see Effects on Electrolyte Balance, above.

Interactions

By rendering the urine alkaline acetazolamide reduces the urinary excretion, and so may enhance the effects, of drugs such as amfetamines, ephedrine, and quinidine; conversely, urinary alkalinisation can reduce the effects of methenamine and its compounds. Acetazolamide may enhance antiepileptic-induced osteomalacia. Use of acetazolamide with aspirin may result in severe acidosis and increase CNS toxicity. Acetazolamide may affect fluid and electrolyte balance leading to interactions similar to those of the thiazide diuretics (see Hydrochlorothiazide, p.1309). Unlike thiazides, however, acetazolamide may increase the excretion of lithium.

Antacids. *Sodium bicarbonate* therapy enhances the risk of renal calculus formation in patients taking acetazolamide.[1]

1. Rubenstein MA, Bucy JG. Acetazolamide-induced renal calculi. *J Urol (Baltimore)* 1975; **114:** 610–12.

Antiepileptics. For severe osteomalacia in patients taking acetazolamide with *phenytoin* and other antiepileptics, see Diuretics, p.499. Acetazolamide may increase serum concentrations of *carbamazepine*, see Diuretics, p.475.

Antineoplastics. Alkalinisation of the urine by acetazolamide increases the solubility of *methotrexate* in the urine and also increases its excretion. This effect has been exploited therapeutically to reduce the nephrotoxicity of methotrexate (see Effects on the Kidneys, p.746).

Benzodiazepines. Ventilatory depression in a mountain climber with acute mountain sickness was considered to be due to the potentiation of *triazolam* by acetazolamide.[1]

1. Masuyama S, *et al*. 'Ondine's Curse': side effect of acetazolamide? *Am J Med* 1989; **86:** 637.

Local anaesthetics. For the effect of acetazolamide on *procaine*, see p.1869.

Salicylates. Salicylates displace acetazolamide from plasma protein binding sites and reduce its renal clearance,[1] leading to elevated plasma-acetazolamide concentrations. In addition acidosis produced by acetazolamide may increase salicylate toxicity by enhancing salicylate tissue penetration.[2] Severe metabolic acidosis has been reported[3] in patients with normal renal function given acetazolamide with salicylates.

Use of salicylates with acetazolamide should be avoided if possible, particularly if renal dysfunction is present. If the combination is used, patients should be carefully monitored for symptoms of CNS toxicity such as lethargy, confusion, somnolence, tinnitus, and anorexia.

3. Cowan RA, *et al*. Metabolic acidosis induced by carbonic anhydrase inhibitors and salicylates in patients with normal renal function. *BMJ* 1984; **289:** 347–8.

Pharmacokinetics

Acetazolamide is fairly rapidly absorbed from the gastrointestinal tract with peak plasma concentrations occurring about 2 hours after oral doses. It has been estimated to have a plasma half-life of about 3 to 6 hours. It is tightly bound to carbonic anhydrase and high concentrations are present in tissues containing this enzyme, particularly red blood cells and the renal cortex; it is highly bound to plasma proteins. It is excreted unchanged in the urine and has been detected in breast milk.

Uses and Administration

Acetazolamide is an inhibitor of carbonic anhydrase with weak diuretic activity and is used mainly in the management of glaucoma. Other indications include epilepsy and high-altitude disorders.

By inhibiting carbonic anhydrase in the eye acetazolamide decreases the formation of aqueous humour and so decreases intra-ocular pressure. It is used in the preoperative management of angle-closure **glaucoma**, or as an adjunct in the treatment of open-angle glaucoma. In the treatment of glaucoma the usual oral dose is 250 to 1000 mg daily; divided doses should be used for amounts greater than 250 mg daily. Modified-release preparations are also available. Although not licensed for children in the UK, the *BNFC* suggests that those aged 1 month to 12 years may be given acetazolamide in oral doses of 10 to 20 mg/kg daily, to a maximum of 750 mg daily, in 2 to 4 divided doses.

Acetazolamide is also used, either alone or with other antiepileptics, for the treatment of various forms of **epilepsy** in oral doses of 250 to 1000 mg daily in divided doses. Licensed product information in the UK suggests an oral dose for children of 8 to 30 mg/kg daily. The *BNFC* recommends an initial oral dose of 2.5 mg/kg 2 or 3 times daily in neonates and children up to 12 years of age; this may then be increased to a maintenance dose of 5 to 7 mg/kg 2 or 3 times daily. The total daily dose for children should not exceed 750 mg.

When oral dosing is impracticable, acetazolamide may be given parenterally as the sodium salt; acetazolamide sodium 275 mg is equivalent to about 250 mg of acetazolamide. It may be given by intramuscular injection but the intravenous route is preferred due to the alkalinity of the solution. Doses are similar to those given orally.

Acetazolamide is also used to prevent or ameliorate the symptoms of **high-altitude disorders**. Prompt descent will still be necessary if severe symptoms such as cerebral oedema or pulmonary oedema occur. The usual oral dose is 500 to 1000 mg daily in divided doses. It may also be given as a modified-release preparation.

Acetazolamide also increases the excretion of bicarbonate and of cations, chiefly sodium and potassium, by inhibiting the reaction catalysed by carbonic anhydrase in the renal tubules, and so promotes an alkaline diuresis. When given orally as an immediate-release preparation, its effect begins within 60 to 90 minutes and lasts for 8 to 12 hours. However, continuous use is associated with metabolic acidosis and an accompanying loss of diuretic activity. Therefore, although acetazolamide has been used as a diuretic, it has largely been superseded by drugs such as the thiazides or furosemide. For **diuresis** the usual oral dose is 250 to 375 mg and is given either once daily or on alternate days; intermittent therapy is required for a continued effect.

Administration in the elderly. For the suggestion that reduced doses may be required in elderly patients see under Precautions, above.

Epilepsy. Acetazolamide may be used in the treatment of epilepsy (p.465) as an alternative or adjunct to first-line drugs for refractory partial seizures with or without secondary generalisation. It is also effective in a number of other refractory forms of epilepsy including atypical absence, tonic, atonic, myoclonic, and menstruation-related seizures (catamenial epilepsy).[1-5] It is believed to act by inhibition of carbonic anhydrase in glial cells in the CNS.[6] The major drawback to the chronic use of acetazolamide is the rapid development of tolerance,[6] but this may be delayed or prevented by using it as an adjunct to other antiepileptics. Acetazolamide has been successfully used in management of seizures in children from 1 year of age.[5]

Glaucoma. Acetazolamide may be given orally or parenterally in the acute management of angle-closure glaucoma (p.1873) and to minimise rises in intra-ocular pressure associated with ocular surgery.[1,2] It may also be given orally in the long-term management of primary and secondary open-angle glaucoma but is usually used as a second-line drug and added to topical beta blockers. However, up to 50% of patients are unable to tolerate oral therapy because of adverse effects[3] although topical carbonic anhydrase inhibitors such as dorzolamide may be better tolerated. Attempts have been made to reduce the adverse effects of acetazolamide by modifying the dosage schedule. A single-dose study[4] showed that doses of acetazolamide greater than 63 mg produced no greater reductions in intra-ocular pressure in patients with ocular hypertension. Another study[5] reported that acetazolamide 250-mg tablets twice daily controlled intra-ocular pressure adequately while producing fewer adverse effects than 250 mg four times daily and it was suggested that there was no advantage in using the modified-release capsule formulation (500 mg twice daily). A study in patients with open-angle glaucoma[6] found that most patients were adequately controlled by a single night-time dose of acetazolamide 500 mg either as tablets or modified-release capsules. The night-time dose also reduced the severity of adverse effects compared with the same dose given in the morning, and could aid compliance.

High-altitude disorders. Acetazolamide is the most frequently used drug for the prophylaxis of high-altitude disorders (p.1168). It accelerates the process of acclimatisation, thus reducing the incidence of acute mountain sickness and associated symptoms such as headache, nausea, vomiting, and lethargy. The optimum dose is not clear. A systematic review[1] concluded that 750 mg daily effectively prevented acute mountain sickness, but that a dose of 500 mg daily was not effective. However, these conclusions have been criticised, and a subsequent controlled study[2] found that a dose of 125 mg twice daily reduced the incidence of acute mountain sickness by about 50%. Acetazolamide may also have some benefit in relieving symptoms once they have developed although experience is limited. It does not prevent or protect against pulmonary or cerebral oedema.

1. Dumont L, *et al.* Efficacy and harm of pharmacological prevention of acute mountain sickness: quantitative systematic review. *BMJ* 2000; **321:** 267–72.
2. Basnyat B, *et al.* Efficacy of low-dose acetazolamide (125 mg BID) for the prophylaxis of acute mountain sickness: a prospective, double-blind, randomized, placebo-controlled trial. *High Alt Med Biol* 2003; **4:** 45–52.

Macular oedema. For mention of the use of acetazolamide to treat macular oedema associated with uveitis, see Uveitis, p.1515.

Ménière's disease. In Ménière's disease (p.564) high concentrations of carbonic anhydrase are found in the labyrinth, and acetazolamide, a carbonic anhydrase inhibitor, has been tried for both diagnosis and treatment.[1] A dose of 500 mg by intravenous injection has been suggested for diagnosis of fluctuating Ménière's disease.[1] Oral treatment with the drug, however, has not been particularly effective and has been associated with a high incidence of adverse effects.[2]

1. Brookes GB. Ménière's disease: a practical approach to management. *Drugs* 1983; **25:** 77–89.
2. Brookes GB, Booth JB. Oral acetazolamide in Ménière's disease. *J Laryngol Otol* 1984; **98:** 1087–95.

Neuromuscular disorders. Acetazolamide may be of benefit in some neuromuscular disorders, including hypokalaemic periodic paralysis (p.1670). Doses of 375 to 500 mg daily were effective in 2 patients with severe paralysis and were well tolerated.[1] Preliminary observations in 5 other patients showed a striking improvement in 3. In a further 12 patients,[2] doses of 125 mg were given three times daily to children and 250 mg two to six times daily to adults. There was dramatic improvement in 10 of the 12 and this lasted for up to 43 months. Chronic weakness between attacks in 10 patients was improved in 8.

Acetazolamide may reduce the frequency of attacks in patients with hyperkalaemic periodic paralysis (p.1669). It has also been used in episodic ataxia.[3]

1. Resnick JS, *et al.* Acetazolamide prophylaxis in hypokalemic periodic paralysis. *N Engl J Med* 1968; **278:** 582–6.
2. Griggs RC, *et al.* Acetazolamide treatment of hypokalemic periodic paralysis: prevention of attacks and improvement of persistent weakness. *Ann Intern Med* 1970; **73:** 39–48.
3. Melberg A, *et al.* Loss of control after a cup of coffee. *Lancet* 1997; **350:** 1220.

Raised intracranial pressure. Acetazolamide has been used to reduce raised intracranial pressure (p.1181). It has a role in the management of idiopathic intracranial hypertension. It has also been tried in the treatment of immunocompromised patients with chronically raised intracranial pressure due to cryptococcal meningitis,[1] although a controlled trial[2] was terminated early due to serious adverse events possibly due to additive toxicity with amphotericin. However, acetazolamide was used successfully for long-term treatment in 2 immunocompetent patients[3] with raised intracranial pressure following fungal meningitis.

The *BNFC* suggests an initial dose of 8 mg/kg of acetazolamide 3 times daily for the treatment of raised intracranial pressure in children aged 1 month to 12 years; the dose may be increased to a maximum of 100 mg/kg daily as necessary. Acetazolamide may be given orally or by slow intravenous injection.

Acetylcholine Chloride *(BAN, rINN)*

Aceticholino chloridas; Acetilkolin-klorid; Acetylcholin chlorid; Acétylcholine, chlorure d'; Acetylcholini chloridum; Acetylkolinklorid; Acetylocholiny chlorek; Asetilkolin Klorür; Asetyylikoliinikloridi; Cloruro de acetilcolina. (2-Acetoxyethyl)trimethylammonium chloride.

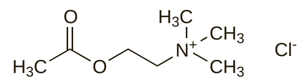
Ацетилхолина Хлорид

$C_7H_{16}ClNO_2$ = 181.7.

CAS — 51-84-3 (acetylcholine); 60-31-1 (acetylcholine chloride).

ATC — S01EB09.

ATC Vet — QS01EB09.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Jpn includes Acetylcholine Chloride for Injection.

Ph. Eur. 6.2 (Acetylcholine Chloride). A very hygroscopic, white or almost white crystalline powder or colourless crystals. Very soluble in water; freely soluble in alcohol; slightly soluble in dichloromethane. Protect from light.

USP 31 (Acetylcholine Chloride). White or off-white crystals or crystalline powder. Very soluble in water; freely soluble in alcohol; insoluble in ether. It is decomposed by hot water and by alkalis. Store in airtight containers.

Adverse Effects

Because it is rapidly hydrolysed in the body by cholinesterases the toxicity of acetylcholine is normally relatively low.

Systemic adverse effects of the choline esters include nausea and vomiting, abdominal pain, flushing, sweating, salivation, lachrymation, rhinorrhoea, eructation, diarrhoea, urinary frequency, headache, bradycardia, peripheral vasodilatation leading to hypotension, and bronchoconstriction.

Ocular adverse effects after local application of choline esters to the eye include corneal oedema, clouding, and decompensation, persistent bullous keratopathy, retinal detachment, and postoperative iritis.

Treatment of Adverse Effects

Atropine sulfate may be given intravenously, intramuscularly, or subcutaneously to control the muscarinic and most nicotinic effects of the choline esters. Supportive treatment may be required.

Precautions

Choline esters are generally contra-indicated for *systemic use* in intestinal or urinary obstruction or where increased muscular activity of the urinary or gastrointestinal tract is liable to be harmful. They are also contra-indicated in asthma and obstructive airways disease, in cardiovascular disorders including bradycardia or heart block and recent myocardial infarction, and in hypotension, vagotonia, epilepsy, parkinsonism, hyperthyroidism, peptic ulceration, and pregnancy. Choline esters should not be given by the intravenous or intramuscular routes as very severe muscarinic adverse effects are liable to occur, calling for emergency treatment with atropine.

Although acetylcholine is normally rapidly hydrolysed in the body, systemic effects have followed *topical application* of choline esters to the eye, albeit rarely, and caution is advisable in the above conditions.

Interactions

As for Neostigmine, p.632. Acetylcholine is hydrolysed in the body by cholinesterase and its effects are markedly prolonged and enhanced if given after anticholinesterases.

Beta blockers. Severe bronchospasm with subsequent pulmonary oedema was reported[1] after intra-ocular injection of acetylcholine chloride in a patient also receiving *metoprolol* by mouth.

1. Rasch D, *et al.* Bronchospasm following intraocular injection of acetylcholine in a patient taking metoprolol. *Anesthesiology* 1983; **59:** 583–5.

NSAIDs. According to licensed product information for acetylcholine chloride ophthalmic preparations, there have been reports that acetylcholine and carbachol were ineffective when used in patients treated with topical (ophthalmic) NSAIDs.

Uses and Administration

Acetylcholine is an endogenous chemical transmitter with a very wide range of actions in the body (see below). It is used as a miotic to reduce postoperative rises in intra-ocular pressure associated with cataract surgery, penetrating keratoplasty, iridectomy, and other anterior segment surgery (see p.1873) but is ineffective when applied topically as it is hydrolysed more rapidly than it can penetrate the cornea. Doses of 0.5 to 2 mL of a freshly prepared 1% solution of acetylcholine chloride are therefore instilled directly into the anterior chamber of the eye (intracameral instillation). Miosis occurs within seconds and lasts for about 20 minutes. A second application may be made if prolonged miosis is required.

Action. Acetylcholine is a powerful quaternary ammonium parasympathomimetic but its action is transient as it is rapidly destroyed by cholinesterase. It is released from postganglionic parasympathetic nerves and also from some postganglionic sympathetic nerves to produce peripheral actions which correspond to those of muscarine. It is accordingly a vasodilator and cardiac depressant, a stimulant of the vagus and the parasympathetic nervous system, and it has a tonic action on smooth muscle. It also increases lachrymal, salivary, and other secretions. All the muscarinic actions of acetylcholine are abolished by atropine.

Acetylcholine also has actions that correspond to those of nicotine and is accordingly a stimulant of skeletal muscle, the autonomic ganglia, and the adrenal medulla. The nicotinic actions of acetylcholine on skeletal muscle are blocked by competitive neuromuscular blockers; they are also inhibited by massive doses or discharge of acetylcholine itself, which has clinical application in relation to the mode of action of suxamethonium (p.1912).

Drugs that mimic or enhance the actions of acetylcholine in the body are known as **parasympathomimetics** and may be classified into 2 distinct pharmacological groups:

- **cholinergic agonists**, such as bethanechol, carbachol, methacholine, and pilocarpine which act directly on effector cells to mimic the effects of acetylcholine. They are sometimes referred to as cholinomimetics or true parasympathomimetics; some such as bethanechol, carbachol, and methacholine are choline esters
- **anticholinesterases** (cholinesterase inhibitors) which inhibit the enzymic hydrolysis of acetylcholine by acetylcholinesterase and other cholinesterases, thereby prolonging and enhancing its actions in the body. They may be classified by the length of time taken to restore active enzyme following binding of enzyme to drug. The 'reversible' anticholinesterases such as ambenonium, neostigmine, physostigmine, and pyridostigmine generally produce enzyme inhibition for a few hours, whereas 'irreversible' anticholinesterases such as dyflos and ecothiopate produce extremely prolonged inhibition, and return of cholinesterase activity depends on synthesis of new enzyme. Centrally acting reversible anticholinesterases include donepezil, galantamine, rivastigmine, and tacrine

Drugs such as fampridine and guanidine, which enhance the release of acetylcholine from nerve terminals, also have similar effects.

Diagnosis and testing. *AUTONOMIC FAILURE.* Acetylcholine has been used in a sweat-spot test for autonomic neuropathy in diabetic patients.[1] An area on the dorsum of the foot is painted with iodine and starch, followed by intradermal injection of acetylcholine into the centre of the area. Sweat produced in response to acetylcholine reacts with the iodine and starch to produce fine black dots corresponding to the pores of the sweat glands; a normal response is indicated by a uniform distribution of dark spots whereas in diabetic autonomic neuropathy this pattern is lost to a varying degree. A similar test has been carried out[2] to assess sympathetic nerve function and therefore predict the success of lumbar sympathectomy in patients with critical limb ischaemia.

2. Altomare DF. Acetylcholine sweat test: an effective way to select patients for lumbar sympathectomy. *Lancet* 1994; **344:** 976–8.

Preparations

USP 31: Acetylcholine Chloride for Ophthalmic Solution.

Proprietary Preparations (details are given in Part 3)
Austral.: Miochol; ***Belg.:*** Miochole; ***Canad.:*** Miochol-E; Miochol†; ***Chile:*** Miochol-E†; ***Fin.:*** Miochol-E; ***Fr.:*** Miochole; ***Ger.:*** Miochol-E; ***Gr.:*** Miochol-E; ***Hong Kong:*** Miochol-E; ***Indon.:*** Miochol-E; ***Irl.:*** Miochol; ***Israel:*** Miochol; Miochol-E; ***Ital.:*** Miochol-E; Miovisin; ***Mex.:*** Iloc; ***Neth.:*** Miochol; ***NZ:*** Miochol; ***Port.:*** Miochol; ***S.Afr.:*** Covochol; Miochol; ***Singapore:*** Miochol-E†; ***Swed.:*** Miochol-E; ***Switz.:*** Miochol; ***Thai.:*** Miochol†; ***Turk.:*** Miochol-E; ***UK:*** Miochol; ***USA:*** Miochol.

Apraclonidine Hydrochloride

(BANM, USAN, rINNM)

AL-02145 (apraclonidine); *p*-Aminoclonidine Hydrochloride; Aplonidine Hydrochloride; Apraclonidine, chlorhydrate d'; Apraclonidini hydrochloridum; Hidrocloruro de apraclonidina; NC-14. 2-[(4-Amino-2,6-dichlorophenyl)imino]imidazolidine hydrochloride; 2,6-Dichloro-N^1-imidazolidin-2-ylidene-*p*-phenylenediamine hydrochloride.

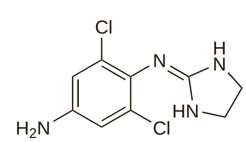
Апраклонидина Гидрохлорид

$C_9H_{10}Cl_2N_4,HCl$ = 281.6.

CAS — 66711-21-5 (apraclonidine); 73218-79-8 (apraclonidine hydrochloride).

ATC — S01EA03.

ATC Vet — QS01EA03.



(apraclonidine)

NOTE. APR is a code approved by the BP 2008 for use on single unit doses of eye drops containing apraclonidine hydrochloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *US.*

USP 31 (Apraclonidine Hydrochloride). A white to off-white, odourless to practically odourless powder. Soluble 1 in 34 of water, 1 in 74 of alcohol, and 1 in 13 of methyl alcohol; insoluble in chloroform, in ethyl acetate, and in hexanes. pH of a 1% solution in water is between 5.0 and 6.6. Store in airtight containers. Protect from light.

Adverse Effects and Precautions

Adverse effects after perioperative instillation of apraclonidine into the eye include hyperaemia, lid retraction, and mydriasis. Some patients may develop an exaggerated reduction in intra-ocular pressure. On regular instillation an ocular intolerance reaction may occur, characterised by hyperaemia, ocular pruritus, increased lachrymation, ocular discomfort, and oedema of the lids and conjunctiva; treatment should be stopped if these symptoms occur. Other adverse effects reported include dry mouth and nose, conjunctivitis, conjunctival blanching, blurred vision, asthenia, headache, and taste disturbances.

Systemic absorption can occur after application to the eye and may result in adverse effects similar to those of clonidine (p.1247). Cardiovascular effects have been reported; therefore apraclonidine should be used with caution in patients with severe cardiovascular disease, including hypertension, and in patients with a history of vasovagal attacks. Drowsiness may also occur. Depression has rarely been associated with use of apraclonidine and it should be used with caution in depressed patients.

Interactions

Systemic absorption may occur after topical application of apraclonidine to the eye and there is a theoretical possibility of interactions similar to those reported with clonidine (p.1248). Since the effects of apraclonidine on circulating catecholamines are unknown, licensed product information recommends that MAOIs should not be given with apraclonidine; tricyclic and related antidepressants and systemic sympathomimetics should also be avoided or used with caution.

Uses and Administration

Apraclonidine is an alpha$_2$-adrenoceptor agonist derived from clonidine (p.1247). It reduces intra-ocular pressure when instilled into the eye and is used in patients undergoing eye surgery, and as an adjunct in the management of glaucoma (p.1873). The reduction in intra-ocular pressure begins within an hour of instillation and is maximal after about 3 to 5 hours.

Apraclonidine is used as the hydrochloride, but the strength of an ophthalmic solution is usually expressed in terms of the base. Apraclonidine hydrochloride 11.5 mg is equivalent to about 10 mg of apraclonidine.

To control or prevent a postoperative increase in intra-ocular pressure in patients undergoing anterior segment laser surgery, a 1% solution is instilled into the eye one hour before surgery and again immediately upon completion of surgery.

For short-term adjunctive therapy in patients with raised intra-ocular pressure not controlled by conventional therapy, a 0.5% solution may be instilled three times daily.

There is a loss of effect over time (tachyphylaxis) with apraclonidine and the benefit in most patients lasts for less than a month.

Preparations

USP 31: Apraclonidine Ophthalmic Solution.

Bimatoprost *(BAN, USAN, rINN)*

AGN-192024; Bimatoprostum. (*Z*)-7-{(1*R*,2*R*,3*R*,5*S*)-3,5-Dihydroxy-2-[(1*E*,3*S*)-3-hydroxy-5-phenyl-1-pentenyl]cyclopentyl}-*N*-ethyl-5-heptenamide.

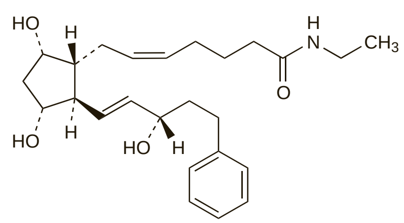
Биматопрост

$C_{25}H_{37}NO_4 = 415.6.$

CAS — 155206-00-1.

ATC — S01EE03.

ATC Vet — QS01EE03.



Adverse Effects and Precautions

As for Latanoprost, p.1882. Ocular pruritus is common. Hypertension and headache also commonly occur.

Pharmacokinetics

Small amounts of bimatoprost are absorbed from eye drops, with peak blood concentrations seen within 10 minutes of dosing. Bimatoprost is metabolised by oxidation, de-ethylation and glucuronidation and is excreted mainly in the urine with about 25% appearing in the faeces. The elimination half-life is 45 minutes.

Uses and Administration

Bimatoprost is a synthetic prostamide, a fatty-acid amide that is structurally related to dinoprost (prostaglandin F_2). It is used to reduce intra-ocular pressure in the treatment of open-angle glaucoma and ocular hypertension (p.1873). Reduction in pressure starts about 4 hours after instillation and is maximal within 8 to 12 hours; the effect lasts for at least 24 hours. It is given once daily in the evening as a 0.03% ophthalmic solution.

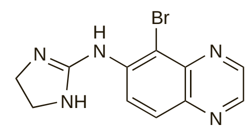
$C_{11}H_{10}BrN_5,C_4H_6O_6 = 442.2.$

CAS — 59803-98-4 (brimonidine); 79570-19-7 (brimonidine tartrate).

ATC — S01EA05.

ATC Vet — QS01EA05.



(brimonidine)

Adverse Effects and Precautions

As for Apraclonidine Hydrochloride, p.1878.

In children. Systemic adverse effects, occasionally severe,[1] have been reported in children treated with brimonidine eye drops. In one study[2] adverse effects were reported in 70 of 83 children given adjunctive brimonidine, the most common effects being lethargy and excessive sleepiness; other effects included ocular irritation and blurred vision. Hypothermia occurred in a few cases, mainly in older children. Effects suggesting CNS depression, such as cyanosis and breathing difficulty, were rare, and were most likely in children less than 6 years of age or weighing less than 20 kg. Alternative medication should be considered in this group. In the UK, licensed product information contra-indicates use in neonates and infants under 2 years of age; use in children under 12 years of age is not recommended.

2. Al-Shahwan S, *et al.* Side-effect profile of brimonidine tartrate in children. *Ophthalmology* 2005; **112:** 2143–8.

Interactions

As for Apraclonidine Hydrochloride, p.1878.

Uses and Administration

Brimonidine is an alpha$_2$-adrenoceptor agonist with actions and uses similar to those of apraclonidine (p.1878). It is used to lower intra-ocular pressure in patients with open-angle glaucoma or ocular hypertension (p.1873), as an alternative or adjunct to topical beta blocker therapy. It may also be used as adjunctive therapy in patients with raised intra-ocular pressure not controlled by topical monotherapy with other drugs such as latanoprost and travoprost. The reduction in intra-ocular pressure is maximal about 2 hours after topical use.

In the management of glaucoma or ocular hypertension, eye drops containing brimonidine tartrate 0.1, 0.15, or 0.2% are instilled two or three times daily.

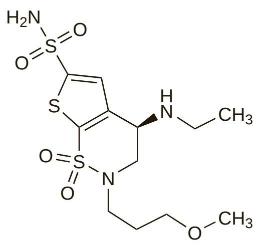
Brinzolamide *(BAN, USAN, rINN)* ⊗

AL-4862; Brintsolamidi; Brinzolamid; Brinzolamida; Brinzolamidum. (*R*)-4-(Ethylamino)-3,4-dihydro-2-(3-methoxypropyl)-2*H*-thieno[3,2-e]-1,2-thiazine-6-sulfonamide 1,1-dioxide.

Бринзоламид

$C_{12}H_{21}N_3O_5S_3$ = 383.5.
CAS — 138890-62-7.
ATC — S01EC04.
ATC Vet — QS01EC04.



Pharmacopoeias. In *US.*

USP 31 (Brinzolamide). A white or almost white powder. Insoluble in water; slightly soluble in alcohol and in methyl alcohol.

Adverse Effects and Precautions

As for Dorzolamide, p.1880.

Effects on the eyes. Corneal oedema has been noted in the eyes of 2 patients after the long-term use of brinzolamide 1% eye drops;[1] both patients recovered after brinzolamide was stopped.

1. Zhao JC, Chen T. Brinzolamide induced reversible corneal decompensation. *Br J Ophthalmol* 2005; **89:** 389–90.

Uses and Administration

Brinzolamide is a carbonic anhydrase inhibitor with actions and uses similar to those of dorzolamide (p.1880). It is used to reduce intra-ocular pressure in the management of open-angle glaucoma and ocular hypertension (p.1873), either alone or as adjunctive therapy with a topical beta blocker. A 1% suspension is instilled into the eye two or three times daily.

Glaucoma. References.

1. Cvetkovic RS, Perry CM. Brinzolamide : a review of its use in the management of primary open-angle glaucoma and ocular hypertension. *Drugs Aging* 2003; **20:** 919–47.

Preparations

USP 31: Brinzolamide Ophthalmic Suspension.

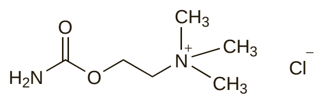
Proprietary Preparations (details are given in Part 3)
Arg.: Azopt; ***Austral.:*** Azopt; ***Austria:*** Azopt; ***Belg.:*** Azopt; ***Braz.:*** Azopt; ***Canad.:*** Azopt; ***Chile:*** Azopt; ***Cz.:*** Azopt; ***Denm.:*** Azopt; ***Fin.:*** Azopt; ***Fr.:*** Azopt; ***Ger.:*** Azopt; ***Gr.:*** Azopt; ***Hong Kong:*** Azopt; ***Hung.:*** Azopt; ***Indon.:*** Azopt; ***Irl.:*** Azopt; ***Israel:*** Azopt; ***Ital.:*** Azopt; ***Malaysia:*** Azopt; ***Mex.:*** Azopt; ***Neth.:*** Azopt; ***Norw.:*** Azopt; ***NZ:*** Azopt; ***Philipp.:*** Azopt; ***Pol.:*** Azopt; ***Port.:*** Azopt; ***Rus.:*** Azopt (Азопт); ***S.Afr.:*** Azoptic; ***Singapore:*** Azopt; ***Spain:*** Azopt; ***Swed.:*** Azopt; ***Switz.:*** Azopt; ***Thai.:*** Azopt; ***Turk.:*** Azopt; ***UK:*** Azopt; ***USA:*** Azopt; ***Venez.:*** Azopt.

Carbachol *(BAN, rINN)*

Carbach.; Carbacholi Cloridum; Carbacholine; Carbacholum; Carbacholum Chloratum; Carbacol; Choline Chloride Carbamate; Karbachol; Karbacholis; Karbakol; Karbakoli; Karbaminocholiny chlorek. *O*-Carbamoylcholine chloride; (2-Carbamoyloxyethyl)trimethylammonium chloride.

Карбахол

$C_6H_{15}ClN_2O_2$ = 182.6.
CAS — 51-83-2.
ATC — N07AB01; S01EB02.
ATC Vet — QA03AB92; QN07AB01; QS01EB02.



NOTE. CAR is a code approved by the BP 2008 for use on single unit doses of eye drops containing carbachol where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Carbachol). A white or almost white, crystalline, hygroscopic powder. Very slightly soluble in water; sparingly soluble in alcohol; practically insoluble in acetone. Store in airtight containers. Protect from light.

USP 31 (Carbachol). A white powder. Freely soluble in water; sparingly soluble in alcohol; practically insoluble in chloroform and in ether. Store in airtight containers.

Incompatibility. Chlorocresol (0.025 to 0.1%) and chlorobutanol (0.5%) were both found to be incompatible with a solution of carbachol (0.8%) and sodium chloride (0.69%), very slight precipitates forming on heating and increasing on standing.[1]

1. *PSGB Lab Report No.911* 1962.

Adverse Effects, Treatment, and Precautions

As described for choline esters under Acetylcholine Chloride, p.1877. Carbachol has substantial nicotinic activity which may be unmasked by the use of atropine to counteract muscarinic effects.

Carbachol also produces adverse effects and requires precautions similar to those of other miotics such as pilocarpine (p.1885) when used in the eye, but may produce more ciliary spasm than pilocarpine.

Effects on the gastrointestinal tract. Fatal oesophageal rupture has been reported[1] after subcutaneous injection of carbachol to relieve urinary retention.

1. Cochrane P. Spontaneous oesophageal rupture after carbachol therapy. *BMJ* 1973; **1:** 463–4.

Overdosage. Life-threatening attacks of profuse sweating, intestinal cramps, explosive defaecation, hypothermia, hypotension, and bradycardia occurred in a 36-year-old man after deliberate poisoning with 30 to 40 mg of carbachol.[1] The patient's 10-year-old son had died after poisoning with a similar dose of carbachol.

1. Sangster B, *et al.* Two cases of carbachol intoxication. *Neth J Med* 1979; **22:** 27–8.

Interactions

NSAIDs. Licensed UK product information for acetylcholine chloride ophthalmic preparations states that there have been reports that acetylcholine and carbachol were ineffective when used in patients treated with topical (ophthalmic) NSAIDs.

Uses and Administration

Carbachol, a choline ester, is a quaternary ammonium parasympathomimetic with the muscarinic and nicotinic actions of acetylcholine (p.1877). It is not inactivated by cholinesterases so its actions are more prolonged than those of acetylcholine.

Carbachol has a miotic action and is usually given intra-ocularly to produce miosis in ocular surgery and to reduce postoperative rises in intra-ocular pressure; up to 0.5 mL of a 0.01% solution is instilled into the anterior chamber of the eye (intracameral instillation). The maximum degree of miosis is usually obtained within 2 to 5 minutes of intra-ocular instillation and miosis lasts for 24 hours.

Eye drops containing up to 3% of carbachol have also been used to lower intra-ocular pressure in glaucoma, usually three times daily with other miotics (see below). Miosis occurs within 10 to 20 minutes of instillation and lasts for 4 to 8 hours; reduction in intra-ocular pressure lasts for 8 hours.

Carbachol has been used for the treatment of urinary retention including postoperative urinary retention. It has also been used in some countries for the treatment of decreased gastrointestinal motility.

Dry mouth. Carbachol has been used as an alternative to pilocarpine in the treatment of radiation-induced xerostomia.[1] The overall treatment of dry mouth is discussed on p.2140.

1. Joensuu H. Treatment for post-irradiation xerostomia. *N Engl J Med* 1994; **330:** 141–2.

Glaucoma and ocular hypertension. Carbachol is sometimes used as an alternative to pilocarpine in the management of glaucoma (p.1873) when resistance or intolerance to pilocarpine develops. It is also instilled into the anterior chamber of the eye (intracameral instillation) to minimise postoperative rises in intra-ocular pressure associated with ocular surgery, and some[1,2] have found it to be more effective than acetylcholine.

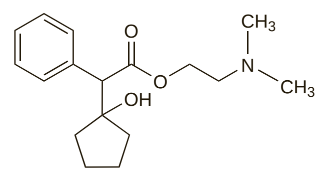
Cyclopentolate Hydrochloride

(BANM, rINNM)

Ciklopentolát-hidroklorid; Ciklopentolato hidrochloridas; Cloridrato de Ciclopentolato; Cyclopentolate, chlorhydrate de; Cyclopentolati hydrochloridum; Cyklopentolát hydrochlorid; Cyklopentolathydroklorid; Hidrocloruro de ciclopentolato; Siklopentolat Hidroklorür; Syklopentolaattihydrokloridi. 2-Dimethylaminoethyl 2-(1-hydroxycyclopentyl)-2-phenylacetate hydrochloride.

Циклопентолата Гидрохлорид

$C_{17}H_{25}NO_3,HCl$ = 327.8.
CAS — 512-15-2 (cyclopentolate); 5870-29-1 (cyclopentolate hydrochloride).
ATC — S01FA04.
ATC Vet — QS01FA04.



(cyclopentolate)

NOTE. CYC is a code approved by the BP 2008 for use on single unit doses of eye drops containing cyclopentolate hydrochloride where the individual container may be too small to bear all the appropriate labelling information. PHNCYC is a similar code approved for eye drops containing phenylephrine hydrochloride and cyclopentolate hydrochloride.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Cyclopentolate Hydrochloride). A white or almost white, crystalline powder. Very soluble in water; freely soluble in alcohol. A 1% solution in water has a pH of 4.5 to 5.5.

USP 31 (Cyclopentolate Hydrochloride). A white crystalline powder, which develops a characteristic odour on standing. Very soluble in water; freely soluble in alcohol; insoluble in ether. pH of a 1% solution in water is between 4.5 and 5.5. Store at a temperature not exceeding 8° in airtight containers.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

Eye drops of cyclopentolate hydrochloride may cause temporary irritation.

Abuse. Cyclopentolate eye drops have been abused.[1] One of 2 patients who did so had been instilling 200 to 400 drops of cyclopentolate into both eyes daily for about 4 months, presumably for its CNS effects, and experienced intense nausea, vomiting, weakness, and tremors on withdrawal.

1. Sato EH, *et al.* Abuse of cyclopentolate hydrochloride (Cyclogyl) drops. *N Engl J Med* 1992; **326:** 1363–4.

Hypersensitivity. Two children developed hypersensitivity reactions shortly after the instillation of 1% cyclopentolate hydrochloride eye drops into each eye.[1] Both children initially had a facial rash but in one of them the rash later spread to include the arms and legs and was accompanied by mild breathlessness.

1. Jones LWJ, Hodes DT. Possible allergic reactions to cyclopentolate hydrochloride: case reports with literature review of uses and adverse reactions. *Ophthalmic Physiol Opt* 1991; **11:** 16–21.

Systemic toxicity. Ten of 66 patients (29 males and 37 females) who received one drop of 2% cyclopentolate in each eye developed mild to moderate systemic toxicity; 9 of the 10 were female.[1] Toxic signs included physical weakness, nausea, lightheadedness, changes in emotional attitude, unprovoked weeping, and loss of equilibrium; tachycardia was always present but changes in blood pressure were insignificant. Spontaneous recovery occurred within 1 hour to several days.

As with atropine, it has been recommended that cyclopentolate eye drops should not be used during the first 3 months of life because of the possible association with development of amblyopia. Systemic toxicity has also been reported in neonates given ocular cyclopentolate.[2]

A 4-year-old boy with cerebral palsy and paraplegia suffered tonic-clonic seizures, facial flushing, and tachycardia 70 minutes after one drop of a 1% cyclopentolate solution was instilled into each eye to dilate his pupils.[3] The child had no history of convulsions and had received 1% cyclopentolate eye drops on 2 previous occasions without incident. In a more recent case,[4] a 23-month-old boy experienced a tonic-clonic seizure lasting 30 minutes after the use of cyclopentolate 1% and phenylephrine 10% eye drops. One drop of each was instilled into both eyes every 5 minutes for 3 doses; the seizure occurred 45 minutes after the last dose. The child was found to have low pseudocholinesterase activity, an enzyme likely to be involved in the metabolism of cyclopentolate.

4. Demayo AP, Reidenberg MM. Grand mal seizure in a child 30 minutes after Cyclogyl (cyclopentolate hydrochloride) and 10% Neo-Synephrine (phenylephrine hydrochloride) eye drops were instilled. Abstract: *Pediatrics* 2004; **113:** 1390–1. Full version: http://pediatrics.aappublications.org/cgi/reprint/113/5/e499 (accessed 24/11/05)

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Uses and Administration

Cyclopentolate hydrochloride is a tertiary amine antimuscarinic with actions similar to those of atropine (p.1219). It is used to produce mydriasis and cycloplegia (p.1874) for ophthalmic diagnostic procedures and also in the treatment of uveitis and iritis (p.1515). It acts more quickly than atropine and has a shorter duration of action; the maximum mydriatic effect is produced 30 to 60 minutes after instillation, and may persist for up to 24 hours or longer in some patients; the maximum cycloplegic effect is produced within 25 to 75 minutes and accommodation recovers within 6 to 24 hours.

For diagnostic procedures, instillation of a 0.5% ophthalmic solution of cyclopentolate hydrochloride, repeated after about 5 to 15 minutes, is usually sufficient for adults. Higher strengths have been used. For children a 1% solution is instilled similarly, although some recommend that strengths greater than 0.5% should not be used in infants and that cyclopentolate should not be used at all during the first 3 months of life.

In the treatment of uveitis and iritis, a 0.5% ophthalmic solution of cyclopentolate hydrochloride is instilled into the eye up to four times daily.

Deeply pigmented eyes are more resistant to pupillary dilatation and may require the use of a 1% solution.

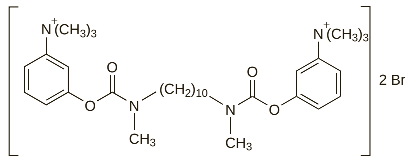
Demecarium Bromide *(BAN, rINN)*

BC-48; Bromuro de demecario; Demecarii Bromidum; Démécarium, Bromure de; Demekariumbromid; Demekariumbromidi. *N,N'*-Decamethylenebis(*N,N,N*-trimethyl-3-methylcarbamoyloxyanilinium) dibromide.

Демекария Бромид

$C_{32}H_{52}Br_2N_4O_4$ = 716.6.
CAS — 16505-84-3 (demecarium); 56-94-0 (demecarium bromide).
ATC — S01EB04.
ATC Vet — QS01EB04.



Pharmacopoeias. In *US.*

USP 31 (Demecarium Bromide). A white or slightly yellow, slightly hygroscopic, crystalline powder. Freely soluble in water and in alcohol; sparingly soluble in acetone; soluble in ether. pH of a 1% solution in water is between 5.0 and 7.0. Store in airtight containers. Protect from light.

Profile

Demecarium is a quaternary ammonium compound that is a reversible inhibitor of cholinesterase with a long duration of action similar to that of ecothiopate iodide (p.1881). It has been used as a 0.125 or 0.25% ophthalmic solution in the treatment of open-angle glaucoma and in the diagnosis and management of accommodative convergent strabismus.

Preparations

USP 31: Demecarium Bromide Ophthalmic Solution.

Proprietary Preparations (details are given in Part 3)
USA: Humorsol†.

Diclofenamide *(BAN, rINN)* ⊗

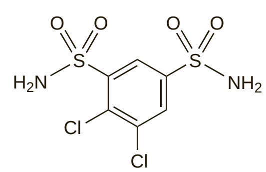
Диклофенамид

$C_6H_6Cl_2N_2O_4S_2$ = 305.2.
CAS — 120-97-8.
ATC — S01EC02.
ATC Vet — QS01EC02.



Pharmacopoeias. In *Chin., Jpn,* and *US.*

Profile

Diclofenamide is an inhibitor of carbonic anhydrase with properties similar to those of acetazolamide (p.1875). When given orally its effect begins within 1 hour and lasts for 6 to 12 hours.

Diclofenamide is used to reduce intra-ocular pressure in glaucoma (p.1873). The usual initial oral dose is 100 to 200 mg, then 100 mg every 12 hours until the desired response is obtained, followed by a maintenance dose of 25 to 50 mg one to three times daily. Diclofenamide sodium has been given by injection.

Preparations

USP 31: Dichlorphenamide Tablets.

Proprietary Preparations (details are given in Part 3)
Belg.: Oratrol†; ***Cz.:*** Oratrol†; ***Gr.:*** Oratrol†; ***Ital.:*** Antidrasi; Fenamide; Glaumid†; ***Spain:*** Glauconide; ***USA:*** Daranide†.

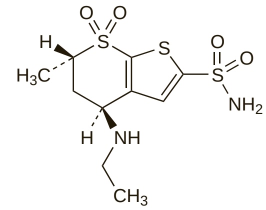
Дорзоламида Гидрохлорид

$C_{10}H_{16}N_2O_4S_3$,HCl = 360.9.
CAS — 120279-96-1 (dorzolamide); 130693-82-2 (dorzolamide hydrochloride).
ATC — S01EC03.
ATC Vet — QS01EC03.



(dorzolamide)

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Dorzolamide Hydrochloride). A white or almost white, crystalline powder. Soluble in water; very slightly soluble in anhydrous alcohol; slightly soluble in methyl alcohol. It exhibits polymorphism.

USP 31 (Dorzolamide Hydrochloride). A white to off-white crystalline powder. Soluble in water. Store at 15° to 30°. Protect from light.

Adverse Effects and Precautions

Local ocular adverse effects may occur with dorzolamide eye drops and include conjunctivitis, keratitis, burning or stinging, eyelid inflammation or irritation, and blurred vision. Dorzolamide may be absorbed systemically, resulting in adverse effects and precautions similar to those of acetazolamide (see p.1875). Other adverse effects reported are headache, bitter taste, epistaxis, fatigue, and nausea.

Interactions

Systemic absorption may occur after topical application of dorzolamide to the eye and there is a theoretical possibility of interactions similar to those reported with acetazolamide (see p.1876).

Uses and Administration

Dorzolamide is a carbonic anhydrase inhibitor with actions similar to those of acetazolamide (p.1876). It is used in the management of open-angle glaucoma, pseudo-exfoliative glaucoma, and ocular hypertension (p.1873), either alone or as an adjunct to a topical beta blocker.

Dorzolamide is given as eye drops containing dorzolamide hydrochloride equivalent to 2% of the base. For monotherapy it is usually given three times daily; a twice-daily regimen is recommended when used with a beta blocker.

Dyflos *(BAN)*

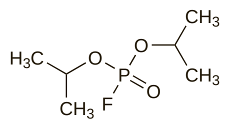
DFP; Difluorophate; Di-isopropyl Fluorophosphate; Di-isopropylfluorophosphonate; Fluostigmine; Isoflurofato; Isoflurophate. Di-isopropyl phosphorofluoridate.

$C_6H_{14}FO_3P$ = 184.1.

CAS — 55-91-4.

ATC — S01EB07.

ATC Vet — QS01EB07.



Pharmacopoeias. In *US*.

USP 31 (Isoflurophate). A clear, colourless, or faintly yellow liquid. Specific gravity about 1.05. Sparingly soluble in water; soluble in alcohol and in vegetable oils. It is decomposed by moisture with the evolution of hydrogen fluoride. Store at 8° to 15° in sealed containers.

Profile

Dyflos is an irreversible inhibitor of cholinesterases with actions similar to those of ecothiopate iodide (below). It has been used mainly in the treatment of open-angle glaucoma, particularly in aphakic patients and when other drugs have proved inadequate; it has usually been given as a 0.025% ophthalmic ointment. It was also used in the diagnosis and management of accommodative convergent strabismus.

Handling. The vapour of dyflos is very toxic. The eyes, nose, and mouth should be protected when handling dyflos, and contact with the skin should be avoided. Dyflos can be removed from the skin by washing with soap and water. Contaminated material should be immersed in a 2% aqueous solution of sodium hydroxide for several hours.

Preparations

USP 31: Isoflurophate Ophthalmic Ointment.

Ecothiopate Iodide *(BAN, rINN)*

Echothiophate Iodide; Ecostigmine Iodide; Écothiopate, Iodure d'; Ecothiopati Iodidum; Ekotiopaattijodidi; Ekotiopatjodid; Ioduro de ecotiopato; MI-217. (2-Diethoxyphosphinylthioethyl)trimethylammonium iodide.

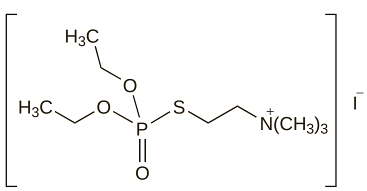
Экотиопата Йодид

$C_9H_{23}INO_3PS$ = 383.2.

CAS — 6736-03-4 (ecothiopate); 513-10-0 (ecothiopate iodide).

ATC — S01EB03.

ATC Vet — QS01EB03.



Pharmacopoeias. In *Jpn* and *US*.

USP 31 (Echothiophate Iodide). A white, crystalline, hygroscopic solid having a slight mercaptan-like odour. Soluble 1 in 1 of water, 1 in 25 of dehydrated alcohol, and 1 in 3 of methyl alcohol; practically insoluble in other organic solvents. Its solutions in water have a pH of about 4. Store in airtight containers preferably at a temperature below 0°. Protect from light.

Adverse Effects

As for Neostigmine, p.631. For adverse effects of miotics, see also Pilocarpine, p.1885.

Ecothiopate is an irreversible cholinesterase inhibitor; its action, and hence its adverse effects, may be prolonged.

Plasma and erythrocyte cholinesterases may be reduced by treatment with eye drops of ecothiopate or other long-acting anticholinesterases, and systemic toxicity occurs more frequently than with shorter-acting miotics. Acute iritis, retinal detachment, or precipitation of acute glaucoma may occasionally occur, and iris cysts (especially in children) or lens opacities may develop on prolonged treatment.

Treatment of Adverse Effects

To treat the systemic effects of poisoning, atropine sulfate may be given parenterally with pralidoxime chloride as for intoxication with organophosphorus insecticides (see p.1460); subconjunctival injection of pralidoxime has been used to reverse severe ocular adverse effects. Supportive treatment, including assisted ventilation, should be given as necessary.

To prevent or reduce development of iris cysts in patients receiving ecothiopate eye drops, phenylephrine eye drops may be given simultaneously.

Precautions

As for Neostigmine, p.632. For precautions of miotics, see also under Pilocarpine, p.1885. In general, as with other long-acting anticholinesterases, ecothiopate should be used only where therapy with other drugs has proved ineffective. Ecothiopate iodide should not be used in patients with iodine hypersensitivity.

Interactions

As for Neostigmine, p.632. The possibility of an interaction remains for a considerable time after stopping long-acting anticholinesterases such as ecothiopate.

Uses and Administration

Ecothiopate is an irreversible inhibitor of cholinesterase; its actions are similar to those of neostigmine (p.632) but much more prolonged. Its miotic action begins within 1 hour of its application and may persist for 1 to 4 weeks; it causes a reduction in intra-ocular pressure, which is maximal after 24 hours and may persist for days or weeks.

Ecothiopate iodide is used mainly in the treatment of open-angle glaucoma (p.1873), particularly in aphakic patients and when other drugs have proved inadequate. It is given as drops of a 0.03 to 0.25% ophthalmic solution. Licensed product information states that 2 daily doses are preferred to allow for diurnal variations in intra-ocular pressure, although it has also been given once daily or on alternate days. It is advisable to give the single dose or one of the 2 daily doses at bedtime.

Ecothiopate iodide eye drops are also used in the diagnosis and management of accommodative convergent strabismus (p.1874).

Preparations

USP 31: Echothiophate Iodide for Ophthalmic Solution.

Proprietary Preparations (details are given in Part 3)

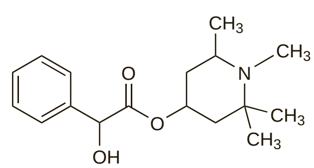
Eucatropine Hydrochloride *(BANM, rINNM)*

Clorhidrato de Euftalmina; Eucatropine, Chlorhydrate d'; Eucatropini Hydrochloridum; Eucatropinium Chloride; Hidrocloruro de eucatropina. 1,2,2,6-Tetramethyl-4-piperidyl mandelate hydrochloride.

Эукатропина Гидрохлорид

$C_{17}H_{25}NO_3$,HCl = 327.8.

CAS — 100-91-4 (eucatropine); 536-93-6 (eucatropine hydrochloride).



(eucatropine)

Pharmacopoeias. In *US*.

USP 31 (Eucatropine Hydrochloride). A white, odourless, granular powder. Very soluble in water; freely soluble in alcohol and in chloroform; insoluble in ether. Its solutions are neutral to litmus. Store in airtight containers. Protect from light.

Profile

Eucatropine hydrochloride is a tertiary amine antimuscarinic that has been used as a mydriatic. It has little or no effect on accommodation.

Preparations

USP 31: Eucatropine Hydrochloride Ophthalmic Solution.

Homatropine *(BAN)*

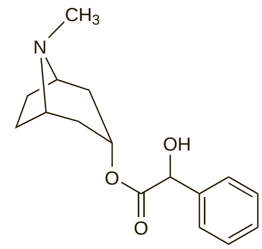
Homatropiini; Homatropin; Homatropina; Homatropinum. (1*R*,3*r*,5*S*)-Tropan-3-yl (*RS*)-mandelate.

$C_{16}H_{21}NO_3$ = 275.3.

CAS — 87-00-3.

ATC — S01FA05.

ATC Vet — QS01FA05.



Homatropine Hydrobromide *(BANM)*

Homatr. Hydrobrom.; Homatropiinihydrobromidi; Homatropina, hidrobromuro de; Homatropine, bromhydrate d'; Homatropin-hidrobromid; Homatropinhydrobromid; Homatropin-hydrobromid; Homatropini hydrobromidum; Homatropinium Bromide; Homatropino hidrobromidas; Homatropinum Bromatum; Homatropiny bromowodorek; Omatropina Bromidrato; Oxytolyltropine Hydrobromide; Tropyl Mandelate Hydrobromide.

$C_{16}H_{21}NO_3$,HBr = 356.3.

CAS — 51-56-9.

ATC — S01FA05.

ATC Vet — QS01FA05.

NOTE. HOM is a code approved by the BP 2008 for use on single unit doses of eye drops containing homatropine hydrobromide where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US*.

Ph. Eur. 6.2 (Homatropine Hydrobromide). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; sparingly soluble in alcohol. A 5% solution in water has a pH of 5.0 to 6.5. Protect from light.

USP 31 (Homatropine Hydrobromide). White crystals or a white crystalline powder. Soluble 1 in 6 of water, 1 in 40 of alcohol, and 1 in 420 of chloroform; insoluble in ether. pH of a 2% solution in water is between 5.7 and 7.0. Store in airtight containers. Protect from light.

Homatropine Methylbromide *(BANM, rINN)*

Homatropiinimetyylibromidi; Homatropine Methobromide; Homatropine, méthylbromure d'; Homatropini methylbromidum; Homatropin-methylbromid; Homatropin-metilbromid; Homatropinmetylbromid; Homatropino metilbromidas; Methylhomatropinium Bromatum; Methylhomatropinium Bromide; Metilbromuro de homatropina. (1*R*,3*r*,5*S*)-3-[(±)-Mandeloyloxy]-8-methyltropanium bromide.

Гоматропина Метилбромид

$C_{16}H_{21}NO_3$,CH_3Br = 370.3.

CAS — 80-49-9.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US*.

Ph. Eur. 6.2 (Homatropine Methylbromide). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; soluble in alcohol. A 5% solution in water has a pH of 4.5 to 6.5. Protect from light.

USP 31 (Homatropine Methylbromide). A white, odourless, powder that slowly darkens on exposure to light. Very soluble in water; freely soluble in alcohol and in acetone containing about 20% of water; practically insoluble in acetone and in ether. pH of a 1% solution in water is between 4.5 and 6.5. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

Ophthalmic use. Antimuscarinic toxicity (including ataxia, restlessness, excitement, hallucinations) has been reported in children[1] and the elderly[2,3] given homatropine eye drops.

1. Hoefnagel D. Toxic effects of atropine and homatropine eyedrops in children. *N Engl J Med* 1961; **264:** 168–71.
2. Reid D, Fulton JD. Tachycardia precipitated by topical homatropine. *BMJ* 1989; **299:** 795–6.
3. Tune LE, *et al.* Anticholinergic delirium caused by topical homatropine ophthalmologic solution: confirmation by anticholinergic radioreceptor assay in two cases. *J Neuropsychiatr Clin Neurosci* 1992; **4:** 195–7.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Uses and Administration

Homatropine is a tertiary amine antimuscarinic with effects similar to those of atropine (p.1219). It is used as the hydrobromide, also a tertiary amine, to produce mydriasis and cycloplegia (p.1874); its actions are more rapid and of shorter duration than those of atropine, but it is less potent and has a relatively weak cycloplegic effect. In general, onset of action is between 30 and 60 minutes, and recovery within 1 to 3 days. Homatropine hydrobromide is generally used as a 1, 2, or 5% ophthalmic solution. For the determination of refraction, instillation may be repeated if necessary 5 to 10 minutes later. In the treatment of uveitis (p.1515), the eye drops should be instilled two or three times daily, or up to every 3 to 4 hours if required.

The *BNFC* recommends that eye drops containing 0.5% homatropine hydrobromide are used once daily or on alternate days for uveitis in children aged 3 months to 2 years; older children may be given 1 or 2% eye drops twice daily.

Homatropine has also been used as the quaternary ammonium methobromide derivative in the treatment of gastrointestinal spasm and as an adjunct in peptic ulcer disease; homatropine methobromide has also been included in preparations used for the treatment of coughs.

Preparations

BP 2008: Homatropine Eye Drops;
USP 31: Homatropine Hydrobromide Ophthalmic Solution; Homatropine Methylbromide Tablets; Hydrocodone Bitartrate and Homatropine Methylbromide Tablets.

Latanoprost *(BAN, USAN, rINN)*

Latanoprosti; Latanoprostum; PhXA-41; XA-41. Isopropyl (*Z*)-7-{(1*R*,2*R*,3*R*,5*S*)-3,5-dihydroxy-2-[(3*R*)-3-hydroxy-5-phenylpentyl]cyclopentyl}-5-heptenoate.

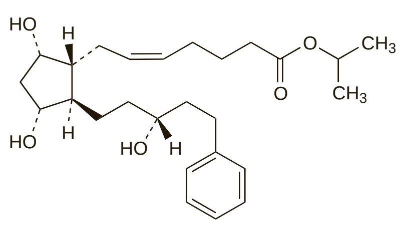
Латанопрост

$C_{26}H_{40}O_5$ = 432.6.

CAS — 130209-82-4.

ATC — S01EE01.

ATC Vet — QS01EE01.



Adverse Effects and Precautions

Latanoprost eye drops may produce a gradual increase in the amount of brown pigment in the iris, due to increased melanin content of melanocytes. This change in eye colour is most evident in patients with mixed colour irises, and may be permanent in some patients. The onset of iris pigmentation is usually within the first 8 months of treatment, rarely during the second or third year, and has not been seen after the fourth year of treatment. Darkening, thickening, and lengthening of eye lashes may occur and are reversible upon stopping treatment. Darkening of the palpebral skin has been reported rarely. Ocular irritation, conjunctival hyperaemia, transient punctate epithelial erosions and eyelid oedema may occur; there have also been rare reports of iritis and/or uveitis, and macular oedema. Systemic effects may also occur, see below for further details. Dizziness, headache, arthralgia, and myalgia have also been reported.

Effects on the eyes. Latanoprost has been associated with various adverse effects on the eyes, including case reports of cystoid macular oedema[1] and bilateral optic disc oedema.[2] Licensed product information states that reports of macular oedema have mainly occurred in aphakic patients, in pseudophakic patients with torn posterior lens capsule or anterior chamber lenses, or in patients with risk factors for cystoid macular oedema such as those with diabetic retinopathy or retinal vein occlusion.

Herpes simplex dendritic keratitis developed in 2 patients during latanoprost therapy.[3] The author suggested that the biochemical changes in the cornea caused by latanoprost may predispose to herpes keratitis.

1. Wardrop DRA, Wishart PK. Latanoprost and cystoid macular oedema in a pseudophake. *Br J Ophthalmol* 1998; **82:** 843–4.
2. Stewart O, *et al.* Bilateral optic disc oedema associated with latanoprost. *Br J Ophthalmol* 1999; **83:** 1092–3.
3. Ekatomatis P. Herpes simplex dendritic keratitis after treatment with latanoprost for primary open angle glaucoma. *Br J Ophthalmol* 2001; **85:** 1008–9.

Systemic effects. The use of latanoprost eye drops has been associated with systemic adverse reactions. In a case report[1] of 2 patients with latanoprost-associated hypertension the authors mentioned that other events including peripheral and facial oedema, dyspnoea, exacerbation of asthma, tachycardia, and chest pain or angina pectoris had been reported. Another case report[2] also referred to exacerbation of angina. Although a study[3] involving 24 stable asthmatics found that latanoprost eye drops had no effect on pulmonary function or asthma symptoms, UK licensed product information recommends caution in patients with asthma.

1. Peak AS, Sutton BM. Systemic adverse effects associated with topically applied latanoprost. *Ann Pharmacother* 1998; **32:** 504–5.
2. Mitra M, *et al.* Exacerbation of angina associated with latanoprost. *BMJ* 2001; **323:** 783.
3. Hedner J, *et al.* Latanoprost and respiratory function in asthmatic patients: randomized, double-masked, placebo-controlled crossover evaluation. *Arch Ophthalmol* 1999; **117:** 1305–9.

Interactions

Paradoxical increases in intra-ocular pressure have been reported after the concomitant ophthalmic use of 2 prostaglandin analogues. UK licensed product information states that the use of 2 or more prostaglandin analogues or derivatives is not recommended.

Uses and Administration

Latanoprost is a synthetic analogue of dinoprost (prostaglandin $F_{2\alpha}$) that is used to reduce intra-ocular pressure in patients with open-angle glaucoma and ocular hypertension (p.1873). Reduction of intra-ocular pressure starts about 3 to 4 hours after instillation and is maximal after 8 to 12 hours; pressure reduction lasts for at least 24 hours. A 0.005% ophthalmic solution is instilled once daily, preferably in the evening.

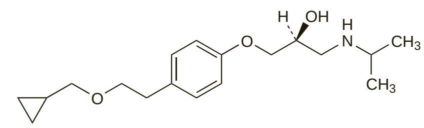
Levobetaxolol Hydrochloride *(USAN, rINNM)* ⊗

AL-1577A (levobetaxolol or levobetaxolol hydrochloride); Hidrocloruro de levobetaxolol; Lévobétaxolol, Chlorhydrate de; Levobetaxololi Hydrochloridum. (−)-(*S*)-1-{*p*-[2-(Cyclopropylmethoxy)ethyl]phenoxy}-3-isopropylaminopropan-2-ol hydrochloride.

Левобетаксолола Гидрохлорид

$C_{18}H_{29}NO_3,HCl$ = 343.9.

CAS — 93221-48-8 (levobetaxolol); 116209-55-3 (levobetaxolol hydrochloride).



(levobetaxolol)

Profile

Levobetaxolol, the *S*-isomer of betaxolol (p.1231) is a cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic activity and to have no significant membrane-stabilising properties.

Levobetaxolol has been used as the hydrochloride to reduce raised intra-ocular pressure in open-angle glaucoma and ocular hypertension.

Preparations

Proprietary Preparations (details are given in Part 3)
USA: Betaxon†.

Levobunolol Hydrochloride

(BANM, USAN, rINNM) ⊗

(−)-Bunolol Hydrochloride; *l*-Bunolol Hydrochloride; Hidrocloruro de levobunolol; Lévobunolol, Chlorhydrate de; Levobunolol Hidroklorür; Levobunololhydroklorid; Levobunololi Hydrochloridum; Levobunololihydrokloridi; W-7000A. (−)-5-(3-*tert*-Butylamino-2-hydroxypropoxy)-1,2,3,4-tetrahydronaphthalen-1-one hydrochloride.

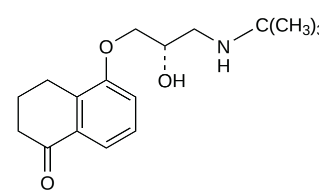
Левобунолола Гидрохлорид

$C_{17}H_{25}NO_3,HCl$ = 327.8.

CAS — 47141-42-4 (levobunolol); 27912-14-7 (levobunolol hydrochloride).

ATC — S01ED03.

ATC Vet — QS01ED03.



(levobunolol)

Pharmacopoeias. In *Br.* and *US.*

BP 2008 (Levobunolol Hydrochloride). A white or pinkish-white crystalline powder. Freely soluble in water; sparingly soluble in alcohol. A 5% solution in water has a pH of between 4.5 and 6.5. Protect from light.

USP 31 (Levobunolol Hydrochloride). A white odourless crystalline powder. Soluble in water and in methyl alcohol; slightly soluble in alcohol and in chloroform. A 5% solution in water has a pH between 4.5 and 6.5.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Pharmacokinetics

Some systemic absorption is reported to occur after topical application to the eye. After oral doses levobunolol is rapidly and almost completely absorbed from the gastrointestinal tract. It is extensively metabolised in the liver; the principal metabolite, dihydrolevobunolol, is reported to possess beta-blocking activity. The metabolites and some unchanged drug are excreted in the urine.

Uses and Administration

Levobunolol is a non-cardioselective beta blocker (p.1225). It is reported to lack intrinsic sympathomimetic activity and membrane-stabilising properties.

Levobunolol is used as the hydrochloride to reduce raised intra-ocular pressure in open-angle glaucoma and ocular hypertension (p.1873). It begins to act 1 hour after instillation with maximal effect seen between 2 and 6 hours; the effect may be maintained for up to 24 hours. Levobunolol hydrochloride is usually used as a 0.5% ophthalmic solution instilled once or twice daily; alternatively a 0.25% solution may be instilled twice daily.

Preparations

BP 2008: Levobunolol Eye Drops;
USP 31: Levobunolol Hydrochloride Ophthalmic Solution.

Proprietary Preparations (details are given in Part 3)
Arg.: Betagan; Levunolol; ***Austral.:*** Betagan; ***Austria:*** Vistagan; ***Belg.:*** Betagan; ***Braz.:*** B-Tablock; Betagan; ***Canad.:*** Betagan; Ophtho-Bunolol†; ***Chile:*** Betagen; ***Cz.:*** Vistagan; ***Denm.:*** Betagan; ***Fr.:*** Betagan; ***Ger.:*** Vistagan; ***Gr.:*** Pentila†; Vistagan; ***Hong Kong:*** Betagan; ***Hung.:*** Vistagan; ***Irl.:*** Betagan; ***Israel:*** Betagan; ***Ital.:*** Vistagan; ***Malaysia:*** Betagan†; ***Mex.:*** Betagan; ***Neth.:*** Betagan; ***NZ:*** Betagan; ***Port.:*** Betagan; ***S.Afr.:*** Betagan; ***Singapore:*** Betagan; ***Spain:*** Betagan; ***Switz.:*** Vistagan; ***Thai.:*** Betagan; ***Turk.:*** Betagan; ***UK:*** Betagan; ***USA:*** Ak-Beta; Betagan; ***Venez.:*** Vistagan.

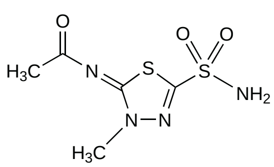
Methazolamide *(BAN, rINN)* ⊗

Metazolamida; Méthazolamide; Methazolamidum. *N*-(4-Methyl-2-sulphamoyl-Δ^2-1,3,4-thiadiazolin-5-ylidene)acetamide.

Метазоламид

$C_5H_8N_4O_3S_2$ = 236.3.
CAS — 554-57-4.
ATC — S01EC05.
ATC Vet — QS01EC05.



Pharmacopoeias. In *US*.
USP 31 (Methazolamide). A white or faintly yellow crystalline powder with a slight odour. Very slightly soluble in water and in alcohol; slightly soluble in acetone; soluble in dimethylformamide. Protect from light.

Adverse Effects and Precautions

As for Acetazolamide, p.1875.

Hypersensitivity. Cholestatic hepatitis with jaundice, rash, and subsequent pure red cell aplasia was associated with methazolamide in a patient.[1] Drug-induced hypersensitivity was suspected as the cause of the reaction.

1. Krivoy N, *et al*. Methazolamide-induced hepatitis and pure RBC aplasia. *Arch Intern Med* 1981; **141:** 1229–30.

Pharmacokinetics

Methazolamide is absorbed from the gastrointestinal tract more slowly than acetazolamide. It has been reported not to be extensively bound to plasma protein, and to have a half-life of about 14 hours. About 15 to 30% of the dose is excreted in the urine; the fate of the remainder is unknown.

Uses and Administration

Methazolamide is an inhibitor of carbonic anhydrase with actions similar to those of acetazolamide (p.1876). It is used in the treatment of glaucoma (p.1873) in oral doses of 50 to 100 mg two or three times daily. Its action is less prompt but of longer duration than that of acetazolamide, lasting for 10 to 18 hours.

The diuretic activity of methazolamide is less pronounced than that of acetazolamide.

Preparations

USP 31: Methazolamide Tablets.

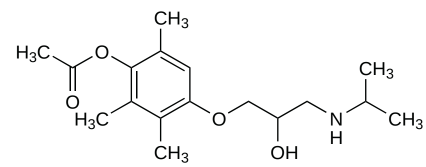
Proprietary Preparations (details are given in Part 3)
Arg.: Glaumetax†; ***Canad.:*** Neptazane†; ***Israel:*** Neptazane†; ***Thai.:*** Neptazane†; ***USA:*** GlaucTabs†; MZM†.

Metipranolol *(BAN, USAN, rINN)* ⊗

BMOI-004; Methypranolol; Métipranolol; Metipranololum; VUAB-6453 (SPOFA); VUFB-6453. 1-(4-Acetoxy-2,3,5-trimethylphenoxy)-3-isopropylaminopropan-2-ol; 4-(2-Hydroxy-3-isopropylaminopropoxy)-2,3,6-trimethylphenyl acetate.

Метипранолол

$C_{17}H_{27}NO_4$ = 309.4.
CAS — 22664-55-7.
ATC — S01ED04.
ATC Vet — QS01ED04.



NOTE. MPR is a code approved by the BP 2008 for use on single unit doses of eye drops containing metipranolol where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Br.*
BP 2008 (Metipranolol). A white crystalline powder. Practically insoluble in water; soluble in alcohol, in acetone, and in methyl alcohol; dissolves in dilute mineral acids. The filtrate of a 2.5% suspension in water has a pH of 9.0 to 10.0. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Beta Blockers, p.1226.

Conjunctivitis, conjunctival leucoplakia, transient stinging, as well as other ocular adverse effects have been reported with metipranolol eye drops. Granulomatous anterior uveitis has been reported rarely; a high incidence reported in the UK may have been associated with changes induced by radiation sterilisation of metipranolol eye drops in their final container, but this preparation is no longer available.

Interactions

The interactions associated with beta blockers are discussed on p.1228.

Uses and Administration

Metipranolol is a non-cardioselective beta blocker (p.1225). It is reported to be largely lacking in intrinsic sympathomimetic activity and membrane-stabilising properties.

Metipranolol is used to reduce raised intra-ocular pressure in the management of open-angle glaucoma and ocular hypertension (p.1873). Eye drops usually containing metipranolol 0.1 or 0.3% are used twice daily.

Metipranolol has also been used by mouth in the management of cardiovascular disorders.

Preparations

BP 2008: Metipranolol Eye Drops.

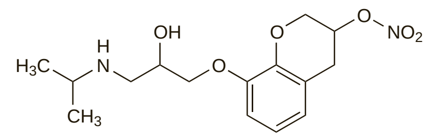
Nipradilol *(rINN)* ⊗

K-351; Nipradilolum; Nipradolol. 8-[2-Hydroxy-3-(isopropylamino)propoxy]-3-chromanol 3-nitrate.

Нипрадилол

$C_{15}H_{22}N_2O_6$ = 326.3.
CAS — 81486-22-8.



Profile

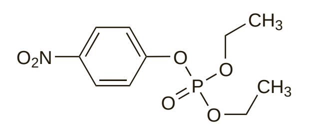
Nipradilol is a non-cardioselective beta blocker (p.1225). It is also reported to have direct vasodilating activity. It is used in the management of glaucoma and ocular hypertension (p.1873); eye drops containing nipradilol 0.05% are instilled twice daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Jpn: Hypadil.

Paraoxon

E-600. Diethyl *p*-nitrophenyl phosphate.
$C_{10}H_{14}NO_6P$ = 275.2.
CAS — 311-45-5.
ATC — S01EB10.
ATC Vet — QS01EB10.



Profile

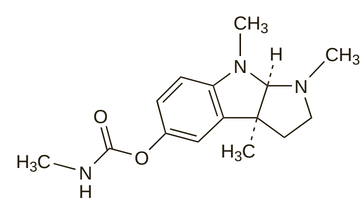
Paraoxon is a potent inhibitor of cholinesterase activity that has been used with other miotics in the treatment of glaucoma. It is the active metabolite of the organophosphorus insecticide parathion (p.2048) and therefore produces similar toxicity but with a faster onset.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: *Ital.:* Mios.

Physostigmine *(BAN)*

Eserine; Fisostigmina; Fysostigmiini; Fysostigmin; Physostigminum. (3a*S*,8a*R*)-1,2,3,3a,8,8a-Hexahydro-1,3a,8-trimethylpyrrolo[2,3-*b*]indol-5-yl methylcarbamate.
$C_{15}H_{21}N_3O_2$ = 275.3.
CAS — 57-47-6.
ATC — S01EB05; V03AB19.
ATC Vet — QA03AX90; QA03FA90; QS01EB05; QV03AB19.



