Ointments are preferred for chronic eczema, whereas cream- or lotion-based treatment may be more appropriate for acute eczema (see Box 29.11). Treatment is once to twice daily (p. 1225). Hydrocortisone (1%) or clobetasone butyrate is generally used on the face, with more potent glucocorticoids restricted to trunk and limbs (see Box 29.12). A good strategy is to employ an intensive regimen with more potent glucocorticoids initially and then taper use according to response. A key principle is to use the least potent glucocorticoid that is effective for the shortest possible time. The patient should be given instructions on how much to apply, using the fingertip unit for guidance (a strip of glucocorticoid cream on distal phalanx pulp should cover two palm-size areas). It is also important to monitor glucocorticoid use and the easiest way to do this is ask how long it takes to use a specific size of glucocorticoid tube. The side-effects of topical glucocorticoid therapy need to be considered but glucocorticoid phobia and under-treatment of eczema are often more of a problem than over-treatment. Particular care should be taken on certain sites, such as the face and flexures, and in children and the elderly (see Box 29.2 and Fig. 29.10, p. 1226).

The clinical features of eczema influence the choice of topical treatment. For example, appropriate treatment of acute exudative eczema could be with potassium permanganate soaks, emollients and topical glucocorticoids under wet wraps. Chronic eczema may be best treated with a potent topical glucocorticoid in an ointment formulation and occlusion with a paste bandage to ease itching and scratching.

The topical calcineurin inhibitors tacrolimus and pimecrolimus may be useful glucocorticoid-sparing agents for eczema, particularly on the face; they cause local cutaneous immunosuppression.

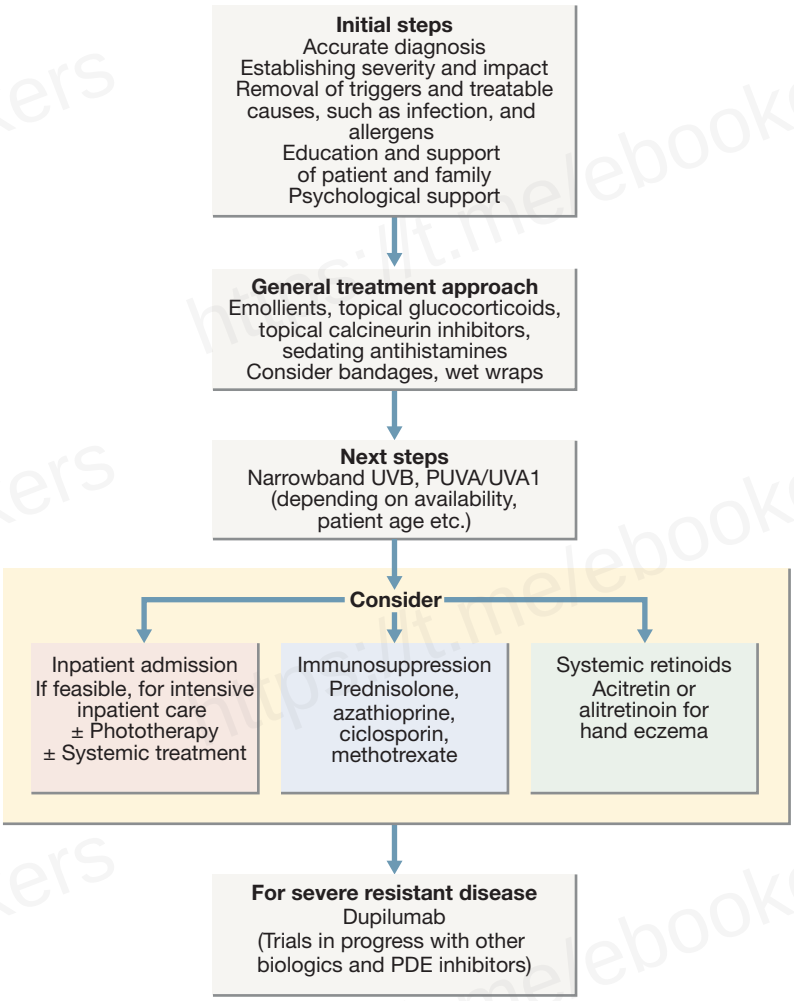

Fig. 29.31 General management approaches: atopic eczema. (PDE = phosphodiesterase; PUVA = psoralen-ultraviolet A; UVA1 = ultraviolet A1; UVB = narrowband ultraviolet B)

Initial burning and stinging may limit use but are usually transient side-effects. Bacterial and viral skin infection risk may be increased due to immunosuppression. Caution should be employed with sun exposure and these agents should not be used in combination with phototherapy because of their immunosuppressive effects.

Atopic eczema

This is the most common subtype of eczema. The prevalence has increased dramatically since the early 1980s, and the disease now affects at least 20% of schoolchildren and 5–10% of adults in the UK.

Pathogenesis

Generalised prolonged hypersensitivity to common environmental antigens, such as pollen and house-dust mite, is the hallmark of atopy, in which there is a genetic predisposition to produce excess IgE. Atopic individuals manifest one or more of a group of diseases that includes asthma, hay fever, food and other allergies, and atopic eczema. Genetic factors play an important role in all of these conditions, supported by higher concordance of atopic disease in monozygotic twins compared with dizygotic twins. Filaggrin gene mutations increase the risk of developing atopic eczema by more than threefold, emphasising the importance of epidermal barrier impairment in this disease. Other genes are also likely to be implicated, with many other susceptibility loci identified, although these studies require further replication. Decreased skin barrier function may also allow greater penetration of allergens through the epidermis, and thus cause immune stimulation and subsequent inflammation. The interaction between genes and environment is important; it has been estimated that 60–80% of individuals are genetically susceptible to the induction of IgE-mediated sensitisation to environmental allergens such as food and animal hair. Eczema is characterised by infiltration of Th2 cells, which are known to play a role in activating mast cells and eosinophils, as well as stimulating IgE production by IgE-producing B cells. The contributing roles of the microbiome are also being explored. Thus, the pathogenesis of atopic eczema is complex and multifactorial, involving an interplay of contributing factors.

Clinical features

Atopic eczema is extremely itchy and scratching accounts for many of the signs (Fig. 29.32). Widespread cutaneous dryness (also known as xeroderma or xerosis) is another feature. The distribution and character of the rash vary with age (Box 29.19). Complications are listed in Box 29.20.

Investigations

The diagnosis of atopic eczema is made using clinical criteria (Box 29.21). Interestingly, while most patients with atopic eczema have raised total IgE levels and IgE-specific antibodies, this is not a prerequisite for the diagnosis, as a significant minority have normal levels of IgE.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

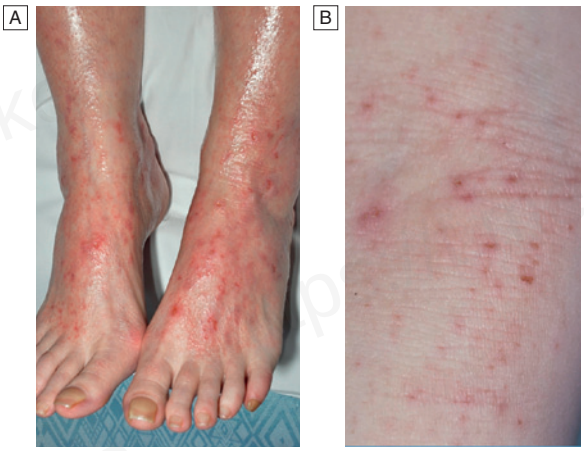

Fig. 29.32 Atopic eczema. A This patient had life-long chronic atopic eczema and experienced a generalised flare of disease triggered by infection. B Lichenification of chronic flexural eczema secondary to rubbing and scratching.

i 29.19 Atopic eczema: distribution and character of rash

Babies and infants

- Often acute and facial involvement prominent
- Trunk involved but nappy area usually spared

Children

- Flexures: behind knees, antecubital fossae, wrists and ankles

Adults

- Face and trunk usually involved, limb involvement not restricted to flexures
- Lichenification common

i 29.20 Complications of atopic eczema

Secondary infection

Bacterial

- *Staphylococcus aureus* most common

Viral

- Herpes simplex virus can cause a widespread severe eruption – eczema herpeticum
- Papillomavirus and molluscum contagiosum are more common in atopic eczema, especially if treated with topical glucocorticoids

Increased susceptibility to irritants

- Defective barrier function

Increased susceptibility to allergy

- Food allergy – mainly relevant in infants; eggs, cow's milk protein, nuts, fish, wheat and soya may cause an immediate reaction with angioedema and/or urticaria rather than exacerbation of eczema
- Anaphylaxis in severe allergy
- Increased risk of sensitisation to type IV allergens because of impaired barrier function

Impact on life and health

- Poor sleep, loss of schooling, behavioural difficulties, failure to thrive in children
- Impact on sleep, work, relationships, hobbies, psychology and quality of life in adults

i 29.21 Diagnostic criteria for atopic eczema

Itchy skin rash (or history of itch or rubbing from parent) and at least three of the following:

- History of involvement of skin creases (or cheeks if <4 years)
- History of atopic disease (asthma, hay fever) (or in a first-degree relative if <4 years)
- Dry skin (xeroderma)
- Visible flexural eczema (cheeks, forehead, outer limbs if <4 years)
- Onset in first 2 years of life

Management

The general principles of management are as described in Figure 29.31. Emollients and topical glucocorticoids, tar and ichthammol paste bandages, or wet wraps in children, are often required. Topical calcineurin inhibitors may be used as glucocorticoid-sparing agents but should not be used in infected eczema. Secondary infection should be treated but positive skin swabs in isolation, without clinical evidence of infection, do not necessarily require treatment with antibiotics, although antiseptics would be appropriate. Sedating antihistamines may help to break the itch/scratch cycle. Identification and avoidance of allergens are important.

Phototherapy is generally the next step, if topical therapies are insufficient (see Fig. 29.31). Narrowband UVB is usually the initial phototherapy of choice and can also be used in children. PUVA or UVA1 can also be chosen if UVB is ineffective, although mainly in adults as PUVA is generally avoided in children. Localised phototherapy may be used for eczema on hands and feet and PUVA may be more effective in that situation. Systemic immunosuppression with, for example, oral glucocorticoids, intermittent ciclosporin, azathioprine or methotrexate may be needed if the response to topical therapies and phototherapy is inadequate. Systemic retinoids, such as acitretin or alitretinoin, may be indicated: for example, in hand and foot eczema.

Encouraging early trial data are emerging to support the use of dupilumab, which blocks IL-4Rα, and the anti-IL-13 agents lebrikizumab and tralokinumab in atopic eczema. Phosphodiesterase 4 inhibitors are also being investigated.

Seborrhoeic eczema

This is an erythematous scaly rash affecting the scalp (dandruff), central face, nasolabial folds, eyebrows, central chest and upper back. It is associated with, and may be due to, overgrowth of *Malassezia* yeasts. When severe, it may resemble psoriasis. Severe or recalcitrant seborrhoeic eczema can be a marker of immunodeficiency, including HIV infection (p. 314). Topical azoles, such as ketoconazole shampoo and cream, often combined with mild glucocorticoid, are mainstays. Treatment often needs to be repeated due to disease recurrence.

Discoid eczema

Discoid eczema, which is also known as nummular eczema, is common and characteristically consists of discrete, coin-shaped eczematous lesions, which are often impetiginised and most commonly occur on the limbs of men. It is an eczema type that can be due to any chronic itchy condition, whether primarily of the skin or secondary to an underlying disease. Initial management should include topical antiseptics, in addition to emollients and topical glucocorticoids. Judicious antibiotic use may also be required for acute flares.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

29.22 Common type IV delayed hypersensitivity allergens

Allergen	Source
Nickel	Jewellery, jean studs, bra clips, watches
Dichromate	Cement, leather, matches
Rubber chemicals	Clothing, shoes, rubber gloves, tyres
Colophony	Sticking plaster, collodion, nail varnish
Paraphenylenediamine	Hair dye, clothing, tattoos
Balsam of Peru	Perfumes, citrus fruits, shower/bath products
Neomycin, benzocaine	Topical medications
Parabens	Preservative in cosmetics and creams
Wool alcohols	Lanolin, cosmetics, creams
Epoxy resin	Resin adhesives, glues
Methyl- and chloromethyl-isothiazolinone	Preservatives, with increasing numbers of cases of allergy reported

Irritant eczema

Detergents, alkalis, acids, solvents and abrasives are common irritants. Strong irritants have acute effects, whereas weaker irritants commonly cause chronic eczema, especially of the hands, after prolonged exposure. Individual susceptibility varies and the elderly, atopic and fair-skinned are predisposed. Irritant eczema accounts for most occupational cases of eczema and is a significant cause of time off work. Irritant avoidance, including protective clothing (such as gloves), is essential. Emollients and topical glucocorticoids are indicated.

Allergic contact eczema

This occurs due to a delayed hypersensitivity reaction following contact with antigens or haptens. Previous allergen exposure is required for sensitisation and the reaction is specific to the allergen or closely related chemicals. Common allergens are listed in Box 29.22.

Allergy persists indefinitely and eczema occurs at sites of allergen contact and can secondarily spread beyond this. The distribution of eczema can be very informative with regard to possible culprits. There are many recognisable patterns of sites of eczema involvement, such as earlobes, wrists and umbilicus due to contact with nickel in earrings, watches and jeans studs; hands and wrists due to rubber gloves; and upper eyelids due to colophony from rubbing of the eyes in nail varnish wearers. Oedema may also be a feature (Fig. 29.33). Allergen avoidance is key and may involve a change of occupation, recreational activities or hobbies. It is important to ensure that patients are fully informed as to the nature and likely occurrence of allergens and good detective work is required to scrutinise lifestyle and daily activities. Treatment with emollients and topical glucocorticoids helps but will not suffice if there is continued allergen exposure.

Asteatotic eczema

This occurs in dry skin and is common in the elderly. Low humidity caused by central heating, over-washing, diuretics and cholesterol-lowering drugs predispose. The most common site is the lower legs, and a 'crazy paving' pattern of fine fissuring on an erythematous background is seen. Emollients are a mainstay, in combination with topical glucocorticoids. Patients must be advised to use caution with flammable emollients and to avoid bathroom slippages related to emollients on floor and feet, and this is particularly relevant for the elderly.

Fig. 29.33 Allergic contact eczema. This was caused by the application of an antihistamine cream. The acute eczematous reaction and bilateral periorbital oedema are typical.

Gravitational eczema

Gravitational or stasis eczema occurs on the lower legs and is often associated with signs of venous insufficiency: oedema, loss of hair, induration, lipodermatosclerosis and ulceration. Emollients should be used and topical glucocorticoids should be applied to eczematous areas but not to ulcers. There is a high risk of sensitisation to topical preservatives (such as chlorocresol), antibiotics (such as neomycin) and bandages (such as rubber additives). Oedema and ulceration are treated by leg elevation and compression bandages (p. 1224).

Lichen simplex

Lichenification of eczema occurs secondary to chronic rubbing and scratching, and lichen simplex is a localised form. Common sites include the neck, lower legs and anogenital region. Treatment with emollients and very potent topical glucocorticoids may be required, often impregnated in tape or with occlusion.

Pompholyx

Intensely itchy vesicles and bullae occur on the palms, palmar surface and sides of the fingers and soles. Pompholyx may have several causes, which include atopic eczema, irritant and contact allergic dermatitis and fungal infection. The underlying cause must be treated or removed.

Psoriasis and other erythematous scaly eruptions

Psoriasis

Psoriasis is a chronic inflammatory, hyperproliferative skin disease. It is characterised by well-defined, erythematous scaly plaques,

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

particularly affecting extensor surfaces, scalp and nails, and usually follows a relapsing and remitting course. Psoriasis affects approximately 1.5–3% of Caucasians but is less common in Asian, South American and African populations. It occurs equally in both sexes and at any age; although it is uncommon under the age of 5 years, more than 50% of patients present before the age of 30 years. The age of onset follows a bimodal distribution, with an early-onset type in the teenage or early adult years, often with a family history of psoriasis, a more severe disease course and strong HLA association. The later-onset type is typically seen between 50 and 60 years, usually without a family history and with a less severe disease course.

Pathogenesis

Both genetic and environmental factors are important. Twin studies show concordance rates of 60–75% and 15–20% for psoriasis arising in monozygotic and dizygotic twins, respectively. The age at onset and severity of disease are often similar in familial cases. If one parent has psoriasis, the chance of a child being affected is about 15–20%; if both parents have the disease, this rises to 50% and the risk is increased further if a sibling also has the disease.

Variants of the HLA-C region within the major histocompatibility complex (MHC) on chromosome 6 account for almost half of the heritability of psoriasis. However, at least 70 other loci are implicated, with susceptibility variants that lie within or close to genes involved in regulating epidermal barrier function, antigen presentation, cytokine production, notably IL-13 and IL-23, T-cell differentiation (especially Th-1 and Th-17 subsets) and nuclear factor kappa B (NFκB) signalling. Some of the loci that predispose to psoriasis overlap with those implicated in Crohn's disease, ankylosing spondylitis and psoriatic arthritis.

Environmental triggers for psoriasis are shown in (Box 29.23). Although the theory is controversial, stress may exacerbate psoriasis in susceptible individuals and psoriasis is itself a cause of psychological stress. Likewise, there is a higher incidence of smoking and heavy alcohol consumption in patients with psoriasis but it is unclear whether this is cause or effect. There is also an association between psoriasis and metabolic syndrome (p. 730).

The histological changes of psoriasis are shown in Figure 29.34. The main features are:

- keratinocyte hyperproliferation and abnormal differentiation, leading to retention of nuclei in the stratum corneum
- inflammation, with a T-cell (mainly activated Th-1 and Th-17) lymphocytic infiltrate and release of cytokines and adhesion molecules, such as interleukins (including IL-17 and IL-23), TNF-α, IFN-γ and intercellular adhesion molecule (ICAM)-1
- vascular changes, with tortuosity of dermal capillary loop vessels and release of mediators, such as vascular endothelial growth factor (VEGF).

The initiating event for psoriasis is unknown. Disordered cell proliferation is a key feature; this was previously thought to be the primary event but is now considered to be secondary to inflammatory change. The transit time for keratinocyte migration, from basal layer to shedding from stratum corneum, is shortened from approximately 28 to 5 days, so that immature cells reach the stratum corneum prematurely. Proliferation rate is also increased in non-lesional skin but to a lesser extent. Similarly, even the clinically unaffected nails of patients with psoriasis grow more quickly than those of controls.

While immunological factors clearly play a key role in psoriasis, the precise mechanisms of disease initiation and the sequence of events that lead to psoriasis are not fully defined.

i 29.23 Exacerbating factors in psoriasis

Trauma

- Lesions can appear at sites of skin trauma, such as scratches or surgical wounds (Köbner isomorphic phenomenon)

Infection

- β-haemolytic streptococcal throat infections often precede guttate psoriasis (see Fig. 29.35C)
- Severe psoriasis may be the initial presentation of HIV infection

Sunlight

- Psoriasis may occur or worsen after sun exposure, mainly due to Köbnerisation at sites of sunburn or polymorphic light eruption

Drugs

- Antimalarials, β-adrenoceptor antagonists (β-blockers), lithium, NSAIDs and TNF-α inhibitors can exacerbate psoriasis
- 'Rebound' flare of psoriasis may occur after withdrawal of systemic glucocorticoids or potent topical glucocorticoids. Rebound psoriasis is often unstable and may be pustular

Psychological factors

- Anxiety and stress may exacerbate psoriasis in predisposed individuals

(NSAID = non-steroidal anti-inflammatory drug; TNF-α = tumour necrosis factor alpha)

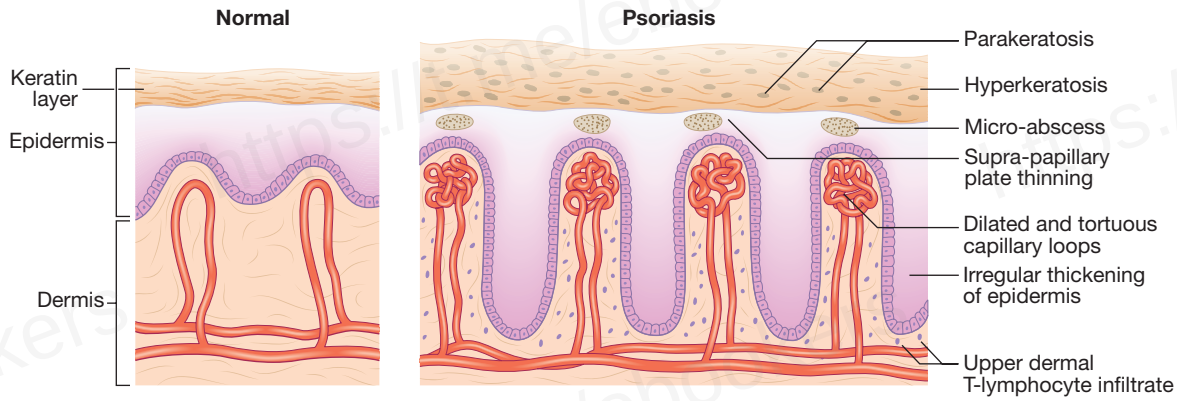

Fig. 29.34 The histology of psoriasis.

Fig. 29.35 Psoriasis. A Chronic plaque psoriasis, most prominent on extensor surfaces. B Nail involvement, with coarse pitting and separation from the nail plate (onycholysis). C Guttate psoriasis following a streptococcal throat infection. D Erythrodermic psoriasis.

Clinical features

Psoriasis has several different presentations (Fig. 29.35).

Plaque psoriasis

This is the most common presentation and usually represents more stable disease. The typical lesion is a raised, well-demarcated erythematous plaque of variable size (Fig. 29.35A). In untreated disease, silver/white scale is evident and more obvious on scraping the surface, which reveals bleeding points (Auspitz sign). The most common sites are the extensor surfaces, notably elbows and knees, and the lower back. Others include:

- *Scalp*: involvement is seen in approximately 60% of patients. Typically, easily palpable, erythematous scaly plaques are evident within hair-bearing scalp and there is clear demarcation at or beyond the hair margin. Occipital involvement is common and difficult to treat. Less often, fine diffuse scaling may be present and difficult to distinguish from seborrhoeic dermatitis. Involvement of other 'seborrhoeic sites', such as eyebrows, nasolabial folds and the pre-sternal area, is not uncommon and again may be confused with seborrhoeic dermatitis. Temporary hair loss can occur but permanent loss is unusual.
- *Nails*: involvement is common, with 'thimble pitting', onycholysis (separation of the nail from the nail bed, Fig. 29.35B), subungual hyperkeratosis and periungual involvement (p. 1210).
- *Flexures*: psoriasis of the natal cleft and submammary and axillary folds is usually symmetrical, erythematous and smooth, without scale.
- *Palms*: psoriasis of the palms can be difficult to distinguish from eczema.

Guttate psoriasis

This is most common in children and adolescents and is often the initial presentation (Fig. 29.35C). It may present shortly after a streptococcal throat infection and evolves rapidly. Individual lesions are droplet-shaped, small (usually less than 1 cm in diameter), erythematous, scaly and numerous. An episode of guttate psoriasis may clear spontaneously or with topical treatment within a few months, but UVB phototherapy is often required and is highly effective. Guttate psoriasis often heralds the onset of plaque psoriasis in adulthood.

Erythrodermic psoriasis

Generalised erythrodermic psoriasis is a medical emergency (Fig. 29.35D).

Pustular psoriasis

Pustular psoriasis may be generalised or localised. Generalised pustular psoriasis is uncommon, unstable and life-threatening. It will often emerge in the context of plaque disease and the onset is usually sudden, with large numbers of small, sterile pustules on an erythematous background, often merging into sheets, with waves of new pustules in subsequent days. The patient is usually febrile and systemically unwell, and this must be dealt with as a medical emergency (p. 1224). Unstable pustular psoriasis may be precipitated as a rebound phenomenon following either topical or systemic glucocorticoid use in a patient with psoriasis. Localised pustular psoriasis of the palms and soles (palmoplantar pustulosis) is more common, chronic and closely associated with smoking; small, sterile pustules and erythema develop and resolve with pigmentation and scaling (p. 1210). A localised form of sterile pustulosis of a few digits (acropustulosis) can also occur. It is unclear whether these localised forms of pustulosis are truly psoriatic.

Arthropathy

Between 5% and 10% of individuals with psoriasis develop an inflammatory arthropathy, which can take on a number of patterns (p. 1035). Joint involvement is more likely in patients with psoriatic nail disease.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Investigations

Skin biopsy is not usually required but may be performed if there is diagnostic doubt. An infection screen, particularly throat swab and/or serology for recent streptococcal infection, may be informative in guttate psoriasis. Assessment of impact on life using the DLQI and disease extent using PASI (Psoriasis Area and Severity Index, p. 1211) is essential. Due to the association of psoriasis with metabolic syndrome, comorbidities and cardiovascular risk factors should be assessed and managed (p. 730). HIV testing should be considered in severe or recalcitrant psoriasis.

Management

Counselling about diagnosis and management of skin involvement and other comorbidities is paramount. Information and services must be available for patients. Psoriasis can have a major impact on all aspects of life and this must not be under-estimated. Reassurance is also needed, as the condition is generally not life-threatening. Advice regarding reduction in risk factors for cardiovascular disease should be given (smoking cessation, reduction of alcohol intake, adequate exercise and a normal body mass index). Associated diseases, such as hypertension and diabetes, should be treated.

Patients need to be involved in their own management, as the disease is usually chronic and the benefit/risk profile of treatments must be discussed and tailored to individuals. The endpoint for treatment also needs to be discussed because complete disease clearance may not be practical or appropriate and patients vary considerably in their treatment requirements. Extent of disease and impact on quality of life must be taken into account. Patient adherence to topical and systemic therapies is essential and dependent on the treatment practicalities.

The treatment approach generally follows a stepwise progression, with treatment categories broadly summarised (Fig. 29.36).

Topical treatments, including emollients, are the first-line approach. Vitamin D receptor agonists, such as calcipotriol, calcitriol and tacalcitol, are often used as first-line topical treatment. The mechanism of action includes increased differentiation and reduction of proliferation, reducing plaque scale and thickness. Calcipotriol is most widely used and can be applied once to twice daily; if less than 100 g of ointment is used each week, there is no risk of hypercalcaemia. Vitamin D analogues can cause irritation but this is often temporary. Topical glucocorticoids may be required in the management of psoriasis, particularly at flexural or facial sites, and may be alternated or combined with vitamin D analogues. However, safe, appropriately supervised and judicious use is necessary, with awareness of the potential risk of rebound unstable or pustular psoriasis with glucocorticoid over-use or sudden cessation. Dithranol and coal tar are effective and, like vitamin D analogues, work by increasing differentiation and inhibiting proliferation. Although often effective, they are messy and time-consuming. Modified versions of Goeckerman's regimen (the combination of coal tar and UVB) are still used, but coal tar has a characteristic odour and can be irritant. Short-contact dithranol therapy at relatively high concentrations applied for 15–30 minutes can be used but causes brown staining of skin and purple discoloration of light hair. In recent years, efforts have been made to improve the tolerance of tar and dithranol preparations, but at reduced efficacy. Overall, the use of tar and dithranol has reduced in recent years but they can be highly effective in selected patients.

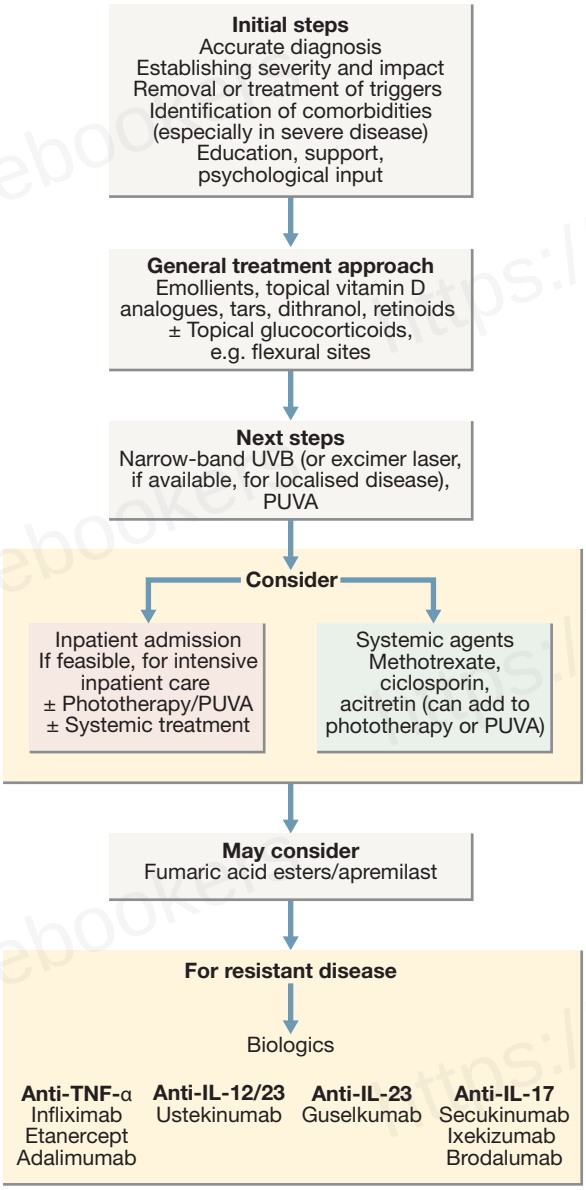

Fig. 29.36 General management approaches: psoriasis. (IL = interleukin; PUVA = psoralen–ultraviolet A; TNF-α = tumour necrosis factor alpha; UVB = ultraviolet B)

If topical treatment is insufficient, then UVB phototherapy or PUVA should usually be the next step. If the patient continues to have active disease or early recurrence, then the addition of systemic retinoid such as acitretin to UVB or PUVA can be effective. Alternatively, immunosuppressants, such as methotrexate or ciclosporin, may be required. For difficult treatment-resistant disease, fumaric acid esters, apremilast and biologics should be considered (p. 1005 and Fig. 29.37).

The active component of fumaric acid ester therapy is dimethyl fumarate and efficacy in psoriasis has been confirmed. Common adverse effects are flushing and diarrhoea. Lymphopenia is also expected at effective doses. Apremilast is indicated for moderate to severe psoriasis resistant to standard measures. Of the biological agents, the anti-TNF-α agents (etanercept, infliximab, adalimumab or golimumab), ustekinumab (an inhibitor

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

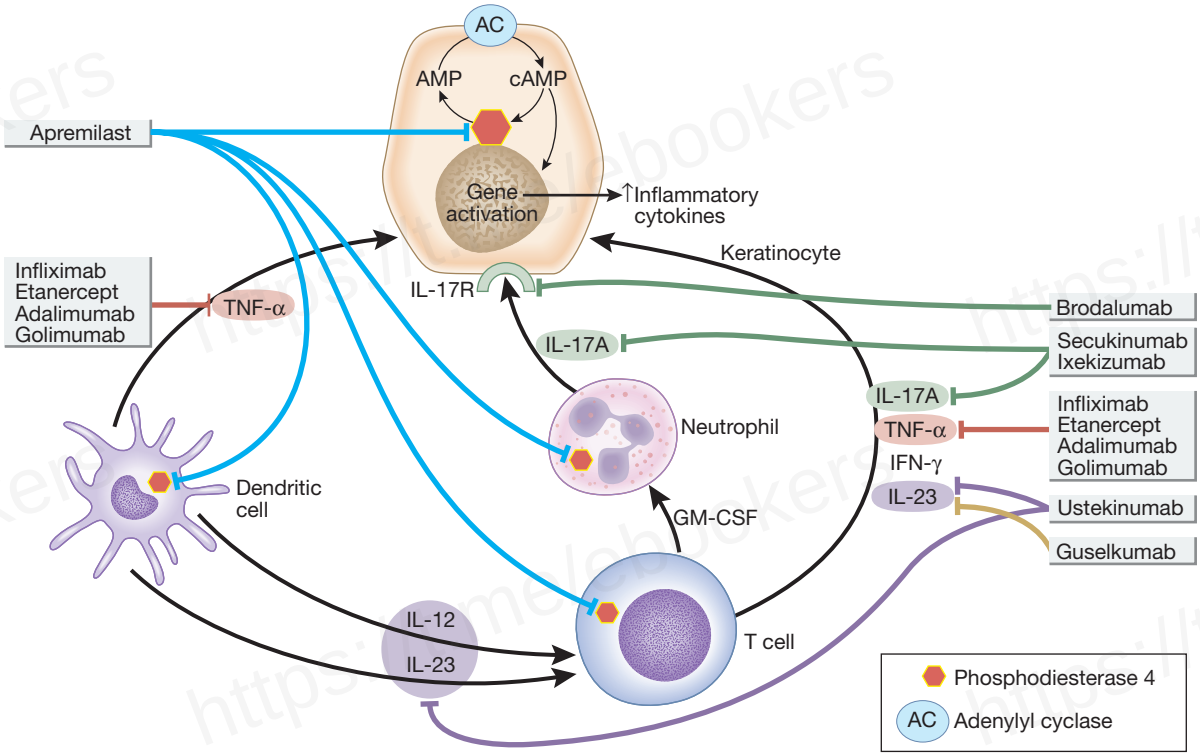

Fig. 29.37 Developments in understanding of key pathways and drug targets in psoriasis. Other drug targets are also under development, such as Janus kinase (JAK) inhibitors (tofacitinib and baricitinib) and sphingosine-1-phosphate receptor (S1PR1) antagonists (ponesimod). This diagrammatic image is illustrative of key pathways and drug targets but is not comprehensive. (AMP = adenosine monophosphate; cAMP = cyclic adenosine monophosphate; GM-CSF = granulocyte macrophage colony-stimulating factor; IL = interleukin; TNF-α = tumour necrosis factor alpha)

of IL-12 and IL-23), guselkumab (an IL-23 inhibitor) and secukinumab or ixekizumab (an IL-17 inhibitor) may all be effective and this is a rapidly evolving field. More details of the mechanisms of action and adverse effects of these agents are provided on page 1006.

Individualised management is essential. For example, a patient with localised plaque psoriasis on elbows, knees and sacrum should respond to topical treatment only, whereas someone with guttate psoriasis is likely to need phototherapy as a first-line approach because of difficulties in topical drug application in extensive disease. A patient with extensive chronic plaque psoriasis and significant arthropathy would be better suited to a systemic drug, such as methotrexate, than phototherapy, which would be unlikely to improve joint symptoms. Thus, whilst a stepwise general approach to management (see Fig. 29.36) may offer guidance, the correct choice for any given patient must be determined on an individual basis.

Pityriasis rosea

This is an acute, self-limiting exanthem that particularly affects young adults and occurs worldwide, with a slight female predominance. It usually presents in spring and summer, although no infective agent has been identified and its aetiology is unknown. It is characterised by the appearance of a 'herald patch', an oval lesion (1–2 cm) with a central pinkish (salmon-coloured) centre, a darker periphery and a characteristic collarette of scale. It is followed 1–2 weeks later by a widespread papulosquamous eruption, which is typically arranged in a symmetrical 'fir tree' pattern on the trunk. Individual lesions also have a collarette of scale. An inverse variant with flexural involvement can occur. Mucosal involvement is rare. There is a small risk of recurrence. Symptomatic relief can be achieved with emollients and mild topical glucocorticoids. Post-inflammatory hyperpigmentation can supervene, particularly in darker skin types.

Pityriasis lichenoides chronica

This is rare but typically presents within the first three decades of life. The aetiology is unclear but the condition is part of a spectrum and remits spontaneously. The more acute variety (pityriasis lichenoides et varioliformis acuta, PLEVA) presents as crops of papules that rapidly evolve with central necrosis, each attack lasting up to 3 months. The more chronic variety presents as a persistent, widespread, scaly eruption. Characteristically, lesions are brown papules with a mica-like scale ('cornflake'). The condition fluctuates but can persist for months or years. Emollients, topical glucocorticoids and long-term oral erythromycin can occasionally be helpful. UVB phototherapy or PUVA is usually effective, although recurrences are high.

Drug eruptions

It is essential to consider a drug cause in anyone presenting with an erythematous maculopapular or papulosquamous eruption, and a careful drug history is critical (p. 1265). Exfoliation ('peeling') and post-inflammatory hyper- or, less commonly, hypopigmentation can occur.

Other causes

Secondary syphilis (p. 337), pityriasis versicolor (p. 1240) and fungal infection with *Tinea corporis* (p. 1240) can all cause an

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

erythematous papulosquamous rash and must be considered in the differential diagnosis of erythematous papulosquamous rashes.

Lichenoid eruptions

Lichen planus

Lichen planus occurs worldwide. It typically presents as a pruritic rash; the mucosae, hair and nails may also be involved.

Pathogenesis

The disease probably has an autoimmune basis since there is an association with inflammatory bowel disease, primary biliary cirrhosis, autoimmune hepatitis, hepatitis B and C, alopecia areata, myasthenia gravis (p. 1141) and thymoma. There are also similarities with graft-versus-host disease (GVHD, p. 937). Lichen planus can occasionally occur in families and possible HLA associations have been reported but there is no clear inheritance pattern. On skin biopsy, characteristic histological changes include hyperkeratosis, basal cell degeneration and a heavy, band-like T-lymphocyte infiltrate in the papillary dermis, with affinity for the epidermis (epidermotropism). The dermo-epidermal junction has a 'sawtooth' appearance.

Clinical features

Lichen planus occurs in both sexes and at any age, although usually between 30 and 60 years. It generally presents on the distal limbs, most commonly on the flexural aspects of the wrists and forearms (Fig. 29.38), and on the lower back. It is intensely itchy and lesions are violaceous, shiny, flat-topped, polygonal papules, with a characteristic fine lacy, white network on the surface (Wickham's striae). New lesions may appear at sites of skin trauma (Köbner phenomenon) and the rash may become generalised. Individual lesions may last for many months and can become hypertrophic and modified by scratching, particularly on the lower legs. The eruption usually remits over months but can become chronic, particularly with hypertrophic disease. Post-inflammatory pigmentary change is common, particularly in darker skin types. Mucous membrane involvement occurs in 30–70% of patients, usually as a network of white, lacy striae on the buccal mucosae (p. 1210) and tongue. These oral changes are often asymptomatic and should be sought on examination. Genital and other mucosal surfaces can also be affected (pp. 334 and 336). Nail involvement occurs in about 10% and can range from longitudinal ridging to a destructive nail dystrophy, scarring (pterygium) and nail loss (p. 1261). Scalp involvement usually presents as an inflammatory scarring alopecia, often with tufting of residual hairs. The classical presentation of lichen planus is unmistakable, but less common atypical variants, which include annular, atrophic, actinic, linear, bullous, follicular, pigmented and ulcerative types, can be a diagnostic challenge.

Fig. 29.38 Lichen planus. Violaceous papules on the flexural aspect of forearm, arising at a site of minor linear trauma (Köbner phenomenon).

Investigations

A skin biopsy should be performed if there is diagnostic doubt. A careful drug history must be taken, as, although the classical presentation of lichen planus is usually 'idiopathic', the main differential is a drug-induced lichenoid reaction (see below). Other differential diagnoses include psoriasis, pityriasis rosea, pityriasis lichenoides chronica and secondary syphilis. Screening for underlying disease, such as hepatitis, must be considered.

Management

The condition is usually self-limiting, although rarely it may persist for years, particularly oral lichen planus. Treatment is symptomatic and potent local glucocorticoids (topical, with occlusion or by injection for hypertrophic disease, or as oral rinse for oral involvement) may help the intense itch; short courses of systemic glucocorticoids are sometimes required for extensive disease. UVB, PUVA or UVA1 can be beneficial and, for recalcitrant disease, retinoids or immunosuppressants, such as ciclosporin or methotrexate, may be needed. A low but significant risk of malignant transformation exists with persistent oral and genital disease, so active treatment, surveillance and smoking cessation are important.

Drug-induced lichenoid eruptions

Drug-induced lichenoid reactions that are clinically and histologically difficult to distinguish from idiopathic lichen planus are important to identify. The likely culprits are gold, quinine, proton pump inhibitors, sulphonamides, penicillamine, antimalarials, antituberculous drugs, thiazide diuretics, β-blockers, angiotensin-converting enzyme (ACE) inhibitors, NSAIDs, sulphonylureas, lithium and dyes in colour developers (see Box 29.35, p. 1266).

Graft-versus-host disease

In the acute stage of graft-versus-host disease (GVHD, p. 937), there is a distinctive dermatitis associated with hepatitis. After about 3 months, chronic GVHD can present with a lichenoid eruption on the palms, soles, face and upper trunk. Progressive sclerodermatous skin thickening, associated with pigmentary changes, may lead to contractures and limited mobility.

Urticaria

Urticaria ('hives') is caused by localised dermal oedema secondary to a temporary increase in capillary permeability. If oedema involves subcutaneous or submucosal layers, the term angioedema is used.

Clinical features

Acute urticaria may be associated with angioedema of the lips, face, tongue, throat and, rarely, wheezing, abdominal pain, headaches and even anaphylaxis (p. 75). Urticaria present for less than 6 weeks is considered to be acute, and chronic if it continues for more than 6 weeks. Individual weals (**definition**: evanescent discrete areas of dermal oedema, often centrally white due to masking of local blood supply by fluid; weals can

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

be papules, macules, patches and plaques – Fig. 29.39) last for less than 24 hours; if they persist, urticarial vasculitis needs to be considered. Clarification of the duration of urticaria can be achieved by drawing around the weal and re-assessing 24 hours later. History-taking should probe for possible causes, including medications (Box 29.24). Physical triggers can also be assessed in challenge testing, such as eliciting dermographism or pressure testing. Enquiry about family history and medication, particularly ACE inhibitors, is important in angioedema. Examination may be unremarkable or weals may be evident (Fig. 29.39). The skin should be stroked firmly with an orange stick in order to ascertain whether dermographism is present or not.

Mast cell degranulation and release of histamine and other vasoactive mediators is the basis of urticaria (Fig. 29.40). Chronic spontaneous urticaria (previously called 'chronic idiopathic' or 'chronic ordinary' urticaria) is the most common chronic urticaria and has an autoimmune pathogenesis in some cases.

Fig. 29.39 Urticaria. Erythema, reflecting dilated dermal vessels, and oedema (with upper dermal oedema obscuring the erythema centrally) are evident. Note the absence of epidermal changes.

Investigations

Investigations should be guided by the history and possible causes but are often negative, particularly in acute urticaria. Some or all of the following may be appropriate:

- *Full blood count*: eosinophilia in parasitic infection or drug cause.
- *Erythrocyte sedimentation rate (ESR) or plasma viscosity*: elevated in vasculitis.
- *Urea and electrolytes, thyroid and liver function tests, iron studies*: may reveal an underlying systemic disorder.
- *Total IgE and specific IgE to possible allergens*: shellfish, peanut, house-dust mite. Particularly relevant if there is angioedema.
- *Autoantibodies, particularly antinuclear factor*: positive in systemic lupus erythematosus (SLE) and often positive in urticarial vasculitis. Other autoimmune diseases, such as

i 29.24 Causes of urticaria

Acute and chronic urticaria

- Autoimmune: due to antibodies that cross-link the IgE receptor on mast cells
- Allergens in foods and inhalants
- Contact allergens: latex, animal saliva
- Drugs: see Box 29.35 (p. 1266)
- Physical stimuli: heat, cold, pressure, sun, sweat, water
- Infections: intestinal parasites, hepatitis
- Others: SLE, pregnancy, thyroid disease
- Idiopathic: chronic spontaneous urticaria and angioedema

Urticarial vasculitis

- Hepatitis B, SLE, idiopathic

(IgE = immunoglobulin E; SLE = systemic lupus erythematosus)

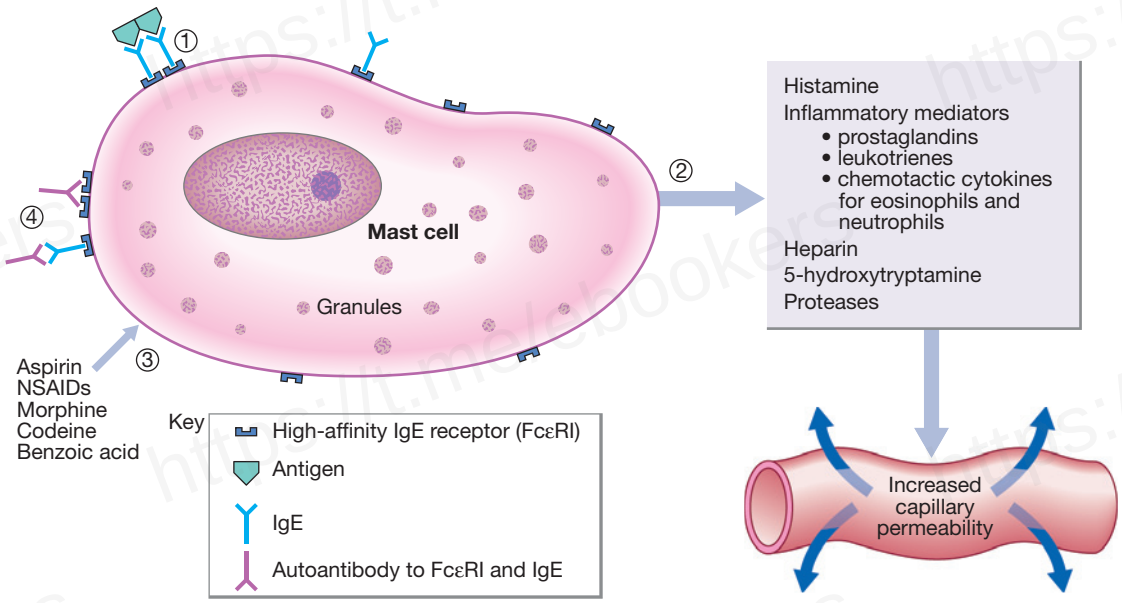

Fig. 29.40 Pathogenesis of urticaria. Mast cell degranulation occurs in a variety of ways. (1) Type I hypersensitivity causes degranulation. (2) Spontaneous mast cell degranulation in chronic urticaria. (3) Chemical mast cell degranulation. (4) Autoimmunity, with IgE antibodies directed against IgE receptors or IgE itself. Histamine and the leukotrienes are especially relevant mediators in urticaria. Heparin release is probably not a major factor in urticaria but plays a role in the osteoporosis that can occur in systemic mastocytosis. (IgE = immunoglobulin E; NSAID = non-steroidal anti-inflammatory drug)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

rheumatoid arthritis and autoimmune hepatitis or thyroid disease, may be associated.
- *Complement C_3 and C_4 levels*: if these are low due to complement consumption, *C_1 esterase inhibitor* activity should be measured.
- *Infection screen*: hepatitis screen and HIV may be indicated.
- *Skin biopsy*: if urticarial vasculitis is suspected.
- *Challenge tests*: to confirm physical urticarias, such as dermographism, pressure, heat, cold.

Management

Removal or treatment of any trigger is essential, although this may not be identified in the majority of cases. Urticaria may be precipitated by aspirin, NSAIDs, codeine and opioids, and it is advisable to suggest alternatives such as paracetamol. In chronic urticaria, non-sedating antihistamines, such as fexofenadine, loratadine or cetirizine, are usually beneficial. If there is lack of response after 2 weeks, an alternative non-sedating antihistamine should be used and an H_2-blocker, such as cimetidine or ranitidine, can be added. Mast cell stabilisers or leukotriene receptor antagonists, such as montelukast, can be used for more recalcitrant disease. For chronic urticaria, narrowband UVB phototherapy is valuable and has proven efficacy. Systemic glucocorticoids are widely prescribed for urticaria but are not indicated in the majority of cases. If systemic glucocorticoids are used, efficacy may be seen only at relatively high doses and they are appropriate only for occasional short courses in the acute setting, usually in association with angioedema. Patients with a history of life-threatening anaphylaxis, as in peanut or wasp sting allergy, should carry a self-administered adrenaline (epinephrine) injection kit. The management of anaphylaxis and hereditary angioedema is discussed on pages 76 and 87. The IgE monoclonal antibody omalizumab may be effective in patients with severe recalcitrant urticaria.

Bullous diseases

Blistering can occur at any level in the skin and there are a variety of different presentations, depending on the underlying defect and level of involvement. Knowledge of the molecular basis of many blistering disorders has advanced considerably through understanding of the basic processes of cell adhesion and studies of rare genetic blistering disorders, particularly epidermolysis bullosa (Box 29.25). This section concentrates on primary blistering skin diseases.

i 29.25 Classification of epidermolysis bullosa

Type	Mode of inheritance	Level of blister*	Abnormality
Simple	Autosomal dominant	Epidermal basal cell	Keratins 5 and 14
Junctional	Autosomal recessive	Lamina lucida	Laminin-5 and $\alpha_6\beta_4$ integrin
Dystrophic	Autosomal dominant and recessive	Dermis below lamina densa	Collagen VII

*See Figure 29.1 (p. 1213).