Description. An alkaloid obtained from the calabar bean (ordeal bean; chopnut), the seed of *Physostigma venenosum* (Leguminosae).

Pharmacopoeias. In *US*.
USP 31 (Physostigmine). An alkaloid usually obtained from the dried ripe seed of *Physostigma venenosum* (Leguminosae). It is a white, odourless, microcrystalline powder which acquires a red tint on exposure to heat, light, or air, or on contact with traces of metals. M.p. not lower than 103°. Slightly soluble in water; freely soluble in alcohol; very soluble in chloroform and in dichloromethane; soluble in fixed oils and in benzene. Store in airtight containers. Protect from light.

Physostigmine Salicylate *(BANM)*

Eserine Salicylate; Ésérine, salicylate d'; Eserini salicylas; Ezerino salicilatas; Fisostigmina, salicilato de; Fizostigmino salicilatas; Fizostygminy salicylan; Fizosztigmin-szalicilát; Fysostigmiinisalisylaatti; Fysostigminsalicylat; Fysostigmin-salicylát; Physostig. Sal.; Physostigmine Monosalicylate; Physostigmini salicylas.
$C_{15}H_{21}N_3O_2,C_7H_6O_3$ = 413.5.
CAS — 57-64-7.
ATC — S01EB05; V03AB19.
ATC Vet — QS01EB05; QV03AB19.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Physostigmine Salicylate). Colourless or almost colourless crystals. It becomes red on exposure to air and light; the colour develops more quickly in the presence of moisture. Sparingly soluble in water; soluble in alcohol. A 0.9% solution in water has a pH of 5.1 to 5.9. Store in airtight containers. Protect from light. Aqueous solutions are unstable.

USP 31 (Physostigmine Salicylate). White, shining, odourless, crystals or white powder. It acquires a red tint on exposure to heat, light, or air, or on contact with traces of metals for long periods. Soluble 1 in 75 of water, 1 in 16 of alcohol, 1 in 6 of chloroform, and 1 in 250 of ether. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°. Protect from light.

Stability. See below.

Physostigmine Sulfate

Ésérine, sulfate d'; Eserine Sulphate; Eserini Sulfas; Ezerino sulfatas; Fisostigmina, sulfato de; Fizostigmino sulfatas; Fizosztigmin-szulfát; Fysostigmiinisulfaatti; Fysostigminsulfat; Fysostigmin-sulfát; Physostig. Sulph.; Physostigmine Sulphate *(BANM)*; Physostigmini sulfas.

$(C_{15}H_{21}N_3O_2)_2,H_2SO_4$ = 648.8.
CAS — 64-47-1.
ATC — S01EB05; V03AB19.
ATC Vet — QS01EB05; QV03AB19.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Physostigmine Sulphate). A white or almost white, hygroscopic crystalline powder. It becomes red on exposure to air and light; the colour develops more quickly in the presence of moisture. Very soluble in water; freely soluble in alcohol. A 1% solution in water has a pH of 3.5 to 5.5. Store in well-filled airtight glass containers. Protect from light. Aqueous solutions are unstable.

USP 31 (Physostigmine Sulfate). A white, odourless, microcrystalline powder. It is deliquescent in moist air, and acquires a red tint on exposure to heat, light, or air, or on contact with traces of metals for long periods. Soluble 1 in 4 of water, 1 in 0.4 of alcohol, and 1 in 1200 of ether. Store in airtight containers. Protect from light.

Stability. In aqueous solutions physostigmine is hydrolysed to eseroline and subsequently oxidised to the red compound rubreserine and other coloured products. Solutions for injection or ophthalmic use should not be used if more than slightly discoloured.

Adverse Effects, Treatment, and Precautions

Systemic effects as for Neostigmine, p.631, although usually more severe. Physostigmine crosses the blood-brain barrier and may therefore produce CNS effects.

For adverse effects and precautions for topical miotics see also under Pilocarpine, p.1885. Physostigmine is not well tolerated when used in the eyes for long periods and may produce follicles in the conjunctiva; hypersensitivity reactions are also common. Prolonged use of ophthalmic ointments containing physostigmine may cause depigmentation of the lid margins in dark-skinned patients.

Overdosage. Symptomatic and supportive treatment, including the use of diazepam and atropine where necessary, is generally recommended for systemic toxicity due to physostigmine. However, in an early report, the use of atropine in a patient who had taken 1 g of physostigmine had to be abandoned after it produced tachycardia and multifocal ventricular ectopic beats.[1] In a similar case of severe poisoning a slow intravenous injection of propranolol 5 mg reduced the high pulse rate and controlled pulse irregularities despite frequent intravenous doses of atropine.[2]

2. Valero A. Treatment of severe physostigmine poisoning. *Lancet* 1968; **ii:** 459–60.

Interactions

As for Neostigmine, p.632.

Pharmacokinetics

Physostigmine is readily absorbed from the gastrointestinal tract, subcutaneous tissues, and mucous membranes. It is largely destroyed in the body by hydrolysis of the ester linkage by cholinesterases; a parenteral dose is claimed to be destroyed within 2 hours. It crosses the blood-brain barrier. Little is excreted in the urine.

◊ Small studies suggest marked interindividual differences in the absorption and metabolism of physostigmine salicylate after doses of up to 4 mg by mouth, perhaps because of saturable presystemic metabolism.[1-3] Oral bioavailability ranged from 5.2 to 11.7% in 3 of 5 subjects.[3]

In a study[4] of a single application of a physostigmine (base) transdermal system in 6 subjects, the mean absolute bioavailability was 36% (range 12.6 to 53.2%); the interindividual variability in absolute bioavailability was decreased by about 30% in comparison with an oral solution of physostigmine salicylate. There was continued absorption of physostigmine after removal of the transdermal system, indicating a drug reservoir in the skin.

In a study[5] of 9 patients with Alzheimer's disease, a mean elimination half-life for physostigmine of 16.4 minutes was reported with intravenous physostigmine salicylate. Cholinesterase inhibition was more prolonged than suggested by its elimination half-life.

Uses and Administration

Physostigmine is a reversible tertiary amine inhibitor of cholinesterase activity with actions similar to those of neostigmine (p.632). Physostigmine has been used, alone or more usually with other miotics such as pilocarpine, to decrease intraocular pressure in glaucoma (p.1873). It is a more potent miotic than pilocarpine but is rarely tolerated for prolonged periods. When it is used in glaucoma physostigmine has usually been given as eye drops containing 0.25 or 0.5% of the salicylate or as an ophthalmic ointment containing 0.25% of the sulfate.

Physostigmine crosses the blood-brain barrier and has been used to reverse the central as well as the peripheral effects of agents with antimuscarinic actions after overdosage but such treatment is not usually recommended. Physostigmine is also under investigation in the management of Alzheimer's disease (see Dementia, below).

Antimuscarinic poisoning. As physostigmine penetrates the blood-brain barrier it has been used to reverse the central effects of poisoning with agents that have antimuscarinic actions including tricyclic antidepressants, antihistamines, some antiemetics, some antiparkinsonian drugs, and phenothiazines. However, reviewers agree that in general such use is inappropriate and hazardous. Physostigmine does not appear to affect the mortality rate in tricyclic antidepressant poisoning[1] and its use can lead to severe cardiac[2,3] and respiratory effects[2,3] and to convulsions.[3,4]

Baclofen overdosage. For references to the use of physostigmine in the treatment of baclofen overdosage, see p.1888.

Cerebellar ataxias. Double-blind controlled studies indicate that physostigmine[1,2] can produce symptomatic improvement in some patients with cerebellar ataxia including those with hereditary forms of spinocerebellar degeneration such as Friedreich's ataxia. However, another study did not show any significant improvement in patients given physostigmine for cerebellar ataxia.[3]

3. Wessel K, *et al.* Double-blind crossover study with physostigmine in patients with degenerative cerebellar diseases. *Arch Neurol* 1997; **54:** 397–400.

Dementia. Physostigmine has been studied in the symptomatic management of Alzheimer's disease (see Dementia, p.362). However, a systematic review concluded that the evidence of its effectiveness was limited and the benefits shown were not convincing.[1] Small early studies with oral physostigmine in Alzheimer's disease were inconclusive; a larger multicentre study[2] using controlled-release physostigmine found that it produced some improvement in cognitive and global function, but gastrointestinal adverse effects were common and led to a high drop-out rate.

Preparations

USP 31: Physostigmine Salicylate Injection; Physostigmine Salicylate Ophthalmic Solution; Physostigmine Sulfate Ophthalmic Ointment.

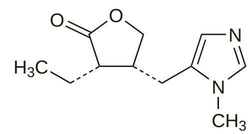
Proprietary Preparations (details are given in Part 3)
Austria: Anticholium; ***Cz.:*** Anticholium; ***Ger.:*** Anticholium; ***Gr.:*** Anticholium; ***USA:*** Antilirium.

Multi-ingredient: ***India:*** Bi-Miotic.

Pilocarpine *(BAN)*

Pilocarpina; Pilocarpinum; Pilokarpiini; Pilokarpin. (3*S*,4*R*)-3-Ethyldihydro-4-[(1-methyl-1*H*-imidazol-5-yl)methyl]furan-2(3*H*)-one.

$C_{11}H_{16}N_2O_2$ = 208.3.
CAS — 92-13-7.
ATC — N07AX01; S01EB01.
ATC Vet — QN07AX01; QS01EB01.



Description. An alkaloid obtained from the leaves of jaborandi, *Pilocarpus microphyllus* (Rutaceae) and other species of *Pilocarpus*.

Pharmacopoeias. In *US.*

USP 31 (Pilocarpine). A viscous, exceedingly hygroscopic, oily liquid or crystals. M.p. about 34°. Soluble in water, in alcohol, and in chloroform; sparingly soluble in ether and in benzene; practically insoluble in petroleum spirit. Store in airtight containers at a temperature not exceeding 8°. Protect from light.

Pilocarpine Borate

Pilocarpina, borato de.

$C_{11}H_{16}N_2O_2,xBH_3O_3$.
CAS — 16509-56-1.
ATC — N07AX01; S01EB01.
ATC Vet — QN07AX01; QS01EB01.

Pilocarpine Hydrochloride *(BANM)*

Pilocarp. Hydrochlor.; Pilocarpina, hidrocloruro de; Pilocarpine, chlorhydrate de; Pilocarpine Monohydrochloride; Pilocarpini Chloridum; Pilocarpini hydrochloridum; Pilocarpinium Chloratum; Pilokarpiinihydrokloridi; Pilokarpin Hidroklorür; Pilokarpin-hidroklorid; Pilokarpin-hydrochlorid; Pilokarpinhydroklorid; Pilokarpino hidrochloridas; Pilokarpiny chlorowodorek.

$C_{11}H_{16}N_2O_2,HCl$ = 244.7.
CAS — 54-71-7.
ATC — N07AX01; S01EB01.
ATC Vet — QN07AX01; QS01EB01.

NOTE. PIL is a code approved by the BP 2008 for use on single unit doses of eye drops containing pilocarpine hydrochloride where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Pilocarpine Hydrochloride). Hygroscopic, colourless crystals or white or almost white crystalline powder. Very soluble in water and in alcohol. A 5% solution in water has a pH of 3.5 to 4.5. Store in airtight containers. Protect from light.

USP 31 (Pilocarpine Hydrochloride). Colourless, translucent, odourless, hygroscopic crystals. Soluble 1 in 0.3 of water, 1 in 3 of alcohol, and 1 in 360 of chloroform; insoluble in ether. Its solutions are acid to litmus. Store in airtight containers. Protect from light.

Stability. Pilocarpine hydrochloride oral solution, prepared from powder or eye drops and buffered at pH 5.5, was found[1] to be stable for 60 days at 25° and for 90 days at 4°.

1. Fawcett JP, *et al.* Formulation and stability of pilocarpine oral solution. *Int J Pharm Pract* 1994; **3:** 14–18.

Pilocarpine Nitrate *(BANM)*

Pilocarp. Nit.; Pilocarpina, nitrato de; Pilocarpine Mononitrate; Pilocarpine, nitrate de; Pilocarpini nitras; Pilocarpinii Nitras; Pilocarpinium Nitricum; Pilokarpiininitraatti; Pilokarpinnitrat; Pilokarpin-nitrát; Pilokarpino nitratas.

$C_{11}H_{16}N_2O_2,HNO_3$ = 271.3.
CAS — 148-72-1.
ATC — N07AX01; S01EB01.
ATC Vet — QN07AX01; QS01EB01.

NOTE. PIL is a code approved by the BP 2008 for use on single unit doses of eye drops containing pilocarpine nitrate where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*

Ph. Eur. 6.2 (Pilocarpine Nitrate). Colourless crystals, or white or almost white crystalline powder. Freely soluble in water; sparingly soluble in alcohol. A 5% solution in water has a pH of 3.5 to 4.5. Protect from light.

USP 31 (Pilocarpine Nitrate). Shining white crystals. Soluble 1 in 4 of water and 1 in 75 of alcohol; insoluble in chloroform and in ether. Its solutions are acid to litmus. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

Systemic effects and cautions are as for Neostigmine, p.631.

With the *oral* use of pilocarpine, sweating is a common problem; caution is needed to avoid dehydration in patients who may sweat excessively and who cannot maintain an adequate fluid intake. Paradoxical hypertension and constipation, confusion, and increased urinary frequency have also been reported. Licensed product information states that it should not be given when miosis is undesirable such as in patients with acute iritis or angle-closure glaucoma. Blurred vision or dizziness may affect the performance of skilled tasks including driving. In addition pilocarpine should be given with care to those with cognitive or psychiatric disturbances, with renal calculi or renal impairment, or with biliary-tract disorders. Dosage should be reduced in patients with hepatic impairment (see Administration in Hepatic Impairment, below).

After *ocular* use pilocarpine is usually better tolerated than the anticholinesterases, but in common with other miotics may produce ciliary spasm, ocular pain and irritation, blurred vision, lachrymation, myopia, and browache. Conjunctival vascular congestion, superficial keratitis, vitreous haemorrhage, and increased pupillary block have been reported. Lens opacities have occurred after prolonged use. Treatment with miotics should be stopped if symptoms of systemic toxicity develop.

Miotics are contra-indicated in conditions where pupillary constriction is undesirable such as acute iritis, acute uveitis, anterior uveitis, and some forms of secondary glaucoma. They should be avoided in acute inflammatory disease of the anterior segment of the eye. If possible, treatment with long-acting miotics should be stopped before surgery on the eye as there is an increased risk of hyphaema. Miotics should be used with extreme caution in patients with a history of retinal detachment and in young patients with myopia. Care is also needed in patients with corneal or conjunctival damage. Miosis may cause blurred vision and difficulty with dark adaptation and caution is necessary with night driving or when hazardous tasks are undertaken in poor illumination. Miotics should not be used by patients wearing soft contact lenses.

Asthma. A reminder that topical miotics can precipitate bronchospasm in susceptible patients.[1] However, the severity of the reaction induced by carbachol has been reported to be less than that produced by timolol. Bronchospastic complications are much less likely to occur with pilocarpine but have nevertheless been reported. As inhalations of methacholine are used to induce bronchospasm in the diagnosis of latent asthma, the risk of exacerbating asthma should be considered before methacholine is used in the eye.

1. Prakash UBS, *et al.* Pulmonary complications from ophthalmic preparations. *Mayo Clin Proc* 1990; **65:** 521–9.

Dementia. In patients with dementia of Alzheimer type, CNS symptoms may be induced or exacerbated by the use of pilocarpine eye drops.[1,2]

2. Fraunfelder FT, Morgan R. The aggravation of dementia by pilocarpine. *JAMA* 1994; **271:** 1742–3.

Glaucoma. Miotics usually lower intra-ocular pressure by decreasing the resistance to outflow of aqueous humour from the anterior chamber through the trabecular network. However, they appear to reduce uveoscleral outflow and this may cause a paradoxical rise in intra-ocular pressure in patients with severely compromised trabecular outflow as was reported in a patient with post-traumatic angle-recession glaucoma.[1] It has been recommended that pilocarpine should be avoided after drainage operations for glaucoma because its miotic effect can increase the occurrence of posterior pupillary synechiae; a topical beta blocker is usually adequate if control of intra-ocular pressure is required.[2] Pilocarpine-induced miosis was shown to cause a significant deterioration in visual field in patients with chronic open-angle glaucoma.[3] It was suggested that this should be an important consideration when choosing therapy for glaucoma, particularly in cases where field loss approaches the permitted legal minimum for driving. Of 53 patients receiving long-term therapy with pilocarpine gel, 15 developed a corneal haze, which persisted for at least 2 years in 13; although the patients remained asymptomatic the long-term effects were unknown.[4] Many patients using the gel also developed superficial punctate keratitis which usually cleared spontaneously during treatment.

4. Johnson DH, *et al.* Corneal changes during pilocarpine gel therapy. *Am J Ophthalmol* 1986; **101:** 13–15.

Hypersensitivity. Contact urticaria involving the eyelids has been reported[1] in a patient after treatment with pilocarpine eye drops for glaucoma.

1. O'Donnell BF, Foulds IS. Contact allergic dermatitis and contact urticaria due to topical ophthalmic preparations. *Br J Ophthalmol* 1993; **77:** 740–1.

Retinal detachment. The use of miotics has been implicated in numerous reports as a cause of retinal detachment but reviews of the subject have concluded that there is little factual evidence to support the association.[1,2] However, there is circumstantial evidence that retinal detachment is more likely to occur with strong miotics. Furthermore, patients with myopia or pre-existing retinal damage appear to be at greater risk and there is the possibility that even low concentrations of relatively mild miotics such as 1% pilocarpine might precipitate retinal detachment.

2. Beasley H, Fraunfelder FT. Retinal detachments and topical ocular miotics. *Ophthalmology* 1979; **86:** 95–8.

Systemic absorption. Systemic adverse effects after the ophthalmic use of pilocarpine are thought to be rare and reports of toxicity mainly involve elderly patients treated for acute angle-closure glaucoma prior to surgery and given relatively high doses.[1,2] It may not be feasible to stop the miotic in these circumstances. In a report of psychotic reaction in such a patient,[2] pilocarpine was continued but the patient was instructed on how to minimise absorption by closing the lachrymal canal; an atypical antipsychotic with minimal antimuscarinic effects (risperidone) was also given.

Interactions

As for Neostigmine, p.632.

Pharmacokinetics

Mean elimination half-lives for pilocarpine have been reported to be 0.76 and 1.35 hours after repeated oral doses of 5 and 10 mg of the hydrochloride, respectively. Inactivation of pilocarpine is thought to occur at neuronal synapses and probably in plasma. About 30% of an oral dose is excreted in the urine as pilocarpine and its inactive metabolites, including pilocarpic acid; the fate of the remaining 70% is unknown. Data from *animal* studies indicate that pilocarpine is distributed into breast milk at concentrations similar to those in the plasma.

Uses and Administration

Pilocarpine is a direct-acting tertiary amine parasympathomimetic that has the muscarinic effects of acetylcholine (p.1877). It is used mainly in the treatment of glaucoma (p.1873) and in the treatment of dry eye (p.2140) or dry mouth (below); it has also been used as a diaphoretic in diagnostic tests for cystic fibrosis and leprosy (below). Topical application of pilocarpine to the eye produces miosis (pupil constriction) by contraction of the iris sphincter muscle; contraction of the ciliary muscle results in increased accommodation. Constriction of the pupil also pulls open the trabecular meshwork in the eye and this in turn facilitates drainage of aqueous humour and reduction of intra-ocular pressure. After the use of eye drops, miosis occurs in about 10 to 30 minutes and lasts 4 to 8 hours while peak reduction in intra-ocular pressure occurs within 75 minutes and the reduction usually persists for 4 to 14 hours.

Pilocarpine is used in the treatment of open-angle **glaucoma** (but see also Glaucoma, under Adverse Effects, above) and is commonly given with topical beta blockers or sympathomimetics. It is used as the hydrochloride or the nitrate, usually as 0.5 to 4% eye drops given up to 4 times daily, adjusted according to response. Solutions containing 0.25 to 10% of the hydrochloride may also be available and the higher strengths may sometimes be required in patients with heavily pigmented irides. A modified-release system inserted into the conjunctival sac and releasing 20 or 40 micrograms of pilocarpine per hour for 7 days, and a 4% ophthalmic gel have also been used. Pilocarpine may be used before surgery as part of the emergency treatment of acute attacks of angle-closure glaucoma.

The miotic action of pilocarpine has been used to antagonise the effects of sympathomimetic mydriatics on the eye and in surgical procedures on the eye. Pilocarpine borate has been used similarly in ophthalmology to the hydrochloride and nitrate.

Pilocarpine hydrochloride is used in the treatment of **dry mouth** following radiotherapy for malignant neoplasms of the head and neck. It increases salivary flow only in patients with residual salivary gland function. The initial oral dose is 5 mg three times daily with or immediately after meals, increased gradually if necessary after 4 weeks until an adequate response is obtained, up to a maximum of 10 mg three times daily. Oral doses of 5 mg four times daily are used to treat **dry eye** or mouth in patients with Sjögren's syndrome; this dose may be increased to a maximum of 30 mg daily. Treatment should be stopped if no improvement occurs after 3 months of use. For doses in patients with hepatic impairment, see below.

Administration in hepatic impairment. UK licensed product information recommends that daily doses of *oral* pilocarpine should be reduced in patients with moderate to severe cirrhosis. The dose may gradually be increased to 5 mg three times daily if tolerated.

In the USA, licensed information suggests that the starting oral dose of pilocarpine should be 5 mg twice daily in patients with moderate hepatic impairment (Child-Pugh category B); it is not recommended in those with severe impairment (Child-Pugh category C) because of a lack of pharmacokinetic studies in these patients.

Diagnosis and testing. *CYSTIC FIBROSIS.* The fact that individuals with cystic fibrosis have abnormally high concentrations of sodium and chloride in their sweat has been used in the diagnosis of this condition and pilocarpine iontophoresis has been used to promote sweating as part of that test.[1] Despite the fact that neonatal genetic screening for cystic fibrosis-causing mutations is now possible, sweat testing using pilocarpine iontophoresis remains the gold standard for diagnosis, and can help avoid the small likelihood of diagnostic error.[2,3] US guidelines[3] note that sweat electrolytes may be transiently elevated during the first 24 hours of life, but sweat testing may be performed from 48 hours onward if an adequate sample can be obtained.

LEPROSY. The induction of sweat secretion by intradermal injection of pilocarpine nitrate has been used to assess the functional status of dermal nerves in patients with leprotic skin lesions.[1]

1. Joshi PB. Pilocarpine test in assesment of therapeutic efficacy in maculoanaesthetic leprosy. *Lepr India* 1976; **48:** 55–60.

Dry mouth. Pilocarpine is used as a sialogogue in the treatment of dry mouth (p.2140) after radiotherapy of the head and neck,[1,2] although benefit may not be entirely related to preservation of salivation.[3,4] A systematic review[5] based on 3 studies found limited evidence to support such use; although about half of the patients responded to pilocarpine, response did not occur in some for up to 12 weeks and adverse effects were common. Pilocarpine may also be of use in the management of drug-induced oral dryness,[6] and is used as a treatment for dry mouth and dry eye in the auto-immune disease, Sjögren's syndrome.[1,7-10]

Reversal of mydriasis. Pilocarpine has been used to reverse the effects of mydriatics after surgery or ophthalmoscopic examination but other miotics may be preferred (see p.1874). It counteracts the mydriatic effects of sympathomimetics, such as phenylephrine and hydroxyamfetamine,[1] but is ineffective against mydriasis produced by antimuscarinics, such as homatropine,[1] and may impair vision further when used with tropicamide.[2] Furthermore, there is also the risk of pilocarpine precipitating angle-closure glaucoma in susceptible patients (see Glaucoma, under Precautions, above and also Glaucoma, in Tropicamide, p.1886).

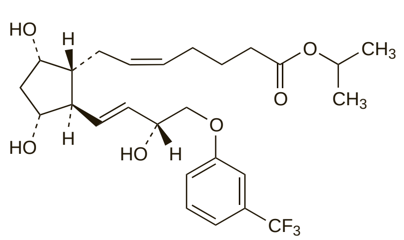
Travoprost *(BAN, USAN, rINN)*

AL-6221; Travoprosti; Travoprostum. Isopropyl (*Z*)-7-((1*R*,2*R*,3*R*,5*S*)-3,5-dihydroxy-2-{(1*E*,3*R*)-3-hydroxy-4-[(α,α,α-trifluoro-*m*-tolyl)oxy]-1-butenyl}cyclopentyl)-5-heptenoate.

Травопрост

$C_{26}H_{35}F_3O_6$ = 500.5.
CAS — 157283-68-6.
ATC — S01EE04.
ATC Vet — QS01EE04.



Adverse Effects and Precautions

As for Latanoprost, p.1882.

Effects on the eyes. Severe iritis and corneal oedema developed in an elderly woman 3 weeks after restarting travoprost after eye surgery;[1] rechallenge was positive. The authors commented that the UK MHRA was aware of one other case of uveitis associated with travoprost.

1. Kumarasamy M, Desai SP. Anterior uveitis is associated with travoprost. *BMJ* 2004; **329:** 205.

Uses and Administration

Travoprost is a synthetic analogue of dinoprost (prostaglandin F_2). It is used in the treatment of open-angle glaucoma and ocular hypertension (p.1873), as a 0.004% ophthalmic solution once daily, preferably in the evening. The reduction in pressure starts about 2 hours after instillation and is maximal after 12 hours; the effect is maintained for at least 24 hours.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Arvo; Glaucoprost; Travatan; ***Austral.:*** Travatan; ***Austria:*** Travatan; ***Belg.:*** Travatan; ***Braz.:*** Travatan; ***Canad.:*** Travatan; ***Chile:*** Travatan; ***Cz.:*** Travatan; ***Denm.:*** Travatan; ***Fin.:*** Travatan; ***Fr.:*** Travatan; ***Ger.:*** Travatan; ***Gr.:*** Travatan; ***Hong Kong:*** Travatan; ***Hung.:*** Travatan; ***Indon.:*** Travatan; ***Irl.:*** Travatan; ***Israel:*** Travatan; ***Ital.:*** Travatan; ***Malaysia:*** Travatan; ***Mex.:*** Travatan; ***Neth.:*** Travatan; ***Norw.:*** Travatan; ***NZ:*** Travatan; ***Philipp.:*** Travatan; ***Pol.:*** Travatan; ***Port.:*** Travatan; ***Rus.:*** Travatan (Траватан); ***S.Afr.:*** Travatan; ***Singapore:*** Travatan; ***Spain:*** Travatan; ***Swed.:*** Travatan; ***Switz.:*** Travatan; ***Thai.:*** Travatan; ***Turk.:*** Travatan; ***UK:*** Travatan; ***USA:*** Travatan; ***Venez.:*** Travatan.

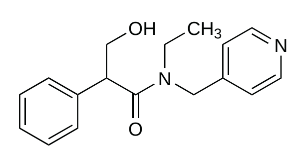
Tropicamide *(BAN, USAN, rINN)*

Bistropamide; Ro-1-7683; Tropicamida; Tropicamidum; Tropikamid; Tropikamidas; Tropikamidi. *N*-Ethyl-*N*-(4-pyridylmethyl)tropamide; (2*RS*)-*N*-Ethyl-3-hydroxy-2-phenyl-*N*-(pyridin-4-ylmethyl)propanamide.

Тропикамид

$C_{17}H_{20}N_2O_2$ = 284.4.
CAS — 1508-75-4.
ATC — S01FA06.
ATC Vet — QS01FA06.



NOTE. TRO is a code approved by the BP 2008 for use on single unit doses of eye drops containing tropicamide where the individual container may be too small to bear all the appropriate labelling information.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Tropicamide). A white or almost white, crystalline powder. M.p. 95° to 98°. Slightly soluble in water; freely soluble in alcohol and in dichloromethane. Protect from light.

USP 31 (Tropicamide). A white or practically white crystalline powder, odourless or having not more than a slight odour. M.p. 96° to 100°. Slightly soluble in water; freely soluble in chloroform and in solutions of strong acids. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for Atropine Sulfate, p.1219.

◊ References.

Glaucoma. The use of mydriatics is considered liable to provoke an acute attack in patients with glaucoma or a tendency to glaucoma; licensed product information generally contra-indicates their use in such patients. However, a systematic review concluded that in fact a history of open-angle glaucoma did not predispose to acute angle closure under mydriasis, and that mydriasis with tropicamide in particular appeared to be safe and should be recommended in all patients when thorough retinal examination was indicated.[1] In contrast, the use of pilocarpine to reverse mydriatics was potentially harmful.

Interactions

As for antimuscarinics in general (see Atropine Sulfate, p.1220).

Uses and Administration

Tropicamide is a tertiary amine antimuscarinic with actions similar to those of atropine (p.1219). It is used as eye drops to produce mydriasis and cycloplegia (p.1874). It has a more rapid onset and a shorter duration of effect than atropine: mydriasis is produced within 20 to 40 minutes of use and usually lasts for about 6 hours; cycloplegia is maximal within about 30 minutes and is short-lasting, with complete recovery of accommodation normally within 6 hours. Tropicamide has been reported to be inadequate for cycloplegia in children.

To produce **mydriasis**, a 0.5% solution is instilled 15 to 20 minutes before examination of the eye. To produce **cycloplegia** a 1% solution is used and repeated after 5 minutes; a further instillation may be necessary to prolong the effect after 20 to 30 minutes.

Dementia. Tropicamide has been studied for use in the differential diagnosis of Alzheimer's disease (see Dementia, p.362). Excessive pupil dilatation in response to tropicamide eye drops occurred in patients with signs and symptoms of Alzheimer's disease.[1] However, a double-blind placebo-controlled study[2] in similar patients and healthy subjects indicated that this was not a reliable diagnostic test for Alzheimer's disease.

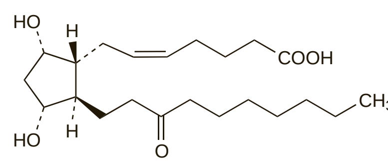
ATC — S01EE02.
ATC Vet — QS01EE02.



(unoprostone)

Profile

Unoprostone, like latanoprost (p.1882), is a synthetic analogue of dinoprost (prostaglandin F_2). It is used as the isopropyl ester for the treatment of glaucoma and ocular hypertension (p.1873). An ophthalmic solution containing unoprostone isopropyl 0.12 or 0.15% is instilled twice daily.

Muscle Relaxants

The muscle relaxants included in this chapter are used in the management of musculoskeletal and neuromuscular disorders. There are 2 main types:

- **centrally acting relaxants**—these generally have a selective action on the CNS and are principally used for relieving painful muscle spasms or spasticity occurring in musculoskeletal and neuromuscular disorders. Their mechanism of action may be due to their CNS-depressant activity. Baclofen and tizanidine are two examples.
- **directly acting relaxants**—dantrolene is a drug that has a direct action on skeletal muscle and is used for the relief of spasticity associated with a variety of conditions.

Also included in this chapter are **botulinum toxins A and B**, which inhibit the release of acetylcholine at the motor nerve terminals.

Some benzodiazepines are also used in the treatment of muscle spasms; further details may be found under Diazepam, p.986.

Other drugs that block transmission at the neuromuscular junction and are used as adjuncts to general anaesthesia are discussed in the chapter on Neuromuscular Blockers, p.1900.

Drugs used to relax *smooth muscle* include the various antispasmodics (p.1692) used for their antimuscarinic or direct smooth-muscle relaxant effects in the management of gastrointestinal disorders, as well as some other drugs such as papaverine (p.2191).

Muscle spasm

Spasm is a painful involuntary contraction of muscle that can cause involuntary movement, interfere with function, and cause distortion. It is a symptom of many muscular and other types of disorders and treatment should primarily be aimed at the underlying cause. Centrally acting muscle relaxants and benzodiazepines are used to treat muscle spasms such as *splinting* that occur in response to local trauma or musculoskeletal and joint disorders. Splinting is a reflex muscular spasm that produces muscular rigidity and acts as a protective mechanism to prevent movement and further damage of the affected part. Short courses of muscle relaxants may be considered in the management of acute low back pain (p.7).

Cramps are muscle spasms of abrupt onset that occur at rest and usually last for a few seconds or minutes. They are often precipitated by dehydration and hyponatraemia produced by vigorous exercise, excessive sweating, diarrhoea, and vomiting, or may be associated with drug therapy or haemodialysis (see Haemodialysis-induced Cramp, p.1671). Pregnant women, the elderly, and those with peripheral vascular disease, appear to be particularly susceptible to night cramps of the feet or legs, the cause of which is not well understood.

The management of muscle cramps has been reviewed.[1,2] Quinine has traditionally been used for *nocturnal cramps* but there has been concern over its efficacy and potential for adverse effects, especially in the elderly. Meta-analyses[3,4] have indicated that although quinine was modestly effective in the treatment of nocturnal cramps in ambulatory patients the risk of serious adverse effects should be borne in mind; patients should be closely monitored over a period of at least 4 weeks while the efficacy of quinine was assessed. In the UK, it is recommended that treatment should be stopped every 3 months to see whether it is still needed.[5] In the USA, the FDA has ruled that quinine products should no longer be used for the management of nocturnal cramps.[6,7] There is little convincing evidence to support the use of other drugs.[1,2,6]

A systematic review[8] concluded that magnesium (as the lactate and citrate) is modestly effective in the treatment of *leg cramps in pregnancy*; calcium salts were ineffective, and although early evidence suggested benefit with sodium chloride, high doses were required with their attendant cardiovascular risks.

Spasticity

The term spasticity has been loosely applied to various disorders of motor control resulting from CNS disease and marked by effects such as increased muscle tone, exaggerated stretch reflexes, impaired voluntary movement, weakness, loss of dexterity, abnormal posture, and often disturbed gait. In some patients muscle spasm and pain may be more distressing than impaired movement. Other complications may include contractures, pressure sores, and infection. Spasticity is a feature of neurological conditions such as multiple sclerosis, cerebral palsy, head injury, and stroke, particularly if there are spinal lesions.

Spasticity is disabling and difficult to treat when severe, but mild or moderate forms may be effectively managed by conservative treatment. Some patients may even use spasticity to provide a means of posture control and care should be taken that treatment does not lead to increased disability.

Various discussions on the management of spasticity have been published.[1-10] The mainstay of management is physiotherapy with antispastic drugs, although the evidence for the latter is rather scanty.[9,11,12] Baclofen, dantrolene, diazepam, and tizanidine are the drugs most often used. These 4 drugs act via different mechanisms, which are not fully understood.

Baclofen is thought to act at the spinal cord level but may also have supraspinal sites of action. It is a powerful neuronal depressant and may exert its inhibitory effects by acting as an agonist at GABA (gamma aminobutyric acid) receptors. *Diazepam* is also thought to act centrally by enhancing the response to GABA. In contrast, *dantrolene* acts directly on muscles, possibly by interfering with the release of calcium from muscular sarcoplasmic reticulum needed for contraction. *Tizanidine* is a centrally acting relaxant and α-adrenergic agonist; it is thought to act at spinal and supraspinal levels by inhibiting the presynaptic activity of excitatory interneurones.[7] It can produce additive effects with baclofen, allowing a reduction in the dosage of both drugs; use with benzodiazepines is not recommended because of the potential for interactions. All these are usually given by mouth but baclofen may also be given intrathecally in severe chronic spasticity.[10,13,14] Injection directly into the spinal subarachnoid space allows immediate delivery to the site of action in the spinal cord and the use of considerably lower doses than those given orally. It has been reported[15] that some patients receiving long-term intrathecal baclofen treatment have been able to stop their therapy without symptoms of spasticity re-appearing, and that others have been able to reduce the dosage required.

Other drugs that may produce some benefit or are being studied in spasticity include *other benzodiazepines, clonidine, gabapentin,* and *memantine*.

Alternative approaches to treatment include nerve blocks using *local anaesthetics*; they should generally only be used when further muscle relaxation would not increase disability. *Chemical neurolysis* using alcohol or phenol is only considered when there is intractable continuous pain. Local injections of *botulinum A toxin* have produced some encouraging results in the management of limb spasticity in post-stroke or spinal injury patients and in children with cerebral palsy;[16-18] its temporary effect may be an advantage over chemical neurolysis but the need for regular injections may limit acceptability in children.[16] Systematic reviews[19,20] have found insufficient evidence to support or refute such use in children with cerebral palsy.

Nondrug treatments have included electrical stimulation techniques such as transcutaneous nerve stimulation and dorsal column stimulation; vibration applied to agonist spastic muscles to improve voluntary movement; cooling to decrease afferent inputs from peripheral receptors; and orthopaedic surgery or neurosurgery.

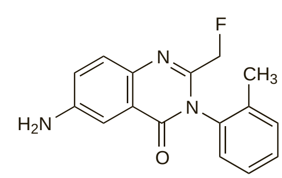
$C_{16}H_{14}FN_3O = 283.3.$

CAS — 56287-74-2.



Pharmacopoeias. In *Jpn.*

Profile

Afloqualone is a centrally acting skeletal muscle relaxant that has been given orally for the treatment of muscle spasm associated with musculoskeletal conditions. Photosensitivity reactions have been reported.

Pharmacopoeias. In *Eur.* (see p.vii), *Jpn,* and *US.*

Ph. Eur. 6.2 (Baclofen). A white or almost white powder. It exhibits polymorphism. Slightly soluble in water; very slightly soluble in alcohol; practically insoluble in acetone; dissolves in dilute mineral acids and in dilute solutions of alkali hydroxides.

USP 31 (Baclofen). A white to off-white, odourless or practically odourless, crystalline powder. Slightly soluble in water; very slightly soluble in methyl alcohol; insoluble in chloroform. Store in airtight containers.

Adverse Effects

Adverse effects associated with baclofen are often transient and dose-related. They may be minimised by increasing doses gradually or controlled by a reduction in dosage.

The most common adverse effects include drowsiness, nausea, dizziness, lassitude, lightheadedness, confusion, fatigue, muscular pain and weakness, and hypotension. Other adverse effects include euphoria, hallucinations, depression, headache, tinnitus, convulsions, paraesthesias, slurred speech, dry mouth, taste alterations, vomiting, diarrhoea or constipation, ataxia, nystagmus, tremors, insomnia, visual disturbances, skin rashes, pruritus, increased sweating, urinary disturbances, respiratory or cardiovascular depression, blood sugar changes, alterations in liver function values, and a paradoxical increase in spasticity. Problems with erection and ejaculation have also been reported with intrathecal baclofen; these are usually reversible on withdrawal of therapy.

Overdosage may lead to muscular hypotonia, hypothermia, drowsiness, respiratory depression, coma, and convulsions (see also below).

Stopping baclofen abruptly may result in a withdrawal syndrome (see under Precautions, below).

Effects on the nervous system. Epilepsy, progressing to status epilepticus, has been associated with the use of baclofen in a patient who had had no history of seizures.[1] Baclofen had been given in a dose of 80 mg daily and symptoms had resolved after gradual withdrawal and the use of antiepileptics.

1. Rush JM, Gibberd FB. Baclofen-induced epilepsy. *J R Soc Med* 1990; **83:** 115–16.

Treatment of Adverse Effects

Treatment of baclofen overdosage is symptomatic. Consideration should be given to the use of activated charcoal in adults who have ingested more than 100 mg, and children who have taken more than 5 mg/kg, within an hour of presentation. Alternatively, gastric lavage may be considered in adults within an hour of ingesting a life-threatening overdose. Haemodialysis should be considered in severe cases. Observation should continue for at least 6 hours after ingestion. For the use of physostigmine salicylate in the treatment of intrathecal baclofen overdosage, see below.

Overdosage. Atropine sulfate 600 micrograms intravenously[1] was used to treat a patient who had ingested 420 mg of baclofen and had failed to improve after gastric lavage and induced diuresis. Bradycardia, hypotension, hypothermia, and respiratory depression all improved and no further treatment was needed. The clinical course and management of acute intoxication in 8 adolescents, who ingested estimated amounts of baclofen ranging from 60 to more than 600 mg, has also been described.[2]

Accidental *intrathecal* overdosage has caused respiratory depression, decreased alertness, coma, muscle weakness, and vomiting.[3] Mild intrathecal bolus overdoses of baclofen in patients without cardiac compromise have been treated using physostigmine although the use of physostigmine in poisoning is now generally considered hazardous (see Antimuscarinic Poisoning, p.1884). Physostigmine salicylate was given intravenously in a dose of 1 to 2 mg over 5 minutes and repeated if necessary at intervals of 30 to 60 minutes.[3,4] Physostigmine was ineffective in a patient who accidentally received 10 mg of baclofen intrathecally;[5] in such severe overdosage, respiratory support and time to recover is needed.[4] A lumbar tap to remove about 30 to 50 mL of CSF may help to reduce the intrathecal concentration of baclofen if implemented soon after the overdose.

Precautions

Baclofen stimulates gastric acid secretion and should be used with caution in patients with a history of peptic ulcer and avoided in those with active peptic ulcer disease. It should also be used with caution in patients with severe psychiatric disorders or epilepsy or convulsive disorders since these disorders may be exacerbated by baclofen. Liver function should be monitored in patients with liver disease; patients with renal impairment need a reduced dose. Baclofen should be used with caution in patients with respiratory impairment. Observations of increased blood sugar concentrations suggest caution in patients with diabetes mellitus. Care is also required in the elderly, in whom adverse effects may be more common, and in patients with cerebrovascular disease (who tolerate baclofen poorly). It should be used with caution in patients who use their spasticity to maintain posture or to increase function. Urine retention may be exacerbated in patients with hypertonic bladder sphincters. Baclofen may cause drowsiness; patients affected should not drive or operate machinery.

Abrupt withdrawal of baclofen may result in a withdrawal syndrome and exacerbation of spasticity; dosage should be reduced gradually over at least 1 to 2 weeks, or longer if symptoms occur.

Anaesthesia. Acute bradycardia and hypotension occurred after rib retraction in 3 patients given baclofen 30 mg orally 90 minutes before thoracic surgery under general anaesthesia, but not in a further 3 patients given placebo.[1] Giving atropine and ephedrine relieved bradycardia and hypotension in 2 patients, but a brief cardiac arrest occurred in 1. Baclofen may disturb autonomic control of the circulation during general anaesthesia and surgery.

1. Sill JC, *et al*. Bradycardia and hypotension associated with baclofen used during general anaesthesia. *Anesthesiology* 1986; **64:** 255–8.

Breast feeding. The concentrations of baclofen found in breast milk are small[1] and UK licensed product information states that no undesirable effects are to be expected in breast-fed infants. The American Academy of Pediatrics also considers that baclofen is usually compatible with breast feeding; no adverse effects have been seen in breast-feeding infants whose mothers were receiving baclofen.[2]

1. Eriksson G, Swahn C-G. Concentrations of baclofen in serum and breast milk from a lactating woman. *Scand J Clin Lab Invest* 1981; **41:** 185–7.

Peptic ulcer. Results of a study of baclofen-stimulated gastric acid secretion in 10 healthy subjects given 600 micrograms/kg intravenously suggested that patients on baclofen might be at risk from baclofen-induced hyperacidity.[1]

1. Pugh S, *et al*. Clinical and experimental significance of the newly discovered activity of baclofen (PCP-GABA) as a stimulant of gastric acid secretion. *Gut* 1985; **26:** A545.

Porphyria. Baclofen is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Pregnancy and the neonate. Two successful pregnancies have been reported[1] in a woman receiving intrathecal baclofen; there was no evidence of teratogenicity, and neurodevelopmental outcome in the children seemed normal. However, convulsions were seen in a week-old infant whose mother had taken oral baclofen during pregnancy.[2] The convulsions, which were refractory to antiepileptics, lidocaine, and pyridoxine, ceased within 30 minutes of giving baclofen to the infant.

2. Ratnayaka BDM, *et al.* Neonatal convulsions after withdrawal of baclofen. *BMJ* 2001; **323:** 85.

Renal impairment. Reports of baclofen toxicity in patients with severe renal impairment.[1] Most patients had received 15 mg or more of baclofen daily although one patient who had received the manufacturer's suggested dose of 5 mg daily still developed toxic symptoms after only 4 days of treatment.

1. Chen K-S, *et al*. Baclofen toxicity in patients with severely impaired renal function. *Ann Pharmacother* 1997; **31:** 1315–20.

Respiratory disorders. Baclofen might precipitate bronchoconstriction in susceptible individuals. A patient with asthma developed symptomatic bronchoconstriction after taking baclofen on two separate occasions.[1] Another patient who had a history of exercise-induced dyspnoea and wheezing was found to have bronchial hyperresponsiveness to methacholine only after taking baclofen.

1. Dicpinigaitis PV, *et al.* Baclofen-induced bronchoconstriction. *Ann Pharmacother* 1993; **27:** 883–4.

Withdrawal. Psychiatric reactions including hallucinations, paranoia, delusions, psychosis, anxiety, confusion, and agitation have been reported[1-4] on abrupt withdrawal of oral baclofen; symptoms generally resolved on restarting. Convulsions have also been reported.[5] The abrupt withdrawal of intrathecal baclofen may also result in high fever, altered mental status, exaggerated rebound spasticity, and muscle rigidity which in rare cases has advanced to rhabdomyolysis, multiple organ failure, and death.[6-8]

Except for serious adverse reactions, the dose of oral baclofen should be gradually reduced: the UK CSM recommends reduction over at least 1 to 2 weeks or longer if symptoms occur. Similarly, the FDA has advised against the abrupt withdrawal of intrathecal baclofen.[8]

Interactions

Alcohol and other CNS depressants may exacerbate the CNS effects of baclofen and should be avoided; severe aggravation of hyperkinetic symptoms may possibly occur in patients taking lithium. There may be increased weakness if baclofen is given to patients taking a tricyclic antidepressant and there may be an increased hypotensive effect if it is given to patients receiving antihypertensive therapy. Ibuprofen (see below) and other drugs that produce renal insufficiency may reduce baclofen excretion leading to toxicity.

Dopaminergics. For reports of patients with Parkinson's disease taking *levodopa* who have had adverse effects when given baclofen, see under Levodopa, on p.808.

NSAIDs. There has been a report of an elderly patient who developed baclofen toxicity after *ibuprofen* therapy was also started.[1] It appeared that acute renal insufficiency caused by ibuprofen had impaired baclofen excretion.

1. Dahlin PA, George J. Baclofen toxicity associated with declining renal clearance after ibuprofen. *Drug Intell Clin Pharm* 1984; **18:** 805–8.

Pharmacokinetics

Baclofen is rapidly and almost completely absorbed from the gastrointestinal tract after an oral dose. Peak plasma concentrations occur about 0.5 to 3 hours after ingestion, but the rate and extent of absorption vary between patients, and may vary inversely with the dose. After oral doses some baclofen crosses the blood-brain barrier, with concentrations in CSF about 12% of those in the plasma. About 30% of baclofen is bound to plasma proteins. About 70 to 80% of a dose is excreted in the urine mainly as unchanged drug; about 15% is metabolised in the liver. The elimination half-life of baclofen is about 3 to 4 hours in plasma and about 1 to 5 hours in the CSF. Baclofen crosses the placenta and is distributed into breast milk.

Absorption. A crossover study in 5 healthy subjects given baclofen 20 mg orally after an overnight fast or a standardised breakfast showed that baclofen was rapidly absorbed in both cases, and the rate and extent of absorption were not significantly altered by the presence of food.[1] There is no need to modify the current practice of giving baclofen with food to minimise gastrointestinal adverse effects.

1. Peterson GM, *et al*. Food does not affect the bioavailability of baclofen. *Med J Aust* 1985; **142:** 689–90.

Uses and Administration

Baclofen, an analogue of gamma-aminobutyric acid (p.2308), is a centrally acting skeletal muscle relaxant. It interferes with the release of excitatory neurotransmitters and inhibits monosynaptic and polysynaptic transmission at the spinal cord level. It may also act at supraspinal sites producing CNS depression. Baclofen is one of the drugs commonly used for the symptomatic relief of severe chronic spasticity associated with a variety of conditions.

Baclofen is given *orally* in divided doses, preferably with or after food or milk. The initial dose of baclofen is 5 mg three times daily for 3 days, increased to 10 mg three times daily for 3 days, then in similar increments and intervals until either a dose of 20 mg three times daily is reached or until the desired therapeutic effect is obtained. Higher doses have been used. Doses of more than 80 to 100 mg daily are not generally recommended although doses of up to 150 mg daily have been given to carefully supervised patients.

In the UK a dosage range of 0.75 to 2 mg/kg daily has been used for children; in children over 10 years a maximum daily dosage of 2.5 mg/kg may be given. It is usual to start with a low dose of 2.5 mg given four times daily, increased cautiously about every 3 days until the desired therapeutic effect is obtained. The recommended daily maintenance doses are: 12 months to 2 years, 10 to 20 mg; 2 to 6 years, 20 to 30 mg; 6 to 10 years, 30 to 60 mg.

Elderly patients should receive lower initial doses, although final maintenance doses may be in the same range as younger adults. For dosage in renal impairment, see below.

If no benefit is apparent within 6 weeks of achieving the maximum dosage, therapy should probably be gradually withdrawn.

Baclofen is also given *by continuous intrathecal infusion* in the treatment of spasticity in patients intolerant of, or unresponsive to, oral baclofen. Before beginning the intrathecal regimen any existing antispastic therapy should be gradually withdrawn to avoid overdosage or drug interactions. Intrathecal test doses are given initially to determine if there is going to be any benefit before implanting a controlled infusion pump. It is important that patients are monitored closely in experienced centres during screening and immediately after implantation of the infusion pump and that resuscitation equipment is available for immediate use.

Test doses start at 25 or 50 micrograms given over at least 1 minute and are increased by 25 micrograms every 24 hours until a dose of 100 micrograms is reached or a positive response of about 4 to 8 hours is obtained. Patients who fail to respond to a test dose of up to 100 micrograms are considered to be unsuitable for intrathecal treatment. For children aged 4 to 18 years with spasticity of cerebral origin an initial test dose of 25 micrograms is recommended. However, the manufacturers do not recommend the use of intrathecal baclofen in patients in this age group with spasticity of spinal origin.

For patients showing a positive response lasting for longer than 8 to 12 hours, the test dose that was required to produce the response can then be given as a 24-hour infusion; if the response to the test dose lasted 8 to 12 hours or less, then a dose equivalent to twice the test dose is given. Daily dosage can then be adjusted as required. Maintenance doses range from about 10 micrograms to 2 mg daily, depending on the cause of spasticity, with most patients being adequately maintained with 300 to 800 micrograms daily.

Administration in renal impairment. Doses of baclofen should be reduced in renal impairment or in patients undergoing chronic haemodialysis; 5 mg daily by mouth has been suggested (but see also under Precautions, above).

Dystonias. There have been reports of improvement in patients with various forms of dystonia (p.809) treated with baclofen[1-5] although there has also been a report[6] of a patient whose condition deteriorated during baclofen therapy.

Gastro-oesophageal reflux disease. Baclofen has been tried[1,2] in the treatment of gastro-oesophageal reflux disease (p.1696). It may control gastro-oesophageal reflux by inhibiting transient sphincter relaxation. Although both studies reported a reduction in the number of reflux episodes there was no effect on acid reflux symptoms. However, a subsequent study[3] has shown a positive effect on the symptoms of acid reflux. It has been suggested that although baclofen may be of benefit, its adverse CNS effects mean that new oral selective GABA-B agonists should be developed for this indication.[4]

Hiccup. Baclofen has been given orally in daily divided doses ranging from 10 to 80 mg for the management of intractable hiccup (p.976) poorly controlled by other drugs. It has also been combined with gabapentin.

References.

Migraine and cluster headache. The efficacy of baclofen in conditions such as trigeminal neuralgia or various types of neuropathic pain suggested that it may be useful in migraine or cluster headache. Pilot studies confirmed these hypotheses with baclofen proving useful for prophylaxis[1] in migraine (p.616) and for treatment[2] in cluster headache (p.616).

Pain. Like some other muscle relaxants baclofen is used in the management of painful conditions associated with muscle spasm or spasticity (see below). The use of muscle relaxants for conditions such as acute low back pain is referred to on p.7. Baclofen does not appear to possess conventional analgesic activity[1] but may potentiate the analgesia produced by opioid analgesics,[2] and has been used as an adjuvant in neuropathic pain,[3,4] notably trigeminal neuralgia[5] (p.9).

Spasticity. Baclofen is one of the main drugs used in the management of spasticity (see p.1887). It is used to reduce muscle spasm and pain especially in spinal cord lesions in conditions such as multiple sclerosis or paraplegia. Baclofen is also used for spasticity of cerebral origin.

Oral doses of 30 to 80 mg daily are usually quite well tolerated,[1] but patients with severe spasticity often require high doses of baclofen before a response occurs and, consequently, some may fail to respond because adverse effects limit increases in dosage. Intrathecal baclofen is therefore sometimes tried as this produces much higher concentrations in the CNS than oral doses.[1-3] It may be given intrathecally by bolus injection or by continuous infusion; infusion is probably preferred[4] to minimise the risk of overdosage. Because patients are screened for response before beginning continuous infusion, results have generally been good.[1]

There is a large interindividual variation in the dose required to produce improvement in spasticity:

- in patients with spasticity of spinal origin, maintenance doses have ranged from 12 micrograms to about 2 mg daily, with most adequately managed on 300 to 800 micrograms daily
- in patients with spasticity of cerebral origin, maintenance doses have ranged from 22 micrograms to 1.4 mg daily, with an average daily dose of 276 micrograms after 12 months and 307 micrograms after 24 months
- for children under the age of 12 years with spasticity of cerebral origin, maintenance doses have ranged from 24 micrograms to about 1.2 mg daily, with an average daily dose of 274 micrograms

An increased dose of baclofen may be given at night to prevent spasms that interfere with sleep.

Although reports of tolerance to the effect of intrathecal baclofen have raised doubt[5] over whether long-term benefit can be maintained, a number of workers have achieved long-term efficacy.[6-9] It has been reported[10] that some patients receiving long-term intrathecal baclofen treatment have been able to stop their therapy without symptoms of spasticity re-appearing and others have been able to reduce the dosage required.

Stiff-man syndrome. There have been anecdotal case reports[1] of benefit with intrathecal baclofen in a patient with stiff-man syndrome (see under Muscle Spasm, p.993) inadequately controlled with other drugs or oral baclofen. However, in a double-blind placebo-controlled study[2] clinical improvement was evident in only 1 of 3 patients given intrathecal baclofen.

Tardive dyskinesia. Baclofen is one of many drugs that have been tried in antipsychotic-induced tardive dyskinesia (see Extrapyramidal Disorders, p.971) but its efficacy is unclear. A systematic review[1] found the effects of baclofen, and other gamma-aminobutyric acid agonists to be inconclusive and unconvincing in the management of antipsychotic-induced tardive dyskinesia. The review also pointed out that the adverse effects caused by use of these drugs might outweigh any benefits.

1. Soares KVS, *et al*. Gamma-aminobutyric acid agonists for neuroleptic-induced tardive dyskinesia. Available in The Cochrane Database of Systematic Reviews; Issue 4. Chichester: John Wiley; 2004 (accessed 20/10/05).

Tetanus. The management of tetanus is described on p.1901 and p.196. Beneficial responses have been seen with baclofen by continuous intrathecal infusion,[1-5] usually in doses of 1 to 2 mg daily.[1,5] However, the therapeutic range of intrathecal baclofen in severe tetanus may be very narrow and deep coma with loss of spontaneous respiration and reflexes has been reported[6] after an increase in dosage from 1.2 mg to 2 mg daily. This adverse effect could be fatal in the absence of ventilatory support. To avoid the risk of secondary infection from an indwelling intraspinal catheter intermittent intrathecal baclofen has also been used.[7,8]

Botulinum Toxins

Toxinas botulínicas.
ATC — M03AX01.
ATC Vet — QM03AX01.

Description. Botulinum toxins A and B are neurotoxins produced by *Clostridium botulinum*. They are proteins comprising a heavy chain thought to be responsible for binding to the target cells and translocation of the toxin across the cell membrane, linked by a disulfide bond to a light chain responsible for the toxic activity.

Botulinum A Toxin

Botuliinitoksiini tyyppi A; Botulinum A Toksini; Toxin typ A mot botulism; Toxina botulínica A; Toxine botulinique type A; Toxinum botulinicum typum A.

Pharmacopoeias. *Eur.* (see p.vii) includes the injection.
Ph. Eur. 6.2 (Botulinum Toxin Type A for Injection; Toxinum Botulinicum Typum A ad Iniectabile). A dried preparation containing purified botulinum neurotoxin type A, which may be present in the form of a complex with haemagglutinins and non-toxic proteins, prepared from a suitable strain of *Clostridium botulinum* type A.

Botulinum B Toxin

Botulinum B Toksini; Toxina botulínica B.

Units

The dose of preparations containing botulinum toxins A or B is expressed in terms of units, but the available preparations are used at different doses for the same indications, and the units of one preparation cannot be considered to apply to another.

Adverse Effects

Injections of botulinum toxins have been associated with a transient burning sensation, bruising at the injection site, and local weakness. Adverse reactions related to the spread of botulinum toxins distant to the site of injection have been reported and sometimes this was associated with significant debility or a fatal outcome in very rare cases. Exaggerated muscle weakness may occur with therapeutic doses. Deep or misplaced injections may paralyse nearby muscle groups and excessive doses may paralyse distant muscles. Overdosage can produce a widespread paralysis.

There have been occasional reports of hypersensitivity reactions such as skin rashes and flu-like symptoms. There have also been rare reports of cardiovascular adverse effects, including arrhythmia and myocardial infarction, and of seizures or convulsions, particularly in predisposed patients.

- The most common adverse effects **after injection into muscles around the eye**, such as in the management of blepharospasm, hemifacial spasm, or strabismus, are ptosis, lachrymation, photophobia, ocular irritation, and facial swelling. Some patients may be unable to close the eyelid completely. Other adverse effects that have been reported include ectropion and entropion, and diplopia. Patients experience a reduction in blinking and this can lead to dry eye, keratitis, and corneal damage. Angle-closure glaucoma has been reported. Vertical deviation has also occurred in patients treated for horizontal strabismus. Needle penetrations of the eye during treatment of strabismus have resulted in vitreous and retrobulbar haemorrhages.
- Dysphagia is the most common adverse effect **after injection into neck muscles** in the treatment of spasmodic torticollis and there may be pooling of saliva with risk of aspiration in severely affected patients (*important*, see also Precautions, below). Dry mouth, paralysis of the vocal cords, and weakness of the neck muscles may also occur. Generalised weakness, malaise, nausea, and visual disturbances have occasionally been reported. Other effects which have occurred rarely include drowsiness, numbness, stiffness, ptosis, and headache. Respiratory difficulties, associated with the use of large doses, have occurred on rare occasions.
- Adverse effects most frequently associated with **injection into the lower limbs** in the treatment of cerebral palsy include falling, leg pain, and local and general weakness; lethargy and leg cramps have also been reported.
- Common adverse effects **after injection into the upper limb** in the treatment of spasticity associated with stroke are arm pain, dysphagia, muscle weakness, and hypertonia. A perceived increase in non-axillary sweating, within one month of the injection, has been reported after treatment for hyperhidrosis of the axillae; rarely, mild transient weakness of the arms has also occurred.
- Headache is the most frequent adverse effect **after injection into the muscles around the forehead** in the treatment of glabellar (frown) lines. Other adverse effects frequently reported include ptosis, facial pain, muscle weakness, and nausea.

◊ Reviews.

1. Klein AW. Complications and adverse reactions with the use of botulinum toxin. *Dis Mon* 2002; **48:** 336–56.

Incidence of adverse effects. It has been suggested that the difference between botulinum A toxin preparations may not be confined to just a numerical dosage adjustment.[1] Reviews of the literature have suggested that there may also be a difference in the incidence of adverse effects. The reported frequency of dysphagia for *Dysport* (28% and 44%) in patients with spasmodic torticollis was greater than that for *Botox* (9.5 to 17%). This variation might relate to differences in bioactivity not recognised by the mouse lethality bioassay which is used to determine the potency of preparations.

1. Borodic G. Therapeutic botulinum toxin. *Lancet* 1994; **344:** 1370.

Angiosarcoma. It has been suggested[1] that botulinum A toxin injection might have acted as a triggering factor for angiosarcoma in a 66-year-old patient being treated for blepharospasm.

1. Kárpáti S, *et al.* Human herpesvirus type 8-positive facial angiosarcoma developing at the site of botulinum toxin injection for blepharospasm. *Br J Dermatol* 2000; **143:** 660–2.

Antibody formation. Neutralising antibodies that reduce or abolish the beneficial effects of treatment have been found after prolonged treatment with botulinum A toxin.[1] A review[2] in 1994 considered that there was growing concern over the development of antibodies after repeated injections, as many of the conditions for which botulinum toxin is indicated require indefinite treatment. Antibody formation was reported to be more common with high doses (as in spasmodic torticollis) than after low doses (as for blepharospasm). The occurrence of antibodies appeared to correlate with the dose per injection, the quantity of botulinum protein given per injection, the number of injections given, and the frequency of injections.

Antibodies have also developed after the use of botulinum B toxin. However, botulinum toxin B is antigenically distinct from botulinum A toxin, and may be of value in patients who develop resistance to treatment associated with antibody formation to type A toxin.[3] Botulinum F toxin is also antigenically distinct and is being studied in a similar way.

3. Brin MF, *et al.* Safety and efficacy of NeuroBloc (botulinum toxin type B) in type A-resistant cervical dystonia. *Neurology* 1999; **53:** 1431–8.

Biliary colic. A 43-year-old woman with no history of gallbladder disease had single episodes of biliary colic after each of 3 sessions of treatment with botulinum A toxin for blepharospasm.[1] Botulinum A toxin might have exerted a systemic effect to block acetylcholine release leading to gallbladder hypomotility with delayed emptying and stasis.

1. Schnider P, *et al.* Gallbladder dysfunction induced by botulinum A toxin. *Lancet* 1993; **342:** 811–12.

Dysphagia. By November 1993, the UK CSM had received 4 reports of severe dysphagia with choking in patients given injections of botulinum A toxin into the neck muscles as a treatment for torticollis.[1] The dysphagia developed 5 to 7 days after the injection and in one patient it was persisting 6 weeks after the injection. The dysphagia led to aspiration of the stomach contents into the lungs and one patient with a history of poor lung function died from bronchopneumonia. Dysphagia is also reported to be a common adverse effect in patients with spasmodic torticollis being treated with Botulinum B toxin.[2]

See also Incidence of Adverse Effects, above for further reference to dysphagia as an adverse effect.

Effects on the eyes. Acute angle-closure glaucoma has been reported[1] in an 83-year-old woman after a series of injections of botulinum A toxin for the treatment of blepharospasm. Permanent extra-ocular muscle damage after botulinum A toxin injection into the left inferior rectus muscle has been reported[2] in a 70-year-old man.

2. Mohan M, *et al.* Permanent extraocular muscle damage following botulinum toxin injection. *Br J Ophthalmol* 1999; **83:** 1309–10.

Treatment of Adverse Effects

The use of artificial tears may relieve keratitis and dry eye. In the event of overdosage general supportive care is required. The patient should be monitored for several days for signs of paralysis and artificial respiration may be necessary. Since the effects of botulinum toxins are irreversible once bound to nerve terminals, it is doubtful that specific botulinum antitoxin (p.2207) will be of value unless given very rapidly after overdosage.

Precautions

Botulinum toxin is contra-indicated in generalised disorders of muscle activity such as myasthenia gravis. As with other biological products, the potential for botulinum toxin to cause anaphylaxis should be considered. Botulinum toxins should be given with extreme caution to patients with neurological disorders or a history of dysphagia or aspiration. Patients or their carers should be advised to seek immediate medical attention if problems with swallowing or speech, or respiratory disorders develop.

Botulinum toxins should only be used by appropriately qualified and trained specialists. Injections must be made with great care, especially those into the neck, to avoid unintended paralysis; the relevant anatomy, and any alterations due to previous surgery, must be understood before injection. Botulinum toxins should not be given if there is any infection at the proposed injection site.

The effects of botulinum toxins in pregnancy are unknown; fetal malformations and abortion have been reported in *rabbits*, and licensed product information recommends that botulinum toxins should not be given to pregnant women. Breast feeding is also considered a contra-indication: it is not clear whether the toxin is distributed into breast milk.

When **injected into the muscles around the eyes**, as for the treatment of blepharospasm, hemifacial spasm, or strabismus, reduced blinking can lead to corneal exposure, persistent epithelial defect, and corneal ulceration, especially in patients with seventh cranial nerve disorders. Corneal sensation should be carefully tested in previously treated eyes, injection into the lower eyelid area avoided, and any resulting epithelial defect vigorously treated.

Handling. Residual botulinum A toxin or spillages should be inactivated by autoclaving or use of a dilute hypochlorite solution (0.5%). Botulinum B toxin may be decontaminated in a similar manner; a strong caustic solution may also be used.

Interactions

The effect of botulinum toxins may theoretically be potentiated by aminoglycosides or spectinomycin. Interactions may also occur with other drugs that have neuromuscular blocking activity, including lincosamides, polymyxins, tetracyclines, and muscle relaxants.

Uses and Administration

Botulinum toxins cause neuromuscular blockade by inhibiting the calcium-ion mediated release of acetylcholine at the motor nerve terminals, resulting in a diminished endplate potential and subsequent flaccid paralysis of the affected muscles. The paralysis persists until new nerve terminals form, usually within 2 to 4 months.

Botulinum A toxin is given as a complex usually with haemagglutinin by local injection in the treatment of hemifacial spasm, blepharospasm, spasmodic torticollis, lower limb spasticity in children with cerebral palsy, and upper limb spasticity associated with stroke in adults. Botulinum A toxin is also used for the management of strabismus and hyperhidrosis, and has also been approved for the treatment of glabellar (frown) lines in adults up to 65 years of age. It is being investigated for use in the management of several other disorders. Botulinum B toxin is also used in the management of spasmodic torticollis and, being antigenically distinct, it has the potential for use in patients who develop resistance to treatment due to the development of antibodies to type A toxin.

Doses of botulinum toxins A and B are expressed in terms of units, which have not been standardised between preparations (see under Units, above). Doses are therefore specific to each individual preparation; details are given below.

Botulinum F toxin is under investigation for the treatment of similar neuromuscular disorders.

Achalasia. The treatment of choice for achalasia (see Oesophageal Motility Disorders, p.1702) is mechanical dilatation of the lower oesophageal sphincter, or if necessary surgery, but more recently injection of botulinum A toxin[1-3] has been found to be effective. However, one year after treatment only 7 of 22 (32%) patients who received botulinum A toxin were in symptomatic remission compared with 14 of 20 (70%) patients treated with mechanical dilatation.[4] It was recommended that its use would be better reserved for patients thought to be at risk from mechanical dilatation or surgery.[3-5] Another study[6] showed that intrasphincteric injection of botulinum toxin A was safe and effective for the treatment of achalasia in the short and medium term, although only a weak correlation with dose emerged.

Anal fissure. Anal fissure is a superficial tear in the mucosa of the distal anal canal characterised by pain on defaecation, rectal bleeding, and spasm of the anal sphincter. Healing, which is usually uneventful, may be helped by conservative management with bran and bulk laxatives and topical local anaesthetics for pain relief. Surgical treatment has been used for patients who develop a chronic condition but has been associated with high rates of long-term incontinence and recurrence. Although systematic reviews considered that surgery was more effective than alternative medical therapies,[1,2] a number of these have been investigated.[3] As hypertonicity of the internal anal sphincter may be involved in the pathophysiology of chronic anal fissure, local injections of botulinum A toxin have been used to produce paresis of this sphincter.[4-6] The duration of the effect appears to be long enough to allow complete healing of the fissure in most patients although some may relapse; a long-term, follow-up trial[7] involving 57 completely healed patients, noted a high recurrence rate (41.5%) once the effects of botulinum toxin disappeared. Temporary incontinence had been the only adverse effect reported during treatment.

Topical application of nitrates can relax the anal sphincter; numerous studies[8-10] have reported benefit from topical application of glyceryl trinitrate, although a high rate of spontaneous resolution with placebo has cast doubt over the degree of advantage in some studies.[1,9] Follow-up[11] of patients treated with glyceryl trinitrate indicated that after 24 to 38 months most had not experienced further problems or had had occasional recurrences which in the majority of cases had responded to further topical treatment. Isosorbide dinitrate ointment has also been tried, and may be of benefit with botulinum A toxin.[12]

Topical calcium antagonists also seem to be effective. Both diltiazem[13-15] and nifedipine[16,17] seem to be of benefit and there is evidence that they may be a better choice than topical glyceryl trinitrate.[16,17] Nifedipine has been combined with botulinum toxin;[17] it has also been given orally.[18]

Anismus. Anismus is a condition in which inappropriate contraction of the anal sphincters occurs when bowel evacuation is attempted; it seems to be a form of dystonia.

Treatment with botulinum A toxin was investigated in 7 patients with intractable constipation due mainly to anismus.[1] The toxin was injected bilaterally into the puborectalis muscle using an electromyographically guided needle; patients were allowed to continue with their laxatives throughout the study if required. Symptoms improved in all but one of the patients, although two patients could not be regarded as treatment successes because they developed faecal incontinence; four patients had an excellent clinical outcome. However, another study involving 24 patients found the clinical effectiveness of botulinum A toxin to be limited, and further studies are needed to determine its role in the treatment of anismus.[2]

2. Ron Y, *et al.* Botulinum toxin type-A in therapy of patients with anismus. *Dis Colon Rectum* 2001; **44:** 1821–6.

Blepharospasm. Blepharospasm is a focal dystonia characterised by repeated involuntary blinking caused by spasms of the orbicularis oculi muscle of the eye, and can result in functional blindness. Blepharospasm is often associated with other dystonias of the head and neck, such as Meige syndrome, in which patients also suffer from involuntary contractures of the muscles around the mouth. Oral drug treatment as used for dystonias in general (see p.809) is usually ineffective, and surgery (facial nerve avulsion) is often followed by recurrent spasm.[1] Local injections of botulinum A toxin into the orbicularis oculi muscle mimic the effect of surgical denervation of the muscle and are reported[2-6] to have been effective in over 70% of patients. Symptomatic improvement has been reported to last from about 9 to 15 weeks; no increase in duration of effect is apparent following multiple injections. In one retrospective study in patients with blepharospasm and Meige syndrome, treatment with botulinum A toxin was still effective in most patients 11 years after the start of therapy.[4]

For blepharospasm botulinum A toxin is injected into the orbicularis oculi of the upper and lower lids; injection into additional sites in the brow area and upper facial area may be indicated if the spasms interfere with vision. Doses of botulinum A toxin are expressed in terms of units, which have not been standardised between preparations. Doses are therefore *specific to each individual preparation*:

- The preparation *Botox* (*Allergan, UK*) is injected intramuscularly in an initial dose of 1.25 to 2.5 units at each site to a total of up to 25 units per eye. An effect is usually obtained within 3 days and reaches a peak after 1 to 2 weeks; each treatment lasts for about 3 months. If the response lasts less than 2 months the dose may be increased up to 5 units at each site but the total dose given in a 12-week period should not exceed 100 units. Giving more often than every 3 months confers no additional benefit. *Botox* (*Allergan*) is also available in the USA and given in similar doses, although higher cumulative doses of up to 200 units are allowed in a 30-day period
- The preparation *Xeomin (Merz, UK)* is injected intramuscularly in an initial dose of 1.25 to 2.5 units at each site to a total of up to 25 units per eye. An effect is usually obtained within 4 days; each treatment lasts for about 3 to 4 months. If the response lasts less than 2 months the dose may be increased up to 5 units at each site but the total dose given in a 12-week period should not exceed 100 units. Giving more often than every 3 months confers no additional benefit.
- For the preparation *Dysport* (*Ipsen, UK*) the initial dose is a total of 120 units per eye given as subcutaneous injections of 20 and 40 units per site. Subsequently the total dose may need to be reduced to 60 to 80 units per eye. With this preparation the relief of symptoms may begin within 2 to 4 days with a maximum effect being obtained within 2 weeks. Injections of *Dysport* should be repeated every 12 weeks or as required.