Toxic epidermal necrolysis

Toxic epidermal necrolysis (TEN) is a medical emergency, as the extensive mucocutaneous blistering is associated with a high mortality rate. It is usually drug-induced (see Box 29.35, p. 1266), with anticonvulsants, sulphonamides, sulphonylureas, NSAIDs, allopurinol and antiretroviral therapy often implicated. Usually 1–4 weeks after drug commencement, the patient becomes systemically unwell and often pyrexial. Erythema and blistering develop, initially on the trunk but rapidly involving all skin; an early warning sign is cutaneous pain. Sheets of blisters coalesce and denude, and the underlying skin is painful and erythematous (Fig. 29.41). Gentle lateral pressure on stroking the skin results in epidermal detachment (Nikolsky sign), demonstrating the severity of skin fragility. Mucous membrane involvement and blistering are usual. Blistering of skin and mucosae may be haemorrhagic. A disease severity score (Box 29.26) is used to predict outcome. The main differential diagnosis is staphylococcal scalded skin syndrome (p. 1236), although the diagnosis is usually obvious in an adult patient with a culprit drug. There is often overlap with Stevens–Johnson syndrome and targetoid lesions, especially on palms and soles, may be evident. Skin

Fig. 29.41 Toxic epidermal necrolysis. Note the extensive erythema, oedema and epidermal loss secondary to carbamazepine.

i 29.26 Disease severity score for toxic epidermal necrolysis: SCORTEN

Factor
- Age >40 years
- Heart rate >120 beats/min
- Cancer or haematological malignancy
- Involved body surface area >10%
- Blood urea >10 mmol/L (28 mg/dL)
- Serum bicarbonate <20 mmol/L
- Blood glucose ≥14 mmol/L (252 mg/dL)

Mortality rates
- 0–1 factor present = 3%
- 2 factors = 12%
- 3 factors = 35%
- 4 factors = 58%
- ≥5 factors = 90%

From Bastuji-Garin S, Fouchard N, Bertocchi M, et al. SCORTEN: a severity-of-illness score for toxic epidermal necrolysis. J Invest Dermatol 2000; 115:149–153.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

snip may allow early diagnosis. If there is diagnostic doubt, then full-thickness skin biopsy should be undertaken for histology and direct immunofluorescence in order to exclude immunobullous or other diagnoses.

Identification and discontinuation of the causative drug are essential. Sepsis and multi-organ failure are major risks. Intensive care in a dedicated dermatology ward or intensive care or burns unit is of paramount importance. Treatment is supportive, with regular sterile dressings and emollients, careful attention to fluid balance and treatment of infection if it develops. Urethral and ocular involvement is common and must be looked for and treated symptomatically. Ocular and urethral scarring can be problematic in survivors. There is no conclusive evidence that intravenous immunoglobulins, systemic glucocorticoids or ciclosporin improve outcomes and survival.

Immunobullous diseases

There are various subtypes of immunobullous disease that affect patients of different ages and have clinical characteristics (Box 29.27). The key investigation is an elliptical biopsy taken from the edge of a recent blister (Box 29.28). The sample is halved: one half is put in formalin for subsequent histology, while the other is sent fresh for direct immunofluorescence. Serum should also be sent for indirect immunofluorescence in suspected immunobullous disease (p. 1215).

Bullous pemphigoid

Bullous pemphigoid (BP) is the most common immunobullous disease and occurs worldwide. It is a disease of the elderly, with an average age of onset of 65 years; males and females are equally affected.

Pathogenesis

The disease is caused by autoantibodies (BP-230 and BP-180) directed against the hemi-desmosomal BP antigens, BPAg-1 (intracellular) and BPAg-2 (transmembranous type XVII collagen), respectively. Antibody–antigen binding initiates complement activation and inflammation, with hemi-desmosomal damage and subepidermal blistering.

Clinical features

There is often a lengthy prodrome of an itchy, urticated, erythematous rash prior to the development of tense bullae (Fig. 29.42A). Milia (**definition**: small epidermal keratin cysts) may develop due to basement membrane disruption. Mucosal involvement is uncommon.

i 29.27 Age of onset in immunobullous skin disorders

Disease	Age
Pemphigus vulgaris	40–60 years
Pemphigus foliaceus	Any age (endemic form in parts of Brazil and South Africa, from teenage years on)
Bullous pemphigoid	Sixties and over
Dermatitis herpetiformis	Young, associated with coeliac disease
Linear IgA disease	Any age
Pemphigoid gestationis	Pregnant females
Epidermolysis bullosa acquisita	Any age
Bullous lupus erythematosus	Young black females

i 29.28 Clinical and investigation findings in the immunobullous disorders

Disease	Site of blisters	Nature of blisters	Mucous membrane involvement	Antigen	Circulating antibody (indirect IF)	Fixed antibody (direct IF)
Pemphigus vulgaris	Trunk, head	Flaccid, fragile, many erosions	100%	Desmoglein-1 and 3 (120 kD)	IgG	IgG, C_3 intercellular (epidermal)
Pemphigus foliaceus	Trunk	Often not present, multiple erosions, may mimic dermatitis	No	Desmoglein-1	IgG	IgG, C_3 intercellular (epidermal)
Bullous pemphigoid	Trunk, flexures and limbs	Tense, milia as blisters resolve	Occasional	BP-230 and 180	IgG (70%)	IgG, C_3 at BMZ
Dermatitis herpetiformis	Elbows, lower back, buttocks	Excoriated and often not present	No	Unknown	Anti-endomysial and tissue transglutaminase	Granular IgA in papillary dermis
Linear IgA disease	Widespread	Tense, often annular configuration, 'string of beads'	Frequent	Unknown	50% have low titres of circulating antibody	Linear IgA at BMZ
Pemphigoid gestationis	Periumbilical and limbs	Tense, milia as blisters resolve	Rare	Collagen XVII (part of hemi-desmosome, BP-180)	Circulating antibodies to BP-180 (type XVII collagen) (and BP-230)	C_3 at BMZ
Epidermolysis bullosa acquisita	Widespread	Tense, scarring, milia	Common (50%)	Type VII collagen	IgG (anti-type VII collagen)	IgG at BMZ
Bullous lupus erythematosus	Widespread	Tense	Rare	Type VII collagen	Anti-type VII collagen	IgG, IgA, IgM at BMZ

(BMZ = basement membrane zone; IF = immunofluorescence; Ig = immunoglobulin)

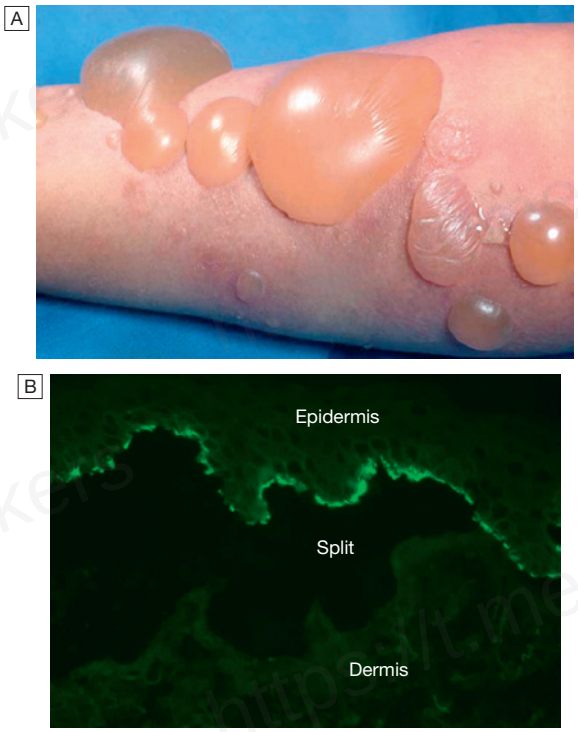

Fig. 29.42 Bullous pemphigoid. A Large, tense, unilocular blisters. B Immunofluorescence on salt-split skin, showing a subepidermal blister and linear IgG and C3 deposition at the basement membrane zone.

Investigations

The diagnosis can be made by skin biopsy, which shows subepidermal blistering with an eosinophil-rich inflammatory infiltrate. Direct immunofluorescence demonstrates the presence of IgG and C3 at the basement membrane (Fig. 29.42B). Indirect immunofluorescence may show positive titres of circulating anti-epidermal antibodies. Distinction from epidermolysis bullosa acquisita requires immunofluorescence studies using the patient's serum on salt-split skin. In BP, the immunoreactants localise to the epidermal side (hemi-desmosome) of split skin, whereas in epidermolysis bullosa acquisita they localise to the base of the split (type VII collagen/anchoring fibrils).

Management

Very potent topical glucocorticoids are effective and may be sufficient in frail elderly patients; they need to be applied to all sites, however, and not just lesional skin. Tetracyclines, such as doxycycline, have an important role and may limit the use of systemic glucocorticoids. However, most patients with extensive disease require systemic glucocorticoids (0.75 mg/kg/day or less), often combined with immunosuppressants as glucocorticoid-sparing agents. In severe refractory disease, other therapies, such as intravenous immunoglobulin or rituximab, are sometimes used but are of unproven efficacy. The condition often burns out over a few years.

Pemphigus

Pemphigus is less common than BP and patients tend to be younger.

Pathogenesis

The cause is IgG1 and IgG4 autoantibodies, directed against desmogleins-1 and 3, resulting in intra-epidermal blistering. The syndrome may occur spontaneously or be secondary to drugs such as penicillamine or captopril and underlying malignancy (paraneoplastic pemphigus). Pemphigus foliaceus is a very superficial form, in which antibodies are directed against desmoglein-1 only and affect just the most superficial epidermis.

Clinical features

Skin and mucosae are usually involved, although disease may be restricted to mucosae only, which may be severely affected. Due to the higher level of split within the epidermis, the blisters are flaccid, easily ruptured and often not seen intact. Erosions are common and the Nikolsky sign is positive. The trunk is usually affected. The condition is associated with significant morbidity and mortality.

Investigations

The diagnosis can be made by skin biopsy, which shows intra-epidermal blistering and acantholysis, with positive direct immunofluorescence for IgG (usually IgG1 or IgG4) and C3 at the periphery of keratinocytes, giving a 'chicken wire' appearance within the epidermis. The titres of circulating epidermal autoantibodies can also be used to monitor disease activity. Investigations should screen for associated autoimmune disease or malignancy if paraneoplastic pemphigus is suspected.

Management

Pemphigus is more difficult to treat than BP and high-dose systemic glucocorticoids such as prednisolone (0.5–1.0 mg/kg/day) are usually required. Azathioprine and cyclophosphamide are most often used as glucocorticoid-sparing agents but a range of other immunosuppressants may be considered for severe recalcitrant disease, including methotrexate, ciclosporin, mycophenolate mofetil, intravenous immunoglobulins, plasma exchange, extracorporeal photopheresis and rituximab. Often, long-term treatment is required to prevent relapse.

Dermatitis herpetiformis

Dermatitis herpetiformis (DH) is an autoimmune blistering disorder that is strongly associated with coeliac disease (CD). While fewer than 10% of individuals with CD develop DH, almost all patients with DH have evidence of partial villous atrophy on intestinal biopsy, even if they have no gastrointestinal symptoms (p. 806). It is unclear why some CD patients develop DH and others do not. Although DH is a bullous disease, intact vesicles and blisters are seldom seen, as the condition is so pruritic that excoriations on extensor surfaces of arms, knees, buttocks, shoulders and scalp may be the only signs.

The diagnosis can be made by skin biopsy, which shows subepidermal vesiculation in the dermal papillae and a neutrophil- and eosinophil-rich infiltrate. Direct immunofluorescence shows granular IgA in the papillary dermis. Anti-endomysial antibodies and tissue transglutaminase should be assessed and jejunal biopsy undertaken if indicated. The condition usually responds to a gluten-free diet but, if not, dapsone can also be used.

Linear IgA disease

This occurs in children (chronic bullous disease of childhood) and adults, and is usually self-limiting, although it can be active for a few years. Drugs, notably vancomycin, can be a secondary cause. Blisters

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

can arise on erythematous, urticated or otherwise normal-looking skin and often form an annular configuration at the edge of the lesion: 'clusters of jewels' (herpetiform) and 'string of beads' (annular/polycyclic). Mucosal involvement is common and ophthalmology input important, as corneal scarring is a risk with longstanding disease. Linear IgA is seen at the basement membrane on direct immunofluorescence and localises to either roof or floor of salt-split skin. Dapsone, sulfapyridine, prednisolone, colchicine or intravenous immunoglobulin may be effective.

Epidermolysis bullosa acquisita

This chronic blistering disease affects skin and mucosae, and scarring, hair loss and nail dystrophy may be problematic. Blisters often follow trauma and milia develop. It can be very difficult to distinguish from other immunobullous diseases, such as bullous pemphigoid. It is caused by an IgG antibody to type VII collagen, which provokes subepidermal blistering and a mixed inflammatory infiltrate, although the latter may not be prominent. Direct immunofluorescence on perilesional skin shows IgG and C3 at the dermo-epidermal junction and pattern analysis may be helpful in distinction from bullous pemphigoid. Indirect immunofluorescence microscopy on salt-split normal human skin typically shows IgG and IgA in the floor of the artificially induced blister, whereas in BP antibody localisation would be to the roof of the blister. Epidermolysis bullosa acquisita is very difficult to treat, as it often does not respond well to immunosuppressants. Mainstays of treatment include systemic glucocorticoids in combination with dapsone or colchicine. Other immunosuppressive approaches may be required and include ciclosporin, azathioprine, immunoglobulins, plasmapheresis and rituximab. The condition may be associated with inflammatory bowel disease, rheumatoid arthritis, multiple myeloma and lymphoma, and thus associated comorbidities should be sought.

Porphyria cutanea tarda and pseudoporphyria

These conditions may also cause blistering (see Boxes 29.9 and 29.35, pp. 1221 and 1266). Porphyria is discussed in more detail on page 378.

Pigmentation disorders

Decreased pigmentation

Disorders causing hypopigmentation and/or depigmentation include:

- vitiligo
- albinism
- pityriasis alba: depigmented areas on the face, particularly in children, with or without scale and usually considered to be eczematous
- pityriasis versicolor (p. 1240): hypopigmentation or, less commonly, hyperpigmentation can occur
- idiopathic guttate hypomelanosis: multiple small areas of depigmentation arising in chronically sun-exposed skin
- rarely, phenylketonuria (p. 369) and hypopituitarism.

Vitiligo

Vitiligo is an acquired condition affecting 1% of the population worldwide. Focal loss of melanocytes results in the development of patches of hypopigmentation. A positive family history of vitiligo is relatively common in those with extensive disease, and this type is also associated with other autoimmune diseases. Trauma and sunburn may (through the Köbner phenomenon) precipitate the appearance of vitiligo. It is thought to be the result of cell-mediated autoimmune destruction of melanocytes but why some areas are targeted and others are spared is unclear.

Clinical features

Generalised vitiligo is often symmetrical and involves hands, wrists, feet, knees and neck, as well as areas around body orifices (Fig. 29.43). The hair of the scalp, beard, eyebrows and lashes may also depigment. Segmental vitiligo is restricted to one part of the body but not necessarily a dermatome. The patches of depigmentation are sharply defined, and in Caucasians may be surrounded by hyperpigmentation. Spotty perifollicular pigment may be seen within the depigmentation and is often the first sign of repigmentation. There is no history or evidence of inflammation within the patches, which may be helpful in distinguishing vitiligo from post-inflammatory hypopigmentation. Sensation in the depigmented patches is normal (unlike in tuberculoid leprosy, p. 267). Wood's light examination enhances the contrast between pigmented and non-pigmented skin. The course is unpredictable but most patches remain static or enlarge; a few repigment spontaneously.

Management

Protecting the patches from excessive sun exposure with clothing or sunscreen may be helpful to avoid sunburn. Camouflage cosmetics may be beneficial, particularly in those with dark skin. In fair skin, photoprotection and cosmetic cover may be all that is required. Very potent or potent topical glucocorticoids have limited efficacy with respect to repigmentation. Topical pimecrolimus or tacrolimus may also have a role as a glucocorticoid-sparing agent. Phototherapy with narrowband UVB or PUVA can also be used. Narrowband UVB is the most effective repigmentary treatment available for generalised vitiligo, but even very prolonged courses often do not produce a satisfactory outcome. The absence of leucotrichia (white hairs in the area of vitiligo) and the presence of a trichrome pattern (three colours – normal skin colour, hypopigmentation and depigmentation) are good prognostic features. Vitiligo on the face, trunk and proximal limbs is more likely to respond than that on hands and feet.

Fig. 29.43 Vitiligo. Symmetrical localised patches of depigmented skin.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Exceptionally, depigmentation of normal non-lesional skin or a surgical approach with autologous melanocyte transfer, using a range of techniques including split-skin grafts and blister roof grafts, is sometimes used on dermabraded recipient skin in specific severe cases.

The impact of vitiligo differs markedly between populations. In the Indian subcontinent, the effects are more readily discernible than in pale-skinned individuals in northern Europe. Depigmentation is also seen in leprosy, which means that individuals with vitiligo are often stigmatised. The emotional impact of vitiligo may be immense; psychological support is essential and is important in conveying realistic expectations of possible treatment approaches.

Oculocutaneous albinism

Albinism results from a range of genetic abnormalities that lead to reduced melanin biosynthesis in the skin and eyes; the number of melanocytes is normal (in contrast to vitiligo). Albinism is usually inherited as an autosomal recessive trait and there are several different types and presentations.

Type 1 albinism is due to a defect in the tyrosinase gene, whose product is rate-limiting in the production of melanin. Affected individuals have an almost complete absence of pigment in the skin and hair at birth, with consequent pale skin and white hair, and failure of melanin production in the iris and retina. Patients have photophobia, poor vision not correctable with refraction, rotatory nystagmus, and an alternating strabismus associated with abnormalities in the decussation of nerve fibres in the optic tract.

A second form of albinism is due to a defect in the *P* gene, which encodes an ion channel protein in the melanosome. Patients may have gross reduction of melanin in the skin and in the eyes, but may be more mildly affected than type 1 albinos. Establishing the subtype of albinism requires genetic analysis, as there is considerable phenotypic heterogeneity.

Oculocutaneous albinos are at grossly increased risk of sunburn and skin cancer. In equatorial regions, many die from squamous cell carcinoma or, more rarely, melanoma in early adult life. Interestingly, they may develop pigmented melanocytic naevi and freckle in response to sun exposure.

Management

Strict photoprotection (p. 1221), with sun avoidance (including occupational exposure), clothing, hats and sunscreens, is important. Early diagnosis and treatment of skin tumours is essential.

Increased pigmentation

- *Diffuse hyperpigmentation*: most commonly due to hypermelanosis but other pigments may be deposited in the skin, such as orange discoloration with carotenaemia and bronze with haemochromatosis (p. 895).
- *Endocrine pigmentation*: may occur in several conditions. Melasma (chloasma) describes discrete patches of facial pigmentation that occur in pregnancy and in some women taking oral contraceptives. The mechanism for this localised increased hormonal sensitivity is unknown. Diffuse pigmentation, sometimes worse in the skin creases and mucosae, may be a feature of Addison's disease (p. 671), Cushing's syndrome (p. 666), Nelson's syndrome (p. 669) and chronic renal failure due to increased levels of pituitary melanotrophic peptides, including adrenocorticotrophic hormone (ACTH; p. 669).

i 29.29 Drug-induced pigmentation

Drug	Appearance
Amiodarone	Photo-exposed sites, slate-grey
Arsenic	Diffuse bronze pigmentation Raindrop depigmentation
Bleomycin	Usually flexural, brown
Busulfan	Diffuse brown
Chloroquine	Photo-exposed sites, blue-grey
Clofazimine	Red
Mepacrine	Yellow
Minocycline	Temples, shins, gingiva, sclera, scar sites, slate-grey
Phenothiazines	Photo-exposed sites, slate-grey
Psoralens	Photo-exposed sites, brown

- *Photo-exposed site hyperpigmentation*: occurs in some of the porphyrias but can also be drug-induced.
- *Drug-induced pigmentation* (Box 29.29): may be diffuse or localised. It is not always due to hypermelanosis but sometimes is caused by deposition of the drug or a metabolite.
- *Focal hypermelanosis*: seen in lesions such as freckles and lentigines, characterised by focal areas of increased pigmentation.

Establishing the cause is important. Photoprotection may minimise the risk of increasing pigmentation. Topical hydroquinone preparations can be used for skin lightening in some types of hyperpigmentation, although caution is required, particularly in darker skin types.

Hair disorders

These can be subdivided into disorders that cause loss of hair (alopecia) or excessive hair growth (hypertrichosis and hirsutism).

Alopecia

Alopecia is characterised by loss of hair. It can be further subdivided into localised and diffuse, and into scarring and non-scarring subtypes (Box 29.30).

Pathogenesis

Alopecia can be observed in association with inflammatory disorders that cause scarring (lichen planus, discoid lupus) and others that do not cause scarring (tinea capitis, psoriasis, seborrhoeic eczema). These conditions are discussed elsewhere. Alopecia areata has an autoimmune basis and there is a strong genetic component, with a family history in approximately 20% of cases. In addition to atopy, it is associated with other autoimmune diseases, particularly thyroid disease, and with Down's syndrome. The cause of androgenetic alopecia is unclear but likely to be multifactorial, with genetic, hormonal and end-organ receptor sensitivity to the factors implicated.

Clinical features

Alopecia areata

This usually presents with well-defined, localised, non-inflammatory, non-scarring patches of alopecia, usually on the

Morphoea (en coup de sabre)	
Idiopathic	
Developmental defects	

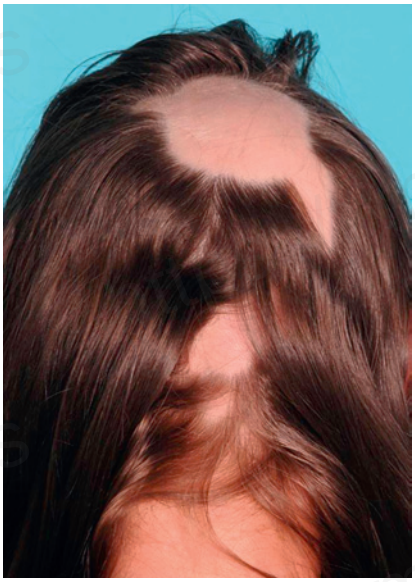

Fig. 29.44 Alopecia areata. The relatively extensive involvement and encroachment on posterior hairline are poor prognostic features.

scalp (Fig. 29.44). Pathognomonic 'exclamation mark' hairs are seen (broken hairs, tapering towards the scalp) during active hair loss. A diffuse pattern can uncommonly occur on the scalp. Eyebrows, eyelashes, beard and body hair can be affected. Alopecia totalis describes complete loss of scalp hair, and alopecia universalis is complete loss of all hair. Nail pitting may occur (p. 1261). Spontaneous regrowth is usual for small patches of alopecia but the prognosis is less good for larger patches, more extensive involvement, early onset and an association with atopy.

Androgenetic alopecia

Male-pattern baldness is physiological in men over 20 years old, although it can also occur in teenagers. It is also found in women, particularly post-menopausal ones. Characteristically, this involves bitemporal recession initially and subsequent involvement of the crown ('male pattern'), although it is often diffuse in women.

Investigations

Important investigations include full blood count, renal and liver function tests, iron studies, thyroid function, autoantibody screen and syphilis serology, as several systemic diseases, particularly iron deficiency and hypothyroidism, can cause diffuse non-scarring alopecia. Hair pull tests may help to establish the ratio of anagen to telogen hairs but require expertise for interpretation. Scrapings and pluckings should be sent for mycology if there is localised inflammation. Scalp biopsy and direct immunofluorescence of scarring alopecia may confirm a diagnosis of lichen planus or discoid lupus erythematosus but expert interpretation is needed.

Management

Any underlying condition, such as iron deficiency, should be treated and may result in clinical improvement. Alopecia can have a major impact on quality of life and psychological support is usually required. It is particularly important to establish realistic expectations.

Hair may spontaneously regrow in alopecia areata and it may be appropriate to offer no active intervention as, while some treatments may induce some hair regrowth, there is no evidence that any treatment fundamentally alters the course of the disease. There may be some response to topical or intralesional glucocorticoids. PUVA or immunotherapy with diphencyprone may be effective, with evidence of hair regrowth, but there is a risk of relapse on discontinuation of treatment. Short courses of systemic glucocorticoids are occasionally used in an attempt to limit acutely progressive extensive alopecia areata but should not be used in the long term; the risk of relapse on discontinuation is high. Ongoing trials of Janus kinase (JAK) inhibitors may provide future hope for patients with this difficult disease.

Some males with androgenetic alopecia may be helped by systemic finasteride. Topical minoxidil can be used in males and females with androgenetic alopecia but, if an effect is obtained, treatment must be continued and is expensive. In females, anti-androgen therapy, such as cyproterone acetate, can be used. Wigs are often appropriate for extensive alopecia. Scalp surgery and autologous hair transplants are expensive but can be used for androgenetic alopecia.

Hypertrichosis

Hypertrichosis is a generalised or localised increase in hair and may be congenital or acquired. It can be primary or secondary: for example, to drugs such as ciclosporin, minoxidil or diazoxide, malignancy or eating disorders. Laser therapy or eflornithine, which inhibits ornithine decarboxylase and arrests hair growth while it is being used, may be helpful. When the hypertrichosis follows a male pattern, it is called hirsutism.

Hirsutism

Hirsutism is the growth of terminal hair in a male pattern in a female (p. 657). The cause of most cases is unknown and, while it may occur in hyperandrogenism, Cushing's syndrome and polycystic ovary syndrome, only a small minority of patients have

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

a demonstrable hormonal abnormality. Psychological distress is often significant and oral contraceptives containing an anti-androgen such as cyproterone acetate, laser therapy or topical eflornithine may be beneficial.

Nail disorders

The nails can be affected by both local and systemic disease. The nail apparatus consists of the nail matrix and the nail plate, which arises from the matrix and lies on the nail bed (Fig. 29.45). The cells of the matrix and, to a lesser extent the bed, produce the keratinous plate.

Important information may be obtained from nail-fold examination, including dilated capillaries and ragged cuticles in connective tissue disease (Fig. 29.46) and the boggy inflammation of paronychia. The latter commonly occurs chronically in individuals undertaking wet work, in those with diabetes or poor peripheral circulation, and subsequent to increased cosmetic nail procedures and vigorous manicuring.

Normal variants

Longitudinal ridging and beading of the nail plate occur with age. White transverse patches (striate leuconychia) are often caused by airspaces within the plate.

Nail trauma

- *Nail biting/picking* is a very common habit. Repetitive proximal nail-fold trauma (often involving the thumb nail) results in transverse ridging and central furrowing of the nail.
- *Chronic trauma* from poorly-fitting shoes and sport can cause thickening and disordered growth of the nail (onychogryphosis) and subsequent ingrowing toenails.
- *Splinter haemorrhages* are fine, linear, dark brown longitudinal streaks in the plate (see Fig. 16.89, p. 529). They are usually caused by trauma, especially if distal. Uncommonly, they can occur in nail psoriasis and are also a hallmark of infective endocarditis.
- *Subungual haematoma* is red, purple or grey–brown discoloration of the nail plate, usually of the big toe (Fig. 29.47). These haematomas are usually due to trauma, although a history of this may not be clear. The main differential is subungual melanoma, although rapid onset, lack of nail-fold involvement and proximal clearing as the nail grows are clues to the diagnosis of haematoma. If there is diagnostic doubt, a biopsy may be needed.

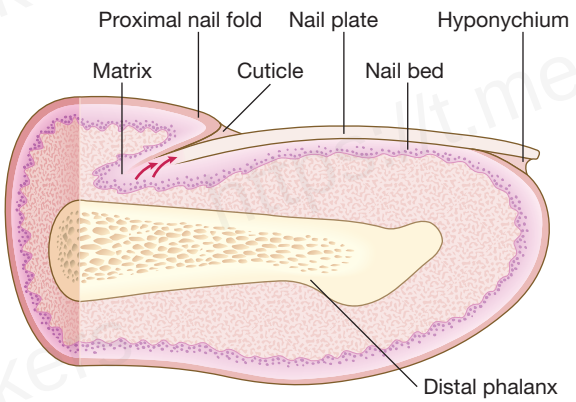

Fig. 29.45 The nail plate and bed. Arrows indicate the direction of nail growth.

Nail involvement in skin diseases

- *Dermatophyte infection/onychomycosis*: this is described on page 1240.
- *Psoriasis*: nail involvement is common (see Fig. 29.35B, p. 1249).

A

B

Fig. 29.46 Dermatomyositis. A Photo-aggravation. B Note the prominent periungual involvement. Erythema, dilated and tortuous capillaries in the proximal nail fold, and ragged cuticles are features of connective tissue disease.

Fig. 29.47 Subungual haematoma.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

- *Eczema*: nails may be shiny due to rubbing skin. Fine pitting can occur. If there is periungual eczema, the nail may become dystrophic, with thickening and transverse ridging. Paronychia is common.
- *Lichen planus*: there may be longitudinal ridging and thinning of the nail, giving a sandpaper texture (trachyonychia), erythematous streaks (erythronychia), subungual hyperkeratosis, pigmentation and, in severe cases, pterygium (splitting of nail due to central fibrosis and scarring, giving a winged appearance) and a destructive nail dystrophy.
- *Alopecia areata*: nail-plate pitting and trachyonychia can occur.

Nail involvement in systemic disease

The nails may be affected in many systemic diseases and important examples are detailed below:

- *Beau's lines*: horizontal ridges/indentations in nail plate occur simultaneously in all nails (Fig. 29.48B). They typically follow a systemic illness and are thought to be due to temporary growth arrest of cells in the nail matrix; they subsequently migrate out as the nail grows. Normal nail growth is approximately 0.1 mm/day for fingers and 0.05 mm/day for toes, so the timing of the systemic upset can usually be estimated by the position of the Beau's lines.
- *Koilonychia*: this concave or spoon-shaped nail-plate deformity is caused by iron deficiency (Fig. 29.48C).
- *Clubbing*: in the early stages, the angle between the proximal nail and nail fold is lost. In its more established form, there may be swelling of the distal digits (Figs 29.48D and E) or toes. Causes include bronchogenic carcinoma, asbestosis (especially with mesothelioma), suppurative or fibrosing lung disease, cyanotic congenital heart disease, infective endocarditis, inflammatory bowel disease, biliary cirrhosis and thyrotoxicosis; rarely, clubbing can be familial or idiopathic.
- *Nail discoloration*: whitening may occur in hypoalbuminaemia. 'Half-and-half' nails (white proximally and red/brown distally) may be found in renal failure. Antimalarials and some other drugs occasionally discolour nails.

Nail involvement in congenital disease

Nails can be affected in congenital diseases, such as pachyonychia congenita, a rare, usually autosomal dominant, condition caused by mutations in differentiation-specific keratin genes 6A, 6B, 16 and 17. This results in palmoplantar keratoderma and gross nail discoloration and thickening, due to subungual hyperkeratosis, from birth.

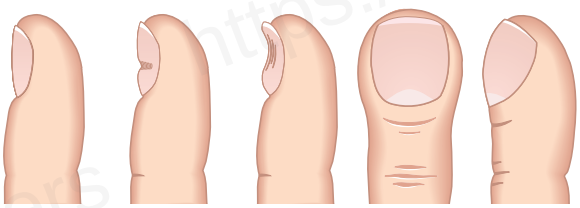

Fig. 29.48 The nail in systemic disease. A Normal nail. B Beau's line. C Koilonychia. D and E Digital clubbing.

Skin disease in general medicine

Many skin conditions present to other medical specialties. These are listed in Box 29.31 and the most common ones that are not discussed elsewhere are detailed below.

Conditions involving cutaneous vasculature

Vasculitis

Vasculitic involvement of the skin usually presents as palpable purpura (see Fig. 24.53, p. 1042). The diagnosis is confirmed by skin biopsy, along with histology and immunofluorescence examination. Underlying causes and their treatment are discussed on page 1040.

Pyoderma gangrenosum

The initial lesion of pyoderma gangrenosum (PG) is usually a painful, tender, inflamed nodule or pustule, which breaks down centrally and rapidly progresses to an ulcer with an indurated, undermined purplish or pustular edge (Fig. 29.49). Lesions may be single or multiple and are classified as ulcerative, pustular, bullous or vegetative. PG usually occurs in adults and, although it may occur in isolation, is usually associated with underlying disease, particularly inflammatory bowel disease, inflammatory arthritis, blood dyscrasias, immunodeficiencies and HIV infection. Investigation should be made with these associations in mind. The diagnosis is largely clinical, as histology is not specific. Analgesia, treatment of secondary bacterial infection and supportive

i 29.31 Skin problems in general medicine

Primary skin problems

- Cellulitis
- Vasculitis
- Leg ulcers
- Pressure sores

Skin involvement in multisystem disease

- Genetic: neurofibromatosis, tuberous sclerosis
- Xanthomas
- Amyloidosis
- Porphyria
- Sarcoidosis
- Systemic lupus erythematosus
- Systemic sclerosis

Non-specific and variable skin reactions to systemic disease

- Urticaria
- Erythema multiforme
- Annular erythemas
- Erythema nodosum
- Pyoderma gangrenosum
- Sweet's syndrome
- Generalised pruritus

Skin conditions associated with malignancy

- Dermatomyositis
- Generalised pruritus
- Acanthosis nigricans
- Superficial thrombophlebitis

Skin problems associated with specific medical disorders

- Liver: generalised pruritus, pigmentation, spider naevi, palmar erythema, nail clubbing
- Kidney: generalised pruritus, uraemic frost, pigmentation
- Diabetes mellitus: necrobiosis lipoidica, diabetic dermopathy
- Cutaneous Crohn's disease

Skin problems secondary to treatment of systemic disease

- Drug eruptions

Miscellaneous

- Granuloma annulare
- Morphoea

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Fig. 29.49 Pyoderma gangrenosum. This young patient had Crohn's disease. Note the cribriform pattern of re-epithelialisation, which is characteristic of this condition.

dressings are important. Systemic treatment with glucocorticoids, dapsone, ciclosporin or other immunosuppressants is often required. Tetracyclines may be added for their anti-inflammatory effects. Treatment with TNF-α inhibitors and ustekinumab may be effective in severe recalcitrant PG. Once healing has taken place, recurrences are typically only intermittent.

Other neutrophilic dermatoses

These include Sweet's acute febrile neutrophilic dermatosis and the neutrophilic dermatosis of rheumatoid disease, which are characterised by intense inflammation, mainly consisting of neutrophils, around dermal blood vessels. There can be damage to vessels ('vasculopathy') but usually no frank vasculitis.

Pressure sores

Localised, prolonged, pressure-induced ischaemia can lead to the development of pressure sores, which can occur in up to 30% of the hospitalised elderly. They are associated with considerable morbidity, mortality and expense to health services. The main risk factors are immobility, poor nutrition, local tissue hypoxia – for example, with anaemia, peripheral vascular disease, diabetes, sepsis and skin atrophy – or barrier impairment, such as in eczema.

A localised area of erythema develops at sites of bony prominences (particularly sacrum, greater trochanter, ischial and calcaneal tuberosities, and lateral malleolus). This progresses to a blister and then erosion, which will develop into a deep necrotic ulcer, usually colonised by *Pseudomonas aeruginosa* if pressure is not alleviated.

Prevention is key and involves identification of at-risk patients and regular repositioning and use of pressure-relieving mattresses. Predisposing factors, such as anaemia and poor nutrition, should be corrected. Once established, significant infection must be treated and necrotic tissue debrided. Dressings encourage granulation, although surgical intervention may sometimes be needed.

Fig. 29.50 Scarring inflammatory alopecia. This patient had systemic lupus erythematosus and additional cutaneous features of scarring inflammatory discoid lupus erythematosus.

Connective tissue disease

Lupus erythematosus

This autoimmune disorder can be subdivided into systemic lupus erythematosus (SLE) and cutaneous lupus, which includes discoid lupus erythematosus (DLE) and subacute cutaneous lupus erythematosus (SCLE). The features of SLE are discussed on page 1035. Drug-induced DLE and SCLE should always be considered (see Box 24.78, p. 1057, and Boxes 29.34 and 29.35 below). DLE typically presents as scaly red plaques with follicular plugging, usually on photo-exposed sites of the face, head and neck, which resolve with scarring and pigmentary change. If the scalp is involved, scarring alopecia usually occurs (Fig. 29.50). Most patients with DLE do not develop SLE. Patients with SCLE may have extensive cutaneous involvement, usually aggravated by sun exposure, with an annular, polycyclic or papulosquamous eruption. Systemic involvement is uncommon and the prognosis usually good. There is a strong association with antibodies to Ro/SS-A antigen. A diagnosis of cutaneous lupus is confirmed by histopathology and direct immunofluorescence. Cutaneous lupus may respond to topical glucocorticoids, antimalarials or immunosuppressants. Antimalarials and photoprotection are important mainstays in the management of cutaneous lupus, and systemic immunosuppression may be required for resistant disease. Paradoxically, low-dose UVA1 phototherapy can be effective for lupus.

Systemic sclerosis

This autoimmune multisystem disease presents with severe Raynaud's syndrome, digital ulcers and skin fibrosis. Dilated nail-fold capillaries and ragged cuticles are frequent. The clinical features and management are described on page 1037.

Morphoea

Morphoea is a localised cutaneous form of scleroderma that can affect any site at any age. It usually presents as a thickened

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

violaceous plaque, which may become hyper- or hypopigmented. Plaques can become generalised. Linear forms exist and, if in the scalp, are associated with scarring hair loss (en coup de sabre). There is usually no systemic involvement. Topical glucocorticoids or immunosuppressants or phototherapy, particularly PUVA or UVA1, can be effective, and systemic immunosuppression may be used for resistant extensive disease.

Dermatomyositis

Dermatomyositis is a multisystem disease, predominantly affecting skin, muscles and blood vessels. Typical cutaneous features include a violaceous 'heliotrope' erythema periorbitally and involving the upper eyelids, but this can sometimes affect the upper trunk, shoulders ('shawl sign') and limbs. Linear erythematous streaks may also be observed on the back of hands and fingers, and papules over the knuckles (Gottron's papules). Tortuous dilated nail-fold capillaries, often best seen with a dermatoscope, and ragged cuticles are usually evident. Photo-aggravation of the cutaneous features is often prominent (see Fig. 29.46A, p. 1260). The clinical features and management are described on page 1039.

Granulomatous disease

Granuloma annulare

This is common and may be reactive, although a trigger is usually not apparent. The hallmark is the presence of dermal granulomas, which are usually palisading and associated with alteration of dermal collagen (necrobiosis). The condition is generally asymptomatic and may present as an isolated dermal lesion with a raised papular annular edge, or may be more generalised. An association between generalised disease and diabetes has been proposed but not confirmed. Lesions often resolve spontaneously. Intralesional glucocorticoids or cryotherapy can be used for localised disease, and UVB or UVA1 phototherapy or PUVA for generalised disease.

Necrobiosis lipoidica

This condition has some histological features in common with granuloma annulare, although necrobiosis predominates. The lesion has a characteristic yellow, waxy, atrophic appearance, often with violaceous edge (Fig. 29.51). Underlying blood vessels are easily seen because of tissue atrophy. Necrobiosis lipoidica typically appears on the shins and is prone to ulceration after trauma. There is a strong association with diabetes: most patients with necrobiosis lipoidica have or develop diabetes, although less than 1% of diabetic patients develop necrobiosis lipoidica. Treatment is difficult and includes very potent topical or intralesional glucocorticoids, topical calcineurin inhibitors, PUVA or UVA1 phototherapy and systemic immunosuppression.

Sarcoidosis

This condition is characterised by the presence of non-caseating granulomas. The cause is unknown, although infectious and genetic factors have been proposed. It is usually a multisystem disease (p. 608), with skin lesions in about one-third of patients. Cutaneous features can occur in isolation and include violaceous infiltrated dermal plaques and nodules, which can affect any site but particularly digits and nose (lupus pernio), more generalised hyper- or hypopigmented or annular papules and plaques, infiltrative changes in scars and erythema nodosum (see Fig. 17.59, p. 609). It has been reported more commonly and may be more severe in those of African, African American or Indian ancestry. Investigation is described on page 609. Cutaneous disease may respond to topical or intralesional glucocorticoids, cryotherapy, UVA1, laser or PDT (pp. 1226–1228). Clinical features and management of systemic disease are discussed on pages 608 and 610.

Fig. 29.51 Necrobiosis lipoidica. Atrophic yellow plaques with violaceous edges, on the shins of a patient with diabetes mellitus.

Cutaneous Crohn's disease

Cutaneous Crohn's disease (p. 813) is rare but may present as perianal and peristomal infiltrative plaques, lymphoedema, sinuses or fistulae, and oral granulomatous disease. These changes are termed 'metastatic' Crohn's and histology shows non-caseating granulomas. Reactive skin changes can also occur in the form of erythema nodosum and pyoderma gangrenosum (pp. 1265 and 1261). Treatment is of the underlying disease (p. 820).

Porphyrias

The porphyrias (described on p. 378) are a diverse group of diseases, caused by reduced or absent activity of specific enzymes in the porphyrin–haem biosynthetic pathway. Due to this loss of enzyme activity, porphyrin precursors proximal to the implicated enzyme step accumulate. If the accumulated porphyrins absorb visible light, then there will be skin features and photosensitivity, which explains why some porphyrias have skin features (porphyria cutanea tarda) and others do not (acute intermittent porphyria; p. 379). The most common skin presentations are photo-exposed site blistering, skin fragility and pain on daylight exposure.

Cutaneous porphyrias: fragility and blisters

Although porphyria cutanea tarda (PCT) may be genetically inherited, this is uncommon and acquired PCT is the most common porphyria worldwide. It is caused by an underlying chronic liver disease, in association with hepatic iron overload. The liver disease is often only diagnosed through investigation of the

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

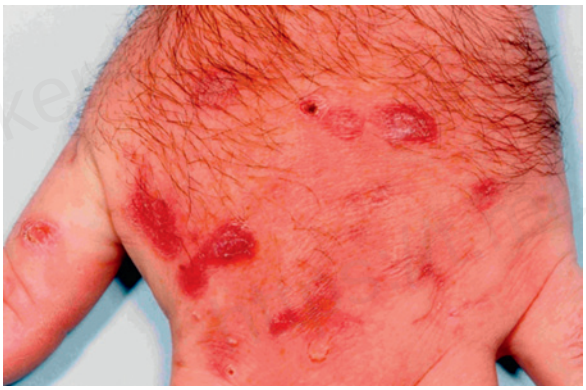

Fig. 29.52 Porphyria cutanea tarda. Skin fragility, blistering, scarring, milia and hypertrichosis on the back of hands and fingers in hepatitis C.

skin presentation and it is thus an important diagnosis not to miss. Typical features are increased skin fragility, blistering, erosions, hypertrichosis, scarring and milia occurring on light-exposed areas, particularly the backs of the hands (Fig. 29.52). Less common features include facial hypertrichosis, hyperpigmentation and morphoea-like changes. Variegate porphyria (VP) and hereditary coproporphyria (HCP) may be indistinguishable on skin features and it is important to make the correct diagnosis, as acute neurovisceral attacks, which may be drug-induced (p. 1265), can occur in VP and HCP but not in PCT. Pseudoporphyria may also be impossible to distinguish from PCT on clinical grounds but is most frequently caused by a drug (commonly naproxen; see Box 29.35) or by sunbed use; on investigation, porphyrins are normal. A PCT-like presentation may also be seen in uraemia due to renal failure, but is caused by raised porphyrins due to impaired elimination rather than an enzyme defect.

Management of PCT requires removal or treatment of any underlying cause, which may involve venesection, iron chelation, very low-dose hydroxychloroquine once or twice per week and photoprotection.

Cutaneous porphyria: pain on sun exposure

Erythropoietic protoporphyria is caused by a genetic defect in the ferrochelatase gene that leads to ferrochelatase enzyme deficiency. It is an important diagnosis to consider. The presentation is usually in early childhood, although the diagnosis is often delayed. In part this is because, although the baby or child cries due to immediate pain on sunlight exposure, physical signs are often absent or minimal and thus a link with sunlight may not always be considered. The deficient ferrochelatase activity leads to accumulation of lipid-soluble protoporphyrins in the skin, explaining the photosensitivity manifest as pain on daylight exposure. Multiple pigment gallstones, anaemia (usually only problematic if considered to be due to iron deficiency) and, rarely, severe liver disease can occur, which may be fatal and requires liver transplantation. In addition to photoprotection, UVB phototherapy may be effective for the symptoms of photosensitivity and, more recently, the use of alpha-melanocyte-stimulating hormone (α-MSH) analogues has been explored.

Abnormal deposition disorders

Xanthomas

Deposits of fatty material in the skin, subcutaneous fat and tendons may be the first clue to primary or secondary hyperlipidaemia (pp. 346 and p. 373).

Amyloidosis

Cutaneous amyloid may present as periocular plaques in primary systemic amyloidosis (p. 81) and amyloid associated with multiple myeloma, but is uncommon in systemic amyloidosis secondary to rheumatoid arthritis or other chronic inflammatory diseases. Amyloid infiltration of blood vessels may manifest as 'pinch purpura' following skin trauma. Macular amyloid is more common in darker skin types and appears as pruritic grey/brown macules or patches, usually on the back. Potent topical glucocorticoids can be beneficial, although it is often treatment-resistant.

Genetic disorders

Neurofibromatosis

This is described in detail on page 1131.

Tuberous sclerosis

This is an autosomal dominant condition and two genetic loci have been identified: *TSC-1* (chromosome 9) encoding hamartin, and *TSC-2* (chromosome 16) encoding tuberin. The hallmark is hamartomas in many systems. The classic triad of clinical features comprises learning disability, epilepsy and skin lesions but there is marked heterogeneity in clinical features. Skin changes include pale oval (ash leaf) macules that occur in early childhood; yellowish/pink papules in the mid-face (angiofibromas, 'adenoma sebaceum'), occurring in adolescence; periungual and subungual fibromas; and connective tissue naevi (shagreen patches, often on lower back). Gum hyperplasia, retinal phakomas (fibrous overgrowths), renal, lung and heart tumours, cerebral gliomas and calcified basal ganglia may also occur.

Reactive disorders

Erythema multiforme

Erythema multiforme has characteristic clinical and histological features and can be triggered by a variety of factors (Box 29.32) but a cause is not always identified. The disease is likely to have an immunological basis. Lesions are multiple, erythematous, annular, targetoid 'bull's eyes' (Fig. 29.53) and may blister. Stevens–Johnson syndrome (pp. 1224 and 1254) is a severe form of erythema multiforme with marked blistering, mucosal involvement (mouth, eyes and genitals) and systemic upset.

Identification and removal/treatment of any trigger are essential. Analgesia and topical glucocorticoids may provide symptomatic relief. Supportive care is required in Stevens–Johnson syndrome, including ophthalmology input.

i 29.32 Provoking factors in erythema multiforme

Infections
• Viral: herpes simplex, orf, infectious mononucleosis, hepatitis B, HIV
• *Mycoplasma* and other bacterial infections
Drugs
• Sulphonamides, penicillins, barbiturates and carbamazepine
Systemic disease
• Sarcoidosis, malignancy, systemic lupus erythematosus
Other
• Radiotherapy, pregnancy

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

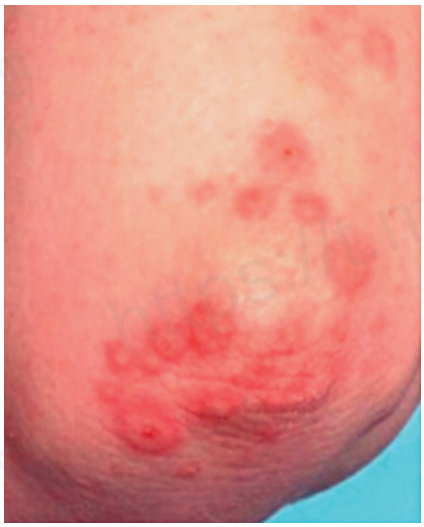

Fig. 29.53 Erythema multiforme in a young woman. Herpes simplex virus infection was the trigger.

i 29.33 Provoking factors in erythema nodosum

Infections
- Bacteria: streptococci, mycobacteria, *Brucella*, *Mycoplasma*, *Rickettsia*, *Chlamydia*
- Viruses: hepatitis B and infectious mononucleosis
- Fungi

Drugs
- Sulphonamides, sulphonylureas, oral contraceptives

Systemic disease
- Sarcoidosis, inflammatory bowel disease, malignancy

Other
- Pregnancy

Erythema nodosum

This is characterised histologically by a septal panniculitis of subcutaneous fat (see Fig. 17.59, p. 609). An identified trigger is often present (Box 29.33). Lesions are typically painful, indurated violaceous nodules on the shins and lower legs. Systemic upset, arthralgias and fever are common. Spontaneous resolution occurs over a month or so, leaving bruise-like marks. Any underlying cause should be identified and removed or treated. Bed rest, leg elevation and an oral NSAID frequently offer symptomatic relief. Systemic glucocorticoids are effective but seldom required, and must be avoided when there is a possibility of infection. Potassium iodide, dapsone or hydroxychloroquine may be effective for resistant disease but these are rarely required.

Acquired reactive perforating dermatosis

The hallmark of this condition is transepidermal elimination of dermal material, particularly collagen and elastic tissue. It presents as keratotic papules, particularly in patients with diabetes and chronic renal disease. Treatment with topical glucocorticoids, retinoids, PUVA or UVA1 therapy may help. There are other related perforating dermopathies, with characteristic histology.

Annular erythemas

This group of chronic, poorly defined, annular, erythematous and often scaly eruptions can be further subdivided and may be secondary to an identifiable cause. Erythema chronicum migrans can be associated with Lyme disease (*Borrelia burgdorferi*, p. 255). Erythema marginatum can occur in rheumatic fever (p. 515) or Still's disease (p. 1040). Erythema gyratum repens typically presents as concentric circles of erythema and scale with an advancing edge and is usually associated with underlying malignancy. Erythema annulare centrifugum presents with expanding, scaly, erythematous rings, with central fading. A trigger may not be apparent but possible associations include fungal infection, drugs, autoimmune or endocrine diseases, such as lupus or thyroid disease, and malignancy, particularly haematological. An underlying trigger must be sought and removed or treated. Topical glucocorticoids or phototherapy may be helpful for chronic disease.

Acanthosis nigricans

Hyperkeratosis and pigmentation are typical and affected sites have a velvety texture. The flexures, especially axillae and, in dark-skinned people, sides of neck, are involved (pp. 1325, 1326 and 720). There are several types, mainly associated with insulin resistance. Most often, acanthosis nigricans is found in conjunction with obesity and regresses with weight loss. It can be associated with malignancy, usually adenocarcinoma (particularly gastric), when it is usually more extensive and pruritic, and can involve mucous membranes.

Drug eruptions

Virtually all drugs may have cutaneous adverse effects (Fig. 29.54) and this should be considered in the differential diagnosis of most presentations of skin disease. Drugs can exert their adverse effects via several mechanisms, which can be broadly subdivided into non-immunological and immunological (Box 29.34).

i 29.34 Types of drug eruption

Non-immunological

Predictable
- Striae due to glucocorticoids (see Fig. 29.10, p. 1226)
- Asteatosis with statins
- Candidal infections with antibiotics
- Worsening of psoriasis with lithium, β-blockers, antimalarials, NSAIDs
- Urticaria with aspirin due to mast cell degranulation
- Bradykinin-mediated angioedema due to ACE inhibitors
- Doxycycline photosensitivity
- Dapsone haemolysis

Immunological

Unpredictable
- Immediate IgE-mediated hypersensitivity (type I): penicillin-induced urticaria and anaphylaxis
- Antibody-mediated (type II): penicillin-induced haemolysis
- Immune complex-mediated (type III): drug-induced serum sickness or vasculitis
- Delayed hypersensitivity (type IV): drug-induced erythema multiforme, lichenoid or pemphigus-like reaction; drug-induced lupus

(ACE = angiotensin-converting enzyme; IgE = immunoglobulin E; NSAIDs = non-steroidal anti-inflammatory drugs)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

29.35 Clinical patterns of drug eruptions

Reaction pattern	Clinical features	Examples of causative drugs
Exanthematous	Erythema, maculopapular	Antibiotics (especially ampicillin), anticonvulsants, gold, penicillamine, NSAIDs, carbimazole, anti-TNF drugs and other biological therapies
Urticaria and angioedema	Sometimes accompanied by angioedema Angioedema alone	Salicylates, opiates, NSAIDs, antibiotics, dextran, ACE inhibitors
Lichenoid	Violaceous, lichen planus-like, dyspigmentation	Gold, penicillamine, antimalarials, thiazides, NSAIDs, β-blockers, ACE inhibitors, sulphonamides, lithium, sulphonylureas, proton pump inhibitors, quinine, antituberculous, dyes in colour developers
Purpura and vasculitis	Palpable purpura and necrosis	Allopurinol, antibiotics, ACE inhibitors, NSAIDs, aspirin, anticonvulsants, diuretics, oral contraceptives
Erythema multiforme	Target-like lesions and bullae on extensor aspects of limbs	See Box 29.32, p. 1264
Erythema nodosum	Tender, painful, dusky, erythematous nodules on shins	See Box 29.33, p. 1265
Exfoliative dermatitis	There may be erythroderma	Allopurinol, carbamazepine, barbiturates, penicillins, PAS, isoniazid, gold, lithium, penicillamine, ACE inhibitors
Toxic epidermal necrolysis	Rapid evolution, extensive blistering, erythema, necrolysis, mucosal involvement	Anticonvulsants, antibiotics, especially sulphonamides, NSAIDs, terbinafine, sulphonylureas, antiretrovirals, allopurinol
Photosensitivity (p. 1220)	Photo-exposed site rash, may be sunburn-like, exfoliation, lichenoid	Thiazides, amiodarone, quinine, NSAIDs, tetracyclines, fluoroquinolones, phenothiazines, sulphonamides, retinoids, psoralens
Drug-induced lupus	Photosensitivity, discoid lesions, urticarial or erythema multiforme-like. May have positive lupus serology and anti-histone antibodies	Allopurinol, thiazides, ACE inhibitors, PAS, anticonvulsants, β-blockers, gold, hydralazine, minocycline, penicillamine, lithium, proton pump inhibitors
Psoriasiform rash	Rash resembles psoriasis	See Box 29.23 (p. 1248)
DRESS	Facial oedema, fever, extensive rash, lymphadenopathy, eosinophilia and systemic involvement	Anticonvulsants, trimethoprim, minocycline, allopurinol, dapsone, terbinafine
AGEP/toxic pustuloderma	Rapid onset of sterile, non-follicular pustules on erythematous base	Ampicillin/amoxicillin, erythromycin, quinolones, sulphonamides, terbinafine, diltiazem, hydroxychloroquine
Acneiform eruptions	Rash resembles acne	Lithium, anticonvulsants, oral contraceptives, androgens, glucocorticoids, antituberculous drugs, EGFR antagonists (cetuximab and erlotinib)
Pigmentation		See Box 29.29 (p. 1258)
Bullous eruptions	Often at pressure sites and there may be other features, such as purpura, milia	Barbiturates, penicillamine, furosemide
Pseudoporphyria	May be indistinguishable from porphyria cutanea tarda clinically	NSAIDs, tetracyclines, retinoids, furosemide, nalidixic acid
Exacerbation of acute hepatic porphyrias		See page 1263 Always check all drugs for safety of use in porphyrias against standard guidelines
Drug-induced immunobullous disease	May resemble pemphigoid, pemphigus, dermatomyositis, scleroderma, epidermolysis bullosa acquisita	Penicillamine, ACE inhibitors, vancomycin
Fixed drug eruptions	Round/oval, erythema, oedema ± bullae Same site every time drug is given Pigmentation on resolution	Tetracyclines, sulphonamides, penicillins, quinine, NSAIDs, barbiturates, anticonvulsants
Hair loss	Diffuse	Cytotoxic agents, oral retinoids, anticoagulants, anticonvulsants, antithyroid drugs, lithium, oral contraceptives, infliximab
Hypertrichosis	Excessive hair growth in non-androgenic distribution	Diazoxide, minoxidil, ciclosporin

(ACE = angiotensin-converting enzyme; AGEP = acute generalised exanthematous pustulosis; DRESS = drug rash with eosinophilia and systemic symptoms; EGFR = epidermal growth factor receptor; NSAIDs = non-steroidal anti-inflammatory drugs; PAS = para-aminosalicylic acid; TNF = tumour necrosis factor)

Fig. 29.54 Drug eruption. Possible drug causes of rash should always be considered. This was doxycycline-induced photosensitivity in a farmer.

Clinical features

Cutaneous drug reactions typically present in specific patterns (Box 29.35). Non-immunologically mediated reactions can theoretically occur in anyone, given sufficient exposure to the drug, although idiosyncratic factors, such as genetic predisposition, may render some more susceptible. There is limited information on genetic determinants of drug responses and adverse effects, although advances have been made, e.g. with azathioprine (p. 1227), and provide exciting opportunities for therapeutic personalised medicine. Immunologically mediated cutaneous drug eruptions typically commence within days to weeks of starting the drug. Detailed history-taking relating to prescribed and non-prescribed medications is essential and there may be other clues (Box 29.36).

Investigations and management

The suspected drug must be stopped. If drug-induced photosensitivity is considered, the patient should be phototested while on the drug to confirm the diagnosis, and again after drug withdrawal to confirm resolution of photosensitivity (p. 1215). An eosinophilia and abnormalities in liver function tests may occur in adverse drug reactions and, for example, specific IgE to penicillin may be raised in penicillin-induced rash but, otherwise, specific investigations are not available. Rechallenge with drug is not usually undertaken unless the reaction is mild, as this can be risky. Drug withdrawal may not be straightforward and substitute drugs may be required. Antihistamines and/or topical or systemic glucocorticoids may provide supportive management, depending on the type of cutaneous reaction. The management of anaphylaxis is described on page 76.

i 29.36 Diagnostic clues to drug eruptions

- Past history of reaction to suspected drug
- Introduction of suspected drug a few days to weeks before onset of rash
- Recent prescription of a drug commonly associated with rashes (penicillin, sulphonamide, thiazide, allopurinol)
- Symmetrical eruption that fits with a well-recognised pattern, caused by a current drug
- Resolution of rash following drug cessation

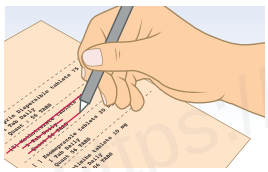
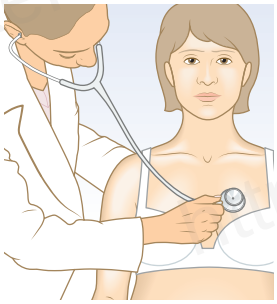
Clinical evaluation in maternal medicine

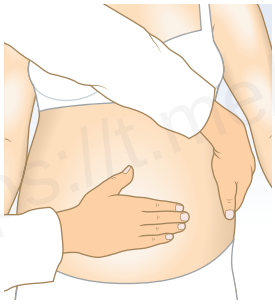
Take a careful history



Ask specifically about:
- Cardiac disease
- Renal disease
- Diabetes
- Rheumatic disease
- Inflammatory bowel disease
- Epilepsy

Take a careful drug history



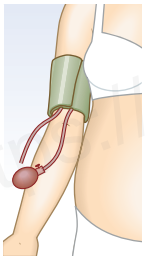


Stop fetotoxic drugs before conception

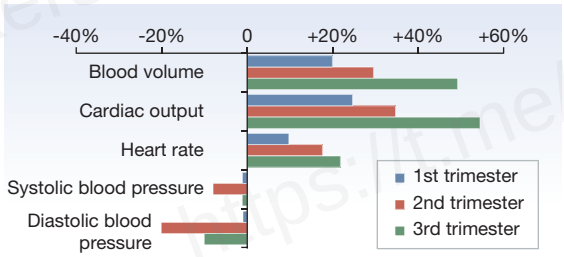
- Methotrexate
- Leflunomide
- Mycophenolate
- Valproate

Perform general examination

Palmar erythema

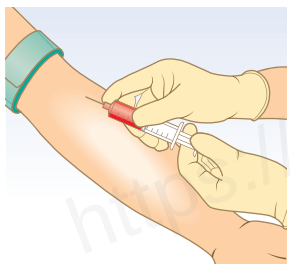


Check for anaemia and jaundice

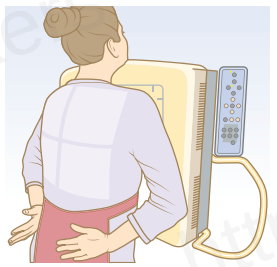


Check for oedema and deep venous thrombosis

Check blood pressure



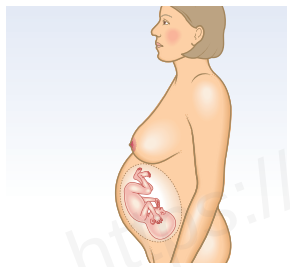
Consider cardiovascular adaptations during pregnancy



Perform urinalysis

Perform further investigations if appropriate

Perform X-ray imaging if indicated



Remember changes of pregnancy when interpreting laboratory results

- Anaemia
- Altered thyroid function tests
- Low creatinine/urea
- Low CO_2
- Raised alkaline phosphatase
- Glycosuria

Consider mother and fetus when prescribing

Major physiological changes occur during pregnancy, which impact on several organ systems. These are necessary to support the growing fetus, to prepare for delivery and to support lactation. These changes can adversely affect the activity and progression of many pre-existing medical conditions. Emphasising this fact, information from the UK Confidential Enquiry into Maternal Deaths has revealed that over recent years, two-thirds of maternal deaths occur as the result of pre-existing medical conditions, rather than from obstetric causes. The most common causes of death were cardiac conditions (23%), pneumonia and influenza (14%), and venous thromboembolism (11%). Although some diseases can undergo remission during pregnancy, others can worsen, potentially jeopardising the health and well-being of the mother and fetus. In this chapter, we review the physiological changes that occur during pregnancy and the impact of pregnancy on the diagnosis, clinical course and management of common medical conditions. In addition, we review the pathogenesis and management of several medical conditions specific to pregnancy.

Planning pregnancy in patients with medical conditions

Patients with pre-existing medical conditions require careful counselling when planning a pregnancy to make them aware of the risks that pregnancy might pose, as well as the changes in symptoms that might be expected to occur during pregnancy. Although each disease is different, as is discussed later in this chapter, the general principles are to ensure that drugs that may be fetotoxic are stopped before pregnancy is attempted; that high-risk patients are kept under close surveillance during their pregnancy; and that new symptoms that emerge during pregnancy are treated seriously and fully investigated where appropriate.

Functional anatomy and physiology

The most important changes that occur in the anatomy and physiology of major organ systems during pregnancy are discussed below.

Bone metabolism

Major changes in bone metabolism take place to meet the demands of the growing fetus. Intestinal calcium absorption increases, due in part to increased production of 1,25-dihydroxyvitamin D (1,25$(OH)_2$D). Calcium is also released from the maternal skeleton due to increased bone resorption, stimulated by production of parathyroid hormone-related protein (PTHrP) by breast and placenta. This results in loss of bone from the maternal skeleton during pregnancy that continues until lactation ceases and then recovers. Serum concentrations of alkaline phosphatase (ALP) can increase by up to fourfold but this is due to release of ALP from the placenta rather than bone.

Cardiovascular system

Heart rate and stroke volume increase during pregnancy; when combined with peripheral vasodilatation and a reduction in systemic blood pressure, this causes a hyperdynamic circulatory state and an increase in cardiac output. Diaphragmatic elevation may affect the electrocardiogram (ECG), causing left axis deviation of up to 15°. Other changes include T-wave inversion in leads III and aVF, ST depression, small Q waves and a sinus tachycardia. Supraventricular and ventricular beats are common. Echocardiography shows a modest increase in the dimensions of the cardiac chambers.

Endocrine system

During early pregnancy there is secretion of human chorionic gonadotrophin (hCG) by trophoblast cells, which act on the corpus luteum in the ovary to stimulate oestradiol and progesterone production (Fig. 30.1). Levels of hCG rise rapidly during early pregnancy to reach a peak around 8 weeks, and then fall before stabilising at a lower level from 20 weeks until term. There is a progressive rise in oestradiol and progesterone levels; initially, these hormones are produced by the corpus luteum but placental production takes over after about 12 weeks. The high levels of gonadal hormones suppress pituitary gonadotrophin production but prolactin levels rise about 10-fold and there is an increase in volume of the anterior pituitary. Serum levels of free T_4 increase during the first trimester but, paradoxically, thyroid-stimulating hormone (TSH) levels fall by almost 50%. This is because hCG is homologous to TSH and mimics the effect of TSH on the thyroid, stimulating both T_3 and T_4 production. The raised levels of T_3 and T_4 feed back to the pituitary and reduce TSH secretion. Later in pregnancy, there is increased degradation of thyroxine by the placenta and levels of thyroxine-binding globulin (TBG) rise, causing the normal range for free T_4 and T_3 to fall progressively during the course of pregnancy. Although TSH levels are difficult to interpret early in pregnancy, they provide the best measure of thyroid function after about 16 weeks' gestation.

Gastrointestinal system

The high levels of progesterone during pregnancy lead to relaxation of smooth muscle in the gastrointestinal tract. This causes the lower oesophageal sphincter to relax, predisposing to gastro-oesophageal reflux and reduced gastrointestinal transit; this in turn leads to delayed gastric emptying and constipation.

Genitourinary system

Glomerular filtration rate (GFR) increases during pregnancy due to an increased cardiac output. By the second trimester, renal perfusion increases by up to 80% and GFR by 50%, leading to a fall in serum urea and creatinine. Mild glycosuria may be observed during normal pregnancy due mainly to an increase in filtered load of glucose. The ureters and renal pelvis are slightly dilated, most prominently on the left side, leading to the physiological hydronephrosis of pregnancy.

Glucose metabolism

Maternal glucose metabolism changes during pregnancy to optimise delivery of glucose and other nutrients to the fetus. During the second half of pregnancy in particular, there is maternal insulin resistance due largely to an increase in circulating levels of human placental lactogen (hPL) (Fig. 30.1). The net effect is to ensure that glucose is preferentially supplied to the fetus rather than the mother. Following delivery of the placenta, there is a rapid decline in hPL and reversal of insulin resistance. During pregnancy, fasting plasma glucose decreases slightly, while post-prandial blood glucose may increase. Glycosuria may occur, even in women who do not have diabetes, due to the

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

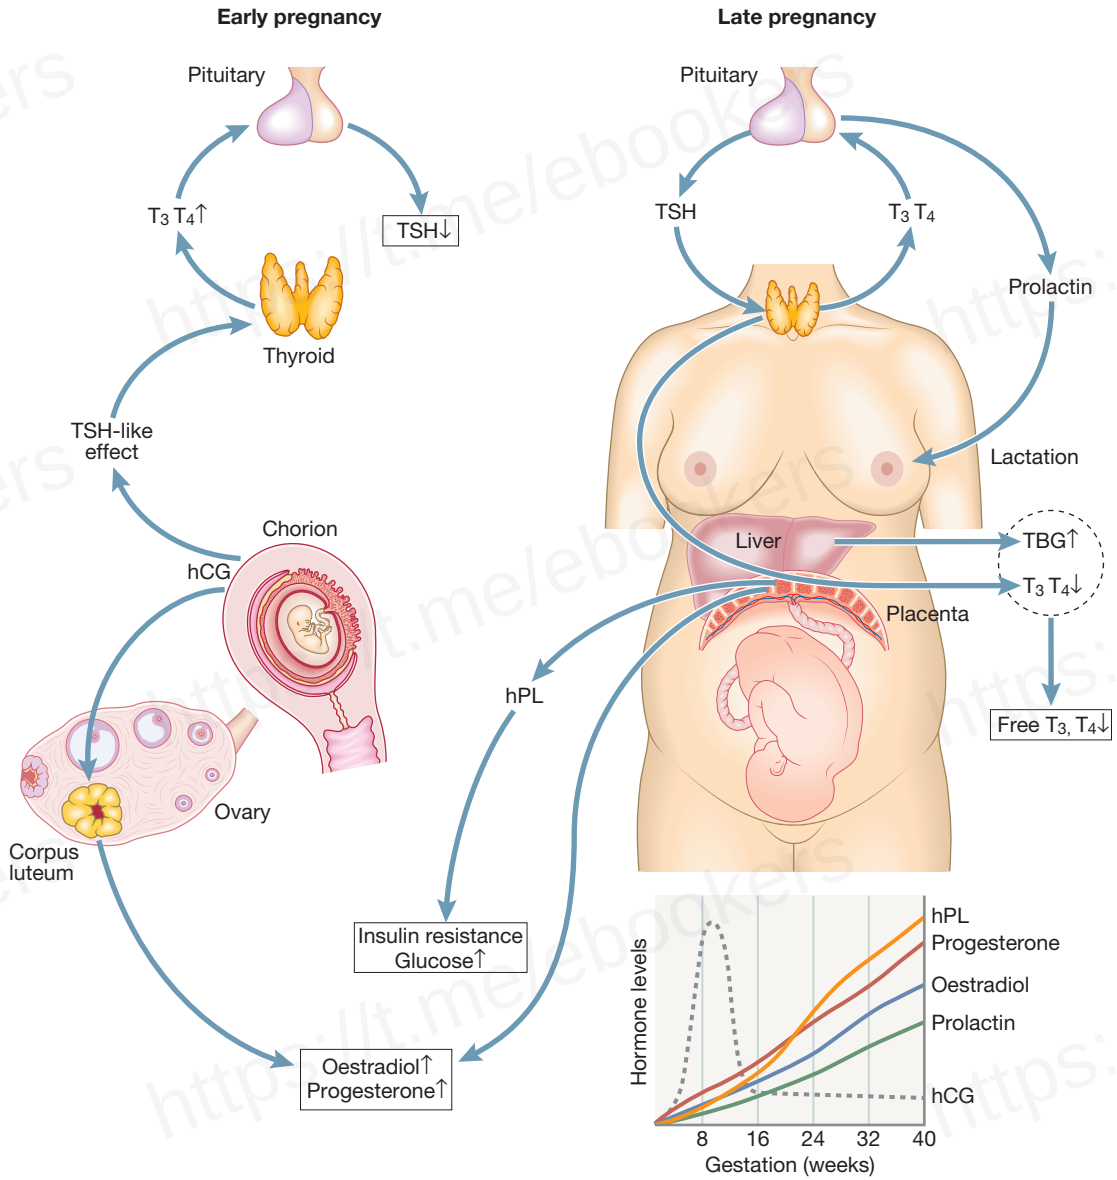

Fig. 30.1 Hormonal changes in pregnancy. In early pregnancy, oestradiol and progesterone are mainly derived from the corpus luteum in response to human chorionic gonadotrophin (hCG), secreted by the trophoblast. The raised levels of hCG also act on the thyroid to stimulate T_3 (triiodothyronine) and T_4 (thyroxine) production, which in turn suppresses thyroid-stimulating hormone (TSH) production by the pituitary. Later in pregnancy, oestradiol and progesterone are derived from the placenta, which also produces human placental lactogen (hPL), impairing glucose tolerance. There is a progressive reduction of free T_3 and T_4 during pregnancy as the result of T_3 and T_4 degradation by the placenta and increased secretion of thyroxine-binding globulin (TBG) by the liver.

increased GFR. Insulin secretion in the fetus is driven by fetal glucose levels, which in turn are dependent on maternal glucose concentrations. Accordingly, in women with diabetes, maternal hyperglycaemia stimulates fetal insulin secretion, which increases fetal growth, resulting in increased birth weight or macrosomia.

Haematological system

Haemoglobin normally falls by about 20% during pregnancy since plasma volume increases more than red cell volume: the so-called physiological anaemia of pregnancy. The reduction in haematocrit lowers blood viscosity but this is offset by an elevation in levels of several clotting factors, resulting in a hypercoagulable state that increases the risk of venous and arterial thrombosis.

Respiratory system

Tidal volume (TV) increases during pregnancy due to an increased vital capacity and reduced residual volume, and by term the increase in TV is about 200 mL. These changes are required to meet the 20% increase in oxygen demand that occurs during pregnancy. The PCO_2 level decreases but this is offset by an increase in renal excretion of bicarbonate, such that the blood pH remains relatively stable. Respiratory rate is unaffected by pregnancy.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Investigations

The profound changes in physiology and anatomy that occur during pregnancy cause changes in the normal reference ranges for several hormones, electrolytes and other analytes, as summarised in Box 30.1. While many investigations can proceed as normal during pregnancy, invasive procedures should generally be avoided unless the potential benefit clearly outweighs the risk. Investigations that can be performed in pregnancy are shown in Box 30.2.

i 30.1 Common laboratory changes during pregnancy

Laboratory test	Change	Cause
Haematology		
Haematocrit	Decrease	Extracellular volume expansion
Routine biochemistry		
GFR	Increase	Increased renal blood flow
Urea and creatinine	Decrease	Increased GFR
Alkaline phosphatase	Increase	Release by placenta
Glucose	Decrease (fasting) Increase (post-prandial)	Raised insulin Insulin resistance
Hormones		
T_4	Increase (first trimester)	Stimulation of thyroid by hCG
	Decrease (later pregnancy)	Placental degradation
TSH	Decrease (first trimester)	Increased T_4 due to stimulation of thyroid by hCG
Prolactin	Increase	Increased production by pituitary
Oestradiol Progesterone	Progressive increase	Production by corpus luteum then placenta
hCG	Increase then decrease	Production by trophoblast
hPL	Progressive increase	Production by placenta

(GFR = glomerular filtration rate; hCG = human chorionic gonadotrophin; hPL = human placental lactogen; TSH = thyroid-stimulating hormone)

Imaging

Imaging during pregnancy should be undertaken only when the clinical benefit outweighs the potential risks to mother and fetus. In suspected pulmonary embolus, radionuclide ventilation/perfusion ($\dot{V}/\dot{Q}$) scanning is preferred over computed tomographic pulmonary angiography (CTPA) in women with a normal chest X-ray since $\dot{V}/\dot{Q}$ scans expose the maternal breast and lungs to less radiation than CTPA. However, if the chest X-ray is abnormal, CTPA should be performed, since it is more likely to yield a definitive diagnosis. The radiation exposure for both investigations is well below the maximum recommended fetal radiation dose in pregnancy (5 rad). Chest X-rays may also be performed safely at any gestation during pregnancy if clinically indicated, since the radiation exposure is very low for the fetus. Magnetic resonance imaging (MRI) is safe in the second and third trimesters and is useful in the assessment of proximal deep vein thrombosis (DVT) and neurological disorders. However, gadolinium-containing contrast agents should be used only if absolutely necessary. If gadolinium contrast agents are used in women who are breastfeeding, the milk should be discarded for 24 hours. Ultrasound imaging is safe during pregnancy and useful in the assessment of patients with DVT or intra-abdominal pathology.

Presenting problems in pregnancy

Breathlessness

The causes of breathlessness during pregnancy are summarised in Box 30.3. Many women experience mild breathlessness as part of normal pregnancy, which is known as physiological

i 30.2 Investigations in pregnancy*

Investigation	Use during pregnancy	Comment
Renal biopsy	Can be performed during pregnancy	<22 weeks is safest; 23–28 weeks is period of highest risk
Gastroscopy	Safe during pregnancy Left lateral position is recommended in the second half of pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Colonoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Flexible sigmoidoscopy	Safe during pregnancy	Fetal monitoring should be offered pre- and post-procedure Low-dose sedation recommended
Magnetic resonance imaging	Not contraindicated at any gestation	Theoretical risks to fetus in first trimester
Computed tomography	Can be performed at any gestation	Radiation exposure to fetus and mother must be considered and addressed in counselling
X-ray	Safe at any gestation	
Ultrasound	Safe at any gestation	
Echocardiogram	Safe at any gestation	
Ambulatory electrocardiogram	Safe at any gestation	

*For any investigation, the potential benefit must outweigh the risk.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

30.3 Breathlessness during pregnancy

Cause	Management
Physiological breathlessness of pregnancy	No treatment required
Asthma	Treatment as in non-pregnant women
Pneumonia	Treatment with antibiotic as in non-pregnant women
Valvular heart disease	Treatment as in non-pregnant women
Heart failure	Treatment as in non-pregnant women
Peripartum cardiomyopathy (PPCM)	Treatment as in non-pregnant women Early delivery if haemodynamic deterioration
Pulmonary embolus	Treatment as in non-pregnant women

breathlessness of pregnancy. It is thought to be progesterone-mediated and is classically of gradual onset and present at rest and on exercise. Physiological breathlessness does not require investigation but severe or persistent breathlessness should be investigated, especially if accompanied by chest pain. The diagnostic approach in pregnant patients with suspected pulmonary embolism differs from that in non-pregnant women. Measurement of D-dimer is not helpful since values normally increase progressively throughout pregnancy. Accordingly, the first-line investigation in suspected pulmonary embolism is a V̇/Q̇ scan in a patient with a normal chest X-ray and CTPA in a patient with an abnormal chest X-ray.

Chest pain

Chest pain does not occur during normal pregnancy but the incidences of acute coronary syndrome (ACS) and aortic dissection are both increased. Accordingly, if a pregnant woman develops acute severe chest pain suggestive of either of these conditions, she should be investigated and treated in the same way as a non-pregnant woman.

Circulatory collapse

The differential diagnosis of circulatory collapse is wide and causes unrelated to pregnancy are discussed on page 199. Obstetric causes include pulmonary embolism, haemorrhage and amniotic fluid embolism (AFE). AFE usually presents with collapse and profound shock during delivery or immediately afterwards, often with profound and early coagulopathy. It can be difficult to differentiate AFE from other causes of maternal collapse, and the diagnosis is clinical when other causes of collapse have been excluded. Management is supportive, with oxygenation, careful fluid balance and, in some cases, correction of coagulopathies, ventilatory support and vasopressors.

Another important cause of circulatory collapse is obstetric haemorrhage, which can be divided into ante-partum and post-partum subtypes. Ante-partum haemorrhage is defined as bleeding from the vagina after 24 weeks' gestation. Primary post-partum haemorrhage is defined as occurring in the first 24 hours after delivery, and secondary post-partum haemorrhage after 24 hours. Haemorrhage may be concealed, and physiological changes such as hypotension, tachycardia and tachypnoea may be late signs. Management is supportive with administration of blood, intravenous fluids and oxygen. Patients with post-partum haemorrhage may also benefit from uterotonic agents such as oxytocin. If the bleeding fails to settle, surgical intervention or interventional radiology may be required.

Headache

Migraine and tension headache may occur during pregnancy and should be assessed along the usual lines, as described on page 1095. Important causes of headache that are specific to pregnancy are pre-eclampsia, which should be suspected in patients with hypertension, oedema and proteinuria, and cerebral venous thrombosis, which should be suspected when there is a neurological deficit or seizures.

Nausea and vomiting

Nausea and vomiting are common during the first trimester of pregnancy and do not usually require any specific investigation or treatment. Other causes of nausea and vomiting are summarised in Box 30.4. Severe vomiting with significant weight loss and/or electrolyte disturbance suggests hyperemesis gravidarum, which is discussed in more detail on page 1277.

30.4 Differential diagnosis of severe nausea and vomiting in pregnancy

Gastrointestinal	
• Peptic ulcer disease	• Appendicitis
• Gastroenteritis	• Pancreatitis
Endocrine and metabolic	
• Thyrotoxicosis	• Hyperparathyroidism
• Addison's disease	• Diabetic ketoacidosis
Neurological	
• Space-occupying lesion	• Migraine
Pregnancy-associated conditions	
• Molar pregnancy	• Hyperemesis gravidarum
• Acute fatty liver of pregnancy	
Genitourinary	
• Urinary tract infection	
Psychological	
• Bulimia nervosa	
Cardiovascular	
• Myocardial infarction	

Oedema

A mild degree of ankle oedema can occur in normal pregnancy but significant oedema raises suspicion of pre-eclampsia. This should be considered in patients who are also hypertensive and those with proteinuria. Further details are on page 1276.

Seizures

The causes and management of seizures during pregnancy are summarised in Box 30.5. An important cause is eclampsia, which should be borne in mind in patients with no previous history of seizures and accompanying features such as hypertension,

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

30.5 Causes of seizures during pregnancy

Cause	Management
Epilepsy	Similar to that in non-pregnant women Avoid valproate
Eclampsia	Antihypertensives Magnesium sulphate Careful fluid balance
Hypoglycaemia	Glucose
Hyponatraemia	Saline infusion
Alcohol withdrawal	Supportive treatment
Drugs	Supportive treatment
Stroke	As in non-pregnant women
Cerebral venous thrombosis	Low-molecular-weight heparin
Thrombotic thrombocytopenic purpura	Plasma exchange Immunosuppressives

oedema and proteinuria. Seizures can also occur secondary to electrolyte disturbances associated with hyperemesis gravidarum or hypoglycaemia. Other disorders that are more common during pregnancy and can present with seizures include cerebral venous thrombosis and thrombotic thrombocytopenic purpura (TTP).

Medical disorders in pregnancy

Many disorders present specific management problems before pregnancy, during pregnancy and in the puerperium; the most important of these are discussed in more detail below.

Hypertension

Hypertension is one of the most common medical problems during pregnancy, occurring in about 10–15% of women. The causes and classification are summarised in Box 30.6.

Pre-existing hypertension

If hypertension is discovered during the first half of pregnancy, it usually indicates that there was pre-existing hypertension. This is most likely to be due to essential hypertension but secondary causes also need to be considered. Hypertension during pregnancy should be managed with vasodilators or methyldopa (Box 30.7), taking care to avoid hypotension, which can cause placental hypoperfusion and increase the risk of fetal growth restriction, stillbirth and miscarriage. Angiotensin-converting enzyme (ACE) inhibitors should be stopped in hypertensive women who are planning to become pregnant and should be avoided during pregnancy since they have fetotoxic effects. Diuretics should also be avoided unless there is heart failure, as they can reduce circulating volume and cause placental hypoperfusion.

Gestational hypertension

Gestational hypertension usually presents in the second half of pregnancy and most often resolves by 3 months post-partum. It should be managed actively with one of the drugs listed in Box 30.7, to reduce the risk of progression to pre-eclampsia.

30.6 Classification of hypertension during pregnancy

Hypertension	Definition
Hypertension in pregnancy	Blood pressure ≥140/90 mmHg on two separate occasions, at least 4 hrs apart
Pre-existing hypertension	Hypertension prior to pregnancy or occurring before 20 weeks' gestation
Gestational hypertension	Hypertension occurring after 20 weeks' gestation without proteinuria or any other features of pre-eclampsia
Pre-eclampsia	Hypertension occurring after 20 weeks' gestation with proteinuria, maternal organ dysfunction or uteroplacental dysfunction
Eclampsia	Generalised seizures in a pregnant woman previously diagnosed with pre-eclampsia
White coat hypertension	Hypertension that only occurs in a clinical environment

Adapted from Tranquilli AL, Dekker G, Magee L, et al. The classification, diagnosis and management of the hypertensive disorders of pregnancy: a revised statement from the ISSHP. Pregnancy Hypertens 2014; 4:97–104.

30.7 Drug treatment of hypertension during pregnancy

Medication	Mechanism of action
Labetalol	α- and β-receptor blocker
Nifedipine Amlodipine	Calcium channel blockers
Methyldopa	Central action
Doxazosin	α-receptor blocker

Pre-eclampsia and eclampsia

Pre-eclampsia is a disorder of vascular endothelial dysfunction that affects about 10% of all pregnancies worldwide. The risk factors for pre-eclampsia are shown in Box 30.8 and the clinical features illustrated in Figure 30.2. Management includes control of blood pressure, administration of magnesium sulphate as prophylaxis against seizures, correction of coagulation abnormalities and monitoring of fluid balance. If pre-eclampsia occurs early in pregnancy, medical management should be initiated with the aim of controlling the condition and maintaining the fetus in utero as long as possible. If these measures are ineffective and eclampsia supervenes (see below), then urgent delivery should be considered, provided the fetus is viable, since this results in an immediate cure.

30.8 Risk factors for pre-eclampsia

- Previous history of pre-eclampsia
- Multiple pregnancy
- Primiparity
- Genetic predisposition
- Obesity
- Increased maternal age
- Pre-existing medical conditions:
  - Chronic kidney disease
  - Hypertension
  - Diabetes mellitus
  - Systemic lupus erythematosus and connective tissue disease

Adapted from Duckitt K, Harrington D. Risk factors for pre-eclampsia at antenatal booking: systematic review of controlled studies. BMJ 2005; 330:565–567.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

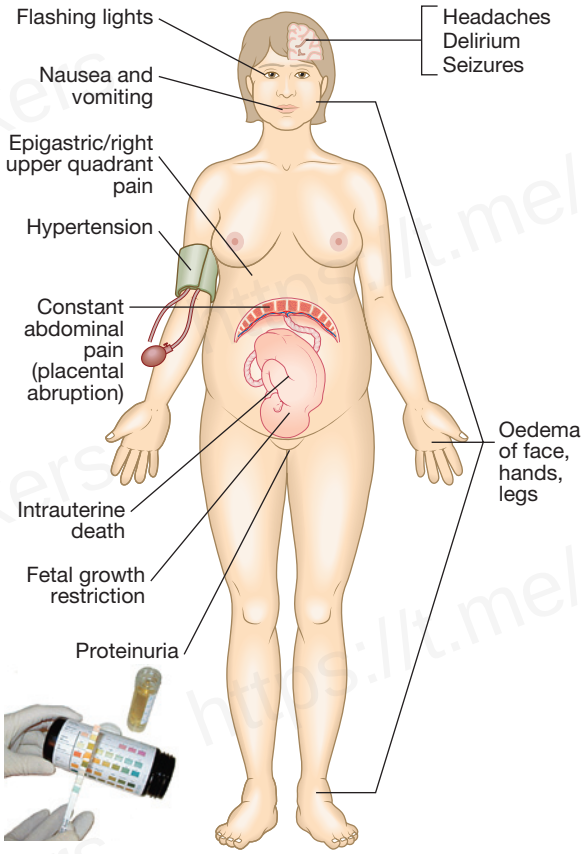

Fig. 30.2 Symptoms and signs of pre-eclampsia.

Eclampsia occurs in about 1% of pregnancies and is associated with significant mortality. It usually presents with seizures on a background of pre-eclampsia but rarely can occur before the onset of hypertension and proteinuria. Treatment is with intravenous magnesium sulphate and delivery of the fetus as soon as possible. Women with pre-eclampsia are more likely to develop hypertension, chronic kidney disease, and cerebrovascular and ischaemic heart disease in later life.

Respiratory disease

Asthma

Women with asthma should be managed aggressively during pregnancy, since poorly controlled asthma is associated with pre-eclampsia, fetal growth restriction, low birth weight and pre-term birth. The management is very similar to that in non-pregnant individuals. Short-acting and long-acting β-agonists, inhaled and oral glucocorticoids and theophylline can be used freely. There is less experience with leukotriene receptor agonists during pregnancy but they can be given if necessary. It is advisable to involve an anaesthetist or intensivist at an early stage in patients with severe exacerbations of asthma since airway management is more difficult in late pregnancy.

Respiratory infection

The most common causes of pneumonia during pregnancy are summarised in Box 30.9. Diagnosis and management are broadly the same as in non-pregnant patients. Prompt treatment of infections is important since mothers with pneumonia are more likely to deliver early and have low-birth-weight infants compared with healthy pregnant women.

i 30.9 Causes of pneumonia during pregnancy

Bacterial	
• *Streptococcus pneumoniae*	• *Haemophilus influenzae*
• *Mycoplasma pneumoniae*	• *Staphylococcus aureus*
• *Legionella*	
Viral	
• Influenza viruses	• Varicella zoster

Adapted from Lim W, Macfarlane J, Colthorpe C. Pneumonia in pregnancy. Thorax 2001; 56:398–405.

Bacterial infections

Antibiotics should be given, depending on the causal organism and sensitivities, along with supplemental oxygen and fluids as required. Penicillins, cephalosporins and macrolides such as erythromycin are all safe during pregnancy but tetracyclines should be avoided because they may be embryotoxic and can cause staining of the teeth in the fetus (see Box 6.19, p. 120).

Viral infections

Viral pneumonia is more common and often more severe during pregnancy. Varicella zoster pneumonia in particular is associated with a high fetal and maternal mortality rate. It presents with cough, breathlessness and pyrexia, and is usually preceded by a vesicular rash up to 1 week before. Varicella infection can be diagnosed clinically, with laboratory confirmation by culture or polymerase chain reaction (PCR) of fluid from vesicles, or by serology. Varicella pneumonia causes an interstitial pneumonitis with a characteristic nodular appearance on chest X-ray (p. 1270). Women with confirmed varicella zoster pneumonia should be admitted to hospital for supportive care and treatment with intravenous aciclovir for 7–10 days.

Tuberculosis

Tuberculosis (TB) may occur during pregnancy and in the UK is more common among African and Asian women. Untreated TB is associated with premature delivery and low birth weight. Transmission to the fetus can occur but is unusual. If the diagnosis of TB is confirmed, then antituberculous chemotherapy should be given as normal, since the benefit of treating TB in pregnancy outweighs any potential risks from the medication. A proportion of pregnant women with TB have coexisting human immunodeficiency virus (HIV) infection, which confers a poorer prognosis and also requires treatment with antiretroviral therapy, as described on page 318.

Gastrointestinal disease

Hyperemesis gravidarum

Hyperemesis gravidarum is a serious condition that affects about 0.5% of pregnant women. It typically presents during the first trimester with severe nausea, vomiting and other clinical features (Box 30.10). It is associated with significant morbidity and mortality, due to malnutrition and electrolyte imbalance. Wernicke's encephalopathy may develop as the result of thiamin deficiency. Recurrence is common in successive pregnancies.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

30.10 Clinical features of hyperemesis gravidarum

- Weight loss of >5%
- Severe nausea and vomiting
- Dehydration
- Ketosis
- Electrolyte imbalance:
  - Hyponatraemia
  - Hypokalaemia
  - Hypomagnesaemia

The cause is unknown and the diagnosis is one of exclusion, since alternative causes of severe nausea and vomiting need to be ruled out, particularly if the onset of symptoms occurs after the first trimester. Management is with lifestyle advice and support, intravenous fluids, electrolyte replacement and antiemetics. Thiamin and glucocorticoids may be required in the most severe cases.

Inflammatory bowel disease

Women with inflammatory bowel disease (IBD) should be counselled prior to planning a pregnancy. Medications such as azathioprine, sulfasalazine, 5-aminosalicylic acid (5-ASA), glucocorticoids and tumour necrosis factor alpha (TNF-α) inhibitors can be continued as normal during pregnancy but methotrexate must be stopped at least 3 months before conception because of its teratogenic effects. Since poorly controlled IBD is associated with an increased risk of pre-term birth, low birth weight and miscarriage, it is important for the disease to be well controlled before conception. The activity of IBD can increase during pregnancy and ulcerative colitis is more likely to flare than Crohn's disease. Women who experience disease flares should be managed by both medical and obstetric teams, and monitored closely. The TNF-α inhibitors infliximab and adalimumab are actively transported across the placenta in the third trimester and there is theoretical concern about immunosuppression in the neonate. Infants of mothers who have been treated with TNF-α inhibitors during the second and third trimesters should not be given live vaccines and should be monitored closely for any signs of infection. Most women with uncomplicated IBD can have a normal vaginal delivery and do not need a caesarean section, but the need for this should be assessed on an individual basis by obstetric and medical teams.

Diabetes

It is important to institute meticulous glucose control in pregnancy, as maternal diabetes is associated with increased risks of congenital malformations, stillbirth, pre-eclampsia, pre-term delivery, operative delivery, neonatal hypoglycaemia and admission to neonatal intensive care.

Gestational diabetes

Gestational diabetes is defined as diabetes with first onset or recognition during pregnancy. This definition will include a few patients who develop type 1 diabetes during pregnancy, where prompt action and early insulin treatment will be required, and some patients who develop type 2 diabetes, or had unknown pre-existing type 2 diabetes, in whom the diabetes does not remit after pregnancy. However, in most cases, gestational diabetes develops due to an inability to increase insulin secretion adequately to compensate for pregnancy-induced insulin resistance, and most women can expect to return to normal glucose tolerance immediately after pregnancy. Risk factors for gestational diabetes are shown in Box 30.11.

30.11 Risk factors for gestational diabetes

- Body mass index >30 kg/m^2
- Previous macrosomic baby weighing ≥4.5 kg
- Previous gestational diabetes
- Family history of diabetes (first-degree relative with diabetes)
- Family origin with a high prevalence of diabetes:
  - South Asian (specifically women whose country of family origin is India, Pakistan or Bangladesh)
  - Black Caribbean
  - Middle Eastern

The diagnosis of gestational diabetes is based on maternal blood glucose measurements that are associated with increased fetal growth. An international consensus recommended that glucose values diagnostic of gestational diabetes should be lower than those for non-gestational diabetes (see Box 20.31, p. 753). Controversy remains about who should be screened, and the screening strategy depends, in part, on the population risk. It is widely accepted that women at high risk for gestational diabetes should have an oral glucose tolerance test at 24–28 weeks, and some guidelines recommend that all high-risk women should be screened by measuring HbA_{1c}, fasting blood glucose or random blood glucose at the first booking visit. It should be noted that measurements of HbA_{1c} cannot reliably be used to diagnose diabetes in early pregnancy and until 3 months post-partum, since HbA_{1c} levels fall due to increased red cell turnover.

Management

The aim is to normalise maternal blood glucose concentrations and reduce the risk of excessive fetal growth. The first element of management is dietary modification, in particular by reducing consumption of refined carbohydrate. Women with gestational diabetes should undertake regular pre- and post-prandial self-monitoring of blood glucose, aiming for pre-meal blood glucose levels of <5.3 mmol/L (96 mg/dL) and a 1-hour post-prandial level of <7.8 mmol/L (142 mg/dL) or a 2-hour post-prandial level of <6.0 mmol/L (109 mg/dL). If pharmacological treatment is necessary, metformin, glibenclamide or insulin can all be used. Glibenclamide should be used rather than other sulphonylureas because it does not cross the placenta. Other oral therapies or injectable incretin-based therapies should not be given in pregnancy.

After delivery, maternal glucose usually returns to pre-pregnancy levels. In the UK, it is currently recommended that women with gestational diabetes should have a fasting blood glucose measured at 6 weeks post-partum and have HbA_{1c} concentrations measured annually to screen for the development of diabetes. This is because even those whose glucose tolerance returns to normal post-partum are at increased risk for developing type 2 diabetes, with a 5-year risk between 15 and 50%, depending on the population. Therefore, all women who have had gestational diabetes should be given diet and lifestyle advice to reduce their risk of developing type 2 diabetes (p. 743).

Pregnancy in women with established diabetes

Maternal hyperglycaemia early in pregnancy (during the first 6 weeks post conception) can adversely affect fetal development, causing cardiac, renal and skeletal malformations, of which the caudal regression syndrome (abnormal development of the lower

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

part of the spine) is the most characteristic. The risk of fetal abnormalities is about 2% for non-diabetic women and about 4% for women with well-controlled diabetes (HbA_{1c} <53 mmol/mol) but more than 20% for those with poor glycaemic control (HbA_{1c} >97 mmol/mol). Therefore, it is important for women with diabetes to aim to achieve good glycaemic control before becoming pregnant. In addition, high-dose folic acid (5 mg daily, rather than the usual 400 μg) should be initiated before conception to reduce the risk of neural tube defects.

As for gestational diabetes, mothers should attempt to maintain near-normal blood glucose levels while avoiding hypoglycaemia throughout their pregnancy, as this minimises excessive fetal growth and neonatal hypoglycaemia. This is often difficult to achieve, however. Pregnancy is also associated with an increased risk of ketosis, particularly, but not exclusively, in women with type 1 diabetes. Ketoacidosis during pregnancy is dangerous for the mother and is associated with a high rate (10–35%) of fetal mortality.

Pregnancy is linked with a worsening of diabetic complications, most notably retinopathy and nephropathy, so careful monitoring of eyes and kidneys is required throughout pregnancy. If heavy proteinuria and/or renal dysfunction exist prior to pregnancy, there is a marked increase in the risk of pre-eclampsia, and renal function can deteriorate irreversibly during pregnancy. These risks need to be carefully discussed before a woman with diabetes is considering pregnancy. The outlook for mother and child has been vastly improved over recent years but pregnancy outcomes are still not equivalent to those of non-diabetic mothers. Perinatal mortality rates remain 3–4 times those of the non-diabetic population (at around 30–40 per 1000 pregnancies) and the rate of congenital malformation is increased 5–6-fold.

Endocrine disease

Thyroid disease

Iodine deficiency

Iodine deficiency is a major public health issue in many countries, particularly in South-east Asia, the Western Pacific and Central Africa. Severe iodine deficiency in pregnancy is associated with miscarriage, stillbirth and cretinism, with significant cognitive impairment, gait abnormalities and deafness in the affected child. More moderate iodine deficiency is associated with milder forms of cognitive impairment and affects millions of people. The World Health Organisation recommends a daily iodine intake of 250 μg/day for pregnant women. Treatment of iodine deficiency in the first and second trimesters can prevent impaired cognitive development but is less effective if started in the third trimester.

Hypothyroidism

Untreated hypothyroidism is associated with subfertility and so is uncommon in pregnancy. Subclinical hypothyroidism is more common, and is often due to poor adherence to levothyroxine in known primary hypothyroidism. Most pregnant women with primary hypothyroidism require an increase in the dose of levothyroxine of approximately 25–50 μg daily to maintain normal TSH levels because there is an increased requirement for thyroxine during pregnancy. Furthermore, inadequately treated maternal hypothyroidism may be associated with impaired brain development in the fetus. Because of this, hypothyroid women should be monitored closely if planning a pregnancy; they should be advised to have their thyroid function checked as soon as possible after conception and increase their daily levothyroxine dose if necessary. During pregnancy, serum TSH and free T_4 should be measured during each trimester and the dose of levothyroxine adjusted to maintain a normal TSH level. Rarely, hypothyroidism may present during pregnancy with weight gain, constipation and lethargy. The diagnosis is easily missed since these symptoms are common in normal pregnancy. If suspected, the diagnosis can be confirmed by checking thyroid function tests, which show a raised TSH and low free T_4.

Hyperthyroidism

The coexistence of pregnancy and thyrotoxicosis is unusual, since anovulatory cycles are common in thyrotoxic patients and autoimmune disease tends to remit during pregnancy, due to suppression of the maternal immune response. Thyroid function tests must be interpreted in the knowledge that thyroid-binding globulin, and hence total T_4 and T_3 levels, are increased in pregnancy and that the normal range for TSH is lower (see Box 18.18, p. 651). Despite this, a fully suppressed TSH is usually indicative of Graves' disease. When thyroid disease during pregnancy is being dealt with, both mother and fetus must be considered, since maternal thyroid hormones, TSH receptor antibodies (TRAb) and antithyroid drugs can all cross the placenta to some degree, exposing the fetus to the risks of thyrotoxicosis, iatrogenic hypothyroidism and goitre. Moreover, poorly controlled thyrotoxicosis can result in fetal tachycardia, intrauterine growth retardation, prematurity, stillbirth and possibly even congenital malformations.