Cosmetic use. Botulinum A toxin has been used for the cosmetic treatment of facial lines and wrinkles and age-related neck degeneration.[1-5]

For the temporary improvement in appearance of moderate to severe glabellar (frown) lines two doses of botulinum A toxin are injected into each of the corrugator muscles and one dose into the procerus muscle. Doses of botulinum A toxin are expressed in terms of units, which have not been standardised between preparations. Doses are therefore *specific to each individual preparation*: the preparation *Botox Cosmetic* (*Allergan, USA*) is injected intramuscularly, not closer than 1 cm above the central eyebrow. A dose of 4 units is given into each of 5 sites to a total dose of

20 units. An effect is obtained in 1 to 2 days which increases in intensity in the first week; each treatment lasts for about 3 to 4 months. More frequent dosing is not recommended as safety and effectiveness have not been evaluated.

A preparation with a similar dosage regimen (*Vistabel; Allergan, UK*) is available in the UK.

Gastric motility disorders. Some benefit has been reported from the use of botulinum A toxin injection in gastric motility disorders (p.1694). In an open-label study[1] 6 diabetic patients with gastroparesis experienced an improvement in gastric emptying after treatment with botulinum A toxin.

1. Ezzeddine D, *et al.* Pyloric injection of botulinum toxin for treatment of diabetic gastroparesis. *Gastrointest Endosc* 2002; **55:** 920–3.

Hand dystonia. Hand dystonia, or hand cramp, is a type of focal dystonia (p.809). It is more commonly reported in people who perform repetitive movements with their hands, such as writers, keyboard operators, and musicians. Treatment was traditionally with antimuscarinics, although with limited success, but botulinum toxin has increasingly become the first-line option.[1] A double-blind study reported that 8 out of 10 patients had greater subjective improvement in focal hand dystonia, compared with placebo, after treatment with botulinum A toxin given by the intramuscular route; objective improvement in muscle strength was seen in 6 patients.[2] However, pain and severe weakness in the shoulder region resembling neuralgic amyotrophy has been reported[3] in 2 patients injected with botulinum A toxin for writer's cramp. It was considered that if unexplained pain occurred in the shoulder or upper arm after a first injection of botulinum A toxin further injections were contra-indicated.

Headache. The therapeutic effect of botulinum A toxin in headache was first seen as a coincidental adverse effect in patients receiving the drug for hyperfunctional facial lines. A review[1] of subsequent studies concluded that efficacy could be demonstrated for the prophylaxis of migraine (p.616); a small number of patients who received treatment during the acute phase of a migraine attack also experienced pain relief. Contradictory results had been reported in the studies evaluating tension-type headache (p.617) and continue to be reported.[2-4] However, in the original review[1] it was emphasised that an important finding had been the need to inject botulinum A toxin at the site of the pain or trigger points and not on a standardised basis, and that this should be considered in future studies. Improvement had been noted in individual cases of cluster headache (p.616) and in some patients with headache attributed to disorders of the neck.

Some benefit has also been seen with botulinum B toxin in the treatment of migraine and tension-type headaches.[5]

Hemifacial spasm. Hemifacial spasm is characterised by involuntary unilateral synchronous contractions of muscles innervated by the facial nerve. The spasms usually begin with twitching of muscles around the eye or mouth but as the disease progresses their frequency increases and they spread to involve the rest of the facial muscles. Hemifacial spasm may be improved by surgery but there is a risk of irreversible paralysis. Few drugs are effective for hemifacial spasm but carbamazepine has been reported to have been of help on occasions. Reports suggest that injections of botulinum A toxin may be effective in relieving symptoms in at least 75% of patients but there do not appear to be any studies comparing it against other treatments. Repeat injections are required by most patients every 3 to 4 months but long-term efficacy appears to be maintained. Dosage regimens of botulinum A toxin used in hemifacial spasm are similar to those used for blepharospasm (see above) although an electromyographically guided needle may be required to identify small muscles around the mouth.

Hyperhidrosis. A number of drugs and surgical techniques have been used in the treatment of hyperhidrosis (p.1580). Botulinum A toxin is used in the management of focal hyperhidrosis because of its ability to block cholinergic transmission at nerve terminals innervating the sweat glands. Encouraging results have been obtained in patients with severe resistant focal hyperhidrosis using intradermal[1,2] or subcutaneous[3,4] injections and results from two larger multicentre studies[5,6] confirm that intradermal injection of botulinum A is effective and well-tolerated for the treatment of axillary hyperhidrosis. In the UK, it is given for this purpose as the preparation *Botox* (*Allergan, UK*), by intradermal injection in doses of 50 units to each axilla, evenly distributed in multiple sites approximately 1 to 2 cm apart. Clinical improvement generally occurs within a week of injection, and may last for 4 to 7 months; repeat injections may be given once the effects of the previous injection have subsided. *Botox* (*Allergan*) is also available in the USA for the treatment of axillary hyperhidrosis; it is given in similar doses.

Some workers[7] prefer to use intradermal injections for palmar hyperhidrosis in order to minimise the risk of reversible weakness of the small muscles of the hand reported with subcutaneous injection.

Micturition disorders. Preliminary results[1] suggest that injection of botulinum A toxin into the detrusor muscle can increase functional bladder capacity and restore continence in patients with urinary incontinence (p.2180) after spinal cord injury who are resistant to antimuscarinics. Similar results[2] have been found in children with detrusor hyperreflexia caused by myelomeningocele.

Botulinum A toxin has also been tried in other bladder dysfunctions.[3,4] Reviews[5,6] have concluded that although there is some evidence that injection of botulinum toxins into the detrusor wall can improve symptoms of overactive bladder syndrome, further studies are warranted.

In a few small studies[7,8] the injection of botulinum A toxin into the prostate gland has been reported to relieve the symptoms of urinary retention associated with benign prostatic hyperplasia (p.2178).

Nystagmus. Surgery, corrective spectacles, and drug therapy have all been tried for the treatment of nystagmus (rapid involuntary movement of the eyeball). Retrobulbar injection of botulinum A toxin has produced improvement in patients with acquired or congenital nystagmus.[1-4] In 6 patients with acquired nystagmus visual acuity was improved, and the amplitude of the nystagmus was reduced, but the frequency was generally unchanged and the need for repeated injections and adverse effects such as diplopia limited patient acceptability.[1]

Ocular surgery. Ptosis is a common adverse effect of botulinum A toxin but therapeutic ptosis induced with botulinum toxin has been described as a useful adjunct in the management of patients undergoing epikeratoplasty since it promoted stabilisation of the epithelium on the graft.[1]

1. Freegard T, *et al.* Therapeutic ptosis with botulinum toxin in epikeratoplasty. *Br J Ophthalmol* 1993; **77:** 820–2.

Pain. There have been anecdotal reports of the use of botulinum A toxin in the treatment of painful disorders such as postcholecystectomy pain associated with sphincter of Oddi dysfunction,[1] and relief of orofacial pain associated with temporomandibular joint dysfunction[2] and facial arthromyalgia.[3] Promising results have been obtained from an open study[4] investigating botulinum toxin as a treatment for chronic refractory tennis elbow in 14 patients. Its efficacy in relieving pain in other chronic conditions such as low back pain, and myofascial pain, in addition to improving function, has also been shown in individual studies.[5] The general management of pain is discussed on p.2 with separate sections on biliary and renal colic (p.5), low back pain (p.7), orofacial pain (p.8), and soft-tissue rheumatism (p.13).

Sialorrhoea. Botulinum toxins may be effective in the treatment of sialorrhoea and drooling associated with conditions such as cerebral palsy[1] and Parkinson's disease.[2] A review[3] found botulinum toxin A to be safe and effective in the treatment of sialorrhoea; however, further studies are warranted.

Spasmodic torticollis. Spasmodic torticollis (cervical dystonia) is a focal dystonia (p.809) characterised by spasmodic rotation of the head as a result of dystonic spasm of the neck muscles. The head may turn to one side (torticollis), extend (retrocollis), or flex (antecollis). Spasms may be repetitive or sustained. Response of spasmodic torticollis to drug therapy is usually poor and surgery has been associated with potentially serious complications. Intramuscular injections of botulinum toxins can be effective but dysphagia, which can have severe consequences (see under Adverse Effects, above) occurs in a significant number of patients. Other adverse effects have included lethargy, local weakness, vertigo, and dysphonia.

When injecting botulinum toxins localisation of the involved muscles with electromyographic guidance may be useful. Multiple injection sites allow more uniform contact with the innervation areas of the dystonic muscle and are especially useful in larger muscles. Bilateral injection of the sternocleidomastoid muscle is not recommended as there is an increased risk of adverse effects, especially dysphagia. Reduced doses may be required for patients with reduced muscle mass.

Doses of botulinum toxins, which are expressed in terms of units, have not been standardised between preparations. Doses are therefore *specific to each individual preparation.*

In the UK the usual initial dose of botulinum A toxin as the preparation *Dysport* (*Ipsen*, *UK*) is 500 units injected in divided doses into the two or three most active neck muscles:

- for *rotational torticollis*, 350 units is given initially into the splenius capitis muscle (ipsilateral to the direction of the chin/head rotation) and 150 units into the sternocleidomastoid muscle (contralateral to rotation)
- for *laterocollis*, 350 units is given initially into the ipsilateral splenius capitis muscle and 150 units into the ipsilateral sternocleidomastoid muscle; if associated with *shoulder elevation*, ipsilateral trapezoid or levator scapulae muscles may also require treatment; if 3 muscles need treatment, 300 units are injected into the splenius capitis muscle, 100 units into the sternocleidomastoid muscle, and 100 units into the third muscle
- for *retrocollis*, 250 units is given into each of the splenius capitis muscles which may be followed after 6 weeks by bilateral trapezius injections in a dose of up to 250 units per muscle; bilateral splenii injections may increase the risk of neck muscle weakness

Subsequent doses may range from 250 to 1000 units, although the higher doses may be accompanied by an increase in adverse effects such as dysphagia; doses above 1000 units are not recommended. An initial effect is usually observed within 1 week; injections usually need to be repeated every 12 weeks or as required.

In the UK, botulinum A toxin as the preparation *Xeomin (Merz, UK)* is indicated for spasmodic torticollis. Licensed product information recommends that doses should be tailored to meet individual patient requirements. In practice, the maximum total dose is usually not more than 200 units but up to 300 units may be given. No more than 50 units should be given at any one injection site; limiting the dose injected into the sternocleidomastoid muscle to less than 100 units may reduce the risk of dysphagia. An initial effect is usually observed within 1 week; each treatment lasts for about 3 to 4 months and injections may be repeated if necessary after at least 10 weeks.

Recommended doses in the UK for botulinum A toxin as the preparation *Botox* (*Allergan*, *UK*) are listed below but licensed product information states that in practice the maximum total dose is not usually more than 200 units. No more than 50 units should be given at any one injection site; limiting the dose injected into the sternocleidomastoid muscle to less than 100 units may reduce the risk of dysphagia.

- *Type I* (head rotated toward side of shoulder elevation)—sternocleidomastoid muscle: total dosage of 50 to 100 units divided amongst at least 2 sites; levator scapulae: total of 50 units amongst 1 or 2 sites; scalene: total of 25 to 50 units amongst 1 or 2 sites; splenius capitis: total of 25 to 75 units amongst 1 to 3 sites; trapezius: total of 25 to 100 units amongst 1 to 8 sites
- *Type II* (head rotation only)—sternocleidomastoid muscle: total dosage of 25 to 100 units divided amongst at least 2 sites if more than 25 units is given
- *Type III* (head tilted toward side of shoulder elevation)—sternocleidomastoid muscle: total dosage of 25 to 100 units at posterior border divided amongst at least 2 sites if more than 25 units is given; levator scapulae: total of 25 to 100 units amongst at least 2 sites; scalene: total of 25 to 75 units amongst at least 2 sites; trapezius: total of 25 to 100 units amongst 1 to 8 sites
- *Type IV* (bilateral posterior cervical muscle spasm with elevation of the face)—splenius capitis and splenius cervicis: a total dosage of 50 to 200 units divided amongst 2 to 8 sites and which include both sides of the neck

Botulinum A toxin as the preparation *Botox* (*Allergan*, *USA*) is also available in the USA for the treatment of spasmodic torticollis. Licensed product information recommends that doses should be tailored to meet individual patient requirements.

In the UK the usual initial dose of botulinum B toxin as the preparation *NeuroBloc* (*Zeneus Pharma*, *UK*) is 5000 to 10 000 units given by intramuscular injection in divided doses into the two to four most affected muscles.

Botulinum B toxin as the preparation *Myobloc* (*Solstice*, *USA*) is also available in the USA. The initial dose is 2500 to 5000 units given by intramuscular injection divided between the affected muscles. Licensed product information recommends that patients with no history of tolerating botulinum injections should be started on a lower initial dose.

Spasticity. The mainstay of management of spasticity, as discussed on p.1887, is physiotherapy together with antispastic drugs. Chemical neurolysis should only be considered when there is intractable continuous pain. Local injections of botulinum A toxin, as an alternative to chemical neurolysis, have been used in the management of limb spasticity in multiple sclerosis,[1] and in post-stroke patients,[1-5] and children with cerebral palsy.[6-12] However, systematic reviews[13,14] have found insufficient evidence to support or refute such use in children with cerebral palsy. Botulinum B toxin has also been tried.[11,15]

Doses of botulinum A toxin, which are expressed in terms of units, have not been standardised between preparations. Doses are therefore *specific to each individual preparation:* Botulinum A toxin is used in the management of dynamic equinus foot deformity associated with spasticity in children with cerebral palsy.

- For children over 2 years of age the recommended total dose of botulinum A toxin as the preparation *Botox* (*Allergan*, *UK*) is 4 units/kg injected into each of 2 sites in the medial and lateral heads of the gastrocnemius muscle. When both lower limbs are to be injected on the same occasion this total dose should be divided between the 2 limbs. Clinical improvement generally occurs within the first 2 weeks. Repeat doses should not be given more frequently than every 2 months.
- For children over 2 years of age the recommended total dose of botulinum A toxin as the preparation *Dysport* (*Ipsen*, *UK*) is 10 to 30 units/kg divided between both calf muscles, primarily targeted to the gastrocnemius muscle. The maximum dose administered should not exceed 1000 units per patient. Clinical improvement generally occurs within the first 2 weeks. Repeat doses should not be given more frequently than every 12 weeks.

Botulinum A toxin is also used in the treatment of upper limb spasticity in adults.

- In the treatment of upper limb spasticity associated with stroke, the exact dosage and number of injection sites of botulinum A toxin as the preparation *Botox* (*Allergan*, *UK*) should be tailored to the individual based on the muscles involved, the severity of the spasticity, and the presence of local weakness. The manufacturer recommends a total dose of 50 units into the flexor digitorum profundus, the flexor digitorum sublimis, the flexor carpi radialis, or the flexor carpi ulnaris, and a total dose of 20 units into the adductor pollicis or flexor pollicis longus. In clinical studies, cumulative doses did not exceed 360 units at any treatment session.
- In the treatment of focal spasticity of the arm, the recommended total dose of botulinum A toxin as the preparation *Dysport* (*Ipsen*, *UK*) is 1000 units divided into: a dose of 150 units into the flexor digitorum profundus, the flexor carpi ulnaris, and the flexor carpi radialis; 150 to 250 units into the flexor digitorum superficialis; and 300 to 400 units into the biceps brachii. All muscles should be injected at one site except the biceps brachii which should be injected at 2 sites. Lower doses are recommended in patients whose target muscles are small, where the biceps brachii is not to be injected, or in patients receiving multi-level injections. Clinical improvement generally occurs within the first 2 weeks.

Stiff-man syndrome. A patient with stiff-man syndrome (see Muscle Spasm, p.993) had marked improvement of ambulation and cessation of pain after injection of botulinum A toxin into affected paraspinal muscles.[1] In another case report, improvement in rigidity and muscle spasm was reported[2] in 2 patients after botulinum treatment; muscle spasms reduced within 3 days of treatment. It was also found that there was an increase in the duration of effect of botulinum A toxin after each subsequent injection and only a gradual return of painful spasm.

Strabismus. Botulinum A toxin has been used to weaken overactive extra-ocular muscles as an alternative or adjunct to surgery in the correction of strabismus (p.1874). Not all patients respond to botulinum A toxin and many patients who do respond require more than one injection to maintain improvement. Botulinum A toxin does not appear to offer a better degree of correction than traditional surgery, and it has been suggested that it should be reserved for use in patients unresponsive to, or unsuitable for, surgery. In the USA botulinum A toxin as the preparation *Botox* (*Allergan*, *USA*) is indicated for the treatment of strabismus in patients 12 years of age or older. Depending on the direction and degree of deviation to be corrected the recommended initial dose of Botox to be injected into any one extra-ocular muscle ranges from 1.25 to 5 units. Paralysis is usually seen within the first 2 days and increases in intensity during the first week. The paralysis lasts for 2 to 6 weeks and gradually resolves over a further 2 to 6 weeks. It is recommended that patients are re-examined 7 to 14 days after injection to assess the effect of the dose given. If treatment is required for residual or recurrent strabismus, patients are either given treatment at the previous dosage if response was judged to have been adequate or up to twice the previous dose if paralysis had been incomplete; no more than 25 units should be injected into any one muscle. Repeat injections should not be given until the effects of the previous dose have dissipated. Injections should be diluted with unpreserved 0.9% sodium chloride solution so that the volume given per muscle is between 0.05 mL and 0.15 mL. Injections should also be made using an electromyographically guided needle to aid location of the target muscle.

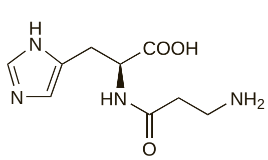
Carisoprodol *(BAN, rINN)*

Carisoprodolum; Isopropylmeprobamate; Karisoprodol; Karisoprodoli; Karizoprodol; Karizoprodolis. 2-Methyl-2-propyltrimethylene carbamate isopropylcarbamate.

Каризопродол

$C_{12}H_{24}N_2O_4$ = 260.3.
CAS — 78-44-4.
ATC — M03BA02.
ATC Vet — QM03BA02.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*

Ph. Eur. 6.2 (Carisoprodol). A white or almost white fine powder. M.p. 92° to 95°. Very slightly soluble in water; freely soluble in alcohol, in acetone, and in dichloromethane.

USP 31 (Carisoprodol). A white crystalline powder having a mild characteristic odour. M.p. 91° to 94°. Soluble 1 in 2083 of water, 1 in 2.5 of alcohol and of acetone, and 1 in 2.3 of chloroform. Store in airtight containers.

Dependence and Withdrawal, Adverse Effects, Treatment, and Precautions

As for Meprobamate, p.1006.

The most common adverse effects reported with carisoprodol are drowsiness, dizziness, and headache. Sedation may affect the performance of skilled tasks and affected patients should not drive or operate machinery. Poor metabolisers, deficient in the cytochrome P450 isoenzyme CYP2C19, may be at greater risk of drowsiness.

Idiosyncratic reactions may occur within minutes of a dose in patients who have not previously received carisoprodol. Such reactions have been reported rarely and include anaphylactic shock, syncope, tachycardia, confusion, transient quadriplegia, and bronchospasm. Cross-reactivity can occur with its metabolite meprobamate.

Overdosage may result in seizures, stupor, coma, shock, respiratory depression, and rarely death.

Carisoprodol should be used with caution in patients with impaired hepatic or renal function.

Cases of dependence and abuse have been reported with the prolonged use of carisoprodol, particularly in patients with a history of addiction; withdrawal reactions have also occurred when treatment is suddenly stopped after prolonged use or the use of high doses. The increased risk of abuse and addiction with carisoprodol, as well as the risk of altered mental state and psychomotor impairment, has led the EMEA and some other authorities to recommend that it is suspended from the market; in the USA, however, it is recommended that use is limited to 2 to 3 weeks.

Abuse. Analysis[1] of data from the Norwegian Prescription Database found that carisoprodol was used in higher doses than recommended indicating its potential as a drug of abuse. Subsequently, the Norwegian Medicines Agency and the EMEA have recommended for suspension (see above).

1. Bramness JG, *et al.* Carisoprodol use and abuse in Norway: a pharmacoepidemiological study. *Br J Clin Pharmacol* 2007; **64:** 210–18.

Breast feeding. Carisoprodol is distributed into breast milk, achieving concentrations 2 to 4 times those in maternal plasma; UK licensed product information and the *BNF* recommend that it is best avoided in women who are breast feeding although US licensed product information states to use with caution.

Dependence. There are reports of carisoprodol dependence, probably due to its metabolism to meprobamate.[1,2] In one case the patient had symptoms of meprobamate withdrawal that resolved with a dose-reducing schedule of meprobamate.

Dependence may occur more often when carisoprodol is given in high doses and for prolonged periods, especially in patients with a history of alcohol or drug dependence or in those with marked personality disorders. One group[2] found that patients with a history of substance abuse were twice as likely to use carisoprodol in larger doses to those prescribed than those with no such history.

The risk of dependence with carisoprodol has led the EMEA and some other authorities to recommend its suspension from the market (see above).

1. Luehr JG, *et al.* Mail-order (veterinary) drug dependence. *JAMA* 1990; **263:** 657.
2. Reeves RR, *et al.* Carisoprodol (Soma): abuse potential and physician unawareness. *J Addict Dis* 1999; **18:** 51–6.

Porphyria. Carisoprodol has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The CNS effects of carisoprodol may be potentiated by alcohol or other CNS depressants. Carisoprodol may cause hepatic enzyme induction and it may therefore affect the metabolism of a number of drugs. The metabolism of carisoprodol is mediated by the cytochrome P450 isoenzyme CYP2C19; use with other drugs that inhibit or induce this isoenzyme may result in changes in plasma concentration of carisoprodol, however, there is a lack of data.

Pharmacokinetics

Carisoprodol is absorbed from the gastrointestinal tract and peak plasma concentrations are reached after 1.5 to 2 hours. It is metabolised in the liver mainly by the cytochrome P450 isoenzyme CYP2C19, which shows genetic polymorphism, and excreted in urine as metabolites, including meprobamate. The terminal elimination half-life of carisoprodol is about 2 hours. It is distributed in substantial amounts into breast milk.

◊ References.

1. Olsen H, *et al.* Carisoprodol elimination in humans. *Ther Drug Monit* 1994; **16:** 337–40.

Uses and Administration

Carisoprodol is a centrally acting skeletal muscle relaxant whose mechanism of action is not completely understood but may be related to its sedative actions. After oral doses its effects begin within about 30 minutes and last for 4 to 6 hours. It is used as an adjunct in the short-term symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. A usual oral dose is 250 to 350 mg given three or four times daily for up to 2 to 3 weeks. Half the usual dose or less is recommended in elderly patients. It is also given with analgesics in compound preparations.

The EMEA and some other authorities have recommended for carisoprodol to be suspended from the market due to the increased risk of abuse and addiction, as well as the risk of altered mental state and psychomotor impairment.

Preparations

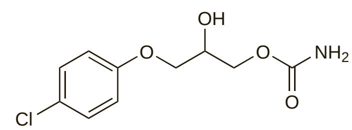
Chlorphenesin Carbamate *(BANM, USAN, pINNM)*

Carbamato de clorfenesina; Chlorphénésine, Carbamate de; Chlorphenesini Carbamatum; U-19646. 3-(4-Chlorophenoxy)propane-1,2-diol 1-carbamate.

Хлорфенезина Карбамат

$C_{10}H_{12}ClNO_4$ = 245.7.
CAS — 104-29-0 (chlorphenesin); 886-74-8 (chlorphenesin carbamate).



Pharmacopoeias. In *Jpn.*

Adverse Effects and Precautions

Chlorphenesin carbamate produces drowsiness and dizziness. There may also be nausea, headache, weakness, confusion, agitation, and insomnia. Hypersensitivity reactions have been reported. There are rare reports of blood disorders.

It should be used with caution in patients with hepatic impairment. Patients affected by drowsiness should not drive or operate machinery.

Interactions

The CNS effects of chlorphenesin carbamate may be potentiated by alcohol or other CNS depressants.

Pharmacokinetics

Chlorphenesin carbamate is readily and completely absorbed from the gastrointestinal tract and partly metabolised in the liver. It is excreted in the urine, mainly as the glucuronide metabolite.

Uses and Administration

Chlorphenesin carbamate is a centrally acting skeletal muscle relaxant related to mephenesin (p.1897). Its mode of action may be related to general depressant effects on the CNS. It is used as an adjunct in the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. The usual initial oral dose is 250 mg three times daily, adjusted according to response. It has been recommended that chlorphenesin carbamate should not be given for longer than 8 weeks.

Chlorphenesin base (p.529) is used as an antifungal.

Preparations

Proprietary Preparations (details are given in Part 3)

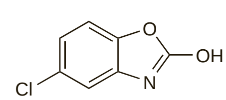
Chlorzoxazone *(BAN, rINN)*

Chlorobenzoxazolinone; Chlorzoxazonum; Clorzoxazona; Klooritsoksatsoni; Klorzoksazon; Klorzoxazon. 5-Chlorobenzoxazol-2(3*H*)-one.

Хлорзоксазон

$C_7H_4ClNO_2$ = 169.6.
CAS — 95-25-0.
ATC — M03BB03.
ATC Vet — QM03BB03.



Pharmacopoeias. In *US.*

USP 31 (Chlorzoxazone). A white or practically white, practically odourless, crystalline powder. Slightly soluble in water; sparingly soluble in alcohol, in isopropyl alcohol, and in methyl alcohol; soluble in solutions of alkali hydroxides and ammonia. Store in airtight containers.

Adverse Effects and Treatment

The most common adverse effects of chlorzoxazone are drowsiness and dizziness. There may occasionally also be gastrointestinal irritation and gastrointestinal bleeding has been reported rarely. Other effects that have occurred are headache, overstimulation, and rarely sensitivity reactions including skin rashes, petechiae, ecchymoses, urticaria and pruritus; very rarely, angioedema or anaphylactoid reactions may occur. Some patients taking chlorzoxazone have developed jaundice and liver damage suspected to be caused by the drug.

After overdosage there may be gastrointestinal disturbances, drowsiness, dizziness, headache, malaise, and sluggishness followed by marked loss of muscle tone, hypotension, and respiratory depression. Emptying the stomach by lavage should be considered, followed by activated charcoal and supportive therapy.

Effects on the liver. Hepatotoxicity, sometimes fatal, has been associated with chlorzoxazone treatment.[1]

1. Powers BJ, *et al.* Chlorzoxazone hepatotoxic reactions: an analysis of 21 identified or presumed cases. *Arch Intern Med* 1986; **146:** 1183–6.

Overdosage. Overdosage and coma occurred on 2 occasions in a patient taking chlorzoxazone; on the second occasion, the patient responded to intravenous flumazenil.[1]

1. Roberge RJ, *et al.* Two chlorzoxazone (Parafon forte) overdoses and coma in one patient: reversal with flumazenil. *Am J Emerg Med* 1998; **16:** 393–5.

Torticollis. There has been a report of a patient with a spasmodic torticollis-like syndrome, consisting of tonic deviation of the head to the right, clenching of the teeth, and dysarthria, which developed repeatedly within 2 hours of ingesting chlorzoxazone for low back pain.[1] Intravenous injection of benzatropine mesilate 1 mg gave rapid relief of symptoms.

1. Rosin MA. Chlorzoxazone-induced spasmodic torticollis. *JAMA* 1981; **246:** 2575.

Precautions

Chlorzoxazone should not be given to patients with impaired liver function and should be stopped if signs of liver toxicity appear. Patients should be advised to report to their doctor any signs or symptoms of possible liver toxicity such as fever, rash, jaundice, dark urine, anorexia, nausea, vomiting, or right upper quadrant pain. Chlorzoxazone may cause drowsiness; patients affected should not drive or operate machinery.

The urine of patients taking chlorzoxazone may be coloured orange or reddish-purple by a phenolic metabolite.

Porphyria. Chlorzoxazone has been associated with acute attacks of porphyria and is considered unsafe in porphyric patients.

Interactions

The CNS effects of chlorzoxazone may be enhanced by alcohol and other CNS depressants.

Disulfiram. A study[1] of the efficacy of disulfiram as an inhibitor of the cytochrome P450 isoenzyme CYP2E1 (an enzyme involved in the metabolism of chlorzoxazone) found that a single 500-mg dose of disulfiram reduced plasma clearance of chlorzoxazone by 85%, resulting in a doubling of the latter's peak plasma concentrations and prolongation of its elimination half-life from a mean of 0.92 to 5.1 hours.

1. Kharasch ED, *et al.* Single-dose disulfiram inhibition of chlorzoxazone metabolism: a clinical probe for P450 2E1. *Clin Pharmacol Ther* 1993; **53:** 643–50.

Isoniazid. Isoniazid inhibited the clearance of chlorzoxazone by 56% when given to 10 slow acetylator subjects resulting in an increase in sedation, headache, and nausea.[1] Two days after stopping isoniazid there had been a rebound increase in the clearance of chlorzoxazone by 56% over the pre-isoniazid clearance value. Similar but less pronounced effects have also been reported[2] in rapid acetylators with chlorzoxazone's pharmacokinetic parameters returning to baseline values in 2 days.

1. Zand R, *et al.* Inhibition and induction of cytochrome P4502E1-catalyzed oxidation by isoniazid in humans. *Clin Pharmacol Ther* 1993; **54:** 142–9.
2. O'Shea D, *et al.* Modulation of CYP2E1 activity by isoniazid in rapid and slow N-acetylators. *Br J Clin Pharmacol* 1997; **43:** 99–103.

Pharmacokinetics

Chlorzoxazone is reported to be completely absorbed after oral doses and peak plasma concentrations are achieved after 1 to 2 hours. It is rapidly metabolised in the liver via the cytochrome P450 isoenzyme CYP2E1, mainly to 6-hydroxychlorzoxazone, and excreted in the urine primarily as the glucuronide metabolite. The elimination half-life of chlorzoxazone is about 1 hour.

Uses and Administration

Chlorzoxazone is a centrally acting skeletal muscle relaxant with sedative properties. It is claimed to inhibit muscle spasm by exerting an effect primarily at the level of the spinal cord and subcortical areas of the brain. Its effects begin within an hour of an oral dose and last for 3 to 4 hours.

It is used as an adjunct in the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. The usual initial oral dose is 500 mg three or four times daily; the dose can often be reduced subsequently to 250 mg three or four times daily, although doses of up to 750 mg three or four times daily may be given if necessary. Chlorzoxazone is also given with analgesics in compound preparations.

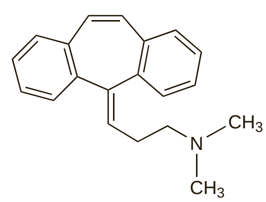
ATC Vet — QM03BX08.



(cyclobenzaprine)

NOTE. The following terms have been used as 'street names' (see p.vi) or slang names for various forms of cyclobenzaprine hydrochloride:

Cyclo; Cyclone.

Pharmacopoeias. In *US.*

USP 31 (Cyclobenzaprine Hydrochloride). A white to off-white, odourless, crystalline powder. Freely soluble in water, in alcohol, and in methyl alcohol; sparingly soluble in isopropyl alcohol; slightly soluble in chloroform and in dichloromethane; insoluble in hydrocarbons.

Adverse Effects, Treatment, and Precautions

Cyclobenzaprine is structurally related to the tricyclic antidepressants and shares their adverse effects and precautions (see Amitriptyline, p.376). Cyclobenzaprine should be used with caution in the elderly and patients with hepatic impairment; use in moderate to severe hepatic impairment is not recommended.

It may cause drowsiness; patients affected should not drive or operate machinery.

The elderly. Symptoms of toxicity[1] (hallucinations, insomnia, and restlessness) were seen in a 76-year-old patient taking cyclobenzaprine at therapeutic doses. US licensed product information states that the elderly may be more likely to experience adverse effects such as hallucinations and confusion..

In another study[2] the mean elimination half-life of cyclobenzaprine in the elderly was longer than in younger subjects and clearance was reduced. It was suggested that it should be used in a reduced dose or frequency in the elderly.

1. Douglass MA, Levine DP. Hallucinations in an elderly patient taking recommended doses of cyclobenzaprine. *Arch Intern Med* 2000; **160:** 1373.
2. Winchell GA, *et al.* Cyclobenzaprine pharmacokinetics, including the effects of age, gender, and hepatic insufficiency. *J Clin Pharmacol* 2002; **42:** 61–9.

Neuroleptic malignant syndrome. Report of a neuroleptic malignant-like syndrome associated with cyclobenzaprine in a 36-year-old man.[1] It was not clear whether the syndrome was due to an idiosyncratic reaction or to an overdose.

1. Theoharides TC, *et al.* Neuroleptic malignant-like syndrome due to cyclobenzaprine. *J Clin Psychopharmacol* 1995; **15:** 79–81.

Overdosage. Treatment of cyclobenzaprine overdose is mainly symptomatic and supportive. A large retrospective study[1] found that cyclobenzaprine hydrochloride overdoses of up to 1 g rarely present with the serious cardiovascular and neurological effects seen with tricyclic antidepressant overdoses. There were no reports of seizures, life-threatening arrhythmias, or fatalities. However, 150 patients required treatment in the intensive care unit, 13 patients needed assisted ventilation, and 8 were unresponsive to stimuli. It was noted that observation may be sufficient for overdoses of under 50 mg in children.

1. Spiller HA, *et al.* Five-year multicentre retrospective review of cyclobenzaprine toxicity. *J Emerg Med* 1995; **13:** 781–5.

Interactions

Cyclobenzaprine is structurally related to the tricyclic antidepressants and may be subject to similar interactions (see Amitriptyline, p.379). The CNS effects of cyclobenzaprine may be enhanced by alcohol or other CNS depressants.

Antidepressants. A patient who already had QT prolongation associated with use of cyclobenzaprine and *fluoxetine*. developed torsade de pointes, progressing into ventricular fibrillation, when given *droperidol* as premedication prior to surgery.[1] QT abnormalities resolved on stopping cyclobenzaprine.

1. Michalets EL, *et al.* Torsade de pointes resulting from the addition of droperidol to an existing cytochrome P450 drug interaction. *Ann Pharmacother* 1998; **32:** 761–5.

Antipsychotics. For a report of an interaction between cyclobenzaprine and *droperidol*, see Antidepressants above.

Pharmacokinetics

Cyclobenzaprine hydrochloride is readily and almost completely absorbed from the gastrointestinal tract, although plasma concentrations vary considerably among individuals given the same dose. About 93% is bound to plasma proteins and has a reported effective half-life of 8 to 37 hours. It is extensively metabolised, principally to glucuronide conjugates, and excreted in the urine. Cytochrome P450 isoenzymes CYP3A4, CYP1A2, and to a lesser extent CYP2D6 mediate its demethylation. Some unchanged drug appears in the bile and is excreted in the faeces.

◊ References.

Uses and Administration

Cyclobenzaprine hydrochloride is a centrally acting skeletal muscle relaxant, related to the tricyclic antidepressants. It acts mainly at the brain stem to decrease tonic somatic motor activity influencing both alpha and gamma motor systems. Additional activity at spinal cord sites may be involved. Effects begin within 1 hour of a dose by mouth; the effects of a single dose have been reported to last as long as 12 to 24 hours.

It is used as an adjunct in the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. The usual dose is 5 mg three times daily given by mouth, increased if necessary to 10 mg three times daily. Treatment for more than 2 or 3 weeks is not recommended. A starting dose of 5 mg with less frequent dosing is recommended for elderly patients. For doses in patients with hepatic impairment, see below. A modified-release preparation of cyclobenzaprine hydrochloride is also available for once-daily dosing.

Administration in hepatic impairment. A starting dose of 5 mg of cyclobenzaprine hydrochloride by mouth, and perhaps less frequent dosing than usual (see above), is recommended for those with mild hepatic impairment; use in moderate to severe hepatic impairment is not recommended.

Back pain. A meta-analysis[1] of 14 studies concluded that cyclobenzaprine hydrochloride, in the short term, improves low back pain (p.7). Doses given to patients were titrated and ranged from 10 to 60 mg daily with a median dose of 30 mg daily. Patients improved moderately in the first 4 days of treatment, with the effects of cyclobenzaprine hydrochloride gradually declining with time although there was some evidence of continued improvement at 2 weeks. Further studies are needed to determine the optimal length of use in the management of acute back pain. Adverse effects were common, occurring in at least 53% of patients.

1. Browning R, *et al.* Cyclobenzaprine and back pain: a meta-analysis. *Arch Intern Med* 2001; **161:** 1613–20.

Fibromyalgia. Studies of the efficacy of cyclobenzaprine in the management of fibromyalgia, a painful musculoskeletal disorder which usually responds poorly to analgesics (see Soft-tissue Rheumatism, p.13), have produced conflicting results but a meta-analysis[1] of 5 such studies suggested that cyclobenzaprine had some modest benefit in the condition. Patients were more likely to report overall improvement and moderate reductions in individual symptoms, particularly sleep, while taking the drug.

Dantrolene Sodium *(BANM, USAN, rINNM)*

Dantrolène Sodique; Dantroleno sódico; F-440; F-368 (dantrolene); Natrii Dantrolenum; Sodyum Dantrolen. The hemiheptahydrate of the sodium salt of 1-[5-(4-nitrophenyl)furfurylideneamino]imidazolidine-2,4-dione.

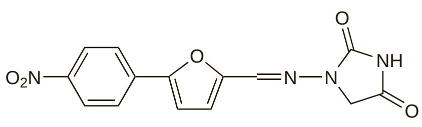
Натрий Дантролен

$C_{14}H_9N_4NaO_5,3\frac{1}{2}H_2O$ = 399.3.

CAS — 7261-97-4 (dantrolene); 14663-23-1 (anhydrous dantrolene sodium); 24868-20-0 (dantrolene sodium, hemiheptahydrate).

ATC — M03CA01.

ATC Vet — QM03CA01.



(dantrolene)

Pharmacopoeias. In *Br., Jpn,* and *US.*

BP 2008 (Dantrolene Sodium). A yellowish-orange to orange crystalline powder. Very slightly soluble in water; slightly soluble in alcohol; practically insoluble in acetone; sparingly soluble in methyl alcohol.

USP 31 (Dantrolene Sodium). A fine orange to orange-brown powder. Sparingly soluble in acetone, in dimethyformamide, and in glycerol. Store in airtight containers. Protect from light.

Adverse Effects

Adverse effects associated with dantrolene sodium tend to occur at the start of treatment, but are often short lived and can be controlled by adjusting the dose. The most common adverse effects are drowsiness, dizziness, fatigue, weakness, and general malaise. Diarrhoea may be severe enough to require withdrawal. If diarrhoea recurs on restarting dantrolene, then treatment should probably be stopped permanently. Other adverse effects reported include nausea and vomiting, anorexia, constipation, abdominal cramps, gastrointestinal bleeding, tachycardia, unstable blood pressure, dyspnoea, rashes (often acneform), pruritus, chills and fever, headache, myalgia, nervousness, insomnia, confusion, visual disturbances, mental depression, dysphagia and speech disturbances, and seizures. Haematuria, crystalluria, urinary frequency and retention, and incontinence may occur. Rare but serious adverse effects include hepatotoxicity which may be fatal (see below) and pleural effusion with pericarditis.

Serious adverse effects do not appear to be a problem with the short-term use of intravenous dantrolene sodium in the treatment of malignant hyperthermia.

Effects on the liver. Dantrolene has caused hepatotoxicity with raised liver enzyme values, jaundice, and hepatitis;[1-3] fatalities have been reported.[1,3] Not all patients experienced symptoms such as anorexia, nausea, or abdominal discomfort before the onset of disease and the severity of hepatic injury was unrelated to clinical presentation. In the first report[1] the 14 fatalities occurred with doses in excess of 200 mg daily; a later review[3] found the mean dose associated with 27 fatalities to be 582 mg daily, while reports of non-fatal liver toxicity (95 cases) were associated with a mean dose of 263 mg daily. The onset of hepatic injury was usually between 1 and 6 months after starting treatment and fatalities were not reported in the first 2 months. Only rarely did injury develop before 45 days of treatment. Females appeared to be at greater risk of serious liver injury and the severity of reaction appeared to be age-related with most fatalities occurring in patients over 30 years of age. The liver injury was usually hepatocellular and might include ascending cholangitis; there was little evidence of hypersensitivity.

3. Chan CH. Dantrolene sodium and hepatic injury. *Neurology* 1990; **40:** 1427–32.

Effects on the lungs. Pulmonary oedema associated with heart failure,[1] and pleural effusions with eosinophilia[2-4] have been reported rarely in patients receiving dantrolene. These reactions generally resolve on withdrawal of the drug but resolution may take several months; corticosteroid therapy may be of benefit in dantrolene-related eosinophilic pleural effusion.[3]

4. Le-Quang B, *et al.* Dantrolene and pleural effusion: case report and review of literature. *Spinal Cord* 2004; **42:** 317–20.

Lymphomas. A case of fatal lymphocytic lymphoma was associated with prolonged dantrolene therapy (600 mg daily) for progressive spastic paraplegia.[1]

1. Wan HH, Tucker JS. Dantrolene and lymphocytic lymphoma. *Postgrad Med J* 1980; **56:** 261–2.

Precautions

It is recommended that dantrolene sodium should not be given to patients with active liver disease. Liver-function tests should be performed in all patients before and during treatment; if abnormal values are found, treatment should generally be stopped. The risk of liver injury may be increased in patients over 30 years of age, in females (especially those taking oestrogens), in those with a history of liver disease, and with doses above 400 mg daily (see under Effects on the Liver, above). Dantrolene sodium should be used with caution in patients with cardiac or pulmonary disorders. It should not be given to patients who use their spasticity to maintain posture or function or to patients with acute muscle spasm.

Dantrolene sodium may cause drowsiness; patients affected should not drive or operate machinery.

Interactions

The CNS effects of dantrolene sodium may be enhanced by alcohol or other CNS depressants. Use with other potentially hepatotoxic drugs such as oestrogens may possibly increase the risk of liver damage and should be avoided.

Calcium-channel blockers. Severe hyperkalaemia and myocardial depression occurred with intravenous dantrolene for prophylaxis of malignant hyperthermia in a patient also taking *verapamil* for angina.[1] The peak serum-potassium concentration was 7.1 mmol/litre 2.5 hours after the dantrolene infusion. *Nifedipine* was substituted for verapamil in a subsequent operation and only a small increase in serum potassium occurred after dantrolene. Ventricular fibrillation and cardiovascular collapse associated with hyperkalaemia have been seen with this combination in *animal* studies, and the manufacturers recommend that calcium-channel blockers and intravenous dantrolene should not be used together.

1. Rubin AS, Zablocki AD. Hyperkalaemia, verapamil, and dantrolene. *Anesthesiology* 1987; **66:** 246–9.

Pharmacokinetics

Dantrolene sodium is slowly and almost completely absorbed from the gastrointestinal tract after oral doses. It is metabolised in the liver mainly to the hydroxylated metabolite, which is nearly as potent as dantrolene sodium, and the acetamide metabolite which has weak muscle relaxant activity. It is excreted in the urine, mainly as metabolites with a small amount of unchanged dantrolene; some is excreted in the bile. Dantrolene is bound extensively to plasma proteins. The elimination half-life of oral dantrolene is about 9 hours, although half-lives of up to 12 hours have been reported after intravenous use.

Uses and Administration

Dantrolene sodium is a muscle relaxant with a direct action on skeletal muscle. It uncouples muscular contraction from excitation, probably by interfering with the release of calcium from the sarcoplasmic reticulum.

It has an important role when given orally, for the symptomatic relief of chronic, severe spasticity (p.1887). It is also given, usually by intravenous injection, for the treatment of malignant hyperthermia.

For **spasticity**, the initial oral dose is 25 mg daily increased gradually as necessary, at 7-day intervals, over about 7 weeks to a maximum dose of 100 mg four times daily. If no response is achieved within 45 days treatment should be stopped. In children, US licensed product information suggests a dose of 500 micrograms/kg once daily, increased gradually if necessary to 2 mg/kg three times daily; dosage four times daily may be necessary for some children but a dose of 100 mg four times daily should not be exceeded.

In the treatment of **malignant hyperthermia**, dantrolene sodium is given, with supportive measures, in an initial dose of 1 mg/kg by rapid intravenous injection, repeated, if necessary, to a total dose of 10 mg/kg. An average dose of 2.5 mg/kg is usually effective. If a relapse or recurrence occurs, dantrolene should be given again at the last effective dose. In the USA, doses of 1 to 2 mg/kg orally four times daily have been recommended for up to 3 days after the crisis to prevent recurrence, and similar doses have been given for 1 to 2 days before surgery in individuals thought to be at risk of developing the syndrome. Prophylactic doses may also be given intravenously; 2.5 mg/kg has been recommended, infused over about 60 minutes, starting about 75 minutes before anticipated anaesthesia, with further doses during anaesthesia and surgery if signs of malignant hyperthermia develop.

Hyperthermia. Dantrolene is used in the treatment of hyperthermia associated with muscle rigidity and fulminant hypermetabolism of skeletal muscle, which occurs in the neuroleptic malignant syndrome (see below and p.972) and in malignant hyperthermia (see below). There is also anecdotal evidence that dantrolene may produce beneficial effects for the treatment of similar symptoms resulting from poisoning with various agents such as carbon monoxide,[1] MAOIs,[2] and ethyltenamfetamine.[3] However, after suggestions that it might also be of use in cocaine intoxication, the manufacturers[4] warned physicians that they should not regard dantrolene as an effective treatment for all types of hyperthermia and rigidity accompanying poisoning.

Dantrolene has been tried as part of treatment for heat stroke (see under Fever and Hyperthermia, p.10) but does not appear to affect outcome.[5]

MALIGNANT HYPERTHERMIA. Malignant hyperthermia (malignant hyperpyrexia) is a rare but potentially fatal syndrome associated with general anaesthesia, in which a sudden increase in the concentration of calcium in muscle cytoplasm initiates a series of metabolic disturbances. The disorder appears to be genetically determined and is more common in males. In susceptible individuals a reaction may be induced by inhalation anaesthetics (mainly halogenated hydrocarbons), suxamethonium, prolonged anaesthesia, pre-operative exercise, muscle trauma, fever, or anxiety. However, many reactions occur in individuals who have had uneventful general anaesthesia previously. Early signs and symptoms of the syndrome include tachycardia, unstable blood pressure, hypercapnia, rising temperature, and hyperventilation followed by metabolic acidosis and hyperkalaemia. Muscle rigidity develops in many patients and later there may be evidence of muscle damage including raised serum concentrations of creatine phosphokinase and other enzymes, myoglobinaemia, and myoglobinuria. Hyperthermia develops relatively late. Other late complications may include renal failure, intravascular coagulopathy, and pulmonary oedema.

Treatment should be started as soon as possible after symptoms appear with dantrolene being given by rapid intravenous injection until symptoms disappear.[1-3] Supportive treatment must also be given including immediate withdrawal of anaesthesia, giving oxygen, correction of acidosis with sodium bicarbonate, control of hyperkalaemia with insulin, and cooling procedures (see p.10).

The incidence of reactions in susceptible individuals can be reduced by avoiding triggering agents. Dantrolene has also been given prophylactically, but a high incidence of adverse effects has been reported,[4] and such use is not generally recommended.[3]

Susceptibility to malignant hyperthermia can be detected by histological examination of muscle fibres obtained by biopsy and study of their response to caffeine and/or halothane *in vitro*. Although such testing remains the gold standard for determining susceptibility, genetic testing is also being developed as an alternative.[5]

Dantrolene has been suggested[6] for use as a secondary drug in the treatment of a related and potentially fatal syndrome that has developed in some children after induction of anaesthesia with halothane and suxamethonium (see also Children, under Precautions of Suxamethonium, p.1911).

6. Rosenberg H, Gronert GA. Intractable cardiac arrest in children given succinylcholine. *Anesthesiology* 1992; **77:** 1054.

Neuroleptic malignant syndrome. Dantrolene has been used, usually alone or with bromocriptine, in the treatment of neuroleptic malignant syndrome (p.972), although some workers have not found it to be of use,[1] and evidence from controlled trials is lacking.[2] Doses reported for dantrolene have varied greatly.[3,4] For those patients unable to swallow and when rapid control of symptoms is required, doses of 1 mg/kg or more have been given initially by intravenous injection. Up to 600 mg has been given daily by mouth in divided doses.

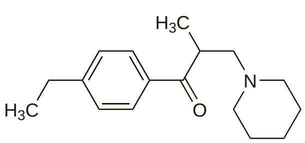
Eperisone Hydrochloride *(rINNM)*

Épérisone, Chlorhydrate d'; Eperisoni Hydrochloridum; Hidrocloruro de eperisona. 4′-Ethyl-2-methyl-3-piperidinopropiophenone hydrochloride.

Эперизона Гидрохлорид

$C_{17}H_{25}NO,HCl = 295.8$.

CAS — 64840-90-0 (eperisone); 56839-43-1 (eperisone hydrochloride).



(eperisone)

Pharmacopoeias. In *Jpn.*

Profile

Eperisone is a centrally acting skeletal muscle relaxant that has been used in the symptomatic treatment of painful muscle spasm (p.1887) and spasticity (p.1887). It may also have a vasodilator action. Eperisone hydrochloride has been given by mouth in usual doses of 50 mg three times daily after food.

Effects on the skin. A non-pigmenting fixed drug eruption developed in a 42-year-old woman after taking oral diclofenac sodium and eperisone hydrochloride.[1] There was no residual hyperpigmentation and the rash and accompanying itching and burning sensation resolved within 7 days after stopping both drugs. On rechallenge with eperisone, an erythematous plaque developed at the same site within a couple of hours. The lesion disappeared within 5 days with no sequelae.

1. Choonhakarn C. Non-pigmenting fixed drug eruption: a new case due to eperisone hydrochloride. *Br J Dermatol* 2001; **144:** 1288–9.

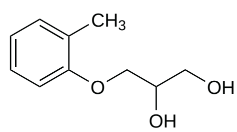
CAS — 59-47-2.
ATC — M03BX06.
ATC Vet — QM03BX06.



NOTE. The name tolynol has been applied to both mephenesin and *p*,α-dimethylbenzyl alcohol (p.2294).

Pharmacopoeias. In *It.*

Profile

Mephenesin is a centrally acting skeletal muscle relaxant used for the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. Its clinical usefulness is considered to be limited by its brief duration of action. It is given orally in doses of 1.5 to 3 g daily in divided doses. It is also applied topically, usually with rubefacients.

Porphyria. Mephenesin is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *in-vitro* systems.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Decontractyl; ***Ger.:*** DoloVisano M.

Multi-ingredient: ***Belg.:*** Algipan; ***Fr.:*** Algipan; Decontractyl; Traumalgyl; ***India:*** Acks; Flamar; Inflazone; Medicreme; Relaxyl; ***Ital.:*** Relaxar; ***S.Afr.:*** Spasmend.

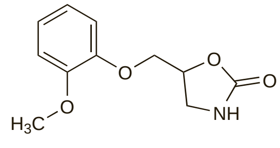
Mephenoxalone *(rINN)*

AHR-233; Mefenoksalon; Mefenoxalona; Méphénoxalone; Mephenoxalonum; Methoxadone; OM-518. 5-(2-Methoxyphenoxymethyl)oxazolidin-2-one.

Мефеноксалон

$C_{11}H_{13}NO_4 = 223.2$.

CAS — 70-07-5.
ATC — N05BX01.
ATC Vet — QN05BX01.



Profile

Mephenoxalone has actions similar to those of meprobamate (p.1006). It has been given orally in a dose of 200 to 400 mg three times daily as a muscle relaxant in the treatment of muscle spasm (p.1887). It has also been given for the treatment of anxiety.

Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Dimexol; Dorsiflex; ***Neth.:*** Dorsiflex; ***Turk.:*** Dorsiflex.

Multi-ingredient: ***Turk.:*** Dorsilon.

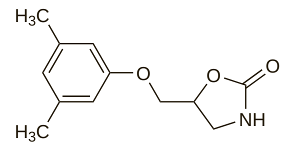
Metaxalone *(BAN, USAN, rINN)*

AHR-438; Metaxalona; Métaxalone; Metaxalonum. 5-(3,5-Xylyloxymethyl)oxazolidin-2-one.

Метаксалон

$C_{12}H_{15}NO_3 = 221.3$.

CAS — 1665-48-1.



Adverse Effects, Treatment, and Precautions

As for Chlorzoxazone, p.1895.

Metaxalone may cause drowsiness; patients affected should not drive or operate machinery.

Patients taking metaxalone excrete in the urine a metabolite which gives a false positive reaction to copper sulfate-based tests for glycosuria.

Interactions

The CNS effects of metaxalone may be enhanced by alcohol and other CNS depressants.

Pharmacokinetics

Metaxalone is absorbed from the gastrointestinal tract, metabolised in the liver, and excreted in urine as metabolites. The plasma elimination half-life is about 2 to 3 hours.

Uses and Administration

Metaxalone is a centrally acting skeletal muscle relaxant. Its mode of action may be related to its sedative properties.

It is used as an adjunct in the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. The usual oral dose is 800 mg three or four times daily.

Preparations

Proprietary Preparations (details are given in Part 3)
USA: Skelaxin.

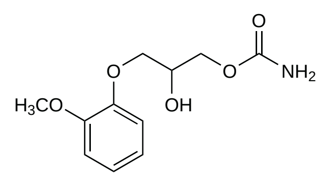
Methocarbamol *(BAN, rINN)*

Guaiphenesin Carbamate; Méthocarbamol; Methocarbamolum; Metocarbamol; Metokarbamol; Metokarbamoli. 2-Hydroxy-3-(2-methoxyphenoxy)propyl carbamate.

Метокарбамол

$C_{11}H_{15}NO_5 = 241.2$.

CAS — 532-03-6.
ATC — M03BA03.
ATC Vet — QM03BA03.



Pharmacopoeias. In *US.*

USP 31 (Methocarbamol). A white powder, odourless or having a slight characteristic odour. M.p. about 94° or, if previously ground to a fine powder, about 90°. Soluble 1 in 40 of water at 20°; sparingly soluble in chloroform; soluble in alcohol only with heating; insoluble in *n*-hexane and in benzene. Store in airtight containers.

Adverse Effects

Adverse effects reported with methocarbamol include nausea, vomiting, anorexia, lightheadedness, dizziness, lassitude, drowsiness, restlessness, anxiety, confusion, tremor, vertigo, blurred vision, fever, headache, convulsions, and hypersensitivity reactions including rashes, pruritus, urticaria, angioedema, and conjunctivitis with nasal congestion.

After injection patients may experience flushing and a metallic taste; incoordination, diplopia, nystagmus, vertigo, syncope, hypotension, bradycardia, and anaphylaxis have been reported. There may be sloughing and thrombophlebitis at the site of injection.

Precautions

Methocarbamol is contra-indicated in coma or pre-coma states, brain damage, myasthenia gravis, or in patients with a history of epilepsy. Caution is advisable in renal or hepatic impairment.

Methocarbamol may cause drowsiness; patients affected should not drive or operate machinery.

Preparations for injection may contain, as a solvent, a macrogol which could increase existing acidosis and urea retention in patients with renal impairment; such preparations should not be used in patients with known or suspected renal disease.

Abnormal coloration. Methocarbamol has been reported to cause brown to black or green discoloration of the urine on standing.[1]

1. Baran RB, Rowles B. Factors affecting coloration of urine and feces. *J Am Pharm Assoc* 1973; **NS13:** 139–42.

Interactions

The CNS effects of methocarbamol may be potentiated by alcohol or other CNS depressants. Methocarbamol has also been reported to potentiate the effects of anorectics and antimuscarinics, and to inhibit the effect of pyridostigmine.

Pharmacokinetics

Methocarbamol is rapidly and almost completely absorbed from the gastrointestinal tract after oral doses. Its plasma half-life is reported to be about 1 to 2 hours. It is metabolised by dealkylation and hydroxylation and is excreted in urine primarily as the glucuronide and sulfate conjugates of its metabolites. A small amount is excreted in faeces.

Uses and Administration

Methocarbamol is a centrally acting skeletal muscle relaxant whose action may be due to general depressant effects on the CNS.

Methocarbamol is used as an adjunct in the short-term symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions. It is sometimes given with analgesics in compound preparations for the treatment of musculoskeletal pain.

The usual initial oral dose for muscle spasm is 1.5 g four times daily, reduced to a maintenance dose of about 4 g daily after 2 to 3 days. A dose of 750 mg three times daily may be sufficient for a therapeutic effect. Half the maximum daily dose or less may be sufficient for elderly patients.

Methocarbamol has also been given intravenously at a rate of not more than 300 mg/minute, by slow injection or by infusion in sodium chloride 0.9% or glucose 5% injection. The parenteral route should not be used for more than 3 consecutive days and the dose should not exceed 3 g daily. The patient should remain lying down during, and for 10 to 15 minutes after, intravenous doses. The US manufacturers state that the injection is hypertonic and extravasation should be avoided. However, it may also be given by intramuscular injection in a dose of up to 500 mg into each gluteal region at intervals of 8 hours.

Preparations

USP 31: Methocarbamol Injection; Methocarbamol Tablets.

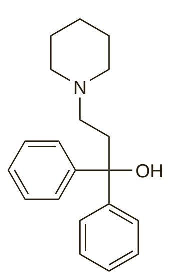
CAS — 511-45-5 (pridinol); 968-58-1 (pridinol hydrochloride); 6856-31-1 (pridinol mesilate).
ATC — M03BX03.
ATC Vet — QM03BX03.



(pridinol)

Profile

Pridinol mesilate is a centrally acting muscle relaxant used in the symptomatic treatment of muscle spasm (p.1887). The usual initial oral dose is 2 to 8 mg three times daily, reduced to 4 to 8 mg daily for maintenance treatment. It is also given by intramuscular injection or rectally, and has been applied in compound topical preparations.

Pridinol has been used as the hydrochloride for its antimuscarinic properties in the management of parkinsonism (p.791).

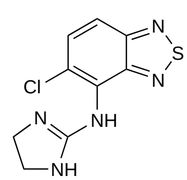
ATC — M03BX02.
ATC Vet — QM03BX02.



(tizanidine)

Pharmacopoeias. In *Jpn* and *US.*

USP 31 (Tizanidine Hydrochloride). Store in airtight containers.

Adverse Effects and Precautions

Tizanidine hydrochloride may cause drowsiness; patients affected should not drive or operate machinery. Other adverse effects include dry mouth, fatigue, dizziness or vertigo, muscle pain and weakness, insomnia, anxiety, headache, bradycardia, nausea, and gastrointestinal disturbances. Hallucinations have occurred on rare occasions. Many adverse effects have been found to be dose related and slow titration of doses appears to reduce the frequency of occurrence. Hypotension may occur.

Increases in liver enzymes and rarely acute hepatitis have been associated with tizanidine and it is contra-indicated in patients with severe hepatic dysfunction. In the UK it is recommended that liver function should be monitored monthly in all patients for the first 4 months and in those who develop symptoms suggestive of hepatic dysfunction; similarly, in the USA baseline assessment and monitoring at 1, 3, and 6 months is advised. Treatment should be stopped if liver enzymes are persistently raised.

Caution is required in the elderly and in patients with renal insufficiency.

Interactions

Tizanidine is metabolised by the cytochrome P450 isoenzyme CYP1A2 and use with ciprofloxacin or fluvoxamine, both potent inhibitors of this isoenzyme, is contra-indicated. Use with other more moderate inhibitors of CYP1A2 (such as other quinolone antibacterials, cimetidine, and antiarrhythmics such as amiodarone, mexiletine, propafenone, and verapamil) should be avoided unless clinically necessary. The CNS effects of tizanidine may be enhanced by alcohol or other CNS depressants. There may be an additive hypotensive effect when tizanidine is used in patients receiving antihypertensive therapy; bradycardia may also be enhanced if given with beta blockers or digoxin. Caution should be exercised when tizanidine is given with drugs known to increase the QT interval. The clearance of tizanidine has been reported to be lower in women receiving hormonal contraceptives.

Antibacterials. In a study of healthy subjects,[1] *ciprofloxacin*, an inhibitor of the cytochrome P450 isoenzyme CYP1A2, was reported to elevate the plasma concentrations of tizanidine thereby potentiating its hypotensive and sedative effects.

1. Granfors MT, *et al.* Ciprofloxacin greatly increases concentrations and hypotensive effect of tizanidine by inhibiting its cytochrome P450 1A2-mediated presystemic metabolism. *Clin Pharmacol Ther* 2004; **76:** 598–606.

Antidepressants. In a study[1] in 10 healthy subjects, *fluvoxamine*, a potent inhibitor of the cytochrome P450 isoenzyme CYP1A2, was reported to increase tizanidine's peak plasma concentrations and elimination half-life 12-fold and 3-fold, respectively. An increased incidence of adverse effects associated with tizanidine such as hypotension, bradycardia, drowsiness, and dizziness was noted in these subjects.

A 70-year-old woman receiving fluvoxamine 150 mg daily and other medications developed bradycardia, dry mouth, urinary retention, and a low body temperature when given tizanidine 3 mg daily;[2] the patient improved when tizanidine was stopped. In a retrospective survey of medical records, the authors reported adverse effects associated with tizanidine in 6 of 23 patients also receiving fluvoxamine.

1. Granfors MT, *et al.* Fluvoxamine drastically increases concentrations and effects of tizanidine: a potentially hazardous interaction. *Clin Pharmacol Ther* 2004; **75:** 331–41.
2. Momo K, *et al.* Drug interaction of tizanidine and fluvoxamine. *Clin Pharmacol Ther* 2004; **76:** 509–10.

Antiepileptics. For reference to an interaction between tizanidine and *phenytoin*, see p.500.

Cardiovascular drugs. Severe hypotension, occurring 2 hours after treatment with tizanidine, has been reported in a patient receiving antihypertensives, including *lisinopril*, and other medications.[1] The patient improved after tizanidine and antihypertensives were stopped; they were later resumed without lisinopril, and caused no problems.

1. Kao C-D, *et al.* Hypotension due to interaction between lisinopril and tizanidine. *Ann Pharmacother* 2004; **38:** 1840–3.

Oral contraceptives. Mean peak plasma concentrations after a single 4-mg dose of tizanidine were 3 times greater in 15 women using an oral contraceptive containing *ethinylestradiol* and *gestodene* than in controls;[1] the elimination half-life was not, however, significantly different. The effect appeared to be due to inhibition of the cytochrome P450 isoenzyme CYP1A2 by the contraceptive, resulting in reduced presystemic metabolism of tizanidine. Because the therapeutic range of tizanidine is narrow, care should be exercised if it is given to patients taking oral contraceptives.

1. Granfors MT, *et al.* Oral contraceptives containing ethinyl estradiol and gestodene markedly increase plasma concentrations and effects of tizanidine by inhibiting cytochrome P450 1A2. *Clin Pharmacol Ther* 2005; **78:** 400–11.

Pharmacokinetics

Tizanidine is well absorbed from the gastrointestinal tract and peak plasma concentrations occur about 1 to 2 hours after oral doses. It is about 30% bound to plasma proteins. Tizanidine undergoes extensive first-pass metabolism in the liver mainly via the cytochrome P450 isoenzyme CYP1A2 and is excreted mainly in the urine as inactive metabolites. Elimination half-lives of 2 to 4 hours have been reported.

Uses and Administration

Tizanidine hydrochloride is a centrally acting skeletal muscle relaxant. It is an α_2-adrenergic agonist structurally related to clonidine (p.1247) and acts mainly at spinal and supraspinal levels to inhibit excitatory interneurones. It is used for the symptomatic relief of spasticity associated with multiple sclerosis or with spinal cord injury or disease. It is also used in the symptomatic treatment of painful muscle spasm (p.1887) associated with musculoskeletal conditions.

Tizanidine hydrochloride is given orally, usually in divided doses; doses are expressed in terms of the base. Tizanidine hydrochloride 1.14 mg is equivalent to about 1 mg of tizanidine. The usual initial daily dose in the UK in the management of spasticity is the equivalent of 2 mg of the base given as a single dose. The dose may be increased thereafter according to response in steps of 2 mg at intervals of at least 3 to 4 days, usually up to 24 mg daily given in 3 or 4 divided doses. A similar schedule, with an initial daily dose of 4 mg, increased as required in steps of 2 to 4 mg, is used in the USA. The maximum recommended dose is 36 mg daily. Maintenance doses have been given in some countries in the form of modified-release preparations. For dosage in renal impairment, see below.

In the treatment of painful muscle spasm tizanidine hydrochloride is given in doses equivalent to 2 to 4 mg of the base three times daily.

Administration in renal impairment. In the UK, licensed product information recommends that in patients with renal insufficiency, treatment with tizanidine hydrochloride should be started with the equivalent of 2 mg of the base once daily; thereafter it advises a slow increase in the once-daily dose before increasing the frequency of administration. Similar recommendations are made in the USA.

Headache. Results from an open-label study[1] and a later controlled study[2] suggested that tizanidine might be of value in the prophylaxis of chronic daily headache. However, an earlier controlled study[3] failed to show any significant advantage over placebo in the treatment of chronic tension-type headache. In another study[4] tizanidine was also effective when given with a long-acting NSAID as part of a detoxification regimen for patients with chronic daily headaches induced by analgesic overuse.

1. Saper JR, *et al.* An open-label dose-titration study of the efficacy and tolerability of tizanidine hydrochloride tablets in the prophylaxis of chronic daily headache. *Headache* 2001; **41:** 357–68.
2. Saper JR, *et al.* Chronic daily headache prophylaxis with tizanidine: a double-blind, placebo-controlled, multicenter outcome study. *Headache* 2002; **42:** 470–82.

4. Smith TR. Low-dose tizanidine with nonsteroidal anti-inflammatory drugs for detoxification from analgesic rebound headache. *Headache* 2002; **42:** 175–7.

Premedication. The value of tizanidine as a premedicant is being studied.[1] A dose of tizanidine 12 mg appears to have sedative and sympatholytic effects comparable with clonidine 150 micrograms.

1. Meittinen TJ, *et al.* The sedative and sympatholytic effects of oral tizanidine in healthy volunteers. *Anesth Analg* 1996; **82:** 817–20.

Spasticity. The efficacy of tizanidine for spasticity (p.1887) associated with cerebral and spinal disorders[1,2] has been shown in several placebo-controlled studies and in comparative studies it has produced similar improvements in muscle tone to baclofen or diazepam. Carefully titrated doses of tizanidine and baclofen used together may have additive beneficial effects[1,2] but use with benzodiazepines is not recommended because of potential interactions.[1] It was considered that tizanidine might have the advantage of being better tolerated than baclofen.

Neuromuscular Blockers

Anaesthesia, p.1900
Intensive care, p.1901
Tetanus, p.1901

Neuromuscular blockers (myoneuronal blockers) affect transmission at the neuromuscular junction and are used as adjuncts to general anaesthesia, particularly to enable adequate muscle relaxation to be achieved with light anaesthesia. There are 2 main types of neuromuscular blockers: competitive (non-depolarising neuromuscular blockers) and depolarising neuromuscular blockers (see Table 1, below).

Table 1. Classification of neuromuscular blockers.

Competitive		Depolarising
Aminosteroidal	*Benzylisoquinolinium*	Suxamethonium
Pancuronium	Alcuronium	
Pipecuronium	Atracurium	
Rapacuronium	Cisatracurium	
Rocuronium	Doxacurium	
Vecuronium	Gallamine	
	Metocurine	
	Mivacurium	
	Tubocurarine	

- **Competitive neuromuscular blockers** act by competing with acetylcholine for receptors on the motor end-plate. Their action can be opposed by increasing the local concentration of acetylcholine, for example by giving an anticholinesterase such as neostigmine (p.631). Tubocurarine (p.1912) was formerly the standard reference drug of this type but its use has declined, therefore details of the actions and uses of competitive neuromuscular blockers are discussed under Atracurium, p.1902.
- **Depolarising neuromuscular blockers** act by depolarising the motor end-plate to prevent the normal response to acetylcholine; their action is not reversed by anticholinesterases. Suxamethonium (p.1909) is the standard reference drug of this type.

Other drugs that have muscle relaxant properties and which are used in the management of musculoskeletal and neuromuscular disorders are discussed in the chapter on Muscle Relaxants, p.1887.

Anaesthesia

Neuromuscular blockers are used in general anaesthesia for their muscle relaxant effects to facilitate intubation at induction and to provide continued relaxation during maintenance. Their use is determined partly by their onset and duration of action (see Table 2, below), but both onset and duration are dose-dependent and can therefore vary. Generally, *competitive neuromuscular blockers*, due to their slower onset and longer duration of action, are used in major operations, while the *depolarising neuromuscular blockers* (usually suxamethonium), with a much faster onset and shorter duration, are used for minor operations or manipulations and particularly for intubation. After use of suxamethonium to aid intubation, a longer-acting competitive drug may then be given to maintain muscle relaxation throughout the operation. Competitive neuromuscular blockers with a short to intermediate duration of action, such as atracurium and vecuronium, are more widely used than those with a longer duration of action such as pancuronium.

Suxamethonium has been widely used after induction of anaesthesia to aid **intubation**; however, because of the adverse effects such as myalgia associated with suxamethonium (see also below), alternative neuromuscular blockers have been investigated for intubation and some questioned the use of suxamethonium for *elective* procedures,[1] especially in day-case patients.[2] Some competitive blockers such as vecuronium have a relatively rapid onset of action and have been used for intubation during routine, planned surgery. However, they act too slowly to enable rapid intubation in an *emergency*, when suxamethonium remains the drug of choice. Although rocuronium, a competitive blocker, is only slightly slower in onset, and may be suitable in emergencies if suxamethonium is contra-indicated,[3-5] it has a much longer duration of action, and needs to be given with an opioid such as alfentanil,[6] or with propofol,[4] to obtain equivalent intubating conditions.

In attempting to create more favourable conditions for rapid intubation with competitive neuromuscular blockers and thus provide an alternative to suxamethonium, anaesthetists have tried using large doses[3] or combinations[7] of competitive blockers. Other methods tried include giving competitive neuromuscular blockers in divided doses in an attempt to shorten the onset to paralysis.[3,8] This so-called *priming principle* involves giving a small initial dose, termed the priming dose, followed by a large paralysing dose. Priming may be with 2 doses of the same competitive relaxant or a combination of 2 different relaxants which may then exhibit synergism. However, some consider[8] that priming techniques are associated with unacceptable adverse effects such as muscle weakness and aspiration, and that they are not safe, especially in the elderly.[3] In another technique, a single large dose of a neuromuscular blocker is given, followed by the induction anaesthetic as soon as the patient complains of weakness.[3] This is called the *timing principle* and although it has been successfully used with some neuromuscular blockers, problems such as perceived muscle weakness or shortness of breath may occur if the anaesthetic is not injected at the right moment.

The use of anaesthetic regimens that avoid or reduce the need for a neuromuscular blocker during intubation has also been investigated. The anaesthetic propofol with a short-acting opioid such as alfentanil has often been tried. In addition to its use alone, such a regimen has been combined successfully with low doses of suxamethonium[9] or rocuronium,[10] or standard doses of vecuronium,[11] to produce suitable conditions for intubation.

Procedures such as intubation can cause **complications**: an undesirable pressor response may occur, resulting in increased heart rate and arterial blood pressure. There may also be an increase in intracranial pressure and intra-ocular pressure. Furthermore, the use of suxamethonium to aid intubation is itself associated with a transient increase in intra-ocular pressure. Small doses of a competitive neuromuscular blocker have been given before suxamethonium[12] to prevent this rise in intra-ocular pressure, although some consider such a measure ineffective.[13] Opioids such as alfentanil and fentanyl appear to be effective in attenuating both the pressor response[14-16] and the rise in intra-ocular pressure[17,18] associated with intubation, but the use of lidocaine has produced conflicting results.[19-23] Many anaesthetics, with the exception of ketamine, reduce intra-ocular pressure to some extent and giving thiopental beforehand may help to counteract the effect of suxamethonium.[24]

Table 2. Relative speed of onset and duration of action of neuromuscular blockers.