Antithyroid drugs are the treatment of first choice for thyrotoxicosis in pregnancy. Newly diagnosed hyperthyroidism during pregnancy can be treated with β-adrenoceptor antagonists (β-blockers) in the short term, followed by antithyroid drugs. Propylthiouracil (PTU) is the preferred antithyroid drug because treatment with carbimazole during the first trimester has been associated with the occurrence of choanal atresia and aplasia cutis. Hyperthyroid women who become pregnant while taking carbimazole or PTU should be advised to continue their current drug in pregnancy, with close monitoring. Both carbimazole and PTU cross the placenta and are effective in treating thyrotoxicosis in the fetus caused by transplacental passage of TRAb. To avoid fetal hypothyroidism, which can affect brain development and cause goitre, it is important to use the smallest dose of antithyroid drug (typically <150 mg PTU or 15 mg carbimazole per day) that will maintain maternal free T_4, T_3 and TSH concentrations within their respective reference ranges. Thyroid surgery is sometimes necessary because of poor drug adherence, drug hypersensitivity or failure of medical treatment and is most safely performed during the second trimester. Radioactive iodine is absolutely contraindicated throughout pregnancy, as it invariably induces fetal hypothyroidism. Frequent review of mother and fetus (monitoring heart rate and growth) is important during pregnancy and in the puerperium. Serum TRAb levels can be measured in the third trimester to predict the likelihood of neonatal thyrotoxicosis. PTU is the drug of choice in the breastfeeding mother, as it is excreted in the milk to a much lesser extent than carbimazole. Thyroid function should be monitored periodically in the breastfed child.

Post-partum thyroiditis

Post-partum thyroiditis typically presents 3–4 months after delivery. It is discussed in more detail on page 647.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Pituitary disease

Prolactinoma

Prolactinomas are the most common pituitary tumours in young women. Although fertility is reduced in patients with prolactinoma, pregnancies can occur and if this happens the tumour may enlarge as part of the physiological pituitary enlargement that takes place during normal pregnancy. Macroprolactinomas (≥10 mm) are at greater risk of enlarging and may cause optic chiasm compression. If women known to have a prolactinoma become pregnant, they should have visual field testing each trimester, followed by pituitary imaging by MRI if enlargement is suspected from changes in visual fields or from symptoms. Measurement of serum prolactin is generally not helpful, since levels increase anyway as part of normal pregnancy. Dopamine receptor agonists such as cabergoline and bromocriptine should normally be stopped during pregnancy, but can be reintroduced if necessary in patients with an enlarging prolactinoma that is threatening the visual fields.

Diabetes insipidus

Women with pre-existing diabetes insipidus may find that their symptoms worsen in pregnancy due to placental production of vasopressinase, a protease that degrades vasopressin (antidiuretic hormone, ADH). Because of this, pregnant women with diabetes insipidus may need higher doses of desmopressin until delivery. The development of symptoms suggestive of diabetes insipidus, such as thirst and polyuria, during pregnancy should raise suspicion of acute fatty liver of pregnancy (AFLP), the syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) or pre-eclampsia, as all of these conditions are also associated with decreased breakdown of vasopressinase by the liver.

Sheehan's syndrome

This is a form of post-partum hypopituitarism caused by infarction of the pituitary, usually associated with hypotension from major post-partum haemorrhage. It can present with failure to establish lactation after birth, amenorrhoea or other features of hypopituitarism. The diagnosis can be confirmed by tests of pituitary function and treated with hormone replacement, as described on page 682.

Parathyroid disease

Primary hyperparathyroidism

Primary hyperparathyroidism (PHPT) is uncommon in women of child-bearing age, but if pregnancy does occur in a patient with pre-existing PHPT, careful monitoring is required. Women with mild disease can be managed conservatively but if serum calcium levels rise above 2.85 mmol/L (11.5 mg/dL), consideration should be given to parathyroidectomy, as fetal mortality is high (up to 40%) in patients with severe hypercalcaemia. If parathyroidectomy is required, it should ideally be performed during the second trimester. Anecdotal evidence suggests that the calcimimetic drug cinacalcet can be used for medical management of PHPT during pregnancy.

Familial hypocalciuric hypercalcaemia

Familial hypocalciuric hypercalcaemia (FHH) is a benign disorder caused by mutations in the calcium-sensing receptor, which is described on page 664. Although FHH poses no risk for pregnant women, the hypercalcemia can suppress PTH secretion in neonates that do not inherit the FHH mutation, resulting in severe hypocalcaemia. Infants of mothers with FHH should have their serum calcium levels monitored during the first few days of life; if hypocalcaemia is detected, intravenous calcium should be given.

Adrenal disease

Women with known adrenal insufficiency can continue their glucocorticoid and mineralocorticoid replacement during pregnancy as normal. Rarely, adrenal insufficiency can present for the first time during pregnancy. If this occurs, the diagnosis is challenging because total cortisol normally increases during pregnancy, and short Synacthen tests (p. 672) can be falsely normal. Specialist assessment is required. In women with Conn's syndrome who become pregnant, amiloride should be substituted for spironolactone to prevent anti-androgenic effects on a male fetus.

Human immunodeficiency virus infection

The course of HIV disease is not altered by pregnancy but treatment with antiretroviral therapy should be given during pregnancy to women that are HIV-positive, as outlined on page 326. In some societies, routine HIV testing is recommended at an early stage in pregnancy in all women.

Inflammatory rheumatic disease

Most women with inflammatory rheumatic disorders have successful pregnancies but it is critically important for them to be given pre-conception counselling and to review medication use, optimise disease control and make them aware of the risks that pregnancy might pose to their condition and vice versa.

Rheumatoid arthritis

Women with rheumatoid arthritis should have a medication review; methotrexate, leflunomide and mycophenolate should be stopped and, if necessary, an alternative substituted before conception (Box 30.12). Rheumatoid arthritis often improves during pregnancy, particularly in those who are negative for rheumatoid factor or anti-cyclic citrullinated peptide antibodies. There is an increased risk of pre-eclampsia, pre-term birth and small babies for women with active disease, emphasising the importance of maintaining disease control during pregnancy. Glucocorticoids, hydrochloroquine, azathioprine and sulfasalazine can all be continued as normal but non-steroidal anti-inflammatory drugs (NSAIDs) should be avoided after 20 weeks (Box 30.12). Inhibitors of TNF-α are safe during pregnancy and can be continued if necessary to maintain control of the disease. Most TNF-α inhibitors are actively transported across the placenta and this can lead to immunosuppression in the neonate if these drugs are used during the second and third trimesters. An exception is certolizumab, which is a pegylated antibody, and this is a good option for women who require TNF-α inhibition during pregnancy. Experience with other biological therapies during pregnancy is limited. Disease flares are common in the post-partum period, regardless of serology, and this can pose a problem for breastfeeding and care of the infant. Glucocorticoids are a good short-term option to control such flares, pending reintroduction of other disease-modifying antirheumatic drugs (DMARDs) that might have been stopped prior to pregnancy.

Systemic sclerosis

Pregnancy in women with diffuse systemic sclerosis (SSc), those with pulmonary hypertension or renal involvement and those with disease of recent onset (<4 years) poses risks to mother and

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

30.12 Safety of antirheumatic drugs during pregnancy and breastfeeding

Drug	Safe during pregnancy	Safe during breastfeeding	Comment
Non-steroidal anti-inflammatory drugs (NSAIDs)	Yes (<20 weeks)	Yes	
Hydroxychloroquine	Yes	Yes	
Glucocorticoids	Yes	Yes	A good short-term option for disease flares
Azathioprine	Yes	Yes	
Sulfasalazine	Yes	Yes	Co-prescribe with folic acid
Ciclosporin	Yes	Yes	Data on breastfeeding limited
Tacrolimus	Yes	Yes	
Mycophenolate	No	No	Stop before planning pregnancy
Methotrexate	No	No	Stop 3 months before planning pregnancy
Leflunomide	No	No	Stop 2 years before planning pregnancy
Cyclophosphamide	No	No	
Tumour necrosis factor (TNF) inhibitors	Yes	Yes	Avoid live vaccines in the neonate for 6 months

Adapted from Ateka-Barrutia O, Nelson-Piercy C. Connective tissue disease in pregnancy. Clin Med 2013; 131:580–584.

30.13 Systemic sclerosis (SSc) and pregnancy

Subtype	Effect of disease on pregnancy
Localised SSc	Good prognosis Raynaud's may improve Oesophagitis may worsen
CREST syndrome	Good prognosis Raynaud's may improve Oesophagitis may worsen
Diffuse SSc	Increased risk of: Pre-term delivery Pre-eclampsia Fetal growth restriction Low-birth-weight babies Maternal and fetal mortality

(CREST = calcinosis, Raynaud's phenomenon, oesophageal involvement, sclerodactyly and telangiectasia)

fetus. In milder forms of the disease, however, the prognosis is better (Box 30.13). Raynaud's phenomenon often improves during pregnancy due to vasodilatation but oesophageal symptoms may worsen. Renal crises are no more frequent during pregnancy, but if one occurs, ACE inhibitors should be given. Although these are normally contraindicated in pregnancy, the potential benefit in this situation outweighs the risk to the fetus. Glucocorticoids, which can be given to promote fetal lung maturation in premature babies, should be avoided in women with SSc where possible because they may provoke renal crisis.

Systemic lupus erythematosus

Pregnancy in women with systemic lupus erythematosus (SLE) poses several risks to both mother and fetus, especially if there is renal involvement. There is an increased risk of pre-eclampsia, thrombosis, fetal growth restriction, pre-term delivery, miscarriage and fetal death. There is also a higher risk of lupus flare during the puerperium. Good control of disease is paramount, since women with SLE who conceive when their disease has been quiescent for at least 6 months are less likely to have complications than those who conceive when their disease has recently been active. It can be difficult to assess disease activity during pregnancy because symptoms such as oedema, hair loss, joint pain and fatigue, which occur in active SLE, are also common during normal pregnancies. The features in Box 30.14 can help differentiate between an SLE flare, normal pregnancy and pre-eclampsia.

30.14 Differential diagnosis of lupus flare during pregnancy

Clinical finding	Lupus flare	Pre-eclampsia	Normal pregnancy
Hypertension	Yes	Yes	No
Proteinuria	Yes	Yes	No
Red cells/casts in urine	Yes	No	No
Liver function tests	Normal	Abnormal	Normal
Anti-double-stranded DNA	Increase	Unchanged	Unchanged
C3 and C4	Low	Elevated or unchanged from baseline	Unchanged

All women with SLE should be tested for anti-Ro and anti-La antibodies, since they can cross the placenta and cause neonatal complete heart block or cutaneous lupus, respectively. Medications should be reviewed prior to pregnancy, to ensure they are safe, and an alternative substituted if necessary (see Box 30.12). The management of patients with antiphospholipid antibodies (aPL) is described below.

Anti-phospholipid syndrome

Primary antiphospholipid syndrome (APS) is associated with an increased risk of adverse pregnancy outcomes, including thrombosis, miscarriage, fetal death and pre-eclampsia. This applies to primary APS and that associated with connective tissue diseases such as SLE. During pregnancy, women with APS should be managed with low-dose aspirin in combination with low-molecular-weight heparin (LMWH).

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Cardiac disease

Congenital heart disease

Women who have a history of surgically corrected congenital heart disease generally tolerate pregnancy well, but are more likely to have babies with congenital heart disease and should be offered fetal cardiac scans. Acyanotic heart diseases, such as atrial septal defect, ventricular septal defect and patent ductus arteriosus, all have a good prognosis in pregnancy. Unrepaired cyanotic heart disease has a very poor prognosis in pregnancy, as does pulmonary hypertension, regardless of the underlying cause. Women with mechanical heart valves require anticoagulation throughout pregnancy but their anticoagulation should be planned with consideration of substituting warfarin with LMWH and aspirin during the first trimester to reduce the risk of warfarin embryopathy. If necessary, warfarin can be used during pregnancy, particularly in the second and third trimesters.

Valvular heart disease

The physiological changes of pregnancy may also unmask previously undiagnosed valvular disease. Women with regurgitant lesions, such as mitral regurgitation and aortic regurgitation, tolerate pregnancy better than those with stenotic lesions. Mitral stenosis causes a reduction in blood flow from the left atrium to left ventricle in diastole, which worsens during pregnancy due to the increased heart rate and hypervolaemia. Those with moderate to severe mitral stenosis (valve area <1.5 cm^2) are at particular risk and may develop arrhythmias, tachycardia and pulmonary oedema. Most patients can be managed medically with β-blockers, LMWH and furosemide as necessary. Surgical intervention is indicated if there is continued haemodynamic compromise despite optimal medical management.

Myocardial infarction

Pregnancy increases the risk of myocardial infarction. While atherosclerosis is the main cause in non-pregnant individuals, coronary artery dissection and coronary thrombosis secondary to the hypercoagulable state are more common causes during pregnancy. Management is similar to that of non-pregnant women, except that statins and glycoprotein IIb/IIIa inhibitors such as apixaban should be avoided. Clopidogrel can be given but should be stopped around the time of delivery to reduce the risk of uterine bleeding and to allow spinal anaesthesia to be used if necessary. Stenting can be performed, but bare-metal stents are preferred because drug-eluting stents require dual antiplatelet therapy that cannot be continued around the time of delivery.

Aortic dissection

Pregnancy is an independent risk factor for aortic dissection and this should be considered when a woman presents with acute severe chest pain during pregnancy. The vast majority of cases in pregnancy are 'type A', involving the ascending aorta (see Fig. 16.72, p. 506), and require careful control of hypertension, caesarean section to deliver the fetus, and emergency surgery to treat the aneurysm.

Peripartum cardiomyopathy

Peripartum cardiomyopathy (PPCM) presents with heart failure secondary to left ventricular systolic dysfunction towards the end of pregnancy or in the months following delivery. It is a diagnosis of exclusion, made when other causes of heart failure have been ruled out. The cause is unknown but PPCM is more prevalent in women who are older, multiparous, hypertensive and Afro-Caribbean. It is treated by conventional medications for heart failure, including ACE inhibitors if necessary, and delivery of the baby. Many women recover within 3–6 months of diagnosis but the prognosis is variable. There is a significant chance of reduction in cardiac function in subsequent pregnancies.

Dilated cardiomyopathy

Dilated cardiomyopathy carries a poor prognosis if the pre-pregnancy ejection fraction is below 30% or if symptoms are in New York Heart Association grades 3 or 4. Management is as described for PPCM.

Renal disease

Renal tract infection

Pregnancy predisposes women to urinary tract infection. If asymptomatic bacteriuria is discovered during pregnancy, it should be treated promptly with antibiotics, to prevent ascending renal tract infection. Pyelonephritis is more common in pregnancy due to the physiological dilatation of the upper renal tract; if it does occur, it can trigger premature labour.

Acute kidney injury

Acute kidney injury (AKI) may occur during pregnancy or in the puerperium due to a variety of causes (Box 30.15). Women with AKI caused by pre-eclampsia are prone to pulmonary oedema, and need very careful fluid balance to avoid fluid overload. In the post-partum period, AKI may occur as the result of post-partum haemorrhage or pre-eclampsia, and sometimes these occur in combination. Although pre-eclampsia resolves after delivery, AKI can be at its worst in the first few days post-partum, especially when exacerbated by obstetric haemorrhage.

Glomerular disease

Proteinuria caused by glomerular disease is usually exacerbated during pregnancy, and nephrotic syndrome may develop without any alteration in the underlying disease activity in individuals who had only slight proteinuria before pregnancy. This further increases the risk of venous thromboembolism, the leading cause of maternal deaths in developed countries.

Chronic kidney disease

Women with chronic kidney disease (CKD) are at increased risk of pre-eclampsia, fetal growth restriction, miscarriage, pre-term delivery and fetal death (Fig. 30.3). Pregnancy can also cause acceleration of maternal renal decline. The factors that influence pregnancy outcome for women with CKD are baseline renal function, hypertension, degree of proteinuria and the underlying cause of CKD. Women with CKD should have pre-pregnancy counselling, be closely monitored by a multidisciplinary team throughout pregnancy, and be given low-dose aspirin as prophylaxis against pre-eclampsia.

Renal replacement therapy

Fertility is reduced among women on renal replacement therapy and there is increased risk of adverse pregnancy outcomes.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

i 30.15 Causes of acute kidney injury in pregnancy

Mechanism	Cause	Features
Pre-renal	Hyperemesis gravidarum	Nausea and vomiting Dehydration Presentation in first trimester
	Post-partum haemorrhage	Vaginal bleeding immediately post-partum
	Placental abruption	Abdominal pain or vaginal bleeding in second or third trimester
	Septic abortion	Presentation with hypotension, shock and pyrexia
Renal	Pre-eclampsia	Presentation in second and third trimesters with new-onset hypertension and proteinuria
	Thrombotic thrombocytopenic purpura	Possible antenatal or post-partum presentation with headache, irritability and drowsiness Haematology shows thrombocytopenia and microangiopathic haemolytic anaemia
	Acute fatty liver of pregnancy	Presentation with vomiting and abdominal pain in third trimester Abnormal liver function tests Liver ultrasound can be normal
	Acute interstitial nephritis	Most common cause is use of non-steroidal anti-inflammatory drugs
Post-renal	Acute urinary retention	Usual presentation is in third trimester due to enlarged uterus causing ureteric obstruction; sometimes presents post-partum

Adapted from Palma-Reis I, Vais A, Nelson-Piercy C, et al. Renal disease and hypertension in pregnancy. Clin Med 2014; 13:57–62.

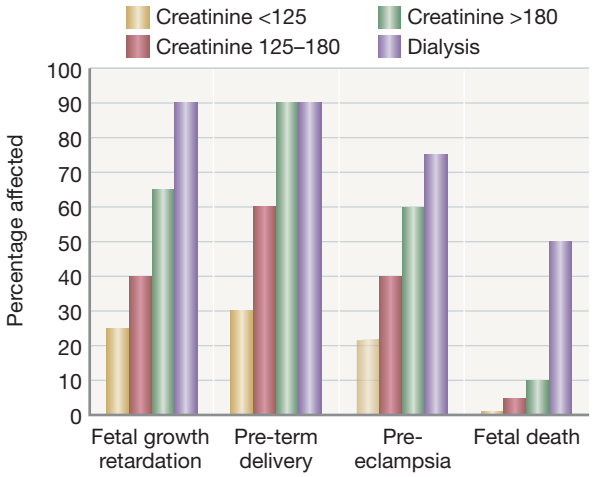

Fig. 30.3 Adverse pregnancy outcomes in chronic kidney disease. Creatinine is in μmol/L. To convert to mg/dL, multiply by 0.011. *Data from Williams D, Davison D. Chronic kidney disease in pregnancy. BMJ 2008; 336:211–115.*

Despite this, many women receiving renal replacement therapy have successful pregnancies. More intensive dialysis is recommended in pregnancy, and particular attention should be paid to addressing issues around blood pressure, fluid balance and anaemia.

Renal transplant recipients

Pregnancy should be delayed for a minimum of 12 months following renal transplantation, to allow the graft to stabilize, on minimum immunosuppressive drugs. The outcome is best for women with a well-functioning graft, with no proteinuria or hypertension. Women with renal transplants can deliver vaginally but in practice there is a higher incidence of caesarean section in this group, due to the higher incidence of pre-term delivery.

Liver disease

Specific causes of liver disease during pregnancy are discussed below.

i 30.16 Criteria for diagnosis of acute fatty liver of pregnancy

- Vomiting
- Abdominal pain
- Polydipsia/polyuria
- Encephalopathy
- Elevated bilirubin (>14 μmol/L (>0.82 mg/dL))
- Low glucose (<4 mmol/L (<72.4 mg/dL))
- Elevated urate (>340 μmol/L (>5.7 mg/dL))
- Leucocytosis (>11×10^9/L)
- Ascites or bright liver on ultrasound
- Elevated transaminases (alanine/aspartate aminotransferase (ALT/AST) >42 U/L)
- Elevated ammonia (>47 μmol/L (>81.7 mg/dL))
- Renal impairment (creatinine >150 μmol/L (>1.7 mg/dL))
- Coagulopathy (prothrombin time >14 secs or activated partial thromboplastin time >34 secs)
- Microvascular steatosis on liver biopsy

Acute fatty liver of pregnancy can be diagnosed when ≥6 of the above features are present in the absence of another explanation.

Adapted from Ch'ng CL, Morgan M, Hainsworth I, et al. Prospective study of liver dysfunction in pregnancy in Southwest Wales. Gut 2002; 51:876–880.

Acute fatty liver of pregnancy

Acute fatty liver of pregnancy (AFLP) is a rare and serious condition that typically presents in the third trimester with vomiting, abdominal pain, jaundice and other symptoms (Box 30.16). It is more common in first pregnancies and multiple pregnancies, and is associated with male fetuses. Rarely, fulminant liver failure may occur. The diagnosis can usually be made on the basis of the clinical features, abnormal liver function tests (LFTs) and the appearances of fatty liver on ultrasound. A liver biopsy is rarely needed to make the diagnosis but shows microvascular steatosis. Management is with supportive care and by delivery of the fetus. The development of AFLP has been linked in some cases with an inherited deficiency of the enzyme long-chain acyl-CoA dehydrogenase (LCHAD) in the baby.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

HELLP syndrome

The syndrome of haemolysis, elevated liver enzymes and low platelets (HELLP) is thought to be part of the spectrum of pre-eclampsia. It usually presents antenatally but can also appear for the first time in the postnatal period. The presenting symptoms can be the same as those of pre-eclampsia but can also include headache, right upper quadrant pain and visual disturbance. HELLP can be complicated by liver haematoma and capsular rupture. Management involves supportive care, control of hypertension, correction of coagulopathy and delivery of the fetus.

Obstetric cholestasis

Obstetric cholestasis is estimated to affect about 1% of pregnancies in Caucasians, although the prevalence is higher in Chinese and South Asian populations. The cause is incompletely understood but the condition is thought to be due in part to the cholestatic effect of high oestrogen levels. The typical presentation is in the third trimester with pruritus, particularly affecting the soles and palms. Laboratory testing reveals raised levels of bile acids and abnormal LFTs. The diagnosis can be made on the basis of these clinical features when other causes of liver dysfunction and pruritus have been excluded. Treatment is with ursodeoxycholic acid in a starting dose of 250 mg twice daily, which usually improves symptoms and liver function. Aqueous cream with menthol can also be effective in soothing pruritus. There is an increased risk of fetal mortality with evidence of a particularly high risk when bile acid levels are over 40 μmol/L (97.9 μg/mL). Treatment therefore aims to bring bile acids below 40 μmol/L and some centres induce labour before 40 weeks in an effort to reduce the risk. The risk of recurrence in future pregnancies is high.

Viral hepatitis

The course of hepatitis B is unchanged in pregnancy, but it is important to identify women who have active infection to reduce the risk of vertical transmission to the fetus; this risk is up to 90% in women who are hepatitis B e-antigen positive. Vaccinations and immunoglobulin should be given to infants of mothers who test positive for hepatitis B, and antiviral agents should be given to the mother after delivery. Vertical transmission rates of hepatitis C are low in the absence of HIV infection and so no action is required for the infant, unless there is co-infection with HIV; in this case, antiviral drugs should be considered. Pregnant women are at greater risk of contracting hepatitis E than the non-pregnant population. It is transferred via the faeco-oral route, and is usually a mild self-limiting illness outside of pregnancy. However, it can cause fulminant hepatic failure in up to 20% of pregnant women.

Neurological disease

Epilepsy

Women with epilepsy should have pre-pregnancy counselling and should be advised to take high-dose folic acid from pre-conception; their antiepileptic drugs (AEDs) should also be reviewed. Maternal treatment with sodium valproate is associated with a higher rate of fetal malformations than other AEDs, and a reduction in intelligence quotient and an increased risk of autistic spectrum disorder in the offspring. Where possible, sodium valproate should be substituted for another AED with a better safety profile in pregnancy, such as lamotrigine, levetiracetam or carbamazepine. While pregnancy does not generally affect the frequency of seizures in women with well-controlled epilepsy, those who enter pregnancy with poorly controlled epilepsy are likely to deteriorate. The plasma levels of some AEDs such as lamotrigine can fall in pregnancy and checking drug levels can be helpful. Seizures are more common at the time of delivery and women should be advised to deliver in a unit staffed with personnel able to manage this.

Idiopathic intracranial hypertension

Idiopathic intracranial hypertension (IIH) may worsen during pregnancy due to weight gain. Treatment with acetazolamide can be continued during pregnancy but should be avoided in the first trimester due to lack of safety data. The mode of delivery is not affected by IIH and spinal analgesia can be given as normal.

Migraine

Migraine often improves during pregnancy but if attacks occur they should be managed with simple analgesia and antiemetics. If necessary, prophylaxis can be given with aspirin, β-blockers or tricyclic antidepressants. Safety data on use of triptans during pregnancy are limited but reassuring. Triptans can therefore be used for the treatment of migraine if other therapies are ineffective.

Stroke

Stroke is twice as common in pregnant women as in non-pregnant women of the same age. The risk is highest during the third trimester and puerperium. The management of stroke during pregnancy is similar to that in non-pregnant patients. The risk of cerebral venous thrombosis is greatly increased during pregnancy. The presentation is with headache, seizures and neurological deficits such as hemiparesis. If the diagnosis is suspected, neuroimaging should be performed with MRI or CT venography. Management of acute infarct should be as for the non-pregnant patient and include consideration of thrombolysis.

Psychiatric disorders

Mood changes are common during pregnancy but more severe psychiatric disorders, such as depression or psychosis, typically present within 2–4 weeks of delivery. These disorders are discussed in more detail on page 1206 and in Box 28.33.

Haematological disease

Anaemia

The causes of anaemia during pregnancy are summarised in Box 30.17. Iron deficiency anaemia is most commonly due to a 20% increased demand for iron. In most cases, it responds well to oral iron supplementation, with a rise in haemoglobin of approximately 0.8 g/L per week. If the haemoglobin does not rise following a 4-week trial of iron supplementation, alternative causes of anaemia should be considered. Non-adherence to oral iron is common and intravenous iron should be considered in women with iron deficiency and failure of oral treatment. It is generally not necessary to investigate iron deficiency anaemia during pregnancy unless there is clinical evidence of gastrointestinal blood loss, which should be investigated in the normal way.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

i 30.17 Causes of anaemia in pregnancy

Microcytic

- Iron deficiency
- Haemoglobinopathies
- Thalassaemia

Normocytic

- Anaemia of chronic disease
- Haemorrhage
- Haemolysis

Macrocytic

- Vitamin B_{12}/folate deficiency
- Liver disease
- Alcohol excess

Rhesus disease

Women who are negative for the Rhesus antigen should be offered treatment with anti-RhD immunoglobulin around the time of delivery to reduce the risk of haemolytic disease of the newborn. More details are provided on page 933 and in Box 23.19.

Thrombocytopenia

The causes of thrombocytopenia during pregnancy are summarised in Box 30.18. The most common cause is gestational thrombocytopenia, which typically occurs towards the end of pregnancy and resolves spontaneously after delivery. It is not associated with adverse pregnancy outcomes and requires no specific intervention. Pregnancy may occur in women with pre-existing idiopathic thrombocytopenic purpura (ITP, p. 971). This should be managed with glucocorticoids and/or immunoglobulin, with the aim of maintaining the platelet count above 80×10^9/L at the time of delivery, in case spinal anaesthesia or caesarean section is required. Thrombocytopenia may also occur as a component of haemolytic uraemic syndrome (HUS, p. 408) and thrombotic thrombocytopenic purpura (TTP, p. 979). Both are characterised by microangiopathic haemolytic anaemia, acute kidney injury and thrombocytopenia, but in TTP neurological symptoms and fever also occur. These conditions are rare but important to recognise since up to one-quarter of cases occur during pregnancy and the post-partum period. TTP is managed with plasma exchange, fresh frozen plasma and sometimes glucocorticoids or rituximab. Platelet transfusion should be avoided.

i 30.18 Causes of thrombocytopenia during pregnancy

- Gestational thrombocytopenia
- Idiopathic thrombocytopenic purpura
- Systemic lupus erythematosus
- HELLP (haemolysis, elevated liver enzymes and low platelets)
- Haemolytic uraemic syndrome
- Thrombotic thrombocytopenic purpura

Venous thromboembolism

The risk of venous thromboembolism (VTE) is 4–5 times higher in pregnancy than in non-pregnant women. DVT is the most common presentation and predominantly affects the left leg in pregnancy, for reasons that are incompletely understood. Doppler ultrasound scan is the investigation of choice, but MRI can also be used if proximal clot is suspected. Measurement of D-dimer is not useful in pregnancy because levels rise as part of normal pregnancy. Treatment of VTE in pregnancy is with LMWH at a higher dose than for the non-pregnant woman, based on the patient's early pregnancy (booking) weight. Women with a previous history of VTE who are receiving warfarin or other oral anticoagulants as prophylaxis should have these stopped prior to conception and LMWH should be substituted.

Historically, childhood illnesses were characterised by a series of acute episodes, often infective, on a background of an otherwise healthy patient. Adult medicine traditionally comprised patients with progressive conditions, and increasing pathology with advancing age. A number of factors have led to the recognition that boundaries between adult medicine and paediatric care are not clear-cut, and recent evidence has confirmed that anticipating and carefully planning the transition of children with long-term conditions (LTCs) into adult services improve care and outcomes. About 14% of children in the developed world are diagnosed with an LTC and in the majority of patients the disorder will persist into adulthood. Common illnesses include asthma, epilepsy, congenital heart disease, diabetes and childhood cancer (Box 31.1). Similar trends are developing worldwide, with increasing survival rates of children with complex pathology, and increasing prevalence of lifestyle-related conditions such as obesity, hypertension and type 2 diabetes. Specific factors that make transition planning important in young people with LTCs are outlined in Figure 31.1.

Planning the process of transition from paediatric to adult health services and improving the assessment of young people as they enter those adult services have been shown to impact positively on long-term health outcomes. There is a need for physicians to gain new skills in the care of young people and adults who have conditions that have arisen in childhood. This includes developing specific skills in the management of adolescents and young adults, managing the process of transition and developing knowledge of relevant medical conditions. The overall approach to transition medicine, as well as important disease-specific issues, will be considered in this chapter.

Transition from paediatric to adult health services

Effectiveness of transition planning

A review of the effectiveness of transition planning has confirmed improved health outcomes when specific interventions to improve coordination between adult and paediatric services are implemented. Most research in this field has been undertaken with young people with diabetes, and many of the outcome measures relate to that condition. The principles of transition planning and the potential benefits are, however, likely to be generalisable to other LTCs that present in childhood. Young people with serious LTCs are among the most complex and high-risk patients to care for in adulthood, and it is important to work closely with them as they move to adult services, to try to improve their long-term outcome.

General principles of transition planning

Paediatric services are organised and delivered in a very different way to adult medical services. They encompass a period of life that spans from infancy to independence, and progress from taking parents' views as paramount to needing to recognise

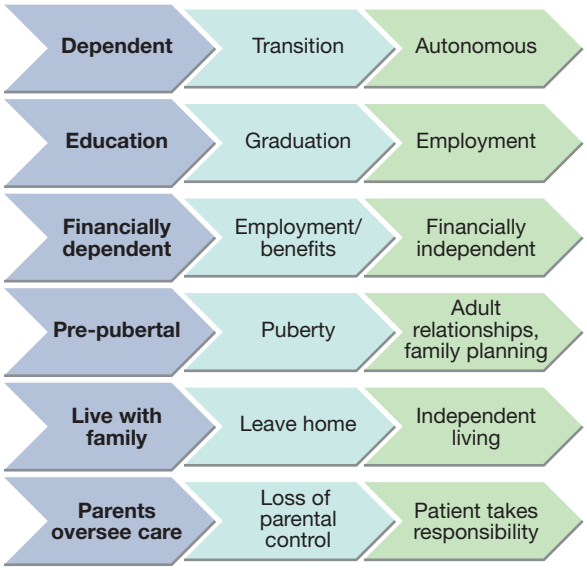

Fig. 31.2 Lifestyle changes during transition to adulthood.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

the wishes of the young person. After transition, young people move from medical services that have been family-centred and focused around maximising the child's development, to a service that encourages patient autonomy, in which employment and reproduction are important measures of outcome. At the same time as undergoing transition within medical services, young people are making multiple other transitions in their lives as they move from a dependent to an independent way of living (Fig. 31.2). They often move away from the family home, and parents who formerly held responsibility for patient management, coordination of care, communication and consent to treatments will be demoted to an advisory role. Paediatric services are not well placed to meet this change in focus from the patient as a child to the patient as an independent adult, and young people benefit from the move to adult services as long as their specific needs as a young adult are recognised.

Principles of prescribing during transition

Hepatic drug metabolism increases from neonatal levels during childhood, eventually decreasing to adult levels after puberty. Once puberty has been completed, teenagers can be considered, in pharmacokinetic and pharmacodynamic terms, to behave like adults. It is important to remember that many young people have considerably lower body mass and therefore body mass index (BMI) than adults, and care needs to be taken to avoid excessive dosage in physically smaller patients. Likewise, obesity needs consideration in terms of prescribing and drug doses. The general advice is that when prescribing a dose per kilogram, the optimal weight for height rather than actual weight should be used for obese young people.

i 31.2 Core elements in developing a transitional care programme

Establishing transition policy

- Develop policy, with input from young people
- Train staff in operation of policy

Tracking and monitoring

- Establish process to identify patients
- Develop systems to track individual progress
- Incorporate transition planning into clinical care

Transition readiness

- Identify suitable adult care provider
- Establish process for introduction to adult team
- Provide written information about joint first consultation

Transition planning

- Ensure communication between paediatric and adult teams
- Identify need for handover consultation
- Prepare written medical handover:
  - Diagnosis
  - Current treatment
  - Previous key issues
- Send relevant information in advance
- Provide information and community support

Transfer to adult services

- Arrange first consultation
- Review transfer package with team
- Identify concerns of young person
- Review young person's health priorities
- Update medical summary and emergency care plans

Integration into adult services

- Communicate with paediatrics and confirm transfer
- Help young adult to access other adult services
- Continue individualised care plan tailored to young person
- Seek feedback from young adult about transition

A systematic approach to transition planning

Several steps need to be undertaken to develop a successful programme for transition of care. The key components are summarised in Box 31.2. The first step is to establish a policy in consultation with young people and train staff in the policy. Subsequently, systems need to be developed to identify patients in need of transition and track them as they pass through the programme. Adult health-care providers need to be identified and processes developed for introducing the young person to the adult team. This should be followed by written communication between the paediatric and adult teams, and then a first consultation with the adult team at which the transfer can be reviewed and

i 31.3 Key features in assessing readiness for transition to adult services

(K) Knowledge

1. Describes condition, effects and prognosis
2. Understands medication purpose and effects
3. Understands treatment purposes and effects
4. Knows key team members and their roles

(S) Self-advocacy

1. Can attend part/whole clinic appointment on their own
2. Knows how to make appointments/alter appointments
3. Has understanding of confidentiality
4. Orders repeat prescriptions
5. Takes some/complete responsibility for medication/other treatment
6. Knows where to get help

(H) Health and lifestyle

1. Understands importance of diet/exercise/dental care
2. Understands impact of smoking/alcohol/substance use
3. Understands sexual health issues/pregnancy/sexually transmitted infections

(A) Activities of daily living

1. Self-care/meal preparation
2. Independent travel/mobility
3. Trips/overnight stays away from home
4. Benefits/financial independence

(V) Vocational

1. Current and future education/impact of condition on career plans
2. School attendance and performance
3. Work experience and access to careers advice
4. Outside activities and interests
5. Disclosure to school/employer

(P) Psychosocial

1. Self-esteem/self-confidence
2. Body/self-image
3. Peer relationships/bullying
4. Support networks/family/disclosure to friends
5. Coping strategies

(T) Transition

1. Understands concept of transition
2. Agrees transition plan
3. Attends transition clinic
4. Visits adult unit (if appropriate)
5. Sees primary care team/other clinical staff independently

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

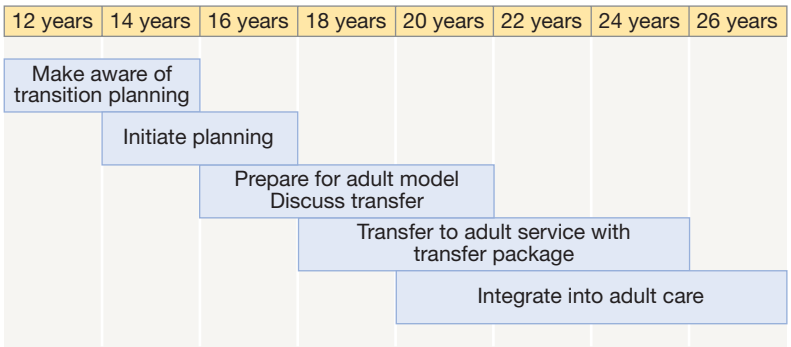

Fig. 31.3 Timing of transition.

a care plan developed. There should subsequently be written communication between the adult and paediatric teams to confirm that handover has occurred, followed eventually by integration of the young person's care into the adult service.

A number of organisations have published guidelines to planning transition services. Two of the best known include the 'Ready Steady Go' programme in the UK and the American Academy of Paediatrics' 'Got Transition' (see 'Further information'). Details of the sorts of competencies that a young person might need before making a full transition to adult medical services are outlined in Box 31.3.

When should transition happen?

The optimum timing for transition is not specifically defined; it is a process that evolves over a number of years, during which puberty and then adolescence occur. Transition should generally be initiated at around 12 years of age. Completion time then varies from person to person, also depending on the model of adult services available. Most commonly, full transition occurs between 16 and 18 years of age (Fig. 31.3). This coincides with many other areas where young people are considered to have made the transition to adulthood, such as the completion of formal education. Marriage and children often follow.

Functional anatomy and physiology

Puberty and adolescence are developmental stages through which children progress during the second decade of life. During this phase, several physical, biochemical and emotional changes occur. The most important are discussed in more detail below.

Endocrine changes

The hormonal and physical stages of progression through puberty in males and females are summarised in Figure 31.4. Puberty is initiated by pulsatile increases in gonadotrophin-releasing hormone (GnRH) by the hypothalamus, which in turn stimulates pulsatile release of luteinising hormone (LH) and follicle-stimulating hormone (FSH) by the pituitary. In males, the increased production of LH stimulates Leydig cells in the testes to produce testosterone, and FSH acts on Sertoli cells to stimulate sperm production, as described on page 651 and shown in Figure 18.13. The rise in testosterone increases skeletal growth, promotes development of the male genital organs and stimulates growth of pubic, facial and axillary hair. In females, FSH and LH act on the ovary to promote follicle production, ovulation and menstruation, as described on page 652 and shown in Figure 18.14. Other hormonal changes in all adolescents include a rise in adrenal androgens and a rise in growth hormone, which in turn stimulates production of insulin-like growth factors 1 and 2 (IGF-1 and IGF-2). Insulin production also rises by about 30% during puberty. These hormonal changes contribute to the biological, morphological and psychological changes seen during the teenage years. Adolescence (as opposed to puberty) comprises not only the physical changes of puberty, but also the wider emotional and psychological changes of progression into early adulthood. The emotional and psychological changes are associated with physical maturation but also with sociocultural influences. The normal feelings and behavioural development of normal adolescence are complex but tend to follow fairly predictable patterns.

Physical changes

In girls, there is an increased rate of growth, followed soon after by the development of breasts and pubic hair. Menstruation typically starts after the rate of growth has peaked. In boys, puberty begins with testicular enlargement, followed soon after by a growth spurt and the development of pubic hair. In clinical practice, Tanner staging is used as a method of documenting progression of physical changes that occur during puberty (Fig. 31.5). The average age at onset of puberty in the UK is about 11 years in girls and 12 years in boys but normal puberty has a very wide range of onset. Factors that are important in predicting age of onset of normal puberty include family history (age of onset is strongly predicted by the parents' pattern of onset) and body mass, with heavier children entering puberty at a younger age. The current trends towards improved nutritional status and increased obesity in particular are driving earlier onset of puberty. Delayed puberty is defined to have occurred when the age at onset is more than 2.5 standard deviations above the national average, which in the UK is about 13 years in girls and 14 years in boys. If puberty is delayed beyond this point, investigations may be needed to determine the underlying cause, as detailed on page 653. Many children who have had long-term health conditions during childhood experience a delayed onset of puberty because chronic ill health slows longitudinal growth and causes functional hypogonadotrophic hypogonadism. Glucocorticoid therapy also contributes to growth retardation in children with chronic inflammatory diseases. An X-ray of the left wrist can be used to assess bone age accurately, and a bone age that is more than 2 years behind the chronological age should prompt consideration of further investigations (p. 654).

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

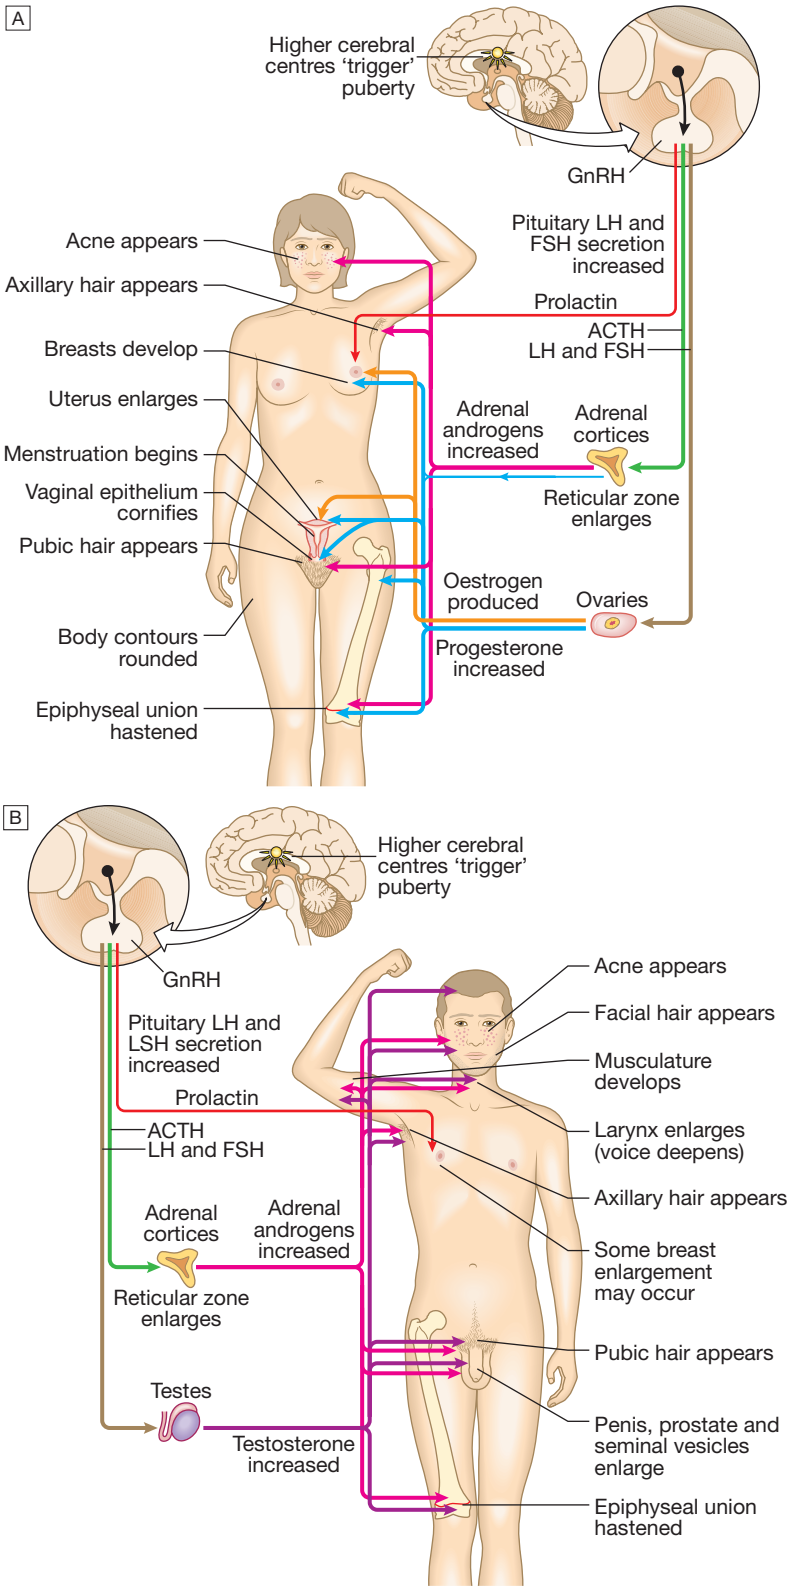

Fig. 31.4 Hormonal events of puberty. A In the ovary, FSH acts on granulosa cells to stimulate oestrogen production, whereas LH acts on theca cells to stimulate progesterone production. Androgens are also produced in small amounts by theca cells in response to LH (not shown). B In the male, LH acts on interstitial Leydig cells to stimulate testosterone production. FSH with testosterone acts on Sertoli cells to stimulate spermatogenesis. (ACTH = adrenocorticotrophic hormone; FSH = follicle-stimulating hormone; GnRH = gonadotrophin-releasing hormone; LH = luteinising hormone) *From Smith RP. Netter's Obstetrics and gynecology, 2nd edn. Philadelphia: Saunders, Elsevier, Inc.; 2008.*

Tanner stage	I	II	III	IV	V
Female					
					
Breast	Pre-adolescent	Elevation of breast and papilla as a small mound	Further enlargement of breast and areola with no separation of contours	Projection of areola and papilla to form mound above breast	Mature stage. Projection of papilla with recession of areola to contour of breast
					
Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult. No spread to medial surface of thighs	Dark, coarse and curled hair extending to inner thighs
Male					
					
Genitalia	Pre-adolescent	Growth of testes and scrotum. Skin on scrotum reddens and becomes wrinkled	Growth of penis and further growth of testes and scrotum. Skin of scrotum becomes darker and more wrinkled	Further growth in length and width of penis, testes and scrotum	Penis, testes and scrotum of adult size
Pubic hair	None	Sparse, long and straight	Darker, coarse and curled hair	Darker, coarse and curled hair but covering smaller area than in adult	Dark, coarse and curled hair extending toward umbilicus

Fig. 31.5 Tanner staging of puberty.

Cognitive and behavioural changes

As young people move from their early teenage years to later adolescence there is a move away from the family towards personal independence. This is often characterised by change from a self-centred focus, associated with a sense of awkwardness and worries about being normal, towards increased self-confidence and an awareness of weaknesses in parents and others in authority. In late adolescence, young people reach a stage of self-reliance, increased emotional stability and improved ability to think ideas through. Finally, young adults begin to develop firm belief systems, autonomy and independence. With time, there is reduced conflict with parents and other figures in authority and full maturity develops.

In terms of cognition, there is a transition from being mostly interested in the present, in short-term outcomes and instant gratification, through to increased concern for the future and a greater focus on one's longer-term role in life. Sexuality and relationships clarify during adolescence, and individuals move from early awkwardness and uncertainty to a firmer sense of their sexual identity, and then development of more serious and longer-term relationships. In terms of morals and values, young people move from a period of risk-taking behaviour and experimentation through to understanding the potential consequences of such behaviour for their future health and well-being. Young adults develop a greater capacity for setting personal goals and an increased focus on self-esteem. Finally, family, social and cultural traditions regain some of their previous importance, and by the time young people emerge from adolescence, they have usually developed insight and a greater focus on self-esteem and long-term well-being. It is the development of these more mature personality traits that are important for the more active role in health care that is needed to function well within an adult model of medicine. Some teenagers do vary slightly from these broad patterns but the feelings and behaviours described are, in general, considered normal for each stage of adolescence. Understanding these changes in emotional and psychological behaviour underpins the approaches that are needed to meet the challenges of managing long-term conditions in older teenagers and young adults.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

31.4 Biochemical changes during transition

Analyte	Comment
Alanine aminotransferase (ALT)	Increased during adolescence Activity may continue to rise, at least in men, until middle age
Alkaline phosphatase (ALP)	Activity higher in infancy, decreases during childhood, and rises again with skeletal growth during puberty Peak in females at median 11 years and in males at 13 years Levels decrease rapidly after puberty, particularly in girls; adult levels achieved after epiphyses fused
Insulin-like growth factor 1	Levels 30% higher during adolescence
Serum creatinine	Increases steadily from infancy to puberty parallel to development of skeletal muscle; until puberty, there is little difference in concentration between males and females
Uric acid concentration	Decreases from high levels at birth until 7–10 years of age, then increases, especially in boys, until 16 years

Investigations

Several changes take place during adolescence in terms of skeletal growth, organ development and body composition, which can influence the interpretation of results. Examples include fusion of the epiphyses as puberty progresses, increases in bone mineral content and density as the skeleton grows, and changes in the reference range of certain biochemical tests. Most of these changes occur gradually during puberty and there are rarely abrupt alterations in adult biochemical concentrations. It is important to use age-adjusted biochemical reference ranges until puberty has been completed. Several biochemical changes take place in the composition of body fluids between infancy and puberty.

Some of the key changes in biochemical markers are outlined in Box 31.4. More detail on reference ranges for specific analytes is provided in Box 35.9 (p. 1363). The elevation in alkaline phosphatase (ALP) levels during adolescence relates to the bone isoenzyme produced by osteoblasts in the growing skeleton during the growth spurt. Further investigations for raised levels of ALP are not required in adolescence, as long as other liver function tests, including γ-glutamyl transferase (GGT), are normal.

In general, under normal physiological conditions, the reference ranges of most biochemical tests remain fairly constant between puberty and menopause in women and between puberty and middle age in men.

Clinical assessment

The initial patient consultation at transition is of vital importance for establishing a potentially life-long professional relationship with the patient, as well as identifying key features in the history, examination and assessment of their overall needs. Parents commonly attend a first adult appointment with their son or daughter, and it is usually necessary to allow longer for this initial assessment. Often, the first transition appointment is undertaken jointly with the paediatrician in a specialist transition clinic and this will enable a thorough face-to-face handover of all the key facts.