Neuromuscular blocker	Onset*	Duration†
Alcuronium	Intermediate	Intermediate
Atracurium	Intermediate	Short/Intermediate
Cisatracurium	Intermediate	Short/Intermediate
Doxacurium	Slow	Long
Gallamine	Rapid	Intermediate
Mivacurium	Intermediate	Short
Pancuronium	Rapid	Long
Pipecuronium	Intermediate	Intermediate/Long
Rocuronium	Rapid	Intermediate
Suxamethonium	Ultra-rapid	Ultra-short
Tubocurarine	Intermediate/Slow	Intermediate
Vecuronium	Rapid	Intermediate

**Onset:*	*†Duration:*
Ultra-rapid, less than 1 minute	Ultra-short, less than 8 minutes
Rapid, 1 to 2 minutes	Short, 8 to 20 minutes
Intermediate, 2 to 4 minutes	Intermediate, 20 to 50 minutes
Slow, more than 4 minutes	Long, more than 50 minutes

Onset and duration of action are dose-dependent

Other drugs that have been used or tried in the prevention of the haemodynamic response to intubation include magnesium sulfate[25] and propofol.[26,27]

Competitive neuromuscular blockers are usually used to provide muscle relaxation during **maintenance** anaesthesia. Patients given a neuromuscular blocker generally require less anaesthetic permitting a state of 'lighter anaesthesia' and hence reducing the adverse effects of the anaesthetic. At the end of the procedure any residual block should be reversed with an anticholinesterase and the patient should be monitored until spontaneous respiration has resumed. For further details see Anaesthesia under Uses of General Anaesthetics, p.1780.

Intensive care

The use of neuromuscular blockers in patients requiring mechanical ventilation as part of intensive care has been discussed in a number of reviews[1-3] and guidelines.[4] Neuromuscular blockers are used to provide additional relaxation and facilitate ventilatory support in patients who fail to respond to sedation alone. It is important to ensure that such patients are adequately sedated and relatively pain free before these drugs are used. Patients who are considered most likely to benefit are those with spontaneous respiration that is counterproductive to mechanical ventilation. Patients with little inherent respiratory muscle activity are less likely to obtain an improvement in oxygenation. Neuromuscular blockers may also improve control of intracranial pressure in patients with intracranial hypertension, including prevention of rises in intracranial pressure associated with routine tracheobronchial suction.

Pancuronium has been widely used as a neuromuscular blocker in intensive care because of its tendency to increase arterial pressure and the majority of patients requiring a neuromuscular blocker can be adequately managed with pancuronium; however, its long duration of action may be a problem in some circumstances, and its vagolytic activity can also produce tachycardia. Vecuronium, atracurium, and cisatracurium have relatively few cardiovascular effects, but there has been some concern over the ability of the atracurium metabolite laudanosine to accumulate in the CNS (see Biotransformation, under Pharmacokinetics, p.1905). Atracurium and cisatracurium may also be more suitable in patients with hepatic or renal impairment as their metabolism does not lead to the accumulation of active metabolites. Other neuromuscular blockers that have been used in intensive care include doxacurium, pipecuronium, and rocuronium.

Close monitoring of neuromuscular blockade is recommended since the pharmacodynamics and pharmacokinetics of neuromuscular blockers may be altered in patients in intensive care;[1-4] this should also allow the lowest effective neuromuscular blocking dose to be used, and reduce adverse events. Prolonged neuromuscular blockade has been related to dosage.

Other factors that may potentiate neuromuscular blockade include drug interactions, electrolyte imbalance, hypothermia, or changes in acid–base balance.[1,3] Conversely, dosage requirements may be increased in patients with burns or in those receiving prolonged therapy. Tachyphylaxis has occurred with some neuromuscular blockers, but may resolve on switching to another blocker.

Prolonged neuromuscular blockade has been associated with adverse effects and should be avoided when possible. Recovery after withdrawal of prolonged treatment may be longer than pharmacologically predicted due to the accumulation of active metabolites; this is a particular problem for neuromuscular blockers with a long duration of action and for patients with hepatic or renal impairment. An acute myopathy has also followed prolonged use, most commonly with aminosteroid neuromuscular blockers (see Table 1, p.1900); there are case reports suggesting that use of corticosteroids might increase the risk.[4,5]

When rapid reversal of paralysis is necessary an anticholinesterase such as neostigmine may be used, but relatively little is known about the efficacy of anticholinesterases in reversing prolonged paralysis.[6]

Neonatal intensive care. Neuromuscular blockers such as pancuronium bromide are used in neonatal intensive care to obtain muscle relaxation during mechanical ventilation in infants with severe pulmonary disease, especially in those whose respiratory efforts are out of phase with the ventilator.[7] They are only used in infants at high risk of complications such as *pneumothorax* or *intraventricular haemorrhage*; their routine use in all ventilated neonates is not recommended.[8]

Abolition of spontaneous respiration during mechanical ventilation has had variable effects on the incidence of *pneumothorax* in infants with respiratory distress syndrome. Although a reduced incidence was found in one study[9] involving infants of less than 33 weeks' gestation, in another study[10] the incidence was reduced only in infants with a gestational age of 27 to 32 weeks; no reduction was obtained in those below 26 weeks' gestation. Paralysis also failed to reduce the incidence of pneumothorax or interstitial emphysema in a study[11] of infants with hyaline membrane disease but did appear to speed recovery of lung function.

The aetiology of *intraventricular haemorrhage* remains obscure but there is a well recognised association with gestational age;[12] less mature neonates are more susceptible and the incidence decreases sharply after 30 weeks' gestation. There appears to be an association between fluctuating cerebral blood-flow velocity in the first day of life and subsequent development of intraventricular haemorrhage.[13] Respiratory paralysis from the first day of life until 72 hours of age has been reported[14] to stabilise both cerebral and arterial blood-flow velocity and to produce a decrease in the incidence and severity of intraventricular haemorrhage in infants with respiratory distress syndrome. However, respiratory paralysis has also been reported to have no effect on the development of intraventricular haemorrhage.[9,10]

The use of neuromuscular blockers in the newborn is not without complications. Multiple joint contractures, possibly potentiated by use of aminoglycosides or phenobarbital, have been reported[15,16] in infants given pancuronium, and regular passive limb movements should be performed during paralysis. Marked oedema, severe disturbances of fluid balance, renal failure and death have been reported in 2 neonates.[17] Hypoxaemia may develop after induction of paralysis unless a significant increase in ventilator support is made;[9,13,18] hypotension may also occur.[19] Drugs such as pancuronium which are metabolised in the liver and excreted in the urine have a prolonged action in premature infants.[7] As with adults (see above), continuous use of neuromuscular blockers in neonates has been associated with prolonged neuromuscular block on withdrawal.[20]

Tetanus

The clinical manifestations of tetanus after infection with *Clostridium tetani* are caused by the highly potent neurotoxin tetanospasmin produced by its germinating spores.

The muscular symptoms of generalised tetanus include trismus (lockjaw), glottal spasm, generalised muscle spasm, opisthotonus (spasm of the back muscles resulting in backward arching of the body), respiratory spasm, and paralysis. Other complications include electrolyte disturbances and autonomic dysfunction leading to cardiovascular effects such as hypertension, tachycardia, and peripheral vasoconstriction. Patients may have a milder form in which the twitching and muscle spasms are limited to the area near the site of the injury, but such localised tetanus is rare and can progress to the generalised form.

Treatment aims to destroy the causative organism and/or neutralise any unbound toxin in the body, to control rigidity and muscle spasms, and to control autonomic dysfunction. For the **antibacterial treatment and prevention** of tetanus and neutralisation of tetanospasmin, see p.196. After antibacterial therapy the mainstay of treatment of **rigidity and spasms** is sedation with *benzodiazepines* such as diazepam or midazolam; they may also reduce patient anxiety. *Opioid analgesics* can be added to treatment to provide analgesia and additional sedation; in addition, *fentanyl*, *morphine*, and *sufentanil* may control autonomic overactivity. *Antiepileptics*, particularly phenobarbital, may also provide additional sedation. *Chlorpromazine* is sometimes used with benzodiazepines to minimise rigidity and muscle spasms. Sedation with *propofol* may also control spasms and rigidity without the need for an additional relaxant; however, mechanical ventilation is required. Centrally acting muscle relaxants have also been tried to control muscle spasms. *Baclofen* has been given by the intrathecal route, but its therapeutic range in severe tetanus may be very narrow and deep coma and loss of spontaneous respiration has been reported. *Dantrolene* has also been reported to be effective. When muscle spasms are severe or interfere with respiration, *competitive neuromuscular blockers* have been used in addition to benzodiazepine sedation, to control spasms and to induce therapeutic paralysis so mechanical ventilation can be initiated.

Control of **autonomic overactivity** may be achieved with sedation; benzodiazepines, antiepileptics, and opioid analgesics have all been used (see above). *Beta blockers* such as propranolol have also been used; however, they are no longer recommended because of the potential for severe cardiovascular effects. Labetalol has both alpha- and beta-blocking activity but offers no advantage over propranolol. More recently, *esmolol*, a short-acting beta blocker, has been used. *Magnesium sulfate* has been found to minimise autonomic disturbance in ventilated patients and controls spasms in non-ventilated patients, but there is need for further investigation. **Electrolyte disturbance** is corrected with calcium and magnesium salts.

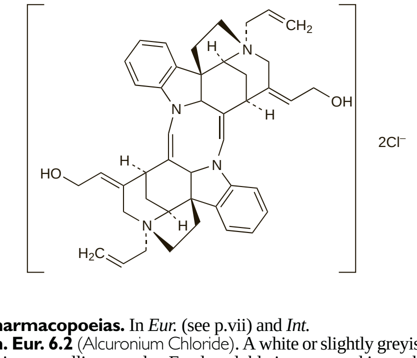
Алкурония Хлорид

$C_{44}H_{50}Cl_2N_4O_2$ = 737.8.

CAS — 23214-96-2 (alcuronium); 15180-03-7 (alcuronium chloride).

ATC — M03AA01.

ATC Vet — QM03AA01.



Pharmacopoeias. In *Eur.* (see p.vii) and *Int.*

Ph. Eur. 6.2 (Alcuronium Chloride). A white or slightly greyish-white, crystalline powder. Freely soluble in water and in methyl alcohol; soluble in alcohol; practically insoluble in cyclohexane. Store under nitrogen in an airtight container. Protect from light.

Profile

Alcuronium chloride is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1905) that is used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900). It can induce histamine release to some degree. Anaphylactoid reactions have been associated with the use of alcuronium. It has some vagolytic action and may produce tachycardia; hypotension may also occur.

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. An initial dose of 150 to 250 micrograms/kg has been given intravenously. Muscle relaxation occurs after about 2 minutes and the effect lasts for about 20 to 30 minutes. Supplementary doses of 30 micrograms/kg have been given to provide additional periods of muscle relaxation.

Porphyria. Alcuronium is considered to be unsafe in patients with porphyria because it has been shown to be porphyrinogenic in *animals*.

Pregnancy. Alcuronium crosses the placenta. No evidence of neuromuscular block was seen in any of the neonates born to 12 women who received alcuronium 15 to 30 mg by intravenous injection, 5 to 10.5 minutes before delivery[1] but caution was advised if alcuronium was given in obstetrics in high doses or for a prolonged period.

1. Ho PC, *et al.* Caesarean section and placental transfer of alcuronium. *Anaesth Intensive Care* 1981; **9:** 113–18.

Renal impairment. Alcuronium is excreted mainly by the kidneys and accumulation, with prolonged paralysis, may therefore be expected in patients with renal impairment given large or repeated doses. A prolonged elimination half-life has been reported in anuria.[1] However, doses of 160 micrograms/kg have been used without any problems in patients with chronic renal failure undergoing renal transplantation.[2] The average duration of action of this dose was 37 minutes and any residual neuromuscular blockade at the end of surgery was successfully reversed using atropine and neostigmine.

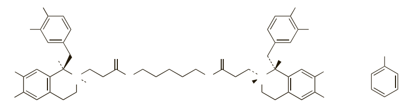
Цисатракурия Безилат

CAS — 96946-42-8.
ATC — M03AC11.
ATC Vet — QM03AC11.



Incompatibility. Neuromuscular blockers are generally incompatible with alkaline solutions, for example barbiturates such as thiopental sodium. It is good practice not to give neuromuscular blockers in the same syringe, or simultaneously through the same needle, as other drugs.

The manufacturers state that cisatracurium is incompatible with ketorolac trometamol or propofol emulsion; in addition, lactated Ringer's injection with glucose 5% or lactated Ringer's solution should not be used as a diluent when preparing solutions of cisatracurium for infusion.

Stability. In a stability study,[1] solutions of cisatracurium (as the besilate) in concentrations of 2 or 10 mg/mL were stable for at least 90 days when stored in the original vials at 4° either exposed to or protected from light; similar solutions stored at 23° were stable for at least 45 days. Solutions of 2 mg/mL stored in plastic syringes at 4° or 23° were stable for at least 30 days. Solutions of 0.1, 2, or 5 mg/mL in 5% glucose injection or 0.9% sodium chloride injection in PVC minibags were stable for at least 30 days stored at 4°; the 5 mg/mL solution was also stable for at least 30 days stored at 23°.

1. Xu QA, *et al.* Stability of cisatracurium besylate in vials, syringes, and infusion admixtures. *Am J Health-Syst Pharm* 1998; **55:** 1037–41.

Adverse Effects

The adverse effects of competitive neuromuscular blockers are generally similar although they differ in their propensity to cause histamine release and associated cardiovascular effects. The latter appear to be rare with the aminosteroidal blockers and the benzylisoquinolinium blocker cisatracurium (see below). Competitive neuromuscular blockers with vagolytic activity may produce tachycardia and a rise in blood pressure. The use of blockers that lack an effect on the vagus will not counteract the bradycardia produced during anaesthesia by the other drugs employed or by vagal stimulation. Reduction in blood pressure with compensatory tachycardia may occur with some competitive neuromuscular blockers, in part because of sympathetic ganglion blockade or the release of histamine. Reduction in gastrointestinal motility and tone may occur as a result of ganglionic blockade.

Histamine release may also lead to wheal-and-flare effects at the site of injection, flushing, occasionally bronchospasm, and rarely anaphylactoid reactions.

Malignant hyperthermia has been associated rarely with competitive neuromuscular blockers.

Some competitive neuromuscular blockers such as pancuronium, tubocurarine, and vecuronium can cause a decrease in the partial thromboplastin time and prothrombin time.

In overdosage there is prolonged apnoea due to paralysis of the intercostal muscles and diaphragm, with cardiovascular collapse and the effects of histamine release.

Atracurium and its isomer cisatracurium have no significant vagal or ganglionic blocking activity at recommended doses. Unlike atracurium, cisatracurium does not induce histamine release and is therefore associated with greater cardiovascular stability.

For possible risks from their major metabolite laudanosine, see Biotransformation, under Pharmacokinetics, below.

Effects on body temperature. Competitive neuromuscular blockers are not considered to be a trigger factor for malignant hyperthermia; however, there have been rare case reports of apparent association. Two cases of mild malignant hyperthermia have been reported[1] where tubocurarine was probably the triggering drug. Each episode developed in a member of a family known to be susceptible to malignant hyperthermia, despite preventive measures such as prophylactic cooling, and avoidance of potent inhalation anaesthetics and depolarising neuromuscular blockers. Another case[2] was associated with the use of pancuronium.

2. Waterman PM, *et al.* Malignant hyperthermia: a case report. *Anesth Analg* 1980; **59:** 220–1.

Effects on the muscles. For reference to acute myopathy and prolonged muscle weakness after withdrawal of long-term continuous infusions of competitive neuromuscular blockers, see Intensive Care, p.1901.

Hypersensitivity. There have been reports of severe anaphylactoid reactions after use of atracurium[1,2] or cisatracurium.[3-5] For a discussion of hypersensitivity reactions associated with neuromuscular blockers, see under Suxamethonium Chloride, p.1910.

Treatment of Adverse Effects

It is essential to maintain assisted respiration in patients who have received a competitive neuromuscular blocker until spontaneous breathing is fully restored; in addition a cholinesterase inhibitor such as neostigmine is usually given intravenously, with atropine or glycopyrronium, to hasten reversal of the neuromuscular block. Patients need to be closely monitored after reversal of block to ensure that muscle relaxation does not return.

Severe hypotension may require intravenous fluid replacement and cautious use of a pressor agent; the patient should be positioned to facilitate venous return from the muscles.

Giving an antihistamine before induction of neuromuscular blockade may help to prevent histamine-induced adverse effects in patients with asthma or those susceptible to bronchospasm.

Reversal of neuromuscular blockade. For a discussion of the use of anticholinesterases for reversal of residual neuromuscular block produced by intermediate- or short-acting blockers after surgical or similar procedures, see under Neostigmine, p.633.

Precautions

Patients who have received a neuromuscular blocker should always have their respiration assisted or controlled until the drug has been inactivated or antagonised.

Atracurium and other competitive neuromuscular blockers should be used with great care, if at all, in respiratory insufficiency or pulmonary disease and in the dehydrated or severely ill patient. The response to neuromuscular blockers is often unpredictable in patients with neuromuscular disorders and they should be used with great care in these patients (see below). Caution is also needed in patients with a history of conditions such as asthma where release of histamine would be a hazard. Care is also required in patients with a history of hypersensitivity to any neuromuscular blocker because high rates of cross-sensitivity have been reported. For a discussion of hypersensitivity reactions associated with neuromuscular blockers, see under Adverse Effects of Suxamethonium Chloride, p.1910.

Resistance to the effects of competitive neuromuscular blockers may occur in patients with burns (see below). The effect of competitive neuromuscular blockers may vary in patients with hepatic impairment: resistance appears to occur to some, such as doxacurium, metocurine, pancuronium, and tubocurarine, while dosage of others, including mivacurium and rocuronium, may need to be reduced because of a prolonged action.

Competitive neuromuscular blockers excreted mainly in the urine should be used with caution in renal impairment; a reduction in dosage may be necessary. Doses may need to be reduced in infants and neonates because of increased sensitivity to competitive muscle relaxants. Doses in obese patients should usually be based upon the patient's ideal body-weight rather than actual body-weight.

The effects of competitive neuromuscular blockers are increased by metabolic or respiratory acidosis and hypokalaemia, hypermagnesaemia, hypocalcaemia, and hypophosphataemia and dehydration. Competitive neuromuscular blockade may also be enhanced by raised body temperature and reduced in hypothermia.

In contrast to other competitive neuromuscular blockers, reduction in body temperature may necessitate a dosage reduction for *atracurium and its isomer cisatracurium* since cooling reduces the rate of inactivation of atracurium and cisatracurium, but physiological variations in body temperature and pH will not significantly affect their action.

Burns. The dose requirements of competitive neuromuscular blockers are increased in patients with burns,[1-3] the dose correlating with both the extent of the burn and time after injury. This resistance is usually not seen in patients with less than 10% body-surface burns but if more than 40% of the body-surface is affected the dose of competitive blocker may need to be up to five times higher than in patients without burns. Resistance peaks about 2 weeks after injury, persists for many months in patients with major burns, and decreases gradually with healing of the burn. The mechanism of resistance is multifactorial but may be partly explained by increased protein binding, increased volume of distribution, and increased numbers of acetylcholine receptors at the motor end-plate requiring more muscle relaxant to produce a given effect. Despite the high doses of competitive relaxants that are required, recovery from neuromuscular blockade is not seriously impaired and their effects can be reversed with usual doses of an anticholinesterase.

Cardiopulmonary bypass. The effect of cardiopulmonary bypass on the pharmacokinetics and pharmacodynamics of competitive neuromuscular blockers can be complex but generally their dosage may need to be reduced. Although the intensity of neuromuscular blockade of most competitive neuromuscular blockers is reduced by hypothermia[1] used during cardiopulmonary bypass, their use during this procedure is associated with rises in plasma concentrations, reduced clearance, and prolongation of the elimination half-life.[2-6] Various mechanisms, including reduced distribution to highly perfused tissues such as the lungs, have been proposed to explain this effect.[2] For atracurium, it appears that it is a reduction in the temperature-dependent inactivation by Hofmann elimination during hypothermia that enables lower doses to be used.[7]

Hepatic impairment. The effect of competitive neuromuscular blockers may vary in patients with hepatic impairment (see Precautions, above) but alterations in the pharmacokinetics of atracurium and cisatracurium in patients with hepatic impairment (see Biotransformation, under Pharmacokinetics, below) do not appear to be clinically significant and a reduction in dosage is not generally recommended.

Neuromuscular disorders. Caution is needed if competitive neuromuscular blockers are given to patients with neuromuscular disease since severe complications have been reported.[1] Increased response may be seen in patients with paraplegia or quadriplegia, but resistance has been reported in patients with hemiplegia. Increased response also may occur in patients with amyotrophic lateral sclerosis, neurofibromatosis, and poliomyelitis; this is of little concern unless the respiratory muscles are involved when prolonged apnoea may occur. Patients with myasthenia gravis usually show increased sensitivity to competitive neuromuscular blockers although small doses have been given without complications. During remission of myasthenia gravis a normal response is usual but since remission is often incomplete, small intermittent doses are advised. A significantly greater exaggeration of response is seen in patients with the myasthenic syndrome. Both normal and increased responses have been reported in patients with myotonias or muscular dystrophies but exquisite sensitivity occurs in patients with ocular muscular dystrophy. A normal response to competitive relaxants may be expected in patients with multiple sclerosis, muscular denervation, Parkinson's disease, and tetanus.

1. Azar I. The response of patients with neuromuscular disorders to muscle relaxants: a review. *Anesthesiology* 1984; **61:** 173–87.

Pregnancy. A review[1] of the pharmacokinetics of neuromuscular blockers in pregnancy concluded that atracurium and mivacurium are the best choice in pregnancy since their actions are predictable; their duration of action is either unchanged or only slightly prolonged. Atracurium also has a low umbilical to maternal vein concentration (uv/mv) ratio. In general, it is advisable[1] to choose a neuromuscular blocker with a low uv/mv ratio and a short duration of action, and to inject the lowest dose required to produce adequate surgical conditions.

Atracurium 300 micrograms/kg given to 26 women undergoing caesarean section, with subsequent incremental doses of 100 or 200 micrograms/kg if necessary, produced good surgical relaxation in all patients without any complications.[2] Of the 26 neonates delivered, respiration was established within 90 seconds in 21, with an Apgar score of 10 at 5 minutes. The remaining 5 neonates were delivered by caesarean section because of fetal distress and were slower to start breathing.

A study[3] of 22 women in the immediate postpartum period found the onset and duration of cisatracurium to be significantly shorter when compared with nonpregnant patients.

3. Pan PH, Moore C. Comparison of cisatracurium-induced neuromuscular blockade between immediate postpartum and nonpregnant patients. *J Clin Anesth* 2001; **13:** 112–17.

Renal impairment. Although some differences in the pharmacokinetics of atracurium and cisatracurium have been reported in patients with renal impairment (see Biotransformation, under Pharmacokinetics, below), duration of their neuromuscular blocking action is not significantly dependent on renal function and usual doses may be given to such patients.[1,2] Atracurium has been given by infusion to patients with end-stage renal failure[3] when the initial dose required for induction of neuromuscular block was 37% higher than that required by patients without renal impairment. The increase could be explained by the larger extracellular fluid volume in patients with chronic renal failure.

Although the pharmacokinetics of atracurium and cisatracurium are not appreciably different in renal impairment, those of their metabolites may be (see Biotransformation, under Pharmacokinetics, below) and therefore it has been suggested that neuromuscular function should be monitored during use of atracurium.[4]

Resistance. The aetiology of resistance to competitive blockers is not clear but might be due to pharmacodynamic or pharmacokinetic alterations associated with disease states such as burn injuries (see above) or hepatic impairment (see above) or therapy with other drugs (see Interactions, below). One review[1] noted that there had been numerous case reports of resistance to competitive neuromuscular blockers; most had been associated with use of single doses or short-term intermittent therapy, but more recent reports had documented resistance during continuous infusions in 9 patients of whom 7 had received atracurium and 2 rocuronium. Resistance to atracurium had followed 2 different patterns. Patients had required either usual or raised doses for initial control but both groups had subsequently required progressive increases. Most patients with resistance to atracurium were successfully managed by transfer to pancuronium or doxacurium.

1. Tschida SJ, *et al.* Resistance to nondepolarizing neuromuscular blocking agents. *Pharmacotherapy* 1996; **16:** 409–18.

Tourniquets. Atracurium might be unsuitable for neuromuscular blockade of a limb that has been isolated with a tourniquet in order to provide a bloodless field for surgery.[1] Atracurium undergoes non-enzymatic degradation in plasma and would therefore continue to degrade locally leading to a loss of blockade in the limb, which could not be corrected by further doses unless the tourniquet was deflated.

Interactions

A number of drugs may influence neuromuscular transmission and thus interfere with the action of both competitive and depolarising neuromuscular blockers, resulting in potentiation or antagonism of neuromuscular block. Some interactions may be advantageous, such as the reversal of competitive neuromuscular block by anticholinesterases. In general, adverse interactions are potentially more serious in patients with impaired neuromuscular function (see Neuromuscular Disorders, above, and under Suxamethonium Chloride, p.1911).

Drug interactions affecting neuromuscular blockers of either type (competitive and depolarising) as well as those specific for competitive neuromuscular blockers are discussed below. For drug interactions specific to depolarising neuromuscular blockers see under Interactions of Suxamethonium Chloride, p.1911.

Antiarrhythmics. *Lidocaine*, *procainamide*, *quinidine*, and *verapamil* all have some neuromuscular blocking activity and may enhance the block produced by neuromuscular blockers. Large doses of lidocaine may reduce the release of acetylcholine and act directly on the muscle membrane. Quinidine has a curare-like action at the neuromuscular junction and depresses the muscle action potential. If given during recovery from neuromuscular block it can result in muscle weakness and apnoea and it should be avoided, if possible, in the immediate postoperative period. For details regarding interactions with calcium-channel blockers, see below.

Antibacterials. Some antibacterials in very high concentration can produce a muscle paralysis that may be additive to or synergistic with that produced by neuromuscular blockers. The neuromuscular block produced by antibacterials may be enhanced in patients with intracellular potassium deficiency, low plasma-calcium concentration, neuromuscular disease, or a tendency to a high plasma-antibacterial concentration, for example after large doses or in renal impairment. The interaction appears to be more important for competitive neuromuscular blockers. The antibacterials most commonly implicated are aminoglycosides, lincosamides, polymyxins, and, more rarely, tetracyclines.

The *aminoglycosides* reduce release of, and sensitivity to, acetylcholine and their effect can be reversed, at least in part, by calcium, fampridine, or an anticholinesterase. The interaction can occur with aminoglycosides given by most routes. There are reports of potentiation of neuromuscular blockade occurring with many different aminoglycoside-neuromuscular blocker combinations[1-6] and all aminoglycosides should be used with extreme caution during surgery and in the postoperative period.

The *lincosamides* (*clindamycin* and *lincomycin*) can prolong the action of muscle relaxants producing a neuromuscular block that may be difficult to reverse with calcium or anticholinesterases.[7-9] Patients should be monitored for prolonged paralysis.

There have been reports of prolonged apnoea[2,5,8] after use of *polymyxins* (*colistin*, *polymyxin B*) with a neuromuscular blocker. The block is difficult to reverse; calcium may be partially successful, but neostigmine may increase the block.

Tetracyclines have weak neuromuscular blocking properties; potentiation of neuromuscular block has been reported in patients with myasthenia gravis.[2] Reversal of the block may be partly achieved with calcium, but the value of anticholinesterases is questionable.

The *ureidopenicillins* (*azlocillin* and *mezlocillin*), and the closely related *piperacillin*, are reported to prolong the block produced by vecuronium.[10,11]

Vancomycin has been reported to increase neuromuscular blockade by vecuronium.[12] Prolonged paralysis and apnoea has occurred in a patient recovering from suxamethonium-induced blockade after being given vancomycin.[13]

Anticholinesterases. Anticholinesterases, including *ecothiopate*, *edrophonium*, *galantamine*, *neostigmine*, *pyridostigmine*, *rivastigmine*, and possibly *donepezil*, antagonise the effect of competitive neuromuscular blockers. Some anticholinesterases such as neostigmine inhibit both acetylcholinesterase and plasma cholinesterase, and are used clinically to antagonise competitive neuromuscular blockade. Conversely, anticholinesterases enhance the action of depolarising muscle relaxants such as suxamethonium thus prolonging neuromuscular block, although suxamethonium-induced phase II block can be reversed with an anticholinesterase. See also Interactions in Suxamethonium Chloride, p.1911.

Antiepileptics. Resistance to competitive neuromuscular blockers has been reported in patients receiving chronic treatment with *carbamazepine*[1,2] or *phenytoin*[3,4] and rapid recovery from neuromuscular block may occur. In addition, children on chronic antiepileptic drugs (carbamazepine and/or phenytoin) were found to recover quicker from rocuronium-induced paralysis than those not on antiepileptics[5]. In a study[6] with cisatracurium, faster recovery rates were also recorded in patients receiving acute or chronic treatment with unspecified antiepileptics. However, atracurium[1] and mivacurium[7] appear to be unaffected by chronic carbamazepine therapy and the effect of chronic phenytoin treatment on atracurium has usually been minimal.[3] Although one study[8] did report that epileptic patients receiving one or more antiepileptics had significantly shorter times to recovery from atracurium, the authors pointed out that the patient populations were different from those in the previous studies.[1,3]

A report of sensitivity to vecuronium[9] has suggested that acute dosage of phenytoin may increase rather than decrease the effect of competitive neuromuscular blockers.

Antineoplastics. It has been recommended that atracurium should be used with care in patients receiving anti-oestrogenic drugs,[1] after a case of prolonged neuromuscular blockade with atracurium in a patient receiving *tamoxifen*. See also under Interactions of Suxamethonium Chloride, p.1911.

1. Naguib M, Gyasi HK. Antiestrogenic drugs and atracurium—a possible interaction? *Can Anaesth Soc J* 1986; **33:** 682–3.

Aprotinin. After reports of apnoea, caution has been advised when aprotinin is used with neuromuscular blockers.[1,2]

5. Driessen JJ, *et al.* Benzodiazepines and neuromuscular blocking drugs in patients. *Acta Anaesthesiol Scand* 1986; **30:** 642–6.

Beta blockers. There is conflicting evidence for the effect of beta blockers on the activity of neuromuscular blockers. Lack of effect on depolarising neuromuscular block[1] and antagonism[2,3] or enhancement[4,5] of both competitive and depolarising block have been reported. The exact mechanism of interaction is not clear. There have also been reports of some neuromuscular blockers such as atracurium[6,7] and alcuronium[8] increasing the hypotension and bradycardia associated with the use of anaesthesia in patients receiving beta blockers; these include reports in patients using beta blockers in eye drops for glaucoma.

Botulinum A toxin. The neuromuscular block induced by botulinum toxins is enhanced by competitive neuromuscular blockers.

Calcium-channel blockers. Calcium-channel blockers such as diltiazem, nicardipine, nifedipine, and verapamil enhance the effect of competitive neuromuscular blockers.[1-6] *Verapamil* may interfere with the release of acetylcholine and prolonged use may lead to a reduction in intracellular calcium concentration. Potentiation of neuromuscular blockade has been reported[1,6] and the block may be resistant to reversal with neostigmine; edrophonium may be required. The dose requirement for vecuronium was reduced by as much as 50% in surgical patients receiving *diltiazem*.[2,3] A similar effect was seen with *nicardipine*,[4] which reduced the requirement for vecuronium in a dose-dependent fashion. The interaction of vecuronium with diltiazem appeared to be due to a pharmacodynamic mechanism[2] but nicardipine also reduced the plasma clearance of vecuronium, indicating a partial pharmacokinetic mechanism as well.[4] *Nifedipine* also caused an increase in the intensity and duration of action of atracurium and vecuronium when given during anaesthesia.[5]

6. Jones RM, *et al.* Verapamil potentiation of neuromuscular blockade: failure of reversal with neostigmine but prompt reversal with edrophonium. *Anesth Analg* 1985; **64:** 1021–5.

Cardiac inotropes. Pancuronium or suxamethonium may interact with *cardiac glycosides*[1] resulting in an increased incidence of arrhythmias; the interaction is more likely with pancuronium.

1. Bartolone RS, Rao TLK. Dysrhythmias following muscle relaxant administration in patients receiving digitalis. *Anesthesiology* 1983; **58:** 567–9.

Corticosteroids. Antagonism of the neuromuscular blocking effects of pancuronium[1] and vecuronium[2] has been reported in patients taking corticosteroids. This interaction may occur only with long-term corticosteroid treatment and may be expected with all competitive neuromuscular blockers.

For reference to a suggestion that use of corticosteroids might increase the risk of acute myopathy associated with prolonged use of neuromuscular blockers, see Intensive Care, p.1901.

2. Parr SM, *et al.* Betamethasone-induced resistance to vecuronium: a potential problem in neurosurgery? *Anaesth Intensive Care* 1991; **19:** 103–5.

Diuretics. *Furosemide*, and possibly *mannitol*, have been reported to enhance tubocurarine neuromuscular block in patients with renal failure,[1] but antagonism of tubocurarine by furosemide has also occurred.[2] Small doses of furosemide (less than 100 micrograms/kg) may inhibit protein kinase, which inhibits muscle contraction and potentiates neuromuscular blockade, whereas high doses inhibit phosphodiesterase, increasing cAMP activity and resulting in antagonism of neuromuscular blockade. The potassium-depleting effect of diuretics may enhance the effect of competitive neuromuscular blockers.

2. Poulton TH, *et al.* Prolonged apnea following trimethaphan and succinylcholine. *Anesthesiology* 1979; **50:** 54–6.

General anaesthetics. Neuromuscular blockers are potentiated in a dose-dependent manner by inhalation anaesthetics.[1-5] The dose of neuromuscular blocker may need to be reduced by up to 70%[1] depending on the anaesthetic used and its concentration, and on the choice of blocker; the interaction is of greater clinical importance with competitive blockers. *Isoflurane, enflurane, desflurane*, and *sevoflurane* produce the greater potentiation, followed by *halothane* and *cyclopropane.* Reversal of competitive block with an anticholinesterase has been reported to be reduced.[6,7] See also under Interactions of Suxamethonium Chloride, p.1911.

Potentiation of the neuromuscular blocking effects of tubocurarine[8] and atracurium[9] has been reported after the intravenous use of *ketamine*. Results from studies *in vitro* suggest that ketamine decreases sensitivity to acetylcholine and it would therefore be expected to potentiate all neuromuscular blockers, but no interaction was reported for pancuronium.[8] Early data[10] suggesting that ketamine potentiates suxamethonium-induced blockade have not been confirmed by later studies.[8,11]

Histamine H_2-antagonists. There are conflicting reports of the effects of histamine H_2-antagonists on neuromuscular blockade. *Cimetidine* has been variously reported to prolong suxamethonium-induced paralysis[1] or to have no effect.[2] *Famotidine* and *ranitidine* have been reported[2] not to interact with suxamethonium. Cimetidine, but not ranitidine, has been reported[3] to delay recovery from vecuronium-induced neuromuscular block. Neither drug appeared to affect recovery after the use of atracurium.

3. McCarthy G, *et al.* Effect of H2-receptor antagonist pretreatment on vecuronium- and atracurium-induced neuromuscular blockade. *Br J Anaesth* 1991; **66:** 713–15.

Immunosuppressants. Antagonism of the neuromuscular blocking effects of competitive neuromuscular blockers has been reported with *azathioprine*,[1] although the effect may not be clinically important. Azathioprine probably inhibits phosphodiesterase activity at the motor nerve terminal resulting in increased release of acetylcholine. There have been reports of prolonged neuromuscular blockade with atracurium, pancuronium, and vecuronium in some patients receiving *ciclosporin* intravenously.[2,3] This effect has been attributed to an interaction with polyethoxylated castor oil used as the solvent for intravenous ciclosporin but a similar reaction has been reported in a patient receiving ciclosporin orally.[4]

1. Gramstad L. Atracurium, vecuronium and pancuronium in end-stage renal failure: dose-response properties and interaction with azathioprine. *Br J Anaesth* 1987; **59:** 995–1003.

2. Hill GE, *et al.* Potentiation of succinylcholine neuromuscular blockade by lithium carbonate. *Anesthesiology* 1976; **44:** 439–42.

Local anaesthetics. Healthy subjects who had undergone regional anaesthesia of the forearm experienced symptoms suggestive of local anaesthetic toxicity on deflation of the tourniquet cuff when mivacurium and *prilocaine* had been used together for anaesthesia;[1] giving prilocaine or mivacurium alone did not produce such an effect. The suggestion that mivacurium may alter vascular permeability, allowing a more rapid diffusion of prilocaine back into the blood from the tissues, should be investigated.[2]

The interaction between neuromuscular blockers and *lidocaine* is discussed in Antiarrhythmics above.

1. Torrance JM, *et al.* Low-dose mivacurium supplementation of prilocaine i.v. regional anaesthesia. *Br J Anaesth* 1997; **78:** 222–3.
2. Torrance JM, *et al.* Interactions between mivacurium and prilocaine. *Br J Anaesth* 1997; **78:** 262.

Magnesium salts. Parenteral magnesium salts may potentiate the effects of competitive and depolarising neuromuscular blockers;[1] the neuromuscular block is deepened and prolonged and a reduction in the dose of the blocker may be needed. Magnesium salts should be used with caution in the postoperative period, as use shortly after recovery from neuromuscular block can lead to recurarisation.[2] Magnesium salts reduce release of and sensitivity to acetylcholine, thus contributing to neuromuscular blockade.

2. Fuchs-Buder T, Tassonyi E. Magnesium sulphate enhances residual neuromuscular block induced by vecuronium. *Br J Anaesth* 1996; **76:** 565–6.

MAOIs. There appears to be a theoretical hazard with pancuronium in patients receiving MAOIs since it releases stored adrenaline;[1] alcuronium, atracurium, or vecuronium would appear to be suitable alternatives.

1. Stack CG, *et al.* Monoamine oxidase inhibitors and anaesthesia: a review. *Br J Anaesth* 1988; **60:** 222–7.

Neuromuscular blockers. A competitive neuromuscular blocker given shortly before a depolarising blocker such as suxamethonium antagonises the depolarising neuromuscular block. This interaction has been used clinically to reduce muscle fasciculations caused by suxamethonium (see Effects on the Muscles, p.1910) and tried for other adverse effects associated with suxamethonium (see Effects on Plasma-potassium Concentration, p.1910). To achieve this antagonism a small non-paralysing dose of a competitive blocker is given before suxamethonium. If a paralysing dose of a competitive blocker is followed some time later with a dose of suxamethonium, for example to facilitate abdominal closure, the resulting neuromuscular block is influenced by the competitive blocker used, the depth of residual block, the dose of suxamethonium, and whether an anticholinesterase is given; antagonism, enhancement, and a combination of the two have been seen.[1,2]

A competitive blocker is often given after the short-acting suxamethonium to maintain neuromuscular blockade during long procedures. The action of the competitive blocker has been reported to be considerably potentiated and prolonged in these circumstances,[3,4] and reduction in the dose of the competitive blocker may be appropriate.

Combination of competitive blockers may have additive or synergistic effects and the interaction may differ depending on which blocker is given first. Caution is needed if a small dose of a shorter-acting blocker is given near the end of an operation in which a long-acting blocker has been given previously, since the resulting block may be greater than expected and much longer than desired.[5-8]

8. Motamed C, *et al.* Interaction between mivacurium and pancuronium: impact of the order of administration. *Eur J Clin Pharmacol* 2005; **61:** 175–7.

Sex hormones. Resistance to the neuromuscular blocking effects of suxamethonium and vecuronium in a patient was attributed to previous long-term therapy with *testosterone*,[1] although the exact mechanism could not be explained. See also under Interactions of Suxamethonium Chloride, p.1912.

1. Reddy P, *et al.* Resistance to muscle relaxants in a patient receiving prolonged testosterone therapy. *Anesthesiology* 1989; **70:** 871–3.

Smoking. Smoking may affect the dose requirements for neuromuscular blockers. One study[1] found that smokers needed more vecuronium than non-smokers; it was considered that the effect might be explained at the receptor level, although increased metabolism of vecuronium could not be excluded. In contrast, an earlier study[2] found the amount of atracurium required was reduced in smokers.

2. Kroeker KA, *et al.* Neuromuscular blockade in the setting of chronic nicotine exposure. *Anesthesiology* 1994; **81:** A1120.

Sympathomimetics. Intravenous *salbutamol* has been reported to enhance the blockade obtained with pancuronium and vecuronium.[1] See also under Interactions of Suxamethonium Chloride, p.1912.

1. Salib Y, Donati F. Potentiation of pancuronium and vecuronium neuromuscular blockade by intravenous salbutamol. *Can J Anaesth* 1993; **40:** 50–3.

Xanthines. Resistance to neuromuscular block with pancuronium, requiring an increase in dosage or transfer to vecuronium, has been reported in patients receiving *aminophylline* with[1] or without[2] corticosteroid therapy. It was suggested that this effect might be due to inhibition of phosphodiesterase by aminophylline resulting in increased release of acetylcholine at the nerve terminal.

2. Daller JA, *et al.* Aminophylline antagonizes the neuromuscular blockade of pancuronium but not vecuronium. *Crit Care Med* 1991; **19:** 983–5.

Pharmacokinetics

On intravenous injection both atracurium besilate and cisatracurium besilate undergo spontaneous degradation via Hofmann elimination (a non-enzymatic breakdown process occurring at physiological pH and temperature) to produce laudanosine and other metabolites. There is also ester hydrolysis by non-specific plasma esterases. The metabolites have no neuromuscular blocking activity.

About 80% of atracurium besilate is bound to plasma proteins. Atracurium besilate and its metabolites cross the placenta in clinically insignificant amounts. Excretion of atracurium and cisatracurium is in urine and bile, mostly as metabolites. The elimination half-life has been reported to be about 20 minutes for atracurium and 22 to 29 minutes for cisatracurium but laudanosine has an elimination half-life of about 3 to 6 hours.

Biotransformation. Atracurium and cisatracurium are degraded by Hofmann elimination and metabolised by non-specific plasma esterases. Hofmann elimination is generally believed to be the main route of degradation but *in-vitro* work suggests ester hydrolysis is more important.[1] Both routes are independent of renal and hepatic function and no dosage reduction is recommended for elderly patients or those with impaired renal or hepatic function. However, the elimination half-life of atracurium has been found to be slightly longer in elderly patients[2] and in those with hepatic cirrhosis[3] compared with young and healthy patients, although others[4] have found no change in the pharmacokinetics of atracurium in the elderly. Renal and hepatic involvement in the metabolism of atracurium[2] may help to explain any tendency to reduced elimination but this does not appear to be clinically significant. Although clearance of cisatracurium has been reported to be reduced in patients with renal failure[5] this appears to have little significant effect on its pharmacodynamics.[6] Differences in the pharmacokinetics of cisatracurium in patients with hepatic impairment have been reported to be minor.[7]

The major biotransformation product of atracurium and cisatracurium is *laudanosine*; it has no clinical neuromuscular blocking activity but has been associated with CNS stimulation in *animal* studies. It is more lipid soluble than atracurium and cisatracurium and has a half-life of around 3 hours compared with one of approximately 20 minutes for atracurium. Higher plasma-laudanosine concentrations have been reported in patients with renal failure[5,8,9] than in patients with normal renal function. The elimination half-life of laudanosine was found to be significantly greater in patients with hepatic cirrhosis[3] and in elderly patients[2] compared with healthy and young patients respectively. High plasma-laudanosine concentrations were also seen in 10 critically ill patients with acute respiratory distress syndrome;[10] no adverse effects were noted.

Laudanosine crosses the blood-brain barrier in man. The concentration of laudanosine in the CSF increases during an infusion of atracurium and the CSF-to-plasma ratio gradually increases. A ratio of 0.14 was found at 125 to 140 minutes[11] during an infusion of atracurium at a mean rate of 510 micrograms/kg per hour. No evidence of CNS stimulation has been reported in man although patients given atracurium[12] had a 20% higher mean arterial-thiopental concentration at awakening compared with patients given vecuronium, suggesting that laudanosine may have had a minor stimulatory effect on the CNS. The blood-brain barrier appears to be effective in preventing a very high concentration of laudanosine from reaching the CNS and it is considered unlikely[13] that concentrations great enough to provoke seizures will be reached. Cisatracurium may be associated with the production of less laudanosine than atracurium.[14]

Uses and Administration

Competitive neuromuscular blockers act by competing with acetylcholine for receptors on the motor end-plate of the neuromuscular junction to produce blockade. The muscles that produce fine rapid movements such as those of the face are the first to be affected, followed by those of the limbs and torso; the last to be affected are those of the diaphragm. The paralysis is reversible with recovery occurring in reverse order. Restoration of normal neuromuscular function can be hastened by increasing the concentration of acetylcholine at the motor end-plate by giving an anticholinesterase such as neostigmine.

Atracurium and cisatracurium are competitive benzylisoquinolinium neuromuscular blockers. The commercial preparation of atracurium is a mixture of 10 stereoisomers of which cisatracurium constitutes about 15%. Cisatracurium, the *R-cis,1′R-cis*-isomer of atracurium, is about 3 times more potent than the mixture of isomers of atracurium. After an intravenous dose of atracurium, muscle relaxation begins in about 2 minutes and lasts for 15 to 35 minutes; onset may be slightly slower for cisatracurium.

Atracurium besilate and cisatracurium besilate are used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage.

For **atracurium besilate**, the usual initial dose for adults and children over 1 month of age is 300 to 600 micrograms/kg by intravenous injection. Subsequent doses of 100 to 200 micrograms/kg may be given as necessary, typically every 15 to 25 minutes for maintenance in prolonged procedures. It is recommended that in patients with cardiovascular disease the initial dose should be given over a period of 60 seconds.

Atracurium besilate may also be given by continuous intravenous infusion at a rate of 5 to 10 micrograms/kg per minute to maintain neuromuscular block during prolonged procedures. Somewhat higher infusion rates may be used in patients undergoing controlled ventilation in intensive care.

Cisatracurium is given as the besilate but doses are expressed as the base. Cisatracurium 1 mg is equivalent to about 1.34 mg of cisatracurium besilate. The usual initial dose for adults is 150 micrograms/kg by intravenous injection. The neuromuscular block may be extended with a maintenance dose of 30 micrograms/kg about every 20 minutes. The usual initial dose for children aged 1 month and over is 150 micrograms/kg. The neuromuscular block may be extended in children aged 2 years and over with a maintenance dose of 20 micrograms/kg about every 9 minutes. The *BNFC* suggests that a maintenance dose of 30 micrograms/kg, repeated about every 20 minutes, may be given to younger children aged 1 month and over; however, such use is unlicensed in the UK.

Cisatracurium besilate may also be given by continuous intravenous infusion to adults and children over 2 years of age at an initial rate equivalent to cisatracurium 3 micrograms/kg per minute followed by a rate of 1 to 2 micrograms/kg per minute after stabilisation.

◊ Reviews.

1. Bryson HM, Faulds D. Cisatracurium besilate: a review of its pharmacology and clinical potential in anaesthetic practice. *Drugs* 1997; **53:** 848–66.

Administration in infants and children. Children generally require larger doses of competitive neuromuscular blockers on a weight basis than adolescents or adults to achieve similar degrees of neuromuscular blockade and may recover more quickly. In contrast, neonates and infants under 1 year of age are more sensitive and usual doses may produce prolonged neuromuscular blockade (see also above for some suggested doses).

References.

1. Brandom BW, Fine GF. Neuromuscular blocking drugs in pediatric anesthesia. *Anesthesiol Clin North America* 2002; **20:** 45–58.

ECT. Competitive neuromuscular blockers have been used to reduce the intensity of muscle contractions and minimise trauma in patients receiving ECT, but suxamethonium (p.1912) is generally preferred because of its short duration of action.

Intravenous regional anaesthesia. Competitive neuromuscular blockers and/or opioid analgesics have been added to the local anaesthetic used in intravenous regional anaesthesia (p.1853) to improve the quality of anaesthesia. However atracurium (see Tourniquets under Precautions, above) and mivacurium (see Tourniquets, p.1907) might be unsuitable for such use.

Shivering. Various drugs have been tried in the treatment of postoperative shivering (p.1779). There are reports of neuromuscular blockers being used to treat shivering after cardiac surgery in order to reduce cardiovascular stress;[1] one study[2] has suggested that vecuronium might be preferable to pancuronium as it does not increase myocardial work and may be associated with fewer complications.

Doxacurium Chloride *(BAN, USAN, rINN)*

BW-A938U; Cloruro de doxacurio; Doksakuriumkloridi; Doxacurii Chloridum; Doxacurium, Chlorure de; Doxakuriumklorid. A mixture of the (1*R*,1′*S*,2*S*,2′*R*), (1*R*,1′*R*,2*S*,2′*S*), and (1*S*,1′*S*,2*R*,2′*R*) stereoisomers (a *meso* isomer and two enantiomers respectively) of 1,1′,2,2′,3,3′,4,4′-octahydro-6,6′,7,7′,8,8′-hexamethoxy-2,2′-dimethyl-1,1′-bis(3,4,5-trimethoxybenzyl)-2,2′-[butanedioylbis(oxytrimethylene)]di-isoquinolinium dichloride, all of which are in a *trans* configuration at the 1 and 2 positions of the isoquinolinium rings.

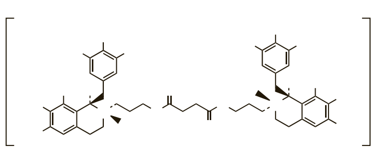
Доксакурия Хлорид

$C_{56}H_{78}Cl_2N_2O_{16}$ = 1106.1.

CAS — 133814-18-3 (doxacurium); 106819-53-8 (doxacurium chloride, meso isomer); 83348-52-1 (doxacurium chloride, total racemate).

ATC — M03AC07.

ATC Vet — QM03AC07.



Profile

Doxacurium chloride is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1902). It has been used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures and to aid controlled ventilation. Doxacurium has little histamine-releasing activity and causes negligible vagal or sympathetic blockade so that significant cardiovascular adverse effects are not a problem.

3 I

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Gallamine Triethiodide). A white, or almost white, hygroscopic powder. Very soluble in water; slightly soluble in alcohol; practically insoluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Gallamine Triethiodide). A white, hygroscopic, odourless, amorphous powder. Very soluble in water; sparingly soluble in alcohol; very slightly soluble in chloroform. pH of a 2% solution in water is between 5.3 and 7.0. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902). Tachycardia often develops due to the vagolytic action of gallamine triethiodide and blood pressure may be raised. It has a small histamine-releasing effect; occasional anaphylactoid reactions have been reported. It should be avoided in patients hypersensitive to iodine and in severe renal impairment. Although competitive muscle relaxants have been given with great care to patients with myasthenia gravis (see Neuromuscular Disorders, p.1903), UK licensed product information for gallamine triethiodide recommended that it should not be used in such patients.

Cardiopulmonary bypass. Alterations in the pharmacokinetics of competitive neuromuscular blockers in patients undergoing surgery involving cardiopulmonary bypass usually necessitate the use of reduced doses (see p.1903). However, the pharmacokinetics of gallamine in patients undergoing cardiopulmonary bypass appear not to differ significantly from those in control patients.[1]

1. Shanks CA, *et al.* Gallamine disposition in open-heart surgery involving cardiopulmonary bypass. *Clin Pharmacol Ther* 1983; **33:** 792–9.

Renal impairment. Gallamine triethiodide is excreted unchanged in the urine and UK licensed product information considered that it should be avoided in severe renal impairment since prolonged paralysis may occur. Significantly prolonged elimination half-life and reduced clearance have been reported[1] in patients with chronic renal failure given gallamine triethiodide in initial doses of 2 mg/kg intravenously.

1. Ramzan MI, *et al.* Gallamine disposition in surgical patients with chronic renal failure. *Br J Clin Pharmacol* 1981; **12:** 141–7.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Pharmacokinetics

After intravenous use gallamine triethiodide is distributed throughout body tissues. It is not metabolised, and is excreted in the urine as unchanged drug.

Uses and Administration

Gallamine triethiodide is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1905). Muscle relaxation occurs within about 1 to 2 minutes after intravenous injection and lasts for about 20 to 30 minutes. It has been used to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. An initial test dose of 20 mg may be given intravenously to the patient before anaesthesia to determine undue sensitivity. In the UK, initial doses of 80 to 120 mg by intravenous injection have been recommended, with further doses of 20 to 40 mg as required. In children, a dose of 1.5 mg/kg has been recommended, reduced to 600 micrograms/kg for neonates.

In some other countries lower doses have generally been used; an initial dose of 1 mg/kg intravenously, up to a maximum of 80 mg, with additional doses of 0.5 to 1 mg/kg after about 50 to 60 minutes if required.

Gallamine triethiodide has also been given intramuscularly, with or without hyaluronidase.

Preparations

BP 2008: Gallamine Injection;
USP 31: Gallamine Triethiodide Injection.

Proprietary Preparations (details are given in Part 3)

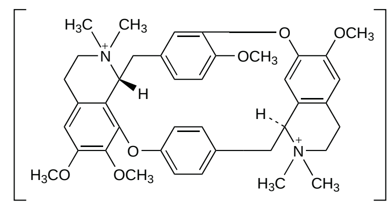
(+)-6,6′,7′,12′-Tetramethoxy-2,2,2′,2′-tetramethyltubocuraranium di-iodide.

$C_{40}H_{48}I_2N_2O_6$ = 906.6.

CAS — 5152-30-7 (metocurine); 7601-55-0 (metocurine iodide).

ATC — M03AA04.

ATC Vet — QM03AA04.



$2I^-$

Profile

Metocurine iodide is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1905) that has been used to provide muscle relaxation in surgical and other procedures.

Metocurine iodide has a moderate risk of inducing histamine release; it also has some ganglion blocking activity.

Mivacurium Chloride *(BAN, USAN, rINN)*

BW-B1090U; Cloruro de mivacurio; Mivacurii Chloridum; Mivacurium, Chlorure de; Mivakuriumklorid; Mivakuriumkloridi; Mivakuryum Klorür. A mixture of the stereoisomers of (*E*)-1,1′,2,2′,3,3′,4,4′-octahydro-6,6′,7,7′-tetramethoxy-2,2′-dimethyl-1,1′-bis(3,4,5-trimethoxybenzyl)-2,2′-[oct-4-enedioylbis(oxytrimethylene)]di-isoquinolinium dichloride.

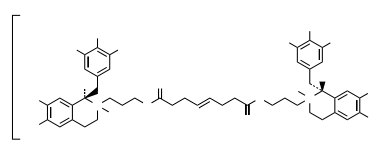
Мивакурия Хлорид

$C_{58}H_{80}Cl_2N_2O_{14}$ = 1100.2.

CAS — 106861-44-3 (mivacurium chloride, total racemate).

ATC — M03AC10.

ATC Vet — QM03AC10.



Incompatibility. See under Atracurium, p.1902 for details regarding the incompatibility of neuromuscular blockers.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902). Mivacurium chloride has no significant vagal or ganglion blocking activity at recommended doses. It may induce histamine release especially when given in large doses rapidly.

Mivacurium should be used with caution, if at all, in patients with plasma cholinesterase deficiency, since its duration of action will be prolonged in such patients.

Burns. In common with other competitive muscle relaxants patients with burns may develop resistance to mivacurium and require increased doses (see under Atracurium, p.1903). However, as these patients may also have reduced plasma cholinesterase activity dosage requirements could also be reduced. Licensed product information recommends that such patients should be given a test dose of 15 to 20 micrograms/kg with subsequent dosage adjustments being guided by monitoring of the block.

Neuromuscular disorders. Neuromuscular blockade was successfully achieved with mivacurium in an obese elderly patient with myasthenia gravis requiring surgery.[1] Only about half the usual dose was required and even then recovery was delayed. See Atracurium, p.1903 for a discussion of the use of competitive neuromuscular blockers in patients with neuromuscular disorders.

1. Seigne RD, Scott RPF. Mivacurium chloride and myasthenia gravis. *Br J Anaesth* 1994; **72:** 468–9.

Plasma cholinesterase deficiency. There have been reports of prolonged neuromuscular block produced by mivacurium in patients with plasma cholinesterase deficiency.[1-4] Time to full recovery varied; one patient required up to 8 hours.

1. Goudsouzian NG, *et al.* Prolonged neuromuscular block from mivacurium in two patients with cholinesterase deficiency. *Anesth Analg* 1993; **77:** 183–5.
2. Sockalingam I, Green DW. Mivacurium-induced prolonged neuromuscular block. *Br J Anaesth* 1995; **74:** 234–6.
3. Fox MH, Hunt PCW. Prolonged neuromuscular block associated with mivacurium. *Br J Anaesth* 1995; **74:** 237–8.
4. Zimmer S. Mivacurium and prolonged neuromuscular block. *Br J Anaesth* 1995; **75:** 823.

Tourniquets. Mivacurium might be unsuitable for neuromuscular blockade of a limb which has been isolated with a tourniquet in order to provide a bloodless field for surgery.[1] It is largely inactivated by the enzymatic action of plasma cholinesterase and would therefore continue to degrade locally leading to a loss of blockade in the limb, which could not be corrected by further doses unless the tourniquet was deflated. However, as for other competitive neuromuscular blockers, the use of mivacurium to supplement regional anaesthesia has produced prolonged muscle weakness well beyond cuff deflation.[2] This suggests that mivacurium is not broken down in the ischaemic limb and that recovery is not dependent on plasma concentrations of mivacurium.

See also Local Anaesthetics, under Interactions of Atracurium, p.1904, for a report of symptoms suggestive of local anaesthetic toxicity when prilocaine and mivacurium were used together.

2. Torrance JM, *et al.* Low-dose mivacurium supplementation of prilocaine i.v. regional anaesthesia. *Br J Anaesth* 1997; **78:** 222–3.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Metoclopramide. Metoclopramide, an inhibitor of plasma cholinesterase, was found to significantly prolong the duration of action of mivacurium in patients undergoing surgery, although in this study only marginal inhibition of plasma cholinesterase by metoclopramide occurred.[1]

1. Skinner HJ, *et al.* Influence of metoclopramide on plasma cholinesterase and duration of action of mivacurium. *Br J Anaesth* 1999; **82:** 542–5.

Pharmacokinetics

Mivacurium is a mixture of 3 stereoisomers, 2 of which (*cis-trans* and *trans-trans*) are considered to account for most of the neuromuscular blocking effect. All 3 isomers are inactivated by plasma cholinesterase. Renal and hepatic mechanisms are involved in their elimination with excretion in urine and bile.

◊ Reviews.

1. Atherton DPL, Hunter JM. Clinical pharmacokinetics of the newer neuromuscular blocking drugs. *Clin Pharmacokinet* 1999; **36:** 169–89.

Uses and Administration

Mivacurium chloride is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1905).

On intravenous injection muscle relaxation occurs within 1.5 to 2.5 minutes, depending on the dose with a duration of action of about 10 to 20 minutes. It is used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. Mivacurium is given as the chloride although doses are expressed in terms of mivacurium base. The initial dose by intravenous injection is 70 to 250 micrograms/kg. Doses up to 150 micrograms/kg may be given over 5 to 15 seconds but higher doses should be given over 30 seconds. In patients with asthma or cardiovascular disease, or those who are sensitive to falls in arterial blood pressure, it should be given over 60 seconds. To give a dose of 250 micrograms/kg for tracheal intubation, an injection of 150 micrograms/kg may be followed 30 seconds later by an injection of 100 micrograms/kg. Maintenance doses of 100 micrograms/kg may be given at intervals of 15 minutes. In children aged 2 to 6 months an initial dose of 150 micrograms/kg has been given; in children aged 7 months to 12 years, an initial dose of 200 micrograms/kg has been given. A maintenance dose of 100 micrograms/kg may be given every 6 to 9 minutes for children aged 2 months to 12 years.

Mivacurium chloride may also be given by continuous intravenous infusion for maintenance of block. For adults the initial rate is 8 to 10 micrograms/kg per minute adjusted every 3 minutes if necessary by increments of 1 microgram/kg per minute to a usual rate of 6 to 7 micrograms/kg per minute; in children aged 2 months to 12 years the usual dose is 11 to 14 micrograms/kg per minute.

Reduced doses may be required in the elderly and in patients with hepatic or renal impairment (see below).

Action. Mivacurium has a shorter duration of action than most other competitive neuromuscular blockers. Studies[1-3] suggest that it is a useful alternative to suxamethonium for the production of neuromuscular block of short duration and has the advantage that its block can be reversed with an anticholinesterase. For a discussion of the choice of anticholinesterase for reversal of neuromuscular block produced by short-acting blockers such as mivacurium, see under Neostigmine, p.633. Although its onset of action may be accelerated by giving a priming dose,[4] mivacurium has a slower onset than suxamethonium and so may not be a suitable alternative[5] when rapid intubation is required. For a general review of neuromuscular blockers, see Anaesthesia, p.1900.

5. Anonymous. Mivacurium—a new neuromuscular blocker. *Med Lett Drugs Ther* 1992; **34:** 82.

Administration in the elderly. In a study[1] comparing the effects of mivacurium in elderly and young adults, the duration of neuromuscular effects was prolonged in elderly patients by about 30%. The mean infusion requirement in elderly patients was 3.67 micrograms/kg per minute compared with 5.5 micrograms/kg per minute in young adults.

Licensed product information states that elderly patients may require decreased infusion rates or smaller or less frequent maintenance bolus doses.

1. Maddineni VR, *et al.* Neuromuscular and haemodynamic effects of mivacurium in elderly and young adult patients. *Br J Anaesth* 1994; **73:** 608–12.

Administration in hepatic or renal impairment. The pharmacokinetics of mivacurium have been studied in patients with renal[1-3] or hepatic impairment.[1,4,5] The duration of relaxation produced by mivacurium was about 1.5 times greater than normal in patients with end-stage renal disease and up to about 3 times greater than normal in patients with end-stage liver disease. Reduced plasma-cholinesterase activity in the patients with hepatic impairment may have played an important part in this effect. Although an anticholinesterase such as neostigmine hastens recovery by only a few minutes in healthy subjects, its use may be indicated in patients in whom recovery is delayed.[2]

Licensed product information recommends that in patients with end-stage renal or liver disease, the dose should be adjusted according to individual clinical response.

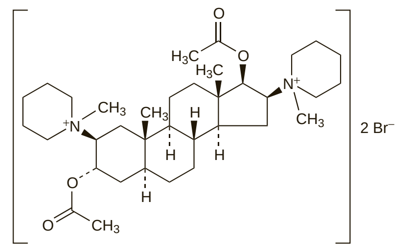
ATC Vet — QM03AC01.



Pharmacopoeias. In *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Pancuronium Bromide). White, yellowish-white, or slightly pink, hygroscopic crystalline powder. Very soluble to freely soluble in water; freely soluble in alcohol; very soluble in dichloromethane. Store in airtight containers. Protect from light.

USP 31 (Pancuronium Bromide). A white, yellowish-white, or slightly pink, crystalline hygroscopic powder. Freely soluble in water, in alcohol, and in dichloromethane. Store in airtight containers at a temperature of 15° to 25°. Protect from light.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902).

Pancuronium has vagolytic and sympathomimetic action, which may cause tachycardia and hypertension, but does not produce ganglionic blockade. It has little histamine-releasing effect. Hypersensitivity reactions are relatively rare but bradycardia, bronchospasm, hypotension, and cardiovascular collapse have been reported. Pancuronium has been associated with excessive salivation in some patients.

Pancuronium should be used with caution in patients with raised catecholamine concentrations, or in those who are receiving drugs with sympathomimetic effects, as cardiovascular adverse effects are more likely in these patients.

Effects on the ears. A study[1] found that neonates who survived congenital diaphragmatic hernia were more likely to suffer from sensorineural hearing loss after prolonged use of pancuronium bromide during the neonatal period. However, the authors commented that the association is not necessarily causal and that further investigation is required.

1. Cheung P-Y, *et al.* Prolonged use of pancuronium bromide and sensorineural hearing loss in childhood survivors of congenital diaphragmatic hernia. *J Pediatr* 1999; **135:** 233–9.

Hypersensitivity. Reports of anaphylactoid or anaphylactic reactions associated with pancuronium bromide.

See also under Suxamethonium Chloride, p.1910.

2. Patriarca G, *et al.* Pancuronium allergy: a case report. *Br J Anaesth* 1989; **62:** 210–12.
3. Moneret-Vautrin DA, *et al.* Simultaneous anaphylaxis to thiopentone and a neuromuscular blocker: a study of two cases. *Br J Anaesth* 1990; **64:** 743–5.
4. Sanchez-Guerrero IM, *et al.* Anaphylactoid reaction induced by pancuronium during general anaesthesia. *Eur J Anaesthesiol* 1998; **15:** 613–14.

Postoperative complications. Because of its prolonged duration of action, pancuronium may be more likely than other neuromuscular blockers to produce residual neuromuscular block; such residual block is associated with an increased incidence of postoperative respiratory complications.[1,2]

1. Berg H, *et al.* Residual neuromuscular block is a risk factor for postoperative pulmonary complications: a prospective, randomised, and blinded study of postoperative pulmonary complications after atracurium, vecuronium and pancuronium. *Acta Anaesthesiol Scand* 1997; **41:** 1095–1103.
2. Bissinger U, *et al.* Postoperative residual paralysis and respiratory status: a comparative study of pancuronium and vecuronium. *Physiol Res* 2000; **49:** 455–62.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Pharmacokinetics

On intravenous injection pancuronium bromide is rapidly distributed into body tissues; about 80% may be bound to plasma proteins. A small proportion is metabolised in the liver to metabolites with weak neuromuscular blocking activity. It is largely excreted in urine as unchanged drug and metabolites; a small amount is excreted in bile. The plasma elimination half-life is about 2 hours. It crosses the placenta in small amounts.

Pregnancy. In 15 patients undergoing caesarean section[1] given pancuronium bromide 100 micrograms/kg intravenously with other agents, mean maternal arterial and umbilical venous serum concentrations of pancuronium bromide and metabolites were 520 and 120 nanograms/mL, respectively at delivery (mean of 13 minutes after injection), giving a fetal to maternal ratio of 0.23.

1. Wingard LB, *et al.* Modified fluorometric quantitation of pancuronium bromide and metabolites in human maternal and umbilical serums. *J Pharm Sci* 1979; **68:** 914–15.

Uses and Administration

Pancuronium bromide is an aminosteroidal competitive neuromuscular blocker (see Atracurium, p.1905). Muscle relaxation occurs within about 1.5 to 2 minutes of intravenous injection and lasts for about 45 to 60 minutes.

Pancuronium bromide is used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. The initial dose for intubation is usually 50 to 100 micrograms/kg by intravenous injection, with maintenance doses of 10 to 20 micrograms/kg. Children may be given similar doses. Some manufacturers recommend a reduction in the initial dose to 20 to 60 micrograms/kg when pancuronium is given following suxamethonium. Doses of 30 to 40 micrograms/kg initially have been suggested in neonates, with maintenance doses of 10 to 20 micrograms/kg as necessary; in the UK, the *BNFC* suggests that higher doses may be used for neonates in some cases. In the USA, dosage based on an initial test dose of 20 micrograms/kg has been advocated for the neonate.

Adult patients under intensive care who require assisted ventilation for conditions such as intractable status asthmaticus or tetanus may be given 60 micrograms/kg intravenously every 1 to 1½ hours or less frequently.

Care should be taken when giving pancuronium to patients with hepatic or renal impairment, see below.

Administration in hepatic impairment. Prolonged neuromuscular blockade may occur in patients with liver disease given pancuronium bromide since increased elimination half-life with increased volume of distribution and reduced clearance has been reported.[1] However, the expanded distribution volume may necessitate an increase in the dose of pancuronium in these patients[1,2] and may be interpreted as resistance to the neuromuscular blocking effects of pancuronium.

1. Duvaldestin P, *et al.* Pancuronium pharmacokinetics in patients with liver cirrhosis. *Br J Anaesth* 1978; **50:** 1131–6.
2. Ward ME, *et al.* Althesin and pancuronium in chronic liver disease. *Br J Anaesth* 1975; **47:** 1199–1204.

Administration in renal impairment. Prolonged neuromuscular blockade may occur when pancuronium is given to patients with severe renal impairment. Pancuronium distributes rapidly into extracellular fluid after intravenous injection and the initial neuromuscular blockade produced will depend upon the peak drug concentration in this fluid. Since extracellular fluid volume is increased in chronic renal failure such patients may require a larger initial dose of pancuronium and a 45% increase in dose requirement has been reported[1] in patients with end-stage renal failure. Renal excretion is the main route of elimination and prolonged elimination half-life with reduced clearance may be expected in renal failure; total dose requirements may be reduced. The main infusion rate of pancuronium to maintain 90% blockade in patients with end-stage renal failure was reported to be 61.5% less than for patients with normal renal function.

1. Gramstad L. Atracurium, vecuronium and pancuronium in end-stage renal failure. *Br J Anaesth* 1987; **59:** 995–1003.

Fetal paralysis. Pancuronium bromide 100 micrograms/kg of the estimated fetal-weight, given into the umbilical vein, produced fetal paralysis for about 40 minutes during intravascular exchange transfusion.[1] A dose of 200 to 300 micrograms/kg produced fetal paralysis for about 1 to 8 hours for more complicated transfusion procedures.[2] No adverse effects were reported.

Pipecuronium Bromide *(BAN, USAN, rINN)*

Bromuro de pipecuronio; Pipecurium Bromide; Pipecuronii Bromidum; Pipécuronium, Bromure de; Pipekuroniumbromid; Pipekuroniumbromidi; RGH-1106. 1,1,1′,1′-Tetramethyl-4,4′-(3α,17β-diacetoxy-5α-androstan-2β,16β-diyl)dipiperazinium dibromide.

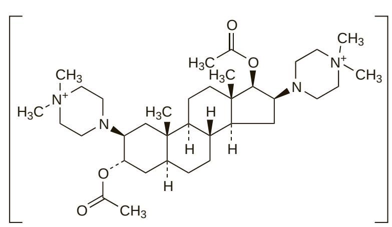
Пипекурония Бромид

$C_{35}H_{62}Br_2N_4O_4$ = 762.7.

CAS — 52212-02-9 (anhydrous pipecuronium bromide); 68399-57-5 (pipecuronium bromide dihydrate).

ATC — M03AC06.

ATC Vet — QM03AC06.



Profile

Pipecuronium bromide is an aminosteroidal competitive neuromuscular blocker (see Atracurium, p.1902). Pipecuronium is reported to have no significant cardiovascular adverse effects or histamine-related effects. On intravenous injection muscle relaxation occurs within 2.5 to 3 minutes with a duration of action of about 30 minutes to 2 hours, depending on the dose.

Pipecuronium bromide has been used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid mechanical ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. Initial doses of 80 to 100 micrograms/kg intravenously have been recommended, with subsequent doses of 10 to 20 micrograms/kg. Lower initial doses are given following suxamethonium or in patients at high risk: 50 to 60 micrograms/kg has been recommended, or 35 micrograms/kg for caesarean section.

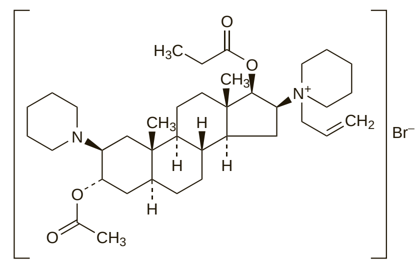
Rapacuronium Bromide *(BAN, USAN, rINN)*

Bromuro de rapacuronio; Org-9487; Rapacuronii Bromidum; Rapacuronium, Bromure de. 1-(3α-Acetoxy-2β-piperidino-17β-propionyloxy-5α-androstan-16β-yl)-1-allylpiperidinium bromide; 1-Allyl-1-(3α,17β-dihydroxy-2β-piperidino-5α-androstan-16β-yl)piperidinium bromide, 3-acetate 17-propionate.

Рапакурония Бромид

$C_{37}H_{61}BrN_2O_4$ = 677.8.

CAS — 156137-99-4.



Profile

Rapacuronium bromide, an analogue of vecuronium (p.1913), is an aminosteroidal competitive neuromuscular blocker (see Atracurium, p.1905). It was used to provide muscle relaxation in general anaesthesia for surgical procedures and for endotracheal intubation, but was withdrawn from the market after reports of severe bronchospasm, including fatalities.