31.5 Features in transition assessment

Features of history and/or examination	Reason
History*	
Main/presenting condition and detailed review of clinical course	Understand detail and severity of illness; understand which treatments have been undertaken and which have been successful
Family history: Draw family tree of all first-degree and any relevant/affected second-degree family members	Many long-term conditions arising during childhood have significant genetic and familial factors to be taken into account
Current drug therapy, significant previous therapies	Many drugs have significant long-term implications, levels may need monitoring, may have teratogenic effects to consider
Any surgical or other relevant medical history	Understand which treatments have been undertaken and which have been successful
Pubertal status/age of menarche	Helps assess disease severity plus patterns of growth Informs about patient's reproductive health and family-planning wishes
Social history: In education or in work? Receiving appropriate benefits/support? Financial or other practical concerns? Living with parents/left home?	Assesses wider effects of patient's health on their independent living, as well as their financial and practical circumstances Can be a proxy measure of disease severity and identifies their support mechanisms, which also helps in the assessment of their current needs
Systems enquiry	Any other related/unrelated symptoms or problems
Physical examination	
Height, weight, calculation of body mass index Blood pressure Urinalysis if relevant Assessment of pubertal status General physical examination	Although young people are often accompanied by a parent, examine them separately and use this opportunity to consider asking about private matters, such as partners, sexual activity, and drug or alcohol use

*Throughout the first consultation, confidence and competence in decision-making/capacity to consent should be assessed. If there are concerns about capacity, clarify key decision-makers.

A detailed transition referral letter should clearly describe the diagnosis, current and previous treatments, and key interventions that have been undertaken while the patient was under the care of paediatric services. It is important to check the main details with the young person and to make sure there are no other factors that they feel are of relevance. There are a few features in the history that merit special attention, particularly at the first consultation, as outlined in Box 31.5. Many young people with an LTC attend their first adult outpatient department consultation with their parents, and it is important either to create a time to ask personal and lifestyle-related questions separately from the main history – that is, privately – or to make sure that these can be confidentially explored in future.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Presenting problems in transition medicine

Problems with adherence

Adherence is defined as 'the extent to which a person's behaviour, in terms of taking medications, following diets, or executing lifestyle changes, coincides with medical or health advice'. The term 'adherence' is used in preference to 'compliance' because it focuses on whether a person actively adheres to the regimen rather than passively follows the doctor's orders. It also implies partnership and cooperation between the patient and the care-giver. More recently, clinicians have moved to seeking patients' concordance with management plans. Concordance refers to a consultation process that has an underlying ethos of shared decision-making. It has become clear that current levels of adherence do not deliver the full benefits of medication. Historical paternalistic medical practice does not maximise the chances of patients adopting the changes and treatments they need to improve their outcomes. Reaching a concordant position with patients involves a range of approaches (such as patient-centredness or shared decision-making) and a number of specific actions (such as exploring anxieties about medication side-effects, individualising regimes to suit the patient's lifestyle, offering a range of treatment options) and has not been evaluated comprehensively.

Adherence to clinic attendance, investigation and treatment often falls significantly in adolescence and during transition to adult services. Measurement of adherence is challenging and reported rates vary according to the method of assessment. Teenagers may also have varying adherence levels within their treatment regimen. An important example is in patients who have undergone organ transplantation, in whom low adherence to immunosuppressive medication is a significant cause of graft rejection and may cause death. Adherence merits careful consideration when caring for adolescents and young adults, and focusing on strategies to improve adherence at this initial stage of patient management can deliver life-long improvements in health outcomes. Young teenagers mainly believe in things that they have directly experienced and do not fully appreciate the unseen consequences of not taking their medications. In time,

i 31.6 Factors affecting adherence

Negative factors

- Older adolescent
- Mental health issues with care-giver
- Family conflicts
- Complex therapy
- Medication with side-effects
- Denial of illness

Positive factors

- Positive family functioning
- Close friends
- Internal locus of control
- Treatment with immediate benefits
- Patient's belief in seriousness of illness and efficacy of treatment
- Physician empathy

i 31.7 SIMPLE strategies to improve adherence

Simplify regimen

- Use once daily/twice daily regimes if possible
- Match regimen to bedtime and meals
- Use pill box or alarms on phone
- Organise services around patient (combined clinics, flexible timing and appointments)

Impart knowledge

- Share decision-making
- Provide clear instructions:
  - Limit to three or four major points
  - Use simple, everyday language
  - Use written information or pamphlets and verbal education at all encounters
- Supply addresses of quality websites
- Provide advice on how to cope with medication costs

Modify patient beliefs

- Empower patients to self-manage their condition:
  - Ask about their needs
  - Ask what might help them become and remain adherent
  - Ensure they understand the risks of not taking their medication
  - Address fears and concerns about taking the medication

Provide communication

- Improve interviewing skills
- Practise active listening
- Provide emotional support – treat the whole patient and not just the disease
- Provide clear, direct and thorough information
- Elicit the patient's input in treatment decisions
- Allow adequate time for patients to ask questions
- Build trust

Leave the bias

- Learn more about low health literacy and how it affects patient outcomes
- Consider care of ethnically and socially diverse patient populations
- Acknowledge biases in medical decision-making (intentional or unintentional)
- Address dissonance of patient–provider race/ethnicity and language
- Take extra time to overcome cultural barriers
- Ask specifically about attitudes, beliefs and cultural norms around medication
- Use culturally and linguistically appropriate targeted patient interventions
- Increase engagement, activation and empowerment
- Tailor education to the patient's level of understanding

Evaluate adherence

- Direct:
  - Number of repeat prescriptions
  - Biomarkers of response
  - Measurement of drug levels
- Indirect:
  - Self-reporting: 'When did you last forget your medicine?'; 'How often have you forgotten your medicines this week?'

adolescents learn to develop hypothetical thinking and to analyse more complex information and decision-making. The ability to engage in formal thinking is inconsistent at first, and at times of stress (such as during an illness) adolescents may regress to more simple ways of problem-solving. Despite their maturing skills, they may remain self-centred and feel invincible. Factors that positively and negatively affect adherence are outlined in Box 31.6. Interventions to improve adherence are summarised in Box 31.7.

Recent literature suggests that two-way communication between patients and professionals about medicines leads to improved satisfaction with care, knowledge of the condition and treatment, adherence, health outcomes and fewer medication-related problems. Younger adults and those coming to adult services following transition from paediatric services have very different expectations in terms of the nature of the patient–doctor relationship and are more likely to require a more collaborative approach to development of management plans to maximise their concordance with treatment in the long term.

High-risk behaviour

The high-risk behaviour that can be undertaken by adolescents is well documented and is seen across many cultures. It is important to assess this by history-taking at the time of transition (Box 31.8) Adolescents who have had LTCs during childhood are at greater risk of undertaking harmful behaviour and there is evidence that a poor long-term health outlook is associated with risk-taking behaviour earlier in life.

Globally, the leading causes of death among adolescents are road injury, human immunodeficiency virus (HIV) infection, suicide, lower respiratory infections and interpersonal violence; many of these deaths are linked to risk-taking behaviours such as excess alcohol and drug intake. Quite apart from mortality, there are other significant adverse events linked to risk-taking behaviour in adolescents: excess alcohol ingestion is also associated with non-fatal road traffic accidents, unwanted and unprotected sexual activity, and violence as both perpetrator and victim.

There are a number of theories about the neurodevelopmental changes associated with these behaviour changes. At around 11 years of age, the prefrontal cortex (PFC) and parietal lobes begin a period of pruning of neuronal axons. It is theorised that these changes represent the start of the process of increasing frontal lobe control. A separate process that occurs at the same time predisposes the adolescent to risk-taking behaviour and impulsivity: frontostriatal reward circuits mature relatively early and encourage the adolescent towards adult activities such as alcohol and drug use, and sexual intercourse, which carry potential health risks. At this stage, the PFC has not yet matured to the point where the individual can assess risk adequately. The PFC and its connections are structurally unable to provide sufficient control. It is thought that this maturational gap in PFC control of the pleasure-seeking brain systems is responsible for the risk-taking lifestyle that characterises the period of adolescence.

A number of studies have investigated personality and other factors that contribute to different risk-taking behaviours during adolescence: essentially, younger adolescents and females tend to rate activities as being more risky, and are therefore less likely to undertake them. Older males and those of lower educational status are higher risk takers. Specific protective factors include high self-esteem and a strong orientation to an internal locus of control; young people who feel they have less control and influence over themselves and their behaviour are more likely to undertake high-risk activities. Many teenagers with serious long-term health conditions are disempowered in a number of ways and there is evidence that they are predisposed to be high risk takers during adolescence. Examples of risk-taking behaviour include not only alcohol and drug intake, but also non-adherence to medicines and other aspects of health care, such as diet in diabetes.

It is not easy to affect behaviour during this period of non-adherence. Isolated educational intervention is not sufficient to improve outcome; for example, there is a wealth of evidence showing that teenagers know about the behaviours needed to prevent transmission of HIV, but many do not adhere to this advice. Long-term health-care providers have an invaluable role in supporting adolescents during this period of their development as adults, as many important health-related and lifestyle habits are established during this period: more than 90% of smokers start smoking in adolescence, and life-long habits around eating and exercise are laid down during the teenage years. Focusing on the needs of the emerging adult for autonomy and using the highest levels of communication and patient engagement significantly improve outcomes for patients with LTCs.

Japan	5.3
Italy	4.5
South Korea	2.2

first pregnancy varies from 19 years in India and parts of Asia, through to 25 years in the USA and around 30 years in Australia and Western Europe. Teenage pregnancy rates are high across the world (Box 31.9). Information from the UK suggests that 1 in 6 pregnancies is unplanned, and 1.5% of women between the ages of 18 and 45 face an unplanned pregnancy each year. It is therefore vital to anticipate and discuss the issues surrounding reproductive health with all young people before and during transition, as well as during early adulthood. Young people with serious LTCs have a number of additional factors to be taken into consideration when discussing reproduction, and these discussions need to take place long before a family is planned. General physicians do not need to be able to undertake complex genetic counselling and investigation, but should be able to provide advice about the recurrence risk of common inherited conditions, as well as that of the more common multifactorial LTCs, many of which have an inherited or genetic component.

Clinical presentations

In almost every clinical setting, there is the potential for a young adult with a serious LTC that has arisen during childhood to present to adult physicians. Medical services can improve the care and outcome for this vulnerable group by planning a systematic approach to transition, as described above, and by focusing the clinical consultation on issues of relevance and importance to each particular patient. The key issues to consider for a number of the most common LTCs of childhood are discussed below.

Neurological disease

Epilepsy

Epilepsy is a chronic disorder, the hallmark of which is recurrent, unprovoked seizures (p. 1097). Epilepsy that has presented during childhood, as opposed to adulthood, is less often associated with underlying central nervous system malignancy and is well controlled with first-line anticonvulsants in around 80% of cases. Young people who still have epilepsy or are on anticonvulsant therapy as they progress into adulthood are more likely to have underlying structural brain disease, such as cerebral palsy, or have more complex or syndromic epilepsy. In many of them, epilepsy may be associated with learning difficulties or other neurological conditions.

Epilepsy presents several problems during transition. Adherence to medication can be an issue and patients with low adherence to epilepsy medicines have higher mortality, higher hospital admission rates and higher emergency department attendances. Conversely, high adherence rates at initiation of epilepsy therapy are associated with improved long-term seizure freedom and higher seizure freedom at 4 years. Epilepsy can also affect employment options for young people, as about 30% of patients still have breakthrough seizures while on treatment. Certain types of employment, such as working within the emergency services or armed forces, or becoming a pilot or driver of a heavy goods vehicle, may therefore not be possible. Driving restrictions may also limit options for some other occupations (p. 1103). Young women with epilepsy should be advised that oral contraceptives are less effective with enzyme-inducing antiepileptic drugs; they should also be made aware of the risk of teratogenicity with many antiepileptic drugs, most notably sodium valproate, which should be avoided in pregnancy if at all possible. Pre-conceptual counselling is desirable for all young girls with epilepsy and pre-conceptual folic acid supplementation is advisable to reduce the risk of neural tube defects.

Alcohol use in moderation does not affect seizure control in the majority of patients, but withdrawal from alcohol in dependent patients is epileptogenic and heavy alcohol use should be discouraged. Information about marijuana and epilepsy risk is lacking, but regular marijuana use and excess drinking are associated with poor adherence to medication regimes and increased seizure risk.

Cerebral palsy

Cerebral palsy comprises a range of non-progressive neurological impairments, present from the time of birth or arising in early childhood. Although the neuropathology is non-progressive, the manifestation of problems can evolve, with progressive motor dysfunction related to increased spasticity and possibly progressive seizure activity.

Patients with severe cerebral palsy present specific problems during transition and early adulthood. They may be paraplegic or quadriplegic and most non-ambulatory individuals have significant intellectual disability. This group of patients will be unable to live independently during adulthood and need ongoing long-term care. Delivering medical care to these individuals poses several problems, including practical issues such as consideration of capacity and consent to treatment. Other comorbidities include gastro-oesophageal reflux (often related to abnormal lower oesophageal function), seizures, and feeding difficulties often requiring gastrostomy. These individuals usually require a complex care package involving many members of the multidisciplinary team. There are also risks of abuse and neglect in the care of adults with severe disability and this needs to be borne in mind when considering atypical problems or unusual presentations in this vulnerable patient group. Depending on the severity of the patient's condition, end-of-life care may need to be discussed and planned with the family and other care-givers.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Muscular dystrophy

The muscular dystrophies are a group of diseases that cause progressive weakness and loss of muscle mass. The disorders differ in terms of which muscle groups are affected, the degree of weakness, and the rate of disease and symptom progression. All the inherited muscular dystrophies that present during childhood need active management during transition (p. 1143). One of the most important and most severe conditions is Duchenne muscular dystrophy (DMD), which is associated with a progressive decline in mobility, coupled with cardiac dysfunction due to cardiomyopathy, and respiratory failure requiring respiratory support as the disease progresses. Physicians should ensure that the whole family are aware of the wider genetic issues. Female carriers of the DMD gene can suffer muscle fatigue and are at risk of cardiomyopathy, as well as there being obvious risks for their male offspring. On average, patients with DMD survive until their late teens to early twenties, and those with less severe muscular dystrophies, such as Becker dystrophy, survive until their thirties. Although fertility is reduced, young men with these conditions may themselves father children. Male offspring will be unaffected but all female infants of affected males will be carriers.

As the muscular dystrophies progress, a complex package of care involving a multidisciplinary team is necessary; it should include respiratory input to assess the need for ventilatory support, which is a common endpoint for many patients. At the present time, there is no definitive treatment. Glucocorticoids (0.75 mg/kg/day) have been shown to improve muscle strength and are frequently used, but carry an increased risk of osteoporosis and vertebral fractures. New therapeutic approaches are being developed with the aim of ameliorating disease progression in patients with nonsense mutations (p. 42). One involves the use of drugs such as ataluren, which promotes binding of transfer RNA (tRNA) molecules at the site of stop codons with a mismatch in one base (near-cognate tRNAs). These cause a full-length protein to be produced with an amino acid substitution rather than a truncated non-functional protein. Patients with DMD usually require social and financial support. It is important to consider end-of-life care plans with patients and family members. Involvement from palliative care teams, as well as psychological, spiritual and wider non-medical support, is essential.

Respiratory disease

Cystic fibrosis

Cystic fibrosis (CF) is a single-gene autosomal recessive disorder that affects about 1 in 2000 to 1 in 3000 individuals of Caucasian descent (p. 580). Clinical manifestations are caused by defects in an ion transporter termed the cystic fibrosis transmembrane conductor regulator (CTFR) protein. With improved supportive care, the median survival in the UK is now more than 50 years. It is well recognised that young people with life-limiting conditions face particular challenges during transition: individuals often exhibit high-risk behaviour during adolescence, and this was particularly true in the past when long-term survival rates were poor. The rates of non-concordance with medication and with time-consuming physiotherapy and nebuliser regimes are high and adversely affect outcome and survival. Exercise tolerance and employment are likely to be restricted as time progresses, and patients need particular support managing the slow decline in function and well-being that occurs throughout their adult lives.

In terms of fertility and child-bearing potential, the picture is complex and merits detailed discussion with patients. It is not often discussed openly by the paediatrician or during childhood, other than with the parents when the patient is young. The vas deferens is absent in 98% of males with CF and seminal vesicular dysfunction means that ejaculates are low in volume. While boys are infertile, newer reproductive therapies, such as the availability of intracytoplasmic sperm injection, mean that fatherhood is possible. The opportunity for assisted reproduction should be discussed early so that people can make informed choices at an appropriate stage of their lives. Females with CF who have good nutritional status and reasonable health status have normal fertility and genetic counselling should be offered early. Contraception needs to be discussed with women who are not planning a pregnancy, since pulmonary hypertension is an absolute contraindication for the oral contraceptive pill (OCP). Women also need to be advised about the effects of antibiotics on OCP effectiveness. New orally available small-molecule therapies, including lumacaftor and ivacaftor, have recently been licensed; they can partially rectify functional defects in the CTFR and have improved outcome. These drugs are having a positive effect on symptom control and are potentially disease-modifying. Other therapeutic approaches, including gene therapy and mRNA editing therapies, are also being explored as treatments for CF. Common issues encountered during transition of CF patients are summarised in Box 17.34 (p. 581).

Cardiovascular disease

Congenital heart disease

Congenital heart disease (CHD) is the most common congenital anomaly, affecting about 1% of live births. Among birth defects, CHD is the leading cause of mortality. Maternal illnesses such as rubella and injection of teratogenic agents during pregnancy, along with paternal age, all play roles in pathogenesis. Although some chromosomal anomalies, such as trisomy 13, 18 and 21 and monosomy X (Turner's syndrome), are strongly associated with CHD, these account for only 5% of cases. Microdeletion and single-gene mutations can also be important, such as in DiGeorge syndrome (22q11.2 microdeletion). Overall, the most common congenital valvular anomalies are aortic and pulmonary stenosis. The most common structural anomaly is ventricular septal defect.

There is a wide range of severity of CHD but many patients with life-limiting conditions (usually complex structural anomalies such as tetralogy of Fallot or hypoplastic left heart syndrome) survive to adulthood. Genetic counselling of affected individuals is important, as there is a 1–2% recurrence risk of any cardiac anomaly in offspring. Affected patients should be transitioned to a cardiologist with experience in CHD since this has become a subspecialty in own right. More details are provided on page 531 and in Box 16.103 (p. 537).

Hypertrophic obstructive cardiomyopathy

Hypertrophic obstructive cardiomyopathy (HOCM, p. 539) is a genetic cardiovascular disease characterised by left ventricular wall hypertrophy, impaired diastolic filling and abnormalities of the mitral valve. These features can cause dynamic obstruction of the left ventricular outflow tract, diastolic dysfunction, myocardial dysfunction and an increased risk of supraventricular and ventricular tachyarrhythmias. HOCM is caused by mutations

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

affecting the genes that encode cardiac sarcomere proteins and is most frequently transmitted as an autosomal dominant trait. It may present for the first time during adolescence with cardiac arrest or sudden cardiac death. Predictive genetic testing is possible but challenging because of the large number of causal mutations. In clinical practice, careful analysis of the family history can be useful in identifying those at risk of inheriting the disease. If no gene anomaly has been identified within a family, first-degree relatives may need screening by electrocardiography (ECG) and echocardiography. Identification of a genetic anomaly is most helpful in allowing identification of family members who do not need echocardiograms or clinical follow-up. Children of affected parents should be screened every 3 years until puberty, and then annually until 20 years of age. If there is no evidence of HOCM in early adulthood, it is unlikely that the condition will develop in later life.

Oncology

Around 1 child in 500 will develop cancer by the age of 14 years. Leukaemia is the most common, accounting for about 33% of cases; central nervous system tumours are the next most common, accounting for around 25% of all childhood cancers. Fifty years ago, 75% of children diagnosed with cancer died, but overall survival rates now range from 75% to 80%. Between 60% and 70% of young adults who have survived childhood cancer will develop at least one medical disability, most commonly as a result of their therapy rather than their primary cancer. There is a 3–6-fold increased risk of a second cancer, with an absolute risk of about 10% before 50 years of age. It is therefore important for these individuals to be kept under surveillance during transition and beyond.

Endocrine and reproductive disturbances are the most common late effects, affecting 40–60% of survivors. Infertility can be an issue in both males and females receiving cytotoxic medications, unless it has been possible to store semen and ovarian tissue in advance of treatment. Other long-term risks include hypopituitarism, growth hormone deficiency and pubertal delay (especially in boys) from brain irradiation. Radiotherapy to the neck can cause hypothyroidism and increases the risk of thyroid cancer. Total-body irradiation offered as conditioning for bone marrow transplantation affects both ovarian and testicular function, and many of the chemotherapeutic agents used have adverse effects on fertility. Chemotherapy-induced ovarian failure is typically associated with high-dose alkylating agents such as cyclophosphamide, and this is an independent risk factor for premature ovarian failure. In recent years, patients have been offered ovarian and testicular tissue retention and fertility issues are being discussed with families during childhood, but often the patients themselves have limited levels of knowledge of the details. Chemotherapy and radiotherapy in childhood significantly reduce ovarian reserves. When combined with the progressive ovarian decline that occurs in all women throughout adulthood there is a significant risk of premature menopause or ovarian failure, with 8% of survivors affected. Young women need to be aware of these risks during their early adulthood to help with family and lifestyle planning; for example, they may wish to plan to have children earlier in their adult life rather than risking ovarian decline.

Cardiomyopathy is another complication of anthracyclines such as doxorubicin and daunorubicin. Serious cardiac complications include arrhythmias, dilated cardiomyopathy from myocardial necrosis, and angina or myocardial infarction arising from vaso-occlusion or vasospasm.

In addition to physical effects, children who have faced life-threatening illness in childhood may experience psychological and family difficulties during adulthood. Cognitive impairment is more common in children who have received chemotherapy or radiotherapy to the brain, and problems can include lower IQ, problems with memory and attention, poor hand–eye coordination and behaviour/personality problems, combined with the well-recognised and physical complications of cancer treatment in childhood.

Increasing recognition of these issues has resulted in active monitoring programmes for survivors of childhood cancer, who are best seen in specialist 'late effects' multidisciplinary clinics, where teams include oncologists, psychologists and specialists from other relevant disciplines.

Renal disease

Chronic kidney disease (CKD, p. 415) accounts for some of the most complex long-term illnesses in childhood. The most common causes during childhood and adolescence are shown in Box 31.10. The primary pathology can be varied and many conditions have no specific treatment, but the overall approach to management of progressive renal insufficiency is the same. Internationally agreed definitions of CKD staging in children differ from those in adults and are summarised in Box 31.11. In adults the rate of albumin excretion is included in CKD definitions, as outcome correlates with the level of albuminuria, but in children similar data are lacking and so the staging system is based on glomerular filtration rate alone. The majority of children with

i 31.10 Causes of renal impairment in childhood and adolescence

- Obstructive uropathy
- Renal hypoplasia/dysplasia
- Reflux nephropathy
- Focal segmental glomerular sclerosis
- Polycystic kidney disease

i 31.11 Staging of chronic kidney disease (CKD) in children over 2 years of age*

Stage	Glomerular filtration rate (GFR) (mL/min/1.73 m^2)	Description
1	>90	Normal or high
2	60–89	Mildly decreased
3a	45–59	Mildly to moderately decreased
3b	30–44	Moderately to severely decreased
4	15–29	Severely decreased
5	<15	Kidney failure

*Kidney Disease: Improving Global Outcomes (KDIGO) 2012 classification. Chronic kidney disease is defined either as GFR <60 mL/min/1.73 m^2 for >3 months, regardless of whether other CKD markers are present, or as GFR <60 mL/min/1.73 m^2 accompanied by evidence of structural damage or other markers of kidney abnormalities, including proteinuria, albuminuria, and pathological abnormalities in histology or imaging. In adults, albumin excretion is also included in CKD staging as the level of albuminuria correlates to outcome. These data are lacking in children and so albuminuria is not used to classify paediatric CKD.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

CKD stage 3 or higher will ultimately require renal replacement therapy but the timescale for reaching this stage can vary widely. The mainstay of support is to delay progression by treatment of secondary factors that are known to be associated with progressive decline in renal function: namely, hypertension, proteinuria and anaemia.

Organ transplantation

Children requiring renal replacement therapy are the most common recipients of kidney transplants in childhood. Liver and heart transplantation, followed by lung and small bowel transplantation, are well-recognised but less commonly undertaken procedures. Non-adherence to immunosuppressive regimes during adolescence is a well-known risk factor for graft failure. The reported incidence of graft failure due to non-adherence is 10–15% but this is likely to be an under-estimate. Rates of non-adherence are highest among adolescents and young adults. As well as non-adherence to immunosuppression, non-adherence to testing and clinic attendance adversely affects the care and outcome of around 1 in 8 kidney transplant patients. Poor adherence is associated with patients with worse psychological status and family dysfunction; adherence has been shown to improve with education and increased motivational factors, as might be expected. This offers the opportunity to improve graft survival. At present, 50% of cadaveric grafts and around 68% of live donor grafts are still functioning 10 years post-transplant. There is no clear difference between children and adults in survival of transplanted kidneys.

Many medications used in transplant medicine and in renal disease can have long-term effects on health. Inhibition of linear growth is seen even with low doses of glucocorticoids, such as 0.125 mg/kg/day on a long-term basis. Alternate-day regimes are generally considered preferable in childhood. The height reduction associated with long-term glucocorticoid use in childhood is dose-dependent, and even for children with asthma treated with inhaled glucocorticoids, an average height reduction of 1.2 cm is reported. This is can also be associated with delayed puberty, as well as an increased risk of osteoporosis in adulthood. Post-transplant lymphoproliferative disorders (PTLDs) are a well-recognised and potentially life-threatening complication in solid organ recipients. PTLD is the most common malignancy complicating solid organ transplantation, accounting for 20% of all cancers. They represent a range of lymphoproliferative disorders, from infectious mononucleosis and lymphoid hyperplasia to malignant lymphoma. Most cases of PTLD are associated with Epstein–Barr virus (EBV), leading to uncontrolled B-cell proliferation and tumour formation. Up to 10% of solid organ transplant recipients develop PTLD but the risk is almost four times higher in patients under 20 years of age, as opposed to those aged 20–50. This increased risk relates mainly to the development of EBV infection after transplantation; most adults are already EBV-seropositive at the time of transplantation and therefore at lower risk of this complication. The type of organ transplant that has been undertaken predicts PTLD risk, with the cumulative incidence over 5 years ranging from 1–2% in haematopoietic cell transplant and liver transplants, 1–3% in renal transplants, 2–6% in heart transplants and 2–9% in lung transplants to as high as 11–33% in intestinal or multi-organ transplants. The different rates possibly relate to the varying degrees of immunosuppression required. The incidence of PTLD is highest in the first year after transplantation, when it is associated with the highest levels of immunosuppression.

Diabetes

Adherence and concordance with medication are a particular challenge in adolescents who have developed diabetes during childhood (p. 753). Studies of adolescents with type 1 diabetes have revealed that 25% were neglecting insulin injections, 81% were not following their diet, and 29% were not measuring their glucose level and were completing a daily diary with fictitious results. Research has also shown that the outcome of diabetes is improved with a formal transition programme (Box 31.12). Good control of diabetes is particularly important during this phase since microvascular disease often emerges around time of transition, although it can occur sooner in patients with early-onset diabetes.

i 31.12 Impact of transition planning on outcome in diabetes

Intervention	Outcome measures
Disease-specific education	Lower HbA_{1C}
Generic education/skills training	Fewer acute complications: Hypoglycaemia Admissions with ketoacidosis
Transition coordinator	Lower rate of loss to follow-up
Joint paediatric/adult clinic	Fewer chronic complications: Hypertension Nephropathy Retinopathy
Separate young adult clinic	Improved self-management Improved disease-specific knowledge
Out-of-hours phone support	Improved screening for complications
Enhanced follow-up	Better quality-of-life scores

Gastrointestinal disease

Inflammatory bowel disease

The prevalence of inflammatory bowel disease (IBD, p. 813) in childhood is increasing, and the incidence of Crohn's disease (CD) in particular is rising in both children and adults, probably due to currently undefined environmental factors. Current treatment aims are outlined in Box 31.13. Standard measures include exclusive enteral nutrition for 6–8 weeks using a whole-protein (polymeric) formula, which induces initial remission in 80% of children. This is equivalent to glucocorticoid therapy but offers improved nutritional status and superior mucosal healing. Glucocorticoids can also be used to induce remission, as well as to treat exacerbations, but should be followed up by immunosuppressive therapy with azathioprine or methotrexate. Adolescents and children are more likely than adults to require biologics and around 20% need treatment with tumour necrosis factor alpha (TNF-α) inhibitors such as infliximab or adalimumab. Around 20% of children with CD require surgery within 5 years of diagnosis; limited resections and stricturoplasty are considered best practice to preserve gut length and prevent short bowel syndrome (p. 707).

Children with ulcerative colitis (UC) are more likely than adults to present with pancolitis (approximately 80% versus 40–50% in adults). Mild disease should be treated initially with oral 5-ASA preparations such as mesalamine or sulfasalazine. If the response is inadequate, oral glucocorticoids can be used, but caution must be exercised because of the adverse effects on skeletal growth and bone mineral density. Thiopurines such as 6-mercaptopurine or azathioprine are frequently used as steroid-sparing agents,

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

i 31.13 Treatment strategy in Crohn's disease

- Induce and maintain clinical remission
- Optimise nutrition
- Optimise bone health
- Optimise growth and pubertal progress
- Minimise adverse drug effects

with progression to anti-TNF-α therapy for those who still do not respond. There is less evidence for efficacy of TNF-α inhibitors in adolescents with UC than those with CD; they seem to be effective at inducing an initial response but less useful for maintaining long-term remission, since a significant proportion of patients still require colectomy (20% at 1 year) or long-term glucocorticoids. Ciclosporin is probably more effective than infliximab in teenagers with refractory UC. As with other adolescents who have long-term conditions, adherence to medication is particularly important to reduce the risk of relapse. In terms of lifestyle advice, smoking is a particular risk since it increases both the rate and severity of relapses. Body image can be a particular challenge for young adults with IBD, and those with colostomies or fistulae, for example, can find this part of their illness particularly difficult. Delayed puberty and short stature are important comorbidities, partly related to medication side effects and also to the nature of the inflammatory bowel disease itself.

Rheumatology and bone disease

Juvenile idiopathic arthritis

Juvenile idiopathic arthritis (JIA) is the term used to describe a wide variety of inflammatory rheumatic diseases that present during childhood (p. 1026). Oligoarticular juvenile arthritis has a good prognosis and often remits during adulthood, and so transitioning patients to adult rheumatology services may not always be required. The same does not hold true for systemic JIA and polyarticular JIA, which often require long-term immunosuppressive therapy through transition and beyond into adulthood. Smoking is a risk because it increases the activity of inflammatory disease and reduces the effectiveness of biologics. Adherence to and concordance with medication remain a challenge, as in other chronic diseases. Functional limitation secondary to joint damage may limit employment opportunities. Contraceptive advice is important in patients on methotrexate.

Glucocorticoid-induced osteoporosis

Osteoporosis is a complication of long-term glucocorticoid therapy that may be required in patients with inflammatory disease, transplantation and DMD.

There is a paucity of evidence about best practice in glucocorticoid-induced osteoporosis in children and adolescents, but in general the teenage years are a period of considerable bone mineral deposition and offer a chance to enhance bone mineral density significantly. It is important to ensure adequate calcium and vitamin D intake and to supplement if necessary. Therapy with bisphosphonates can be considered in symptomatic patients, although the evidence base for prevention of fractures is poor.

Osteogenesis imperfecta

Osteogenesis imperfecta (p. 1055) typically presents with multiple low-trauma fractures during infancy and childhood. Although fractures become less common during adolescence due to the increase in bone mass, they still occur frequently during transition and in young adults. Intravenous bisphosphonates are widely used in the treatment of children with osteogenesis imperfecta (those with long-bone deformities, vertebral compression fractures, and three or more fractures per year, in whom the benefit:risk ratio is thought to be positive), although the evidence base for prevention of fractures is poor and based on observational studies.

There is much debate about whether continuing bisphosphonate therapy into adulthood is beneficial due to concerns about suppression of bone turnover in the long term. Affected individuals and their parents can find this change in treatment strategy confusing and it is important to explain the underlying rationale in order to manage expectations.

Hypophosphataemic rickets

Hypophosphataemic rickets is described in more detail on page 1052. Adherence to phosphate supplements and, to a lesser extent, vitamin D metabolites represents an important issue in optimising management during childhood and this becomes even more challenging in transitioning patients. While skeletal deformity does not progress following closure of the epiphyses, different problems arise in adolescent patients when there is suboptimal control of hypophosphataemia, including painful pseudofractures and arthralgia associated with enthesopathy. The renal phosphate leak tends to improve to an extent during adolescence and the requirement for phosphate is reduced, but most patients still require treatment with active vitamin D metabolites.

Summary

Young people who have suffered long-term conditions during childhood represent a particularly high-risk group of patients as they progress through adolescence to become young and, finally, mature adults. They bring with them specific medical risks and complications related to their previous medical treatment, and knowledge of these is important to identify the long-term complications of the therapies to which they have been exposed. They are a patient group that can display complex and often abnormal illness behaviour. Understanding this and implementing an effective process for transition from paediatric to adult services can reduce the significant risks that these patients face in early adulthood. As they mature and develop more adult intellectual and emotional behaviour patterns, the risks to their health and well-being reduce. Patients in transition can be a particularly challenging group to manage, but investment of time and effort at this stage of their lives can be extremely rewarding and can bring significant improvements in long-term health-related outcomes.

History

- Slow down the pace
- Ensure the patient can hear
- Establish the speed of onset of the illness
- If the presentation is vague, carry out a systematic enquiry
- Obtain full details of:
  - All drugs, especially any recent prescription changes
  - Past medical history, even from many years previously
  - Usual function: Can the patient walk normally? Has the patient noticed memory problems? Can the patient perform all household tasks?
- Obtain a collateral history: confirm information with a relative or carer and the GP, particularly if the patient is confused or communication is limited by deafness or speech disturbance

Examination

- Thorough to identify all comorbidities
- Tailored to the patient's stamina and ability to cooperate
- Includes functional status: cognitive function, gait and balance, nutrition, and hearing and vision

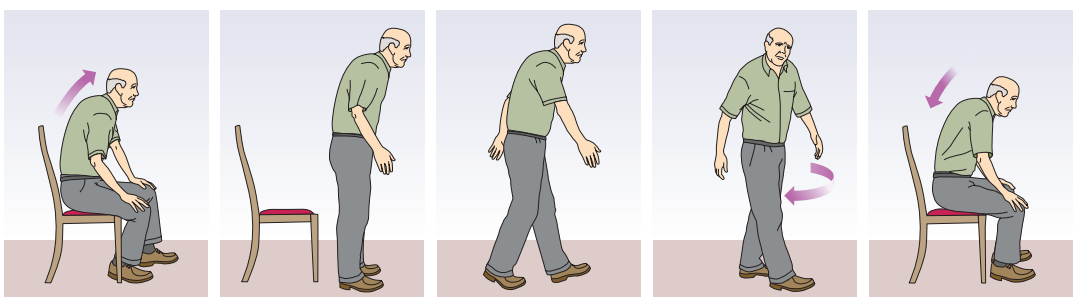
Domains of Comprehensive Geriatric Assessment.

Social assessment

Home circumstances

- Living alone, with another person or in a care home

Activities of daily living (ADL)



- Tasks for which help is needed:
  - Domestic ADL: shopping, cooking, housework
  - Personal ADL: bathing, dressing, walking
- Informal help: relatives, friends, neighbours
- Formal social services: home help, meals on wheels
- Carer stress

Multidisciplinary team (MDT) roles

Team member	Activity assessed and promoted
Physiotherapist	Mobility, balance and upper limb function
Occupational therapist	ADL, such as dressing, cooking Home environment and care needs
Dietitian	Nutrition
Speech and language therapist	Communication and swallowing
Social worker	Care needs and discharge planning; organisation of institutional care
Nurse	Motivation and initiation of activities; promotion of self-care Education Feeding, continence, skin care Communication with relatives and other professionals Assessment of care needs for discharge
Doctor	Diagnosis and management of medical problems Coordinator of assessment, management and rehabilitation programme

12 Get up and go test

To assess gait and balance, ask the patient to stand up from a sitting position, walk 3 m, turn and go back to the chair. A normal performance takes less than 12 seconds.

Difficulty rising? | Unsteady on standing? | Unsteady gait? | Unsteady on turning? | Unsteady on sitting down?

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Sweeping demographic change has meant that older people now represent the core practice of medicine in many countries. A good knowledge of the effects of ageing and the clinical problems associated with old age is therefore essential in most medical specialties. The older population is extremely diverse; a substantial proportion of 90-year-olds enjoy an active healthy life, while some 70-year-olds are severely disabled by chronic disease. The terms 'chronological' and 'biological' ageing have been coined to describe this phenomenon. Biological rather than chronological age is taken into consideration when making clinical decisions about, for example, the extent of investigation and intervention that is appropriate.

Geriatric medicine is concerned particularly with frail older people, in whom physiological capacity is so reduced that they are incapacitated even by minor illness. They frequently have multiple comorbidities, and acute illness may present in non-specific ways, such as delirium, falls or loss of mobility and day-to-day functioning. These patients are prone to adverse drug reactions, partly because of polypharmacy and partly because of age-related changes in responses to drugs and their elimination (p. 32). Disability is common, but patients' function can often be improved by the interventions of the multidisciplinary team (p. 1303).

Older people have been neglected in research terms and, until recently, were rarely included in randomised controlled clinical trials. Accordingly, there is often little high-quality evidence on which to base practice.

Demography

The demography of all countries has changed rapidly in recent decades. For example, in the UK, the total population has grown by 11% over the last 30 years, but the number of people aged over 65 years has grown by 24%. The steepest rise occurred in those aged over 85 – from 600 000 in 1981 to 1.5 million in 2011; this number is projected to increase to 2.4 million by 2026, while the working-age population (20–64 years) is expected to grow by only 4% between 2011 and 2026. Similarly, the proportion of people over 65 in India has increased by 35.5% from 76 million in 2000 to 103 million in 2011, which is almost twice the rate of growth of the general population over this period. In both of these countries and many others across the world, the old-age dependency ratio, which is the ratio of people of working age for each person over retirement age, has substantially increased. Since young people support older members of the population both directly and indirectly through taxation and pension contributions, the consequences of a reduced ratio are far-reaching. It is important to emphasise, however, that many older people support the younger population, through the care of children and other older people.

Life expectancy in the developed world is now prolonged, even in old age (Box 32.1); women aged 80 years can expect to live for a further 10 years. However, rates of disability and chronic illness rise sharply with ageing and have a major impact on health and social services. In the UK, the reported prevalence of a chronic illness or disability sufficient to restrict daily activities is around 25% in those aged 50–64, but 66% in men and 75% in women aged over 85.

i 32.1 Mean life expectancy in years, UK and India

	Males		Females	
	UK	India	UK	India
At birth	79.1	65.1	83.0	67.2
At 60 years	22.8	16.7	25.5	18.9
At 70 years	15.0	10.9	17.1	12.4
At 80 years	8.7	7.5	9.9	8.0

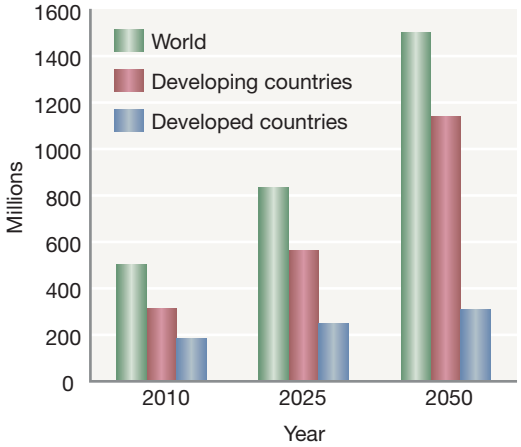


Fig. 32.1 Number of people aged 65 years and over projected in the world population.

Although the proportion of the population aged over 65 years is greater in developed countries, two-thirds of the world population aged over 65 live in developing countries at present, and this is projected to rise to 75% in 2025. The rate of population ageing is much faster in developing countries (Fig. 32.1) and so there will be less time to adjust to its impact.

Functional anatomy and physiology

Biology of ageing

Ageing can be defined as a progressive accumulation through life of random molecular defects that build up within cells and tissues. Eventually, and despite multiple repair and maintenance mechanisms, these result in age-related functional impairment of tissues and organs. There is evidence that variants in many genes contribute to ageing. The implicated genes include those that are involved in regulation of DNA repair, telomere length (p. 41) and insulin signalling. Genetic factors only account for around 25% of the variance in human lifespan, however; nutritional and environmental factors determine the rest. At a cellular level, production of reactive oxygen species is thought to play a major role in ageing. These molecules cause oxidative damage at a number of targets:

- *Nuclear chromosomal DNA*, causing mutations and deletions that ultimately lead to aberrant gene function and potential for malignancy.
- *Telomeres*, the structures at the ends of chromosomes that shorten with each cell division because telomerase (which copies the end of the 3′ strand of linear DNA in germ cells) is absent in somatic cells. When telomeres are sufficiently eroded, cells stop dividing. It has been suggested that telomeres represent a 'biological clock' that prevents uncontrolled cell division and cancer. Telomeres are particularly shortened in patients with

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

premature ageing due to Werner's syndrome, in which DNA is damaged due to lack of a helicase.
- *Mitochondrial DNA and lipid peroxidation*, resulting in reduced cellular energy production and ultimately cell death.
- *Proteins*, especially those that are modified by glycosylation due to spontaneous reactions between proteins and sugars. These damage structure and function of the affected protein, which becomes resistant to breakdown.

The rate at which damage occurs is variable and this is where the interplay with environment, and particularly nutrition, takes place. There is evidence in some organisms that this interplay is mediated by insulin signalling pathways. Chronic inflammation also plays an important role, again in part by driving the production of reactive oxygen species.

Physiological changes of ageing

The physiological features of normal ageing have been identified by examining disease-free populations of older people to separate the effects of pathology from those due to age alone. The fraction of older people who age without disease ultimately declines to very low levels, however, so that use of the term 'normal' becomes debatable. There is a marked increase in inter-individual variation in function with ageing; many physiological processes deteriorate substantially when measured across populations but some individuals show little or no change. This heterogeneity is a hallmark of ageing, meaning that each person must be assessed individually and that the same management cannot be applied unthinkingly to all people of a certain age.

Although some genetic influences contribute to heterogeneity, environmental factors, such as poverty, nutrition, exercise, cigarette smoking and alcohol misuse, play a large part, and a healthy lifestyle should be encouraged even when old age has been reached.

The effects of ageing are usually not enough to interfere with organ function under normal conditions but reserve capacity is significantly reduced. Some changes of ageing, such as depigmentation of the hair, are of no clinical significance. Figure 32.2 shows the many changes that occur with ageing that are clinically important.

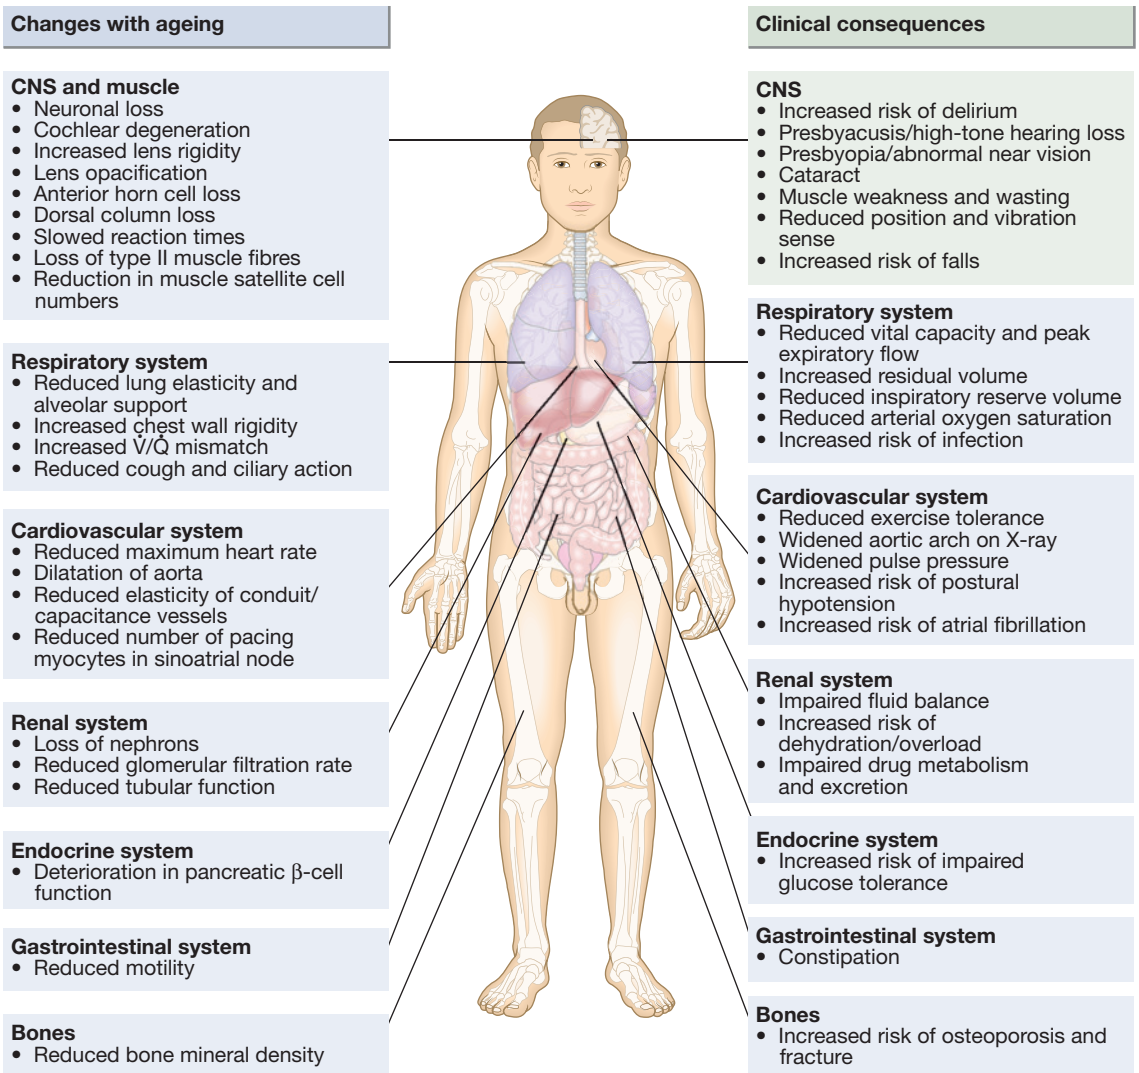

Fig. 32.2 Features and consequences of normal ageing.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Frailty and multimorbidity

Frailty is defined as the loss of an individual's ability to withstand minor stresses because the reserves in function of several organ systems are so severely reduced that even a trivial illness or adverse drug reaction may result in organ failure and death. The same stresses would cause little upset in a fit person of the same age.

It is important to understand the difference between 'disability', 'multimorbidity' and 'frailty'. Disability indicates established loss of function while frailty indicates increased vulnerability to loss of function. Disability may arise from a single pathological event (such as a stroke) in an otherwise healthy individual. After recovery, function is largely stable and the patient may otherwise be in good health. When frailty and disability coexist, function deteriorates markedly even with minor illness, to the extent that the patient can no longer manage independently.

Multimorbidity (the number of diagnoses present) is also not equivalent to frailty; it is quite possible to have several diagnoses without major impact on homeostatic reserve. Multimorbidity is, however, an important concept in its own right and is an almost invariable accompaniment to advanced age. Recent Scottish population-based data show that 60% of those aged 65 and over have at least two chronic diseases. Multimorbidity is a driver for future disability, hospitalisation and death, and often leads to polypharmacy, as multiple medications are used to treat each chronic disease individually. Current health-care systems are poorly equipped to manage multimorbidity; each disease is dealt with by a separate team of specialists, which at best places a high burden on the patient, and at worst leads to mutually incompatible approaches to management of each disease.

Unfortunately, the term 'frail' is often used rather vaguely, sometimes to justify a lack of adequate investigation and intervention in older people. It can be specifically identified, however, by assessing function in a number of domains. Two main approaches to evaluating frailty exist: measurement of physiological function across a number of domains, an example being the Fried Frailty score (Box 32.2), or use of a score based on the number of deficits or problems, such as the Rockwood score.

Frail older people particularly benefit from a clinical approach that addresses both the precipitating acute illness and their underlying loss of reserves. It may be possible to prevent further loss of function through early intervention; for example, a frail woman with myocardial infarction will benefit from specific cardiac investigation and drug treatment, but may benefit even further from an exercise programme to improve musculoskeletal function, balance and aerobic capacity, with nutritional support to restore lost weight. Establishing a patient's level of frailty also helps inform decisions regarding further investigation and management, and the need for rehabilitation.

32.2 How to assess a Fried Frailty score

- Hand grip strength in bottom 20% of healthy elderly distribution*
- Walking speed in bottom 20% of healthy elderly distribution*
- Self-reported exhaustion
- Physical inactivity
- At least 6 kg weight loss within 1 year

Patient is defined as frail if 3 or more factors are present; 1–2 factors indicate a 'pre-frail' state.