(rocuronium)

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Rocuronium Bromide). An almost white or pale yellow, slightly hygroscopic, powder. Freely soluble in water and in dehydrated alcohol. A 1.0% solution in water has a pH of 8.9 to 9.5. Store in airtight containers. Protect from light.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902). Rocuronium is reported to have minimal cardiovascular and histamine-releasing effects. High doses (greater than 900 micrograms/kg of rocuronium bromide) have mild vagolytic activity. It should be used with caution in patients with biliary disease or hepatic or renal impairment.

Hepatic impairment. There have been conflicting reports of the pharmacokinetics and pharmacodynamics of rocuronium in patients with hepatic impairment. In contrast to earlier studies[1,2] one group of workers[3] found a significant reduction in the plasma clearance of rocuronium in patients with cirrhosis. The elimination half-life has been variously reported to be unchanged[1] or prolonged[2,3] with delayed recovery.[3] Some studies[2,3] found that the onset of action was not affected while one group of workers[1] reported a delay.

Licensed product information recommends that care should be taken when giving rocuronium to patients with clinically significant hepatic impairment (see also under Uses and Administration, below).

3. van Miert MM, *et al.* The pharmacokinetics and pharmacodynamics of rocuronium in patients with hepatic cirrhosis. *Br J Clin Pharmacol* 1997; **44:** 139–44.

Hypersensitivity. Although rocuronium is considered to have minimal histamine-releasing effects, histaminoid reactions have been reported[1] on induction of anaesthesia in 3 patients who had been given rocuronium. An increased incidence of severe hypersensitivity reactions (particularly anaphylactic shock) has been reported with rocuronium compared with other neuromuscular blockers available in France.[2] Fatalities have occurred.[3]

See also the discussion of the relative risks of hypersensitivity associated with neuromuscular blockers, under Suxamethonium Chloride, p.1910.

3. Baillard C, *et al.* Anaphylaxis to rocuronium. *Br J Anaesth* 2002; **88:** 600–602.

Pain on administration. Severe transient burning pain associated with injection of rocuronium was considered[1] to be responsible for the spontaneous movement sometimes seen in the arm or wrist into which rocuronium is given. It is recommended that rocuronium should be given only when a deep stage of unconsciousness has been achieved.

1. Borgeat A, Kwiatkowski D. Spontaneous movements associated with rocuronium: is pain on injection the cause? *Br J Anaesth* 1997; **79:** 382–3.

Renal impairment. In a study[1] of the pharmacokinetics and neuromuscular effects of rocuronium, the clearance of rocuronium was reduced in patients with renal failure when compared with healthy patients, but the accompanying increase in duration of clinical relaxation did not reach statistical significance. However, it was recommended that rocuronium should be used with caution in the presence of renal failure as there were large interpatient variations in both clinical response and pharmacokinetic parameters. It has been suggested[2] that chronic renal failure may have played a role in the prolongation of neuromuscular blockade in a 47-year-old woman given rocuronium 1 mg/kg. Although this dose is within the recommended adult dose range, it was criticised[3] as being excessive for a patient with renal impairment.

For recommendation that care should be taken when giving rocuronium to patients with renal failure, see under Uses and Administration, below.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Pharmacokinetics

On intravenous use plasma concentrations of rocuronium follow a three-compartment open model. There is an initial distribution phase with a half-life of 1 to 2 minutes followed by a slower distribution phase with a half-life of 14 to 18 minutes. It is reported to be about 30% bound to plasma proteins. The elimination half-life is about 1.2 to 1.4 hours. Up to 40% of a dose may be excreted in the urine within 24 hours; rocuronium is also excreted in the bile. The main metabolite of rocuronium, 17-desacetylrocuronium, is reported to have a weak neuromuscular blocking effect.

Intensive care. The pharmacokinetics of rocuronium appear to differ between intensive care patients given prolonged dosage and surgical patients.[1] The volume of distribution at steady state may be increased, the plasma clearance decreased, and the terminal half-life prolonged. Recovery time on stopping may also be longer.

1. Sparr HJ, *et al.* Pharmacodynamics and pharmacokinetics of rocuronium in intensive care patients. *Br J Anaesth* 1997; **78:** 267–73.

Pregnancy. The mean concentration of rocuronium in venous plasma of 32 patients given a dose of 600 micrograms/kg before undergoing caesarean section was 2412 nanograms/mL at delivery;[1] the ratio of mean concentrations of rocuronium in umbilical venous plasma to maternal venous plasma at this time was 0.16. In 12 of these patients the mean concentration of rocuronium in umbilical arterial plasma was 271 nanograms/mL giving a ratio of 0.62 for the mean concentration of rocuronium in arterial to venous umbilical plasma. The concentration of 17-desacetylrocuronium in maternal venous plasma was 178 nanograms/mL and was less than 25 nanograms/mL in umbilical plasma.

Uses and Administration

Rocuronium bromide is an aminosteroidal competitive neuromuscular blocker (see Atracurium, p.1905). After intravenous injection it produces muscle relaxation within 1 to 2 minutes with a duration of about 30 to 50 minutes. Rocuronium bromide is used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. A usual initial dose is 600 micrograms/kg by intravenous injection; however, higher doses of 1 mg/kg are recommended for intubation during rapid sequence induction of anaesthesia. Usual maintenance doses are 150 micrograms/kg by injection, although these should be reduced to 75 to 100 micrograms/kg if prolonged inhalational anaesthesia is planned. Maintenance may also be by infusion at a rate of 300 to 600 micrograms/kg per hour although higher rates have been used in the USA. Similar doses to those used in adults have been used in the UK in infants and children older than one month but maintenance doses may be required more frequently. In the USA, rocuronium is licensed for use in children aged 3 months and over; again doses are similar to those used in adults.

For obese patients weighing more than 30% over their ideal body-weight UK licensed product information recommends that doses should be calculated according to lean body-mass; in the USA it is recommended that dosage should be based on actual body-weight. UK product information also recommends reduced maintenance doses of 75 to 100 micrograms/kg by injection in the elderly. For doses in hepatic or renal impairment, see below.

Administration in children. In a study involving 70 children, conditions for intubation were judged to be good to excellent within one minute of intravenous doses of rocuronium 600 or 900 micrograms/kg, with a trend to better conditions with the higher dose.[1]

1. Fuchs-Buder T, Tassonyi E. Intubating conditions and time course of rocuronium-induced neuromuscular block in children. *Br J Anaesth* 1996; **77:** 335–8.

INTRAMUSCULAR ROUTE. Intramuscular injection of rocuronium 1 mg/kg into the deltoid muscle permitted tracheal intubation to be carried out in lightly anaesthetised infants after 2.5 minutes.[1] In children a dose of 1.8 mg/kg enabled tracheal intubation after 3 minutes. However, the mean time to initial recovery after these large doses was 57 minutes in infants and 70 minutes in children. This prolonged duration of action may limit intramuscular use for brief procedures, particularly in children.

1. Reynolds LM, *et al.* Intramuscular rocuronium in infants and children: dose-ranging and tracheal intubating conditions. *Anesthesiology* 1996; **85:** 231–9.

Administration in hepatic or renal impairment. UK licensed product information recommends a reduced maintenance dose of 75 to 100 micrograms/kg in patients with hepatic or biliary-tract disease, or renal failure. Initial doses remain unaltered.

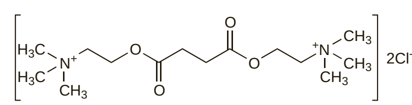
ATC — M03AB01.

ATC Vet — QM03AB01.



Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Suxamethonium Chloride). A white or almost white, hygroscopic, crystalline powder. Freely soluble in water; slightly soluble in alcohol. A 0.5% solution in water has a pH of 4.0 to 5.0. Protect from light.

USP 31 (Succinylcholine Chloride). A white, odourless, crystalline powder. The anhydrous form is hygroscopic. Soluble 1 in 1 of water and 1 in 350 of alcohol; slightly soluble in chloroform; practically insoluble in ether. Its solutions in water have a pH of about 4. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Incompatibility. Incompatibilities of neuromuscular blockers are discussed under Atracurium, p.1902.

Stability. A study of the loss of potency of suxamethonium chloride 20 mg/mL in water indicated that decomposition occurred at a considerably higher rate at 40° than at 25° and that the pH range of maximum stability was 3.75 to 4.50 for unbuffered solutions.[1] Assuming the usual conditions of manufacturing, transit, and storage the total loss of potency was estimated to be 7% and 9% respectively for injections kept at room temperature for 4 and 6 weeks. If unbuffered, suxamethonium chloride injection complying with USP 31 pH limits (3.0 to 4.5) must be stored at room temperature; it should not be kept for longer than 4 weeks.

Adverse Effects

The neuromuscular blocking action of suxamethonium chloride is terminated by the enzyme plasma cholinesterase and prolonged apnoea may occur in patients with an atypical enzyme or with low enzyme activity. Apnoea may also occur following development of phase II block (see Uses and Administration, below) after high or repeated doses of suxamethonium chloride, although tachyphylaxis may also occur with repeated doses.

Transient fasciculations occur during the onset of depolarising block. Rhabdomyolysis, myoglobinaemia, and myoglobinuria have been reported and may be associated with muscle damage following fasciculations. Postoperative muscle pain occurs in some patients but is not directly related to the degree of fasciculation. A transient rise in intra-gastric pressure may occur secondary to fasciculation of abdominal muscles. A transient increase in intra-ocular pressure often occurs. Depolarisation of skeletal muscle produces an immediate increase in plasma-potassium concentration and this can have serious consequences in some patients (see below).

Stimulation of the vagus nerve and parasympathetic ganglia by suxamethonium chloride may be followed by bradycardia, other arrhythmias, and hypotension, and may be exacerbated by the raised plasma-potassium concentration; cardiac arrest has been reported. Tachycardia and an increase in blood pressure due to stimulation of sympathetic ganglia have also been reported.

Suxamethonium chloride may cause an increase in salivary, bronchial, and gastric secretion and other muscarinic effects. Salivary gland enlargement has occurred.

Direct release of histamine from mast cells occurs but this is not the main mechanism of hypersensitivity reactions (see Hypersensitivity, below). Flushing, skin rash, bronchospasm, and shock have been reported.

Other reported effects include prolonged respiratory depression and apnoea.

Suxamethonium chloride is implicated in the development of malignant hyperthermia (p.1896) in those patients with a genetic predisposition to the syndrome.

Effects on intra-ocular pressure. Doses of suxamethonium are often followed 20 to 30 seconds later by a transient increase in intra-ocular pressure, which may be due in part to contracture of extra-ocular muscles. If suxamethonium is used during eye surgery after incision of the eyeball or in patients with a penetrating eye injury, there is a theoretical risk that any increase in intra-ocular pressure may result in extrusion of ocular contents and loss of sight. However, there appear to be few reports of vitreous extrusion associated with suxamethonium,[1] and a large retrospective study[2] has failed to find any evidence that suxamethonium caused additional eye damage in patients with penetrating eye injuries. Furthermore, the procedure of intubation itself is associated with a greater increase in intra-ocular pressure than that seen with suxamethonium. Nonetheless, some suggest that a rapid competitive neuromuscular blocker would be preferable to aid intubation in patients with penetrating eye injuries, after incision of the eyeball, and in glaucoma, although others consider that the risk of a transient rise of intra-ocular pressure in these situations should be weighed against the need for rapid intubation.[1,3] For a discussion on the use of various drugs to counteract the rise in intra-ocular pressure associated with suxamethonium and intubation in general, see under Anaesthesia, p.1900.

Effects on the muscles. Muscle fasciculations and postoperative muscle pain commonly follow use of suxamethonium. **Fasciculations** (generalised and desynchronised contractions of skeletal muscle fibres) occur during the onset of depolarising block in almost all patients given suxamethonium and may cause muscle damage. They are seen especially in the 'fine' muscles of the hands and face, and can be useful as an indication that suxamethonium is working. Attempts have been made to prevent their development with the aim of reducing postoperative muscle pain. However, there appears to be no direct correlation between the extent of visible fasciculations and muscle pain.[1,2] Slow infusion of suxamethonium[3] or giving divided doses[4] reduces fasciculations but not muscle pain.

Postoperative **muscle pain** is one of the most common adverse effects of suxamethonium and has been noted in about 50% of patients, although the reported incidence varies widely from around 1.5 to about 90%.[2] It usually occurs on the first postoperative day and lasts for 2 or 3 days, and most often affects muscles of the neck, shoulders, and upper abdomen.[2] The incidence and severity of muscle pain is increased in patients who are mobile soon after surgery and in females, but it occurs less often in children, pregnant women, and the elderly.[2]

The mechanism of suxamethonium-induced muscle pain is not fully understood; there have been many attempts to prevent it. Pretreatment with a small dose of a competitive neuromuscular blocker reduces both visible fasciculations and the incidence and severity of muscle pain,[1,2,5-8] but may delay the onset and alter the intensity of subsequent suxamethonium block[9] and impair conditions for intubation[1,9] (see Neuromuscular Blockers, under Interactions in Atracurium, p.1905). In addition, larger doses of suxamethonium are required;[10] consequently the practice is considered controversial by some authors.[10,11] Pretreatment with a small dose (10 mg) of suxamethonium in a 'self-taming' technique appears to offer no protection against muscle pain.[1,2] The choice of anaesthetic induction agent has been suggested to be significant, as has the timing of doses, but despite claims for benefit with, for example, propofol, this remains questionable.[2] Pretreatment with benzodiazepines or NSAIDs has produced conflicting results.[2] Other drugs that have been tried include lidocaine, calcium gluconate, and vitamin C; there is some evidence that lidocaine may be the most effective pretreatment.[2] Not all methods have concentrated on drug treatment. A simple regimen of stretching exercises before premedication has reduced the incidence of both fasciculations and postoperative muscle pain.[12]

Suxamethonium may also produce an increase in **jaw tension** (masseter spasm or trismus)[13] in both adults[14] and children[15,16] during the onset of neuromuscular blockade. Tracheal intubation is greatly hindered in affected patients. It is not possible to predict which patients will show this response and the mechanism is unknown, although in about 50% of patients it may indicate the onset of malignant hyperthermia. Pretreatment with a paralysing dose of a competitive neuromuscular blocker prevents the response[16] but it is not known whether this is clinically useful.

Effects on plasma-potassium concentration. Suxamethonium causes depolarisation of motor end-plates in skeletal muscle, resulting in an immediate increase in plasma-potassium concentration. The rise is usually small, being about 0.5 mmol or less per litre, but suxamethonium is best avoided in patients whose plasma-potassium concentration is already high, such as those with renal impairment. An exaggerated response, with severe hyperkalaemia resulting in ventricular fibrillation and cardiac arrest, has been reported in patients with burns,[1,2] massive trauma, closed head injury, neuromuscular disease (see Neuromuscular Disorders, under Precautions, below), and severe long-lasting sepsis.[3] See also Children, under Precautions, below for reference to fatal cardiac arrest associated with hyperkalaemia in children. With burns or trauma the period of greatest risk is from about 10 to 90 days after the injury, but may be further prolonged if there is delayed healing or persistent infection. These patients may still react abnormally to suxamethonium 2 years after the injury. In neuromuscular disease the greatest risk period is usually from 3 weeks to 6 months after onset, but severe hyperkalaemia may occur after 24 to 48 hours or later than 6 months. Patients with severe sepsis for more than a week should be considered at risk of hyperkalaemia and suxamethonium should not be given until the infection has cleared. The mechanism of this hyperkalaemic response appears to be a supersensitivity of acetylcholine receptors in which the entire muscle fibre membrane, rather than discrete motor end-plate sites, becomes directly excitable by depolarising drugs. Depolarisation by suxamethonium thus results in release of potassium over the entire muscle fibre membrane and hyperkalaemia results.

Various methods have been tried to attenuate the hyperkalaemia, including pretreatment with a small dose of a competitive neuromuscular blocker[3,4] or with suxamethonium itself.[5,6] No method is reliable enough to be used clinically.

Anaesthetics such as thiopental and halothane can increase the hyperkalaemic response.[4]

Hypersensitivity. Hypersensitivity reactions to neuromuscular blockers are more common in women than in men,[1,2] in atopic patients and those who have a history of asthma or allergy,[2] and in patients who have had a previous reaction to anaesthetic drugs.[2] Circulatory collapse, flushing, skin rash, urticaria, and bronchospasm have occurred in hypersensitivity reactions associated with suxamethonium;[1,3,4] deaths have been reported.[3,5]

Data from intradermal testing has been used to qualify the **risk** of allergic reactions associated with the neuromuscular blockers:[6]

- benzylisoquinolinium blockers *alcuronium* and *tubocurarine* and the depolarising blocker *suxamethonium* were considered to be associated with the highest risk
- benzylisoquinolinium blockers *atracurium*, *cisatracurium*, *gallamine*, and *mivacurium* and the aminosteroid *rocuronium* presented an intermediate risk
- the aminosteroids *pancuronium* and *vecuronium* were considered to have the lowest risk

A type I immediate hypersensitivity reaction involving IgE antibodies is considered to be the **mechanism** of most hypersensitivity reactions associated with neuromuscular blockers.[2,5,7,8] Antibodies reacting with neuromuscular blockers, including suxamethonium, have been demonstrated.[5,8] The antibodies appear to be directed against quaternary or tertiary ammonium-ion groups which are present in neuromuscular blockers; such groups are also found in other drugs, cosmetics, disinfectants, and foods. This may help explain the cross-reactivity reported between different neuromuscular blockers[1,2,5,8,9] and how sensitisation occurs without prior exposure to any neuromuscular blocker.[2,5] At least 50% of patients sensitive to one neuromuscular blocker will react to one or more others[10] with some patients sensitive to most.[1] Intradermal skin tests are used to investigate and predict sensitivity to neuromuscular blockers, but their interpretation is controversial and it cannot be concluded that all patients with positive skin tests will have clinical sensitivity.[1,10] Although radioallergosorbent tests can detect antibodies to suxamethonium, alcuronium, and thiopental[3,11] some consider that their routine use is not justified as reactions could be avoided by taking an adequate patient history.[12]

However, neuromuscular blockers also have a direct effect on mast cells, releasing histamine without immunological involvement, and could cause anaphylactoid reactions. Histamine release associated with use of aminosteroidal blockers is rare compared with the benzylisoquinolinium blockers.[13] Tubocurarine is considered to be the most potent releaser of histamine, with pancuronium and vecuronium having only very weak activity. Suxamethonium is considered to have only 1% of the histamine-releasing activity of tubocurarine but is more likely to produce serious hypersensitivity reactions.

Treatment of Adverse Effects

Once suxamethonium chloride has been given assisted respiration should be maintained until spontaneous respiration has been fully restored. Transfusion of fresh frozen plasma or other source of plasma cholinesterase will help the destruction of the suxamethonium when prolonged paralysis is a result of atypical or low serum concentrations of plasma cholinesterase. Anticholinesterases should not normally be used since they potentiate the usual phase I block (see Uses and Administration, below). If the neuromuscular block ceases to be depolarising in type and acquires some features of a competitive block (phase II block) the cautious use of an anticholinesterase may be considered. A short-acting anticholinesterase such as edrophonium may be given intravenously and if an obvious improvement is maintained for several minutes, neostigmine may be given with atropine.

Severe hypersensitivity reactions should be treated promptly with supportive and symptomatic measures.

If malignant hyperthermia develops, it may be treated as described on p.1896.

The muscarinic effects of suxamethonium chloride, such as bradycardia and excessive salivary secretion, may be reduced by giving an antimuscarinic such as atropine before suxamethonium. A small dose of a competitive neuromuscular blocker given before suxamethonium has been used to reduce some of the adverse effects of suxamethonium on the muscles (see Effects on the Muscles, above).

Precautions

Patients given a neuromuscular blocker should always have their respiration assisted or controlled until the drug has been inactivated or antagonised.

Suxamethonium chloride is contra-indicated in patients with atypical plasma cholinesterase and should be used with caution in patients with reduced plasma cholinesterase activity (see below), which may occur in certain disease states and following exposure to certain drugs. Plasma cholinesterase concentrations fall during pregnancy and the puerperium and therefore maternal paralysis may be mildly prolonged. Suxamethonium is contra-indicated in patients with burns, massive trauma, renal impairment with a raised plasma-potassium concentration, severe long-lasting sepsis, and severe hyperkalaemia, since suxamethonium-induced rises in plasma-potassium concentration can have serious consequences in such patients; patients who have been immobilised for prolonged periods may be at similar risk. It is contra-indicated in patients with a history of hypersensitivity to the drug and, because high rates of cross-sensitivity have been reported (see above), should be used with caution when hypersensitivity to any neuromuscular blocker has previously occurred. Suxamethonium should be avoided in patients with a penetrating eye injury, raised intra-ocular pressure or glaucoma, or those about to undergo incision of the eyeball in eye surgery, because of the risks from increased intra-ocular pressure (although see under Adverse Effects, above). Suxamethonium chloride produces muscle contractions before relaxation and should therefore be used with caution in patients with bone fractures. It is contra-indicated in patients with a personal or family history of malignant hyperthermia.

The response to suxamethonium chloride is often unpredictable in patients with neuromuscular disorders and it should be used with great caution in these patients (see below). Caution is also needed if it is given to a patient with cardiac or respiratory disease. Children may be at special risk from cardiac arrest associated with hyperkalaemia (see below).

Hypothermia may enhance the neuromuscular blocking effects of suxamethonium chloride and an increase in body temperature may reduce them.

Children. Reports of fatal cardiac arrests[1,2] in apparently healthy children and adolescents, who were subsequently found to have had undiagnosed myopathies, led to restrictions in the USA on the use of suxamethonium in this age group. Suxamethonium was contra-indicated except for emergency tracheal intubation or where an immediate securing of an airway was essential. Many anaesthetists disagreed[2] with this contra-indication and an FDA Committee advised[3] that it should be replaced by a warning about the possibility of cardiac arrest associated with hyperkalaemia with special attention being paid to male children who are considered to be at the highest risk. One British anaesthetist who questioned the rationale behind restricting the elective use of suxamethonium pointed out that alternatives to suxamethonium had not been shown to be as safe or effective for airway management.[4] The rare occurrence of cardiac arrest in children might be further reduced by taking a careful family history to exclude undiagnosed myopathies and by using an intravenous as opposed to inhalation induction when suxamethonium is to be used.[4] A survey had found that most cases of cardiac arrest in children in the UK associated with the use of suxamethonium had been caused by vagal overactivity in non-atropinised patients.

4. Hopkins PM. Use of suxamethonium in children. *Br J Anaesth* 1995; **75:** 675–7.

Neuromuscular disorders. Caution is needed if suxamethonium is to be given to patients with neuromuscular disease, since severe complications have been reported.[1] Hyperkalaemia and cardiac arrhythmias or cardiac arrest have been reported after use of suxamethonium in patients with hemiplegia, diffuse intracranial lesions (head injury, encephalitis, ruptured cerebral aneurysm), tetanus, paraplegia, acute anterior horn cell disease, and muscular dystrophies. An exaggerated response to suxamethonium has been reported in the myasthenic syndrome but resistance may occur in patients with neurofibromatosis. Resistance may also occur in patients with myasthenia gravis, but uneventful use has also been reported, although early onset of phase II block is possible in these patients. Muscle contractures and hyperkalaemia may be expected in amyotrophic lateral sclerosis and muscular denervation. Suxamethonium should be avoided in patients with myotonias, as response is unpredictable. It is recommended that suxamethonium is also avoided in hemiplegia, paraplegia, muscular denervation, and muscular dystrophies.

Plasma cholinesterase deficiency. Suxamethonium is normally rapidly hydrolysed by plasma cholinesterase and the clinical effects usually last for only several minutes. Activity of the enzyme varies between individuals and prolonged paralysis following suxamethonium is commonly due to a hereditary or acquired reduction in plasma cholinesterase activity. The genes involved in the control of plasma cholinesterase production are termed usual, atypical (dibucaine-resistant), fluoride-resistant, and silent. About 96% of the population are homozygous for the usual gene. The commonest variant in western populations is the atypical form with about 3 to 4% of the population being heterozygous for this variant. They exhibit a slightly prolonged response to suxamethonium. Homozygotes for the atypical variant have a frequency of about 0.04%. They exhibit markedly prolonged apnoea following a standard dose of suxamethonium but can be readily identified by biochemical tests. The fluoride-resistant and silent variants occur very rarely. A measure of plasma cholinesterase activity can be obtained from the percentage inhibition of the enzyme by the local anaesthetic cinchocaine (commonly known in this context by its American name, dibucaine) to give the **dibucaine number**. Most normal people have a dibucaine number of about 80.

Acquired plasma cholinesterase deficiency is clinically less important than genetically determined deficiency. The enzyme is synthesised in the liver and **severe liver impairment** or malnutrition may cause abnormally low enzyme levels with some prolongation of suxamethonium activity. Reduced enzyme activity may also be found in severe anaemia, burns, cancer, collagen diseases, severe dehydration, severe infections, malnutrition, myocardial infarction, myxoedema, and renal impairment; plasmapheresis or plasma exchange removes significant amounts of plasma cholinesterase.

During **pregnancy** there is a rapid fall in plasma cholinesterase concentration that persists throughout pregnancy and for up to several weeks into the puerperium. The concentration of atypical plasma cholinesterase is also reduced in pregnancy and the puerperium. A number of **drugs** reduce plasma cholinesterase synthesis or activity and may prolong suxamethonium paralysis as discussed under Interactions, below.

Renal impairment. Suxamethonium chloride may be given in usual doses to patients with renal failure[1,2] although it is usually recommended that it should be avoided if hyperkalaemia is also present (see Effects on Plasma-potassium Concentration above). However, in a retrospective review[3] of 38 patients with serum potassium levels greater than 5.5 mmol/litre given a standard intubation dose of suxamethonium, there were no reports of dysrhythmias or unexpected admissions to the intensive care unit.

Patients with renal failure given repeated doses of suxamethonium did not show an excessive increase in serum potassium; however sinus bradycardia commonly occurred and it was recommended that repeated injections should be avoided in such patients.[2] If necessary, pretreatment with glycopyrrolate or atropine to protect against bradycardia should be considered.

Interactions

A number of drugs may interact with depolarising neuromuscular blockers such as suxamethonium. The mechanisms of interaction can include a direct effect on neuromuscular transmission or an alteration of enzyme activity and may result in potentiation or antagonism of neuromuscular block. In general, such interactions are potentially more serious in patients with impaired neuromuscular function or reduced activity of plasma cholinesterase, who are more sensitive to suxamethonium's effects.

Interactions common to competitive and depolarising neuromuscular blockers are covered under Atracurium, p.1903 whereas those specific for depolarising blockers are discussed below.

Antiarrhythmics. See under Atracurium, p.1903.

Antibacterials. See under Atracurium, p.1903.

Anticholinesterases. The action of suxamethonium may be markedly prolonged in patients using eye drops containing *ecothiopate*, a long-acting anticholinesterase that inhibits both acetylcholinesterase and plasma cholinesterase. After systemic absorption of ecothiopate, plasma cholinesterase activity may rapidly be reduced to 5% or less of normal and prolonged apnoea after use of suxamethonium has occurred. On stopping ecothiopate, enzyme activity remains depressed for 1 to 2 months. If a patient has used ecothiopate eye drops in the previous 2 months, suxamethonium should not be given unless normal plasma cholinesterase activity can be demonstrated; a competitive neuromuscular blocker is preferable. Exposure to *organophosphorus insecticides* may also reduce plasma cholinesterase activity resulting in prolonged paralysis after use of suxamethonium; enzyme activity may be totally abolished. Anticholinesterases including *edrophonium, neostigmine, pyridostigmine, rivastigmine, tacrine,* and possibly *donepezil* enhance the action of suxamethonium, although suxamethonium-induced phase II block can be reversed with an anticholinesterase. Care should be taken if there is a need to use suxamethonium for urgent short procedures after a competitive-neuromuscular-induced block has been antagonised with an anticholinesterase, as the resulting block may be greatly prolonged.[1]

Antiepileptics. The mean time to recovery from suxamethonium-induced neuromuscular block was 14.3 minutes in 9 patients receiving chronic treatment with *phenytoin* and/or *carbamazepine* compared with 10.0 minutes in 9 patients not receiving antiepileptics.[1]

1. Melton AT, *et al.* Prolonged duration of succinylcholine in patients receiving anticonvulsants: evidence for mild upregulation of acetylcholine receptors? *Can J Anaesth* 1993; **40:** 939–42.

Antineoplastics. *Cyclophosphamide* has been reported to prolong the neuromuscular block produced by suxamethonium through reduction of plasma cholinesterase activity, possibly by alkylation of the enzyme.[1] Since enzyme activity may be reduced by up to 70% for several days to several weeks, it was suggested[2] that suxamethonium should be avoided if possible in patients receiving cyclophosphamide. A more recent case report[3] would also support this suggestion. Other alkylating agents also reported to reduce plasma cholinesterase activity include *chlormethine, thiotepa,* and *tretamine*.[2]

Aprotinin. See under Atracurium, p.1904.

Benzodiazepines. See under Atracurium, p.1904.

Beta blockers. See under Atracurium, p.1904.

Cardiac inotropes. See under Atracurium, p.1904.

Ganglion blockers. See under Atracurium, p.1904.

General anaesthetics. Tachyphylaxis and phase II block (see Uses and Administration, below) develop earlier, and after smaller total doses of suxamethonium, when inhalation anaesthetics are used. *Halothane* may increase the incidence of arrhythmias associated with suxamethonium and can potentiate suxamethonium-induced muscle damage.[1] Suxamethonium should be used with caution with other drugs that might produce additive cardiovascular effects. Severe bradycardia and asystole have occurred when used in anaesthetic regimens with *propofol* and opioids such as *fentanyl*.

See also under Interactions of Atracurium, p.1904.

Histamine H_2 antagonists. See under Atracurium, p.1904.

Lithium. See under Atracurium, p.1904.

Local anaesthetics. *Procaine*, *cocaine*, and *chloroprocaine* are ester-type local anaesthetics which are hydrolysed by plasma cholinesterase and may competitively enhance the neuromuscular blocking activity of suxamethonium. See also Antiarrhythmics under Atracurium, p.1903.

Magnesium salts. See under Atracurium, p.1904.

MAOIs. Reduction of plasma cholinesterase activity by *phenelzine* has been reported[1] to cause significant prolongation of suxamethonium paralysis. Enzyme activity may be reduced to 10% of normal and recovery can take up to a month. The dosage of suxamethonium may need to be substantially reduced or a competitive neuromuscular blocker used.

1. Bodley PO, *et al.* Low serum pseudocholinesterase levels complicating treatment with phenelzine. *BMJ* 1969; **3:** 510–12.

Metoclopramide. Dose-dependent prolongation of suxamethonium-induced neuromuscular blockade has been reported in patients given metoclopramide.[1,2] The potent inhibitory effect of metoclopramide on plasma cholinesterase may account for this interaction.

1. Turner DR, *et al.* Neuromuscular block by suxamethonium following treatment with histamine type 2 antagonists or metoclopramide. *Br J Anaesth* 1989; **63:** 348–50.
2. Kao YJ, *et al.* Dose-dependent effect of metoclopramide on cholinesterases and suxamethonium metabolism. *Br J Anaesth* 1990; **65:** 220–4.

Neuromuscular blockers. See under Atracurium, p.1905.

Sex hormones. *Oestrogens* and oestrogen-containing *oral contraceptives* reduce plasma cholinesterase activity[1] possibly due to suppression of hepatic synthesis of the enzyme, but little prolongation of suxamethonium paralysis may be expected since activity is reduced by only about 20%. See also under Atracurium, p.1905.

Sympathomimetics. *Bambuterol* can inhibit plasma cholinesterase activity and so prolong the activity of suxamethonium.[1] Phase II block has been reported in some patients with abnormal plasma cholinesterase.[2]

1. Staun P, *et al.* The influence of 10 mg and 20 mg bambuterol on the duration of succinylcholine-induced neuromuscular blockade. *Acta Anaesthesiol Scand* 1990; **34:** 498–500.
2. Bang U, *et al.* The effect of bambuterol on plasma cholinesterase activity and suxamethonium-induced neuromuscular blockade in subjects heterozygous for abnormal plasma cholinesterase. *Acta Anaesthesiol Scand* 1990; **34:** 600–604.

Pharmacokinetics

After injection, suxamethonium is rapidly hydrolysed by plasma cholinesterase. One molecule of choline is split off rapidly to form succinylmonocholine which is then slowly hydrolysed to succinic acid and choline. About 10% of suxamethonium is excreted unchanged in the urine. Succinylmonocholine has weak muscle-relaxant properties mainly of a competitive nature.

The gene responsible for the expression of plasma cholinesterase exhibits polymorphism and enzyme activity varies between individuals (see under Precautions, above).

Small amounts of suxamethonium cross the placenta.

Uses and Administration

Suxamethonium is a depolarising neuromuscular blocker used to produce muscle relaxation. It combines with cholinergic receptors of the motor end-plate to produce depolarisation but is resistant to breakdown by acetylcholinesterase. This prevents repolarisation and subsequent depolarisation, and a flaccid muscle paralysis occurs. This initial depolarisation block is commonly known as a **phase I block.** The muscles that produce fine rapid movements such as those of the face are the first to be affected followed by those of the limbs, abdomen, and chest; the diaphragm is affected last. Recovery occurs in reverse order. When excessive amounts of suxamethonium accumulate at the neuromuscular junction, for example after high or prolonged dosage, the nature of the block may change to one with characteristics similar to competitive block. This is commonly termed **phase II block** or **dual block** and may be associated with prolonged neuromuscular blockade and apnoea.

After intravenous injection suxamethonium chloride acts in about 30 to 60 seconds and has a duration of action of about 2 to 6 minutes. After intramuscular injection it acts in 2 to 3 minutes and has a duration of action of about 10 to 30 minutes.

Suxamethonium is used in surgical and other procedures in which a rapid onset and brief duration of muscle relaxation is needed (see Anaesthesia, p.1900), including intubation, endoscopies, and ECT. It is used as suxamethonium chloride, and is normally given by intravenous injection. The content of preparations of suxamethonium chloride may be described in terms of either the dihydrate or the anhydrous form, depending on the country of origin, and this should be borne in mind when evaluating the literature although the differences are small (anhydrous suxamethonium chloride 1 mg is equivalent to about 1.1 mg of the dihydrate).

Suxamethonium should be given after induction of general anaesthesia because paralysis is usually preceded by painful muscle fasciculations. A competitive neuromuscular blocker may sometimes be given before suxamethonium to try to reduce some of the adverse effects on the muscles (see Effects on the Muscles, above). Premedication with an antimuscarinic may be of value in reducing bradycardia and excessive salivation. Assisted ventilation is necessary.

An initial test dose of 100 micrograms/kg, or 5 to 10 mg, of suxamethonium chloride may be given intravenously if increased sensitivity is suspected. Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. The response to suxamethonium varies considerably and the usual single dose of suxamethonium chloride for an adult is 0.3 to 1.1 mg/kg by intravenous injection. Supplementary doses of 50 to 100% of the initial dose may be given at 5 to 10 minute intervals if required but the total dose given by repeated intravenous injection or continuous infusion (see below) should not exceed 500 mg/hour. Infants and children are more resistant to suxamethonium than adults. A recommended intravenous dose for infants under one year of age is 2 mg/kg; a dose of 1 mg/kg is recommended for children 1 to 12 years old.

When a suitable vein is inaccessible suxamethonium chloride has been given by intramuscular injection in a dose of 3 to 4 mg/kg to a maximum total dose of 150 mg. The intramuscular dose for infants is up to 4 to 5 mg/kg and for older children up to 4 mg/kg to a maximum total dose of 150 mg.

For prolonged procedures in adults sustained relaxation may be obtained by continuous intravenous infusion of a 0.1 to 0.2% solution. A rate of 2.5 to 4 mg/minute is usually adequate but may be adjusted as necessary. The total dose given by repeated intravenous injection (see above) or continuous infusion should not exceed 500 mg/hour.

Suxamethonium bromide and suxamethonium iodide have also been used.

ECT. Suxamethonium chloride is used to decrease the muscular contractions associated with electrically induced convulsions. It temporarily paralyses muscles during ECT, preventing violent muscle contractions which can potentially result in broken bones and fractures.

Suxamethonium chloride remains the most commonly used neuromuscular blocker in ECT. However, patients with a history of malignant hyperthermia, neuroleptic malignant syndrome, catatonic schizophrenia, and organophosphate poisoning are more susceptible to adverse effects.[1] Mivacurium has been used, with satisfactory results, in at-risk-patients, although histamine release and hypotension may be a problem. Other competitive neuromuscular blockers tried include atracurium and vecuronium.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, and *US.*

Ph. Eur. 6.2 (Tubocurarine Chloride). A white or slightly yellowish crystalline powder. Soluble in water and in alcohol; practically insoluble in acetone; dissolves in solutions of alkali hydroxides. A 1% solution in water has a pH of 4.0 to 6.0. Store in airtight containers.

USP 31 (Tubocurarine Chloride). A white or yellowish-white to greyish-white, crystalline powder. Soluble 1 in 20 of water and 1 in 45 of alcohol. Store in airtight containers.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902). A transient fall in blood pressure commonly occurs, due in part to ganglionic blockade and the release of histamine; there may be an increase in heart rate. Tubocurarine has a greater propensity to cause histamine release than other competitive neuromuscular blockers in clinical use. Tubocurarine should be used with caution in patients with renal impairment. Resistance to the effect of tubocurarine may occur in patients with hepatic impairment.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Pharmacokinetics

Tubocurarine chloride is a quaternary ammonium compound and absorption from the gastrointestinal tract is extremely poor. Absorption is slow and irregular when given intramuscularly. After intravenous injection tubocurarine is widely distributed throughout body tissues; less than 50% is bound to plasma proteins. After a single dose extensive redistribution to tissues is responsible for the termination of activity, but after a large single dose or repeated small doses tissue saturation occurs and renal excretion becomes the main determinant of duration. When given in usual doses it does not pass the blood-brain barrier, and does not appear to cross the placenta in significant amounts. Up to 75% of a dose is excreted unchanged in the urine in 24 hours, and up to 12% in bile. Biliary excretion is increased in renal impairment. A small proportion of a dose is metabolised in the liver.

Uses and Administration

Tubocurarine is a benzylisoquinolinium competitive neuromuscular blocker (see Atracurium, p.1905). It may be obtained from extracts of the stems of *Chondodendron tomentosum* (Menispermaceae) and is one of the active principles of curare, by which name it is sometimes referred to in anaesthetic literature. Tubocurarine chloride is the chloride of (+)-tubocurarine. After intravenous injection of tubocurarine chloride neuromuscular block appears within 1 minute and lasts for about 30 minutes; the maximum effect is attained within 2 to 5 minutes.

Tubocurarine chloride has been used similarly to other competitive neuromuscular blockers to produce muscle relaxation in various procedures but has largely been replaced by other drugs with fewer cardiovascular effects and a lower potential for histamine release.

Doses used have varied according to the degree of muscle relaxation required. Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. An initial dose of 6 to 9 mg intravenously has been suggested followed by 3 to 4.5 mg after 3 to 5 minutes if necessary; additional doses of 3 mg may be given as required for prolonged procedures. Higher doses have been given in some countries. It has also been given intramuscularly but absorption is slow and erratic. Tubocurarine should be given with caution in reduced doses to patients with renal impairment; if large or repeated doses are given neuromuscular block may be prolonged.

Tubocurarine chloride has also been used to control the muscle spasms of tetanus (p.1901).

Preparations

USP 31: Tubocurarine Chloride Injection.

Proprietary Preparations (details are given in Part 3)
Arg.: Decurin; ***Israel:*** Curarine†; Tubarine†.

Vecuronium Bromide *(BAN, USAN, rINN)*

Bromuro de vecuronio; Org-NC-45; Vecuronii bromidum; Vécuronium, bromure de; Vekuroniumbromid; Vekuronium-bromid; Vekuroniumbromidi; Vekuronyum Bromür; Wekuroniowy bromek. 1-(3α,17β-Diacetoxy-2β-piperidino-5α-androstan-16β-yl)-1-methylpiperidinium bromide.

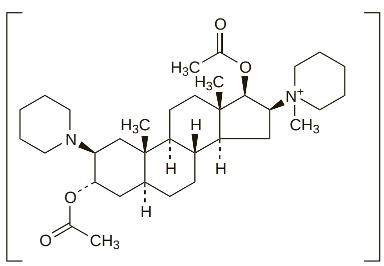
Векурония Бромид

$C_{34}H_{57}BrN_2O_4$ = 637.7.

CAS — 50700-72-6.

ATC — M03AC03.

ATC Vet — QM03AC03.



Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Vecuronium Bromide). White or almost white crystals or crystalline powder. Slightly soluble in water; sparingly soluble in dehydrated alcohol and in acetonitrile; freely soluble in dichloromethane. Store in airtight containers. Protect from light and moisture.

USP 31 (Vecuronium Bromide). White or creamy white crystals, or a crystalline powder. Slightly soluble in water and in acetone; sparingly soluble in alcohol. Store in airtight containers.

Incompatibility. A solution containing vecuronium bromide 1 mg/mL was found to be visually incompatible with furosemide.[1] For incompatibilities of competitive neuromuscular blockers in general, see under Atracurium on p.1902.

1. Chiu MF, Schwartz ML. Visual compatibility of injectable drugs used in the intensive care unit. *Am J Health-Syst Pharm* 1997; **54:** 64–5.

Adverse Effects, Treatment, and Precautions

As for competitive neuromuscular blockers in general (see Atracurium, p.1902).

Vecuronium bromide has little histamine-releasing activity although a local reaction at the site of injection has been reported; bronchospasm and anaphylactoid reactions have been rarely reported. It also has little vagolytic or ganglion-blocking activity and produces no significant adverse cardiovascular effects at usual doses.

Caution may be needed in patients with hepatic or renal impairment (see under Uses and Administration, below); dosage adjustments may be required in renal failure.

The elderly. It has been recommended that neuromuscular function should be monitored in elderly patients receiving vecuronium since there may be a risk of prolonged block.[1]

1. Slavov V, *et al.* Comparison of duration of neuromuscular blocking effect of atracurium and vecuronium in young and elderly patients. *Br J Anaesth* 1995; **74:** 709–11.

Pregnancy. The proportion of vecuronium crossing the placenta after doses of 60 to 80 micrograms/kg was considered clinically insignificant and its use during obstetric anaesthesia was considered safe for the newborn.[1]

1. Demetriou M, *et al.* Placental transfer of Org NC 45 in women undergoing caesarean section. *Br J Anaesth* 1982; **54:** 643–5.

Interactions

For interactions associated with competitive neuromuscular blockers, see Atracurium, p.1903.

Pharmacokinetics

On intravenous injection vecuronium is rapidly distributed. It is taken up by the liver and partly metabolised; the metabolites have some neuromuscular blocking activity. It is excreted mainly in bile as unchanged drug and metabolites; some is also excreted in urine. The plasma elimination half-life is reported to range from about 30 to 80 minutes.

Uses and Administration

Vecuronium bromide is an aminosteroidal competitive neuromuscular blocker (see Atracurium, p.1905).

After intravenous injection muscle relaxation occurs within about 1.5 to 2 minutes and lasts for about 20 to 30 minutes.

Vecuronium bromide is used for endotracheal intubation and to provide muscle relaxation in general anaesthesia for surgical procedures (see Anaesthesia, p.1900) and to aid controlled ventilation (see Intensive Care, p.1901).

Doses of neuromuscular blockers need to be carefully titrated for individual patients according to response, and may vary with the procedure, the other drugs given, and the state of the patient; monitoring of the degree of block is recommended in order to reduce the risk of overdosage. The usual initial dose for intubation is 80 to 100 micrograms/kg by intravenous injection, although reduced initial doses of 30 to 50 micrograms/kg are suggested following the use of suxamethonium. Higher initial doses ranging from 150 to 300 micrograms/kg have sometimes been used for other procedures. However, it is recommended that the dose should not exceed 100 micrograms/kg in caesarean section or neonatal surgery. Maintenance doses of 20 to 30 micrograms/kg may be given as required during prolonged procedures; in the USA a lower maintenance dose of 10 to 15 micrograms/kg is recommended. Neuromuscular blockade may also be maintained with an intravenous infusion given at a rate of 0.8 to 1.4 micrograms/kg per minute but should be preceded by an initial bolus injection of 40 to 100 micrograms/kg. UK licensed product information recommends that in obese patients the dosage of vecuronium should be reduced taking into account lean body-mass.

Children older than 5 months can be given adult doses but children up to 1 year may have a more rapid response and the high initial dose for intubation may not be necessary. Neonates and infants below 5 months of age may be more sensitive to vecuronium and it is recommended that they should be given an initial test dose of 10 to 20 micrograms/kg, followed by increments according to response. The duration of action and recovery is longer in neonates and infants than in children and adults and they may require smaller maintenance doses given less frequently.

Administration in hepatic impairment. Although the manufacturers make no specific recommendations for dosage reduction in hepatic impairment, the duration of action of vecuronium was reported to be significantly prolonged in patients with cholestasis[1] or cirrhosis with oesophageal varices[2] given a dose of 200 micrograms/kg intravenously. Plasma clearance was significantly reduced and the elimination half-life significantly increased from a mean of 58 to 98 minutes.[1] A dose of 150 micrograms/kg was found to have a similar onset and duration of action in patients with hepatic impairment and healthy controls,[2] but a dose of 100 micrograms/kg had a slower onset and slightly shorter duration of action in those with liver disturbance.[3] After a dose of vecuronium, rapid and extensive hepatic uptake occurs, which largely determines its short duration of action. However, as the dose increases this mechanism becomes saturated, and hepatic elimination becomes more important in terminating activity. This would help to explain the variation in results seen with the different doses. Caution is needed if large single doses or repeated doses are given to patients with hepatic impairment.

3. Bell CF, *et al.* Use of atracurium and vecuronium in patients with oesophageal varices. *Br J Anaesth* 1985; **57:** 160–8.

Administration in renal impairment. A small proportion of vecuronium bromide is excreted in urine and it may be given in usual doses to patients with renal failure.[1,2] No clinically significant difference in elimination half-life, clearance, or duration of action were reported[1] between patients with renal failure and those with normal renal function. The onset of neuromuscular block may be slightly slower in renal failure[2] and these patients may require an increase of around 20% in the initial dose of vecuronium.[3] However, the dosage requirement for maintenance of neuromuscular block may be reduced by about 20%[3] and slight prolongation of block may occur if dosage is not adjusted, but reversal of residual block with neostigmine is prompt and effective.[2]

Resistance to vecuronium has been reported[2] in 2 anephric patients. Total doses of 620 and 660 micrograms/kg produced maximum neuromuscular block of 77% and 36%, respectively but, despite the high doses used, there were no adverse effects or residual curarisation.

Nonionic Surfactants

A surfactant is a compound that can reduce the interfacial tension between 2 immiscible phases. This is because the molecule contains 2 localised regions, one hydrophilic in nature and the other hydrophobic. Nonionic surfactants differ from anionic surfactants (p.2138) by the absence of charge on, or ionisation of, the molecule; they are generally less irritant than anionic or cationic surfactants.

Hydrophilic groups include the oxyethylene group (–O.CH_2.CH_2–) and the hydroxyl group (–OH). By varying the number of these groups in a hydrophobic molecule, such as a fatty acid, substances are obtained that range from strongly hydrophobic and water-insoluble compounds, such as glyceryl monostearate, to strongly hydrophilic and water-soluble compounds, such as the macrogols. These 2 extreme types are not satisfactory as emulsifying agents, though they are useful stabilisers in the presence of efficient emulsifying agents. Between these extremes are the nonionic emulsifying agents in which the proportions of hydrophilic and hydrophobic groups are more evenly balanced; these include some of the macrogol esters and ethers, and sorbitan derivatives. Nonionic surfactants may be classified according to their *hydrophilic-lipophilic balance* (HLB). This is an arbitrary scale of values denoting the relative affinity of the surfactant for oil and water. Lipophilic surfactants have low HLB values (less than 10) and are generally used as antifoaming agents, water-in-oil emulsifying agents, and as wetting agents; hydrophilic surfactants have higher HLB values (greater than 10) and are generally used as oil-in-water emulsifying agents and solubilising agents.

Nonionic surfactants also have applications in the food, cosmetic, paint, pesticide, and textile industries as well as being used as oil slick dispersants. Some macrogol ethers such as nonoxinol 9 are used as spermicides.

By virtue of the processes used in their manufacture, nonionic surfactants are usually mixtures of related compounds; the properties of a particular material may vary from one manufacturer to another and there may be variation in batches from an individual source. Since nonionic surfactants do not ionise to any great extent in solution, they are generally compatible with both anionic and cationic substances, but they reduce the antimicrobial action of many preservatives.

The range of nonionic surfactants used in pharmaceutical practice is large and their classification can be varied and complex. The principal groups of nonionic surfactants are outlined below.

Glycol and glycerol esters are a group of nonionic surfactants consisting of fatty acid esters of glycols and glycerol. Hydrophobic properties predominate and these compounds are poor emulsifying agents if used alone, though they are useful stabilisers for both oil-in-water and water-in-oil emulsions. If a small amount of soap, sulfated fatty alcohol, or other surfactant is added to the esters, a 'self-emulsifying' product is formed, which is capable of producing satisfactory oil-in-water emulsions. **Acetoglycerides** are mixed glyceryl esters in which the glycerol is esterified partly with a fatty acid and partly with acetic acid.

Macrogol esters are polyoxyethylene esters of fatty acids, mainly stearates. The hydrophilic properties of the oxyethylene group are weaker than those of the hydroxyl group but by introducing a sufficient number into a fatty acid molecule, substances are produced in which the hydrophilic and hydrophobic properties are sufficiently well balanced for the esters to act as efficient oil-in-water emulsifying agents. They may also be used as wetting and solubilising agents. Since the ester linkage is prone to hydrolysis, these compounds are less resistant to acids and alkalis than the macrogol ethers.

Macrogol ethers are condensation products prepared by reaction between fatty alcohols or alkylphenols and ethylene oxide. The ether linkage confers good stability to acids and alkalis. Macrogol ethers are widely used in the preparation of oil-in-water emulsions and as wetting and solubilising agents.

Sorbitan derivatives are derivatives of the cyclic mono- or di-anhydrides of sorbitol. They consist of *sorbitan esters*, which are prepared by esterification of one or more of the hydroxyl groups in the anhydrides with a fatty acid such as stearic, palmitic, oleic, or lauric acid, and *polysorbates*, which are polyoxyethylene derivatives of the sorbitan esters. Sorbitan esters are oil-soluble, water-dispersible, nonionic surfactants and are effective water-in-oil emulsifiers. Polysorbates are more hydrophilic, water-soluble compounds and are used as oil-in-water emulsifying agents. By varying the number of oxyethylene groups in the molecule, and the type of fatty acid in the sorbitan ester, surfactants with a wide range of properties may be obtained.

Poloxamers are copolymers of polyoxyethylene and polyoxypropylene. They are used as oil-in-water emulsifiers and as solubilising and wetting agents in pharmaceutical preparations intended for internal use.

Other nonionic compounds with surface activity such as the higher fatty alcohols are covered in the chapter on Paraffins and Similar Bases (p.2028).

Diacetylated Monoglycerides

Monoglicéridos diacetilados.

Моноглицериды Диацетилированные

Pharmacopoeias. In *USNF.*

USNF 26 (Diacetylated Monoglycerides). Consists of glycerol esterified with edible fat-forming fatty acids and acetic acid. A clear liquid. Very soluble in alcohol 80%, in vegetable oils, and in mineral oils; sparingly soluble in alcohol 70%. Store in airtight containers. Protect from light.

Profile

Diacetylated monoglycerides have been used as plasticisers, pharmaceutical excipients, and food additives.

Diethylene Glycol Monopalmitostearate

Diethylene Glycol Monostearate; Diéthylène Glycol (Stéarate de); Diéthylèneglycol, palmitostéarate de; Diethylenglycoli Monopalmitostearas; Diethylenglycoli palmitostearas; Diethylenglykol monopalmitostearát; Diethylenglykol palmito stearát; Diethyleni Glycoli Stearas; Dietilenglicol, monopalmitoestearato de; Dietilenglikolio palmitostearatas; Dietilénglikol-monopalmitát és monosztearát; Dietyleenliglykolipalmitostearaatti; Dietylenglykolpalmitostearat; Diglycol Stearate.

Диэтиленгликоля Монопальмитостеарат

CAS — 106-11-6 (diethylene glycol monostearate); 36381-62-1 (diethylene glycol monopalmitate).

Pharmacopoeias. In *Eur.* (see p.vii). *USNF* includes Diethylene Glycol Stearates.

Ph. Eur. 6.2 (Diethylene Glycol Palmitostearate). A mixture of diethylene glycol mono- and di-esters of stearic and palmitic acids produced by esterification of diethylene glycol and stearic acid of vegetable or animal origin. It contains 45.0 to 60.0% of monoesters and 35.0 to 55.0% of diesters, and a maximum of 2.5% of free diethylene glycol. A white or almost white, waxy solid. Practically insoluble in water; soluble in hot alcohol and in acetone. M.p. 43° to 50°. Protect from light.

USNF 26 (Diethylene Glycol Stearates). A mixture of diethylene glycol mono- and di-esters of stearic and palmitic acids. It contains not less than 45.0% of monoesters produced from the condensation of ethylene glycol and stearic acid of vegetable or animal origin. A white or almost white, waxy solid. Practically insoluble in water; soluble in hot alcohol and in acetone. M.p. 43° to 50°. Store in airtight containers.

Profile

Diethylene glycol monopalmitostearate has similar properties and uses to glyceryl monostearate or self-emulsifying glyceryl monostearate (p.1915). Diethylene glycol monolaurate and mono-oleate have also been used.

Ethylene Glycol Monopalmitostearate

Ethylene Glycol Monostearate; Ethylene Glycol Stearate; Éthylène Glycol (Stéarate d'); Éthylèneglycol, monopalmitostéarate d'; Ethyleneglycoli Monopalmitostearas; Ethylenglycoli monopalmitostearas; Ethylenglycoli Monostearas; Ethylenglykol-monopalmitostearát; Ethyleni Glycoli Stearas; Etilenglicol, monopalmitoestearato de; Etilenglikolio monopalmitostearatas; Etilénglikol-monopalmitát és monosztearát; Etyleeniglykolimonopalmitostearaatti; Etylenglykolmonopalmitostearat.

Этиленгликоля Монопальмитостеарат

CAS — 111-60-4 (ethylene glycol monostearate); 4219-49-2 (ethylene glycol monopalmitate).

Pharmacopoeias. In *Eur.* (see p.vii). *USNF* includes Ethylene Glycol Stearates.

Ph. Eur. 6.2 (Ethylene Glycol Monopalmitostearate). A mixture of ethylene glycol mono- and di-esters of stearic and palmitic acids. It contains not less than 50% of monoesters produced from the condensation of ethylene glycol and stearic acid and not more than 5% of free ethylene glycol. A white or almost white, waxy solid. Practically insoluble in water; soluble in hot alcohol and in acetone. M.p. 54° to 60°. Protect from light.

USNF 26 (Ethylene Glycol Stearates). A mixture of ethylene glycol mono- and di-esters of stearic and palmitic acids. It contains not less than 50% of monoesters produced from the condensation of ethylene glycol and stearic acid of vegetable or animal origin. A white or almost white, waxy solid. Practically insoluble in water; soluble in hot alcohol and in acetone. M.p. 54° to 60°. Store in airtight containers.

Profile

Ethylene glycol monopalmitostearate has similar properties and uses to glyceryl monostearate or self-emulsifying glyceryl monostearate (p.1915). Ethylene glycol monolaurate and mono-oleate have also been used.

Glyceryl Behenate

Glicerol, behenato de.

Глицерил Бегенат

Pharmacopoeias. In *USNF. Eur.* (see p.vii) includes Glycerol Dibehenate.

Ph. Eur. 6.2 (Glycerol Dibehenate; Glyceroli Dibehenas). A mixture of diacylglycerols, mainly dibehenoylglycerol, together with variable quantities of mono- and triacylglycerols. It contains 15 to 23% of monoacylglycerols, 40 to 60% of diacylglycerols, and 21 to 35% of triacylglycerols, obtained by esterification of glycerol and behenic acid. A hard, waxy mass or powder or white or almost white, unctuous flakes. Practically insoluble in water; partly soluble in hot alcohol; soluble in dichloromethane. M.p. 65° to 77°.

USNF 26 (Glyceryl Behenate). A mixture of glycerides of fatty acids, mainly behenic acid. A fine powder with a faint odour. M.p. about 70°. Practically insoluble in water and in alcohol; soluble in chloroform. Store in airtight containers at a temperature not exceeding 35°.

Profile

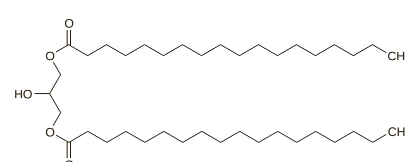
Glyceryl behenate is used as a lubricant and binder in tablet-making.

Glyceryl Distearate

Glicerin-disztearát; Glicerol, diestearato de; Glicerolio distearatas; Glycerol Distearate; Glycérol, distéarate de; Glyceroldistearat; Glycerol-distearát; Glyceroli distearas; Glyserolidistearaatti.

Глицерилдистеарат

CAS — 1323-83-7.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Glycerol Distearate). A mixture of diacylglycerols, mainly distearoylglycerol, together with variable quantities of mono- and triacylglycerols. It contains 8 to 22% of monoacylglycerols, 40 to 60% of diacylglycerols, and 25 to 35% of triacylglycerols, obtained by partial glycerolysis of vegetable oils containing triacylglycerols of palmitic or stearic acid or by esterification of glycerol with stearic acid. The fatty acids may be of vegetable or animal origin.

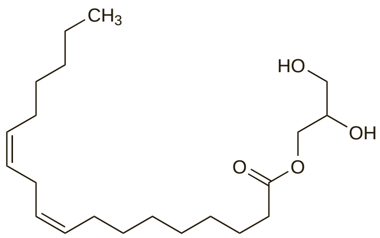
A hard, waxy mass or powder, or white or almost white, unctuous flakes. Practically insoluble in water; partly soluble in hot alcohol; soluble in dichloromethane. M.p. 50° to 60° (types I and II) or 50° to 70° (type III).
USNF 26 (Glyceryl Distearate). A mixture of diglycerides, mainly glyceryl distearate, together with variable quantities of monoglycerides and triglycerides. It contains 8 to 22% of monoglycerides, 40 to 60% of diglycerides, and 25 to 35% of triglycerides. It is obtained by partial glycerolysis of vegetable oil that consists mainly of triglycerides of palmitic or stearic acid or by esterification of glycerol with stearic acid. The fatty acids may be of vegetable or animal origin.
Hard, waxy mass or powder, or white or almost white flakes. Insoluble in water; partly soluble in hot alcohol; soluble in dichloromethane and in tetrahydrofuran. Store in airtight containers.

Profile
Glyceryl distearate is used as an emulsifying and/or solubilising agent.

Glyceryl Monolinoleate
Glicerin-monolinoleát; Glicerol, monolinoleato de; Glicerolio monolinoleatas; Glycerol Monolinoleate; Glycérol, monolinoléate de; Glyceroli monolinoleas; Glycerol-monolinolát; Glycerolmonolinoleat; Glyserolimonolinoleaatti; Monolinolein.

Глицерилмонолинолеат

CAS — 26545-74-4.



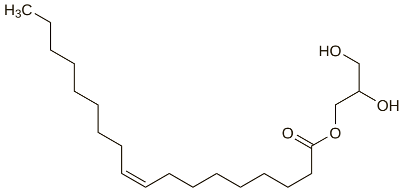
Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Glycerol Monolinoleate). A mixture of monoacylglycerols, mainly mono-oleoylglycerol and monolinoleoylglycerol, together with variable quantities of di- and triacylglycerols. It contains 32 to 52% of monoacylglycerols, 40 to 55% of diacylglycerols, and 5 to 20% of triacylglycerols, obtained by partial glycerolysis of vegetable oils mainly containing triacylglycerols of linoleic acid. A suitable antoxidant may be added.
Amber, oily liquids which may be partially solidified at room temperature. Practically insoluble in water; freely soluble in dichloromethane. Store in airtight containers. Protect from light.
USNF 26 (Glyceryl Monolinoleate). A mixture of monoglycerides, mainly glyceryl mono-oleate and glyceryl monolinoleate, together with variable quantities of diglycerides and triglycerides. It is obtained by partial glycerolysis of vegetable oil that consists mainly of triglycerides of linoleic acid. It contains 32 to 52% of monoglycerides, 40 to 55% of diglycerides, and 5 to 20% of triglycerides. A suitable antoxidant may be added.
Amber, oily liquids that may be partially solidified at room temperature. Practically insoluble in water; freely soluble in dichloromethane; soluble in tetrahydrofuran. Store in airtight containers.

Profile
Glyceryl monolinoleate is used as an emulsifying and/or solubilising agent.

Glyceryl Mono-oleate
Glicerol, monooleato de; Glycérol, mono-oléate de; Glyceroli mono-oleas; Monolein.

Глицерилмоноолеат

CAS — 25496-72-4.



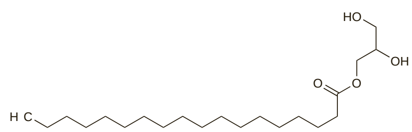
Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Glycerol Mono-oleates). Mixtures of monoacylglycerols, mainly mono-oleoylglycerol, together with variable quantities of di- and triacylglycerols. They are defined by the nominal content of monoacylglycerols and obtained by partial glycerolysis of vegetable oils mainly containing triacylglycerols of oleic acid, or by esterification of glycerol by oleic acid. A suitable antoxidant may be added.
Amber, oily liquids which may be partially solidified at room temperature. Practically insoluble in water; freely soluble in dichloromethane. Store in airtight containers. Protect from light.
USNF 26 (Glyceryl Monooleate). A mixture of monoglycerides, mainly glyceryl mono-oleate, together with variable quantities of di- and triglycerides. It is obtained by partial glycerolysis of vegetable oil that consists mainly of triglycerides of oleic acid, or by esterification of glycerol with oleic acid of vegetable or animal origin. It is defined by the nominal content of monoglycerides. A suitable antoxidant may be added.
Amber, oily liquids that may be partially solidified at room temperature. Practically insoluble in water; freely soluble in dichloromethane; soluble in tetrahydrofuran. Store in airtight containers.

Profile
Glyceryl mono-oleate has similar properties to glyceryl monostearate or self-emulsifying glyceryl monostearate (below).

Glyceryl Monostearate
Gliceril, monoestearato de; Glicerin-monosztearát; Glicerolio monostearatas; Glicerolu monostearynian; Glycérol, monostéarate de; Glyceroli monostearas; Glycerolmonostearat; Glycerol-monostearát; Glyserolimonostearaatti; GMS; Monostearin.

Глицерилмоностеарат

CAS — 31566-31-1 (glyceryl monostearate); 26657-96-5 (glyceryl monopalmitate).



Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *Jpn.* Also in *USNF.*
Ph. Eur. 6.2 (Glycerol Monostearate 40-55). A mixture of monoacylglycerols, mainly monostearoylglycerol, together with variable quantities of di- and triacylglycerols. It contains 40 to 55% of monoacylglycerols, 30 to 45% of diacylglycerols, and 5 to 15% of triacylglycerols, obtained by partial glycerolysis of vegetable oils mainly containing triacylglycerols of palmitic or stearic acid, or by esterification of glycerol with stearic acid. The fatty acids may be of vegetable or animal origin.
A white or almost white, hard, waxy mass or unctuous powder or flakes. Practically insoluble in water; soluble in alcohol at 60°. M.p. 54° to 66°.
USNF 26 (Glyceryl Monostearate). It contains not less than 90% of monoglycerides of saturated fatty acids, chiefly glyceryl monostearate ($C_{21}H_{42}O_4$ = 358.6) and glyceryl monopalmitate ($C_{19}H_{38}O_4$ = 330.5). It may contain a suitable antoxidant.
A white to yellowish wax-like solid, beads, flakes, or powder with a slight, agreeable, fatty odour. M.p. not below 55°. Insoluble in water but may be dispersed in hot water with the aid of a small amount of soap or other suitable surfactant; soluble 1 in 10 of chloroform, 1 in 100 of ether and of methyl alcohol, 1 in 33 of isopropyl alcohol; dissolves in hot organic solvents such as alcohol, acetone, mineral or fixed oils, and benzene. Store in airtight containers. Protect from light.

Self-emulsifying Glyceryl Monostearate
Glicerol autoemulsionable, monoestearato de; Monostearato de glicerilo autoemulsionable; Monostearin Emulsificans; Self-emulsifying Mono- and Diglycerides of Food Fatty Acids; Self-emulsifying Monostearin.

Глицерилмоностеарат Самоэмульгирующийся

Pharmacopoeias. In *Br.*
BP 2008 (Self-emulsifying Glyceryl Monostearate). A mixture consisting principally of mono-, di-, and triglycerides of stearic and palmitic acids, and of minor proportions of other fatty acids; it may also contain free fatty acids, free glycerol, and soap. It contains not less than 30% of monoglycerides, not more than 7% of free glycerol, and not more than 6% of soap, calculated as sodium oleate, all calculated with reference to the anhydrous substance.
A white to cream-coloured, hard, waxy solid with a faint fatty odour. Dispersible in hot water; soluble in hot dehydrated alcohol and in hot liquid paraffin; soluble in hot vegetable oils, but may give turbid solutions at concentrations below 20%.

Incompatibility. Because of the presence of soap, self-emulsifying glyceryl monostearate is incompatible with acids and high concentrations of ionisable salts, hard water, calcium compounds, zinc oxide, and oxides of heavy metals.

Profile
Glyceryl monostearate is a poor water-in-oil emulsifying agent but it is a useful stabiliser of water-in-oil and oil-in-water emulsions in preparations for internal and external use. It has emollient properties. Glyceryl monostearate is also used in the food and cosmetic industries.
It is usual to add a small amount of soap, sulfated fatty alcohol, or other surfactant, to glyceryl monostearate, which has the effect of making the product self-emulsifying and capable of producing satisfactory oil-in-water emulsions. Self-emulsifying glyceryl monostearate is used as an emulsifying agent for oils, fats, solvents, and waxes in the preparation of bases of the non-emulsified, emulsified, and vanishing-cream types. It is not intended for inclusion in preparations for internal use.
Aqueous preparations containing self-emulsifying glyceryl monostearate should contain a preservative to prevent fungal or bacterial growth.

Macrogol Cetostearyl Ethers
Ceteareth Compounds; Macrogol, éteres cetoestearílicos de; Macrogol, ether cétostéarylique de; Macrogoli aether cetostearylicus; Makrogol-cetil-sztearil-éter; Makrogolcetostearyleter; Makrogolio cetostearilo eteris; Makrogolisetostearyylieetteri.

Полиэтиленгликоля и Цетостеарилового Спирта Эфиры

CAS — 68439-49-6.

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Macrogol Cetostearyl Ether). A mixture of ethers of mixed macrogols with linear fatty alcohols, mainly cetostearyl alcohol. It may contain some free macrogols and it contains various amounts of free cetostearyl alcohol. The amount of ethylene oxide reacted with cetostearyl alcohol is from 2 to 33 units per molecule (nominal value). White or yellowish-white waxy, unctuous mass, pellets, microbeads, or flakes. Macrogol cetostearyl ether with low numbers of ethylene oxide units per molecule is practically insoluble in water; soluble in alcohol and in dichloromethane. Macrogol cetostearyl ether with higher numbers of ethylene oxide units per molecule is dispersible or soluble in water; soluble in alcohol and in dichloromethane. Macrogol cetostearyl ether solidifies at 32° to 52°. Store in airtight containers. The labelling states the amount of ethylene oxide reacted with cetostearyl alcohol (nominal value).

Cetomacrogol 1000 *(BAN, rINN)*
Cétomacrogol 1000; Cetomacrogolum 1000; Éter monocetílico de polietilenglicol 1000; Polyethylene Glycol 1000 Monocetyl Ether; Polyoxyethylene Glycol 1000 Monocetyl Ether.

Кетомакрогол 1000; Цетомакрогол 1000

CAS — 9004-95-9 (macrogol cetyl ethers); 68439-49-6 (macrogol cetostearyl ethers).

Description. Cetomacrogol 1000 is a macrogol ether containing 20 to 24 oxyethylene groups in the polyoxyethylene chain. It may be prepared from either cetyl alcohol or from cetostearyl alcohol. It is represented by the formula $CH_3.[CH_2]_m.[O.CH_2.CH_2]_n.OH$, where m may be 15 or 17 and n may be 20 to 24. The more specific term macrogol cetostearyl ether (22), representing such an ether in which n = 22, has replaced cetomacrogol 1000 in BP formulations.
Macrogol cetyl ethers are also sometimes termed ceteth compounds.

Pharmacopoeias. In *Int.*

Incompatibility. Cetomacrogol has been reported to be incompatible with phenols and to reduce the antibacterial activity of quaternary ammonium compounds. Cetomacrogol may separate from solutions in the presence of a high concentration of electrolytes.

Polyoxyl 20 Cetostearyl Ether
Polioxil 20, éter cetoestearílico de.

Полиоксиэтилендиола 20 и Цетостеариловой Кислоты Эфир

CAS — 68439-49-6.

Pharmacopoeias. In *USNF.*
USNF 26 (Polyoxyl 20 Cetostearyl Ether). A mixture of the monocetostearyl (mixed hexadecyl and octadecyl) ethers of mixed macrogols, the average polymer length being equivalent to 17.2 to 25.0 oxyethylene units. A cream-coloured waxy unctuous mass, melting, when heated, to a clear brownish-yellow liquid. Soluble in water, in alcohol, and in acetone; insoluble in petroleum spirit. A 10% solution in water has a pH of 4.5 to 7.5. Store at a temperature of 8° to 15° in airtight containers.

Profile
Macrogol cetostearyl ethers are used as surfactants and emulsifiers. Macrogol cetostearyl ether (22) is used with cetostearyl alcohol (for example, in the form of Cetomacrogol Emulsifying Wax BP 2008) as an emulsifying agent for making oil-in-water emulsions that are unaffected by moderate concentrations of electrolytes and that are stable over a wide pH range. It is also used to disperse volatile oils in water to form transparent sols.

Preparations

BP 2008: Cetomacrogol Emulsifying Wax.

Macrogol 15 Hydroxystearate

Macrogol 15, hydroxystéarate de; Macrogoli 15 hydroxystearas; Makrogol hydroxystearát; Makrogol-15-hydroxistearat; Makrogoli-15-hydroksistearaatti; Makrogolio 15 hidroksistearatas.

Полиэтиленгликоля 15 Гидроксистеарат

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Macrogol 15 Hydroxystearate). A mixture of mainly mono- and di-esters of 12-hydroxystearic acid and macrogols obtained by ethoxylation of 12-hydroxystearic acid. The number of moles of ethylene oxide reacted per mole of 12-hydroxystearic acid is 15 (nominal value). It contains free macrogols. A yellowish, waxy mass. It solidifies at about 25°. Very soluble in water; soluble in alcohol; insoluble in liquid paraffin. Store in airtight containers.

Profile

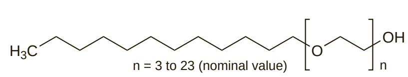
Macrogol 15 hydroxystearate is a nonionic surfactant used as a solubilising agent.

Macrogol Lauril Ethers

α-Dodecyl-ω-hydroxypoly(oxyethylene); Éteres laurílicos de macrogol; Laureth Compounds; Lauromacrogols; Macrogol, éteres láuricos de; Macrogol, éther laurique de; Macrogol Lauryl Ethers; Macrogoli aether laurilicum; Makrogolilauryylieetteri; Makrogolio laurilo eteris; Makrogollauryleter; Oxypolyethoxydodecanes; Polyoxyl Lauryl Ethers.

Полиэтиленгликоля и Лаурилового Спирта Эфиры

CAS — 9002-92-0.



Description. Macrogol lauril ethers have the general formula $C_{12}H_{25}(OCH_2CH_2)_nOH$.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn*. Also in *USNF.*

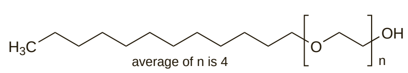
Ph. Eur. 6.2 (Macrogol Lauryl Ether). A mixture of ethers of mixed macrogols with fatty alcohols, mainly $C_{12}H_{26}O$. It contains a variable amount of free $C_{12}H_{26}O$ and it may contain free macrogols. The number of moles of ethylene oxide reacted per mole of $C_{12}H_{26}O$ is 3 to 23 (nominal value). Macrogol lauril ether with 3 to 5 units of ethylene oxide per molecule is a colourless liquid. Practically insoluble in water and in petroleum spirit; soluble or dispersible in alcohol. Macrogol lauril ether with 9 to 23 units of ethylene oxide per molecule is a white or almost white, waxy mass. Soluble or dispersible in water; soluble in alcohol; practically insoluble in petroleum spirit. Macrogol lauril ether should be stored in airtight containers.