*Varies between populations. Grip cut-off is 30 kg for men and 18 kg for women in US adults; 5 m walk time cut-off is 7 seconds in US adults for both sexes.

Investigations

Comprehensive Geriatric Assessment

One of the most powerful tools in the management of older people is the Comprehensive Geriatric Assessment, which identifies all the relevant factors contributing to their presentation (p. 1302). Comprehensive Geriatric Assessment is in fact a misnomer; it is not merely an assessment, but a process of identifying and managing all relevant factors affecting the health and well-being of older people. It is iterative in nature, management being followed by reassessment and a new management plan. In frail patients with multiple pathology, it may be necessary to perform the assessment in stages to allow for their reduced stamina. The outcome should be a management plan that not only addresses the acute presenting problems but also improves the patient's overall health and function.

Comprehensive Geriatric Assessment is performed by a multidisciplinary team (p. 1303). Such an approach was pioneered by Dr Marjory Warren at the West Middlesex Hospital in London in the 1930s; her comprehensive assessment and rehabilitation of supposedly incurable, long-term bedridden older people revolutionised the approach of the medical profession to frail older people and laid the foundations for the modern specialty of geriatric medicine. There is excellent evidence from systematic reviews that Comprehensive Geriatric Assessment, when performed by a specialist team on a specialist geriatric medicine ward, reduces death or deterioration, increases the chances of living independently at home, and may also improve cognitive function in the short to medium term. Current evidence suggests that the process works when delivered on a specialist inpatient unit, but the evidence for effectiveness when it is delivered by a visiting team or in the community is less strong.

Decisions about investigation and treatment

Accurate diagnosis is important at all ages but frail older people may not be able to tolerate lengthy or invasive procedures, and diagnoses may be revealed for which patients could not withstand intensive or aggressive treatment. On the other hand, disability should never be dismissed as due to age alone. For example, it would be a mistake to supply a patient no longer able to climb stairs with a stair lift when simple tests would have revealed osteoarthritis of a hip and vitamin D deficiency, for which appropriate treatment would have restored his or her strength. So how do doctors decide when and how far to investigate?

The views of the patient and family

Older people may have strong views about the extent of investigation and the treatment they wish to receive, and these should be sought from the outset. A key issue is to establish what the patient wants from investigation and treatment. Many

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

older people do not desire prolongation of life; rather they aspire to maintain physical function, gain relief from symptoms, and preserve the ability to live independently. Such aims differ widely between patients, however, and a careful exploration of what is important to the individual is essential. If the patient wishes, the views of relatives can also be taken into account. If the patient is not able to express a view or lacks the capacity to make decisions because of cognitive impairment or communication difficulties, then relatives' input becomes particularly helpful. They may be able to give information on views previously expressed by the patient or on what the patient would have wanted under the current circumstances. However, families should never be made to feel responsible for difficult decisions.

The patient's general health

Does this patient have the physical and mental capacity to tolerate the proposed investigation? Do they have the aerobic capacity to undergo bronchoscopy? Will delirium prevent them from remaining still in the magnetic resonance imaging (MRI) scanner? The more comorbidities a patient has, the less likely he or she will be able to withstand an invasive intervention.

Will the investigation alter management?

Would the patient be fit for, or benefit from, the treatment that would be indicated if investigation proved positive? The presence of comorbidity and frailty is more important than age itself in determining this. When a patient with severe heart failure and a previous disabling stroke presents with a suspicious mass lesion on chest X-ray, detailed investigation and staging may not be appropriate if they are not fit for surgery, radical radiotherapy or chemotherapy. On the other hand, if the same patient presented with dysphagia, investigation of the cause would be important, as they might be able to tolerate endoscopic treatment (for example, to palliate an obstructing oesophageal carcinoma).

Will management benefit the patient?

It is important to consider whether interventions that might be considered as standard-of-care for younger people are likely to be beneficial in frail older people. For example, while oral anticoagulation might be indicated by guidelines for a patient with atrial fibrillation, such treatment may not accord with the wishes of a patient in a care home who finds regular blood tests distressing, or who is more worried about bleeding than about avoiding a stroke. Another example would be the use of anti-osteoporosis medications to reduce the risk of fracture in very old patents, where the risk of death from other causes would be greater than the risk of fracture.

Advance directives

Advance directives or 'living wills' are statements made by adults at a time when they have the capacity to decide about the interventions they would refuse or accept in the future, should they no longer be able to make decisions or communicate them. An advance directive cannot authorise a doctor to do anything that is illegal and doctors are not bound to provide a specific treatment requested if, in their professional opinion, it is not clinically appropriate. However, any advance refusal of treatment, made when the patient was able to make decisions based on adequate information about their implications, is legally binding in the UK. It must be respected when it clearly applies to the patient's present circumstances and when there is no reason to believe that the patient has changed his or her mind.

Presenting problems in geriatric medicine

Characteristics of presenting problems in old age

Problem-based practice is central to geriatric medicine. Most problems are multifactorial and there is rarely a single unifying diagnosis. All contributing factors have to be taken into account and attention to detail is paramount. Two patients who share the same presenting problem may have completely disparate diagnoses. A wide knowledge of adult medicine is required, as disease in any, and often many, of the organ systems has to be managed at the same time. There are a number of features that are particular to older patients.

Late presentation

Many people (of all ages) accept ill health as a consequence of ageing and may tolerate symptoms for lengthy periods before seeking medical advice. Comorbidities may also contribute to late presentation; in a patient whose mobility is limited by stroke, angina may only present when coronary artery disease is advanced, as the patient has been unable to exercise sufficiently to cause symptoms at an earlier stage.

Atypical presentation

Infection may present with delirium and without clinical pointers to the organ system affected. Stroke may present with falls rather than symptoms of focal weakness. Myocardial infarction may present as weakness and fatigue, without chest pain or dyspnoea. The reasons for these atypical presentations are not always easy to establish. Perception of pain is altered in old age, which may explain why myocardial infarction presents in other ways. The pyretic response is blunted in old age so that infection may not be obvious at first. Cognitive impairment may limit the patient's ability to give a history of classical symptoms.

Acute illness and changes in function

Atypical presentations in frail elderly patients include 'failure to cope', 'found on floor', 'delirium' and 'off feet', but these are *not* diagnoses. The possibility that an acute illness has been the precipitant must always be considered. To establish whether the patient's current status is a change from his or her usual level of function, it helps to ask a relative or carer (by phone if necessary). Investigations aimed at uncovering an acute illness will not be fruitful in a patient whose function has been deteriorating over several months but are important if function has suddenly changed.

Multiple pathology

Presentations in older patients have a more diverse differential diagnosis because multiple pathology is so common. There are frequently a number of causes for any single problem, and adverse effects from medication often contribute. A patient may fall because of osteoarthritis of the knees, postural hypotension due to diuretic therapy for hypertension, and poor vision due to cataracts. All these factors have to be addressed to prevent further falls and this principle holds true for most of the common presenting problems in old age.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

32.3 Screening investigations for acute illness

- Full blood count
- Urea and electrolytes, liver function tests, calcium and glucose
- Chest X-ray
- Electrocardiogram
- C-reactive protein: useful marker for occult infection or inflammatory disease
- Blood cultures if pyrexial

Approach to presenting problems in old age

For the sake of clarity, the common presenting problems are described individually but, in reality, older patients often present with several at the same time, particularly delirium, incontinence and falls. These share some underlying causes and may precipitate each other.

The approach to most presenting problems in old age can be summarised as follows:

- *Obtain a collateral history.* Find out the patient's usual status with regard to mobility and cognitive function from a relative or carer. Call these people by phone if they are not present.
- *Check all medication.* Have there been any recent changes?
- *Search for and treat any acute illness* (Box 32.3).
- *Identify and reverse predisposing risk factors.* These depend on the presenting problem.

Falls

Around 30% of those over 65 years of age fall each year and this figure rises to more than 40% in those aged over 80. Although only 10–15% of falls result in serious injury, virtually all fragility fractures in the elderly are caused by falls. Age-related osteoporosis contributes to the dramatic rise in hip and other fragility fractures that occurs with ageing but the most important contributory factor is an increased risk of falling (Fig. 32.3). Falls also lead to loss of confidence and fear, and are frequently the 'final straw' that makes an older person decide to move to institutional care. Management will vary according to the underlying cause.

Acute illness

Falls are one of the classical atypical presentations of acute illness in frail people. The reduced reserves in older people's neurological function mean that they are less able to maintain their balance when challenged by an acute illness. Suspicion should be high when falls have suddenly occurred over a period of a few days. Common underlying illnesses include infection, stroke, metabolic disturbance and heart failure. Thorough examination and investigation are required (Box 32.3). It is also important to establish whether any drug that precipitates falls, such as a psychotropic or hypotensive agent, has been started recently. Once the underlying acute illness has been treated, falls may stop.

Blackouts

A proportion of older people who 'fall' have, in fact, had a syncopal episode. A collateral history from a witness is of utmost importance in anyone falling over; people who lose consciousness do not always remember having done so. If loss of consciousness is suggested by the patient or witness, it is important to perform appropriate investigations (pp. 181 and 1080).

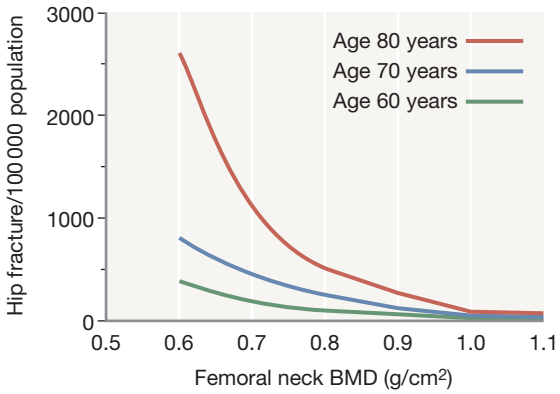

Fig. 32.3 **Age and bone mineral density (BMD) interact to influence fracture risk.**

32.4 Risk factors for falls

- Muscle weakness
- History of falls
- Gait or balance abnormality
- Use of a walking aid
- Visual impairment
- Arthritis
- Impaired activities of daily living
- Depression
- Cognitive impairment
- Age over 80 years
- Psychotropic medication

Mechanical and recurrent falls

Among patients who have tripped or are uncertain how they fell, those who have fallen more than once in the past year and those who are unsteady during a 'get up and go' test (p. 1303) require further assessment. Patients with recurrent falls are commonly frail, with multiple medical problems and chronic disabilities. Obviously, such patients may present with a fall resulting from an acute illness or syncope but they will remain at risk of further falls even when the acute illness has resolved. The risk factors for falls (Box 32.4) should be considered. If problems are identified with muscle strength, balance, vision or cognitive function, the causes of these must be identified by specific investigation, and treatment commenced if appropriate. Careful assessment of the patient's gait may provide important clues to an underlying diagnosis (Box 32.5). Common pathologies identified include cerebrovascular disease (Ch. 26), Parkinson's disease (p. 1112) and osteoarthritis of weight-bearing joints (p. 1007). Calculation of fracture risk using tools such as FRAX or QFracture should be performed and dual X-ray absorptiometry (DXA) bone density scanning considered in patients with a 10-year risk of major fracture of more than 10%.

Prevention of falls and fractures

Falls can be prevented by multiple risk factor intervention (Box 32.6). The most effective intervention is balance and strength training by physiotherapists or exercise practitioners; an alternative with good evidence is tai chi training. An assessment of the

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

32.5 Abnormal gaits and probable causes

Gait abnormality	Probable cause
Antalgic	Arthropathy
Waddling	Proximal myopathy
Stamping	Sensory neuropathy
Foot drop	Peripheral neuropathy or radiculopathy
Ataxic	Sensory neuropathy or cerebellar disease
Shuffling/festination	Parkinson's disease
Marche à petits pas	Small-vessel cerebrovascular disease
Hemiplegic	Cerebral hemisphere lesion
Apraxic	Bilateral hemisphere lesions

32.6 Interventions to reduce the risk of falls and fractures

- Exercise (should include components of lower limb strength and balance training):
  - Multimodal group exercise and tai chi both effective
- Calcium and vitamin D supplementation:
  - Evidence of effectiveness only in patients in institutional care
  - Large doses of vitamin D may increase risk of falls and fractures
- Home environment assessment and modification
- Medication review:
  - Particularly medications with central actions such as hypnotics but also those with anticholinergic and hypotensive actions
- Cataract surgery:
  - Effective if for first cataract
  - Other vision interventions ineffective and may increase falls risk
- Anti-slip shoes:
  - Effective only in icy conditions
- Cardiac pacemaker for carotid sinus hypersensitivity

patient's home environment for hazards should be undertaken by an occupational therapist, who may also provide personal alarms so that patients can summon help, should they fall again. Rationalising psychotropic medication may help to reduce sedation, although many older patients are reluctant to stop hypnotics. If postural hypotension is present (defined as a drop in blood pressure of >20 mmHg systolic or >10 mmHg diastolic pressure on standing from supine), reducing or stopping hypotensive drugs may be helpful. Evidence supporting the efficacy of other interventions for postural hypotension is lacking but drugs, including fludrocortisone and midodrine, are sometimes used to try to improve dizziness on standing. Other interventions, such as cataract extraction and podiatry, can also have a significant impact on function in those who fall.

If osteoporosis is diagnosed, specific drug therapy should be considered (p. 1046). In the frailest patients, such as those in institutional care, calcium and vitamin D_3 administration has been shown to reduce both falls and fracture rates, probably by exerting positive effects on bone mineral density and on neuromuscular function. Supplementation does not reduce falls risk beyond this very frail group, however, and very high doses of vitamin D may paradoxically increase the risk of falls and fractures.

In the UK, government policy and National Institute for Health and Clinical Excellence guidelines (www.nice.org.uk) for falls prevention have led to the development of specific Falls and Fracture Prevention Services in many parts of the country.

Dizziness

Dizziness is very common, affecting at least 30% of those aged over 65 years in community surveys. It can be disabling in its own right and is also a risk factor for falls. Acute dizziness is relatively straightforward and common causes include:

- *hypotension* due to arrhythmia, myocardial infarction, gastrointestinal bleed or pulmonary embolism
- *posterior fossa stroke* onset
- *vestibular neuronitis*.

Although older people more commonly present with recurrent dizzy spells and often find it difficult to describe the sensation they experience, the most effective way of establishing the cause(s) of the problem is nevertheless to determine which of the following is predominant (even if more than one is present):

- *lightheadedness*, suggestive of reduced cerebral perfusion
- *vertigo*, suggestive of labyrinthine or brainstem disease (p. 1086)
- *unsteadiness/poor balance*, suggestive of joint or neurological disease.

In lightheaded patients, structural cardiac disease (such as aortic stenosis) and arrhythmia must be considered, but disorders of autonomic cardiovascular control, such as vasovagal syndrome and postural hypotension, are the most common causes in old age. Antihypertensive medications may exacerbate these conditions. Further investigation and treatment are described on page 181.

Vertigo in older patients is most commonly due to benign positional vertigo (p. 1086), but if other brainstem symptoms or signs are present, MRI of the brain is required to exclude a cerebello-pontine angle lesion.

Delirium

Delirium is a syndrome of transient, reversible cognitive dysfunction that affects 30% of older hospital inpatients. Differential diagnosis, assessment and management are discussed on page 183.

Urinary incontinence

Urinary incontinence is defined as the involuntary loss of urine and comes to medical attention when sufficiently severe to cause a social or hygiene problem. It occurs in all age groups but becomes more prevalent in old age, affecting about 15% of women and 10% of men aged over 65. It may lead to skin damage if severe and can be socially restricting. While age-dependent changes in the lower urinary tract predispose older people to incontinence, it is not an inevitable consequence of ageing and requires investigation and appropriate treatment. Urinary incontinence is frequently precipitated by acute illness in old age and is commonly multifactorial (Fig. 32.4).

The initial assessment should seek to identify and address contributory factors. If incontinence fails to resolve, further diagnosis and management should be pursued, as described on page 437.

- *Urge incontinence* is usually due to detrusor over-activity and results in urgency and frequency.
- *Stress incontinence* is almost exclusive to women and is due to weakness of the pelvic floor muscles, which allows leakage of urine when intra-abdominal pressure rises, such as on coughing. It may be compounded by atrophic

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

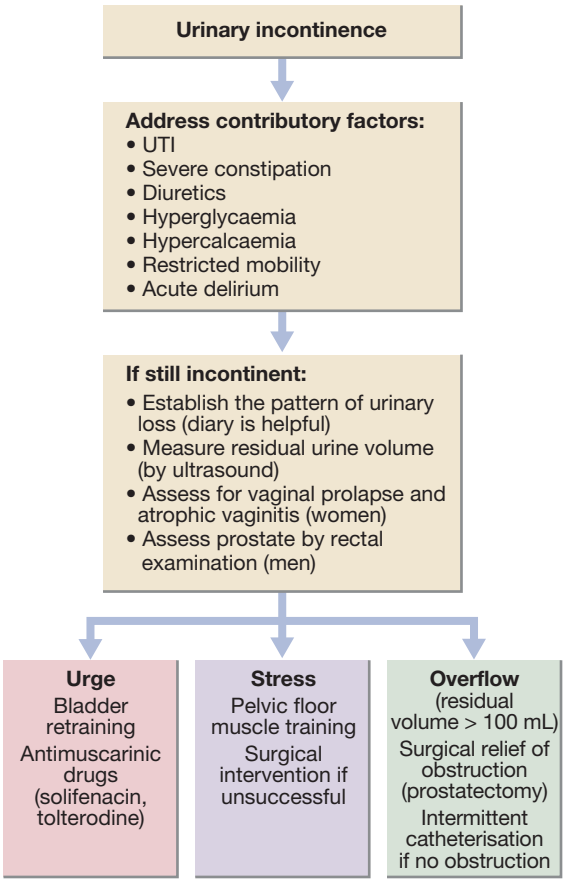

Fig. 32.4 Assessment and management of urinary incontinence in old age. See also page 436 and NICE guideline on the Management of Incontinence in Women: nice.org.uk. (UTI = urinary tract infection)

vaginitis, associated with oestrogen deficiency in old age, which can be treated with oestrogen pessaries.

- *Overflow incontinence* is most commonly seen in elderly men with prostatic enlargement, which obstructs bladder outflow.

In patients with severe stroke disease or dementia, treatment may be ineffective, as frontal cortical inhibitory signals to bladder emptying are lost. A timed/prompted toileting programme may help. Other than in overflow incontinence, urinary catheterisation should never be viewed as first-line management, but may be required as a final resort if the perineal skin is at risk of breakdown or quality of life is affected.

Prescribing and deprescribing

The large number of comorbidities that accompany ageing often leads to polypharmacy. This has been defined as the use of four or more drugs, and is associated with several adverse outcomes including falls, hospitalisation and increased risk of death. While some of these outcomes are caused by drug–drug interactions and adverse effects, others are as much due to the underlying multimorbidities for which the drugs were prescribed in the first place

In view of this, it is essential for prescribing for older people to be appropriate. For many older people, taking multiple drugs is appropriate, as such therapy is required to treat multiple diseases (Box 32.7). However, the more drugs that are taken, the greater the risk of an adverse drug reaction (ADR). ADRs and the effects of drug interactions are discussed on page 21. They may result in symptoms, abnormal physical signs and altered laboratory test results (Box 32.8). ADRs are the cause of around 5% of all hospital admissions but account for up to 20% of admissions in those aged over 65. The risk of polypharmacy is compounded by age-related changes in pharmacodynamic and pharmacokinetic factors (p. 14), and by impaired homeostatic mechanisms, such as baroreceptor responses, plasma volume and electrolyte control.

Older people are thus especially sensitive to drugs that can cause postural hypotension or volume depletion (Box 32.8). Non-adherence to drug therapy also rises with the number of drugs prescribed.

The clinical presentations of ADRs are diverse, so for *any* presenting problem in old age the possibility that the patient's medication is a contributory factor should *always* be considered. Failure to recognise this may lead to the use of a further drug to treat the problem, making matters worse, when the better

i 32.7 Factors leading to polypharmacy in old age

- Multiple pathology
- Poor patient education (see Box 2.20, p. 31)
- Lack of routine review of all medications
- Patient expectations of prescribing
- Over-use of drug interventions by doctors
- Attendance at multiple specialist clinics
- Poor communication between specialists

i 32.8 Common adverse drug reactions in old age

Drug class	Adverse reaction
NSAIDs	Gastrointestinal bleeding and peptic ulceration Renal impairment
Diuretics	Renal impairment, electrolyte disturbance Gout Hypotension, postural hypotension
Warfarin	Bleeding
ACE inhibitors	Renal impairment, electrolyte disturbance Hypotension, postural hypotension
β-blockers	Bradycardia, heart block Hypotension, postural hypotension
Opiates	Constipation, vomiting Delirium Urinary retention
Antidepressants	Delirium Hyponatraemia (SSRIs) Hypotension, postural hypotension Falls
Benzodiazepines	Delirium Falls
Anticholinergics	Delirium Urinary retention Constipation

(ACE = angiotensin-converting enzyme; NSAIDs = non-steroidal anti-inflammatory drugs; SSRIs = selective serotonin re-uptake inhibitors)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

course would be to stop or reduce the dose of the offending drug or to find an alternative.

Appropriate prescribing and deprescribing

The key to appropriate prescribing is first to ensure that medications are started only for reasons that accord with the patient's goals and wishes. Thoughtless adherence to guidelines quickly leads to polypharmacy that may be inappropriate. Some medications (such as chronic use of non-steroidal anti-inflammatory medications) are much less suitable for older people because of the much higher risk of side-effects. Other medications, such as statins and bisphosphonates, lack evidence of efficacy in very old people, who may not live for long enough to derive benefit.

Deprescribing is as important as prescribing in older people. Regular review of medications should be undertaken to ensure that medications are still required, to establish that they are still working, to check that they are not causing side-effects, and to ascertain whether the patient is actually taking them. If any of the above issues is problematic, the medication should be deprescribed. This may need to be done in a controlled manner, with dose reduction to ensure that rebound symptoms or withdrawal effects do not occur. The patient or carer should therefore be asked to bring all medication for review rather than the doctor relying on previous records; such reviews should take place regularly, not just at a point of crisis such as after a fall or on hospital admission.

Other problems in old age

A vast range of other presenting problems in older people present to many medical specialties. End-of-life care is an important facet of clinical practice in old age and is discussed on page 1354. Relevant sections in other chapters are referenced in Box 32.9.

Within each chapter, 'In Old Age' boxes highlight the areas in which presentation or management differs from that in younger individuals.

i 32.9 Other presenting problems in old age

• Bone disease and fracture	pp. 994 and 1049
• Stroke	p. 1147
• Dementia	p. 1191

Rehabilitation

Rehabilitation aims to improve the ability of people of all ages to perform day-to-day activities and to optimise their physical, mental and social capabilities. Acute illness in older people is often associated with loss of their usual ability to walk or care for themselves, and common disabling conditions such as stroke, fractured neck of femur, arthritis and cardiorespiratory disease become increasingly prevalent with advancing age. Doctors tend to focus on health conditions and impairments but patients are more concerned with the effect on their activities and ability to participate in everyday life.

The rehabilitation process

Rehabilitation is a problem-solving process focused on improving the patient's physical, psychological and social function. It entails:

- *Assessment.* The nature and extent of the patient's problems can be identified using the International Classification of Functioning, Disability and Health framework, which focuses on health conditions (such as stroke), the associated physical impairments (such as arm weakness caused by the stroke), the effect on activity (such as the inability to dress oneself due to arm weakness) and restriction of participation in activities (such as inability to go out of the house due to the inability to dress oneself). Such an approach helps to ensure a whole-person approach to participation in society, rather than a focus merely on disease. Specific assessment scales, such as the Elderly Mobility Scale or Barthel Index of Activities of Daily Living (Box 32.10), are useful to quantify components of disability but additional assessment is needed to determine the underlying causes or the interventions required in individual patients.
- *Goal-setting.* Goals should be specific to the patient's problems, realistic, and agreed between the patient and the rehabilitation team.
- *Intervention.* This includes the active treatments needed to achieve the established goals and to maintain the patient's health and quality of life. Interventions include hands-on treatment by therapists using a functional, task-orientated approach to improve day-to-day activities, and also psychological support and education. The emphasis on the type of intervention will be individualised, according to the patient's disabilities, psychological status and progress. The patient and carer(s) must be active participants.
- *Re-assessment.* There is ongoing re-evaluation of the patient's function and progress towards the goals by the rehabilitation team, the patient and the carer. Interventions may be modified as a result.

Multidisciplinary team working

The core rehabilitation team includes all members of the multidisciplinary team (p. 1303). Others may also be involved, such as audiometrists to correct hearing impairment, podiatrists for foot problems, and orthoticists where a prosthesis or splinting is required. Good communication and mutual respect are essential. Regular team meetings allow sharing of assessments, agreement on rehabilitation goals and interventions, evaluation of progress and planning for the patient's discharge home. Rehabilitation is *not* when the doctor orders 'physiotherapy' or 'a home visit' and takes no further role.

32.10 How to assess dependency using the Modified Barthel Index*

Mobility	
Independent = 3 Needs help = 2 Wheelchair independent = 1 Immobile = 0	
Stairs	
Independent = 2 Needs help = 1 Unable = 0	
Transfers (e.g. from bed to chair)	
Independent = 3 Needs minor help = 2 Needs major help = 1 Unable = 0	
Bladder	
Continent = 2 Occasional incontinence = 1 Incontinent = 0	
Bowels	
Continent = 2 Occasional incontinence = 1 Incontinent = 0	
Grooming	
Independent = 1 Needs help = 0	
Toilet use	
Independent = 2 Needs help = 1 Unable = 0	
Feeding	
Independent = 2 Needs help = 1 Unable = 0	
Dressing	
Independent = 2 Needs some help = 1 Completely dependent = 0	
Bathing	
Independent = 1 Needs help = 0	

*The 20-point version is illustrated. The total score reflects the degree of dependency; scores of 14 and above are usually consistent with living in the community; scores below 10 suggest the patient is heavily dependent on carers.

Rehabilitation outcomes

There is evidence that rehabilitation improves functional outcomes in older people following acute illness, stroke and hip fracture. It also reduces mortality after stroke and hip fracture. These benefits accrue from complex multicomponent interventions, but occupational therapy to improve personal ADLs and individualised exercise interventions have now been shown to be effective in improving functional outcome in their own right.

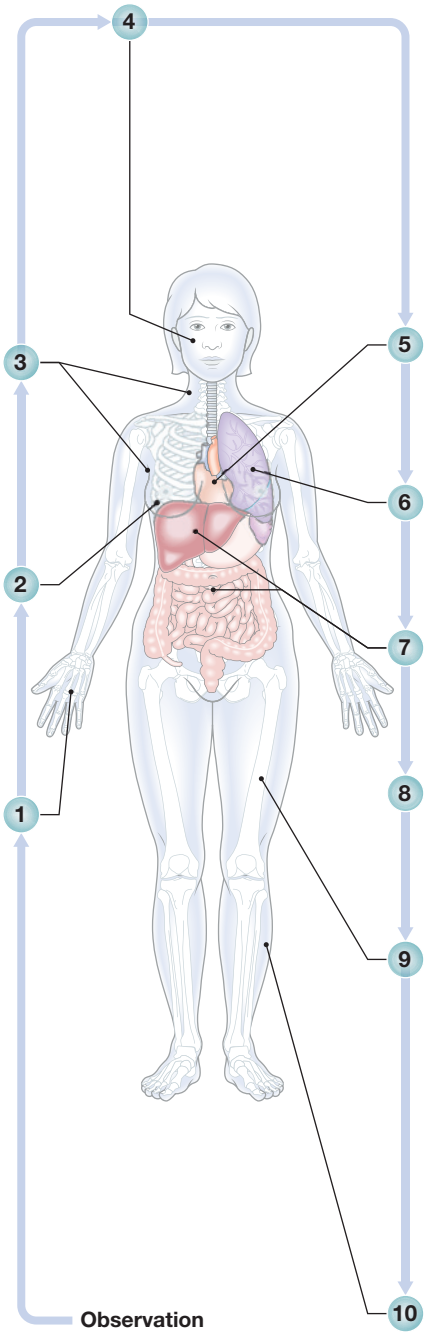
Clinical examination of the cancer patient

4 Face
Conjunctival pallor
Icterus, jaundice
Horner's syndrome
Cushingoid features

3 Lymph nodes
Neck
Supraclavicular
Axillary
Antecubital
Inguinal
Para-aortic

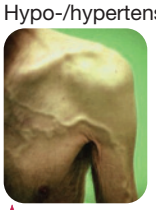
2 Breast

Skin tethering above the nipple



1 Hands
Clubbing
Signs of smoking
Pallor
Tylosis of palms

Finger clubbing in lung cancer



Cushing's syndrome in a patient with ectopic adrenocorticotrophic hormone (ACTH) production

Observation
- Skin changes
- Ascites
- Cushingoid appearance
- Cachexia
- Dehydration

5 Cardiovascular
Superior vena cava (SVC) obstruction
Atrial fibrillation
Pericardial effusion
Hypo-/hypertension

SVC obstruction in a patient with a mediastinal mass

6 Respiratory
Stridor
Consolidation
Pleural effusion

7 Abdomen
Surgical scars
Umbilical nodule
Mass in epigastrium
Visible peristalsis
Abdominal distension
Ascites
Hepatomegaly
Splenomegaly
Renal mass
Pelvic or adnexal mass

Ascites (ovarian carcinoma)

8 Neurological
Focal neurological signs
Sensory deficit
Spinal cord compression
Memory deficit
Personality change

9 Skeletal survey
Focal bone tenderness (pelvis, spine, long bones)
Wrist tenderness (hypertrophic pulmonary osteoarthropathy)

10 Periphery
Calf tenderness, venous thrombosis
Clubbing (if present in hands)

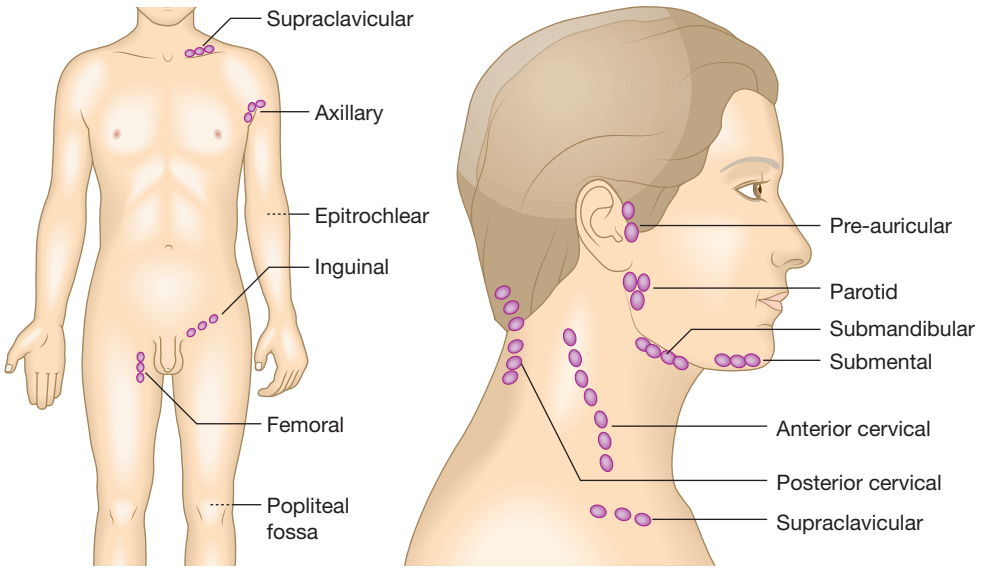
i Examination of the skin



Important features of skin lesions that should alert suspicion include:

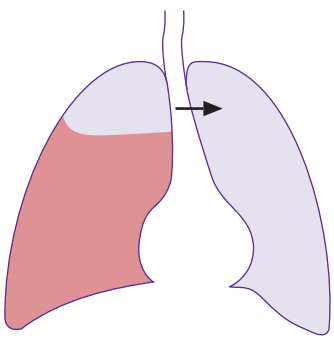
- Asymmetry: irregular shape
- Bleeding
- Border: not a smooth edge
- Colour: uneven, variegated or changing colour
- Diameter: >6 mm in diameter or growing
- Itching or pain in a pre-existing mole

7 Abdominal examination

- Are there scars from previous surgery?
- Is the umbilicus everted, suggesting ascites?
- Is there a firm nodule at the umbilicus due to ovarian or gastric cancer metastasis, causing a Sister Mary Joseph nodule (p. 1334)?
- Is there smooth hepatomegaly – possibly primary liver cancer or heart failure?
- Is the liver firm or knobbly, suggesting metastasis?
- Is the ascites too tense to demonstrate hepatomegaly?
- Are other masses palpable in the abdomen?
- Are there signs of obstruction or paralytic ileus with absence of bowel sounds?
- Palpate for inguinal nodes (occasionally involved in ovarian cancer)
- Percuss for flank dullness and shifting dullness
- Perform vaginal and rectal examinations to detect adnexal or rectal masses

3 Examination of the lymph nodes

5 Superior vena cava obstruction



- Venous distension of neck
- Elevated but non-pulsatile jugular venous pulse
- Venous distension of chest wall
- Facial oedema
- Cyanosis
- Plethora of face
- Oedema of arms

5 Pericardial effusion

- Tachycardia
- Falling blood pressure
- Rising jugular venous pressure
- Muffled heart sounds
- Kussmaul's sign (p. 544)

6 Malignant pleural effusions

Large right pleural effusion

Inspection
Tachypnoea
Palpation
↓Expansion on R
Trachea and apex may be moved to L
Percussion
Stony dull
R mid- and lower zones
Auscultation
Absent breath sounds and diminished or absent vocal resonance R base
Crackles above effusion

Cancer represents a significant economic burden for the global economy and is now the third leading cause of death worldwide. By 2030, it is projected that there will be 26 million new cancer cases and 17 million cancer deaths per year. The developing world is disproportionately affected by cancer and in 2008 developing nations accounted for 56% of new cancer cases and 75% of cancer deaths. These deaths happen in countries with limited or no access to treatment and with low per capita expenditure on health care.

The most common solid organ malignancies arise in the lung, breast and gastrointestinal tract (Fig. 33.1), but the most common form worldwide is skin cancer. Cigarette smoking accounts for more than 20% of all global cancer deaths, 80% of lung cancer cases in men and 50% of lung cancer cases in women worldwide, which could be prevented by smoking cessation. Diet and alcohol contribute to a further 30% of cancers, including those of the stomach, colon, oesophagus, breast and liver. Lifestyle modification could reduce these if steps were taken to avoid animal fat and red meat, reduce alcohol, increase fibre, fresh fruit and vegetable intake, and avoid obesity. Infections account for a further 15% of cancers, including those of the cervix, stomach, liver, nasopharynx and bladder, and some of these could be prevented by infection control and vaccination.

The 10 hallmarks of cancer

The formation and growth of cancer constitute a multistep process, during which sequentially occurring gene mutations result in the formation of a cancerous cell. For cells to initiate carcinogenesis successfully, they require key characteristics, collectively referred to as the hallmarks of cancer.

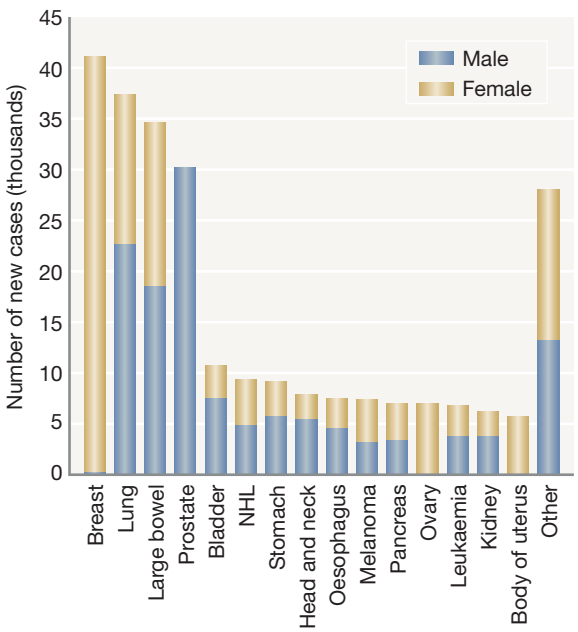

Fig. 33.1 The most commonly diagnosed cancers in the UK. (NHL = non-Hodgkin lymphoma) *Statistics from Cancer Research UK website (http://info.cancerresearchuk.org).*

1. Genome instability and mutation

Random genetic mutations occur continuously throughout all cells of the body and very rarely confer a selective advantage on single cells, allowing overgrowth and dominance in local tissue environments. Multistep carcinogenesis results from successive clonal expansions of pre-malignant cells, each expansion being triggered by acquisition of a random enabling genetic mutation. Under normal circumstances, cellular DNA repair mechanisms are so effective that almost all spontaneous mutations are corrected without producing phenotypic changes, keeping the overall mutation rates very low. In cancer cells, the accumulation of mutations can be accelerated by compromising the surveillance systems that normally monitor genomic integrity and force genetically damaged cells into either senescence or apoptosis. They can therefore become more sensitive to mutagenic actions or develop DNA repair mechanism failure.

2. Resisting cell death

There are three principal mechanisms through which cell death occurs in healthy tissues: apoptosis, autophagy and necrosis.

Apoptosis

This is programmed cell death. It is frequently found at markedly reduced rates in cancers, particularly those of high grade or those resistant to treatment. The cellular apoptotic system has regulatory elements that sense intrinsic and extrinsic pro-apoptotic signals and initiate a cascade of proteolysis and cell disassembly with nuclear fragmentation, chromosomal condensation, and shrinking of the cell with loss of intercellular contact, followed by cellular fragmentation and the formation of apoptotic bodies that are phagocytosed by neighbouring cells. The most important regulator of apoptosis is the *TP53* tumour suppressor gene, often described as the 'guardian of the genome', as it is able to induce apoptosis in response to sufficient levels of genomic damage. The largest initiator of apoptosis via *TP53* is cellular injury, particularly that due to DNA damage from chemotherapy, oxidative damage and ultraviolet (UV) radiation.

Autophagy

This is a catabolic process during which cellular constituents are degraded by lysosomal machinery within the cell. It is an important physiological mechanism; it usually occurs at low levels in cells but can be induced in response to environmental stresses, particularly radiotherapy and cytotoxic chemotherapy, which induce elevated levels of autophagy that are cytoprotective for malignant cells, thus impeding rather than perpetuating the killing actions of these stress situations. Severely stressed cancer cells have been shown to shrink via autophagy to a state of reversible dormancy.

Necrosis

This is the premature death of cells and is characterised by the release of cellular contents into the local tissue microenvironment, in marked contrast to apoptosis, where cells are disassembled in a step-by-step fashion and the resulting cellular fragments are phagocytosed. Necrotic cell death results in the recruitment of inflammatory immune cells, promotion of angiogenesis, and release of stimulatory factors that increase cellular proliferation

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

and tissue invasion, thereby enhancing rather than inhibiting carcinogenesis.

3. Sustaining proliferative signalling

Cancer cells can sustain proliferation beyond what would be expected for normal cells; this is typically due to growth factors, which are able to bind to cell surface-bound receptors that activate an intracellular tyrosine kinase-mediated signalling cascade, ultimately leading to changes in gene expression and promoting cellular proliferation and growth. Sustained proliferative capacity can result from over-production of growth factor ligands or receptors and production of structurally altered receptors, which can signal in the absence of ligand binding and activation of intracellular signalling pathway components, so that signalling is no longer ligand-dependent.

The cell cycle

The cell cycle is composed of four ordered, strictly regulated phases referred to as G_1 (gap 1), S (DNA synthesis), G_2 (gap 2) and M (mitosis) (Fig. 33.2). Normal cells grown in culture will stop proliferating and enter a quiescent state called G_0 once they become confluent or are deprived of serum or growth factors. The first gap phase (G_1) prior to the initiation of DNA synthesis represents the period of commitment that separates M and S phases as cells prepare for DNA duplication. Cells in G_0 and G_1 are receptive to growth signals, but once they have passed a restriction point, they are committed to enter DNA synthesis (S phase). Cells demonstrate arrest at different points in G_1 in response to different inhibitory growth signals. Mitogenic signals promote progression through G_1 to S phase, utilising phosphorylation of the retinoblastoma gene product (pRB, p. 40). Following DNA synthesis, there is a second gap phase (G_2) prior to mitosis (M), allowing cells to repair errors that have occurred during DNA replication and thus preventing propagation of these errors to daughter cells. Although the duration of individual phases may vary, depending on cell and tissue type, most adult cells are in a G_0 state at any one time.

Cell cycle regulation

The cell cycle is orchestrated by a number of molecular mechanisms: most importantly, by cyclins and cyclin-dependent kinases (CDKs). Cyclins bind to CDKs and are regulated by both activating and inactivating phosphorylation, with two main checkpoints at G_1/S and G_2/M transition. The genes that inhibit progression play an important part in tumour prevention and are referred to as tumour suppressor genes (e.g. *TP53*, *TP21*, *TP16* genes). The products of these genes deactivate the cyclin–CDK complexes and are thus able to halt the cell cycle. The complexity of cell cycle control is susceptible to dysregulation, which may produce a malignant phenotype.

Stimulation of the cell cycle

Many cancer cells produce growth factors, which drive their own proliferation by a positive feedback known as autocrine stimulation. Examples include transforming growth factor-alpha (TGF-α) and platelet-derived growth factor (PDGF). Other cancer cells express growth factor receptors at increased levels due to gene amplification or express abnormal receptors that are permanently activated. This results in abnormal cell growth in response to physiological growth factor stimulation or even in the absence of growth factor stimulation (ligand-independent signalling). The epidermal growth factor receptor (EGFR) is often over-expressed in lung and gastrointestinal tumours and the human epidermal growth factor receptor 2 (HER2)/neu receptor is frequently over-expressed in breast cancer. Both receptors activate the Ras–Raf–mitogen activated protein (MAP) kinase pathway, causing cell proliferation.

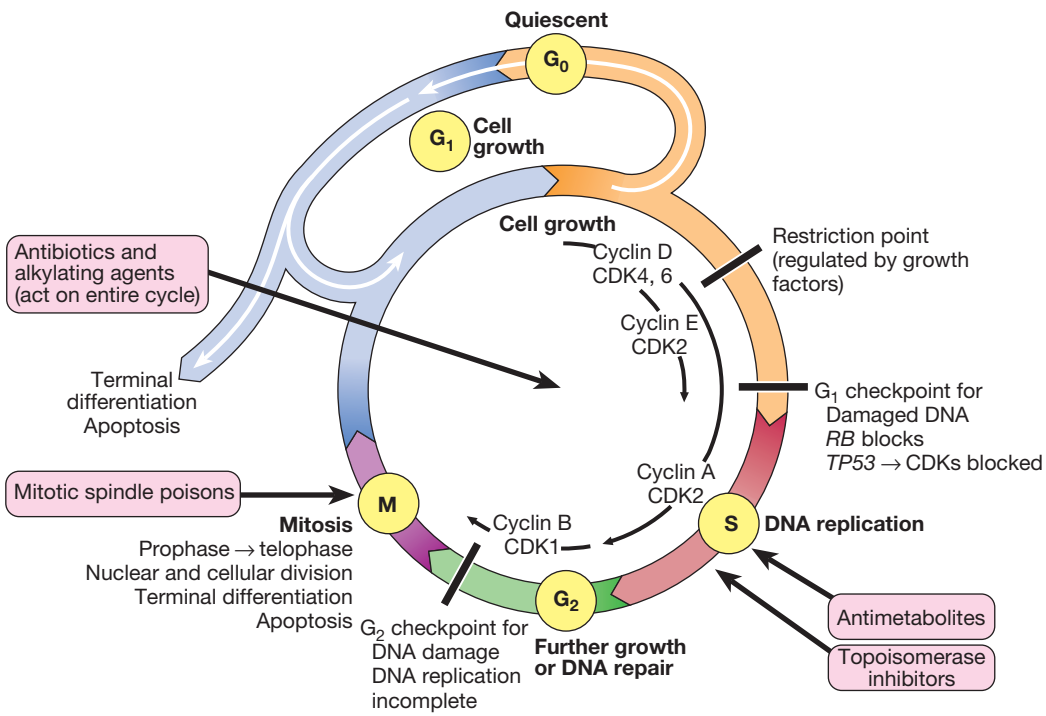

Fig. 33.2 The cell cycle and sites of action of chemotherapeutic agents. (CDK = cyclin-dependent kinase; *RB* = retinoblastoma gene)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

4. Evading growth suppressors

In healthy tissues, cell-to-cell contact in dense cell populations acts as an inhibitory factor on proliferation. This contact inhibition is typically absent in many cancer cell populations. Growth-inhibitory factors can modulate the cell cycle regulators and produce activation of the CDK inhibitors, causing inhibition of the CDKs. Mutations within inhibitory proteins are common in cancer. Loss of restriction by disruption of pRB regulation can be found in human tumours, which produces a loss of restraint on transition from G_1 to S phase of the cell cycle. Disruption of *TP53* function will have downstream effects on *p21* that alter the coordination of DNA repair with cycle arrest, and that result in the affected cell accumulating genomic defects. Down-regulation of *p21* and *p27*, which can be found in tumours with normal *TP53* function, correlates notably with high tumour grade and poor prognosis.

5. Enabling replicative immortality

For cancer cells to evolve into macroscopic tumours, they need to acquire the ability for unlimited proliferation. Telomeric DNA sequences, which protect and stabilise chromosomal ends, play a central role in conferring this limitless replicative potential. During replication of normal cells, telomeres shorten progressively as small fragments of telomeric DNA are lost with successive cycles of replication. This shortening process is thought to represent a mitotic clock and eventually prevents the cell from dividing further. Telomerase, a specialised polymerase enzyme, adds nucleotides to telomeres, allowing continued cell division and thus preventing premature arrest of cellular replication. The telomerase enzyme is almost absent in normal cells but is expressed at significant levels in many human cancers.

6. Inducing angiogenesis

All cancers require a functional vascular network to ensure continued growth and will be unable to grow beyond 1 mm^3 without stimulating the development of a vascular supply. Tumours require sustenance in the form of nutrients and oxygen, as well as an ability to evacuate metabolic waste products and carbon dioxide. This entails the development of new blood vessels, which is termed angiogenesis (Figs 33.3 and 33.4).

Angiogenesis is dependent on the production of angiogenic growth factors, of which vascular endothelial growth factor (VEGF) and platelet-derived growth factor (PDGF) are the best characterised. During tumour progression, an angiogenic switch is activated and remains on, causing normally quiescent vasculature to sprout new vessels continually that help sustain expanding tumour growth. Angiogenesis is governed by a balance of pro-angiogenic stimuli and angiogenesis inhibitors, such as thrombospondin (TSP)-1, which binds to transmembrane receptors on endothelial cells and evokes suppressive signals.

A number of cells can contribute to the maintenance of a functional tumour vasculature and therefore sustain angiogenesis. These include pericytes and a variety of bone marrow-derived cells such as macrophages, neutrophils, mast cells and myeloid progenitors.