USNF 26 (Polyoxyl Lauryl Ether). A mixture of the monolauril ethers of mixed polyethylene glycols, the average polymer length being equivalent to not less than 3 and not more than 23 oxyethylene units (nominal value). It contains various amounts of free lauril alcohol, and it may contain some free polyethylene glycols. Store in airtight containers in a dry place at a temperature of 8° to 15°.

Laureth 4 *(USAN)*

Лаурет 4

CAS — 9002-92-0.



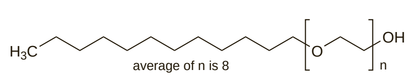
Description. A mixture of monolauril ethers of macrogols where the average value of *n* in the formula given above is 4.

Lauromacrogol 400 *(rINN)*

Laureth 9 *(USAN)*; Lauromacrogolum 400; Polidocanol; Polidocanolum; Polidokanol; Polidokanoli.

Лауромакрогол 400

CAS — 9002-92-0; 3055-99-0.
ATC — C05BB02.
ATC Vet — QC05BB02.



Description. Lauromacrogol 400 is a mixture of monolauril ethers of macrogols where the average value of *n* in the formula given above is 9 and the number 400 corresponds approximately to the average molecular mass of the macrogol portion. It has sometimes, however, been erroneously described as containing 8, rather than 9, oxyethylene groups. However, note that Lauromacrogol *(BAN)* is described as containing an average of 8 ethylene oxide groups per molecule.

Adverse Effects

There have been occasional reports of allergic skin reactions after topical application of preparations containing macrogol lauril ethers.

◊ A 63-year-old man developed pulmonary oedema, a dramatic fall in heart rate, transient left pyramidal syndrome and died after sclerotherapy with lauromacrogol 400 to control gastric variceal bleeding;[1] the fatality was attributed to the action of the drug that had passed into the systemic circulation. Another patient[2] suffered a reversible ischaemic neurological deficit after sclerotherapy with lauromacrogol 400 for varicose veins of the leg, and ischaemic stroke[3] and other neurological symptoms,[4] probably due to embolism after passage of foam through a patent foramen ovale, have been reported after foam injection sclerotherapy using the compound.

1. Paterlini A, *et al*. Heart failure and endoscopic sclerotherapy of variceal bleeding. *Lancet* 1984; **i:** 1241.
2. Van der Plas JPL, *et al*. Reversible ischaemic neurological deficit after sclerotherapy of varicose veins. *Lancet* 1994; **343:** 428.
3. Forlee MV, *et al*. Stroke after varicose vein foam injection sclerotherapy. *J Vasc Surg* 2006; **43:** 162–4.
4. Ceulen RPM, *et al*. Microembolism during foam sclerotherapy of varicose veins. *N Engl J Med* 2008; **358:** 1525–6.

Uses and Administration

Macrogol lauril ethers (laureth compounds) have been used as surfactants and spermicides. Lauromacrogol 400 is used as a sclerosant in the treatment of oesophageal and gastric varices (p.2346) and varicose veins (p.2347), and has been tried in endoscopic injection therapy for bleeding peptic ulcer (p.1702); it has also been used as a local anaesthetic and antipruritic (see p.1582) in combination topical preparations.

Macrogol Monomethyl Ethers

Éteres monometílicos de polietilenglicol; Macrogol, éteres monometílicos de; Polyethylene Glycol Monomethyl Ethers. α-Methyl-ω-hydroxypoly(oxyethylene).

Полиэтиленгликоля и Метилового Спирта Эфиры

CAS — 9004-74-4.

Pharmacopoeias. In *USNF.*

USNF 26 (Polyethylene Glycol Monomethyl Ether). Addition polymers of ethylene oxide and methyl alcohol, represented by the formula $CH_3(OCH_2CH_2)_nOH$, where *n* represents the average number of oxyethylene groups. The name is usually designated by a number that corresponds approximately to its average molecular weight.

As the average molecular weight increases, the water solubility, vapour pressure, hygroscopicity, and solubility in organic solvents decrease while congealing temperature, specific gravity, flash-point, and viscosity increase. Liquid grades occur as clear to slightly hazy, colourless or practically colourless, slightly hygroscopic, viscous liquids with a slight characteristic odour. Solid grades occur as practically odourless, white, waxy, plastic material with a consistency similar to beeswax, or as creamy white flakes, beads, or powders. Liquid grades are miscible with water; solid grades are freely soluble in water; all grades are soluble in alcohol, in acetone, in chloroform, in ethyl acetate, in ethylene glycol monoethyl ether, and in toluene; all grades are insoluble in ether and in hexane. Store in airtight containers.

Profile

Macrogol monomethyl ethers may be used as ointment bases, solvents, and plasticisers.

Macrogol Oleyl Ethers

Macrogol, éteres oleílicos de; Macrogol, éther oléique de; Macrogoli aether oleicum; Macrogoli Aetherum Oleicum; Makrogolio oleilo eteris; Makrogolioleyylieetteri; Makrogol-oleil-éter; Makrogololeyleter; Oletho Compounds.

Полиэтиленгликоля и Олеилового Спирта Эфиры

Pharmacopoeias. In *Eur.* (see p.vii).

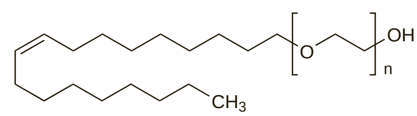
Ph. Eur. 6.2 (Macrogol Oleyl Ether). A mixture of ethers of mixed macrogols with linear fatty alcohols, mainly oleyl alcohol. It may contain some free macrogols and it contains various amounts of free oleyl alcohol. Macrogol oleyl ether with 2 to 5 units of ethylene oxide per molecule is a yellow liquid. Practically insoluble in water and in petroleum spirit; soluble in alcohol. Macrogol oleyl ether with 10 to 20 units of ethylene oxide per molecule is a yellowish-white, waxy mass. Dispersible or soluble in water; soluble in alcohol; practically insoluble in petroleum spirit. Macrogol oleyl ethers should be stored in airtight containers. Protect from light.

Polyoxyl 10 Oleyl Ether

Polioxil 10, éter oleílico de; Polyethylene Glycol Mono-oleyl Ether.

Полиоксиэтиленгликоля и Олеиновой Кислоты Эфир

CAS — 9004-98-2.



Pharmacopoeias. In *USNF.*

USNF 26 (Polyoxyl 10 Oleyl Ether). A mixture of the monooleyl ethers of mixed macrogols, the average polymer length being equivalent to not less than 9.1 and not more than 10.9 oxyethylene units. It may contain suitable stabilisers.

A soft white semisolid or pale yellow liquid with a bland odour. Soluble in water and in alcohol; dispersible in liquid paraffin and in propylene glycol with possible separation on standing. Store at a temperature of 8° to 15° in airtight containers.

Profile

Macrogol oleyl ethers such as polyoxyl 10 oleyl ether are used as surfactants.

Macrogol Stearates

Ésteres de polietilenglicol; Ésteres de polioxietileno; Macrogol, ésteres del; Macrogol, stéarate de; Macrogoli stearas; Makrogolio stearatas; Makrogolistearaatti; Makrogolstearat; Makrogol-stearát; Makrogol-sztearát; Polyoxyethylene Glycol Stearates; Polyoxyethylene Stearates; Polyoxyl Stearates.

Макрогола Стеараты; Полиэтиленгликоля Стеараты

CAS — 9004-99-3.

Nomenclature. There are two systems of nomenclature used for these compounds; these substances have the general formula $C_{17}H_{35}COO.[O.CH_2CH_2]_n.H$. In the systems used by *BAN* and *USAN* the numbers in the names refer to the approximate polymer length in oxyethylene units whereas in the system used by *INN* the number refers to the average molecular weight of the polymer chain. Thus, the names Macrogol 8 Stearate (*BAN*), Polyoxyl 8 Stearate (*USAN*), and Macrogol Stearate 400 (*rINNM*) all describe the same compound.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Macrogol Stearate). A mixture of the mono- and di-esters of mainly stearic acid and/or palmitic acid and macrogols. It may be obtained by ethoxylation or by esterification of macrogols with stearic acid 50 (type I) or stearic acid 95 (type II). The average polymer length is equivalent to 6 to 100 ethylene oxide units per molecule (nominal value). It may contain free macrogols. White or slightly yellowish waxy mass. Soluble in alcohol and in isopropyl alcohol. Compounds containing 6 to 9 units of ethylene oxide per molecule are practically insoluble but freely dispersible in water; miscible with fatty oils and with waxes. Compounds containing 20 to 100 units of ethylene oxide per molecule are soluble in water; practically insoluble in fatty oils and in waxes. Store in airtight containers.

Polyoxyl 40 Stearate *(USAN)*

Macrogol Stearate 2000 *(rINNM)*; E431; Estearato de macrogol 2000; Estearato de Polioxila 40; Macrogol 40 Stearate *(BAN)*; Macrogol 2000, Stéarate de; Macrogol Ester 2000; Macrogoli Stearas 2000; Polyoxyethylene 40 Stearate; Stearethate 40.

Макрогола 2000 Стеарат

Pharmacopoeias. In *Jpn.* Also in *USNF.*

USNF 26 (Polyoxyl 40 Stearate). A mixture of the mono- and diesters of stearic acid and mixed macrogols, the average polymer length being about 40 oxyethylene units. It contains not less than 17% and not more than 27% of free macrogols. It is a waxy, white to light tan solid, odourless or with a faint fat-like odour. Congealing range 37° to 47°. Soluble in water, in alcohol, in acetone, and in ether; insoluble in liquid paraffin and in vegetable oils. Store in airtight containers.

Incompatibility. Macrogol stearates have been reported to be generally stable with electrolytes and weak acids or bases although strong acids or bases may cause hydrolysis and saponification. Discoloration or precipitation may occur with phenolic substances and complexation with preservatives. Decrease in the antimicrobial activity of bacitracin, chloramphenicol, phenoxymethylpenicillin, and tetracycline has been stated to occur with concentrations of macrogol stearates exceeding 5%.

Profile

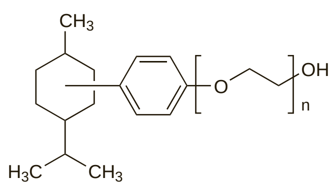
Macrogol stearates are macrogol esters that are used as emulsifying and solubilising agents.

Menfegol *(rINN)*

Menfégol; Menfegolum; Menphegol. α-[*p*-(*p*-Menthyl)phenyl]-ω-hydroxypoly(oxyethylene).

Менфегол

CAS — 57821-32-6.



Profile

Menfegol consists of menthylphenyl ethers of macrogols represented by the formula $C_{16}H_{23}(OCH_2CH_2)_nOH$. It is a nonionic surfactant used as a spermicide.

Adverse effects. Frequent use of menfegol in spermicidal foaming tablets has been associated with a high incidence of genital ulceration, which could increase the risk of infection by HIV.[1]

1. Goeman, J. *et al.* Frequent use of menfegol spermicidal vaginal foaming tablets associated with a high incidence of genital lesions. *J Infect Dis* 1995; **171:** 1611–14.

Preparations

Proprietary Preparations (details are given in Part 3)
Hong Kong: Neo Sampoon; ***Malaysia:*** Neo Sampoon; ***Philipp.:*** Neo Sampoon; ***Singapore:*** Neo Sampoon.

Mono- and Di-glycerides

E471 (mono- and di-glycerides of fatty acids); Mono y diglicéridos.

Моно- и Диглицериды

Pharmacopoeias. In *USNF.*

USNF 26 (Mono- and Di-glycerides). A mixture of glycerol mono- and di-esters, with minor amounts of tri-esters, of fatty acids from edible oils. It contains not less than 40% of monoglycerides. It may contain suitable stabilisers. Store in airtight containers. Protect from light.

Profile

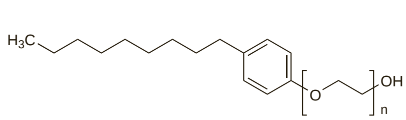
A mixture of mono- and di-glycerides is used as an emulsifying agent and food additive.

Nonoxinols

Macrogol Nonylphenyl Ethers; Nonoxinoles; Nonoxynols. α-(4-Nonylphenyl)-ω-hydroxypoly(oxyethylene).

Ноноксинолы

CAS — 26027-38-3.



Nomenclature. Nonoxinols are a series of nonylphenyl ethers of macrogols of differing chain lengths, represented by the formula $C_{15}H_{23}.[O.CH_2.CH_2]_n.OH$.

Nonoxinol is *BAN* and *rINN*. The name may be followed by a figure indicating the approximate number of oxyethylene groups in the polyoxyethylene chain. *USAN* specifies Nonoxynol 4, Nonoxynol 9, Nonoxynol 15, and Nonoxynol 30.

Nonoxinol 9 *(BAN, rINN)*

Nonoksinoli-9; Nonoxinol-9; Nonoxinolum 9; Nonoxynol 9 *(USAN)*. α-(4-Nonylphenyl)-ω-hydroxynona(oxyethylene).

Ноноксинол 9

$C_{33}H_{60}O_{10}$ (nominal) = 616.8.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, and *US.*

Ph. Eur. 6.2 (Nonoxinol 9). A mixture consisting mainly of monononylphenyl ethers of macrogols corresponding to the formula: $C_{15}H_{23}.(O.CH_2.CH_2)_n.OH$ where the average value of *n* is 9. A clear, colourless to light yellow, viscous liquid. Miscible with water, with alcohol, and with vegetable oils. Store in airtight containers.

USP 31 (Nonoxynol 9). An anhydrous liquid mixture consisting chiefly of monononylphenyl ethers of macrogols corresponding to the formula $C_{15}H_{23}.[O.CH_2.CH_2]_n.OH$, in which the average value of *n* is about 9. A clear, colourless to light yellow, viscous liquid. Soluble in water, in alcohol, and in maize oil. Store in airtight containers.

Nonoxinol 10 *(BAN, rINN)*

Nonoxinolum 10; Nonoxynol 10. α-(4-Nonylphenyl)-ω-hydroxydeca(oxyethylene).

Ноноксинол 10

$C_{35}H_{64}O_{11}$ (nominal) = 660.9.

Nonoxinol 11 *(BAN, rINN)*

Nonoxinolum 11; Nonoxynol 11. α-(4-Nonylphenyl)-ω-hydroxyundeca(oxyethylene).

Ноноксинол 11

$C_{37}H_{68}O_{12}$ (nominal) = 704.9.

Adverse Effects and Precautions

Nonoxinols used as vaginal spermicides may cause local irritation.

Genito-urinary infections. Use of spermicidal foam or jelly containing nonoxinol 9 may disturb the normal vaginal flora and predispose to colonisation with *Escherichia coli* and the development of bacteriuria.[1] An increased risk of acute *E. coli* urinary-tract infection has been reported[2] associated with the use of condoms coated with nonoxinol 9. However, another study[3] of women using nonoxinol-9 spermicidal contraceptives showed that most users experienced minimal disruption to the vaginal microbial ecosystem.

For reference to an increased incidence of some sexually transmitted diseases in women using nonoxinol 9, see Antimicrobial Activity, below.

1. Hooton TM, *et al.* Escherichia coli bacteriuria and contraceptive method. *JAMA* 1991; **265:** 64–9.
2. Fihn SD, *et al.* Association between use of spermicide-coated condoms and Escherichia coli urinary tract infection in young women. *Am J Epidemiol* 1996; **144:** 512–20.
3. Schreiber CA, *et al.* Effects of long-term use of nonoxynol-9 on vaginal flora. *Obstet Gynecol* 2006; **107:** 136–43.

Pregnancy. Maternal use of spermicidal contraceptives has been linked to an increased frequency of congenital abnormalities, including trisomy, but it has been suggested that such studies may be flawed by recall bias.[1] Meta-analysis of 9 studies also supported the view that peri- and postconceptual maternal use of spermicides was not associated with adverse fetal outcome.[2]

1. Mishell DR. Contraception. *N Engl J Med* 1989; **320:** 777–87.
2. Einarson TR, *et al.* Maternal spermicide use and adverse reproductive outcome: a meta-analysis. *Am J Obstet Gynecol* 1990; **162:** 655–60.

Toxic shock syndrome. Toxic shock syndrome has been associated with the use of a vaginal contraceptive sponge impregnated with nonoxinol 9. A review[1] of 13 cases reported in the USA up to November 1984 found that in 4 of the cases there were other predisposing conditions: postpartum use, use during menstruation, and prolonged retention.

1. Faich G, *et al.* Toxic shock syndrome and the vaginal contraceptive sponge. *JAMA* 1986; **255:** 216–18.

Uses

Nonoxinols have surface active properties and may be used as solubilising agents. Nonoxinol 9 is used as a spermicide (see Contraception, p.2070).

Antimicrobial activity. Nonoxinol 9 has activity *in vitro* against a number of bacteria and viruses and it was hoped[1,2] that use of spermicidal contraceptives containing nonoxinol 9 might provide some protection against sexually transmitted diseases, including chlamydial, gonococcal, and HIV infection. However, controlled studies involving HIV-negative female sex workers or other high-risk women have found that use of nonoxinol 9 does not reduce the rate of new HIV,[3,4] or gonorrhoea or chlamydia infection;[3,5] meta-analyses[6,7] including these and other studies have come to similar conclusions. Furthermore, nonoxinol 9 has an irritant action and may increase the risk of genital ulceration, leading to an increased risk of infection by HIV. The United Nations,[8] WHO,[9] and FDA[10] have therefore advised against its use by women at high risk.

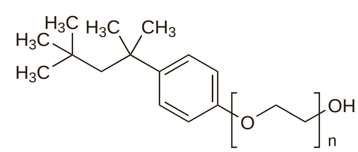
Octoxinols

Macrogol Tetramethylbutylphenyl Ethers; Octoxinoles; Octoxynols; Octylphenoxy Polyethoxyethanol. α-[4-(1,1,3,3-Tetramethylbutyl)phenyl]-ω-hydroxypoly(oxyethylene).

Октоксинолы

CAS — 9002-93-1.



Nomenclature. Octoxinols are a series of tetramethylbutylphenyl ethers of macrogols of differing chain lengths, represented by the formula $C_{14}H_{21}.[O.CH_2.CH_2]_n.OH$.

Octoxinol is *BAN* and *rINN*. The name may be followed by a figure indicating the approximate number of oxyethylene groups in the polyoxyethylene chain. *USAN* specifies Octoxynol 9.

The name *p*-di-isobutyl-phenoxypolyethoxyethanol has been used to describe octoxinol 9 but may have also been applied to other octoxinols.

Octoxinol 9 *(BAN, rINN)*

Octoxinolum 9; Octoxynol 9 *(USAN)*.

Октоксинол 9

$C_{32}H_{58}O_{10}$ (nominal) = 602.8.

Pharmacopoeias. In *USNF.*

USNF 26 (Octoxynol 9). An anhydrous liquid mixture consisting chiefly of mono-octylphenyl ethers of macrogols, corresponding to the formula $C_{14}H_{21}.[O.CH_2.CH_2]_n.OH$, in which the average value of *n* is about 9. A clear, pale yellow, viscous liquid with a faint odour. Miscible with water, with alcohol, and with acetone; soluble in toluene and in benzene; practically insoluble in petroleum spirit. Store in airtight containers.

Octoxinol 10 *(BAN, rINN)*

Octoxinolum 10; Oktoksinoli-10; Oktoksinolis 10; Oktoksynol 10; Oktoxinol-10; Oktoxinol 10.

Октоксинол 10

$C_{34}H_{62}O_{11}$ (nominal) = 646.8.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Octoxinol 10). A mixture consisting mainly of mono-octylphenyl ethers of macrogols corresponding to the formula: $C_{14}H_{21}.(O.CH_2.CH_2)_n.OH$ where the average value of *n* is

The symbol † denotes a preparation no longer actively marketed

10. A clear, colourless or light yellow, viscous liquid. Miscible with water, with alcohol, and with vegetable oils. Store in airtight containers.

Profile

Octoxinols have surface active properties and may be used as solubilising agents. They are also used as spermicides.

Preparations

Proprietary Preparations (details are given in Part 3)
Austral.: Ortho-Gynol; ***NZ:*** Ortho-Gynol; ***USA:*** Ortho-Gynol†.

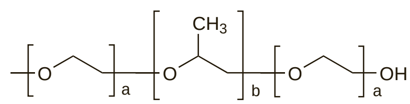
Multi-ingredient: ***Austral.:*** Summers Eve Feminine; ***Chile:*** Summer's Eve Hierbas†.

Poloxamers

Polioxietilen-propilenglicol; Poloksameerit; Poloksamerai; Poloxamera; Poloxamerek; Poloxamerer; Poloxamères; Poloxámeros; Poloxamery; Polyethylene-polypropylene glycol. α-Hydro-ω-hydroxypoly(oxyethylene)poly(oxypropylene)poly(oxyethylene) block copolymer.

Полоксамеры

CAS — 9003-11-6.



Nomenclature. Poloxamer is *BAN* and *rINN*. The name is followed by a figure, the first 2 digits of which, when multiplied by 100, correspond to the approximate average molecular weight of the polyoxypropylene portion and the third digit, when multiplied by 10, corresponds to the percentage by weight of the polyoxyethylene portion. *USAN* specifies Poloxamer 182D, Poloxamer 182LF, Poloxamer 188, Poloxamer 188LF, and Poloxamer 331.
Poloxalene (*BAN*, *USAN*, *rINN*) is also a poloxamer.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Poloxamers). A synthetic block copolymer of ethylene oxide and propylene oxide represented by the general formula: $HO(C_2H_4O)_a(C_3H_6O)_b(C_2H_4O)_aH$. It may contain a suitable antioxidant. Poloxamer 124 is a colourless or almost colourless liquid. Poloxamer 237 and poloxamer 338 are white or almost white, waxy powders, microbeads or flakes; m.p. about 50°. Poloxamers 124, 237, and 338 are very soluble in water and in alcohol; practically insoluble in petroleum spirit (50° to 70°). pH of a 10% solution in water is 5.0 to 7.5. Store in airtight containers.
USNF 26 (Poloxamer). A synthetic block copolymer of ethylene oxide and propylene oxide with the general formula $HO(C_2H_4O)_a(C_3H_6O)_b(C_2H_4O)_aH$. It may contain a suitable antoxidant. Poloxamer 124 is a colourless liquid with a mild odour. Poloxamers 237 and 338 are white, prilled or cast solids, odourless or with a mild odour. All poloxamers are freely soluble in water and in alcohol. Poloxamer 124 is freely soluble in isopropyl alcohol and in propylene glycol; poloxamer 237 is sparingly soluble in isopropyl alcohol and in xylene; poloxamer 338 is sparingly soluble in propylene glycol; poloxamer 124 is freely soluble in xylene. A 2.5% solution in water has a pH of 5.0 to 7.5. Store in airtight containers.

Incompatibility. Poloxamers have been reported to be incompatible with hydroxybenzoates and phenols.

Poloxalene *(BAN, USAN, rINN)*

Poloxalène; Poloxaleno; Poloxalenum; SKF-18667.

Полоксален

CAS — 9003-11-6.

Pharmacopoeias. In *US* for veterinary use only.
USP 31 (Poloxalene). A synthetic block copolymer of ethylene oxide and propylene oxide. A colourless or pale yellow liquid. Soluble in water, in chloroform, and in ethylene dichloride. A 2.5% solution in water has a pH of 5.0 to 7.5. Store in airtight containers at a temperature of 8° to 15°. Protect from light.

Poloxamer 188 *(BAN, USAN, rINN)*

Poloxalkol; Poloxamère 188; Poloxámero 188; Poloxamerum 188.

Полоксамер 188

NOTE. Compounded preparations of poloxamer 188 may be represented by the following names:

- Co-danthramer *x/y* (*BAN*)—where *x* and *y* are the strengths in milligrams of dantron and poloxamer respectively.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Poloxamers). Poloxamer 188 is a poloxamer in which *a* in the general formula given above is 75 to 85 and *b* is 25 to 30; it has an average molecular weight of 7680 to 9510. It is a white or almost white, waxy powder, microbeads, or flakes. M.p. about 50°. Very soluble in water and in alcohol; practically insoluble in petroleum spirit (50° to 70°). pH of a 10% solution is 5.0 to 7.5. Store in airtight containers.
USNF 26 (Poloxamer). Poloxamer 118 is a poloxamer in which *a* in the general formula averages 80 and *b* averages 27; it has an average molecular weight of 7680 to 9510. A white prilled or cast solid, odourless or with a very mild odour. M.p. about 52°. Freely soluble in water and in alcohol. Store in airtight containers.

Poloxamer 407 *(BAN, rINN)*

Poloxamère 407; Poloxámero 407; Poloxamerum 407.

Полоксамер 407

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Poloxamers). Poloxamer 407 is a poloxamer in which *a* in the general formula given above is 95 to 105 and *b* is 54 to 60; it has an average molecular weight of 9840 to 14 600. It is a white or almost white, waxy powder, microbeads, or flakes. M.p. about 50°. Very soluble in water and in alcohol; practically insoluble in petroleum spirit (50° to 70°). pH of a 10% solution in water is 5.0 to 7.5. Store in airtight containers.
USNF 26 (Poloxamer). Poloxamer 407 is a poloxamer in which *a* in the general formula averages 101 and *b* averages 56; it has an average molecular weight of 9840 to 14 600. A white, prilled or cast solid, odourless or with a very mild odour. M.p. about 56°. Freely soluble in water, in alcohol, and in isopropyl alcohol. Store in airtight containers.

Precautions

Poloxamers may increase the absorption of liquid paraffin and other fat-soluble substances.

Uses and Administration

Poloxamers are used as emulsifying agents for intravenous fat emulsions, as solubilising agents to maintain clarity in elixirs and syrups, and as wetting agents for antibacterials. They may also be used in ointment or suppository bases and as tablet binders or coaters.

Poloxamer 188 is used as a wetting agent in the treatment of constipation. It is usually given with a laxative such as dantron. It has also been used as an emulsifying agent in fluorocarbon blood substitutes. Poloxamer 188 has been investigated for its ability to improve blood flow in sickle-cell crisis; it has also been tried in myocardial infarction. Other investigational uses include the treatment of burns.

Poloxamer 407 is used in solutions for contact lens care, as is poloxamer 338.

Poloxalene is used as a defoaming agent in the treatment of bloat in ruminants.

Polyoxyl Castor Oils

Aceites de ricino polioxietilenados; Macrogolglycerol Ricinoleate; Macrogolglycérol, ricinoléate de; Macrogolglyceroli ricinoleas; Makrogol-glicerin-éter -ricinoleát; Makrogolglicerolio ricinoleatas; Makrogolglycerolricinoleat; Makrogliglyserolirisiinioleaatti; Makrogologlicerolu rycynooleinian; Polyethoxylated Castor Oils; Polyoxyethylene Castor Oils.

Полиэтиленгликоля Касторовые Масла

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Macrogolglycerol Ricinoleate; Polyoxyl Castor Oil BP 2008). It contains mainly ricinoleyl glycerol ethoxylated with 30 to 50 molecules of ethylene oxide (nominal value), with small amounts of macrogol ricinoleate and of the corresponding free glycols. It results from the reaction of castor oil with ethylene oxide. A clear, yellow, viscous liquid or semi-solid. Relative density about 1.05; viscosity, at 25°, 500 to 800 mPa s. Freely soluble in water and in alcohol; very soluble in dichloromethane. Protect from light.

Polyoxyl 35 Castor Oil

Aceite de ricino polioxil 35.

Полиэтиленгликоля 35 Касторовое Масло

Pharmacopoeias. In *USNF.*
USNF 26 (Polyoxyl 35 Castor Oil). A mixture of the triricinoleate ester of ethoxylated glycerol with smaller amounts of macrogol ricinoleate and the corresponding free glycols. It is produced by reacting 1 mole of glycerol ricinoleate with about 35 moles of ethylene oxide.
A yellow oily liquid with a faint characteristic odour. Sp. gr. 1.05 to 1.06; viscosity, at 25°, 650 to 850 mPa s. Very soluble in water, producing a practically odourless and colourless solution; soluble in alcohol and in ethyl acetate; insoluble in mineral oils. Store in airtight containers.

Incompatibility. Polyoxyl castor oils are reported to affect polyvinyl chloride containers and apparatus adversely.

Adverse Effects

Polyoxyl castor oils (such as *Cremophor EL*) used as vehicles in intravenous injections have been associated with severe anaphylactoid reactions, hyperlipidaemias, alterations in blood viscosity, and erythrocyte aggregation. They may also lead to adverse effects due to alterations in the pharmacokinetics of the formulated drug.

Uses

Polyoxyl castor oils are macrogol esters used as emulsifying and solubilising agents. Polyoxyl 35 castor oil has been used as a solvent in vehicles for various intravenous injections.

Polyoxyl Hydrogenated Castor Oils

Aceites de ricino hidrogenados y polioxietilenados; Macrogolglycerol Hydroxystearate; Macrogolglycérol, hydroxystéarate de; Macrogolglyceroli hydroxystearas; Makrogol-glicerin-éter-hidroxisztearát; Makrogolglicerolio hidroksisteratas; Makrogolglycerolhydroxistearat; Makrogoliglyserolihydroksistearaatti.

Полиэтиленгликоля Касторовые Масла Гидрогенизированные

Pharmacopoeias. In *Eur.* (see p.vii).
Ph. Eur. 6.2 (Macrogolglycerol Hydroxystearate; Hydrogenated Polyoxyl Castor Oil BP 2008). It contains mainly trihydroxystearyl glycerol ethoxylated with 7 to 60 molecules of ethylene oxide (nominal value), with small amounts of macrogol hydroxystearate and of the corresponding free glycols. It results from the reaction of hydrogenated castor oil with ethylene oxide. Polyoxyl hydrogenated castor oil with less than 10 units of ethylene oxide per molecule is a yellowish, turbid, viscous liquid. Practically insoluble in water; dispersible in alcohol; soluble in acetone. Polyoxyl hydrogenated castor oil with more than 20 units of ethylene oxide per molecule is a white or yellowish, semi-liquid or pasty mass. Freely soluble in water, in alcohol, and in acetone; practically insoluble in petroleum spirit.

Polyoxyl 40 Hydrogenated Castor Oil

Aceite de ricino hidrogenado polioxil 40.

Полиэтиленгликоля 40 Касторовое Масло Гидрогенизированное

Pharmacopoeias. In *USNF.*
USNF 26 (Polyoxyl 40 Hydrogenated Castor Oil). A mixture of mainly the trihydroxystearate ester of ethoxylated glycerol, with smaller amounts of macrogol trihydroxystearate and the corresponding free glycols. It is produced by reacting 1 mole of glycerol trihydroxystearate with about 40 to 45 moles of ethylene oxide.
A white to yellowish paste or pasty liquid with a faint odour. Congealing range 20° to 30°. Very soluble in water, producing an odourless, colourless solution; soluble in alcohol and in ethyl acetate; insoluble in liquid paraffin. Store in airtight containers.

Profile

Polyoxyl hydrogenated castor oils are used as surfactants.

Polysorbates

Polisorbatos.

Полисорбаты

Description. A series of mixtures of fatty acid esters of sorbitol and its anhydrides copolymerised with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides.

Incompatibility. Polysorbates have been reported to be stable with electrolytes and weak acids and bases although saponification may occur in the presence of strong acids and bases. Discoloration or precipitation may occur with phenolic substances. The oleic acid esters are sensitive to oxidation. For reference to the possible incompatibility of polysorbate 80 with hydroxybenzoates, see p.1649.

Polysorbate 20 *(BAN, USAN, rINN)*

E432; Monolaurato de polietileno 20 sorbitano; Monolaurato de polioxietileno 20 sorbitano; Polisorbat 20; Polisorbatas 20; Polisorbato 20; Poliszorbát 20; Polyoxyethylene 20 Sorbitan Monolaurate; Polysorbaatti 20; Polysorbát 20; Polysorbat 20; Polysorbatum 20; Sorbimacrogol Laurate 300; Sorboxaethenum Laurinicum.

Полисорбат 20

$C_{58}H_{114}O_{26}$ (approximate).
CAS — 9005-64-5.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.* Also in *USNF.*

Ph. Eur. 6.2 (Polysorbate 20). A mixture of partial esters of fatty acids, mainly lauric acid, with sorbitol and its anhydrides ethoxylated with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A clear or slightly opalescent yellowish to brownish-yellow oily liquid. Relative density about 1.10. Soluble in water, in dehydrated alcohol, in ethyl acetate, and in methyl alcohol; practically insoluble in liquid paraffin and in fatty oils. Store in airtight containers. Protect from light.

USNF 26 (Polysorbate 20). A laurate ester of sorbitol and its anhydrides copolymerised with approximately 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A lemon to amber liquid with a faint characteristic odour. Soluble in water, in alcohol, in dioxan, in ethyl acetate, and in methyl alcohol; insoluble in liquid paraffin. Store in airtight containers.

Polysorbate 40 *(BAN, USAN, rINN)*

E434; Monopalmitato de polietileno 20 sorbitano; Monopalmitato de polioxietileno 20 sorbitano; Polisorbatas 40; Polisorbato 40; Poliszorbát 40; Polyoxyethylene 20 Sorbitan Monopalmitate; Polysorbaatti 40; Polysorbát 40; Polysorbat 40; Polysorbatum 40; Sorbimacrogol Palmitate 300.

Полисорбат 40

$C_{62}H_{122}O_{26}$ (approximate).
CAS — 9005-66-7.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Polysorbate 40). Mixture of partial esters of fatty acids, mainly palmitic acid, with sorbitol and its anhydrides ethoxylated with about 20 moles of ethylene oxide for each mole of sorbitol and sorbitol anhydrides. An oily, viscous, yellowish or brownish-yellow liquid. Relative density about 1.10. Miscible with water, with dehydrated alcohol, with ethyl acetate, and with methyl alcohol; practically insoluble in fatty oils and in liquid paraffin. Store in airtight containers. Protect from light.

The BP 2008 gives Polyoxyethylene 20 Sorbitan Monopalmitate as an approved synonym.

USNF 26 (Polysorbate 40). A palmitate ester of sorbitol and its anhydrides copolymerised with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A yellow liquid with a faint characteristic odour. Soluble in water and in alcohol; insoluble in liquid paraffin and in vegetable oils. Store in airtight containers.

Polysorbate 60 *(BAN, USAN, rINN)*

E435; Monoestearato de polietileno 20 sorbitano; Monoestearato de polioxietileno 20 sorbitano; Polisorbat 60; Polisorbatas 60; Polisorbato 60; Poliszorbát 60; Polyoxyethylene 20 Sorbitan Monostearate; Polysorbaatti 60; Polysorbát 60; Polysorbat 60; Polysorbatum 60; Sorbimacrogol Stearate 300; Sorboxaethenum Stearinicum.

Полисорбат 60

$C_{64}H_{126}O_{26}$ (approximate).
CAS — 9005-67-8.

Pharmacopoeias. In *Eur.* (see p.vii) and *Int.* Also in *USNF.*

Ph. Eur. 6.2 (Polysorbate 60). A mixture of partial esters of fatty acids, mainly stearic acid 50, with sorbitol and its anhydrides ethoxylated with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A yellowish-brown gelatinous mass which becomes a clear liquid at temperatures above 25°. Relative density about 1.10. Soluble in water, in dehydrated alcohol, in ethyl acetate, and in methyl alcohol; practically insoluble in liquid paraffin and in fatty oils. Store in airtight containers. Protect from light.

USNF 26 (Polysorbate 60). A mixture of stearate and palmitate esters of sorbitol and its anhydrides copolymerised with approximately 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A lemon to orange-coloured oily liquid or semi-gel with a faint characteristic odour. Soluble in water, in ethyl acetate, and in toluene; insoluble in liquid paraffin and in vegetable oils. Store in airtight containers.

Polysorbate 80 *(BAN, USAN, rINN)*

E433; Monooleato de polietileno 20 sorbitano; Monooleato de polioxietileno 20 sorbitano; Olethytan 20; Polisorbat 80; Polisorbatas 80; Polisorbato 80; Poliszorbát 80; Polyäthylenglykol-Sorbitanoleat; Polyoxyethylene 20 Sorbitan Mono-oleate; Polysorbaatti 80; Polysorbát 80; Polysorbat 80; Polysorbatum 80; Polysorbitanum 80 Oleinatum; Sorbimacrogol Oleate 300; Sorboxaethenum Oleinicum; Sorethytan 20 Mono-oleate.

Полисорбат 80

$C_{64}H_{124}O_{26}$ (approximate).
CAS — 9005-65-6.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int.*, and *Jpn*. Also in *USNF.*

Ph. Eur. 6.2 (Polysorbate 80). A mixture of partial esters of fatty acids, mainly oleic acid, with sorbitol and its anhydrides ethoxylated with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. An oily, yellowish or brownish-yellow, clear or slightly opalescent liquid. Relative density about 1.10. Dispersible in water, in dehydrated alcohol, in ethyl acetate, and in methyl alcohol; practically insoluble in liquid paraffin and in fatty oils. Store in airtight containers. Protect from light.

USNF 26 (Polysorbate 80). An oleate ester of sorbitol and its anhydrides copolymerised with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides. A lemon to amber-coloured oily liquid with a faint characteristic odour. Sp. gr. between 1.06 and 1.09; viscosity, at 25°, between 300 and 500 mPa s. Very soluble in water, producing an odourless and practically colourless solution; soluble in alcohol and in ethyl acetate; insoluble in liquid paraffin. Store in airtight containers.

Polysorbate 85 *(BAN, USAN, rINN)*

Polisorbatas 85; Polisorbato 85; Poliszorbát 85; Polyoxyethylene 20 Sorbitan Trioleate; Polysorbaatti 85; Polysorbat 85; Polysorbát 85; Polysorbatum 85; Sorbimacrogol Trioleate 300; Trioleato de polietileno 20 sorbitano; Trioleato de polioxietileno 20 sorbitano.

Полисорбат 85

$C_{100}H_{188}O_{28}$ (approximate).
CAS — 9005-70-3.

Description. A mixture of mainly trioleate esters of sorbitol and its anhydrides copolymerised with about 20 moles of ethylene oxide for each mole of sorbitol and its anhydrides.

Adverse Effects and Precautions

Polysorbates may increase the absorption of fat-soluble substances.

There have been occasional reports of hypersensitivity after topical application of preparations containing polysorbates.

For discussion of fatalities in low-birth-weight infants associated with the injection of a polysorbate-containing preparation, see below.

Polysorbates used as excipients may also lead to adverse effects due to alterations in the pharmacokinetics of the formulated drug.

◊ References.

Effects in infants. After the introduction in the USA of an intravenous preparation of vitamin E (*E-Ferol*) there were a number of reports of unusual liver and kidney disorders, with 38 deaths being reported among treated low-birth-weight infants. Affected infants had unexplained hypotension, thrombocytopenia, renal dysfunction, hepatomegaly, cholestasis, ascites, and metabolic acidosis;[1-3] the preparation was subsequently withdrawn from the market in April 1984 about 5 months after it was introduced. *In-vitro* evidence was produced showing that *E-Ferol* suppressed the response of human lymphocytes to phytohaemagglutinin. However, it was the mixture of polysorbates, polysorbate 20 and in particular polysorbate 80, that was shown to be responsible for this suppression rather than the α-tocopherol acetate component. Despite this *in-vitro* data, overwhelming infection was not a feature in the affected infants.[2] Large doses of polysorbates were unavoidably injected when *E-Ferol* was used and it was suggested that polysorbates may accumulate as a result of an alteration in the metabolism by low-birth-weight infants; polysorbate-induced alteration of membrane fluidity in cells of vessel walls may have led to changes in structure and function.[2]

2. Balistreri WF, *et al.* Lessons from the E-Ferol tragedy. *Pediatrics* 1986; **78:** 503–6.
3. Golightly LK, *et al.* Pharmaceutical excipients: adverse effects associated with inactive ingredients in drug products. *Med Toxicol* 1988; **3:** 128–65 and 209–240.

Hypersensitivity. Local inflammatory reactions after intramuscular injection of a vitamin A preparation were considered[1] to be due to a hypersensitivity reaction to polysorbate 80, included as an excipient. Anaphylactoid reactions which occurred in 2 patients after treatment with omalizumab for 27 and 13 months respectively, were likely to be due to the polysorbate excipient and not to the monoclonal antibody itself.[2] The presence of polysorbate 80 in the injection may also contribute to hypersensitivity reactions to docetaxel (see Adverse Effects of Docetaxel, p.710).

Uses

Polysorbates are hydrophilic nonionic surfactants that are used as emulsifying agents for the preparation of stable oil-in-water emulsions in pharmaceutical products; they are frequently used with a sorbitan ester in varying proportions to produce products with a range of texture and consistency. Polysorbates have also been used in the formulation of insecticide and herbicide sprays, industrial detergents, and cosmetic products. They are also used as emulsifiers in the food industry.

Polysorbates are used as solubilising agents for a variety of substances including essential oils and oil-soluble vitamins such as vitamins A, D, and E, and as wetting agents in the formulation of oral and parenteral suspensions. However, hypersensitivity reactions have been attributed to the presence of polysorbates, see Hypersensitivity, above.

Polysorbates may also be used for their surfactant properties in preparations for the removal of ear wax, and for the management of dry eyes and upper respiratory-tract disorders.

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Sinroncar; ***Belg.:*** Oleosorbate; ***Canad.:*** Diopteаrs; Tears Encore; ***Fr.:*** Cerumenol; ***USA:*** OptiZen; Viva-Drops.

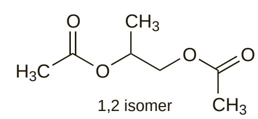
Propylene Glycol Diacetate

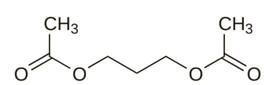
Propilenglicol, diacetato de. Propanediol diacetate.

Диацетат Пропиленгликоля

$C_7H_{12}O_4$ = 160.2.
CAS — 623-84-7 (1,2-isomer); 628-66-0 (1,3-isomer).



1,2 isomer



1,3 isomer

Profile

Propylene glycol diacetate is an emulsifying and/or solubilising agent, and a solvent. It is included in some external preparations for ear infection.

Preparations

Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Canad.:*** VoSoL HC†; ***NZ:*** VoSoL; ***USA:*** Acetasol; Acetasol HC; VoSoL HC†; VoSoL†.

Propylene Glycol Laurates

E477 (propylene glycol esters of fatty acids); Propilenglicol, laurato de.

Пропиленгликоля Лаураты

Propylene Glycol Dilaurate

E477 (propylene glycol esters of fatty acids); Propilenglicol, dilaurato de; Propilenglikolio dilauratas; Propyleeniglykolidilauraatti; Propylene Dilaurate; Propylèneglycol, dilaurate de; Propylenglycoli dilauras; Propylenglykoldilaurat; Propylenglykol-dilaurát.

Пропиленгликоля Дилаурат
CAS — 22788-19-8.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Propylene Glycol Dilaurate). A mixture of the propylene glycol mono- and di-esters of lauric acid. It contains a minimum of 70% of di-esters and a maximum of 30% of mono-esters. The content of free propylene glycol is not more than 2%. A colourless or slightly yellow, clear oily liquid at 20°. Practically insoluble in water; very soluble in alcohol, in methyl alcohol, and in dichloromethane. Protect from moisture.

USNF 26 (Propylene Glycol Dilaurate). A mixture of the propylene glycol mono- and di-esters of lauric acid. It contains not less than 70.0% of di-esters and not more than 30.0% of mono-esters. Protect from moisture.

Propylene Glycol Monolaurate

E477 (propylene glycol esters of fatty acids); Propilenglicol, monolaurate de; Propilenglikolio monolauratas; Propyleeniglykolimonolauraatti; Propylèneglycol, monolaurate de; Propylenglycoli monolauras; Propylenglykol monolaurát; Propylenglykolmonolaurat.

Пропиленгликоля Монолаурат

CAS — 27194-74-7.

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Propylene Glycol Monolaurate). A mixture of the propylene glycol mono- and di-esters of lauric acid. It contains 45 to 70% of mono-esters and 30 to 55% of di-esters (type I) or a minimum of 90% of mono-esters and a maximum of 10% of di-esters (type II). The content of free propylene glycol is not more than 5% (type I) or not more than 1% (type II). A colourless or slightly yellow, clear oily liquid at 20°. Practically insoluble in water; very soluble in alcohol, in methyl alcohol, and in dichloromethane. Protect from moisture.
USNF 26 (Propylene Glycol Monolaurate). A mixture of the propylene glycol mono- and di-esters of lauric acid. It contains 45 to 70% of mono-esters and 30 to 55% of di-esters (type I) or a minimum of 90% of mono-esters and a maximum of 10% of di-esters (type II). The content of free propylene glycol is not more than 5.0% (type I) or not more than 1.0% (type II). Protect from moisture.

Profile

Propylene glycol mono- and dilaurate have similar properties to propylene glycol monopalmitostearate (below) and are used as emulsifying and solubilising agents, including in food.

Propylene Glycol Monopalmitostearate

E477 (propylene glycol esters of fatty acids); Propilenglicol, monopalmitoestearato de; Propilenglikolio monopalmitostearatas; Propilénglikol-monopalmitil-sztearát; Propyleeniglykolimonopalmitostearaatti; Propyleeniglykolimonostearaatti; Propylene Glycol Monostearate; Propylene Glycol Stearate; Propylèneglycol, monopalmitostéarate de; Propylèneglycol (Stéarate de); Propylenglycoli monopalmitostearas; Propylenglycoli Monostearas; Propylenglykolmonopalmitostearat; Propylenglykol-monopalmitostearát; Propylenglykolmonostearat; Prostearin.

Пропиленгликоля Монопальмитостеарат

CAS — 1323-39-3 (propylene glycol monostearate); 29013-28-3 (propylene glycol monopalmitate).

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Propylene Glycol Monopalmitostearate). A mixture of the propylene glycol mono- and di-esters of stearic and palmitic acids. It contains a minimum of 50% of mono-esters produced from the condensation of propylene glycol and stearic acid 50. A white or almost white, waxy solid. M.p. 33° to 40°. Practically insoluble in water; soluble in hot alcohol and in acetone. Protect from light.
USNF 26 (Propylene Glycol Monostearate). A mixture of the propylene glycol mono- and di-esters of stearic and palmitic acids. It contains not less than 90% of mono-esters of saturated fatty acids, chiefly propylene glycol monostearate and propylene glycol monopalmitate. A white, wax-like solid, beads, or flakes, with a slight agreeable fatty odour. Congealing temperature not less than 45°. Insoluble in water but it may be dispersed in hot water with the aid of a small amount of soap or other suitable surfactant; soluble in organic solvents such as alcohol, acetone, ether, benzene, and fixed or mineral oils.

Profile

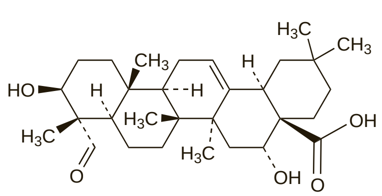
Propylene glycol monopalmitostearate is used as a stabiliser or emulsifier similarly to glyceryl monostearate (p.1915).

Quillaia

Corteza de Panamá; Corteza de quillay; Corteza palo de jabón; E999 (quillaia extract); Panama Wood; Quilaya; Quillaia Bark; Quillaiae cortex; Quillay; Quillaya, écorce de; Seifenrinde; Soap Bark.

Кора Мыльного Дерева

CAS — 631-01-6 (quillaic acid).



(quillaic acid)

Pharmacopoeias. In *Br., Fr.,* and *Swiss.*
BP 2008 (Quillaia). The dried inner part of the bark of *Quillaja saponaria* and other species of *Quillaja* containing not less than 22% of alcohol (45%)-soluble extractive. It is odourless or almost odourless, but the dust or powder is strongly sternutatory.

Adverse Effects

Quillaia taken by mouth has been reported to produce gastrointestinal irritation. It has been suggested that the ingestion of large amounts may produce liver damage, respiratory failure, convulsions, and coma.

Uses

Quillaia contains 2 amorphous saponin glycosides, quillaic acid and quillaiasapotoxin. It is used as an emulsifying agent and frothing agent, including in foodstuffs; it is often used with tragacanth mucilage or another thickening agent. Quillaia is also used for its surfactant properties in preparations for skin and respiratory-tract disorders.

Preparations

BP 2008: Quillaia Liquid Extract; Quillaia Tincture.

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Braz.:*** Bluderm†; ***Chile:*** Fitotos; Notosil†; Sedotus†; ***Cz.:*** Solutan†; ***Fin.:*** Kvilla; ***Hong Kong:*** Pectoral†; ***Rus.:*** Solutan (Солутан); ***Swed.:*** Quilla simplex; ***Switz.:*** Expectoran Codein†; Expectoran†.

Sorbitan Esters

Sorbitán, ésteres del.

Эфиры Сорбитана

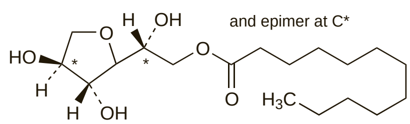
Description. A series of mixtures of the partial esters of sorbitol and its mono- and di-anhydrides with fatty acids.

Sorbitan Laurate *(BAN, rINN)*

E493; Laurato de sorbitán; Monolaurato de sorbitán; Sorbitaanilauraatti; Sorbitan, laurate de; Sorbitan Monolaurate *(USAN)*; Sorbitani lauras; Sorbitanlaurat; Sorbitan-laurát; Sorbitano lauratas; Szorbitán-laurát.

Сорбитана Лаурат

$C_{18}H_{34}O_6$ (approximate).
CAS — 1338-39-2.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Sorbitan Laurate). A mixture of the partial esters of sorbitol and its mono- and di-anhydrides with lauric acid. A brownish-yellow viscous liquid. Relative density about 0.98. Practically insoluble but dispersible in water; miscible with alcohol; slightly soluble in cottonseed oil. Protect from light.
USNF 26 (Sorbitan Monolaurate). A partial ester of sorbitol and its mono- and di-anhydrides with lauric acid. A yellow to amber oily liquid with a bland characteristic odour. Insoluble in water; soluble in liquid paraffin; slightly soluble in cottonseed oil and in ethyl acetate. Store in airtight containers.

Sorbitan Oleate *(BAN, rINN)*

E494; Monooleato de sorbitán; NSC-406239; Oleato de sorbitán; Sorbitaanioleaatti; Sorbitan Monooleate *(USAN)*; Sorbitan Mono-oleate; Sorbitan, oléate de; Sorbitani oleas; Sorbitano oleatas; Sorbitanoleat; Sorbitan-oleát; Szorbitán-oleát.

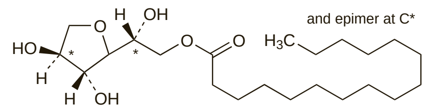
$C_{22}H_{42}O_6$ (approximate).
CAS — 26266-57-9.



Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Sorbitan Palmitate). A mixture of the partial esters of sorbitol and its mono- and di-anhydrides with palmitic acid. A yellowish or yellow powder, waxy flakes, or hard masses. M.p. 44° to 51°. Practically insoluble in water; slightly soluble in alcohol; soluble in fatty oils. Protect from light.
USNF 26 (Sorbitan Monopalmitate). A partial ester of sorbitol and its mono- and di-anhydrides with palmitic acid. A cream-coloured, waxy solid with a faint fatty odour. Insoluble in water; soluble in warm dehydrated alcohol; soluble with haze in warm liquid paraffin and in warm arachis oil.

Sorbitan Sesquioleate *(BAN, USAN, rINN)*

Sesquioleato de sorbitán; Sorbitaaniseskvioleaatti; Sorbitan, sesquioléate de; Sorbitani sesquioleas; Sorbitano seskvioleatas; Sorbitanseskvioleat; Sorbitan-seskvioleát; Szorbitán-szeszkvioleát.

Сорбитана Сесквиолеат

$C_{33}H_{60}O_{6.5}$ (approximate).
CAS — 8007-43-0.

Pharmacopoeias. In *Eur.* (see p.vii) and *Jpn.* Also in *USNF.*
Ph. Eur. 6.2 (Sorbitan Sesquioleate). A mixture usually obtained by esterification of 2 moles of sorbitol and its mono- and di-anhydrides per 3 moles of oleic acid. A suitable antoxidant may be added. Relative density about 0.99. A pale yellow or slightly brownish-yellow paste, which becomes a viscous, oily, brownish-yellow liquid at about 25°. Dispersible in water; slightly soluble in dehydrated alcohol; soluble in fatty oils. Protect from light.
USNF 26 (Sorbitan Sesquioleate). A partial oleate ester of sorbitol and its mono- and di-anhydrides. A yellow to amber-coloured, oily viscous liquid. Insoluble in water and in propylene glycol; soluble in alcohol, in isopropyl alcohol, in cottonseed oil, and in liquid paraffin. Store in airtight containers.

Sorbitan Stearate *(BAN, rINN)*

E491; Estearato de sorbitán; Monoestearato de sorbitán; Sorbitaanistearaatti; Sorbitan Monostearate *(USAN)*; Sorbitan, stéarate de; Sorbitani stearas; Sorbitano stearatas; Sorbitanstearat; Sorbitan-stearát; Szorbitán-sztearát.

Uses

Sorbitan esters are lipophilic nonionic surfactants that are used as emulsifying agents in the preparation of emulsions, creams, and ointments for pharmaceutical and cosmetic use. When used alone they produce stable water-in-oil emulsions but they are frequently used with a polysorbate in varying proportions to produce water-in-oil or oil-in-water emulsions or creams with a variety of different textures and consistencies. Sorbitan esters are also used as emulsifiers and stabilisers in food.

Sucrose Esters

Эфиры Сахарозы

Pharmacopoeias. *Eur.* (p.vii) includes Sucrose Monopalmitate and Sucrose Stearate.

Ph. Eur. 6.2 (Sucrose Monopalmitate). A mixture of sucrose monoesters, mainly sucrose monopalmitate, obtained by transesterification of palmitic acid methyl esters of vegetable origin with sucrose. It contains 55.0% monoesters, a maximum 40.0% diesters, and a maximum of 20.0% for the sum of triesters and polyesters. A white or almost white, unctuous powder. Very slightly soluble in water; sparingly soluble in alcohol. Protect from humidity.

Ph. Eur. 6.2 (Sucrose Stearate). A mixture of sucrose esters, mainly sucrose stearate, obtained by transesterification of stearic acid methyl esters of vegetable origin with sucrose. Sucrose stearate type I contains a minimum 50.0% monoesters, a maximum 40.0% diesters, and a maximum of 25.0% for the sum of triesters and polyesters. Sucrose stearate type II contains 20.0 to 45.0% monoesters, 30.0 to 40.0% diesters, and a maximum of 30.0% for the sum of triesters and polyesters. A white or almost white, unctuous powder. Very slightly soluble in water; sparingly soluble in alcohol. Protect from humidity.

Profile

Sucrose esters are nonionic compounds with surface-active properties produced by esterification of 1 or more hydroxyl groups in sucrose with a fatty acid such as stearic or palmitic acid. Commercial sucrose esters are mixtures of the mono-, di-, and tri-esters of palmitic and stearic acids with sucrose; various grades are available. Sucrose esters are used as dispersing, emulsifying, and stabilising agents in food and cosmetic preparations.

Tyloxapol *(BAN, USAN, rINN)*

m < 6

Pharmacopoeias. In *US.*

USP 31 (Tyloxapol). A polymer of 4-(1,1,3,3-tetramethylbutyl)phenol with ethylene oxide and formaldehyde. A viscous amber liquid, sometimes slightly turbid, with a slight aromatic odour. Slowly but freely miscible with water; soluble in chloroform, in glacial acetic acid, in carbon disulfide, in carbon tetrachloride, in toluene, and in benzene. A 5% solution has a pH of 4.0 to 7.0. Tyloxapol should not be allowed to come into contact with metals. Store in airtight containers.

Adverse Effects

Slight inflammation of the eyelids has been reported after prolonged use of aqueous inhalations of tyloxapol. It has been reported that occasional febrile reactions may occur.

Uses and Administration

Tyloxapol is a nonionic surfactant of the alkyl aryl polyether alcohol type. It is used in solutions for cleansing contact lenses and artificial eyes. Aqueous solutions have been used for inhalation as a mucolytic for tenacious bronchopulmonary secretions. Tyloxapol has also been used as a vehicle for aerosol medication and for antibacterials given in irrigation solutions for pyogenic bone or joint infections.

Nutritional Agents and Vitamins

Dietary Modification, p.1922
Enteral and Parenteral Nutrition, p.1923
Trace Elements, p.1925
Vitamins, p.1925

The principal constituents of food are carbohydrates, fats, minerals, proteins, vitamins, indigestible fibre, and water. Energy is provided by the metabolism of carbohydrates, fats, surplus protein, and alcohol.

Carbohydrates found in foods may be classified according to their degree of polymerisation into three main groups, namely sugars, oligosaccharides, and polysaccharides; all of these are made up only of carbon, hydrogen, and oxygen. Sugars can be further subdivided into *monosaccharides* (single-molecule sugars), such as fructose and glucose, *disaccharides* (whose molecules consist of two monosaccharides joined together), such as lactose and sucrose, and *sugar alcohols* (polyols) such as sorbitol and mannitol. *Oligosaccharides* typically consist of 3 to 9 monosaccharides joined together, and include malto-oligosaccharides such as maltodextrins. *Polysaccharides* consist of many monosaccharides joined together and include starches and non-starch polysaccharides such as cellulose. Non-starch polysaccharides are the major fraction of dietary fibre, and many authorities now consider this term to be preferable to dietary fibre.

Fats have the same elemental composition as carbohydrates, but with a lower proportion of oxygen. Dietary fat is usually in the form of triglycerides, esters of glycerol with three fatty acid molecules. Essential fatty acids are ones that cannot be made in the body and which must be supplied by the food.

Proteins are made up of carbon, hydrogen, oxygen, and nitrogen; most proteins also contain sulfur and some contain phosphorus. They are required for the regulation of body processes such as growth and tissue maintenance. Excess protein can be converted into carbohydrate and used to provide energy.

Proteins consist of chains of **amino acids** of which there are *essential* and *non-essential* types. Essential amino acids (indispensable amino acids) cannot be synthesised in sufficient amounts in the body and must therefore be present in food; non-essential amino acids can be synthesised in the body. There are eight essential amino acids: isoleucine, leucine, lysine, methionine, phenylalanine, threonine, tryptophan, and valine. Arginine and histidine are also essential for infant growth while synthesis of cysteine, taurine, and tyrosine may be inadequate in premature infants.

Several inorganic elements, or minerals, are essential dietary constituents; those which are required in relatively small amounts are known as **trace elements** (see below). Their main function is to act as essential cofactors in various enzyme systems.

Vitamins and their general role in health are described below.

Dietary Modification

Infants, children, elderly people, and pregnant or lactating women have particular nutritional requirements, but in most cases, provided that they are in good general health, adjustment to intake is all that is required rather than extensive modification or supplementation.

Dietary modification is important in the management of some disorders. Calorie restriction is fundamental to the management of obesity, although it may be difficult to motivate patients to accept long-term changes to their eating habits, and some fashionable diets are at best of little value.

The role of diet in the aetiology of cardiovascular disorders (such as salt intake in hypertension and fat intake in ischaemic heart disease) is recognised to be of importance and has lead to public health campaigns for healthier eating patterns.

Dietary modification is also an accepted part of the management of diabetes mellitus, while protein restriction is important in the management of uraemia or hepatic encephalopathy.

There are also metabolic disorders such as phenylketonuria, or forms of intolerance to dietary components, such as coeliac disease, in which the diet must be modified to exclude or drastically reduce certain food components.

Amino acid metabolic disorders. Various inborn errors of amino-acid metabolism are known. They are not common but their consequences are often serious or fatal. Although in some cases there is no effective treatment, early diagnosis is important as some conditions can be managed by dietary modification and/or the use of vitamins. Two of the better known syndromes, homocystinuria and phenylketonuria, are discussed briefly below. Cystinosis, another disorder of amino acid metabolism, is discussed on p.2341. Urea cycle disorders are discussed under Hyperammonaemia on p.1929.

Homocystinuria. Homocystinuria in its classical form is an autosomal recessive disorder in which a genetic deficiency of the enzyme cystathionine synthetase (cystathionine β-synthase), results in accumulation of homocysteine (oxidised extracellularly to homocystine).[1,2] Manifestations may include mental retardation, atherosclerosis, thromboembolism, osteoporosis, and ocular symptoms including lens dislocation, glaucoma, cataract, and retinal detachment.[2] Dietary restriction of methionine with cystine supplementation has been used for treatment; some patients may respond to treatment with B vitamins (pyridoxine, cobalamins, and folic acid),[1-3] or to betaine.[2-4] Compliance with betaine is often poor, however; choline, which is converted to betaine by the liver, has also been given, although experience with its use is limited.[3]

Phenylketonuria. Phenylketonuria is an autosomal recessive disorder that is usually due to a defect in the enzyme phenylalanine hydroxylase. This results in raised blood concentrations of phenylalanine in the neonate, and if untreated produces a syndrome of skin rash, depigmentation, hypertonia, seizures, and severe mental retardation.[5,6] Variants of phenylalanine hydroxylase deficiency include atypical or mild phenylketonuria and hyperphenylalaninaemia; some patients have an inherited defect in the metabolism of tetrahydrobiopterin causing a 'malignant phenylketonuria'.[7]

The disease is controlled by use of a diet very low in phenylalanine,[5,8,9] which if started early can permit relatively normal intellectual development. Protein substitutes are recommended, but the optimal dose remains to be determined; there is some evidence that phenylalanine tolerance increases, and blood phenylalanine levels decrease, when total protein intake from the protein substitute is increased.[10] Controversy exists as to whether dietary restrictions may eventually be relaxed,[7,9] and most consider lifelong metabolic control necessary.[5,11] Metabolic control is important in pregnant women as the consequences of fetal exposure to high phenylalanine concentrations include microcephaly, mental deficiency, and congenital heart disease.[5,12,13]

No consensus exists as to optimal blood concentrations of phenylalanine, although frequent monitoring is necessary. In the UK and USA, values between 2 and 6 mg per 100 mL are usually recommended for neonates, children up to age 12, and pregnant women; for patients over 12 years, concentrations between 2 and 10 mg per 100 mL have been advocated.[5]

High-dose tyrosine does not appear to be an effective alternative to a diet low in phenylalanine.[14-18] The active form of tetrahydrobiopterin, sapropterin (p.2383), has been used, with dietary phenylalanine restriction, neurotransmitter replacement, and folinic acid, to treat malignant phenylketonuria;[7,19] it has also shown some promise for the treatment of maternal phenylketonuria.[20] Some have suggested sapropterin may even replace a low-phenylalanine diet in certain patients.[21] Enzyme replacement or substitution are under investigation.[6,7,22]

Cardiovascular disease. Modification of the diet may be helpful in patients with, or at risk of, cardiovascular disease. In patients with hypertension (p.1171), reduction in salt intake may be tried before starting drug therapy or used as an adjunct to such therapy. Reduction in the total intake of dietary fat, and in particular of saturated fatty acids, is considered important for both the general population and those considered at high risk of ischaemic heart disease (see Cardiovascular Risk Reduction, p.1164). An increased intake of long chain n-3 polyunsaturated fatty acids has been recommended and also a restriction on *trans* fatty acids. Dietary cholesterol should be restricted although it may make less of a contribution to plasma cholesterol levels than dietary saturates.[1,2]

For discussion of the possibility that antoxidant vitamins may reduce the risk of ischaemic heart disease see under Vitamins, below. The link between folic acid, homocysteine, and ischaemic heart disease is discussed on p.1941.

Coeliac disease. Coeliac disease (gluten-sensitive enteropathy; coeliac sprue) is an inflammatory disorder of the small intestine that results from an immunological reaction to the protein fraction of gluten (p.2314). The inflammation leads to mucosal atrophy with subsequent malabsorption, although the extent and severity of mucosal inflammation varies widely, and some patients are asymptomatic. In adults, anaemia and mild gastrointestinal symptoms that may be confused with irritable bowel syndrome are the usual symptoms. In infants and children there may be growth retardation or failure to thrive, and gastrointestinal symptoms may be more marked. Other nutritional deficiencies, including calcium malabsorption leading to osteopenia, may also occur, and mouth ulcers are also common. Provisional diagnosis usually involves serological tests for IgA anti-transglutaminase 2 or antiendomysial antibodies, and multiple intestinal biopsies.

Treatment of coeliac disease involves a strict, life-long, gluten-free diet. Nutritional supplements may be necessary at the start of treatment but can usually be stopped once mucosal recovery has occurred. Diagnosis is confirmed by clinical improvement or normalisation of the mucosa on repeat biopsy after 3 to 4 months. Dermatitis herpetiformis (p.1578) is a non-gastrointestinal manifestation of coeliac disease. Patients may have no gastrointestinal symptoms, although mucosal abnormalities are generally apparent on biopsy. These patients also respond to a gluten-free diet.

Coeliac disease is associated with a number of auto-immune diseases, including type 1 diabetes, thyroid disease, and IgA deficiency. Patients with coeliac disease have an increased incidence of small-bowel lymphoma and a slight increase in the incidence of some other gastrointestinal cancers. There is some evidence that this incidence is reduced in patients maintaining a strict diet.

Diabetes mellitus. Dietary control is important in both type 1 and type 2 diabetes mellitus (p.431). The goals of dietary modification are to maintain glucose concentrations in the normal range or as close to normal as possible, and a lipid and lipoprotein profile and blood pressure that reduce the risk of macrovascular disease.

Fish odour syndrome. Fish odour syndrome (trimethylaminuria) is an inherited metabolic disorder in which there is impaired hepatic *N*-oxidation of trimethylamine. Trimethylamine is formed in the intestine by bacterial degradation of foods rich in choline and carnitine, and is readily absorbed from the gut. If not oxidised in the liver, it is excreted in the breath, urine, sweat, and vaginal secretions. It smells of rotting fish, and has a high olfactory potency. Treatment involves dietary modification to avoid choline-rich foods such as eggs, liver, peas, soya beans, and sea fish. Short-term treatments to reduce the intestinal flora, and thereby decrease the production of trimethylamine, are occasionally used; examples include metronidazole, neomycin, and lactulose.

Hepatic encephalopathy. Restriction of dietary protein intake is a mainstay of the treatment of hepatic encephalopathy, but care is required to avoid malnutrition (see p.1697).

Inflammatory bowel disease. In inflammatory bowel diseases (p.1697) dietary modification or **supplementation** may often be necessary to maintain the nutritional status of the patient. Specific nutritional problems include protein deficiency, fluid and electrolyte depletion, iron deficiency, and deficiencies of certain minerals, vitamins and trace elements, such as magnesium, calcium and vitamin D, vitamin K, and folic acid.[1,2] Supplementation may be oral, nasogastric, or parenteral. In general, although they are considered to have equal efficacy,[3] enteral feeding is preferred to parenteral nutrition. The latter is generally reserved for those who cannot tolerate the enteral route, for perioperative use, or for specific clinical circumstances such as bowel obstruction or perforation.[4,5]

Improvement in nutritional status, elimination of dietary antigens, down-regulation of inflammatory cytokines or up-regulation of anti-inflammatory cytokines, or alteration in bacterial flora are also possible mechanisms whereby nutritional therapy may exert a **therapeutic** effect in inflammatory bowel disease.[5-7] Although controversial as primary therapy, enteral feeding, particularly with elemental diets, has been shown to be effective in the treatment of active *Crohn's disease*,[8] but probably less effective than corticosteroids.[9-11] It may also have some benefit in maintaining remission.[12] There are beneficial effects in children with growth failure, which is exacerbated by corticosteroids,[13,14] and some consider enteral nutrition the first choice of management in paediatric patients with Crohn's disease.[3] Combining an elemental diet with low-dose corticosteroids has also been suggested as a therapeutic approach in children, although it is as yet untested.[14] Adult patients with Crohn's disease who are considered candidates for enteral nutrition include those on potentially high cumulative corticosteroid doses, or who are corticosteroid-refractory or corticosteroid-intolerant, or those at high risk for osteoporosis.[5]

Data are considered insufficient to assess the efficacy of enteral nutrition in *ulcerative colitis*.[5,7]

The term **elemental diet** was originally coined to describe diets containing free amino acids and glucose and was often prefixed by the phrase 'chemically defined'. However, it came to embrace diets whose nitrogen sources included peptides and were often also called predigested diets. It was suggested[15] that the term elemental diet could be used for either type but that for those with an amino acid nitrogen source the term chemically defined elemental diet should be used whereas for those with a peptide nitrogen source predigested elemental diet was suitable. The term polymeric diet should be used for those diets with a whole protein nitrogen source (such as milk or soya).

There appears to be little difference between formulas in terms of therapeutic response, although compliance may be better with polymeric feeds due to the unpalatability of elemental diets.[3,5,13] Several different elemental diets are available; some contain long-chain triglycerides as the fat source, but for patients with impaired fat digestion, medium-chain triglycerides are considered preferable.[1] There is some suggestion that the effectiveness of enteral diets in treating active Crohn's disease might relate to the fat rather than nitrogen composition,[1,3,7] with less inflammation occurring with those containing the fewest long-chain triglycerides.[1]

Other potentially beneficial components of diets for Crohn's disease include omega-3 triglycerides, which may have beneficial effects on inflammatory processes, and in achieving remission;[4,14,16] no clinical benefit has been seen with fatty acid or dietary fish oil supplementation in active ulcerative colitis.[17] Short-chain fatty acids have been proposed as a means of increasing butyrate levels, which may have a direct anti-inflammatory effect on the colon; butyrate enemas have shown benefit in ulcerative colitis.[5,13,17] The use of a substrate ('pre-biotic') to deliver short-chain fatty acids, or directly delivering probiotics to the intestine, have also been proposed.[5,17] Glutamine has been suggested as being beneficial for epithelial integrity of the small intestine,[1,16] although useful data are lacking.[1,4,5]

Much interest also surrounds the use of **growth factors** in enteral formulas, such as epidermal growth factor or transforming growth factor-β, which may have anti-inflammatory actions on the gut mucosa.[7]

Elimination diets, whereby foods are slowly reintroduced once remission has been achieved, aim to reduce relapse rates in Crohn's disease, but the process is prolonged and complicated.[1,3] In a study of patients with ulcerative colitis in remission, consumption of red and processed meat, protein, or alcohol increased the likelihood of relapse;[18] these foods are rich sources of sulfur or sulfate, and sulfide toxicity may be important in the pathogenesis of ulcerative colitis.[17] There is also some suggestion that titanium may be harmful in Crohn's disease, and diets low in titanium have been advocated, with preliminary data suggesting a benefit.[3]

Malignant neoplasms. For a discussion of the possible link between an increased intake of antoxidant vitamins and a reduced risk of developing malignancies, see under Vitamins, below.

Obesity. Obesity is relatively common in the developed world, and is accompanied by an increased risk of cardiovascular disease, diabetes, and other disorders. Methods such as dietary modification, behaviour therapy, and exercise with adjunctive drug therapy, where indicated (see p.2149) can produce weight loss, but the essence of treatment is a reduction in calorific intake, usually by about 300 to 500 kcal daily in patients with a body-mass index (BMI) of 27 to 35, and 500 to 1000 kcal in those with a BMI greater than 35. This would be expected to produce a weight loss of about 0.25 to 1 kg weekly. Very low calorie diets (less than 600 to 800 kcal daily) should only be considered after the failure of determined attempts to lose weight by conventional calorie restriction. For weight loss to be achieved and sustained, eating behaviour must be permanently modified, which may pose difficulties. The proportion of calories from fat in particular, and also alcohol and sugars should be reduced and those from high carbohydrate foods increased. It is obviously important to maintain an adequate intake of essential nutrients.

Artificial sweeteners or other non-sucrose sweeteners are often used as part of weight-reducing diets.

Renal failure. Low-protein diets may be of value in preventing or slowing the progression of chronic renal failure (p.1672). Patients with renal failure who adopt a protein-restricted diet have fewer symptoms of uraemia than those on a normal diet. Some results have also suggested that protein restriction can slow the progression of renal failure, but the value of low-protein diets in delaying the onset of end-stage renal disease has been the subject of much controversy.[1] Two large multicentre studies provided little evidence of a substantial benefit,[2,3] but a systematic review[4] provided support for dietary protein restriction. *Animal* studies suggest that modification of the protein source from animal to soya protein might slow renal disease progression, especially at high intakes.[5]

Generally, low-protein diets providing between 0.6 to 0.8 g/kg daily have been recommended,[1,6-8] although a very low-protein diet providing 0.3 g of vegetable origin protein, supplemented with a mixture of essential amino acids, has been recommended for highly motivated patients with advanced renal failure.[1]

Once the patient starts dialysis, however, protein losses through the dialysis membrane or peritoneum may require an increase of protein intake to between 1.2 and 1.3 g/kg daily.[6,8] Because energy intake needs to remain constant, food selection has to change qualitatively.[6] Sodium, potassium and phosphate intake also need to be controlled.[6,8] During dialysis, restricting dietary phosphate while maintaining sufficient protein intake may be difficult, and modification of the protein source may be necessary.[9]

After kidney transplantation, if renal function stabilises, protein restriction is again advisable;[6] between 1.3 and 1.5 g/kg daily is recommended initially, then 1 g/kg daily for maintenance.[8] However, adverse effects of immunosuppressant drugs may complicate the dietary targets, with the patient at risk of diabetes, dyslipidaemia, and possible hypertension.[6] The importance of salt restriction and reduction of the sodium dialysate content in controlling hypertension in renal patients has been emphasised.[10]

It has been suggested that the benefit of other interventions such as the use of ACE inhibitors,[11] as well as the difficulties in obtaining patient compliance with such a restrictive diet,[12] may have limited the benefits to be obtained from protein restriction, but there is also evidence that response and outcome vary depending on the cause of renal failure.[3,13]

Enteral and Parenteral Nutrition

Malnutrition of varying degrees is not uncommon in hospitalised patients, and some form of nutritional support is important in patients who cannot eat an adequate normal diet. Such support should provide for the patient's requirements for energy, in the form of carbohydrate and fat, nitrogen as amino acids or protein, water and electrolytes; where appropriate, vitamins and trace elements should also be supplied. Indications for nutritional support may include unconsciousness, obstruction or inability to swallow, inflammatory bowel disease, fistula, short bowel syndrome, and weakness and malnutrition associated with trauma, surgery, or malignant disease. If possible, nutritional support should be by the enteral route; it is easier, more physiological, and less prone to complications than the parenteral route.

Enteral nutrition includes feeding by mouth, by nasogastric or nasoenteric tube, or directly into a gastrostomy or other enterostomy. It may be supplemental, if normal food intake is possible but inadequate, or total. Individual patients vary in their requirements according to age, size, and metabolic state, but a diet supplying 2000 to 3000 kcal of energy and 10 to 15 g of nitrogen (as 60 to 90 g of protein) in 2 to 3 litres of fluid is fairly typical; because absorption from the gastrointestinal tract is incomplete requirements are higher than by the parenteral route. Preparations containing whole protein (often derived from milk or soya) are generally preferred; elemental diets, in which nitrogen is supplied as amino acids or oligopeptides, are less well tolerated and less palatable, although they may have a role in impaired digestion or when a zero-residue diet is desired.

Although preferred to parenteral nutrition, enteral feeding is not without complications. Patients may be at risk of oesophagitis, aspiration, and regurgitation as a result of the tube insertion; other potential problems include diarrhoea, nausea and vomiting, gastric retention, hyperglycaemia, fluid and electrolyte disturbances, and microbial contamination of the feed regimen.

Parenteral nutrition is reserved for situations in which it is impossible to meet nutritional requirements by the enteral route. Like enteral nutrition it may be given supplementally or as the sole source of body requirements (total parenteral nutrition or TPN). It is normally given via a dedicated central venous catheter. However, peripheral veins are increasingly used for short-term feeding. This reduces some complications and insertion is less complex, but because of the risk of thrombophlebitis the feeds used should have low osmolality and neutral pH. Other measures to delay the development of peripheral thrombophlebitis are mentioned under Adverse Effects and Precautions, below.

The formulation of the nutritional solution must be adjusted according to the patient's requirements. The solution should supply sufficient energy to allow for the resting energy expenditure (around 25 kcal/kg in the average adult) but must also take into account any increased energy expenditure of illness. Conversely, starvation can reduce resting metabolism and energy requirements. Various formulae exist for the calculation of energy expenditure in patients. Energy is best supplied in the form of carbohydrate (at least 30%, and preferably 60% of energy requirements should be in this form) and fat. Glucose is the optimal carbohydrate energy source, while fat is supplied as a lipid emulsion, often of soya oil. Nitrogen is supplied as amino acids, but to ensure that these are used for protein synthesis rather than as sources of energy it is important to control the ratio of non-protein energy to nitrogen in the solution. A ratio of 150 to 200 kcal per g of nitrogen is usually considered optimal but in hypercatabolic patients (e.g. in sepsis) lower ratios of 120 kcal per g or less may be appropriate. All essential amino acids are supplied although there is some variation between solutions as to which non-essential amino acids are present.

Parenteral nutrition must also supply the patient's requirements for fluid, essential electrolytes such as sodium, potassium, magnesium, bicarbonate, and calcium (as well as phosphate, since glucose infusion may provoke hypophosphataemia), and, particularly if treatment is prolonged, vitamins and trace elements. If glucose loading produces signs of hyperglycaemia insulin may be added to correct it.

The major complication of parenteral nutrition is bacterial colonisation of the catheter, which can lead to septicaemia. Other problems may include venous thrombosis or air embolism, extravasation due to misplacement of the catheter tip, and metabolic disturbances. Adverse effects of overfeeding include respiratory and hepatic dysfunction. Complications of long-term total parenteral nutrition include gallbladder sludging, gallstones, cholestasis, and abnormal liver function tests.

Stability and compatibility. The complex nature of solutions for parenteral nutrition renders them susceptible to compatibility problems.[1-18] Stability is dependent upon several factors including pH and relative concentrations of the components. Amino acids exert a buffering effect on the overall pH of mixed solutions containing amino acids, glucose, and fat emulsions but amino acids with glucose undergo the Maillard reaction (browning) and the life of combined solutions is therefore limited. Solutions containing electrolytes, particularly divalent cations, are not stable, and aggregation will eventually occur. Additives should be added only if there is known compatibility, and any additions performed aseptically before the start of the infusion.

The most significant cause of precipitation is higher concentrations of calcium and phosphate,[13,18] and the most important factor governing calcium phosphate precipitation is the final pH of the mixture. The pH is itself determined by a number of factors, including the commercial source of the amino acid infusion, and the final amino acid and glucose concentrations. The use of organic phosphate compounds may reduce the likelihood of precipitation. Trace element precipitation may also occur and amino acid infusions can contain detectable quantities of trace elements as contaminants. The most significant cause of chemical instability is the degradation of specific vitamins, through exposure to light or binding with the plastic of the bag or giving sets. Two particular reactions, the oxidation of ascorbic acid, and the reduction of thiamine, are of concern.

Adverse effects and precautions. *ENTERAL NUTRITION.* Complications of enteral feeding can arise from mechanical, gastrointestinal, metabolic or other causes, such as infection or aspiration.[1] The most common nutritional complication of enteral feeding is failure to meet nutritional requirements, and overzealous feeding may lead to the 'refeeding syndrome' manifested by glucose intolerance, fluid retention, and electrolyte imbalances.[2] High-protein formulas with low water intake may also cause this syndrome.[1] These rapid metabolic and electrolyte changes can lead to severe or even fatal cardiopulmonary and neurological problems.[3] To avoid these problems, low levels of feeding for the first few days have been recommended; about 20 kcal/kg daily has been suggested but even this may be too high, especially in patients with existing electrolyte abnormalities, and about 10 kcal/kg daily may be more suitable for high-risk patients.[4] Mechanical or physical complications include displacement or clogging of the tube, or patient discomfort.[1-5] Many of the problems encountered can be avoided by using a fine bore tube, giving the feed by continuous infusion, and by careful monitoring of the patient for metabolic abnormalities.[6] However, tubes become clogged more often if the calibre of the tube is small, the tube is long, placed in the stomach, the feeding continuous, or if medication is given through the tube.[2,5] Inadequate flushing and protein precipitation may also occur.[3]

Positioning the tube in the small bowel rather than the stomach has been suggested to reduce the incidence of aspiration,[2,5,7] although few studies have been done comparing intraduodenal and intragastric feeding in terms of clinical outcomes, and there are concerns about appropriate placement, infection, and reflux.[8] A meta-analysis[9] failed to find any clinical benefit of post-pyloric feeding over gastric feeding in terms of the incidence of pneumonia, length of stay, and mortality; the study was limited by a relatively small number of patients, and did not include patients considered at high risk of aspiration. Prokinetic drugs such as metoclopramide, or erythromycin, have been used to promote gastric emptying and reduce residual gastric volumes.[7-9]

Complexation of the nutrients with aluminium-containing antacids, also given via the tube, may occur and this deposition of solid masses may cause oesophageal obstruction.[10]

Diarrhoea in patients receiving enteral nutrition may not necessarily be caused by the tube feeding itself;[11,12] malabsorption, infections and microbial contamination, underlying disease, and concomitant drug therapy can be possible contributors.[1,2,4,13,14] However, enteral feeding has been shown to be associated with increased colonic secretion, which can be reversed by infusion of short-chain fatty acids.[15] Because colonic microflora may play a role in the pathogenesis of diarrhoea associated with enteral feeds, manipulation of the microflora using pre- or probiotics has been suggested as a means of reducing the incidence, duration or severity thereof, and some enteral feeding formulas contain prebiotics. However, few studies have investigated the effect on diarrhoea, and further research is warranted.[14]

While enteral tube feeding and the presence of a nasogastric tube are risk factors for infection, optimal nourishment through enteral feeding in high-risk patients unable to tolerate oral nutrition may also improve their immune status.[16]

PARENTERAL NUTRITION. A common complication of parenteral nutrition is infection of the intravenous feeding catheter site,[1-3] which can lead to septicaemia. Infection and colonisation of central venous catheters may be reduced if the catheter is tunnelled through subcutaneous tissue before emerging through the skin.[4] Strict aseptic techniques should be used[1] for changing the dressing or bags containing the nutrient fluids. Misplacement of the catheter has been reported.[3,5] Precipitation of minerals, lipids, and medications can cause line occlusion.[3]

Thrombophlebitis can occur after the use of either peripheral or central veins. Although it has been suggested that infusion of hyperosmolar solutions via a central line is less likely to produce thrombophlebitis, because the feed is immediately diluted by a large volume of blood, major thrombotic complications such as pulmonary embolism and right atrial thrombosis could be more common than hitherto recognised in children and adolescents receiving long term parenteral nutrition via central catheters.[6,7] The use of a fine-bore silicone catheter peripherally may avoid the need for central vein cannulation[8] and there is a lower incidence of thrombophlebitis when fine-bore silicone catheters rather than teflon ones are used for peripheral parenteral nutrition.[9] The use of giving sets with filters may decrease thrombophlebitis during peripheral infusion.[10,11] The addition of heparin or buffer solutions to the feed, and the use of local hydrocortisone and glyceryl trinitrate, has also been reported to prolong the survival of peripheral infusion sites.[11,12] Extravasation may also be a problem, particularly with hyperosmolar solutions, and has led to severe tissue damage; hyaluronidase or thiomucase may be used in the treatment of such extravasation.[13]

Parenteral nutrition may be associated with atrophic changes in the mucosal structure and enzymic activity of the intestine, leading to increased permeability with a possible increased risk of bacteraemia and endotoxaemia. These changes, which have been attributed to lack of glutamine (which is unstable in solution), can reportedly be prevented by addition of glutamine-releasing dipeptides to solutions for total parenteral nutrition—see p.1947. Some have questioned the extent of this mucosal atrophy or bacterial translocation associated with parenteral feeding.[14,15]

Prolonged parenteral nutrition has been associated with hepatobiliary complications, especially in children;[16,17] cholelithiasis and cholestasis have been reported, with the latter sometimes progressing to liver failure.[18] Although the aetiology is considered multifactorial,[18] contamination of the solution with manganese (see Accumulation under Adverse Effects of Manganese, p.1956) or aluminium[19] has been suggested as one possible cause of the cholestasis.

Aluminium toxicity has also been implicated in the osteomalacia seen in patients on long-term parenteral nutrition.[3,17] Osteopenia and osteoporosis have also been reported;[17] possible mechanisms include calcium, phosphate, or magnesium deficiencies, vitamin D deficiency or toxicity, vitamin K deficiency, or excessive protein.[3] A review, however, considered the risk to be minimal, with little deleterious effect on cortical bone and an improvement on trabecular bone.[5] Other factors implicated in possible metabolic bone disease include calcium deficiency and vitamin D toxicity.[17]

Other metabolic complications associated with parenteral nutrition include hyperglycaemia, hypoglycaemia, hyperlipidaemia, hypercapnia, acid–base disturbances, and 'refeeding syndrome'.[20] Hyperglycaemia may be due to excessive glucose infusion, and can lead to immunodepression and an increased risk of infection; insulin therapy is indicated if it persists. Hypoglycaemia, although less common, may occur if parenteral nutrition is interrupted or as a result of an insulin overdose. Hyperlipidaemia is caused by excessive fatty acid synthesis from glucose, or impaired lipid clearance. The use of a mixture of medium-chain and long-chain triglycerides (rather than long-chain triglyceride emulsions alone) may result in fewer serum lipid abnormalities since medium-chain triglycerides are oxidised faster than long-chain triglycerides. Overfeeding of total calories and glucose can lead to hypercapnia which can cause acute respiratory acidosis.[20] While most acid–base disturbances are related to the underlying condition, excess chloride or acetate in the parenteral nutrition solution may cause metabolic acidosis or alkalosis, respectively.[17] The 'refeeding syndrome' can occur when severely malnourished patients are given rapid nutritional repletion, leading to fluid and electrolyte imbalances, glucose intolerance, and vitamin deficiencies. These may result in significant or even fatal cardiac, pulmonary, renal, gastrointestinal, and neuromuscular complications. Electrolyte disturbances include sodium retention, hypophosphataemia, hypokalaemia, and hypomagnesaemia; thiamine deficiency may lead to Wernicke's encephalopathy in malnourished patients or in thiamine-deficient patients given high carbohydrate loads.[20]

Trace Elements

Trace elements are inorganic substances found in small amounts in the tissues and required for various metabolic processes; together with the vitamins (see below) they are sometimes referred to as micronutrients. The elements considered essential are chromium, copper, fluorine, iodine, iron, manganese, molybdenum, selenium, and zinc. Iron, in the form of haem, plays an essential role in oxygen transport while iodine is required by the thyroid for the formation of thyroid hormones; most of the other essential trace elements are cofactors for various enzymes. Boron, nickel, silicon, and vanadium may also be essential, and it has been suggested on the basis of *animal* studies that there might be a requirement for tin.

Well-defined deficiency syndromes exist for copper, iodine, iron, selenium, and zinc; although deficiency of other trace elements is possible, their deficiency syndromes are not well defined because of their ubiquity in the diet. Guidance concerning the intake of various trace elements has been published—see also Human Requirements under Vitamins, below.

Vitamins

Vitamins are organic substances required by the body in small amounts for various metabolic processes. Most are not synthesised in the body, or are synthesised in small or insufficient quantities. Vitamins are sometimes classified as fat soluble or water soluble. Substances in the vitamin A, D, E, and K groups are generally fat soluble, and biotin, folic acid, niacin, pantothenic acid, vitamins B_1, B_2, B_6, and B_{12}, and vitamin C substances are generally water soluble.

Vitamin deficiency may result from an inadequate diet, perhaps due to increased requirements such as during pregnancy, or may be induced by disease or drugs. Vitamins may be used clinically for the prevention and treatment of specific vitamin deficiency states and details of these uses are provided under the individual drug monographs.

Large doses of vitamins (megavitamin therapy) have been proposed for a variety of disorders, but adequate evidence of their value is lacking. Excessive intakes of most water-soluble vitamins have little effect due to their rapid excretion in urine, but excessive intakes of fat-soluble vitamins accumulate in the body and are potentially dangerous.

Stability. Water-soluble vitamins are liable to degrade in solution especially if exposed to light. Addition of vitamin mixtures to infusion solutions for parenteral nutrition should therefore be carried out as soon as possible before infusion. Solutions should be used within 24 hours of preparation and be protected from light.

Carcinogenicity. For mention of an increased risk of lung cancer in patients receiving betacarotene and vitamin A, and an increased incidence of second primary cancers in patients given vitamin E (and betacarotene initially), see Prophylaxis of Malignant Neoplasms, p.1927. For a discussion of possible carcinogenic effects in children given vitamin K intramuscularly, see Carcinogenicity, p.1996.

Effects on mortality. Although vitamin supplements have been widely taken in the hope of improving mortality from various diseases, a large systematic review[1] concluded that there was no evidence that antioxidant vitamin supplements improved mortality, and some, such as vitamin A, betacarotene, and vitamin E, might increase it.

For mention of possible adverse effects on mortality with betacarotene supplementation, see Effects on Mortality, p.1931. For discussion on the effects on mortality with Vitamin A, see p.1972. For mention of possible beneficial effects of high serum ascorbic acid levels on all-cause mortality, see under Vitamin C, p.1984. For mention of possible dose-dependent adverse effects on mortality with use of vitamin E, see Effects on Mortality, p.1993. For discussion of the effects of various antioxidant vitamins on cardiovascular disease and cancer, see Prophylaxis of Ischaemic Heart Disease, below, and Prophylaxis of Malignant Neoplasms, p.1927, below.

Human requirements. Vitamins and trace elements are essential nutrients and in many countries guidance has been published concerning their intake.

In the UK various terms are used to define intake:[1]

- estimated average requirement (**EAR**) is used for the requirements of energy, proteins, vitamins, or minerals of a group of people and usually about half will need more and half less than the specified figure
- lower reference nutrient intake (**LRNI**) is applied to proteins, vitamins, or minerals and is that amount that is enough for only a few people who have low needs
- reference nutrient intake (**RNI**) is also applied to proteins, vitamins, or minerals and is an amount that is enough, or more than enough, for about 97% of people in a group
- a safe intake is used to indicate an intake or range of intakes where there is not enough information to estimate EAR, LRNI, or RNI, but rather it is an amount enough for almost everyone but is not so large as to cause undesirable effects
- dietary reference value (**DRV**) is used to cover EAR, LRNI, RNI, and safe intake.

It is emphasised in a 1991 report[1] that these intakes are not meant to be recommendations for any individual or group; they do not reflect either a recommendation that such an amount should be taken daily in the diet or as a supplement. They are intended rather as yardsticks for the assessment of dietary surveys and food supply statistics; to provide guidance on appropriate dietary composition and meal provision; or for food labelling purposes in which case it is envisaged that an EAR will be used.

An Expert Group on Vitamins and Minerals, established in the UK to review data on the safe intake of vitamins and minerals from food and food supplements, recommended the use of safe upper levels (**SULs**). These were the doses of vitamins and minerals that individuals could take daily on a lifelong basis without significant risk to health on the basis of available evidence.[2]

In the USA the National Academy of Sciences has traditionally set recommended dietary allowances (**RDAs**),[3] defined as the levels of intake of essential nutrients that, on the basis of scientific knowledge, are judged to be adequate to meet the known nutrient needs of practically all healthy persons. The allowances are amounts that are intended to be consumed as part of a normal diet. However, new dietary reference intakes (**DRIs**) have been developed,[4] which include 3 reference values in addition to the traditional RDA as follows:

- the estimated average requirement is the intake that meets the needs of half the individuals in a group
- the adequate intake is the mean intake level that appears to sustain a desired marker of health, and will be set when there is insufficient evidence to establish an RDA
- the tolerable upper intake level is the maximum intake that is not likely to adversely affect health.

Information pertaining to the requirements of specific vitamins and minerals is provided under the individual monographs.

Supplementation. An adequate dietary intake of vitamins is necessary for good health but whether vitamin supplementation in the absence of any demonstrable deficiency is beneficial or even worthwhile remains debatable.

It is generally considered that healthy persons eating a normal balanced diet should have no need for vitamin supplementation.[1,2] A review of the topic[1] pointed out that the vitamins that people chose for self medication are often not the ones that are actually present in inadequate amounts in their diets and that the commercial preparations available often do not make it clear whether the amounts they contain are near the physiological requirements or many times greater. Supplementation should concentrate on groups of people at risk of deficiency such as neonates, who need vitamin K; pregnant and lactating women, who need calcium, folic acid, and iron; and certain groups who need vitamin D; vegans and their infants may require vitamin B_{12} supplements. A multivitamin supplement might be considered for some groups such as the elderly and those with reduced calorie intake.[1,3] However, one might have difficulty in finding a good multivitamin preparation containing all 13 vitamins but no non-vitamins. Also with many of the multivitamin preparations the doses and ratios varied inexplicably.[1]

A review[4] of supplementation specifically in children concluded that, provided schoolchildren and adolescents eat a wide variety of foods, there was no need for vitamin supplementation. However, it was recommended that supplementation with vitamins A, C, and D should be given to those between the ages of 6 months and 2 years and preferably up to the age of 5 years. Several authorities in different countries have set upper safety limits for vitamins; these vary considerably.[5]

Vitamin and mineral supplementation has been investigated in various disorders (see below). However, a systematic review for the National Institutes of Health in the USA led to the consensus that evidence was insufficient to recommend either for or against the use of multivitamin and mineral supplements to prevent cancer and chronic disease.[6,7] (For a systematic review that concluded against use of antioxidant supplements see Effects on Mortality, above.)

EYE DISORDERS. Vitamin therapy has been investigated for the prophylaxis or treatment of various eye disorders. Vitamin A is used in the management of xerophthalmia, see p.1974. There is some suggestion of benefit with vitamin A for retinitis pigmentosa, p.1974; results with vitamin E are conflicting. Vitamin E has been used for the treatment of retinopathy of prematurity, p.1994. For discussion of the effect of vitamins C, E, betacarotene, and zinc on age-related macular degeneration, see under Betacarotene, p.1931.

HIV INFECTION AND AIDS. Low serum micronutrient concentrations are common in HIV-positive individuals, especially in the developing world; malabsorption, anorexia, diarrhoea, and increased energy demands contribute to malnutrition,[1,2] which in turn contributes to immune impairment and increased mortality. Conflicting results have been found with the use of vitamin A in the prevention of vertical transmission, see under Vitamin A, p.1974. A meta-analysis of trials of vitamins to prevent vertical transmission found no strong evidence of benefit and failed to exclude the possibility of harm, having included trials of vitamin A supplementation.[3] A randomised trial found that multivitamin plus selenium supplementation increased CD4 and CD8 cell counts compared with placebo, but also unexpectedly increased the levels of genital HIV-1 shedding.[4] Two other trials have also found that multivitamins, but not vitamin A, increased CD4 and CD8 cell counts;[5,6] delaying the progression of disease in one,[6] and decreasing adverse pregnancy outcomes in the other.[5] While some advise against vitamins as a therapy to prevent vertical transmission,[3] and others recommend it as an adjunctive treatment to antiretroviral therapy,[1,2] most agree that in the setting of poverty and lack of adequate nutrition, provision of food programs and/or supplementation along with antiretroviral treatment for HIV-infected individuals, is vital.[7]

INFECTION. Vitamin A has an important role in the prevention of complications from measles (see p.1974), but evidence for benefit in respiratory-tract infections is less compelling (see p.1974). Some studies show evidence of benefit for vitamin C in treating the common cold (p.850), but routine high-dose prophylaxis is not considered justified. Vitamin E has shown conflicting results in respiratory-tract infections, see p.1994.

For a discussion of the role of vitamins in HIV infection and AIDS see above.

MENTAL FUNCTION. Giving vitamin and mineral supplements to children was reported in 1988 to increase non-verbal intelligence[1] and the topic has since remained highly controversial. In the next 2 years more studies were published but these failed to substantiate the earlier possible effect and concluded that vitamin supplementation did not improve mental functioning or reasoning in children.[2,3] Suggestions were made shortly after these publications that there might be a subset of children with poor nutritional status who would receive some benefit[4] but this again was disputed.[5]

In 1991 another study was published,[6] this time coinciding with the launch of the proprietary product used in the study, with the publication of a book on the subject, and with the showing on British television of a documentary concerning the study. This study purported to demonstrate that supplementation with exactly the recommended dietary allowances of vitamins improved the IQ of children, a finding that was said not to occur significantly with other quantities of vitamin supplementation. This view attracted extremely harsh criticism[7-9] from physicians, nutritionists, psychologists, and epidemiologists.

Despite conflicting data on the effect of vitamin E intake on cognitive decline, US guidelines have suggested that vitamin E be considered in patients with Alzheimer's disease in an attempt to slow progression of the disease. A subsequent large trial found no benefit for vitamin E over placebo (see Dementia, p.1994). A cohort study found low folate concentrations to be the predominant risk factor for cognitive decline in elderly people.[10] Raised homocysteine concentrations have also been found in patients with cognitive decline and dementia.[11] While a 2-year controlled study found that daily homocysteine-lowering treatment with folate, vitamin B_6, and vitamin B_{12} did not improve cognitive performance,[12] another found that daily folic acid supplementation for 3 years significantly improved measures of cognitive function.[13]

Similarly, low folate concentrations and increased homocysteine concentrations have been implicated in depression, and supplementation has been proposed,[11] both as monotherapy, or as a means of augmenting antidepressant efficacy.[14]

PREGNANCY. Folic acid protects against the development of neural tube defects (p.1942) and supplementation during pregnancy is advised; vitamin B_{12} supplementation may also be warranted. Vitamin A, however, may be teratogenic and maximum intakes in pregnancy have been recommended, see p.1972. The risks to the fetus of untreated maternal hypoparathyroidism are considered greater than the risks of hypercalcaemia due to vitamin D therapy (see p.1988). Systematic reviews[1,2] of supplementation in pregnancy lacked enough data to indicate whether vitamin C or E, alone or with other supplements, were of benefit. There was some suggestion of decreased risk of developing pre-eclampsia with either vitamin C or E; however, preterm births may have increased with vitamin C supplementation.

PROPHYLAXIS OF ISCHAEMIC HEART DISEASE. Hypercholesterolaemia is a major risk factor for the development of atherosclerosis and consequently ischaemic heart disease. Since oxidation of lipids, particularly low-density-lipoprotein (LDL) cholesterol,[1] has been proposed as a factor in atherogenesis, the possibility of preventing atherosclerosis by the use of dietary antoxidants such as vitamins E and C and betacarotene has been investigated. A six-year trial of supplementation with vitamins C and E in hypercholesterolaemic patients showed a slowing of atherosclerotic progression, especially in men.[2] Prospective epidemiological studies have revealed a reduced risk of ischaemic heart disease in individuals taking vitamin E supplements,[3,4] and those with a high carotene intake (particularly smokers).[3] In a further prospective cohort study,[5] dietary vitamin E consumption, but not vitamin E supplementation, was associated with decreased risk of death from ischaemic heart disease. Intake of vitamin C, however, did not appear to be associated with a decreased risk of ischaemic heart disease in these studies,[3-5] although another study[6] found a significantly lower risk in those taking vitamin C supplements. Data from some studies assessing serum or fat concentrations also provide evidence that high betacarotene concentrations are associated with decreased cardiovascular disease.[7-9]

However, despite these promising results, randomised placebo-controlled trials have failed to find any benefit for betacarotene supplements in the primary or secondary prevention of ischaemic heart disease, and those for vitamin E supplements are inconclusive. In the Alpha Tocopherol, Beta Carotene Cancer Prevention (ATBC) study, which monitored cardiovascular disease as a secondary end-point, vitamin E was not associated with a decreased incidence of ischaemic heart disease, and betacarotene was associated with a small increased risk.[10] In further analyses, neither supplement appreciably altered the incidence of angina pectoris,[11] nor showed any beneficial effect on cardiovascular deaths in the subset of men with previous myocardial infarction.[12] It has been suggested that the lack of effect of vitamin E in this study may be due to an insufficiently high dose of tocopherol. Similarly, neither the Betacarotene and Retinol Efficacy Trial (CARET)[13] nor the Skin Cancer Prevention Study[9] found an effect for betacarotene supplementation on the risk of death from cardiovascular disease.

In studies specifically on cardiovascular end-points, no benefit from betacarotene supplements was seen in a large, randomised, placebo-controlled study[14] in healthy men. Studies of supplementation with high-dose vitamin E in patients with evidence of ischaemic heart disease,[15] or after myocardial infarction,[16] failed to show any beneficial effect on cardiovascular deaths, although in one study[15] there was a reduction in non-fatal myocardial infarction and major cardiovascular events. The Heart Outcomes Prevention Evaluation (HOPE) study also showed that vitamin E treatment for 4 to 6 years had no effect on cardiovascular events in high-risk patients;[17] further follow-up[18] raised the possibility of an increased risk of heart failure with vitamin E. Another large-scale study, the Heart Protection Study, assessed the effect of a 'cocktail' of vitamin E, vitamin C, and betacarotene on the development of ischaemic heart disease in high-risk subjects, and again found no evidence of benefit.[19] Another study[20] using a similar cocktail in patients with established heart disease found no effect on clinical outcome. In view of the lack of evidence of benefit with vitamin supplements, it has been recommended that the emphasis should instead be on consuming a balanced diet including antioxidant-rich fruits, vegetables, and whole grains rather than vitamin supplements;[21,22] authors of a meta-analysis[23] of trials of antioxidant vitamins for the prevention of cardiovascular disease concluded that, in view of a possibly harmful effect of betacarotene and inefficacy of vitamin E, the use of these supplements be discouraged. It has been pointed out[24] that differences between the observational and clinical trials may be due to intrinsic differences between individuals who choose to take supplements and the high-risk populations studied in randomised trials, who may be less amenable to cardiovascular risk reduction with antioxidant supplementation.

For a discussion of the possibility that folic acid and vitamin B may reduce ischaemic heart disease through a homocysteine-lowering effect, see p.1941.

PROPHYLAXIS OF MALIGNANT NEOPLASMS. There is evidence that a diet rich in fruit and vegetables is associated with a lower incidence of malignant disease, particularly of the respiratory and digestive tracts.[1] It has been hypothesised that some of the benefits of such a diet derive from the role of antioxidant vitamins such as the carotenoids and vitamins C and E in scavenging free radicals.[2,3] However, it is by no means certain that these are the only, or necessarily the most important, dietary components responsible for benefit, since components such as dietary fibre may also play a role. In addition, different antioxidants may vary in their properties and efficacy,[3,4] and the appropriate dosage remains largely conjectural, and perhaps as a result the evidence of benefit is often conflicting.

Several clinical studies of the use of **vitamin A** or **betacarotene** in the secondary or primary prevention of malignancy have been reported. Prolongation of disease-free interval in patients with various malignant neoplasms was reported in 1 study of betacarotene,[5] and others reported remission of oral leucoplakia in patients treated with betacarotene and vitamin A,[6,7] or betacarotene alone.[8] Vitamin A alone was reported to reduce the incidence of primary tobacco-related neoplasms in a study of patients treated surgically for lung cancer.[9] In a prospective, cohort study,[10] vitamin A intake, including preformed vitamin A and carotenoids, was associated with a reduced risk of breast cancer among smokers. However, other results have largely failed to substantiate any benefit for secondary prevention. No reduction in the incidence of new skin cancers,[11-13] or in malignant transformation of cervical dysplasia,[14] or in new colorectal adenomas[15] was reported in other studies. In a primary prevention study, a combination of betacarotene, vitamin E, and selenium was associated with a reduction in stomach and oesophageal cancers in a population at high risk of these cancers and with a diet low in micronutrients in China.[16] In contrast, other primary prevention studies have failed to show any benefit, and possibly some harm, from betacarotene supplements in well-nourished populations. A study in smokers[17-19] showed an increase in lung cancer and associated mortality in those receiving betacarotene, but not those receiving vitamin E. Similarly, an increased risk of lung cancer was noted in recipients of betacarotene with vitamin A in another study in individuals at high risk of lung cancer, and this study was stopped early as a result.[20,21] In a 6-year follow-up,[22] this risk was found to persist, albeit at lower and not statistically significant levels. A third study in healthy men found no benefit or harm for betacarotene supplements in terms of incidence of malignant neoplasms, including those of the lung;[23] a subgroup analysis of this study suggested that supplementation may reduce the risk of prostate cancer in those men with low baseline betacarotene levels.[24] Among subjects with colorectal adenoma,[25] who neither smoked nor drank alcohol, betacarotene supplementation was associated with a decrease in the risk of recurrent adenoma, but risk was increased in those who smoked or drank alcohol. A meta-analysis[26] of trials of antioxidant supplementation found that betacarotene had no anticarcinogenic effects on gastrointestinal cancer, and that given alone, it increased mortality. When given with vitamin A and E, mortality increased further. A further systematic review and meta-analysis[27] found that betacarotene supplementation was associated with an increased incidence of cancer among smokers, but not among non-smokers. There was also a trend towards increased cancer mortality with betacarotene supplementation.

Vitamin C has also been proposed for prevention of malignancy but there is no real evidence to justify it. It certainly appears to be ineffective as adjuvant therapy in the treatment of advanced malignancy,[28] and combination with betacarotene and vitamin E failed to show any effect in preventing colorectal adenoma.[15] At physiological concentrations vitamin C is an important antioxidant,[3] but while low serum ascorbic acid concentrations have been inversely related to cancer mortality,[29,30] supplementation is unlikely to be justified in anyone eating a balanced diet.[1]

There is epidemiological evidence that **vitamin D** has protective effects against the development of malignant neoplasms,[31] but evidence from controlled studies is scanty, and it is unclear whether supplementation, and if so to what degree, would be appropriate.

Vitamin E substances are also known to play an important antioxidant role in the body. *Animal* studies have suggested that they should inhibit tumour production, and the Chinese study mentioned above found combined antioxidant therapy including vitamin E to be of benefit in the primary prevention of stomach and oesophageal cancers.[16] Other studies in western populations have generally been disappointing; vitamin E had no effect on lung cancer incidence in those at risk,[17,18] and did not prevent the development of new colorectal adenomas.[15] In a study of patients with head and neck cancer, supplementation with vitamin E led to a higher incidence of second primary cancers and reduced cancer-free survival; patients on supplements had initially also been given betacarotene. While noting the fact that the study population were at high-risk for second primary cancers, the authors cautioned against the use of high-dose vitamin E supplements for cancer prevention.[32] There is also suggestion of increased all-cause mortality with high-dose vitamin E (see p.1993). However, further analysis of the lung-cancer study[33] suggests that vitamin E may have protected against prostate cancer. There is preliminary evidence that selenium (see p.1961) or vitamin E supplementation may reduce the risk of prostate cancer, and a large randomised study is underway to further investigate this.

Results from the Nurses' Health Study have indicated that prolonged use of multivitamins was associated with reduced risk of developing cancer of the colon.[34] This effect was thought to be due to the **folate** component and could be demonstrated after 15 years of use, but not after shorter-term ingestion. Dietary folate was also associated with a modest reduction in risk for colon cancer, and folic acid intake might reduce the risk of breast cancer, especially in those regularly consuming alcohol.[35,36] For the suggestion that folic acid may have dual modulatory effects on carcinogenesis, see Carcinogenicity, under Folic Acid, p.1940.

While a diet involving frequent consumption of fruits and vegetables is likely to be beneficial,[1,37] others have also suggested that these associations may have been overstated, and that weight control and regular exercise should be prioritised.[35]

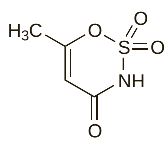
Acesulfame Potassium *(BANM, rINNM)*

Acesulfam draselná sůl; Acesulfam potasowy; Acesulfame K; Acésulfame potassique; Acesulfamkalium; Acesulfamo kalio druska; Acesulfamo potásico; Acesulfamum kalicum; Aceszulfám-kálium; Asesulfaamikalium; E950; H73-3293; H-733293; Hoe-095K; Kalii Acesulfamum. 6-Methyl-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide potassium.

Калия Ацесульфам

$C_4H_4KNO_4S$ = 201.2.

CAS — 55589-62-3.



(acesulfame)

Pharmacopoeias. In *Eur.* (see p.vii). Also in *USNF.*

Ph. Eur. 6.2 (Acesulfame Potassium). A white or almost white, crystalline powder or colourless crystals. Soluble in water; very slightly soluble in alcohol and in acetone.

USNF 26 (Acesulfame Potassium). A white, crystalline powder or colourless crystals. Soluble in water; very slightly soluble in alcohol and in acetone. Protect from light.

Profile

Acesulfame potassium is an intense sweetener about 200 times as sweet as sucrose. It is used in beverages, cosmetics, pharmaceuticals, and foods and does not appear to be affected by cooking.

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Arg.:*** Equalsweet; Genser Sweet; Rondo Sweet; ***Chile:*** Marco Sweet Light; ***UK:*** Sweet 'n Low; ***Venez.:*** Hermesetas Gold; Sweet 'n' Low†.

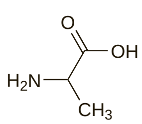
Alanine *(USAN, rINN)*

A; Ala; Alaniini; Alanin; Alanina; Alaninas; L-Alanine; Alaninum; NSC-206315. L-2-Aminopropionic acid.

Аланин

$C_3H_7NO_2$ = 89.09.

CAS — 56-41-7.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Alanine). A white or almost white crystalline powder or colourless crystals. Freely soluble in water; very slightly soluble in alcohol. Protect from light.

USP 31 (Alanine). White, odourless, crystals or crystalline powder. Freely soluble in water; slightly soluble in 80% alcohol; insoluble in ether. pH of a 5% solution in water is between 5.5 and 7.0. Store in airtight containers.

Profile

Alanine is an aliphatic non-essential amino acid. It is used as a dietary supplement. The dipeptide *N*(2)-L-alanyl-L-glutamine is used similarly.

Hypoglycaemia. References to the investigational use of alanine in the management of insulin-induced hypoglycaemia.[1-4]

Preparations

Proprietary Preparations (details are given in Part 3)

Fr.: Abufene; ***Singapore:*** Abufene.

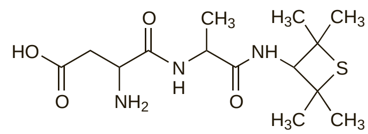
Multi-ingredient: ***Arg.:*** Normoprost Compuesto; ***Ital.:*** Chetonex; ***Spain:*** Tebetane Compuesto.

Alitame *(USAN)*

CP-54802. (3*S*)-Amino-*N*-{(1*R*)-1-[(2,2,4,4-tetramethyl-3-thietanyl) carbamoyl] ethyl} succinamic acid hydrate.

$C_{14}H_{25}N_3O_4S.2\frac{1}{2}H_2O$ = 376.5.

CAS — 80863-62-3 (anhydrous alitame); 99016-42-9 (alitame hydrate).



(anhydrous alitame)

Profile

Alitame is an intense sweetener used in foods. It is about 2000 times sweeter than sucrose.

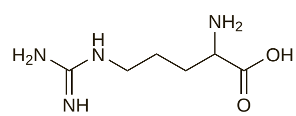
Arginine *(rINN)*

Arg; Argininii; Arginin; Arginina; Argininas; L-Arginine; Argininum; R. L-2-Amino-5-guanidinovaleric acid.

Аргинин

$C_6H_{14}N_4O_2$ = 174.2.

CAS — 74-79-3.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Arginine). A white or almost white crystalline powder, or colourless crystals. Freely soluble in water; very slightly soluble in alcohol. Protect from light.

USP 31 (Arginine). White, practically odourless crystals. Freely soluble in water; sparingly soluble in alcohol; insoluble in ether.

Arginine Aspartate

Arginiiniaspartaatti; Arginina, aspartato de; Argininaspartat; Arginin-aspartát; Arginine, aspartate d'; Arginini aspartas; Arginino aspartatas; Asparginінum. (2*S*)-2-Amino-5-guanidinopentanoic acid (2*S*)-2-aminobutanedioate.

$C_{10}H_{21}N_5O_6$ = 307.3.

CAS — 7675-83-4.

Pharmacopoeias. In *Eur.* (see p.vii).

Ph. Eur. 6.2 (Arginine Aspartate). White or almost white granules or powder. Very soluble in water, practically insoluble in alcohol and in dichloromethane.

Arginine Glutamate *(BAN, USAN, rINNM)*

Arginine, Glutamate d'; Arginini Glutamas; Glutamato de arginina. L-Arginine L-glutamate.

Аргинина Глутамат

$C_6H_{14}N_4O_2,C_5H_9NO_4$ = 321.3.

CAS — 4320-30-3.

ATC — A05BA01.

ATC Vet — QA05BA01.

Arginine Hydrochloride *(USAN, rINNM)*

Arginiinihydrokloridi; Arginine, chlorhydrate d'; L-Arginine Monohydrochloride; Arginin-hidroklorid; Arginin-hydrochlorid; Argininhydroklorid; Arginini hydrochloridum; Arginino hidrochloridas; Hidrocloruro de arginina.

Аргинина Гидрохлорид

$C_6H_{14}N_4O_2,HCl$ = 210.7.

CAS — 1119-34-2.

ATC — B05XB01.

ATC Vet — QB05XB01.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Arginine Hydrochloride). A white or almost white crystalline powder, or colourless crystals. Freely soluble in water; very slightly soluble in alcohol. Protect from light.

USP 31 (Arginine Hydrochloride). White, practically odourless, crystals or crystalline powder. Freely soluble in water.

Adverse Effects and Precautions

Nausea, vomiting, flushing, headache, numbness, and local venous irritation may occur if arginine solutions are infused too rapidly. Elevated plasma-potassium concentrations have been reported in uraemic patients and arginine should therefore be used with caution in patients with renal disease or anuria. Arginine hydrochloride should be given cautiously to patients with electrolyte disturbances as its high chloride content could lead to the development of hyperchloraemic acidosis.

Extravasation. Full-thickness skin necrosis has been reported[1,2] after extravasation of a 10% solution of arginine hydrochloride. Both osmotic and local hyperkalaemic effects have been proposed as a mechanism for the injury.[1]

1. Bowlby HA, Elanjian SI. Necrosis caused by extravasation of arginine hydrochloride. *Ann Pharmacother* 1992; **26:** 263–4.
2. Salameh Y, Shoufani A. Full-thickness skin necrosis after arginine extravasation—a case report and review of literature. *J Pediatr Surg* 2004; **39:** E9–E11.

Hyperkalaemia. Two alcoholic patients with severe liver disease and moderate renal insufficiency developed severe hyperkalaemia when given arginine hydrochloride and one died.[1] Both patients had received a total of 300 mg of spironolactone some time before arginine hydrochloride, but the contribution of spironolactone to the hyperkalaemia was not known. In a study to investigate the mechanism of metabolic changes due to arginine, plasma-potassium concentrations were found to be significantly higher in diabetic subjects than those for normal subjects, leading the authors to suppose that while arginine-induced hyperkalaemia may be promoted by low insulin blood levels, it could not be attributed to glucagon, pH changes, or aldosterone inhibition.[2]

In another fatal case due to an overdose of arginine,[3] a 21-month-old girl developed an acute metabolic acidosis with transient but severe hyponatraemia, and irreversible brain death; no hyperkalaemia was observed. Unlike the previously reported case, the patient had normal renal function, and the authors supposed the absence of hyperkalaemia to be due to a rapid increase in renal potassium excretion.

3. Gerard JM, Luisiri A. A fatal overdose of arginine hydrochloride. *J Toxicol Clin Toxicol* 1997; **35:** 621–5.

Hypersensitivity. There are 2 reports of anaphylactic reactions shortly after the start of infusions of arginine 5 or 10% given to test growth-hormone output.[1,2] Anaphylaxis to arginine was considered to be a very rare event and only one other apparent allergic reaction had been reported to the manufacturers.

2. Resnick DJ, *et al.* Case report of an anaphylactoid reaction to arginine. *Ann Allergy Asthma Immunol* 2002; **88:** 67–8.

Myocardial infarction. A placebo-controlled trial investigated whether the addition of arginine to standard therapy after myocardial infarction would decrease vascular stiffness and improve left ventricular function. The study was stopped early due to an increased number of deaths in the arginine group. The authors commented that, while the results could be due to chance, nevertheless arginine should not be given to patients after a myocardial infarction.[1]

Uses and Administration

Arginine is a basic amino acid that is essential for infant growth. It is used as a dietary supplement.

Arginine stimulates the release of growth hormone by the pituitary gland and may be used instead of, or in addition to, other tests such as insulin-induced hypoglycaemia, for the evaluation of growth disorders; false-positive and false-negative results are relatively common and evaluation therefore should not be made on the basis of a single arginine test. It is used as a 10% solution of the hydrochloride in usual doses of 30 g by intravenous infusion given over 30 minutes; children should be given 500 mg/kg.

Arginine is used in certain conditions accompanied by hyperammonaemia; for further details see below.

Arginine hydrochloride has also been used as an acidifying agent. In severe metabolic alkalosis intravenous doses have been calculated by the formula:

$$\text{intravenous dose (in grams)} = \text{desired decrease in plasma-bicarbonate concentration (mEq or mmol/litre)} \times \text{[patient's body-weight (in kg)/9.6]}$$

In forced acid diuresis to hasten drug elimination after overdose a suggested dose has been 10 g intravenously over 30 minutes. However, this has the potential to cause myoglobinuria with acute renal failure, and is rarely used.

Arginine may also be used in the form of the acetylasparaginate, aspartate, citrate, glutamate, oxoglurate, tidiacicate (thiazolidine-2,4-dicarboxylate), and timonacicate (thiazolidine-4-carboxylate). Formulation as an arginine salt is used to improve the solubility of a number of drugs, notably analgesics and antibacterials.

Hyperammonaemia. Hyperammonaemia is a characteristic feature of inborn errors of the urea cycle, caused by defects in the enzymes carbamyl phosphate synthetase (CPS), ornithine transcarbamylase (OTC), argininosuccinate synthetase (ASS), argininosuccinate lyase (ASL), arginase (causing hyperargininaemia), or *N*-acetylglutamate synthase (NAGS).[1,2] During the urea cycle, waste ammonia, in the form of the ammonium ion, is normally condensed with bicarbonate and ATP to form carbamoyl phosphate which undergoes several more reactions, including one leading to the synthesis of arginine, and ultimate transformation to urea for excretion. Thus, in defects of this cycle ammonia accumulates and arginine synthesis is deficient.[3] Hyperammonaemia is most severe when the enzyme defect occurs in the early steps of the urea cycle, such as in CPS or OTC deficiency, and is less severe at later stages, as in ASL or arginase deficiency.[2] Hyperammonaemia is often associated with respiratory alkalosis in patients with urea cycle disorders.[3]

The basis of treatment is dietary protein restriction, to decrease the requirement for waste nitrogen synthesis,[4] and the use of drugs to stimulate alternative pathways of waste nitrogen excretion.[5,6] These include arginine, citrulline, sodium benzoate, sodium phenylacetate, and sodium phenylbutyrate. In the initial management of severe hyperammonaemia, haemodialysis is preferred over peritoneal dialysis because it is more effective.[3,7]

Arginine supplements are given except in hyperargininaemia.[5,7] Citrulline may be used in some cases instead;[8] it may be useful for CPS and OTC deficiency (in doses of about 170 mg/kg daily or 3.8 g/m^2 daily),[5,6,9] but it is not recommended for patients with ASS or ASL deficiency, as levels of citrulline are already elevated.[5,10] Some recommend citrulline with arginine in acute hyperammonaemia to aid additional removal of nitrogen.[9] For the treatment of acute hyperammonaemia, some recommend a loading dose of arginine 600 mg/kg over 90 minutes pending definitive diagnosis.[3,10] Alternatively, a loading dose of 200 mg/kg or 4 g/m^2 has been advocated for CPS or OTC deficiency,[6,9,10] and 600 mg/kg or 12 g/m^2 for ASS or ASL deficiency.[6,9,10] The same dose as the loading dose is then given over 24 hours, as a constant maintenance infusion,[6,9,10] until conversion to oral medication is made.[10] For long-term management of ASS or ASL deficiency, doses of arginine ranging from 400 to 700 mg/kg daily have been recommended.[5,6,9,10]

Patients also receive treatment with sodium benzoate and sodium phenylacetate[6,10] or sodium phenylbutyrate.[5,6] ASL deficiency can be managed with protein restriction and arginine alone,[6,11] although some still advocate the use of sodium phenylbutyrate.[5,8] When sodium benzoate is conjugated with glycine and excreted as hippuric acid it provides an alternative pathway of nitrogen excretion, while sodium phenylacetate and sodium phenylbutyrate provide a second and even more effective pathway by conjugation with glutamine.[6,7,10] Some consider intravenous sodium benzoate and sodium phenylacetate the treatment of choice in acute hyperammonaemia; sodium phenylbutyrate is recommended for chronic management.[9] In a 25-year, open-label, uncontrolled study, intravenous therapy with sodium phenylacetate and sodium benzoate clearly improved survival in patients with acute hyperammonaemia, with an overall survival rate of 84%; survival was also related to peak plasma ammonium concentration and age. Haemodialysis was also used to control hyperammonaemia, especially in neonates and older patients who were less responsive to intravenous therapy.[12]

It has been suggested that carnitine supplementation (at 100 mg/kg daily[9] either orally or intravenously) should be added to minimise neurological symptoms and toxicity, but its value is uncertain.[4,13] Low carnitine levels have been reported to be uncommon in patients with urea cycle disorders and, in patients treated with sodium benzoate, benzoyl carnitine may form, negating any potential benefit from carnitine supplementation.[8]

Liver transplantation (p.1815) may achieve long-term correction of urea cycle disorders, even in the very young patient, and gene replacement therapy is under investigation.[14]

Hyperammonaemia and hepatic encephalopathy (p.1697) can also arise from other causes[7,13] for which arginine may not be advocated. Carglumic acid (p.2277) is the treatment of choice for patients with hyperammonaemia arising from NAGS deficiency.

Hypotensive action. Arginine is the physiological precursor of nitric oxide and this has been suggested as an explanation for the hypotensive effect that has been reported in healthy subjects[1-3] and hypertensive patients[1,4] given infusions of arginine, although effects unrelated to nitric oxide generation cannot be excluded.[4]

Oral arginine has also been reported to significantly decrease mean systolic blood pressure in hypertensive patients,[5] in patients on haemodialysis, and in renal transplant recipients.[6] In patients with essential hypertension, a single dose of arginine by mouth had no effect on blood pressure, although it did improve endothelium-dependent flow-mediated dilatation of the brachial artery compared with placebo.[7] In patients with pulmonary hypertension, short-term use of arginine has reduced pulmonary arterial pressure.[8-10]

In pregnant women with pre-eclampsia (see Hypertension, p.1171), plasma-arginine concentrations were found to be markedly reduced compared with control subjects.[11] Arginine infusions of 20 g, given to women with mild to moderate gestational hypertension,[12] and 30 g given to pre-eclamptic women,[13] significantly reduced systolic and diastolic blood pressure, with no adverse effect on fetal heart rate in the one study.[12] In a study of pre-eclamptic women given arginine 12 g daily for 2 days by mouth, no significant differences in diastolic blood pressure were seen compared with those receiving placebo.[14] However, in another study of pre-eclamptic women given 3 g arginine daily for 3 weeks, systolic, diastolic and mean arterial pressure were significantly reduced compared with those taking placebo.[15]

Because of apparent improvement in endothelial function with arginine, some interest has surrounded its potential role in other cardiovascular diseases, such as coronary artery disease and heart failure.[16] Decrease in plasma-cholesterol concentrations has also been reported in 2 hypercholesterolaemic patients given arginine infusions.[17] However, long-term supplementation was found not to be helpful (and possibly harmful) in patients with peripheral arterial disease,[18] and arginine therapy has been implicated in increased mortality when given to patients after myocardial infarction (see under Adverse Effects and Precautions, above).

Necrotising enterocolitis. A systematic review[1] considered that although there was evidence suggesting that supplementation of the feed of premature neonates with arginine could prevent the development of necrotising enterocolitis (p.173), it was insufficient to recommend the practice without further study.

Arrowroot

Amylum Marantae; Araruta; Arruruz; Maranta; Pfeilwurzelmehl; Sagú del monte; Yuquilla silvestre.

Profile

Arrowroot consists of the starch granules of the rhizomes of *Maranta arundinacea* (Marantaceae). It has the general properties of starch (p.1968). It has been used as a suspending agent in the preparation of barium meals and has sometimes been used in place of starch in tablet manufacture.

Diarrhoea. In a pilot study in 11 patients with irritable bowel syndrome given 10 mL arrowroot powder three times daily for 1 month, 4 patients reported an improvement in diarrhoea.[1]

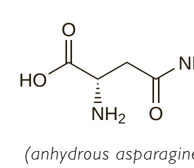
Asparagine Monohydrate

L-α-Aminosuccinamic Acid Monohydrate; Asparagiinimonohydraatti; Asparagin monohydrát; Asparagina, monohidrato de; Asparaginas monohidratas; L-Asparagine Monohydrate; Asparagine monohydratée; Asparaginmonohydrat; Asparaginum monohydricum; Asparamide; Aspartamic acid; Aspartic acid beta-amide; N (asparagine); NSC-82391. (2*S*)-2,4-Diamino-4-oxobutanoic acid monohydrate.

$C_4H_8N_2O_3,H_2O = 150.1.$

CAS — 70-47-3 (anhydrous asparagine); 5794-13-8 (asparagine monohydrate).



(anhydrous asparagine)

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii). Also in *USNF*, which specifies the anhydrous form or the monohydrate.

Ph. Eur. 6.2 (Asparagine Monohydrate). A white or almost white, crystalline powder or colourless crystals. Slightly soluble in water; practically insoluble in alcohol and in dichloromethane. A 2% solution in water has a pH of 4.0 to 6.0.
USNF 26 (Asparagine). It is anhydrous or contains one molecule of water of hydration. A white, crystalline powder or white crystals. Soluble in water; practically insoluble in alcohol and in ether. Its solutions are acid to litmus. Protect from light.

Profile

Asparagine is a non-essential amino acid.

Preparations

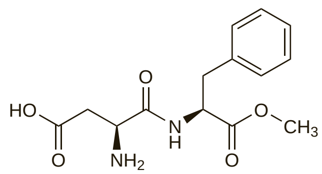
Proprietary Preparations (details are given in Part 3)
Multi-ingredient: ***Ital.:*** Acutil Fosforo; Neuralfa; Tiofort; ***Spain:*** Agudil.

Aspartame *(BAN, USAN, rINN)*

APM; Aspartaami; Aspartam; Aspartamas; Aspartamo; Aspartamum; Aszpartám; E951; SC-18862. Methyl *N*-L-α-aspartyl-L-phenylalaninate; 3-Amino-*N*-(α-methoxycarbonylphenethyl)succinamic acid; *N*-L-α-aspartyl-L-phenylalanine, 1-methyl ester.

Аспартам

$C_{14}H_{18}N_2O_5$ = 294.3.
CAS — 22839-47-0.



Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii). Also in *USNF.*
Ph. Eur. 6.2 (Aspartame). A white or almost white, slightly hygroscopic, crystalline powder. Sparingly or slightly soluble in water and in alcohol; practically insoluble in dichloromethane and in *n*-hexane. Store in airtight containers.
USNF 26 (Aspartame). White, odourless, crystalline powder having a sweet taste. Sparingly soluble in water; slightly soluble in alcohol. pH of a 0.8% solution in water is about 5.

Stability. In the presence of moisture aspartame hydrolyses to form aspartylphenylalanine and a diketopiperazine derivative, with a resulting loss of sweetness.

Adverse Effects and Precautions

Excessive use of aspartame should be avoided by patients with phenylketonuria since one of its metabolic products is phenylalanine. Aspartame's sweetness is lost during prolonged cooking.

Adverse effects. The safety and adverse effects of aspartame as a pharmaceutical excipient have been reviewed.[1,2]

Aspartame is hydrolysed in the gastrointestinal tract to methyl alcohol, aspartic acid, and phenylalanine. However, even with extraordinary consumption, methyl alcohol toxicity stemming from aspartame use is extremely unlikely. Aspartate concentrations in blood do not rise significantly after a very large dose (50 to 100 mg/kg) and therefore toxicity related to aspartate is also not expected to occur. Despite the similarity of aspartate to glutamate, studies in glutamate-sensitive persons have shown that they are not affected by aspartame consumption. Plasma concentrations of phenylalanine are also unlikely to be markedly elevated after modest consumption of aspartame by healthy persons but persons with phenylketonuria should avoid or limit their use of aspartame.

A number of adverse effects have been reported[1,2] after the use of aspartame, either as spontaneously recorded complaints from consumers or as published case reports in the medical literature. Most frequently reported problems have been headache, neuropsychiatric or behavioural symptoms, seizures, gastrointestinal symptoms, and hypersensitivity or dermatological symptoms. Available data do not provide evidence for serious widespread health consequences attendant upon the use of aspartame but it would appear that certain individuals may have an unusual sensitivity to the product. A safety review[3] by the European Commission Scientific Committee on Food (ECSCF) concluded that no causal link could be established between the consumption of aspartame and the occurrence of epilepsy or seizures, or cognition, mood and behaviour; this included individuals considered sensitive to aspartame.

Studies have confirmed aspartame's lack of effect on children's behaviour or cognitive function.[4,5]

An increased incidence of brain cancer was postulated to be related to aspartame use in one report;[6] however, the FDA[7] and the ECSCF[3] maintained that the available evidence did not support an association. Multiple malignancies have been reported[8] in *rats* given doses lower than the current acceptable daily intake of 40 or 50 mg/kg. The European Food Safety Authority assessed this study and concluded,[9] on the basis of all current available evidence, that the increased incidence of cancers in the *rats* was unrelated to aspartame treatment, and that there was no need to further review the safety of aspartame, nor to revise the established acceptable daily intake for aspartame of 40 mg/kg.

Breast feeding. Aspartame 50 mg/kg given orally to healthy women resulted in small but significant increases in breast milk aspartate, phenylalanine, and tyrosine concentrations.[1] However, it was noted that these levels were similar to postprandial milk samples and were unlikely to impact upon total amounts of amino acids ingested by the infant. Furthermore, the dose of aspartame given in the study was considerably higher than the projected intake of about 7.5 to 8.5 mg/kg daily, assuming all sucrose intake were replaced by aspartame, and no aspartame abuse. Nonetheless, the American Academy of Pediatrics[2] considers that caution is required when aspartame is ingested by mothers where either the mother or breast-fed infant has phenylketonuria.

Pharmacokinetics

Aspartame is hydrolysed in the gastrointestinal tract to its 3 primary constituents, methyl alcohol, aspartic acid, and phenylalanine.

Uses

Aspartame is an intense sweetening agent about 180 to 200 times as sweet as sucrose. It is used in foods, beverages, and pharmaceuticals. Each g provides about 17 kJ (4 kcal).

Sickle-cell disease. There is some preliminary evidence that aspartame may have beneficial effects in sickle-cell disease.[1]

Aspartame Acesulfame

L-Phenylalanine, L-α-aspartyl-2-methyl ester, compound with 6-methyl-1,2,3-oxathiazin-4(3*H*)-one 2,2-dioxide (1:1).

$C_{18}H_{23}O_9N_3S$ = 457.5.
CAS — 106372-55-8.

Pharmacopoeias. In *USNF.*
USNF 26 (Aspartame Acesulfame). White, odourless, crystalline powder. Slightly soluble in water and in alcohol. It contains not less than 63.0% and not more than 66.0% of aspartame, calculated on the dried basis, and not less than 34.0% and not more than 37.0% of acesulfame, calculated as the acid form on the dried basis.

Profile

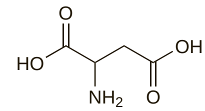
Aspartame acesulfame is a compound of aspartame (see above) and acesulfame (see p.1928), and is used similarly in foods. It is an intense sweetener about 350 times as sweet as sucrose.

Aspartic Acid *(USAN, rINN)*

Acide aspartique; Ácido aspártico; Acidum asparticum; Asp; Asparagiinihappo; Asparaginsyra; L-Aspartic Acid; Asparto rūgštis; Aszparaginsav; D; Kwas asparaginowy; Kyselina asparagová. L-Aminosuccinic acid.

Аспарагиновая Кислота

$C_4H_7NO_4$ = 133.1.
CAS — 56-84-8.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Jpn*, and *US.*
Ph. Eur. 6.2 (Aspartic Acid). A white or almost white crystalline powder, or colourless crystals. Slightly soluble in water; practically insoluble in alcohol. It dissolves in dilute solutions of alkali hydroxides and in dilute mineral acids. Protect from light.
USP 31 (Aspartic Acid). A white or almost white crystalline powder, or colourless crystals. Slightly soluble in water; practically insoluble in alcohol and in ether; soluble in dilute solutions of alkali hydroxides and in dilute mineral acids. Protect from light.

Profile

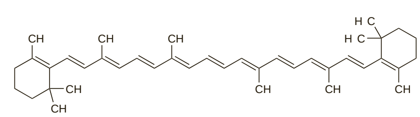
Aspartic acid is a non-essential amino acid. It is used as a dietary supplement.

Betacarotene *(BAN, rINN)*

all-*trans*-β-Carotene; Beetakaroteeni; Beta Carotene *(USAN)*; Bétacarotène; Betacaroteno; Betacarotenum; Betakaroten; Betakarotenas; Bétakarotin; E160(a); Provitamin A. β,β-Carotene; (*all-E*)-1,1′-(3,7,12,16-Tetramethyl-1,3,5,7,9,11,13,15,17-octadecanonaene-1,18-diyl)bis[2,6,6-trimethylcyclohexene].

Бетакаротен

$C_{40}H_{56}$ = 536.9.
CAS — 7235-40-7.
ATC — A11CA02; D02BB01.
ATC Vet — QA11CA02; QA11HA90; QD02BB01.



Description. Carotene exists in 3 isomeric forms, all of which are converted to some extent into vitamin A in the livers of man and *animals*. Of the 3 isomers of carotene, the *beta* compound is more active than the *alpha-* or *gamma-*isomers. The vitamin A activity of plants is due to the presence of *alpha-*, *beta-*, and *gamma-*carotenes and to kryptoxanthine; that of *animal* tissues is due to both vitamin A and carotene, while fish-liver oils contain vitamin A but no carotene.

Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Betacarotene). A brown-red or brownish-red crystalline powder. Practically insoluble in water and in dehydrated alcohol; slightly soluble in cyclohexane. It is sensitive to air, heat and light, especially in solution. Store in airtight containers at a temperature not exceeding 25°. Protect from light.
USP 31 (Beta Carotene). Red or reddish-brown to violet-brown crystals or crystalline powder. Insoluble in water, in acids, and in alkalis; practically insoluble in alcohol and in methyl alcohol; soluble in carbon disulfide, in chloroform, and in benzene; sparingly soluble in ether, in petroleum spirit, and in vegetable oils. Store in airtight containers. Protect from light.

Units

Vitamin A activity in foods is expressed in terms of retinol equivalents: 6 micrograms of betacarotene represents 1 retinol equivalent (or 10 of the former International units for provitamin A—see p.1971).

Adverse Effects and Precautions

Loose stools may occasionally occur during treatment with betacarotene and the skin may assume a slightly yellow discoloration. Bruising, dizziness, and arthralgia have been reported rarely.

Excessive intake of betacarotene does not result in hypervitaminosis A (see Pharmacokinetics, below).

Carcinogenicity. For reference to studies finding an increased incidence of lung cancers in individuals given betacarotene supplements to protect against malignancy, see under Prophylaxis of Malignant Neoplasms, p.1927.

Effects on mortality. A systematic review of the effect of antoxidant supplements on mortality in randomised primary and secondary prevention studies found that betacarotene, used either singly or with other antioxidants, significantly increased all-cause mortality.[1] In another review and meta-analysis, betacarotene supplementation showed a trend towards increased cancer mortality.[2]

1. Bjelakovic G, *et al.* Antioxidant supplements for prevention of mortality in healthy participants and patients with various diseases. Available in The Cochrane Database of Systematic Reviews; Issue 2. Chichester: John Wiley; 2008 (accessed 18/06/08).
2. Bardia A, *et al.* Efficacy of antioxidant supplementation in reducing primary cancer incidence and mortality: systematic review and meta-analysis. *Mayo Clin Proc* 2008; **83:** 23–34.

Effects on the skin. Yellow pigmentation of the skin may result from an unusually high consumption of carrots or other source of carotene,[1] or from a defect in the enzyme that normally metabolises betacarotene to vitamin A.[2] Hypercarotenaemia can be distinguished from jaundice by the fact that the sclerae retain their normal white colour. Pigmentation occurs first on the palms and soles and may extend to the nasolabial folds. Although it has been stated that the condition is harmless as the body converts carotene to retinol only as required,[1] others consider that longstanding hypercarotenaemia can have clinical sequelae:[2] neutropenia[3] and amenorrhoea[4] have been reported to be associated with the condition.

4. Kemmann E, *et al.* Amenorrhoea associated with carotenemia. *JAMA* 1983; **249:** 926–9.

Pharmacokinetics

Gastrointestinal absorption of betacarotene depends on the presence of bile and is increased by dietary fat. About 20 to 60% of betacarotene is metabolised to retinol in the intestinal wall, and a small amount is converted to vitamin A in the liver. The proportion of betacarotene converted to vitamin A decreases as the intake of betacarotene increases, and high doses of betacarotene do not lead to abnormally high serum concentrations of vitamin A. Unchanged betacarotene is distributed to various tissues including fat, the adrenal glands, and ovaries.

Human Requirements

Carotenes, of which betacarotene has the highest activity, are major dietary sources of vitamin A—see p.1972.

UK and US recommended dietary intake. There is currently no UK dietary reference value (see p.1925) for betacarotene, and in the USA recommended dietary allowances or dietary reference intakes (see p.1925) have not been set. However, the Expert Group on Vitamins and Minerals[1] has established a safe upper level (SUL) for betacarotene of 7 mg daily, or about 0.11 mg/kg daily for a 60-kg adult.

1. Expert Group on Vitamins and Minerals. Safe Upper Levels for vitamins and minerals (May 2003). Available at: http://www.food.gov.uk/multimedia/pdfs/vitmin2003.pdf (accessed 06/01/06)

Uses and Administration

Betacarotene is a carotenoid precursor of vitamin A (p.1971). In the *treatment* of vitamin A deficiency, vitamin A is preferred to betacarotene. However, betacarotene has been used for the *prevention* of vitamin A deficiency at a dose of 6 to 15 mg daily for adults and 3 to 6 mg daily for children.

Betacarotene may be given by mouth to reduce the severity of photosensitivity reactions in patients with erythropoietic protoporphyria (see also Porphyria, below). Doses are in the range of 30 to 300 mg daily for adults and 30 to 150 mg daily for children, depending upon severity; they may be taken as either single daily doses or divided doses but should preferably be taken with meals. The protection offered by betacarotene is not total and generally 2 to 6 weeks of treatment resulting in a yellow coloration of palms and soles is necessary before patients should attempt to increase their exposure to sunlight.

Betacarotene and other carotenoids (alphacarotene and gammacarotene) are used as colouring agents for foods and medicinal products.

Betacarotene has antoxidant activity and has been studied for its possible protective benefit in a number of disorders (but see Effects on Mortality, above).

Age-related macular degeneration. A study in patients with age-related macular degeneration (p.785) indicated that the risk of developing this disorder (a leading cause of irreversible blindness among elderly persons) was markedly decreased amongst those with the highest dietary carotenoid intake;[1] in particular, lutein and zeaxanthin, or green leafy vegetables (which contain high concentrations of these carotenoids) were associated with a lower risk. Increasing the dietary intake of these carotenoids may be of benefit in reducing the development of this disorder. Despite this, systematic reviews found no evidence that antoxidant vitamin and mineral supplementation would either prevent[2,3] or delay the onset of macular degeneration. However, one study[4] has shown modest benefit from vitamin C, vitamin E, betacarotene, and zinc supplementation in those with moderate to severe signs of the disease. A systematic review to assess the effects of antoxidant vitamin or mineral supplementation on the progression of age-related macular degeneration included this study, and noted that the generalisability of these findings to other populations (with differing nutritional status) was unknown. Long-term harm from supplementation could not be ruled out.[5]

Deficiency states. A study in Senegalese children with vitamin A deficiency found that supplementation with betacarotene (in a single dose equivalent to 200 000 units of vitamin A) was as effective as a single 200 000 unit dose of vitamin A palmitate in reversing ocular changes.[1] Since betacarotene is less toxic than vitamin A itself it would have some advantages for supplementation, either as an oral supplement or by encouraging the consumption of carotenoid-rich fruit and vegetables. A study in anaemic Indonesian women found that a supplement containing betacarotene with iron, vitamin C, and folate improved vitamin A status, whereas an additional daily portion of dark-green leafy vegetables containing a similar amount of betacarotene did not.[2] However, others contended that consumption of food sources of carotenoids were effective in improving vitamin A status in deficiency states,[3,4] and that it might not be appropriate to extrapolate these findings in adults (not necessarily deficient in vitamin A) to vitamin A deficient children.[3,5] WHO policy was to promote dietary adjustment wherever vitamin A deficiency was endemic.[5] Despite further studies confirming improved vitamin A status among those given foods high in betacarotene,[6,7] a review[8] considered the bioavailability of betacarotene from plant foods to be low, and questioned the retinol equivalency determined by WHO (see Units, above). Another study[9] found that increasing dietary fat consumption and eliminating helminthic infection further increased serum retinol concentrations in children given food high in betacarotene.

For a trial reporting improved vitamin A status with betacarotene plus zinc compared with betacarotene or zinc alone, and the suggestion that zinc may have a role in the conversion of betacarotene to retinol, see Vitamin A Deficiency, under Zinc, p.2001.

For further discussion of vitamin A deficiency and the value of supplementation in various disease states, see under Vitamin A Substances, p.1973.

Ischaemic heart disease. There are results from epidemiological studies suggesting the potential benefits of dietary betacarotene in preventing ischaemic heart disease, particularly in smokers; however, randomised placebo-controlled studies of betacarotene supplements have returned negative results, as discussed on p.1926.

Malignant neoplasms. Some evidence from epidemiological studies suggested that higher dietary intakes of carotenoids and especially betacarotene had a protective effect against cancer. Consequently several randomised placebo-controlled trials examining the use of betacarotene supplements in the primary or secondary prevention of malignancy were instigated. However, the results of studies so far published have generally been disappointing. Moreover, some results suggest that supplementation with betacarotene may actually be harmful (see Prophylaxis of Malignant Neoplasms, p.1927 and Effects on Mortality, above).

Porphyria. Despite a lack of robust evidence, betacarotene is the most widely used systemic drug for the management of erythropoietic protoporphyria,[1,2] a non-acute porphyria characterised by cutaneous photosensitivity (p.1448). It has been given with canthaxanthin to reduce the skin discoloration caused by betacarotene alone.

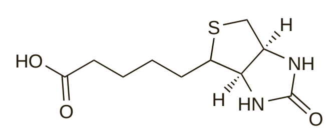
Biotin *(rINN)*

Biotiini; Biotina; Biotinas; Biotine; Biotinum; Coenzyme R; Vitamin H. *cis*-5-(Hexahydro-2-oxo-1*H*-thieno[3,4-*d*]imidazol-4-yl)valeric acid.

Биотин

$C_{10}H_{16}N_2O_3S$ = 244.3.
CAS — 58-85-5.
ATC — A11HA05.
ATC Vet — QA11HA05.



Pharmacopoeias. In *Eur.* (see p.vii) and *US.*
Ph. Eur. 6.2 (Biotin). A white or almost white, crystalline powder or colourless crystals. Very slightly soluble in water and in alcohol; practically insoluble in acetone. It dissolves in dilute solutions of alkali hydroxides. Protect from light.
USP 31 (Biotin). A practically white crystalline powder. Very slightly soluble in water and in alcohol; insoluble in other common organic solvents. Store in airtight containers.