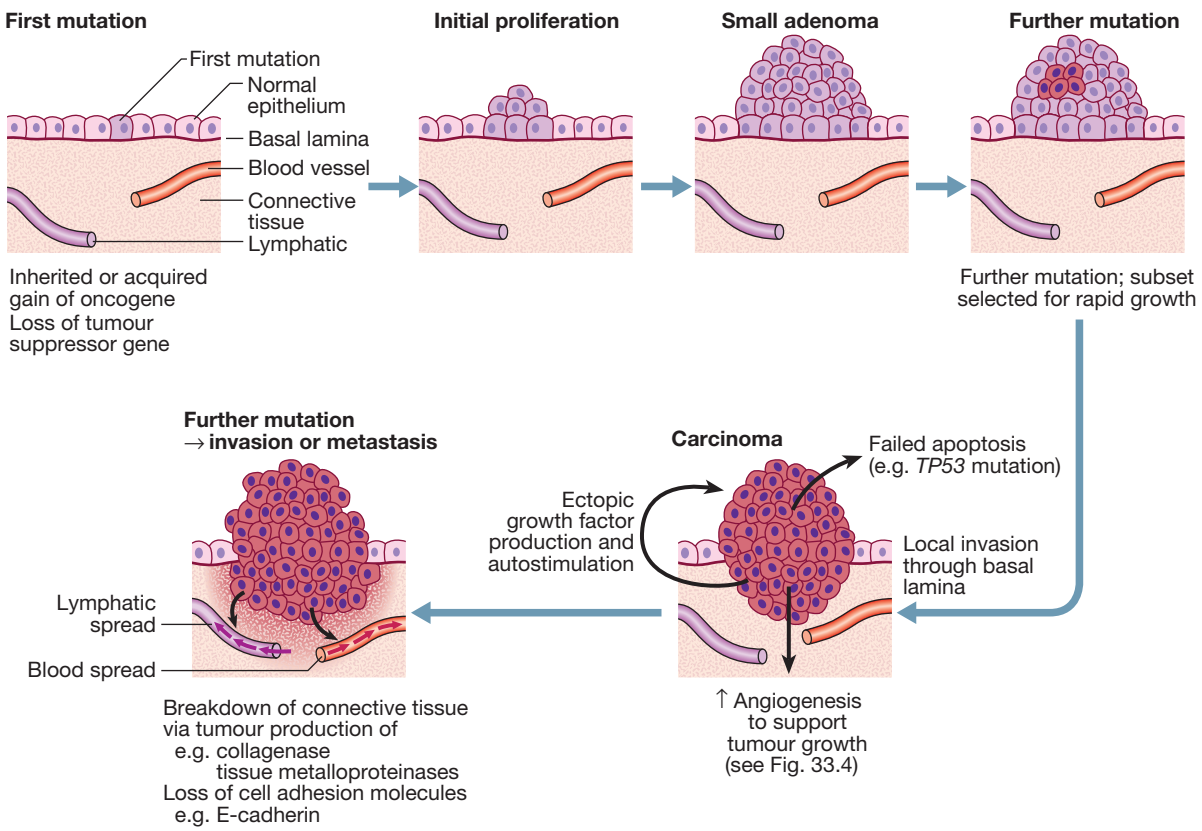

Fig. 33.3 Oncogenesis. The multistep origin of cancer, showing events implicated in cancer initiation, progression, invasion and metastasis.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

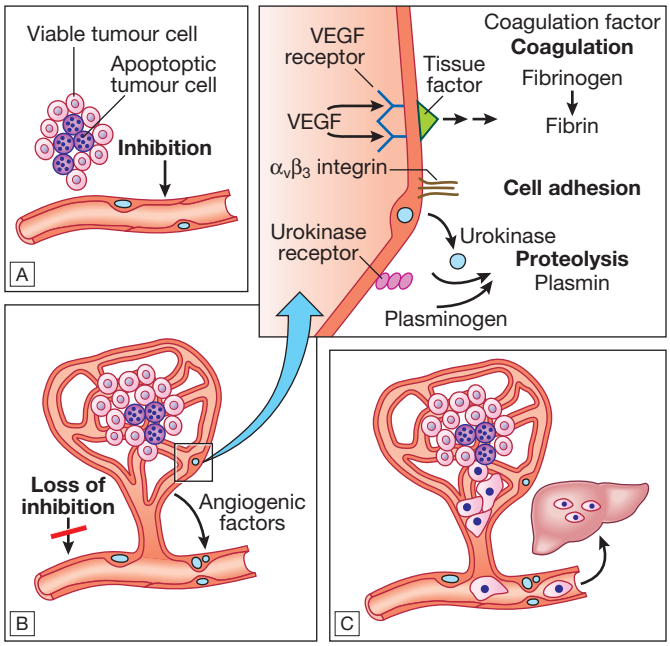

Fig. 33.4 Angiogenesis, invasion and metastasis. A For any cancer to grow beyond 1 mm^3, it must evoke a blood supply. B New vessel formation results from the release of angiogenic factors by the tumour cells and loss of inhibition of the endothelial cells. C The loss of cellular adhesion and disruption of the extracellular matrix allow cells to extravasate into the blood stream and metastasise to distant sites. (VEGF= vascular endothelial growth factor)

7. Activating invasion and metastasis

Invasion and metastasis are complex processes involving multiple discrete steps; they begin with local tissue invasion, followed by infiltration of nearby blood and lymphatic vessels by cancer cells. Malignant cells are eventually transported through haematogenous and lymphatic spread to distant sites within the body, where they form micrometastases that will eventually grow into macroscopic metastatic lesions (see Fig. 33.3).

Cadherin-1 (CDH1) is a calcium-dependent cell–cell adhesion glycoprotein that facilitates assembly of organised cell sheets in tissues, and increased expression is recognised as an antagonist of invasion and metastasis. In situ tumours usually retain CDH1 production, whereas loss of CDH1 production due to down-regulation or occasional mutational inactivation of CDH1 has been observed in human cancers, supporting the theory that CDH1 plays a key role in suppression of invasion and metastasis.

Cross-talk between cancer cells and cells of the surrounding stromal tissue is involved in the acquired capability for invasive growth and metastasis. Mesenchymal stem cells in tumour stroma have been found to secrete CCL5, a protein chemokine that helps recruit leucocytes into inflammatory sites. With the help of particular T-cell-derived cytokines (interleukin (IL)-2 and interferon-gamma (IFN-γ)), CCL5 induces proliferation and activation of natural killer cells and then acts reciprocally on cancer cells to stimulate invasive behaviour. Macrophages at the tumour periphery can foster local invasion by supplying matrix-degrading enzymes such as metalloproteinases and cysteine cathepsin proteases.

8. Reprogramming energy metabolism

Under aerobic conditions, oxidative phosphorylation functions as the main metabolic pathway for energy production; cells process glucose, first to pyruvate via glycolysis and thereafter to carbon dioxide in the mitochondria. While under anaerobic conditions, glycolysis is favoured to produce adenosine triphosphate (ATP). Cancer cells can reprogram their glucose metabolism to limit energy production to glycolysis, even in the presence of oxygen. This has been termed 'aerobic glycolysis'. Up-regulation of glucose transporters, such as GLUT1, is the main mechanism through which aerobic glycolysis is achieved.

This reprogramming of energy metabolism appears paradoxical, as overall energy production from glycolysis is significantly lower (18-fold) than that from oxidative phosphorylation. One explanation may be that the increased production of glycolytic intermediates can be fed into various biosynthetic pathways, including those that generate the nucleosides and amino acids, necessary for the production of new cells.

9. Tumour-promoting inflammation

Almost all tumours show infiltration with immune cells on pathological investigation and historically this finding was thought to represent an attempt of the immune system to eradicate the cancer. It is now clear that tumour-associated inflammatory responses promote tumour formation and cancer progression.

Cytokines are able to alter blood vessels to permit migration of leucocytes (mainly neutrophils), in order to permeate from the blood vessels into the tissue, a process known as extravasation. Migration across the endothelium occurs via the process of diapedesis, where chemokine gradients stimulate adhered leucocytes to move between endothelial cells and pass through the basement membrane into the surrounding tissues. Once within the tissue interstitium, leucocytes bind to extracellular matrix proteins via integrins and CD44 to prevent their loss from the site.

As well as cell-derived mediators, several acellular biochemical cascade systems consisting of pre-formed plasma proteins act in parallel to initiate and propagate the inflammatory response. These include the complement system activated by bacteria, and the coagulation and fibrinolytic systems activated by necrosis, and also in burns and trauma, as well as cancer. Other bioactive molecules, such as growth factors and pro-angiogenic factors, may be released by inflammatory immune cells into the surrounding tumour microenvironment. In particular, the release of reactive

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

oxygen species, which are actively mutagenic, will accelerate the genetic evolution of surrounding cancer cells, enhancing growth and contributing to cancer progression.

10. Evading immune destruction

The immune system operates as a significant barrier to tumour formation and progression, and the ability to escape from immunity is a hallmark of cancer development. Cancer cells continuously shed surface antigens into the circulatory system, prompting an immune response that includes cytotoxic T-cell, natural killer cell and macrophage production. The immune system is thought to provide continuous surveillance, with resultant elimination of cells that undergo malignant transformation.

However, deficiencies in the development or function of $CD8^+$ cytotoxic T lymphocytes, $CD4^+$ Th1 helper T cells or natural killer cells can each lead to a demonstrable increase in cancer incidence. Also, highly immunogenic cancer cells may evade immune destruction by disabling components of the immune system. This is done through recruitment of inflammatory cells, including regulatory T cells and myeloid-derived suppressor cells, both actively immunosuppressive against the actions of cytotoxic lymphocytes (see Fig. 4.12, p. 80).

Cancers develop and progress when there is loss of recognition by the immune system, lack of susceptibility due to escape from immune cell action and induction of immune dysfunction, often via inflammatory mediators.

Environmental and genetic determinants of cancer

The majority of cancers do not have a single cause but rather are the result of a complex interaction between genetic factors and exposure to environmental carcinogens. These are often tumour type-specific but some general principles do apply.

Environmental factors

Environmental triggers for cancer have mainly been identified through epidemiological studies that examine patterns of distribution of cancers in patients in whom age, sex, presence of other illnesses, social class, geography and so on differ. Sometimes, these give strong pointers to the molecular or cellular causes of the disease, such as the association between aflatoxin production within contaminated food supplies and hepatocellular carcinomas. For many solid cancers, such as breast and colorectal, however, there is evidence of a multifactorial pathogenesis, even when there is a principal environmental cause (Box 33.1).

Smoking is now established beyond all doubt as a major cause of lung cancer, but there are obviously additional predisposing factors since not all smokers develop cancer. Similarly, most carcinomas of the cervix are related to infection with human

i 33.1 Environmental factors that predispose to cancer

Environmental aetiology	Processes	Diseases
Occupational exposure (see 'Radiation' below)	Dye and rubber manufacturing (aromatic amines) Asbestos mining, construction work, shipbuilding (asbestos) Vinyl chloride (PVC) manufacturing Petroleum industry (benzene)	Bladder cancer Lung cancer and mesothelioma Liver angiosarcoma Acute leukaemia
Chemicals	Chemotherapy (e.g. melphalan, cyclophosphamide)	Acute myeloid leukaemia
Cigarette smoking	Exposure to carcinogens from inhaled smoke	Lung and bladder cancer
Viral infection	Epstein–Barr virus Human papillomavirus Hepatitis B and C viruses	Burkitt's lymphoma and nasopharyngeal cancer Cervical cancer Hepatocellular carcinoma
Bacterial infection	*Helicobacter pylori*	Gastric MALT lymphomas, gastric cancer
Parasitic infection	Liver fluke (*Opisthorchis sinensis*) *Schistosoma haematobium*	Cholangiocarcinoma Squamous cell bladder cancer
Dietary factors	Low-roughage/high-fat content diet High nitrosamine intake Aflatoxin from contamination of *Aspergillus flavus*	Colonic cancer Gastric cancer Hepatocellular cancer
Radiation	UV exposure Nuclear fallout following explosion (e.g. Hiroshima) Diagnostic exposure (e.g. CT) Occupational exposure (e.g. beryllium and strontium mining) Therapeutic radiotherapy	Basal cell carcinoma Melanoma Non-melanocytic skin cancer Leukaemia Solid tumours, e.g. thyroid Cholangiocarcinoma following Thorotrast usage Lung cancer Medullary thyroid cancer Sarcoma
Inflammatory diseases	Ulcerative colitis	Colon cancer
Hormonal	Use of diethylstilbestrol Oestrogens	Vaginal cancer Endometrial cancer Breast cancer

(CT = computed tomography; MALT = mucosa-associated lymphoid tissue; UV = ultraviolet)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

papillomavirus (HPV subtypes 16 and 18). For carcinomas of the bowel and breast, there is strong evidence of an environmental component. For example, the risk of breast cancer in women of Far Eastern origin remains relatively low when they first migrate to a country with a Western lifestyle, but rises in subsequent generations to approach that of the resident population of the host country. The precise environmental factor that causes this change is unclear but may include diet (higher intake of saturated fat and/or dairy products), reproductive patterns (later onset of first pregnancy) and lifestyle (increased use of artificial light and shift in diurnal rhythm).

Genetic factors

A number of inherited cancer syndromes are recognised that account for 5–10% of all cancers (Box 33.2). Their molecular basis is discussed in Chapter 3, but in general they result from inherited mutations in genes that regulate cell growth, cell death and apoptosis. Examples include the *BRCA1*, *BRCA2* and *AT* (ataxia telangiectasia) genes that cause breast and some other cancers, the *FAP* gene that causes bowel cancer and the *RB* gene that causes retinoblastoma. Although carriers of these gene mutations have a greatly elevated risk of cancer, none has 100% penetrance and additional modulating factors, both genetic and environmental, are likely to be operative. Exploration of a possible genetic contribution is a key part of cancer management, especially with regard to ascertaining the risk for an affected patient's offspring.

Investigations

When a patient is suspected of having cancer, a full history should be taken; specific questions should be included as to potential risk factors such as smoking and occupational exposures or potential complications of the disease. A thorough clinical examination is essential to identify sites of metastases, and to discover any other conditions that may have a bearing on the management plan (pp. 1314–1315). In order to make a diagnosis and to plan the most appropriate management, information is needed on:

- the type of tumour
- the extent of disease, as assessed by staging investigations
- the patient's general condition and any comorbidity.

i 33.2 Inherited cancer predisposition syndromes

Syndrome	Malignancies	Inheritance	Gene
Ataxia telangiectasia	Leukaemia, lymphoma, ovarian, gastric, brain, colon	AR	*AT*
Bloom's syndrome	Leukaemia, tongue, oesophageal, colonic, Wilms' tumour	AR	*BLM*
Breast/ovarian	Breast, ovarian, colonic, prostatic, pancreatic	AD	*BRCA1, BRCA2*
Cowden's syndrome	Breast, thyroid, gastrointestinal tract, pancreatic	AD	*PTEN*
Familial adenomatous polyposis	Colonic, upper gastrointestinal tract	AD	*APC, MUTYH*
Familial atypical multiple mole melanoma (FAMMM)	Melanoma, pancreas	AD	*CDKN2A (TP16)*
Fanconi anaemia	Leukaemia, oesophageal, skin, hepatoma	AR	*FACA, FACC, FACD*
Gorlin's syndrome	Basal cell skin, brain	AD	*PTCH*
Hereditary diffuse gastric cancer	Diffuse gastric cancer	AD	*E-cadherin*
Hereditary non-polyposis colon cancer (HNPCC)	Colonic, endometrial, ovarian, pancreatic, gastric	AD	*MSH2, MLH1, MSH6, PMS1, PMS2*
Li–Fraumeni syndrome	Sarcoma, breast, osteosarcoma, leukaemia, glioma, adrenocortical	AD	*TP53*
Multiple endocrine neoplasia (MEN) 1	Pancreatic islet cell, pituitary adenoma, parathyroid adenoma and hyperplasia	AD	*MEN1*
MEN 2	Medullary thyroid, phaeochromocytoma, parathyroid hyperplasia	AD	*RET*
Neurofibromatosis 1	Neurofibrosarcoma, phaeochromocytoma, optic glioma	AD	*NF1*
Neurofibromatosis 2	Vestibular schwannoma	AD	*NF2*
Papillary renal cell cancer syndrome	Renal cell cancer	AD	*MET*
Peutz–Jeghers syndrome	Colonic, ileal, breast, ovarian	AD	*STK11*
Prostate cancer	Prostate	AD	*HPC1*
Retinoblastoma	Retinoblastoma, osteosarcoma	AD	*RB1*
von Hippel–Lindau syndrome	Haemangioblastoma of retina and CNS, renal cell, phaeochromocytoma	AD	*VHL*
Wilms' tumour	Nephroblastoma, neuroblastoma, hepatoblastoma, rhabdomyosarcoma	AD	*WT1*
Xeroderma pigmentosum	Skin, leukaemia, melanoma	AR	*XPA, XPC, XPD (ERCC2), XPF*

(AD = autosomal dominant; AR = autosomal recessive; CNS = central nervous system)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

33.3 Eastern Cooperative Oncology Group (ECOG) performance status scale

0	Fully active, able to carry on all usual activities without restriction and without the aid of analgesics
1	Restricted in strenuous activity but ambulatory and able to carry out light work or pursue a sedentary occupation. This group also contains patients who are fully active, as in grade 0, but only with the aid of analgesics
2	Ambulatory and capable of all self-care but unable to work. Up and about more than 50% of waking hours
3	Capable of only limited self-care, confined to bed or chair more than 50% of waking hours
4	Completely disabled, unable to carry out any self-care and confined totally to bed or chair

33.4 TNM classification

Extent of primary tumour*	
TX	Not assessed
T0	No tumour
T1, T2, T3, T4	Increases in primary tumour size or depth of invasion
Increased involvement of nodes*	
NX	Not assessed
N0	No nodal involvement
N1, N2/3	Increases in involvement
Presence of metastases	
MX	Not assessed
M0	Not present
M1	Present

*Exact criteria for size and region of nodal involvement have been defined for each anatomical site.

The overall fitness of a patient is often assessed by the Eastern Cooperative Oncology Group (ECOG) performance status scale (Box 33.3). The outcome for patients with a performance status of 3 or 4 is worse in almost all malignancies than for those with a status of 0–2, and this has a strong influence on the approach to treatment in the individual patient.

The process of staging determines the extent of the tumour; it entails clinical examination, imaging and, in some cases, surgery, to establish the extent of disease involvement. The outcome is recorded using a standard staging classification that allows comparisons to be made between different groups of patients. Therapeutic decisions and prognostic predictions can then be made using the evidence base for the disease. One of the most commonly used systems is the T (tumour), N (regional lymph nodes), M (metastatic sites) approach of the International Union against Cancer (UICC, Box 33.4). For some tumours, such as colon cancer, the Dukes system (p. 832) is used rather than the UICC classification.

Histology

Histological analysis of a biopsy or resected specimen is pivotal in clinching the diagnosis and in deciding on the best form of management. The results of histological analysis are most informative when combined with knowledge of the clinical picture; biopsy results should therefore be reviewed and discussed within the context of a multidisciplinary team meeting.

Light microscopy

Examination of tumour samples by light microscopy remains the core method of cancer diagnosis and, in cases where the primary site is unclear, may give clues to the origin of the tumour:

- Signet-ring cells favour a gastric primary.
- Presence of melanin favours melanoma.
- Mucin is common in gut/lung/breast/endometrial cancers, but particularly common in ovarian cancer and rare in renal cell or thyroid cancers.
- Psammoma bodies are a feature of ovarian cancer (mucin +) and thyroid cancer (mucin –).

Immunohistochemistry

Immunohistochemical (IHC) staining for tumour markers can provide useful diagnostic information and can help with treatment decisions. Commonly used examples of IHC in clinical practice include:

- *Oestrogen (ER) and progesterone (PR) receptors.* Positive results indicate that the tumour may be sensitive to hormonal manipulation.
- *Alpha-fetoprotein (AFP)* and *human chorionic gonadotrophin (hCG) with or without placental alkaline phosphatase (PLAP).* These favour germ-cell tumours.
- *Prostate-specific antigen (PSA)* and *prostatic acid phosphatase (PAP).* These favour prostate cancer.
- *Carcinoembryonic antigen (CEA), cytokeratin* and *epithelial membrane antigen (EMA).* These favour epithelial carcinomas.
- *HER2 receptor.* Breast cancers that have high levels of expression of HER2 indicate that the tumour may respond to trastuzumab (Herceptin), an antibody directed against the HER2 receptor.

The pattern of immunoglobulin, T-cell receptor and cluster designation (CD) antigen expression on the surface is helpful in the diagnosis and classification of lymphomas. This can be achieved by IHC staining of biopsy samples or flow cytometry.

Electron microscopy

Electron microscopy (EM) can sometimes be of diagnostic value. Examples include the visualisation of melanosomes in amelanotic melanoma and dense core granules in neuro-endocrine tumours. EM may help to distinguish adenocarcinoma from mesothelioma, as the ultrastructural properties of these two diseases are different (mesothelioma appears to have long, narrow, branching microvilli while adenocarcinomas appear to have short, stubby microvilli). EM is also useful for differentiating spindle-cell tumours (sarcomas, melanomas, squamous cell cancers) from small round-cell tumours, again due to their ultrastructural differences.

Cytogenetic analysis

Some tumours demonstrate typical chromosomal changes that help in diagnosis. The utilisation of fluorescent in situ hybridisation (FISH) techniques can be useful in Ewing's sarcoma and peripheral neuro-ectodermal tumours where there is a translocation between chromosome 11 and 22–t(11;22)(q24;q12). In some cases, gene amplification can be detected via FISH (e.g. determining over-expression of HER2/neu).

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Imaging

Imaging plays a critical role in oncology, not only in locating the primary tumour but also in staging the disease and determining the response to treatment. The imaging modality employed depends primarily on the site of the disease and likely patterns of spread, and may require more than one modality.

Ultrasound

Ultrasound is useful in characterising lesions within the liver, kidney, pancreas and reproductive organs. It can be used for guiding biopsies of tumours in breast and liver. Endoscopic ultrasound is helpful in staging upper gastrointestinal and pancreatic cancers, involving a special endoscope with an ultrasound probe attached.

Computed tomography

Computed tomography (CT) is a key investigation in cancer patients and is particularly useful in imaging the thorax and abdomen. With modern scanners it is possible to visualise the large bowel if it is prepared (CT colonography), allowing accurate detection of colorectal cancers and adenomas ≥10 mm.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) has a high resolution and is the preferred technique for brain and pelvic imaging. It is widely employed for the staging of rectal, cervical and prostate cancers.

Positron emission tomography

Positron emission tomography (PET) visualises metabolic activity of tumour cells and is widely used, often in combination with CT (PET–CT), to evaluate the extent of the disease, particularly in the assessment of potential distant metastasis (Fig. 33.5). It can accurately assess the severity and spread of cancer by detecting tumour metabolic activity following injection of small amounts of radioactive tracers such as fluorodeoxyglucose (FDG). In addition to having a role in diagnosis, PET can be used in some patients to assess treatment response.

Biochemical markers

Many cancers produce substances called tumour markers, which can assist in diagnosis and surveillance. Some are useful in population screening, diagnosis, determining prognosis, response evaluation, detection of relapse and imaging of metastasis. Unfortunately, most tumour markers are neither sufficiently sensitive nor sufficiently specific to be used in isolation for diagnosis and need to be interpreted in the context of the other clinical features. Some can be used for antibody-directed therapy or imaging, however, where they have a greater role in diagnosis. Tumour markers in routine use are outlined in Box 33.5.

Presenting problems in oncology

In the early stages of cancer development, the number of malignant cells is small and the patient is usually asymptomatic. With tumour progression, localised signs or symptoms develop due to mass effects and/or invasion of local tissues. With further progression, symptoms may occur at distant sites as a result of metastatic disease or from non-metastatic manifestations due to production of biologically active hormones by the tumour or as the result of an immune response to the tumour. The possible presentations are summarised in Boxes 33.6 and 33.7, and common presenting features discussed below. Although the incidence of cancer increases with patient age, the approach to investigation and management is similar at all ages (Box 33.8).

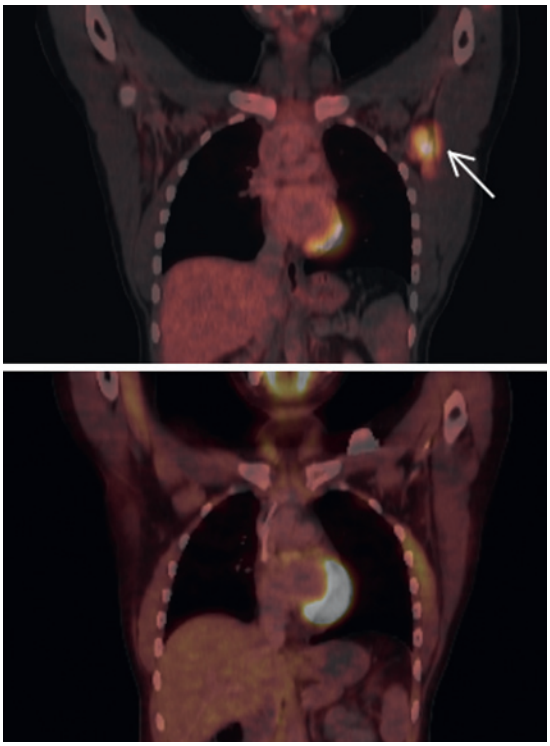

Fig. 33.5 Positron emission tomography–computed tomography (PET–CT) images. A There is a neoplastic lesion (arrow) in the left axilla, evidenced by the increased uptake of fluorodeoxyglucose (FDG) tracers. B Imaging after chemotherapy, demonstrating that the abnormal uptake has disappeared and indicating a response to treatment. *Courtesy of Dr J. Wilsdon, Freeman Hospital, Newcastle upon Tyne.*

Palpable mass

A palpable mass detected by the patient or physician may be the first sign of cancer. Primary tumours of the thyroid, breast, testis and skin are often detected in this way, whereas palpable lymph nodes in the neck, groin or axilla may indicate secondary spread of tumour. Hepatomegaly may be the first sign of primary liver cancer or tumour metastasis, whereas skin cancer may present as an enlarging or changing pigmented lesion.

Weight loss and fever

Unintentional weight loss is a characteristic feature of advanced cancer, but can have other causes such as thyrotoxicosis, chronic inflammatory disease and chronic infective disorders. Fever can occur in any cancer secondary to infection, but may be a primary feature in Hodgkin and non-Hodgkin lymphoma, leukaemia, renal cancer and liver cancer. The presence of unexplained weight loss or fever warrants investigation to exclude the presence of occult malignancy.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

i 33.5 Commonly used serum tumour markers

Name	Natural occurrence	Tumours
Alpha-fetoprotein (AFP)	Glycoprotein found in yolk sac and fetal liver tissue. Transient elevation in liver diseases. Has a role in screening during pregnancy for the detection of neural tube defects and Down's syndrome	Ovarian non-seminomatous germ cell tumours (80%), testicular teratoma (80%), hepatocellular cancer (50%)
Beta-2-microglobulin	A human leucocyte antigen (HLA) common fragment present on surface of lymphocytes, macrophages and some epithelial cells. Can be elevated in autoimmune disease and renal glomerular disease	Non-Hodgkin lymphoma, myeloma
Calcitonin	32-amino-acid peptide from C cells of thyroid. Used to screen for MEN 2	Medullary cell carcinoma of thyroid
Cancer antigen 125 (CA-125)	Differentiation antigen of coelomic epithelium (Müller's duct). Raised in any cause of ascites, pleural effusion or heart failure. Can be raised in inflammatory conditions	Ovarian epithelial cancer (75%), gastrointestinal cancer (10%), lung cancer (5%) and breast cancer (5%)
CA-19.9	A mucin found in epithelium of fetal stomach, intestine and pancreas. It is eliminated exclusively via bile and so any degree of cholestasis can cause levels to rise	Pancreatic cancer (80%), mucinous tumour of the ovary (65%), gastric cancer (30%), colon cancer (30%)
Carcinoembryonic antigen (CEA)	Glycoprotein found in intestinal mucosa during embryonic and fetal life. Elevated in smokers, cirrhosis, chronic hepatitis, ulcerative colitis, pneumonia	Colorectal cancer, particularly with liver metastasis, gastric cancer, breast cancer, lung cancer, mucinous cancer of the ovary
Human chorionic gonadotrophin (hCG)	Glycoprotein hormone, 14 kD α subunit and 24 kD β subunit from placental syncytiotrophoblasts. Used for disease monitoring in hydatidiform mole and as the basis of a pregnancy test	Choriocarcinoma (100%), hydatidiform moles (97%), ovarian non-seminomatous germ cell tumours (50–80%), seminoma (15%)
Placental alkaline phosphatase (PLAP)	Isoenzyme of alkaline phosphatase	Seminoma (40%), ovarian dysgerminoma (50%)
Prostate-specific antigen (PSA)	Glycoprotein member of human kallikrein gene family. PSA is a serine protease that liquefies semen in excretory ducts of prostate. Can be elevated in benign prostatic hypertrophy and prostatitis	Prostate cancer (95%)
Thyroglobulin	Matrix protein for thyroid hormone synthesis in normal thyroid follicles	Papillary and follicular thyroid cancer

i 33.6 Local features of malignant disease

Symptom	Typical site or possible tumour
Haemorrhage	Stomach, colon, bronchus, endometrium, bladder, kidney
Lump	Breast, lymph node (any site), testicle
Bone pain or fracture	Bone (primary sarcoma, secondary metastasis from breast, prostate, bronchus, thyroid, kidney)
Skin abnormality	Melanoma, basal cell carcinoma (rodent ulcer)
Ulcer	Oesophagus, stomach, anus, skin
Dysphagia	Oesophagus, bronchus, gastric
Increasing constipation, abdominal discomfort or pain	Colon, rectum, ovary
Airway obstruction, stridor, cough, recurrent infection	Bronchus, thyroid
Odynophagia, early satiety, vomiting	Bronchus, stomach, oesophagus, colon, rectum
Abdominal swelling (ascites)	Ovary, stomach, pancreas

Thromboembolism

Thrombosis and disseminated intravascular coagulation (DIC) are common complications in patients with cancer. The prothrombotic state is caused by cancer cells activating the coagulation system via factors such as tissue factor, cancer procoagulant and inflammatory cytokines. The interaction between tumour cells, monocytes/macrophages, platelets and endothelial cells can promote thrombus formation, as part of a host response to the cancer (i.e. acute phase, inflammation, angiogenesis) or via a reduction in the levels of inhibitors of coagulation or impairment

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

33.7 Non-metastatic manifestations of malignant disease

Feature	Common cancer site associations
Weight loss and anorexia	Lung, gastrointestinal tract
Fatigue	Any
Hypercalcaemia	Myeloma, breast, kidney
Prothrombotic tendency	Ovary, pancreas, gastrointestinal tract
SIADH **Ectopic ACTH**	Small cell lung cancer
Lambert–Eaton myasthenic syndrome	Small cell lung cancer
Subacute cerebellar degeneration	Small cell lung cancer, ovarian cancer
Acanthosis nigricans	Stomach, oesophagus
Dermatomyositis/polymyositis	Stomach, lung

(ACTH = adrenocorticotrophic hormone; SIADH = syndrome of inappropriate antidiuretic hormone (vasopressin) secretion)

33.8 Cancer in old age

- **Incidence**: around 50% of cancers occur in the 15% of the population aged over 65 years.
- **Screening**: women aged over 65 in the UK are not invited to breast cancer screening but can request it. Uptake is low despite increasing incidence with age.
- **Presentation**: may be later for some cancers. When symptoms are non-specific, patients (and their doctors) may initially attribute them to age alone.
- **Life expectancy**: an 80-year-old woman can expect to live 8 years, so cancer may still shorten life and an active approach remains appropriate.
- **Prognosis**: histology, stage at presentation and observation for a brief period are better guides to outcome than age.
- **Rate of progression**: malignancy may have a more indolent course. This is poorly understood but may be due to reduced effectiveness of angiogenesis with age, inhibiting the development of metastases.
- **Response to treatment**: equivalent to that in younger people – well documented for a range of cancers and for surgery, radiotherapy, chemotherapy and hormonal therapy.
- **Treatment selection**: chronological age is of minor importance compared to comorbid illness and patient choice. Although older patients can be treated effectively and safely, aggressive intervention is not appropriate for all. Symptom control may be all that is possible or desired by the patient.

of fibrinolysis. Furthermore, the prothrombotic tendency can be enhanced by therapy such as surgery, chemotherapy, hormone therapy and radiotherapy, and by in-dwelling access devices (i.e. central venous catheters). In some patients, the thromboembolism is the first presenting feature of the underlying cancer.

Ectopic hormone production

In some cases, the first presentation of cancer is with a metabolic abnormality due to ectopic production of hormones by tumour cells, including insulin, ACTH, vasopressin (antidiuretic hormone, ADH), fibroblast growth factor (FGF)-23, erythropoietin and parathyroid hormone-related protein (PTHrP). This can result in a wide variety of presentations, as summarised in Box 33.9. Further details on the presentation and management of ACTH- and vasopressin-producing tumours are given on page 670, and those of FGF23-producing tumours on page 1053. The management of hypercalcaemia associated with malignancy is discussed below.

33.9 Ectopic hormone production by tumours

Hormone	Consequence	Tumours
ACTH	Cushing's syndrome	SCLC
Erythropoietin	Polycythaemia	Kidney, hepatoma, cerebellar haemangioblastoma, uterine fibroids
FGF-23	Hypophosphataemic osteomalacia	Mesenchymal tumours
PTHrP	Hypercalcaemia	NSCLC (squamous cell), breast, kidney
Vasopressin (ADH)	Hyponatraemia	SCLC

(ACTH = adrenocorticotrophic hormone; ADH = antidiuretic hormone; FGF = fibroblast growth factor; NSCLC = non-small cell lung cancer; PTHrP = parathyroid hormone-related protein; SCLC = small cell lung cancer)

Neurological paraneoplastic syndromes

These form a group of conditions associated with cancer that are thought to be due to an immunological response to the tumour that results in damage to the nervous system or muscle. The cancers most commonly implicated are those of the lung (small cell and non-small cell), pancreas, breast, prostate, ovary and lymphoma.

- *Peripheral neuropathy* results from axonal degeneration or demyelination.
- *Encephalomyelitis* can present with diverse symptoms, depending on which region of the brain is involved. Lumbar puncture shows raised protein in the cerebrospinal fluid and a pleocytosis, predominantly that of lymphocytes. In some centres, flow cytometry of the cerebrospinal fluid can be used to detect carcinomatous cells. MRI shows meningeal enhancement, particularly at the level of the brainstem, and anti-Hu antibodies may be detectable in serum. Encephalomyelitis is due to perivascular inflammation and selective neuronal degeneration. Most cases are caused by small cell lung cancer (75%).
- *Cerebellar degeneration* may be the presenting feature of an underlying malignancy and presents with rapid onset of cerebellar ataxia. Diagnosis is by MRI or CT, which may show cerebellar atrophy. Patients with these neurological paraneoplastic syndromes may be found to have circulating anti-Yo, Tr and Hu antibodies, but these are not completely specific and negative results do not exclude the diagnosis.
- *Retinopathy* is a rare complication of cancer and presents with blurred vision, episodic visual loss and impaired colour vision. If left untreated, it may lead to blindness. The diagnosis should be suspected if the electroretinogram is abnormal and anti-retinal antibodies are detected.
- *Lambert–Eaton myasthenic syndrome* (LEMS) is due to underlying cancer in about 60% of cases. It presents with

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

proximal muscle weakness that improves on exercise and is caused by the development of antibodies to pre-synaptic calcium channels (p. 1143). The diagnosis is made by electromyelogram (EMG), which shows a low-amplitude compound muscle action potential that enhances to near normal following exercise.
- *Dermatomyositis* or *polymyositis* may be the first presentation of some cancers. Clinical features and management of these conditions are discussed on page 1039.

Cutaneous manifestations of cancer

Many cancers can present with skin manifestations that are not due to metastases:
- *Pruritus* may be a presenting feature of lymphoma, leukaemia and central nervous system tumours.
- *Acanthosis nigricans* may precede cancers by many years and is particularly associated with gastric cancer.
- *Vitiligo* may be associated with malignant melanoma and is possibly due to an immune response to melanocytes.
- *Pemphigus* may occur in lymphoma, Kaposi's sarcoma and thymic tumours.
- *Dermatitis herpetiformis* associated with coeliac disease may precede tumour development by many years, and is associated with gastrointestinal lymphoma.

The clinical features and management of these skin conditions are discussed in Chapter 29.

Emergency complications of cancer

Spinal cord compression

Spinal cord compression complicates 5% of cancers and is most common in myeloma, prostate, breast and lung cancers that involve bone. Cord compression often results from posterior extension of a vertebral body mass but intrathecal spinal cord metastases can cause similar signs and symptoms. The thoracic region is most commonly affected.

Clinical features

The earliest sign is back pain, particularly on coughing and lying flat. Subsequently, sensory changes develop in dermatomes below the level of compression and motor weakness distal to the block occurs. Finally, sphincter disturbance, causing urinary retention and bowel incontinence, is observed. Involvement of the lumbar spine may cause conus medullaris or cauda equina compression (Box 33.10). Physical examination reveals findings consistent with an upper motor neuron lesion, but lower motor neuron findings may predominate early on or in cases of nerve root compression.

33.11 Management of suspected spinal cord compression

- Confirm diagnosis with urgent MRI scan
- Administer high-dose glucocorticoids:
  Dexamethasone 16 mg IV stat
  Dexamethasone 8 mg twice daily orally
- Ensure adequate analgesia
- Refer for surgical decompression or urgent radiotherapy

Management

Spinal cord compression is a medical emergency and should be treated with analgesia and high-dose glucocorticoid therapy (Box 33.11). Neurosurgical intervention produces superior outcome and survival compared to radiotherapy alone, and should be considered first for all patients. Radiotherapy is used for the remaining patients and selected tumour types when the cancer is likely to be radiosensitive. The prognosis varies considerably, depending on tumour type, but the degree of neurological dysfunction at presentation is the strongest predictor of outcome, irrespective of the underlying diagnosis. Mobility can be preserved in more than 80% of patients who are ambulatory at presentation, but neurological function is seldom regained in patients with established deficits such as paraplegia.

Superior vena cava obstruction

Superior vena cava obstruction (SVCO) is a common complication of cancer that can occur through extrinsic compression or intravascular blockage. The most common causes of extrinsic compression are lung cancer, lymphoma and metastatic tumours. Patients with cancer can also develop SVCO due to intravascular blockage in association with a central catheter or thromboembolism secondary to the tumour.

Clinical features

The typical presentation is with oedema of the arms and face, distended neck and arm veins and dusky skin coloration over the chest, arms and face. Collateral vessels may develop over a period of weeks and the flow of blood in the collaterals helps to confirm the diagnosis. Headache secondary to cerebral oedema arising from the backflow pressure may also occur and tends to be aggravated by bending forwards, stooping or lying down. The severity of symptoms is related to the rate of obstruction and the development of a venous collateral circulation. Accordingly, symptoms may develop rapidly or gradually. Clinical features are summarised in Box 33.12.

33.10 Comparison of features of neurological deficit

Clinical feature	Spinal cord	Conus medullaris	Cauda equina
Weakness	Symmetrical and profound	Symmetrical and variable	Asymmetrical, may be mild
Reflexes	Increased (or absent) knee and ankle reflexes with extensor plantar reflex	Increased knee reflex, decreased ankle reflex, extensor plantar reflex	Decreased knee and ankle reflexes with flexor plantar reflex
Sensory loss	Symmetrical, sensory level	Symmetrical, saddle distribution	Asymmetrical, radicular pattern
Sphincters	Late loss	Early loss	Often spared
Progression	Rapid	Variable	Variable

33.12 Common symptoms and physical findings in superior vena cava obstruction*

Symptoms

- Dyspnoea (63%)
- Facial swelling and head fullness (50%)
- Cough (24%)
- Arm swelling (18%)
- Chest pain (15%)
- Dysphagia (9%)

Physical findings

- Venous distension of neck (66%)
- Venous distension of chest wall (54%)
- Facial oedema (46%)
- Cyanosis (20%)
- Plethora of face (19%)
- Oedema of arms (14%)

*Percentage of patients affected.

Investigations and management

The investigation of choice is a CT scan of the thorax to confirm the diagnosis and distinguish between extra- and intravascular causes. A biopsy should be obtained when the tumour type is unknown because tumour type has a major influence on treatment. CT of the head may be indicated if cerebral oedema is suspected. Tumours that are exquisitely sensitive to chemotherapy, such as germ cell tumours and lymphoma, can be treated with chemotherapy alone, but for most other tumours mediastinal radiotherapy is required. This relieves symptoms within 2 weeks in 50–90% of patients. In many centres, stenting is now increasingly favoured over radiotherapy, as it produces rapid results and can be repeated with reasonable effectiveness. This technique is particularly useful when dealing with tumours that are relatively chemo- or radio-resistant, such as non-small cell lung cancer or carcinoma of unknown primary. Where possible, these measures should be followed by treatment of the primary tumour, as long-term outcome is strongly dependent on the prognosis of the underlying cancer.

Hypercalcaemia

Hypercalcaemia is the most common metabolic disorder in patients with cancer and has a prevalence of up to 20% in cancer patients. The incidence is highest in myeloma and breast cancer (approximately 40%), intermediate in non-small cell lung cancer, and uncommon in colon, prostate and small cell lung carcinomas. It is most commonly due to over-production of PTHrP (80%), which binds to the PTH receptor and elevates serum calcium by stimulating osteoclastic bone resorption and increasing renal tubular reabsorption of calcium. Direct invasion of bone by metastases accounts for around 20% of cases while other mechanisms, such as ectopic PTH secretion, are rare.

Clinical features

The symptoms of hypercalcaemia are often non-specific and may mimic those of the underlying malignancy. They include drowsiness, delirium, nausea and vomiting, constipation, polyuria, polydipsia and dehydration.

Investigations and management

The diagnosis is made by measuring serum total calcium and adjusting for albumin. It is especially important to correct for albumin in cancer because hypoalbuminaemia is common and total calcium values under-estimate the level of ionised calcium. The principles of management are outlined in Box 33.13.

33.13 Medical management of severe hypercalcaemia

- IV 0.9% saline 2–4 L/day
- Zoledronic acid 4 mg IV *or* pamidronate 60–90 mg IV
- For patients with severe, symptomatic hypercalcaemia that is refractory to zoledronic acid, denosumab (initial dose 60 mg SC, with repeat dosing based on response) is an alternative option

Patients should initially be treated with intravenous 0.9% saline to improve renal function and increase urinary calcium excretion. This alone often results in clinical improvement. Concurrently, intravenous bisphosphonates should be given to inhibit bone resorption. Calcitonin acts rapidly to increase calcium excretion and to reduce bone resorption, and can be combined with fluid and bisphosphonate therapy for the first 24–48 hours in patients with life-threatening hypercalcaemia. Bisphosphonates will usually reduce the serum calcium levels to normal within 5 days, but, if not, treatment can be repeated. The duration of action is up to 4 weeks and repeated therapy can be given at 3–4-weekly intervals in the outpatient department. Hypercalcaemia is frequently a sign of tumour progression and the patient requires further investigation to establish disease status and review of the anti-cancer treatment strategy.

Neutropenic fever

Neutropenia is a common complication of malignancy. It is usually secondary to chemotherapy but may occur with radiotherapy if large amounts of bone marrow are irradiated; it may also be a component of pancytopenia due to malignant infiltration of the bone marrow. Neutropenic fever is defined as a pyrexia of 38°C for over 1 hour in a patient with a neutrophil count of $<0.5\times10^9$/L or $<1.0\times10^9$/L if the nadir is anticipated to drop to $<0.5\times10^9$/L in the next 24 hours. The risk of sepsis is related to the severity and duration of neutropenia and the presence of other risk factors, such as intravenous cannulae or bladder catheters. Neutropenic fever is an emergency in cancer patients as, if left untreated, it can result in sepsis with a high mortality rate.

Clinical features

The typical presentation is with high fever, and affected patients are often non-specifically unwell. Examination is usually unhelpful in defining a primary source of the infection. Hypotension is an adverse prognostic feature and may progress to systemic circulatory shutdown and organ failure.

Investigations and management

An infection screen should be performed to include blood cultures (both peripheral and from central lines), urine culture, chest X-ray, and swabs for culture (throat, central line, wound). High-dose intravenous antibiotics should then be commenced, pending the results of cultures. The standard approach is to commence empirical antibiotics according to local hospital policies agreed with microbiologists and based on the local antibiotic resistance patterns observed. First-line empirical therapy is either monotherapy with piperacillin–tazobactam or meropenem, or with the addition of gentamicin. Metronidazole may be added if anaerobic infection is suspected, and teicoplanin where Gram-positive infection is suspected (e.g. in patients with central lines). Antibiotics should be adjusted according to culture results, although these are often negative. If there is no response after 36–48 hours, antibiotics should be reviewed with microbiological advice, and antifungal cover should be considered

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

(liposomal amphotericin B). Granulocyte–colony-stimulating factor (G–CSF) is not routinely used for all patients with neutropenia and guidelines for use have been established. Other supportive therapy, including intravenous fluids, inotrope therapy, ventilation or haemofiltration, may be required.

Tumour lysis syndrome

The acute destruction of a large number of cells can be associated with metabolic sequelae and is called tumour lysis syndrome. It is usually related to bulky, chemosensitive disease, including lymphoma, leukaemia and germ cell tumours. More rarely, it can occur spontaneously.

Clinical features

Cellular destruction results in the release of potassium, phosphate, nucleic acids and purines that can cause transient hypocalcaemia, hyperphosphataemia, hyperuricaemia and hyperkalaemia. This can lead to acute impairment of renal function and the precipitation of uric acid crystals in the renal tubular system. These can manifest with symptoms associated with multiple underlying electrolyte abnormalities, including fatigue, nausea, vomiting, cardiac arrhythmia, heart failure, syncope, tetany, seizures and sudden death.

Investigations and management

Serum biochemistry should be monitored regularly for 48–72 hours after treatment in patients at risk. Elevated serum potassium may be the earliest biochemical marker but pre-treatment serum lactate dehydrogenase (LDH) correlates with tumour bulk and may indicate increased risk. Good hydration and urine output should be maintained throughout treatment administration. Prophylaxis with allopurinol should be considered and recombinant urate oxidase (rasburicase) can be used to reduce uric acid levels when other treatments fail. Adequate hydration is vital, as it has a dilution effect on the extracellular fluid, improving electrolyte imbalance, and increases circulating volume, improving filtration in the kidneys. In high-risk patients, hydration should be commenced 24 hours before the start of treatment. If normal treatment methods fail to correct the problems, haemodialysis should be considered at an early stage to prevent progression to irreversibility.

Metastatic disease

Metastatic disease is the major cause of death in cancer patients and the principal cause of morbidity. For the majority, the aim of treatment is palliative but treatment of a solitary metastasis can occasionally be curative.

Brain metastases

Brain metastases occur in 10–30% of adults and 6–10% of children with cancer, and are an increasingly important cause of morbidity. Tumours that typically metastasise to the brain are shown in Box 33.14. Most involve the brain parenchyma but can also affect the cranial nerves, the blood vessels and other intracranial structures. In cases of solitary metastasis to the brain, the use of surgery and adjuvant radiotherapy has been shown to increase survival. Practices vary, however, for patients with more advanced brain metastases. In these cases, median survival without treatment is approximately 1 month. Glucocorticoids can increase survival to 2–3 months and whole-brain radiotherapy improves survival to 3–6 months, but the true efficacy of these interventions has not been proven adequately in a randomised trial setting. Patients with brain metastases as the only manifestation of an undetected primary tumour have a more favourable prognosis, with an overall median survival of 13.4 months. Tumour type also influences prognosis; breast cancer patients have a better prognosis than those with other types of cancer, and those with colorectal cancer tend to have a poorer prognosis.

i 33.14 Primary tumour sites that metastasise to the brain

Primary tumour	Patients (%)
Lung	48
Breast	15
Melanoma	9
Colon	5
Other known primary	13
Unknown primary	11

Clinical features

Presentation is with headaches (40–50%), focal neurological dysfunction (20–40%), cognitive dysfunction (35%), seizures (10–20%) and papilloedema (<10%).

Investigations and management

The diagnosis can be confirmed by CT or contrast-enhanced MRI. Treatment options include high-dose glucocorticoids (dexamethasone 4 mg 4 times daily) for tumour-associated oedema, anticonvulsants for seizures, whole-brain radiotherapy and chemotherapy. Surgery may be considered for single sites of disease and can be curative; stereotactic radiotherapy may also be considered for solitary site involvement where surgery is not possible.

Lung metastases

These are common in breast cancer, colon cancer and tumours of the head and neck. The presentation is usually with a lesion on chest X-ray or CT. Solitary lesions require investigation, as single metastases can be difficult to distinguish from a primary lung tumour. Patients with two or more pulmonary nodules can be assumed to have metastases. The approach to treatment depends on the extent of disease in the lung and elsewhere. For solitary lesions, surgery should be considered, with a generous wedge resection. Radiotherapy, chemotherapy or endocrine therapy can be used as systemic treatment and is dependent on the underlying primary cancer diagnosis.

Liver metastases

Metastatic cancer in the liver can represent the sole or life-limiting component of disease for many with colorectal cancer, ocular melanoma, neuro-endocrine tumours (NETs) and, less commonly, other tumour types. The most common clinical presentations are with right upper quadrant pain due to stretching of the liver capsule, jaundice, deranged liver function tests or an abnormality detected on imaging. In selected cases, resection of the metastasis can be contemplated. In colorectal cancer, successful resection of metastases improves 5-year survival from 3% to 30–40%. Other techniques, such as chemoembolisation or radiofrequency ablation, can also be used, provided the number

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

and size of metastases remain small. If these are not feasible, symptoms may respond to systemic chemotherapy.

Bone metastases

Bone is the third most common organ involved by metastasis, after lung and liver. Bone metastases are a major clinical problem in patients with myeloma and breast or prostate cancers, but other tumours that commonly metastasise to bone include those of the kidney and thyroid. Bone metastases are an increasing management problem in other tumour types that do not classically target bone, due to the prolonged survival of patients generally. Accordingly, effective management of bony metastases has become a focus in the treatment of patients with many incurable cancers.

Clinical features

The main presentations are with pain, pathological fractures and spinal cord compression (see above). The pain tends to be progressive and worst at night, and may be partially relieved by activity, but subsequently becomes more constant in nature and is exacerbated by movement. Most pathological fractures occur in metastatic breast cancer (53%); other tumour types associated with fracture include the kidney (11%), lung (8%), thyroid (5%), lymphoma (5%) and prostate (3%).

Investigations and management

The most sensitive way of detecting bone metastases is by isotope bone scan. This can have false-positive results in healing bone, particularly as a flare response following treatment and false-negative results occur in multiple myeloma due to suppression of osteoblast activity. Plain X-ray films are therefore preferred for any sites of bone pain, as lytic lesions may not be detected by a bone scan. In patients with a single lesion, it is especially important to perform a biopsy to obtain a tissue diagnosis, since primary bone tumours may look very similar to metastases on X-ray.

The main goals of management are:

- pain relief
- preservation and restoration of function
- skeletal stabilisation
- local tumour control (e.g. relief of tumour impingement on normal structure).

Surgical intervention may be warranted where there is evidence of skeletal instability (e.g. anterior or posterior spinal column fracture) or an impending fracture (e.g. a large lytic lesion on a weight-bearing bone with more than 50% cortical involvement). Intravenous bisphosphonates (pamidronate, zoledronic acid or denosumab) are widely used for bone metastases and are effective at improving pain and in reducing further skeletal related events, such as fractures and hypercalcaemia. In certain types of cancer, such as breast and prostate, hormonal therapy may be effective. Radiotherapy, in the form of external beam therapy or systemic radionuclides (strontium treatment), can also be useful for these patients. In some settings (e.g. breast carcinoma), chemotherapy may be used in the management of bony metastases.