Profile

Biotin is traditionally considered to be a vitamin B substance. It is an essential coenzyme in fat metabolism and in other carboxylation reactions. Biotin deficiency may result in the urinary excretion of organic acids and changes in skin and hair. Deficiency of biotin is very unlikely in man because of its widespread distribution in food. Egg-yolk and offal are especially good sources. Biotin deficiency has been reported however during long-term parenteral nutrition and in patients with biotinidase deficiency, an inherited metabolic disorder. For dosage in biotinidase or isolated carboxylase deficiency see below. A combination of biotin and chromium tripicolinate (p.1934) has been promoted as an adjunct for the management of diabetes mellitus.

Biotin combines with avidin, a glycoprotein present in raw egg-white, to form an inactive compound.

Adverse effects. For reference to life-threatening eosinophilic pleuropericarditis in a patient receiving biotin and pantothenic acid see p.1959.

Deficiency states. Biotin has been used to treat deficiency of biotinidase or holocarboxylase synthetase, enzymes responsible for the recycling and incorporation of biotin. In the UK, the *BNFC* suggests the following doses:

- for isolated carboxylase defects, biotin may be given to neonates in a dose of 5 mg once daily by mouth or slow intravenous injection, adjusted according to response; older patients may be given 10 mg daily. The usual maintenance dose ranges from 10 to 50 mg daily, though up to 100 mg daily may be needed
- for defects of biotin metabolism, 10 mg once daily may be given by mouth or slow intravenous injection, adjusted according to response. Usual maintenance doses are 5 to 20 mg daily but higher doses may be needed

Human requirements. In the UK neither a reference nutrient intake (RNI) nor an estimated average requirement (EAR—see p.1925) has been set for biotin although it was considered that an intake of between 10 and 200 micrograms daily was both safe and adequate.[1] Similarly in the USA an adequate intake of 30 micrograms daily has been set for adults.[2]

Calcium Ferrous Citrate

Ferrous Calcium Citrate. Dicalcium iron(2+) bis(2-hydroxypropane-1,2,3-tricarboxylate).

$C_{12}H_{10}Ca_2FeO_{14}$ = 514.2.
CAS — 53684-61-0.

Profile

Calcium ferrous citrate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

Preparations

Proprietary Preparations (details are given in Part 3)
Israel: Ferrocal.

Multi-ingredient: ***India:*** Raricap; Raricap L.

Calcium Fluoride

Fluoruro cálcico.

CaF_2 = 78.07.
CAS — 7789-75-5.

Pharmacopoeias. In *Ger.*

Profile

Calcium fluoride is used as a fluoride supplement (see Sodium Fluoride, p.1962) for the prevention of dental caries. Calcium fluoride is also used as a source of calcium.

Homoeopathy. Calcium fluoride has been used in homoeopathic medicines under the following names: Calcarea Fluorica; Calc. Fluor; Calcium Fluoratum; Cal. fl.

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Calcifluor†.

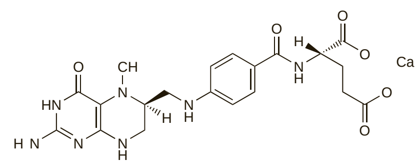
Multi-ingredient: ***Cz.:*** Bifluorid†; ***Denm.:*** Bifluorid; ***India:*** Calcinol; ***Ital.:*** Bifluorid†; ***Pol.:*** Bifluorid; ***Swed.:*** Bifluorid.

Calcium Mefolinate

Calcii Mefolinas; Calcio Mefolinato; Calcium L-Methylfolate; Calcium (6*S*)-5-Methyltetrahydrofolate.

Кальция L-Метилфолат

$C_{20}H_{23}CaN_7O_6$ = 497.5.
CAS — 26560-38-3.



NOTE. Metafolin is a trade name that has been used for calcium mefolinate.

Profile

Calcium mefolinate is the calcium salt of 5-methyltetrahydrofolate, the biologically active metabolite of folic acid (p.1940). It is used as a food supplement and also has similar uses to folic acid.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Biofolic; Furoic; Prefolic; ***USA:*** Deplin.

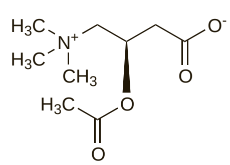
Multi-ingredient: ***USA:*** Cerefolin; Metanx.

Carnitine Derivatives

Acetylcarnitine Hydrochloride

Acetilcarnitina, hidrocloruro de; Acetyl-L-carnitine Chloride; Levacecarnine Hydrochloride; Levocarnitinum acetilum hydrochloricum; ST-200. (3-Carboxy-2-hydroxypropyl)trimethylammonium acetate (ester) chloride.

$C_9H_{17}NO_4,HCl$ = 239.7.
CAS — 5080-50-2.
ATC — N06BX12.
ATC Vet — QN06BX12.



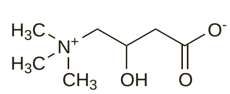
(acetyl-L-carnitine)

Carnitine *(rINN)*

Carnitina; Carnitinum; Karnitin; ST-198; Vitamin B_T. (3-Carboxy-2-hydroxypropyl)trimethylammonium hydroxide, inner salt; 3-Hydroxy-4-trimethylammoniobutyrate.

Карнитин

$C_7H_{15}NO_3$ = 161.2.
CAS — 461-06-3.

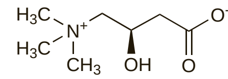


Levocarnitine *(BAN, USAN, rINN)*

L-Carnitine; L-Karnitin; Levocarnitina; Lévocarnitine; Levocarnitinum; Levokarnitiini; Levokarnitin; Levokarnitinas. (*R*)-(3-Carboxy-2-hydroxypropyl)trimethylammonium hydroxide, inner salt; (*R*)-3-Hydroxy-4-trimethylammoniobutyrate.

Левокарнитин

$C_7H_{15}NO_3$ = 161.2.
CAS — 541-15-1.
ATC — A16AA01.
ATC Vet — QA16AA01.



Pharmacopoeias. In *Eur.* (see p.vii) and *US*.

Ph. Eur. 6.2 (Levocarnitine). A white or almost white, hygroscopic, crystalline powder or colourless crystals. Freely soluble in water; soluble in warm alcohol; practically insoluble in acetone. A 5% solution in water has a pH of 6.5 to 8.5. Store in airtight containers.

USP 31 (Levocarnitine). White, hygroscopic, crystals or crystalline powder. Freely soluble in water and in hot alcohol; practically insoluble in acetone, in ether, and in benzene. pH of a 5% solution in water is between 5.5 and 9.5. Store in airtight containers.

Levocarnitine Hydrochloride *(BANM, rINNM)*

Hidrocloruro de levocarnitina; Lévocarnitine, Chlorhydrate de; Levocarnitini Hydrochloridum. (*R*)-3-Hydroxy-4-trimethylammoniobutyrate hydrochloride.

Левокарнитина Гидрохлорид

$C_7H_{15}NO_3,HCl$ = 197.7.
CAS — 6645-46-1.

Levocarnitine Propionate *(rINNM)*

L-Carnitine propionate; Lévocarnitine, Propionate de; Levocarnitini Propionas; Propionato de levocarnitina; Propionylcarnitine; L-Propionylcarnitine; Propionyl-L-carnitine; ST-261.

Левокарнитина Пропионат

$C_{10}H_{19}NO_4$ = 217.3.
CAS — 20064-19-1.

Levocarnitine Propionate Hydrochloride *(USAN)*

Propionyl-L-carnitine Hydrochloride; STI-261. (2*R*)-3-Carboxy-*N,N,N*-trimethyl-2-(propanoyloxy)propan-1-aminium chloride.

$C_{10}H_{20}ClNO_4$ = 253.7.
CAS — 119793-66-7.

Adverse Effects and Precautions

Gastrointestinal disturbances such as nausea, vomiting, diarrhoea, and abdominal cramps have been reported after the use of levocarnitine. Body odour has also been noticed in some patients, possibly due to the formation of the metabolite trimethylamine (see Fish Odour Syndrome, p.1923). Decreasing the dosage may reduce or eliminate these effects; oral levocarnitine should be consumed slowly to decrease gastrointestinal disturbances. Seizures have been reported.

Patients with severe renal impairment should not be given high oral doses of levocarnitine for long periods, because of the accumulation of the metabolites trimethylamine and trimethylamine-*N*-oxide. This is said not to occur to the same extent after intravenous dosage. Diabetic patients given carnitine while receiving insulin or hypoglycaemic drugs should be monitored for hypoglycaemia.

Renal impairment. Of 30 patients given DL-carnitine intravenously after dialysis sessions 3 developed myasthenia-like symptoms but when these 3 were given only levocarnitine the symptoms did not occur.[1] It was considered that in anuric uraemic patients the D-isomer was not excreted adequately and that accumulation had blocked neuromuscular transmission. It was therefore suggested that levocarnitine, rather than the DL-form, should be used. (High and prolonged oral doses of levocarnitine should, however, be avoided—see above.)

1. Bazzato G, *et al.* Myasthenia-like syndrome after but not -carnitine. *Lancet* 1981; **i:** 1209.

Pharmacokinetics

Oral doses of levocarnitine are absorbed slowly and incompletely from the small intestine. Bioavailability has been reported to be only about 10 to 15%, with peak plasma concentrations attained about 3 to 4 hours after an oral dose. Plasma concentrations after oral doses represent the sum of endogenous and exogenous material. Levocarnitine does not appear to bind to plasma proteins. It is mainly eliminated by the kidneys, undergoing extensive tubular reabsorption. After intravenous doses, levocarnitine appears to undergo minimal metabolism. Levocarnitine given orally may undergo degradation in the gastrointestinal tract, leading to the formation of metabolites such as trimethylamine-*N*-oxide and γ-butyrobetaine, recovered in the urine and faeces, respectively.

Uses and Administration

Carnitine is an amino acid derivative that is an essential cofactor of fatty acid metabolism.

Carnitine is used in the treatment of primary carnitine deficiency and in carnitine deficiency secondary to a variety of defects of intermediary metabolism or other conditions such as haemodialysis. Both the L- and the DL-isomers have been used, but it is believed that only levocarnitine is effective and in addition, that DL-carnitine supplementation can lead to carnitine deficiency.

In the UK, depending on the condition, up to 200 mg/kg daily of levocarnitine is given orally, in 2 to 4 divided doses. Rarely, higher doses of up to 400 mg/kg daily may be needed. In the USA, lower doses of about 2 to 3 g daily are recommended for adults; the dose given for infants and children is 50 to 100 mg/kg daily in divided doses, to a maximum of 3 g daily.

When given intravenously, up to 100 mg/kg daily is given in 3 to 4 divided doses by slow intravenous injection over 2 to 3 minutes. Higher intravenous doses have been given, but are associated with an increased incidence of adverse effects.

In patients with carnitine deficiency secondary to haemodialysis, the recommended dose of levocarnitine is 10 to 20 mg/kg intravenously after each dialysis session, adjusted according to plasma-carnitine concentrations. An oral maintenance dose of 1 g daily may be considered (but see Adverse Effects and Precautions, above).

Levocarnitine is under investigation for the treatment of zidovudine-induced mitochondrial myopathy. Carnitine derivatives have been used to treat conditions including cardiovascular disease, peripheral arterial disease, cerebrovascular insufficiency, peripheral neuropathies, and neurological disorders, see below.

Carnitine chloride, carnitine hydrochloride, carnitine orotate, and bicarnitine chloride have also been used.

Carnitine supplementation. Carnitine occurs as distinct L- and D-isomers although naturally-occurring carnitine is almost exclusively the L-isomer.[1] Carnitine is an essential co-factor of fatty acid metabolism in the heart, liver, and skeletal muscle.[1,2] It is normally synthesised in the liver, brain, and kidneys in sufficient quantities to meet human requirements but dietary sources such as meat and dairy products also provide carnitine.[1-4] In plasma and tissues carnitine is present in the free form and as acylated esters of which acetylcarnitine is the most abundant.

Although DL-carnitine is the form often present in over-the-counter preparations and dietary supplements, levocarnitine should be preferred, as the two isomers differ in their actions. Levocarnitine acts as a substrate for carnitine acetyltransferase while D-carnitine acts as a competitive inhibitor; also, levocarnitine-induced stimulation of palmitate oxidation is competitively inhibited by D-palmitoylcarnitine. Such differences are believed to account for findings of benefit only with the L-isomer, or unwanted effects when D-carnitine or DL-carnitine was used.[1,5]

Primary **carnitine deficiency** is a disorder of the membrane transport of carnitine and patients have presented with hypoglycaemia and encephalopathy, skeletal myopathy, and cardiomyopathy. Therapy with carnitine in these primary deficiency states is considered to have a rational basis.[2,4-6] Secondary carnitine deficiency occurs in many inherited metabolic disorders, especially in the organic acidurias and disorders of beta-oxidation. The value of carnitine for these conditions is controversial.[2,4,6-8]

Carnitine deficiency may also arise during the long-term use of **drugs** such as valproic acid,[5,9-11] pivampicillin,[12,13] or pivmecillinam,[12] which are conjugated with carnitine. Whether carnitine supplementation can prevent or reverse this type of deficiency is unclear: although treatment with carnitine raised plasma-carnitine concentrations, it had no more effect than placebo on the well-being of children receiving valproic acid therapy in one study,[14] but others have found levocarnitine supplementation of value in attenuating valproate-induced hyperammonaemia after a protein-rich meal,[15] and some paediatric neurologists consider supplementation justified in selected children with epilepsy,[16,17] including those with, or at risk of, valproate-induced hepatotoxicity and hyperammonaemic encephalopathy. There is some suggestion that carbamazepine and phenobarbital can also decrease carnitine concentrations.[10,11] Therapy with cisplatin[18] or ifosfamide[19] has been reported to cause increased urinary excretion of carnitine.

There is also some evidence[5,20] that carnitine supplements may be of benefit to low birth-weight preterm **infants**, but a double-blind study[21] failed to confirm this effect. A systematic review concluded that there are insufficient data to support the use of carnitine supplementation for the treatment of apnoea of prematurity, despite a plausible rationale for such treatment.[22] While some evidence of benefit exists for carnitine supplementation of neonates receiving parenteral nutrition,[5] a systematic review found no evidence of effect on weight gain, fat utilisation, or ketogenesis.[23]

Low concentrations of carnitine have also been reported to occur in a variety of other conditions (see below).

Cardiovascular disease. There is some evidence that carnitine supplementation may exert a cardioprotective role. Benefit in patients with *cardiomyopathies*,[1-3] reduction of infarct size in patients with *myocardial infarction*,[4] and increased exercise performance in patients with *angina*[5] or *intermittent claudication*,[6-8] have all been described in patients given carnitine. While variable effects on cholesterol and triglyceride plasma concentrations have been described,[5] studies in diabetic[9] and hyperlipoproteinaemic[10] patients have reported reductions in plasma lipoprotein(a) concentrations. However, carnitine supplementation in patients with chronic *heart failure* failed to increase exercise capacity,[11] and its value outside of actual deficiency is still considered uncertain.[5]

Exercise performance. Improved exercise performance in patients with angina or peripheral vascular disease has been described in patients given carnitine supplementation (see above). However, evidence of benefit from the use of carnitine in healthy subjects in an attempt to improve athletic performance is lacking.[1,2]

Fatigue. Placebo-controlled studies in elderly subjects found that levocarnitine supplementation significantly reduced physical and mental fatigue,[1,2] while an open study in patients with chronic fatigue syndrome reported improvement in mental fatigue with acetylcarnitine, and general fatigue improvement with propionylcarnitine.[3] In a crossover study with amantadine, patients with chronic fatigue syndrome given levocarnitine for 8 weeks showed improvement in 12 out of 18 parameters measuring fatigue; patients who were most ill at the start of the study improved the most.[4] There is also some suggestion that levocarnitine supplementation may be of benefit in alleviating fatigue induced by antineoplastic chemotherapy,[5] or interferon.[6] For reports of carnitine use for fatigue in multiple sclerosis patients, see Neurological Disorders, below.

Haemodialysis. Carnitine homoeostasis is altered in renal failure[1] and a functional deficiency may develop in patients on dialysis.[2] This dialysis-related carnitine disorder manifests notably as anaemia, intradialytic hypotension, cardiomyopathy, and muscle weakness and fatigability. Treatment with intravenous levocarnitine 20 mg/kg after each dialysis session has been recommended. Clinical response should be evaluated at 3-monthly intervals, and treatment stopped if no improvement is seen within 9 to 12 months.[2] A systematic review suggested a beneficial effect of levocarnitine for the management of anaemia in haemodialysis patients.[3] Since carnitine supplementation has been associated with a reduction[4,5] in the incidence of haemodialysis-induced cramps (p.1671) it has been suggested that these cramps might be due in part to carnitine deficiency.

HIV infection. Carnitine deficiency has been reported in HIV-infected patients. Causes may include malabsorption or increased excretion due to a wasting syndrome commonly found in these patients, or toxicity from antiretroviral drugs causing metabolic changes or altered lipid metabolism in the patient.[1] Small, mostly uncontrolled studies have suggested benefit from supplementation with levocarnitine or acetylcarnitine in relieving complications of HIV infection and adverse effects of antiretroviral drugs,[2] notably toxic neuropathy.[3,4]

Male infertility. Increases in sperm motility have been reported in some infertile men treated with carnitine,[1-3] although clinical benefit needs to be further evaluated.[4]

Neurological disorders. A meta-analysis of 21 studies concluded that acetylcarnitine improved mild cognitive impairment and prevented deterioration in patients with mild *Alzheimer's disease*.[1] However, a systematic review of 11 of these trials concluded that, although some evidence of benefit on clinical global impression exists, use of acetylcarnitine could not be routinely recommended in the treatment of Alzheimer's disease.[2]

Although no differences were found in serum carnitine concentrations in *multiple sclerosis* patients with or without disabling fatigue,[3] there is some suggestion of benefit with acetylcarnitine treatment for those patients with fatigue.[4] Carnitine has been reported to be of benefit in other cases of fatigue (see above).

In *Rett syndrome*, a severe neurodevelopmental disorder, supplementation with levocarnitine led to improvements in sleep efficiency, energy levels, and communication skills.[5] Parental and medical assessment of patient well-being improved in another study;[6] girls with classical Rett syndrome also improved in motor behaviour as assessed medically.

Casein

Kazeina.
CAS — 9000-71-9.

Profile

Casein is a protein found in milk and has been used as a source of protein in preparations for enteral and parenteral nutrition; it may be used in the production of protein hydrolysate injection. Calcium caseinate has also been used.

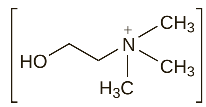
Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Secalbum; ***Canad.:*** Casec†; ***Israel:*** Casec; ***Mex.:*** Calsein; Caseincal†; K-Sein; ***USA:*** Casec.

Multi-ingredient: ***Mex.:*** Calciyodina; ***Switz.:*** Cicafissan; Fissan†; Vitafissan N.

Choline Bitartrate

Bitartarato de Colina; Choline Acid Tartrate; Choline Hydrogen Tartrate; Cholinii Tartras; Colina, bitartrato de. 2-Hydroxyethyltrimethylammonium hydrogen tartrate.
$C_9H_{19}NO_7$ = 253.2.
CAS — 87-67-2.



(choline)

Pharmacopoeias. In *US.*

USP 31 (Choline Bitartrate). A white, hygroscopic, crystalline powder; odourless or with a faint trimethylamine odour. Clear and colourless in solution. Freely soluble in water; slightly soluble in alcohol; insoluble in chloroform and in ether. pH of a 10% solution in water is between 3.0 and 4.0.

Choline Chloride *(rINN)*

Choline, Chlorure de; Cholini Chloridum; Cholinii Chloridum; Choliny chlorek; Cloruro de colina; Koliinikloridi; Kolinklorid. 2-Hydroxyethyltrimethylammonium chloride.
Холина Хлорид
$C_5H_{14}ClNO$ = 139.6.
CAS — 62-49-7 (choline); 67-48-1 (choline chloride).

Pharmacopoeias. In *Fr.* and *US.*

USP 31 (Choline Chloride). Hygroscopic, colourless or white crystals or crystalline powder, usually having a slight odour of trimethylamine. Clear and colourless in solution. Soluble in water and in alcohol. pH of a 10% solution in water is between 4.0 and 7.0.

Profile

Choline is an acetylcholine precursor. It is involved in lipid metabolism and acts as a methyl donor in various other metabolic processes. Choline has traditionally been considered to be a vitamin B substance although its functions do not justify its classification as a vitamin. Choline can be synthesised in the body. However, its absence in total parenteral nutrition causes hepatic steatosis, and it is also thought to be a requirement in the diet of neonates. Sources of choline, which occurs mostly as lecithin, include egg-yolk and vegetable and animal fat.

Choline is used as a dietary supplement and has been used to treat liver disorders such as fatty liver and cirrhosis. It has been tried in the management of Alzheimer's disease (see Dementia, p.362) but without success. Choline is used as the dihydrogen citrate, and orotate salts as well as the bitartrate and the chloride.

Human requirements. In the USA, an adequate intake (see p.1925) of 550 mg daily in men and 425 mg daily in women has been determined for choline.[1] The tolerable upper intake level for adults is 3.5 g daily.[1]

Chondroitin Sulfate–Iron Complex

Chondroitin Sulphate–Iron Complex; Ferropolichondrum; Hierro y sulfato de condroitina, complejo de.
CAS — 54391-57-0.
ATC — B03AB07.
ATC Vet — QB03AB07.

Profile

Chondroitin sulfate-iron complex is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in doses of up to 900 mg daily, equivalent to up to 90 mg of iron daily.

Preparations

Proprietary Preparations (details are given in Part 3)
Ital.: Condrofer†; Isairon.

Chromium

Chrom; Chrome; Cromo.
Cr = 51.9961.

Chromium Trichloride

Chromic Chloride; Cromo, tricloruro de.
$CrCl_3,6H_2O$ = 266.4.
CAS — 10025-73-7 (anhydrous chromium trichloride); 10060-12-5 (chromium trichloride hexahydrate).

Pharmacopoeias. In *US.*

USP 31 (Chromic Chloride). Dark green, odourless, slightly deliquescent crystals. Soluble in water and in alcohol; slightly soluble in acetone; practically insoluble in ether. Store in airtight containers.

Chromium Tripicolinate

Chromium Picolinate; Cromo, tripicolinato de.
$C_{18}H_{12}N_3O_6Cr$ = 418.3.

Pharmacopoeias. In *US.*

USP 31 (Chromium Picolinate). Store in airtight containers.

Adverse Effects

Trivalent salts of chromium, such as chromium trichloride, are generally considered to produce few adverse effects. However, hexavalent forms of chromium are notably toxic (see under Chromium Trioxide, p.2281).

Effects on the kidneys. Two cases of renal failure were attributed to ingestion of excessive doses of chromium tripicolinate in women with no history of renal dysfunction.[1,2] Acute renal failure with features of acute tubular necrosis, and requiring haemodialysis, has been reported after ingestion of a chromium picolinate-containing supplement. The amount of chromium in the supplement could not be determined.[3] For mention of decreases in glomerular filtration rate in children receiving chromium-supplemented total parenteral nutrition, see Supplementation, below.

3. Wani S, *et al.* Acute tubular necrosis associated with chromium picolinate-containing dietary supplement. *Ann Pharmacother* 2006; **40:** 563–6.

Effects on the skin. There have been rare reports[1,2] of cutaneous reactions to oral chromium tripicolinate, including one of acute generalised exanthematous pustulosis.

1. Young PC, *et al.* Acute generalized exanthematous pustulosis induced by chromium picolinate. *J Am Acad Dermatol* 1999; **41:** 820–3.
2. Fowler JF. Systemic contact dermatitis caused by oral chromium picolinate. *Cutis* 2000; **65:** 116.

Uses and Administration

Chromium is an essential trace element that potentiates insulin action and thus influences carbohydrate, lipid, and protein metabolism. Dietary sources rich in chromium include brewers' yeast, meat, whole grains, and nuts. Chromium trichloride has been given as a chromium supplement in total parenteral nutrition. Chromium tripicolinate is used as a chromium supplement, and is being investigated for improving glycaemic control in patients with diabetes mellitus.

Diabetes mellitus. A review[1] of trivalent chromium in the management of diabetes mellitus (p.431) concluded that it may have an adjunctive role. A meta-analysis[2] found no effect of chromium on glucose or insulin concentrations in non-diabetic subjects; data for diabetic patients were inconclusive. A systematic review[3] found no significant effect with chromium supplementation on lipid or glucose metabolism in non-diabetic subjects, but it may have a modest beneficial effect on glycaemia and dyslipidaemia in those patients with diabetes. Meta-analysis was hampered by the overall poor quality and heterogeneity of available studies,[3] and further research was considered necessary.[1-3]

3. Balk EM, *et al.* Effect of chromium supplementation on glucose metabolism and lipids: a systematic review of randomized controlled trials. *Diabetes Care* 2007; **30:** 2154–63.

Human requirements. In the UK neither a reference nutrient intake (RNI) nor an estimated average requirement (EAR—see p.1925) has been set for chromium although a safe and adequate intake was believed to be above 25 micrograms daily for adults.[1] Similarly, in the USA a recommended dietary allowance has not been published but the adequate intake was estimated to be 35 micrograms daily for young men and 25 micrograms daily for young women.[2] WHO considers that the minimum population mean intake likely to meet normal needs for chromium might be about 33 micrograms daily, and that supplementation of this element should not exceed 250 micrograms daily until more is known.[3]

3. WHO. Chromium. In: *Trace elements in human nutrition and health*. Geneva: WHO, 1996: 155–60.

Supplementation. Although a daily chromium intake of 200 nanograms/kg has been suggested in children given total parenteral nutrition (TPN), a study in 15 children[1] given long-term parenteral nutrition found that supplementation at about this level was associated with serum-chromium concentrations 4 to 42 times higher than the mean value in 15 children not receiving TPN. Raised serum-chromium concentrations were associated with a decrease in glomerular filtration rate; one year after stopping chromium supplementation, which reduced intake to 50 nanograms/kg daily (as contaminants of water and TPN solutions), chromium concentrations, although lower, were still higher than controls and renal function had not altered. The authors subsequently ceased chromium supplementation in both children and adults, since chromium contamination of TPN solutions appeared adequate to prevent deficiency, although it was acknowledged that signs of chromium deficiency might take some years to appear. Chromium contamination in various preparations used in paediatric parenteral nutrition has been studied.[2]

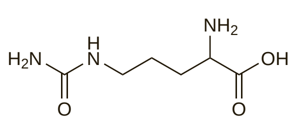
Citrulline

N^5-(Aminocarbonyl)-L-ornithine; N^δ-Carbamylornithine; Citrulina; L-citrulline; NSC-27425. α-Amino-δ-ureidovaleric acid.

$C_6H_{13}N_3O_3$ = 175.2.
CAS — 372-75-8.



Profile

Citrulline is a non-essential amino acid that is involved in the urea cycle. Citrulline and citrulline malate are used as dietary supplements.

Hyperammonaemia. Citrulline has been given as an alternative to arginine in the management of hyperammonaemia (p.1929) due to **urea cycle disorders**.

Lysinuric protein intolerance is another condition associated with hyperammonaemia and similar neurological sequelae. In this condition there is no deficiency of urea-cycle enzymes but a deficiency of urea-cycle substrate, such as ornithine, which results in reduced synthesis of citrulline. Patients are treated with dietary protein restriction and citrulline supplementation, which improves protein tolerance and nutrition but only slightly ameliorates growth retardation. Osteoporosis may be severe in children with this disorder.[1] A child presenting with osteopenia and diagnosed with lysinuric protein intolerance was given large oral doses of citrulline (up to 5.7 g daily). Aside from a substantial increase in protein tolerance, a striking acceleration in linear growth and bone mass was reported.[2] Lysine deficiency may be implicated in growth retardation,[1] but lysine supplementation may precipitate diarrhoea and malabsorption.[2] Six patients with lysinuric protein intolerance and receiving oral citrulline were supplemented with oral lysine. Larger lysine doses of 0.55 mmol/kg and 1.1 mmol/kg given consecutively, caused profuse diarrhoea, but smaller doses of 0.05 mmol/kg, given three times daily (up to a maximum dose of 2.5 mmol) were well tolerated. Plasma lysine concentrations were normalised with no adverse effects on the urea cycle.[1]

Cod-liver Oil *(BAN)*

Aceite de hígado de bacalao; Balık yağı; Cod Liver Oil; Csukamájolaj; Foie de morue, huile de; Huile de Foie de Morue; Iecoris aselli oleum; Kalanmaksaöljy; Lebertran; Menkių kepenų taukai; Ol. Morrh.; Óleo de Bacalhau; Oleum Jecoris Aselli; Oleum Morrhuae; Olio di Fegato di Merluzzo; Rybí olej; Torskleverolja.

Тресковый Печёночный Жир
CAS — 8001-69-2.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Jpn*, and *US.*

Ph. Eur. 6.2 (Cod-liver Oil (Type A) and Cod-liver Oil (Type B)). Purified fatty oils obtained from the fresh livers of *Gadus morhua* and other species of Gadidae, solid substances being removed by cooling and filtering. The oils contain not less than 600 units (180 micrograms) and not more than 2500 units (750 micrograms) of vitamin A per g and not less than 60 units (1.5 micrograms) and not more than 250 units (6.25 micrograms) of vitamin D_3 (colecalciferol) per g. Authorised antioxidants in concentrations not exceeding those prescribed by the competent authority may be added.

Clear yellowish viscous liquids. Practically insoluble in water; slightly soluble in alcohol; miscible with petroleum spirit. Store in well-filled airtight containers. Store under an inert gas if no antioxidant is added. Protect from light.

USP 31 (Cod Liver Oil). The partially destearinated fixed oil obtained from the fresh livers of *Gadus morrhua* and other species of Gadidae. It contains not less than 600 units (180 micrograms) and not more than 2500 units (750 micrograms) of vitamin A per g and not less than 60 units (1.5 micrograms) and not more than 250 units (6.25 micrograms) of vitamin D per g. It may be flavoured by the addition of not more than 1% of a suitable flavour or a mixture of flavours. A suitable antioxidant may be added.

A thin, oily liquid, having a characteristic, slightly fishy but not rancid odour. Slightly soluble in alcohol; freely soluble in carbon disulfide, in chloroform, in ether, and in ethyl acetate. Store in airtight containers. It may be bottled or packaged in containers from which air has been expelled by the production of a vacuum or by an inert gas.

Profile

Cod-liver oil is a rich source of vitamin D (p.1986) and a good source of vitamin A (p.1971). It also contains several essential fatty acids.

Cod-liver oil dressings or ointment have been advocated to accelerate healing in burns, ulcers, pressure sores, and superficial wounds, but controlled observations have failed to substantiate claims of their value.

Preparations

USP 31: Cod Liver Oil Capsules.

Copper

Cobre; Cuivre; Cuprum; Koppar; Kupari; Kupfer; Miedź.
Cu = 63.546.
CAS — 7440-50-8.

Pharmacopoeias. *Eur.* (see p.vii) includes Copper for Homoeopathic Preparations.

Ph. Eur. 6.2 (Copper for Homoeopathic Preparations; Cuprum ad Praeparationes Homoeopathicae). A reddish-brown powder. Practically insoluble in water and in alcohol; soluble in hydrochloric acid and in nitric acid.

Calcium Copperedetate

Cuproedetato cálcico. Calcium [ethylenediaminetetra-acetato(4−)-*N,N′,O,O′*]copper (II) dihydrate.
$C_{10}H_{12}CaCuN_2O_8,2H_2O$ = 427.9.
CAS — 66317-91-7 (anhydrous calcium copperedetate).

Pharmacopoeias. In *BP(Vet).*

BP(Vet) 2008 (Calcium Copperedetate). A blue crystalline powder. It contains 9.1 to 9.7% of Ca and 14.4 to 15.3% of Cu. Freely soluble in water, the solution gradually precipitating the tetrahydrate; practically insoluble in alcohol.

Copper Chloride

Cobre, cloruro de; Cupric Chloride; Miedzi chlorek.
$CuCl_2,2H_2O$ = 170.5.
CAS — 7447-39-4 (anhydrous copper chloride); 10125-13-0 (copper chloride dihydrate).

Pharmacopoeias. In *US.*

USP 31 (Cupric Chloride). Bluish-green, deliquescent crystals. Freely soluble in water; soluble in alcohol; slightly soluble in ether. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Copper Gluconate

Cobre, gluconato de. Copper D-gluconate (1:2); Bis(D-gluconato-O^1,O^2) copper.
$C_{12}H_{22}CuO_{14}$ = 453.8.
CAS — 527-09-3.

Pharmacopoeias. In *US.*

Copper Sulfate

Cobre, sulfato de; Copper Sulph.; Copper Sulphate; Cuivre (Sulfate de); Cuivre, sulfate de; Cupri sulfas; Cupri Sulphas; Cupric Sulfate; Kopparsulfat; Kuparisulfaatti; Kupfersulfat; Miedzi(II) siarczan; Réz(II)-szulfát; Síran měďnatý; Sulfato de Cobre; Vario sulfatas. Copper (II) sulphate pentahydrate.
$CuSO_4,5H_2O$ = 249.7.
CAS — 7758-98-7 (anhydrous copper sulfate); 7758-99-8 (copper sulfate pentahydrate).
ATC — V03AB20.
ATC Vet — QV03AB20.

NOTE. Crude copper sulfate is sometimes known as 'blue copperas', 'blue stone', and 'blue vitriol'.

Pharmacopoeias. In *Eur.* (see p.vii), *US*, and *Viet.*
Eur. and *Viet.* also include anhydrous copper sulfate.

Ph. Eur. 6.2 (Copper Sulphate Pentahydrate). A blue crystalline powder or transparent blue crystals. Freely soluble in water; practically insoluble in alcohol; soluble in methyl alcohol.

Ph. Eur. 6.2 (Copper Sulphate, Anhydrous). A greenish-grey, very hygroscopic, powder. Freely soluble in water; practically insoluble in alcohol; slightly soluble in methyl alcohol. Store in airtight containers.

USP 31 (Cupric Sulfate). Deep blue, triclinic crystals, or blue, crystalline granules or powder. It effloresces slowly in dry air. Soluble 1 in 3 of water, 1 in 0.5 of boiling water, 1 in 500 of alcohol, and 1 in 3 of glycerol. Its solutions are acid to litmus. Store in airtight containers at a temperature of 25°, excursions permitted between 15° and 30°.

Adverse Effects and Treatment

Adverse effects from copper have tended to arise after absorption of the metal from cooking utensils and during dialysis. Ingestion of copper from cooking utensils is associated mainly with hepatotoxicity. Dialysis procedures may supply copper through the water supply or from parts of the equipment and when this happens patients may suffer haemolysis and other haematological reactions, kidney involvement, and hepatotoxicity; the toxicity is generally a result of poor equipment maintenance.

Adverse effects attributed to copper have been reported in women with copper-containing intra-uterine devices. There have been isolated case reports of various effects such as allergy and endometrial changes. However, it is difficult to separate those adverse effects that are due to the device from those due solely to the copper.

The symptoms of Wilson's disease (hepatolenticular degeneration) (see p.1459) are due to an accumulation of copper in various parts of the body.

Copper salts if ingested can produce severe gastrointestinal effects and there may be systemic absorption of copper leading to the effects discussed above. The use of sprays of copper salts in agriculture has been associated with lung changes. Treatment of copper poisoning is symptomatic and may involve the use of a chelating agent to remove any absorbed metal. Dialysis has been tried.

Effects on the liver. Cirrhosis and acute liver failure have been attributed to chronic excessive copper supplement ingestion.[1] Supplementation with 10 mg daily of copper (around the safe upper limit) for 2 months has been reported to be associated with transient mild increases in serum aminotransferase values.[2]

1. O'Donohue J, *et al.* Micronodular cirrhosis and acute liver failure due to chronic copper self-intoxication. *Eur J Gastroenterol Hepatol* 1993; **5:** 561–2.
2. Araya M, *et al.* Supplementing copper at the upper level of the adult dietary recommended intake induces detectable but transient changes in healthy adults. *J Nutr* 2005; **135:** 2367–71.

Interactions

Large doses of zinc supplements may inhibit the gastrointestinal absorption of copper.

Uses and Administration

Copper is an essential trace element although severe copper deficiency, which is associated with anaemia, neutropenia, and bone demineralisation, is rare in humans. Copper sulfate is added to parenteral feeds as a source of copper in the prophylaxis and treatment of deficiency states. Doses that have been used for prophylaxis range from 0.5 to 1.5 mg (7.9 to 23.6 micromoles) of copper daily although up to 3 mg daily has been suggested in established deficiency; infants have received 20 micrograms/kg (0.3 micromol/kg) of copper daily. The dose should be governed by the serum-copper concentration, which in healthy adults ranges between 0.7 and 1.6 micrograms/mL (0.01 to 0.025 micromol/mL).

Copper sulfate and other soluble salts of copper have an astringent action on mucous surfaces and in strong solutions they are corrosive. Copper nitrate has been used in preparations for the removal of warts. The uses of copper acetate are discussed on p.2287.

Copper has a contraceptive effect (p.2070) when present in the uterus, and is added to some intra-uterine contraceptive devices; such devices are considered to be effective and safe for several years after insertion, and may be the most effective method for emergency contraception (p.2071). Copper is also reported to have an antimicrobial action.

Copper sulfate has been used to prevent the growth of algae in reservoirs, ponds, and swimming pools and as a molluscicide in the control of fresh-water snails that act as intermediate hosts in the life-cycle of the parasites causing schistosomiasis.

Reagents containing copper sulfate are used in tests for reducing sugars.

In veterinary medicine calcium copperedetate, copper methionate, copper oxide, and cuproxoline are used for the prevention and treatment of copper deficiency.

Copper bracelets are worn as a folk remedy for rheumatic disorders: there is no good evidence to justify such a practice.

Homoeopathy. Copper has been used in homoeopathic medicines under the following names: Cuprum metallicum; Cuprum; Cuprum met.; Cup. met.

Copper sulfate has been used in homoeopathic medicines under the following names: Cuprum sulfuricum; Cuprum sulphuricum; Cup. s.

Deficiency states. Acquired copper deficiency is very rare and the small number of cases have usually involved patients on total parenteral nutrition or long-term enteral nutrition.[1] Copper deficiency may also be due to malnutrition,[2] malabsorption, or secondary to excessive zinc consumption.[3,4] Clinical manifestations of deficiency include hypocupraemia, hypoceruloplasminaemia, neutropenia, anaemia, osteoporosis, and fracture of the long bones.[2] However, cases may present with neurological signs resembling the subacute combined degeneration normally associated with vitamin B_{12} deficiency.[3,4] Effects on blood may be absent, and zinc concentrations normal;[3] however, hyperzincaemia may be seen even in the absence of exogenous zinc consumption.[4]

Menkes' disease is an X-linked genetic disorder associated with a defect in copper transport, which almost invariably results in death due to progressive cerebral degeneration by the age of 3 years.[5,6] Clinical features include skeletal abnormalities, severe mental retardation, thrombosis, hypothermia, arterial abnormalities, and characteristic facial features.[7] Early parenteral treatment with copper-histidine complex may be of benefit in such children.[5-8] Optimal response to copper therapy appears to occur only in patients who are identified in the newborn period and who have some residual copper-transport activity. More than 3 years of copper replacement therapy may not be necessary or desirable.[6]

Human requirements. In the UK dietary reference values (see p.1925) have been published for copper.[1] Although an estimated average requirement (EAR) could not be derived a reference nutrient intake (RNI) of 1.2 mg (19 micromoles) daily was set for adults; RNIs of lower values were also specified for infants and children.[1] The Expert Group on Vitamins and Minerals[2] have established a safe upper level (SUL) for copper of 160 micrograms/kg daily.

In the USA the recommended dietary allowance (RDA) for copper is 900 micrograms daily in adults, and the tolerable upper intake level is 10 mg daily.[3]

WHO has estimated a minimum population mean intake of 1.2 mg daily for women and 1.3 mg daily for men, and safe upper limits of population mean intakes of 10 mg daily for women and 12 mg daily for men;[4] values are also estimated for infants and children.

Schistosomiasis. Although most control programmes for schistosomiasis (p.138) use niclosamide as a molluscicide, and copper salts have largely been abandoned for snail control, WHO noted in 1993 that copper sulfate was still used for this purpose in Egypt.[1]

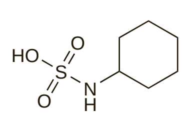
Cyclamic Acid *(BAN, USAN)*

Ciclámico, ácido; Cyclam. Acid; E952; Hexamic Acid. *N*-Cyclohexylsulphamic acid.

$C_6H_{13}NO_3S = 179.2.$

CAS — 100-88-9.



Calcium Cyclamate

Calc. Cyclam.; Calcium Cyclohexanesulfamate; Ciclamato de calcio; Cyclamate Calcium; E952. Calcium *N*-cyclohexylsulphamate dihydrate.

$C_{12}H_{24}CaN_2O_6S_2,2H_2O = 432.6.$

CAS — 139-06-0 (anhydrous calcium cyclamate); 5897-16-5 (calcium cyclamate dihydrate).

Potassium Cyclamate

Cyclamate potassium; HSDB 1239; Monopotassium cyclohexanesulfamate; potassium cyclohexanesulfamate. Potassium *N*-cyclohexysulphamate.

$C_6H_{12}NO_3SK = 217.3.$

CAS — 7758-04-5.

Sodium Cyclamate *(BAN, rINN)*

Ciclamato de sodio; Cyclamate de Sodium; Cyclamate Sodium; E952; Natrii cyclamas; Natrio ciklamatas; Nátrium-ciklamát; Natriumcyklamat; Natrium-cyklamát; Natriumsyklamaatti; Siklamat Sodyum; Sod. Cyclam.; Sodium, cyclamate de; Sodium Cyclohexanesulphamate. Sodium *N*-cyclohexylsulphamate.

Натрия Цикламат

$C_6H_{12}NNaO_3S = 201.2.$

CAS — 139-05-9.

Pharmacopoeias. In *Chin.* and *Eur.* (see p.vii).

Ph. Eur. 6.2 (Sodium Cyclamate). A white or almost white, crystalline powder or colourless crystals. Freely soluble in water; slightly soluble in alcohol. A 10% solution in water has a pH of 5.5 to 7.5.

Profile

Cyclamic acid and its salts are intense sweetening agents. In dilute solutions (up to about 0.17%) sodium cyclamate is about 30 times as sweet as sucrose but this factor decreases at higher concentrations. When the concentration approaches 0.5%, a bitter taste becomes noticeable. It is stable to heat.

The use of cyclamates as artificial sweeteners in food, soft drinks, and artificial sweetening tablets was at one time prohibited in Great Britain and some other countries because of concern about the metabolite cyclohexylamine. However, after reappraisal their use is now allowed.

Preparations

Proprietary Preparations (details are given in Part 3)

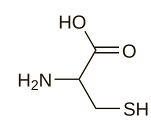
Cysteine *(rINN)*

C; Cisteína; Cys; Cystéine; L-Cysteine; Cysteinum; E920; L-Cysteina. L-2-Amino-3-mercaptopropionic acid.

Цистеин

$C_3H_7NO_2S = 121.2.$

CAS — 52-90-4.



Pharmacopoeias. In *Ger.*

Cysteine Hydrochloride *(rINNM)*

Cisteíno hidrochloridas monohidratas; Cisztein-hidroklorid-monohidrát; Cys Hydrochloride; Cystéine, Chlorhydrate de; Cystéine (chlorhydrate de) monohydraté; L-Cysteine Hydrochloride Monohydrate; Cystein-hydrochlorid monohydrát; Cysteinhydrokloridmonohydrat; Cysteini Hydrochloridum; Cysteini hydrochloridum monohydricum; Hidrocloruro de cisteína; Kysteiinihydrokloridimonohydraatti; L-Cysteiny chlorowodorek. L-2-Amino-3-mercaptopropionic acid hydrochloride monohydrate.

Цистеина Гидрохлорид

$C_3H_7NO_2S,HCl,H_2O = 175.6.$

CAS — 52-89-1 (anhydrous L-cysteine hydrochloride); 7048-04-6 (L-cysteine hydrochloride monohydrate).

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *US.*

Ph. Eur. 6.2 (Cysteine Hydrochloride Monohydrate; Cysteine Hydrochloride BP 2008). A white or almost white crystalline powder or colourless crystals. Freely soluble in water; slightly soluble in alcohol. Protect from light.

USP 31 (Cysteine Hydrochloride). White crystals or crystalline powder. Soluble in water, in alcohol, and in acetone.

Profile

Cysteine is a non-essential amino acid. Cysteine and cysteine hydrochloride are used as dietary supplements.

Cysteine and cysteine hydrochloride are included in preparations used in ophthalmology; eye drops have been used to prevent corneal ulceration after chemical burns.

Proprietary Preparations (details are given in Part 3)
Port.: Elmex.

Multi-ingredient: ***Austria:*** Elmex; ***Belg.:*** Elmex; ***Cz.:*** Elmex; ***Fin.:*** Elmex; ***Ger.:*** Elmex; Lawefluor N†; Multifluorid; ***Hung.:*** Elmex; ***Israel:*** Elmex; ***Ital.:*** Elmex; ***Neth.:*** Elmex; ***Switz.:*** Elmex; Paro aux fluorures d'amines Gelee.

Dextrin *(BAN)*

British Gum; Dekstriini; Dekstrinas; Dextrina; Dextrine; Dextrinum; Dextrinum Album; Starch Gum.

$[C_6H_{10}O_5]_n.xH_2O$.
CAS — 9004-53-9.

Pharmacopoeias. In *Chin., Eur.* (see p.vii), and *Jpn.* Also in *USNF.*

Ph. Eur. 6.2 (Dextrin). Maize, potato, or cassava starch partially hydrolysed and modified by heating with or without the presence of acids, alkalis, or pH control agents. A white or almost white, free-flowing powder. Very soluble in boiling water forming a mucilaginous solution; slowly soluble in cold water; practically insoluble in alcohol. A 5% dispersion in water has a pH of 2.0 to 8.0.

USNF 26 (Dextrin). It is starch, or partially hydrolysed starch, modified by heating in a dry state, with or without acids, alkalis, or pH control agents. A white, yellow, or brown free-flowing powder. Its solubility in water varies; it is usually very soluble, but often contains an insoluble portion.

Icodextrin *(BAN, USAN, rINN)*

Icodextrina; Icodextrine; Icodextrinum; Ikodekstriini; Ikodextrin.

Икодекстрин

$[C_6H_{10}O_5]_n$.
CAS — 337376-15-5.

Profile

Dextrin, a glucose polymer, is (1→4)-α-D-glucan derived from the hydrolysis of starch. Icodextrin is dextrin with more than 85% of its molecules with molecular weights between 1640 and 45 000, and a weight-average molecular weight of about 20 000. Dextrin is a source of carbohydrate sometimes used in oral dietary supplements and tube feeding. Glucose is rapidly released in the gastrointestinal tract but because of the high average molecular weight of dextrin, solutions have a lower osmolarity than isocaloric solutions of glucose. Additionally, preparations based on dextrin (such as maltodextrin p.1955), and intended for dietary supplementation, usually have a low electrolyte content and are free of lactose and sucrose. These properties make such preparations suitable for dietary supplementation in a variety of diseases including certain gastrointestinal disorders where malabsorption is a problem, in disaccharide intolerance (without isomaltose intolerance), and in acute and chronic hepatic and renal diseases where protein, mineral, and fluid restriction are often necessary.

Dextrin is used as a tablet and capsule diluent, and as a binding, suspending, and viscosity-increasing agent. It has also been used as an adhesive and stiffening agent for surgical dressings.

Dextrin sulfate intravaginal gel has been investigated in the prophylaxis of HIV infection and AIDS.

Icodextrin is used in dialysis fluids as an alternative to glucose-based solutions (see also below). Icodextrin-based fluids are instilled intraperitoneally to reduce adhesions after gynaecological and other abdominal surgery. They have also been used as vehicles for drugs given via the peritoneal cavity.

Dialysis. Glucose-based solutions are commonly used in dialysis solutions for continuous ambulatory peritoneal dialysis (CAPD). However, there is rapid absorption of glucose across the peritoneal membrane, reducing the duration of ultrafiltration and leading to long-term metabolic complications such as hyperglycaemia, hyperinsulinaemia, hyperlipidaemia and obesity. Other osmotic agents have been investigated. One study reported results in 11 patients[1] receiving CAPD who had suffered repeated fluid overload from glucose-based dialysis solutions, and suggested that replacement of glucose with dextrin as the osmotic agent could reverse fluid overload and possibly reduce the frequency of exchange. However, others[2] considered that the proposed frequency of exchange would not provide adequate removal of urea, and that in addition to underdialysis there would be an accumulation of poorly-metabolisable glucose polymers in the blood.

Icodextrin is another alternative.[3,4] It is a glucose polymer, given in iso-osmolar solution. Studies supported by the manufacturers have found that it can be used in ultrafiltration for up to 12 hours, with lower transperitoneal absorption and potential calorie load than glucose solutions.[5,6] It can also be metabolised by amylases in the blood, so is less likely to accumulate than other glucose polymers if absorbed,[6] although the resultant concentrations of maltose (the primary metabolite) have resulted in falsely elevated blood-glucose measurements with some test methods.[7-9] Licensed product information states that glucose dehydrogenase pyrroloquinolinequinone (GDH-PQQ) or glucose-dye-oxidoreductase based methods should not be used for this reason. In a study in CAPD patients, icodextrin was well-tolerated and produced at least equivalent ultrafiltration to glucose solutions.[5] Another study found that peritoneal dialysis patients on icodextrin lost weight and had improved fluid status compared with patients on glucose.[10] In a small study of peritoneal dialysis patients with fluid overload and due to be transferred to haemodialysis, substitution of icodextrin for one long-dwell exchange daily significantly increased ultrafiltration and extended technique survival-time.[11]

A combination of icodextrin and glucose has also been investigated as a means to reduce glucose exposure while increasing ultrafiltration.[12,13]

Peritonitis. Sterile peritonitis attributed to icodextrin has been reported.[1,2] Subsequently, several batches were withdrawn by the manufacturer in May 2002 because of bacterial contamination with high levels of peptidoglycan.[2,3] However, further incidents of peritonitis have been reported with icodextrin in patients previously exposed to the withdrawn batches,[4-6] prompting theories of sensitisation to icodextrin or peptidoglycans. Concerns were expressed regarding possible cross-sensitisation to dextran polymers in these patients,[6] as well as the possibility that even low levels of peptidoglycans might trigger peritonitis.[7] Histological changes similar to bacterial peritonitis have been found in patients with icodextrin-associated sterile peritonitis.[8] It was suggested that if cloudy dialysate reappeared upon rechallenge, icodextrin should be withdrawn.[8]

In an effort to determine the cause of the aseptic peritonitis, a manufacturer-sponsored analysis determined that recalled batches of dialysis solution were within product and pharmacopoeial specifications for content, safety, and sterility. However, both dialysate solution and icodextrin raw material caused increases in interleukin-6 response *in vitro*, suggesting a non-endotoxin contaminant as the cause of the aseptic peritonitis. Further analysis found peptidoglycan contamination of the raw icodextrin by *Alicyclobacillus acidocaldarius* to be the cause.[3]

Preparations

USNF 26: Liquid Glucose.

Proprietary Preparations (details are given in Part 3)
Austral.: Poly-Joule; ***Fr.:*** Caloreen; ***Gr.:*** Caloreen†; ***Neth.:*** Dexemel†; ***UK:*** Adept; Caloreen; Dexemel†.

Multi-ingredient: ***Fr.:*** Picot†.

Ferric Ammonium Citrate

381; Ammonium Ferric Citrate; Citrato amónico férrico; Demir III Amonyum sitrat; Ferricum Citricum Ammoniatum; Iron and Ammonium Citrate.

CAS — 1185-57-5.
ATC — V08CA07.
ATC Vet — QV08CA07.

Pharmacopoeias. In *US.*

USP 31 (Ferric Ammonium Citrate). It contains between 16.5% and 18.5% of iron. Store in airtight containers at a temperature of 8° to 15°. Protect from light.

Profile

Ferric ammonium citrate is given orally as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is also used as a food additive, as an acidity regulator, anticaking agent, or source of iron. It has been used as a colouring agent.

Preparations

USP 31: Ferric Ammonium Citrate for Oral Solution.

Proprietary Preparations (details are given in Part 3)
Braz.: Vinho Ferruginoso†; ***Gr.:*** Ferriseltz†; ***India:*** Rubraplex; ***Ital.:*** Sciroppo Fenoglio†; ***Neth.:*** FerriSeltz; ***Port.:*** Cobalti†; ***Spain:*** Ferriseltz; ***Turk.:*** Ferro; Nuklofer Tonik; Samson; Tonoferrin; ***Venez.:*** Dociron†.

Multi-ingredient: ***Arg.:*** ITE B12 Forte; ***Austria:*** Ferrovin-Chinaeisenwein; ***Braz.:*** Ferroben†; Ferrotrat B12 Plus; Ferrotrat B12†; Hematiase B12; Hepavitose†; Regulador Xavier N-2†; Rubrobion†; ***Canad.:*** Maltlevol; ***Ger.:*** Praefeminon plus†; ***Hong Kong:*** Nutroplex; ***India:*** Blosyn; Dexorange; Ferradol; Ferrochelate; Genfol; Globac-Z; Haem Up; Hepatoglobine; Vitamon; ***Ital.:*** Emopon; ***Malaysia:*** Nutroplex†; ***Singapore:*** Nutroplex; ***UK:*** Ironorm; Lexpec with Iron-M†; Lexpec with Iron†; ***USA:*** Geritol; Geritonic; ***Venez.:*** Beferron; Cianofer; Fercobre B-12†; Fercobre†.

Ferric Carboxymaltose *(USAN, rINN)*

Carboximaltosa Férrica; Carboxymaltose Ferrique; Ferricum Carboxymaltosum; VIT-45.

Феррик Карбоксимальтоз

CAS — 9007-72-1.

Profile

Ferric carboxymaltose is used as a source of parenteral iron (p.1949) for iron-deficiency anaemia (p.1951) when oral iron therapy is ineffective or impractical. Dosage should be individualised and the calculated total cumulative dose of iron should not be exceeded. Ferric carboxymaltose is given by intravenous bolus injection over 1 to 2 minutes, in doses supplying up to 200 mg of iron up to 3 times weekly, or diluted in sodium chloride 0.9% by intravenous infusion in a dose of up to 1 g of iron no more than once weekly. It should not be given by intramuscular or subcutaneous injection. In patients on dialysis it may be given undiluted directly into the venous limb of the dialyser. For further information relating to the parenteral use of iron, see Iron Dextran, p.1951.

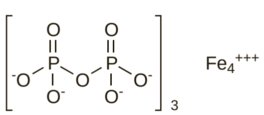
Preparations

Proprietary Preparations (details are given in Part 3)
Cz.: Ferinject; ***Switz.:*** Ferinject; ***UK:*** Ferinject.

Ferric Pyrophosphate

Férrico, pirofosfato; Iron Pyrophosphate.

$Fe_4(P_2O_7)_3$ = 745.2.
CAS — 10058-44-3.



Profile

Ferric pyrophosphate is given orally as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Austral.:*** Incremin Iron; ***Chile:*** Incremin†; ***Mex.:*** Incremin Con Hierro; ***USA:*** Vitafol; Vitalize.

Ferritin

Ferritina.

Profile

Ferritin is the major iron storage protein of vertebrates, found mainly in the liver, spleen, intestinal mucosa, and bone marrow and consisting of a soluble protein shell (apoferritin) with a core of crystalline ferric hydroxyphosphate complex. It has been given orally as a source of iron (p.1949) in iron-deficiency anaemias (p.1951).

Preparations

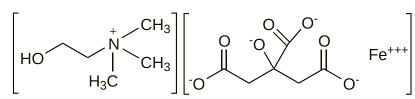
Proprietary Preparations (details are given in Part 3)
Mex.: Ferrivax; ***Spain:*** Ferroprotina; Hierco†; Kilor; Profer.

Ferrocholinate *(rINN)*

Ferrocholinatum; Ferrocolinato.

Феррохолинат

$C_{11}H_{20}FeNO_9,2H_2O$ = 402.2.
CAS — 1336-80-7.



Profile

Ferrocholinate is a chelate prepared by reacting equimolar quantities of freshly precipitated ferric hydroxide with choline dihydrogen citrate. It is given orally as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

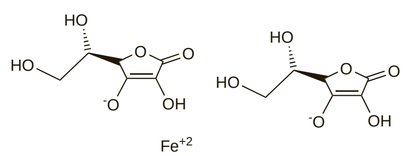
Preparations

Proprietary Preparations (details are given in Part 3)
Spain: Podertonic.

Ferrous Ascorbate

Ferroso, ascorbato.

$C_{12}H_{14}FeO_{12}$ = 406.1.
CAS — 24808-52-4.
ATC — B03AA10.
ATC Vet — QB03AA10.



Profile

Ferrous ascorbate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in usual doses of up to 1.47 g daily (equivalent to about 200 mg of iron daily).

Preparations

Proprietary Preparations (details are given in Part 3)
Fr.: Ascofer.

Multi-ingredient: ***Austria:*** China-Eisenwein.

Ferrous Aspartate

Ferroso, aspartato.

$C_8H_{12}FeN_2O_8,4H_2O$ = 392.1.
ATC — B03AA09.
ATC Vet — QB03AA09.

Profile

Ferrous aspartate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in usual doses of up to 750 mg daily (equivalent to about 100 mg of iron daily).

Preparations

Proprietary Preparations (details are given in Part 3)
Belg.: Spartocine†; ***Fin.:*** Spartocine; ***Ger.:*** Spartocine N†; ***USA:*** FE Aspartate.

Ferrous Chloride

Ferroso, cloruro. Iron (II) chloride tetrahydrate.

$FeCl_2,4H_2O$ = 198.8.
CAS — 7758-94-3 (anhydrous ferrous chloride); 13478-10-9 (ferrous chloride tetrahydrate).
ATC — B03AA05.
ATC Vet — QB03AA05.

Profile

Ferrous chloride is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in a usual dosage of about 350 to 700 mg daily in divided doses (equivalent to about 100 to 200 mg of iron daily).

Preparations

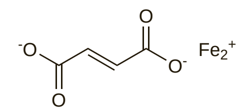
Proprietary Preparations (details are given in Part 3)
Fr.: Fer UCB; ***Pol.:*** Hemofer; ***Switz.:*** Ferrascorbin.

Multi-ingredient: ***Switz.:*** Ferrascorbin.

Ferrous Fumarate

Demir Fumarat; Ferrofumaraatti; Ferrofumarat; Ferrosi fumaras; Ferroso, fumarato; Fumaran železnatý; Fumarate ferreux; Geležies(II) fumaratas; Vas(II)-fumarát.

$C_4H_2FeO_4$ = 169.9.
CAS — 141-01-5.
ATC — B03AA02.
ATC Vet — QB03AA02; QB03AD02.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., US,* and *Viet.*

Ph. Eur. 6.2 (Ferrous Fumarate). A fine, reddish-orange or reddish-brown powder. Slightly soluble in water; very slightly soluble in alcohol. Store in airtight containers. Protect from light.

USP 31 (Ferrous Fumarate). A reddish-orange to red-brown, odourless powder, which may contain soft lumps that produce a yellow streak when crushed. Slightly soluble in water; very slightly soluble in alcohol. Its solubility in dilute hydrochloric acid is limited by the separation of fumaric acid.

Profile

Ferrous fumarate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in usual doses of up to 600 mg daily (equivalent to about 200 mg of iron daily); doses of up to 1.2 g daily (equivalent to about 400 mg of iron daily) may be used if necessary.

Preparations

BP 2008: Ferrous Fumarate and Folic Acid Tablets; Ferrous Fumarate Capsules; Ferrous Fumarate Oral Suspension; Ferrous Fumarate Tablets;
USP 31: Ferrous Fumarate and Docusate Sodium Extended-release Tablets; Ferrous Fumarate Tablets.

Proprietary Preparations (details are given in Part 3)

Ferrous Gluceptate

Ferroso, gluceptato; Ferrous Glucoheptonate.

$Fe(C_7H_{13}O_8)_2$ = 506.2.
CAS — 25126-38-9.

Profile

Ferrous gluceptate is given orally as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

Preparations

Proprietary Preparations (details are given in Part 3)
Chile: Unifer.

Multi-ingredient: ***Arg.:*** Egestan Hierro; ***Spain:*** Clamarvit†; Normovite Antianemico.

Ferrous Gluconate

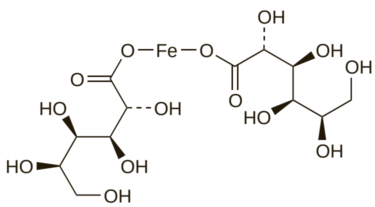
E579; Eisen(II)-Gluconat; Ferroglukonaatti; Ferroglukonat; Ferrosi gluconas; Ferrosi Gluconas Hydricus; Ferroso, gluconato; Geležies(II) gliukonatas; Gluconate ferreux; Glukonan železnatý hydrát; Vas(II)-glükonát; Żelaza(II) glukonian. Iron (II) di(D-gluconate).

$C_{12}H_{22}FeO_{14},xH_2O$.

CAS — 299-29-6 (anhydrous ferrous gluconate); 12389-15-0 (ferrous gluconate dihydrate).

ATC — B03AA03.

ATC Vet — QB03AA03.



(anhydrous ferrous gluconate)

Pharmacopoeias. In *Eur.* (see p.vii).
Chin. and *US* specify the dihydrate.
Ph. Eur. 6.2 (Ferrous Gluconate). A greenish-yellow to grey powder or granules. It contains not less than 11.8% and not more than 12.5% of ferrous iron calculated with reference to the dried substance. Freely but slowly soluble in water producing a greenish-brown solution, more readily soluble in hot water; practically insoluble in alcohol. A 10% solution in water has a pH of 4.0 to 5.5 three to four hours after preparation. Protect from light.
USP 31 (Ferrous Gluconate). A yellowish-grey or pale greenish-yellow, fine powder or granules having a slight odour resembling that of burnt sugar. Soluble 1 in 5 of water; practically insoluble in alcohol. A 5% solution in water is acid to litmus. Store in airtight containers.

Profile

Ferrous gluconate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in doses of up to 1.8 g daily (equivalent to up to 210 mg of iron daily).

Preparations

BP 2008: Ferrous Gluconate Tablets;
USP 31: Ferrous Gluconate Capsules; Ferrous Gluconate Elixir; Ferrous Gluconate Tablets.

Proprietary Preparations (details are given in Part 3)

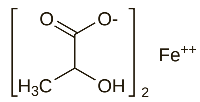
Ferrous Lactate

E585; Ferroso, lactato; Iron Lactate.

$C_6H_{10}FeO_6,3H_2O = 288.0.$

CAS — 5905-52-2 (anhydrous ferrous lactate); 6047-24-1 (ferrous lactate trihydrate).



(anhydrous ferrous lactate)

Profile

Ferrous lactate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Cromatonbic Ferro†; ***S.Afr.:*** Ferro Drops L; ***Spain:*** Cromatonbic Ferro.

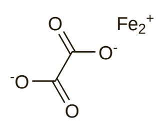
Multi-ingredient: ***Hung.:*** Fagifor†.

Ferrous Oxalate

Ferroso, oxalato; Ferrum Oxalicum Oxydulatum; Iron Protoxalate.

$C_2FeO_4,2H_2O = 179.9.$

CAS — 516-03-0 (anhydrous ferrous oxalate); 6047-25-2 (ferrous oxalate dihydrate).



(anhydrous ferrous oxalate)

Profile

Ferrous oxalate has been used as a source of iron (p.1949).

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Fr.:*** Disulone.

Ferrous Succinate

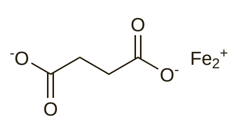
Ferroso, succinato.

$C_4H_4FeO_4 = 171.9.$

CAS — 10030-90-7.

ATC — B03AA06.

ATC Vet — QB03AA06.



Profile

Ferrous succinate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally in doses of up to about 600 mg daily (equivalent to up to about 200 mg of iron daily).

Preparations

Proprietary Preparations (details are given in Part 3)
Arg.: Ferdromaco; ***Ger.:*** Ferrlecit 2; ***Swed.:*** Ferromyn S.

Multi-ingredient: ***India:*** Hematrine.

Ferrous Sulfate

Demir Sülfat; Eisen(II)-Sulfat; Ferreux (Sulfate); Ferrosi Sulfas; Ferrosi sulfas heptahydricus; Ferroso, sulfato; Ferrosulfaattiheptahydraatti; Ferrosulfatheptahydrat; Ferrous Sulphate; Ferrum Sulfuricum Oxydulatum; Geležies(II) sulfatas heptahidratas; Iron (II) Sulphate Heptahydrate; Iron Sulphate; Síran železnatý heptahydrát; Sulfate ferreux heptahydraté; Vas(II)-szulfát; Żelaza(II) siarczan.

$FeSO_4,7H_2O = 278.0.$

CAS — 7720-78-7 (anhydrous ferrous sulfate); 7782-63-0 (ferrous sulfate heptahydrate).

ATC — B03AA07.

ATC Vet — QB03AA07; QB03AD03.

NOTE. Crude ferrous sulfate is known as Green Vitriol or Green Copperas.

Pharmacopoeias. In *Chin.*, *Eur.* (see p.vii), *Int.*, *Jpn*, *US*, and *Viet.*
Swiss also includes ferrous sulfate sesquihydrate.
Ph. Eur. 6.2 (Ferrous Sulphate Heptahydrate). A light green crystalline powder or bluish-green crystals, efflorescent in air. It is oxidised in moist air, becoming brown. Freely soluble in water; very soluble in boiling water; practically insoluble in alcohol. A 5% solution in water has a pH of 3.0 to 4.0. Store in airtight containers.
USP 31 (Ferrous Sulfate). Pale bluish-green, odourless, crystals or granules. It is efflorescent in dry air and oxidises readily in moist air to form brownish-yellow basic ferric sulfate. Soluble 1 in 1.5 of water and 1 in 0.5 of boiling water; insoluble in alcohol. A 10% solution in water is acid to litmus, having a pH of about 3.7. Store in airtight containers.

Dried Ferrous Sulfate *(USAN)*

Dried Ferrous Sulphate; Exsiccated Ferrous Sulphate; Ferreux (sulfate) desséché; Ferrosi sulfas desiccatus; Ferrosi Sulfas Exsiccatus; Ferroso desecado, sulfato.

CAS — 13463-43-9.

Pharmacopoeias. In *Eur.* (see p.vii), *Int.*, *US*, and *Viet.*
Ph. Eur. 6.2 (Ferrous Sulphate, Dried). Hydrated ferrous sulphate deprived of part of its water of hydration by drying. A greyish-white powder which is oxidised in moist air, becoming brown. It contains 86.0 to 90.0% of $FeSO_4$. Slowly but freely soluble in water, very soluble in boiling water; practically insoluble in alcohol. A 5% solution in water has a pH of 3.0 to 4.0. Store in airtight containers.
USP 31 (Dried Ferrous Sulfate). A greyish-white to buff-coloured powder consisting primarily of ferrous sulfate monohydrate with varying amounts of ferrous sulfate tetrahydrate. It contains 86.0 to 89.0% of $FeSO_4$. Slowly soluble in water; insoluble in alcohol.

Profile

Ferrous sulfate is used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951). It is given orally; the dried form is often used in solid dosage forms and the heptahydrate in liquid dosage forms. Usual doses of dried ferrous sulfate are up to 600 mg daily (equivalent to 180 to 195 mg of iron daily, this figure being somewhat variable depending on the purity and water content of the salt).

Ferrous sulfate oxidised with nitric and sulfuric acids yields ferric subsulfate solution, also known as Monsel's solution, which has been used as a haemostatic.

Preparations

BP 2008: Ferrous Sulphate Tablets; Paediatric Ferrous Sulphate Oral Solution; Prolonged-release Ferrous Sulphate Tablets;
BPC 1973: Compound Ferrous Sulphate Tablets;
USP 31: Ferric Subsulfate Solution; Ferrous Sulfate Oral Solution; Ferrous Sulfate Syrup; Ferrous Sulfate Tablets.

Proprietary Preparations (details are given in Part 3)

Ferrous Tartrate

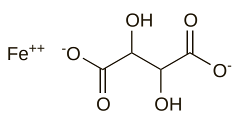
Ferrosi Tartras; Ferroso, tartrato.

$C_4H_4FeO_6,2H_2O = 249.0$.

CAS — 2944-65-2 (anhydrous ferrous tartrate).

ATC — B03AA08.

ATC Vet — QB03AA08.



(anhydrous ferrous tartrate)

Profile

Ferrous tartrate has been used as a source of iron (p.1949) for iron-deficiency anaemia (p.1951).

Preparations

Proprietary Preparations (details are given in Part 3)

Multi-ingredient: ***Denm.:*** Ferroplex-frangula.

Ferumoxytol *(USAN)*

Code 7228.

Ферумокситол

CAS — 1309-38-2.

Profile

Ferumoxytol is a superparamagnetic iron oxide that is coated with a low-molecular-weight semisynthetic carbohydrate, polyglucose sorbitol carboxymethyl ether. It is under investigation as a source of iron for iron-deficiency anaemia in patients with chronic kidney disease. Ferumoxytol may potentially be used as a contrast medium in magnetic resonance imaging (p.1474).

Folic Acid *(BAN, rINN)*

Acide folique; Ácido fólico; Acidum folicum; Folacin; Folik Asit; Folinsyre; Folio rūgštis; Folsav; Folsyra; Foolihappo; Kwas foliowy; Kyselina listová; PGA; Pteroylglutamic Acid; Pteroylmonoglutamic Acid; Vitamin B_9; Vitamin B_{11}. *N*-[4-(2-Amino-4-hydroxypteridin-6-ylmethylamino)benzoyl]-L(+)-glutamic acid.

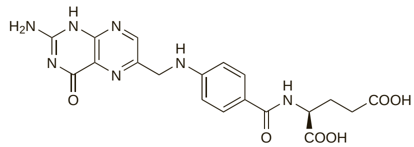
Фолиевая Кислота

$C_{19}H_{19}N_7O_6 = 441.4$.

CAS — 59-30-3 (folic acid); 6484-89-5 (sodium folate).

ATC — B03BB01.

ATC Vet — QB03BB01.



Pharmacopoeias. In *Chin., Eur.* (see p.vii), *Int., Jpn,* and *US.*

Ph. Eur. 6.2 (Folic Acid). A yellowish or orange crystalline powder. Practically insoluble in water and in most organic solvents. It dissolves in dilute acids and in alkaline solutions. Protect from light.

USP 31 (Folic Acid). A yellow, yellow-brownish, or yellowish-orange, odourless crystalline powder. Very slightly soluble in water; insoluble in alcohol, in acetone, in chloroform, and in ether. It readily dissolves in dilute solutions of alkali hydroxides and carbonates; soluble in hot, 3N hydrochloric acid and in hot, 2N sulfuric acid; soluble in hydrochloric acid and in sulfuric acid, yielding pale yellow solutions. Protect from light.

Adverse Effects

Folic acid is generally well tolerated. Gastrointestinal disturbances and hypersensitivity reactions have been reported rarely.

Hypersensitivity. A woman had 3 episodes of hypersensitivity, including anaphylaxis, on exposure to synthetic folic acid. Intradermal testing with folic acid solution was positive and a blinded challenge to folic acid solution led to widespread urticaria. Sensitisation to folic acid may have occurred after supplementation with vitamin B, at which time she had recurrent episodes of urticaria. The patient appeared to tolerate dietary folates, and the authors suggested that foods fortified with folic acid be clearly labelled.[1]

1. Smith J, *et al.* Recurrent anaphylaxis to synthetic folic acid. *Lancet* 2007; **370:** 652.

Precautions

Folic acid should never be given alone or with inadequate amounts of vitamin B_{12} for the treatment of undiagnosed megaloblastic anaemia, since folic acid may produce a haematopoietic response in patients with a megaloblastic anaemia due to vitamin B_{12} deficiency without preventing aggravation of neurological symptoms. This masking of the true deficiency state can lead to serious neurological damage, such as subacute combined degeneration of the spinal cord (see also Vitamin B_{12} Deficiency, below).

Breast feeding. Folic acid is excreted into breast milk. No adverse effects have been observed in breast-fed infants whose mothers were receiving folic acid, and the American Academy of Pediatrics considers that it is therefore usually compatible with breast feeding.[1]