Malignant pleural effusion

This is a common complication of cancer and 40% of all pleural effusions are due to malignancy. The most common causes are lung and breast cancers, and the presence of an effusion indicates advanced and incurable disease. The presentation may be with dyspnoea, cough or chest discomfort, which can be dull or pleuritic in nature. Diagnosis and management of ascites are discussed on page 863.

33.15 How to aspirate a malignant pleural effusion

- Ask the patient to sit up and lean forwards slightly.
- Identify a suitable site for aspiration. Typically, this should be in the mid-scapular line, below the top of the fluid level and above the diaphragm.
- Confirm that the site is below the fluid level by reviewing the chest X-ray and percussing the chest.
- Infiltrate the skin and the intercostal space immediately above the rib below with 1% lidocaine.
- As you advance the needle, aspirate at each step prior to injecting the local anaesthetic.
- On reaching the pleural cavity, you should be able to aspirate pleural fluid; when you do, note the depth of the needle.
- Insert a thoracentesis needle into the pleural space by advancing it along the same track as was used for the local anaesthetic and connect it to a three-way tap and container to collect the fluid.
- Drain the pleural effusion, to a maximum of 1.5 L. If the effusion is larger than this, repeat the procedure on further occasions as necessary.
- Consider using ultrasound-guided placement of a drainage catheter if the effusion proves difficult to drain.
- Permanent drains can be useful for some patients with recurrent effusions where pleurodesis is not possible.

Investigations and management

Pleural aspirate is the key investigation and may show the presence of malignant cells. Malignant effusions are commonly blood-stained and are exudates with a raised fluid to serum LDH ratio (>0.6) and a raised fluid to serum protein ratio (>0.5). Treatment should focus on palliation of symptoms and be tailored to the patient's physical condition and prognosis. Aspiration alone may be an appropriate treatment in frail patients with a limited life expectancy (Box 33.15). Those who present with malignant pleural effusion as the initial manifestation of breast cancer, small cell lung cancer, germ cell tumours or lymphoma should have the fluid aspirated and should be given systemic chemotherapy to try to treat disease in the pleural space. Treatment options for patients with recurrent pleural effusion include pleurodesis, pleurectomy and pleuroperitoneal shunt. Ideally, pleurodesis should be attempted once effusions recur after initial drainage.

Therapeutics in oncology

Anti-cancer therapy may be either curative or palliative, and this distinction influences the approach to management of individual patients. The goal of treatment should be recorded in the medical notes.

- *Palliative chemotherapy* is the most common treatment and is primarily used to treat patients with metastatic disease. The goal is an improvement in symptoms with a focus on improving quality of life, and any survival increments are secondary. As a result, the treatment should be well tolerated and should aim to minimise adverse effects.
- *Adjuvant chemotherapy* is given after an initial intervention that is designed to cyto-reduce the tumour bulk and remove all macroscopic disease. Chemotherapy is then given with the intention of eradicating the micrometastatic disease that remains. The focus is on achieving an improvement in disease-free and overall survival.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

- *Neoadjuvant chemotherapy* or primary medical therapy is where chemotherapy is administered first before a planned cyto-reductive procedure. This can result in a reduced requirement for surgery, increase the likelihood of successful debulking, reduce the duration of hospitalisation and improve the fitness of the patient prior to interval debulking. This approach has the same goals as adjuvant treatment but creates an opportunity for translational research to measure responses to treatment and correlate with subsequent specimens removed at the time of surgery.
- *Chemoprevention* is the use of pharmacological agents to prevent cancer developing in patients identified as being at particular risk. The agents used therefore aim to modify risk and, as such, should not have significant adverse effects.

Surgical treatment

Surgery has a pivotal role in the management of cancer. There are three main situations in which it is necessary.

Biopsy

In the vast majority of cases, a histological or cytological diagnosis of cancer is necessary, and tissue will also provide important information such as tumour type and differentiation, to assist subsequent management. Cytology can be obtained with fine needle aspiration but a biopsy is usually preferred. This can be a core biopsy, an image-guided biopsy or an excision biopsy.

Excision

The main curative management of most solid cancers is surgical excision. In early, localised cases of colorectal, breast and lung cancer, cure rates are high with surgery. There is increasing evidence that outcome is related to surgical expertise, and most multidisciplinary teams include surgeons experienced in the management of a particular cancer. There are some cancers for which surgery is one of two or more options for primary management, and the role of the multidisciplinary team is to recommend appropriate treatment for a specific patient. Examples include prostate and transitional cell carcinoma of the bladder, in which radiotherapy and surgery may be equally effective.

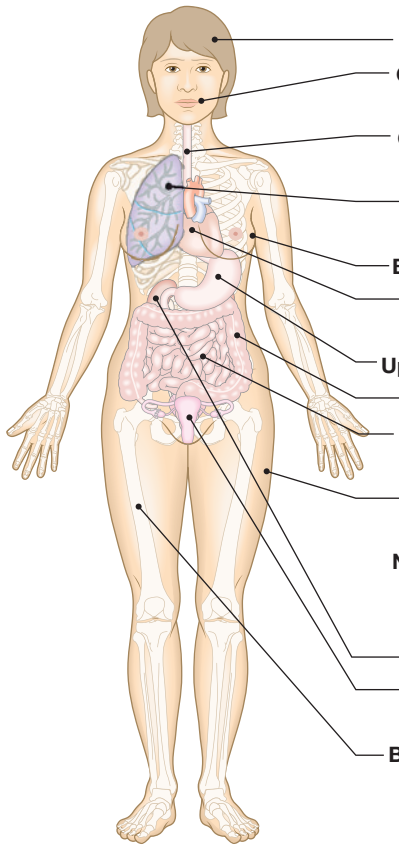
Palliation

Surgical procedures are often the quickest and most effective way of palliating symptoms. Examples include the treatment of faecal incontinence with a defunctioning colostomy; fixation of pathological fractures and decompression of spinal cord compression; and the treatment of fungating skin lesions by 'toilet' surgery. A more specialist role for surgery is in resection of residual masses after chemotherapy and, in very selected cases, resection of metastases.

Systemic chemotherapy

Chemotherapeutic drugs are classified by their mode of action. They have the greatest activity in proliferating cells and this provides the rationale for their use in the treatment of cancer. Chemotherapeutic agents are not specific for cancer cells, however, and the side-effects of treatment are a result of their antiproliferative actions in normal tissues such as the bone marrow, skin and gut.

Combination therapy



The dosing schedule and interval are determined by the choice of drugs and recovery of the cancer and normal tissues. For most common chemotherapy regimens, the treatment is administered every 21 or 28 days, which defines one cycle. A course of treatment often uses up to 6 cycles of treatment. An increase in effectiveness can be achieved by changing the approach to treatment. In some cases this will increase toxicity too, but it can change the nature of the toxicity and such developments are evaluated in clinical trials.

- *Low-dose therapy* is the standard approach and most palliative chemotherapy is given in this manner. The next cycle is started once bone marrow function has recovered sufficiently to start the treatment (neutrophils $>1.0\times10^9$/L and platelets $>100\times10^9$/L).
- *High-dose therapy* uses a higher individual drug dose to achieve a higher cell kill but results in more bone marrow toxicity. This can be minimised by using G–CSF. This approach allows more drug to be delivered within the same schedule of administration, but the total received dose can be less than the intended dose due to limitations of non-haematological toxicity.
- *Dose-dense therapy* involves fractionating the intended dose of drug and administering each fraction on a more frequent basis (often weekly). Each individual dose produces less toxicity but the anti-cancer effect is related to the accumulative dose over time. Such an approach can overcome drug resistance, produce a greater cell kill and, in some cases, produce a response with weekly administration when the 3-weekly schedule demonstrates a lack of response or even disease progression.
- *Alternating therapy* involves giving different drugs in an alternating manner. This is most commonly used with haematological malignancies and is designed to treat different subpopulations of cancer cells where individual clones of cells might be resistant to one or more of the agents.

Adverse effects

Most cytotoxics have a narrow therapeutic window or index and can have significant adverse effects, as shown in Figure 33.6. Considerable supportive therapy is often required to enable patients to tolerate therapy and achieve benefit. Nausea and vomiting are common, but with modern antiemetics, regimens such as the combination of dexamethasone and highly selective 5-hydroxytryptamine (5-HT_3, serotonin) receptor antagonists like ondansetron, most patients now receive chemotherapy without any significant problems. Myelosuppression is common to almost all cytotoxics and this not only limits the dose of drug but also can cause life-threatening complications. The risk of neutropenia can be reduced with the use of specific growth factors that accelerate the repopulation of myeloid precursor cells. The most commonly employed is G–CSF, which is widely used in conjunction with chemotherapy regimens that induce a high rate of neutropenia. More recently, it has been used to 'accelerate' the administration of chemotherapy, enabling standard doses to be given at shorter intervals where the rate-limiting factor has been the time taken for the peripheral neutrophil count to recover. Accelerated chemotherapy regimens have now been demonstrated to offer therapeutic advantages in small cell lung cancer, lymphoma and possibly breast cancer.

Children		Reduced growth

Fig. 33.6 Adverse effects of chemotherapy and radiotherapy. Acute effects are shown in pink and late effects in blue.

Radiation therapy

Radiation therapy (radiotherapy) involves treating the cancer with ionising radiation; for certain localised cancers it may be curative. Ionising radiation can be delivered by radiation emitted from the decay of radioactive isotopes or by high-energy radiation beams, usually X-rays. Three methods are usually employed:

- *Teletherapy*: application from a distance by a linear accelerator.
- *Brachytherapy*: direct application of a radioactive source on to or into a tumour. This allows the delivery of a very high, localised dose of radiation and is integral to the management of localised cancers of the head and neck, and cancer of the cervix and endometrium.
- *Intravenous injection of a radioisotope*: such as ^{131}iodine for cancer of the thyroid and ^{89}strontium for the treatment of bone metastases from prostate cancer.

The majority of treatments are delivered by linear accelerators, which produce electron or X-ray beams of high energy that are used to target tumour tissue. The biological effect of ionising radiation is to cause lethal and sublethal damage to DNA. Since normal tissues are also radiosensitive, treatment has to be designed to maximise exposure of the tumour and minimise exposure of normal tissues. This is possible with modern imaging techniques such as CT and MRI, which allow better visualisation of normal and tumour tissue. In addition, techniques such as conformal radiotherapy, in which shaped rather than conventional square or rectangular beams are used, allow much more precise targeting of therapy to the tumour, and reduce the volume of normal tissue irradiated by up to 40% compared to non-conformal techniques.

Biological differences between normal and tumour tissues are used to obtain therapeutic gain. Fundamental to this is fractionation, which entails delivering the radiation as a number of small doses on a daily basis. This allows normal cells to recover from radiation damage but recovery occurs to a lesser degree in malignant cells. Fractionation regimens vary, but radical treatments given with curative intent are usually delivered in 20–30 fractions given daily on 5 days a week, over 4–6 weeks. Radiotherapy can be extremely useful for the alleviation of symptoms, and for palliative treatments such as this a smaller number of fractions (1–5) is usually adequate.

Both normal and malignant tissues vary widely in their sensitivity to radiotherapy. Germ cell tumours and lymphomas are extremely radiosensitive and relatively low doses are adequate for cure, but most cancers require doses close to or beyond that which can be tolerated by adjacent normal structures. Normal tissue also varies in its radiosensitivity, the central nervous system, small bowel and lung being among the most sensitive. The side-effects of radiotherapy (see Fig. 33.6) depend on the normal tissues treated, their radiosensitivity and the dose delivered.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Adverse effects

An acute inflammatory reaction commonly occurs towards the end of most radical treatments and is localised to the area treated. For example, skin reactions are common with breast or chest wall radiotherapy, and proctitis and cystitis with treatment to the bladder or prostate. These acute reactions settle over a period of a few weeks after treatment, assuming normal tissue tolerance has not been exceeded. Late effects of radiotherapy develop 6 weeks or more after treatment and occur in 5–10% of patients. Examples include brachial nerve damage and subcutaneous fibrosis after breast cancer treatment, and shrinkage and fibrosis of the bladder after treatment for bladder cancer. There is a risk of inducing cancer after radiotherapy, which varies depending on the site treated and on whether the patient has had other treatment such as chemotherapy.

Hormone therapy

Hormone therapy is most commonly used in the treatment of breast cancer and prostate cancer. Breast tumours that are positive for expression of the oestrogen receptor (ER) respond well to anti-oestrogen therapy, and assessment of ER status is now standard in the diagnosis of breast cancer. Several drugs are now available that reduce oestrogen levels or block the effects of oestrogen on the receptor. When targeted appropriately, adjuvant hormone therapy reduces the risk of relapse and death at least as much as chemotherapy, and in advanced cases can induce stable disease and remissions that may last months to years, with acceptable toxicity. Hormonal manipulation may be effective in other cancers. In prostate cancer, hormonal therapy (e.g. luteinising hormone releasing hormone (LHRH) analogues such as goserelin and/or anti-androgens such as bicalutamide) aimed at reducing androgen levels can provide good long-term control of advanced disease, but there is no convincing evidence that it is an effective therapy following potentially curative surgery. Progestogens are active in the treatment of endometrial and breast cancer. In the metastatic setting, progestogen use (e.g. megestrol acetate) is associated with response rates of 20–40% in endometrial cancer. In breast cancer, progestogens are used in patients whose disease has progressed with conventional anti-oestrogen therapy. Their exact mechanism in this setting is not fully understood.

Immunotherapy

A profound stimulus to the patient's immune system can sometimes alter the natural history of a malignancy, and the discovery of interferons was the impetus for much research. Although solid tumours show little benefit, interferons are active in melanoma and lymphoma, and there is evidence that they are beneficial as adjuvants (after surgery and chemotherapy, respectively) to delay recurrence. Whether interferon-induced stimulation of the immune system is capable of eradicating microscopic disease remains unproven. More powerful immune responses can be achieved with potent agents like IL-2 but the accompanying systemic toxicity is a problem still to be overcome. The most striking example of successful immunotherapy is that with rituximab, an antibody against the common B-cell antigen CD20. It increases complete response rates and improves survival in diffuse large cell non-Hodgkin lymphoma when combined with chemotherapy, and is effective in palliating advanced follicular non-Hodgkin lymphoma (p. 965).

Biological therapies

Advances in knowledge about the molecular basis of cancer have resulted in the development of a new generation of treatments to block the signalling pathways responsible for the growth of specific tumours. This has created the potential to target cancer cells more selectively, with reduced toxicity to normal tissues. Some examples are discussed below, but in the years to come many more such agents will come into clinical use, with the potential to revolutionise our approach to some cancers.

Gefitinib/erlotinib

These agents inhibit the activity of the EGFR, which is over-expressed in many solid tumours. However, the drugs' activity does not depend on the amount of receptor over-expression but rather on factors such as gene copy number and mutation status.

Imatinib

Imatinib was developed to inhibit the *BCR-ABL* gene product, tyrosine kinase, that is responsible for chronic myeloid leukaemia (p. 958), and it does this extremely effectively. It is also active in malignant gastrointestinal stromal tumour (GIST), a type of sarcoma that has over-expression of another cell surface tyrosine kinase, c-kit. This agent has good tolerability and is particularly useful in GIST, where conventional chemotherapy is less effective.

Bevacizumab

This is a humanised monoclonal antibody that inhibits vascular endothelial growth factor A (VEGF-A), a key stimulant of angiogenesis in tumours. Bevacizumab has activity in colorectal, lung, breast, renal and ovarian cancers, although the licence was subsequently revoked for breast cancer; while bevacizumab slows the rate of progression of metastatic breast cancer, it had little impact on survival or improved quality of life.

Trastuzumab

Trastuzumab (Herceptin) targets the HER2 receptor, an oncogene that is over-expressed in around one-third of breast cancers and in a number of other solid tumours (e.g. gastric cancer). It is effective as a single-agent therapy, but also improves survival in patients with advanced breast cancer when used in conjunction with chemotherapy. Unfortunately, trastuzumab can induce cardiac failure by an unknown biological mechanism, especially in combination with doxorubicin.

Evaluation of treatment

The evaluation of treatment includes an assessment of overall survival duration, response to treatment, remission rate, disease-free survival and response duration, quality of life and treatment toxicity. Uniform criteria have been established to measure these, including the response evaluation criteria in solid tumours (RECIST, Box 33.16) and common toxicity criteria. This allows clinicians to inform patients accurately about the prognosis, effectiveness and toxicity of chemotherapy and empowers patients to take an active role in treatment decisions.

Late toxicity of therapy

The late toxicities of treatment for cancer are particularly important for patients where the multimodality therapy is given with curative

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

33.16 Response evaluation criteria in solid tumours (RECIST)

Response	Criteria
Complete response (CR)	Disappearance of all target lesions
Partial response (PR)	At least a 30% decrease in the sum of the longest diameter (LD) of target lesions, taking as reference the baseline sum LD
Progressive disease (PD)	At least a 20% increase in the sum of the LD of target lesions, taking as reference the smallest sum LD recorded since the treatment started and at least 5 mm increase or the appearance of one or more new lesions
Stable disease (SD)	Neither sufficient shrinkage to qualify for PR nor sufficient increase to qualify for PD, taking as reference the smallest sum LD since the treatment started

intent, the patient is young and more patients are living longer. This can cause considerable morbidity: for example, radiotherapy can retard bone and cartilage growth, impair intellect and cognitive function, and cause dysfunction of the hypothalamus, pituitary and thyroid glands. Late consequences of chemotherapy include heart failure due to cardiotoxicity, pulmonary fibrosis, nephrotoxicity and neurotoxicity.

Premature gonadal failure can result from chemotherapy or radiotherapy and leave a patient subfertile. Patients should be made aware of this before treatment is initiated, as it may be possible to store sperm for male patients before treatment starts; this should always be offered, if practical. Egg or embryo banking after in vitro fertilisation may be an option for young women. Sterility develops at higher radiotherapy doses but erectile dysfunction is seen in patients receiving high radiotherapy doses to the pelvis, as in prostate cancer. Additional social or psychological support may be required. Infertility and pubertal delay are potential late effects of therapy in children, especially boys.

Second malignancies may be induced by cancer treatment and occur at greatest frequency following chemoradiation. Secondary acute leukaemia (mostly AML) can occur 1–2 years after treatment with topoisomerase II inhibitors, or 2–5 years after treatment with alkylating agents. The most common second malignancy within a radiation field is osteosarcoma but others include soft tissue sarcoma and leukaemia.

Specific cancers

The diagnosis and management of cancers are discussed in more detail elsewhere in the book (Box 33.17). Here we discuss the pathogenesis, clinical features, investigation and management of common tumours that are not covered elsewhere.

Breast cancer

Globally, the incidence of breast cancer is second only to that of lung cancer, and the disease represents the leading cause of cancer-related deaths among women. Invasive ductal carcinoma with or without ductal carcinoma in situ (DCIS) is the most common histology, accounting for 70%, whilst invasive lobular carcinoma accounts for most of the remaining cases. DCIS constitutes 20% of breast cancers detected by mammography

33.18 Five-year survival rates for breast cancer by stage

Tumour stage	Stage definition	5-year survival (%)
I	Tumour <2 cm, no lymph nodes	96
II	Tumour 2–5 cm and/or mobile axillary lymph nodes	81
III	Chest wall or skin fixation and/or fixed axillary lymph nodes	52
IV	Metastasis	18

screening. It is multifocal in one-third of women and has a high risk of becoming invasive (10% at 5 years following excision only). Pure DCIS does not cause lymph node metastases, although these are found in 2% of cases where nodes are examined, owing to undetected invasive cancer. Lobular carcinoma in situ (LCIS) is a predisposing risk factor for developing cancer in either breast (7% at 10 years). The survival for breast cancer by stage is outlined in Box 33.18.

Pathogenesis

Both genetic and hormonal factors play a role; about 5–10% of breast cancers are hereditary and occur in patients with mutations of *BRCA1*, *BRCA2*, *AT* or *TP53* genes. Prolonged oestrogen exposure associated with early menarche, late menopause and use of hormone replacement therapy (HRT) has been associated with an increased risk. Other risk factors include obesity, alcohol intake, nulliparity and late first pregnancy. There is no definite evidence linking use of the contraceptive pill to breast cancer.

Clinical features

Breast cancer usually presents as a result of mammographic screening or as a palpable mass with nipple discharge in 10% and pain in 7% of patients. Less common presentations include inflammatory carcinoma with diffuse induration of the skin of the

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

breast, and this confers an adverse prognosis. Around 40% of patients will have axillary nodal disease, with likelihood correlating with increasing size of the primary tumour. Distant metastases are infrequently present at diagnosis and the most common sites of spread are bone (70%), lung (60%), liver (55%), pleura (40%), adrenals (35%), skin (30%) and brain (10–20%).

Investigations

Following clinical examination, patients should have imaging with mammography or ultrasound evaluation, and a biopsy using fine needle aspiration for cytology or core biopsy for histology. Histological assessment should be carried out to assess tumour type and to determine oestrogen and progesterone receptor (ER/PR) status and HER2 status. If distant spread is suspected, CT of the thorax and abdomen and an isotope bone scan are required. Molecular subtyping is being used to classify tumours into four major subtypes: luminal A, luminal B, HER2 type and basal-like (often called 'triple negative', as these tumours are ER-, PR- and HER2-negative). This may allow more targeted selection of therapies in future.

Management

Surgery is the mainstay of treatment for most patients, and this can range from a lumpectomy, where only the tumour is removed, to mastectomy, where the whole breast is removed. Breast-conserving surgery is as effective as mastectomy if complete excision with negative margins can be achieved. Lymph node sampling is performed at the time of surgery. Adjuvant radiotherapy is given to reduce the risk of local recurrence to 4–6%. Adjuvant hormonal therapy improves disease-free and overall survival in pre- and post-menopausal patients who have tumours that express ER. Patients at low risk, with tumours that are small and ER-positive, require only adjuvant hormonal therapy with tamoxifen. Patients with tumours that are ER-positive and who are pre-menopausal should receive an LHRH analogue. Aromatase inhibitors also have benefit in this setting but are still under investigation.

Adjuvant chemotherapy is considered for patients at higher risk of recurrence. Factors that increase the risk of recurrence include a tumour of >1 cm, a tumour that is ER-negative or the presence of involved axillary lymph nodes. Such patients should be offered adjuvant chemotherapy, which improves disease-free and overall survival. The role of adjuvant treatment has been studied by meta-analyses and data support the use of adjuvant trastuzumab, a humanised monoclonal antibody to HER2, in addition to standard chemotherapy for women with early HER2-positive breast cancer.

Metastatic disease management includes radiotherapy to palliate painful bone metastases and second-line endocrine therapy with aromatase inhibitors, which inhibit peripheral oestrogen production in adrenal and adipose tissues. Advanced ER-negative disease may be treated with combination chemotherapy.

Ovarian cancer

Ovarian cancer is the most common gynaecological tumour in Western countries. Most ovarian cancers are epithelial in origin (90%), and up to 7% of women with ovarian cancer have a positive family history. Patients often present late in ovarian cancer with vague abdominal discomfort, low back pain, bloating, altered bowel habit and weight loss. Occasionally, peritoneal deposits are palpable as an omental 'cake' and nodules in the umbilicus (Sister Mary Joseph nodules).

Pathogenesis

Genetic and environmental factors play a role. The risk of ovarian cancer is increased in patients with *BRCA1* or *BRCA2* mutations, and Lynch type II families (a subtype of hereditary non-polyposis colon cancer, HNPCC) have ovarian, endometrial, colorectal and gastric tumours due to mutations of mismatch repair enzymes. Advanced age, nulliparity, ovarian stimulation and Caucasian descent all increase the risk of ovarian cancer, while suppressed ovulation appears to protect, so pregnancy, prolonged breastfeeding and the contraceptive pill have all been shown to reduce the risk of ovarian cancer.

Investigations

Initial workup for patients with suspected ovarian cancer includes imaging in the form of ultrasound and CT. Serum levels of the tumour marker CA-125 are often measured. Surgery plays a key role in the diagnosis, staging and treatment of ovarian cancer, and in early cases, palpation of viscera, peritoneal washings and biopsies are generally performed to define disease extent.

Management

In early disease, surgery followed by adjuvant chemotherapy with carboplatin, or carboplatin plus paclitaxel, is the treatment of choice. Surgery should include removal of the tumour along with total abdominal hysterectomy, bilateral salpingo-oophorectomy, and omentectomy. Even in advanced disease, surgery is undertaken to debulk the tumour and is followed by adjuvant chemotherapy, typically using carboplatin and paclitaxel. Bevacizumab is indicated for patients with high-grade tumours that are suboptimally debulked or those with a more aggressive biological pattern. Monitoring for relapse is achieved through a combination of serum CA-125 and clinical examination with CT imaging for those with suspected relapse. Second-line chemotherapy is aimed at improving symptoms and should not be used for CA-125 elevation only in the absence of symptoms. Treatments can include further platinum/paclitaxel in combination, liposomal doxorubicin or topotecan. These regimens are associated with a response rate of 10–40%. The best responses are observed in patients with a treatment-free interval of more than 12 months.

Endometrial cancer

Endometrial cancer accounts for 4% of all female malignancies, producing a 1 in 73 lifetime risk. The majority of patients are post-menopausal, with a peak incidence at 50–60 years of age. Mortality from endometrial cancer is currently falling. The most common presentation is with post-menopausal bleeding, which often results in detection of the disease before distant spread has occurred.

Pathogenesis

Oestrogen plays an important role in the pathogenesis of endometrial cancer, and factors that increase the duration of oestrogen exposure, such as nulliparity, early menarche, late menopause and unopposed HRT, increase the risk. Endometrial cancer is 10 times more common in obese women and this is thought to be due to elevated levels of oestrogens.

Investigations

The diagnosis is confirmed by endometrial biopsy.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Management

Surgery is the treatment of choice and is used for staging. A hysterectomy and bilateral salpingo-oophorectomy are performed with peritoneal cytology and, in some cases, lymph node dissection. Where the tumour extends beyond the inner 50% of the myometrium or involves the cervix and local lymph nodes, or there is lymphovascular space invasion, adjuvant pelvic radiotherapy is recommended. Chemotherapy is used as adjuvant therapy and hormonal therapy and chemotherapy are used to palliate symptoms in recurrent disease.

Cervical cancer

This is the second most common gynaecological tumour worldwide and the leading cause of death from gynaecological cancer. The incidence is decreasing in developed countries but continues to rise in developing nations. The most common presentation is with an abnormal smear test, but with locally advanced disease the presentation is with vaginal bleeding, discomfort, discharge or symptoms attributable to involvement of adjacent structures, such as bladder, or rectal or pelvic wall. Occasionally, patients present with distant metastases to bone and lung.

Pathogenesis

There is a strong association between cervical cancer and sexual activity that includes sex at a young age and multiple sexual partners. Infection with HPV has an important causal role, and this has underpinned the introduction of programmes to immunise teenagers against HPV in an effort to prevent the later development of cervical cancer (p. 342).

Investigations

Diagnosis is made by smear or cone biopsy. Further examination may require cystoscopy and flexible sigmoidoscopy if there are symptoms referable to the bladder, colon or rectum. In contrast to other gynaecological malignancies, cervical cancer is a clinically staged disease, although MRI is often used to characterise the primary tumour. A routine chest X-ray should be obtained to help rule out pulmonary metastasis. CT of the abdomen and pelvis is performed to look for metastasis in the liver and lymph nodes, and to exclude hydronephrosis and hydroureter.

Management

This depends on the stage of disease. Pre-malignant disease can be treated with laser ablation or diathermy, whereas in microinvasive disease a large loop excision of the transformation zone (LLETZ) or a simple hysterectomy is employed. Invasive but localised disease requires radical surgery, while chemotherapy and radiotherapy, including brachytherapy, may be given as primary treatment, especially in patients with adverse prognostic features such as bulky or locally advanced disease, or lymph node or parametrium invasion. In metastatic disease, cisplatin-based chemotherapy may be beneficial in improving symptoms but does not increase survival significantly.

Head and neck tumours

Head and neck cancers are typically squamous tumours that arise in the nasopharynx, hypopharynx and larynx. They are most common in elderly males but now occur with increasing frequency in a younger cohort, as well as in women, especially where oropharyngeal cancers are concerned. The rising incidence of oropharyngeal cancers, especially in the developed world, is thought to be secondary to HPV infection. Presentation depends on the location of the primary tumour and the extent of disease. For example, early laryngeal cancers may present with hoarseness, while more extensive local disease may present with pain due to invasion of local structures or with a lump in the neck. Patients who present late often have pulmonary symptoms, as this is the most common site of distant metastases (Box 33.19).

i 33.19 Common presenting features by location in head and neck cancer

Hypopharynx	
• Dysphagia	• Referred otalgia
• Odynophagia	• Enlarged lymph nodes
Mouth	
• Non-healing ulcers	• Ipsilateral otalgia
Nasal cavity and sinuses	
• Discharge (bloody) or obstruction	
Nasopharynx	
• Nasal discharge or obstruction	• Diplopia
• Conduction deafness	• Hoarse voice
• Atypical facial pain	• Horner's syndrome
Oropharynx	
• Dysphagia	• Otalgia
• Pain	
Salivary gland	
• Painless swelling	• Facial nerve palsy

Pathogenesis

The tumours are strongly associated with a history of smoking and excess alcohol intake, but other recognised risk factors include Epstein–Barr virus for nasopharyngeal cancer and HPV infection for oropharyngeal tumours.

Investigations

Careful inspection of the primary site is required as part of the staging process, and most patients will require endoscopic evaluation and examination under anaesthesia. Tissue biopsies should be taken from the most accessible site. CT of the primary site and the thorax is the investigation of choice for visualising the tumour, while MRI may be useful in certain cases.

Management

Generally speaking, the majority of patients with early or locally advanced disease are treated with curative intent. In localised disease where there is no involvement of the lymph nodes, long-term remission can be achieved in up to 90% of patients with surgery or radiotherapy. The choice of surgery versus radiotherapy often depends on patient preference, as surgical treatment can be mutilating with an adverse cosmetic outcome. Patients with lymph node involvement or metastasis are treated with a combination of surgery and radiotherapy (often with chemotherapy as a radiosensitising agent – proven agents include cisplatin or cetuximab), and this produces long-term remission in approximately 60–70% of patients. Recurrent or metastatic tumour may be palliated with further surgery or radiotherapy to aid local control, and systemic chemotherapy has a response rate of around 20–30%. Second malignancies are common (3%

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

per year) following successful treatment for primary disease, and all patients should be encouraged to give up smoking and drinking alcohol to lower their risk.

Carcinoma of unknown origin

Some patients are found to have evidence of metastatic disease at their initial presentation, prior to diagnosis of a primary site. In many cases, a subsequent biopsy reveals adenocarcinoma but the primary site is not always clear.

Investigations

In this situation, there is a temptation to investigate the patient endlessly in order to determine the original primary site. There is a compromise, however, between exhaustive investigation and obtaining sufficient information to plan appropriate management. For all patients, histological examination of an accessible site of metastasis is required. The architecture of the tissue can assist the pathologist in determining the likely primary site, and therefore it is better to perform a biopsy rather than fine needle aspiration. The greater volume of tissue permits the use of immunohistochemistry. Extensive imaging to search for the primary is rarely indicated; a careful history to identify symptoms and risk factors (including familial) will often permit a judicious choice of imaging and other diagnostic tests, reserving additional tests for specific patients (Box 33.20).

Management

Management of the patient will depend on that person's circumstances, as well as on the site(s) involved and the likely primary sites. The overriding principle is to ensure that a curable diagnosis has been excluded. For example, lung metastases from a testicular teratoma do not preclude cure; nor do one or two liver metastases from a colorectal cancer. Early discussion with an oncologist within a multidisciplinary team is essential and avoids unnecessary investigation; for example, a single hCG-based pregnancy test in a young man with lung metastases might confirm the presence of a teratoma and allow rapid administration of potentially curative chemotherapy. Treatment should not necessarily wait for a definitive diagnosis; appropriate analgesia, radiotherapy and surgical palliation can all be helpful. Some patients remain free of cancer for some years after resection of a single metastasis of an adenocarcinoma of unknown primary, justifying this approach in selected patients.

In those with no obvious primary, systemic chemotherapy may achieve some reduction in tumour burden and alleviation of symptoms, but long-term survival is rare.

i 33.20 Initial diagnostic tests in patients presenting with carcinoma of unknown primary*

- Detailed history and examination, including breast, nodal areas, skin, genital, rectal and pelvic regions
- Full blood count, urea and electrolytes, renal function, liver function tests, calcium, urinalysis, lactate dehydrogenase
- Chest X-ray
- Myeloma screen (if lytic bone lesions)
- CT scan of chest, abdomen and pelvis
- Symptom-directed upper and lower gastrointestinal endoscopy
- Tumour markers: prostate-specific antigen (PSA) in men, cancer antigen 125 (CA-125) in women with peritoneal malignancy or ascites, α-fetoprotein (AFP) and human chorionic gonadotrophin (hCG)
- Testicular ultrasound (if clinical features suggest germ cell tumour)
- Histological examination of biopsy, with immunohistochemistry if required

*Offer when clinically appropriate.

Multidisciplinary teams

The multidisciplinary team (MDT) is well established in oncology and meets on a regular basis to discuss patient progress and provide a forum for patient-centred, interdisciplinary communication to coordinate care and decision-making. It is a platform on which individual clinicians can discuss complex cases or situations and draw on the collective experience of the team membership to decide on the best approach for an individual patient. This can be particularly important when discussing patients with a rare condition or in a rare situation.

Specific roles of the MDT include:

- planning the diagnostic and staging procedures
- deciding on the appropriate primary treatment modality (most commonly surgery but the use of neoadjuvant chemotherapy before interval surgery is increasing)
- arranging review by the oncology team to plan assessment of the patient prior to systemic therapy or radiotherapy
- discussing additional support requirements for the individual patient, such as physiotherapy; psychological support; symptom control; nutritional care or rehabilitation in the post-operative period
- ensuring access to accurate information on treatment, prognosis, side-effects and other related matters, such as stoma care
- planning surveillance strategies
- ensuring the appropriate transition from treatment with curative intent to that of palliation of symptoms
- promoting recruitment into clinical trials
- agreeing on operational policies to deliver high-quality care to patients
- planning and reviewing audit data to ensure the delivery of quality care to patients by the team.

Pain

Pain is defined as 'an unpleasant sensory and emotional experience associated with actual or potential tissue damage or described in terms of such damage'. It is one of the most common symptoms for which people seek health-care advice. Our understanding of the mechanisms of pain has evolved considerably from Hippocrates' suggestion in 450 BC that pain arose as a result of an imbalance in vital fluids. We now know that pain is a complex symptom that is influenced and modified by many social, cultural and emotional factors, as illustrated in Figure 34.1. The sensation of acute pain that occurs in response to inflammation or tissue damage plays an important role in protection from further injury. Chronic pain serves no useful function but results in significant distress and suffering for the patient affected, as well as having a wider societal impact.

Functional anatomy and physiology

The functional anatomy of the somatosensory system is shown in Figures 25.3 and 25.6 (pp. 1065 and 1068). Here, discussion will focus on the mechanisms and mediators that are involved in pain processing.

Peripheral nerves

Peripheral nerves contain several types of neuron. These can be classified into two groups, depending on whether or not they are surrounded by a myelin sheath. Myelinated neurons have a fast conduction velocity and are responsible for transmission of various sensory signals, such as proprioception, light touch, heat and cold, and the detection of localised pains, such as pin-prick. Unmyelinated fibres have a much slower conduction velocity and are responsible for transmitting diffuse and poorly localised pain, as well as other sensations (Box 34.1).

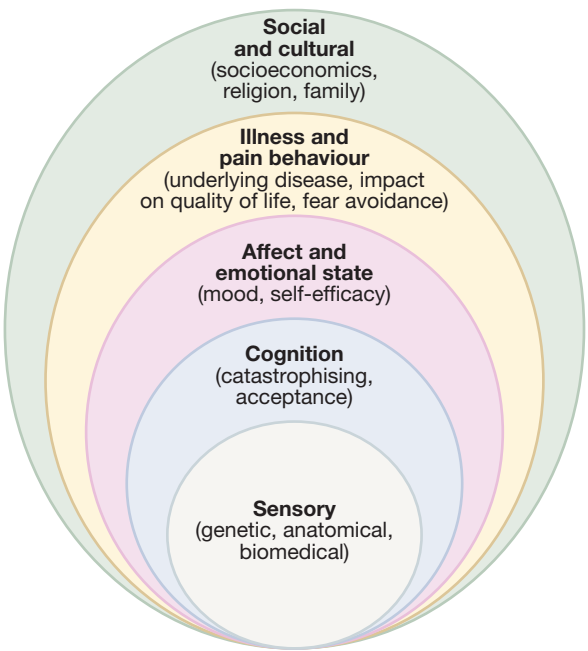

Fig. 34.1 The biopsychosocial model of pain. The perception of pain as a symptom is dependent not only on sensory inputs but also on the individual's cognitive reaction to the pain, their emotional state, their underlying disease and their social and cultural background.

i 34.1 Types of nerve fibre

Fibre type	Diameter (μm)	Conduction velocity (ms^{-1})	Function
Large myelinated			
Aα	12–20	70–120	Proprioception Motor to muscle fibres
Aβ	5–12	30–70	Light touch, pressure
A-	3–6	15–30	Motor to muscle spindles
Small myelinated			
A	2–5	12–30	Well-localised pain Thermal sensation
B	<3	3–15	Pre-ganglionic autonomic
Unmyelinated			
C	0.4–1.3	0.5–3	Diffuse pain Poorly localised thermal sensation Post-ganglionic autonomic

Sensory neurons (also known as primary afferent neurons) connect the spinal cord to the periphery and supply a defined territory or a dermatome, which can be used to identify the position of a nerve lesion (see Fig. 25.10, p. 1071). In healthy individuals dermatomes have distinct borders, but in pathological pain syndromes these may become blurred as the result of neuronal plasticity, which means that pain may be felt in an area adjacent to that supplied by a specific nerve root. Autonomic neurons also contain pain fibres and are responsible for transmitting visceral sensations, such as colic. In general, visceral pain is diffuse and less well localised than pain transmitted by sensory neurons.

Anatomical features of the afferent pain pathway are illustrated in Figure 34.2. Pain signals are transmitted from the periphery to the spinal cord by sensory neurons. These have the following components:

- *A cell body*, containing the nucleus, which is situated in the dorsal root ganglion close to the spinal cord. The cell body is essential for survival of the neuron, production of neurotransmitters and neuronal function.
- *The nerve fibre (axon) and peripheral nerve endings*, which are located in the periphery and contain a range of receptors in the neuronal membrane.
- *Specialised receptors* in the periphery, consisting of bare nerve endings known as nociceptors or pain receptors, which are activated by various mediators. They are situated mainly in the epidermis.
- *The central termination*, which travels to the dorsal horn of the spinal cord to form the first central synapse with neurons that transmit pain sensation to the brain.

When a noxious stimulus is encountered, activation of nociceptors leads to generation of an action potential, which travels upwards to the dorsal root ganglion and also stimulates the release of neurotransmitters that have secondary effects on surrounding neurons.

Spinal cord

Sensory neurons, through their central termination, synapse with second-order neurons in the dorsal horn of the spinal cord. There is considerable modulation of pain messages at

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

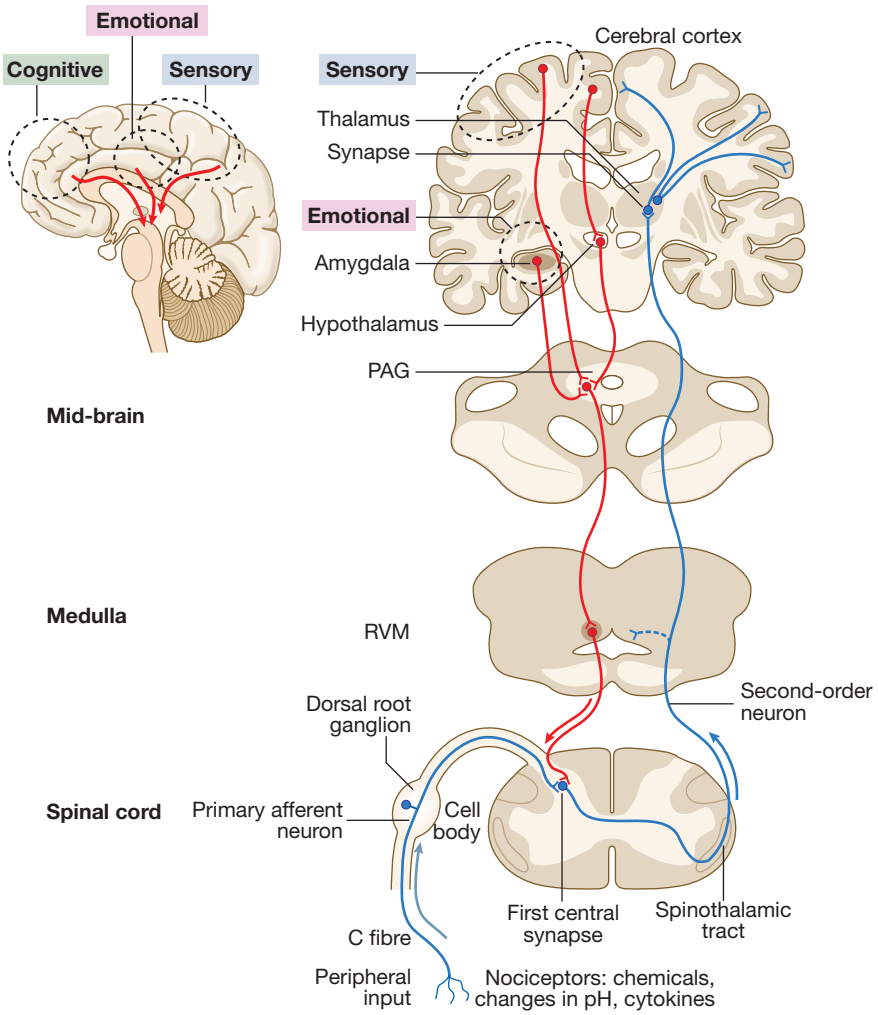

Fig. 34.2 Ascending and descending pain pathways. Ascending pathways are shown in blue and descending in red. Pain signals are detected in the periphery by nociceptors, which are activated by chemicals, changes in pH and cytokines. The signal is transmitted by the primary afferent neuron to the spinal cord, where there is a synapse with a second-order neuron, which transmits the signal onwards to the thalamus. Thereafter, the pain signal is transmitted to the cerebral cortex. The intensity of pain signals is subject to extensive modulation at several levels within the nervous system. Cognitive influences derived from the frontal lobe, coupled with sensory influences from cortex and emotional influences from the amygdyla, affect pain perception in the mid-brain around the periaqueductal gray matter (PAG) and the rostroventrolateral medulla (RVM) in the medulla. These structures form part of the descending modulatory systems, which, under normal circumstances, inhibit pain perception. In some chronic pain states, however, dysfunction of the descending pathways can occur, increasing pain.

this site, both from local neurons within the spinal cord and from neurons that descend from the brain, as depicted in Figure 25.11 (p. 1072). Several neurotransmitters are involved in pain processing at this level and these are summarised in Box 34.2. They include amino acids, such as glycine and γ-aminobutyric acid (GABA), which are inhibitory, and glutamate, which is excitatory; neuropeptides, such as substance P and calcitonin gene-related peptide (CGRP); and endorphins. Whether or not they increase or decrease pain perception depends on the connectivity of the neurons on which they act.

Central processing of pain

The signals transmitted by second-order neurons in the spinal cord are relayed to the sensory cortex by third-order neurons, which synapse with second-order neurons in the thalamus. At this site, perception of pain is influenced by interactions between a range of structures in the brain, where sensory, cognitive and emotional aspects are integrated. This is termed the pain neuromatrix (Fig. 34.2). Signals within the neuromatrix are multidirectional in nature, involving modulation of incoming messages by the cerebral cortex (top-down regulation), as well as a complex network of connections between other subcortical structures. Under normal conditions, there is a degree of descending inhibition from the brainstem that reduces input from peripheral stimuli.

It is thought that chronic widespread pain (CWP) and opioid-induced hyperalgesia may result, at least in part, from abnormalities in central processing of pain signals. It has also been suggested that variations in the levels of descending inhibition between individuals may make some people more vulnerable than others to developing chronic pain. Over recent years, there has been increasing interest in the role that glial cells (see Fig. 25.1, p. 1064) play in pain processing. Both astrocytes and microglial cells can become activated in chronic pain states and release

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

34.2 Neurotransmitters and receptors involved in pain processing in the spinal cord

Neurotransmitter	Receptor(s)	Receptor type	Comments*
Amino acids			
Glutamate	AMPA	Ion channel	Excitatory; permeable to cations: can be Ca^{2+}, Na^+ or K^+, depending on subunit structure
	NMDA	Ion channel	Excitatory; blocked by Mg^{2+} in the resting state; block can be altered if membrane potential changes; permeable to Ca^{2+}, Na^+ and K^+
	Kainate	Ion channel	Post synaptic – excitatory
	Gp I	GPCR	Pre-synaptic – inhibitory through GABA release; permeable to Na^+ and K^+
	Gp II	GPCR	Activates a range of signalling pathways; long-term effects on synaptic excitability
	Gp III	GPCR	Probably inhibitory; can decrease cAMP production; pre-synaptic; decreases glutamate release
Glycine	GlyR	Ion channel	Mainly inhibitory; permeable to Cl^-; blocked by caffeine
GABA	$GABA_A$	Ion channel	Mainly inhibitory in spinal cord; permeable to Cl^-; indirectly modulated by benzodiazepines (increased ion channel opening); not specifically involved in nociception, generally depressant effect on spinal cord activity
	$GABA_B$	GPCR	Predominantly inhibitory; activated by baclofen
Neuropeptides			
Substance P	Neurokinin receptors	GPCR	Mainly excitatory; increased in inflammation, decreased in neuropathic pain
Cholecystokinin	CCKRs1–8	GPCR	Excitatory; clinical trials of antagonists in progress
Calcitonin gene-related peptide	CALCRL	GPCR	Excitatory; slows degradation of substance P; implicated in migraine
Opioids			
Dynorphin	OP1 (kappa)	GPCR	Excitatory?; may be pro-nociceptive
β-endorphin	OP3 (mu)	GPCR	Inhibitory
Nociceptin	ORL-1	GPCR	Inhibitory; also expressed by immune cells

*Excitatory = increased pain; inhibitory = reduced pain.
(AMPA = α-amino 3-hydroxy, 5-methyl, 4-isoxazole propionic acid; CALCRL = calcitonin receptor-like receptor; cAMP = cyclic adenosine monophosphate; GABA = γ-aminobutyric acid; Gp = group; GPCR = G-protein-coupled receptor; NMDA = *N*-methyl-D-aspartate; OP = opioid; ORL = opioid-like receptor)

pro-inflammatory cytokines, as well as altering re-uptake of excitatory neurotransmitters such as glutamate, which can influence pain perception considerably. As our understanding of these processes improves, there is increasing potential to develop novel therapies targeted at these mediators, with some early clinical studies in neuropathic pain.

Sensitisation

Sensitisation is one of the key features of pain processing. It refers to the fact that both peripheral and central nervous systems adapt rapidly to the presence of pain, especially in response to tissue damage. This adaptive process is called neuronal plasticity. In some situations, neuronal plasticity can lead to prolonged changes in the pathways that are involved in detecting and processing nociceptive stimuli, resulting in chronic pain syndromes. The specific changes in key neurotransmitters and receptors differ between chronic pain states, with implications for the efficacy of treatments. For example, μ-opioid receptors are down-regulated in neuropathic pain, potentially leading to limited opioid responsiveness.

Peripheral sensitisation

Peripheral sensitisation can occur in association with a variety of clinical conditions, including sepsis, cancer, inflammatory disease, injury, surgery and obesity. The final common pathway by which sensitisation takes place in all of these conditions is inflammation. Inflammation is accompanied by increased capillary permeability and tissue oedema with the release of a diverse range of mediators, including bradykinin, hydrogen ions, prostaglandins and adenosine, which bind to receptors and ion channels on nociceptors of primary afferent neurons (Fig. 34.3). The signalling pathways activated by these mediators generate action potentials, which are transmitted by sensory neurons to the spinal cord. If these pain-provoking stimuli persist, the activation threshold of sensory neurons is reduced, resulting in an increased transmission of pain signals to the spinal cord.

Central sensitisation

Sensitisation may also take place at the level of the spinal cord in response to a sustained painful stimulus. It can occur acutely and rapidly, such as immediately after surgery, or may progress to chronic changes, such as chronic infection, cancer, repeated surgery or multiple traumatic episodes. Glutamate, acting via the *N*-methyl-D-aspartate (NMDA) receptor complex, plays a key role in central sensitisation (Fig. 34.4). In response to a sustained peripheral painful stimulus, increased amounts of glutamate are released in the spinal cord, overcoming the inhibitory action of magnesium ions and resulting in activation of the NMDA receptor. This initiates a cascade of intracellular signalling events that lead to prolonged modifications of somatosensory processing, with amplification of pain responses within the spinal cord and continued neuronal firing, even after the noxious stimulus has stopped. This phenomenon is termed 'after-discharge'. In neuropathic pain, prolonged activation of the NMDA pathway results in a decrease in the number of inhibitory interneurons, which further potentiates pain.

Genetic determinants of pain perception

There are marked ethnic and individual variations in how people respond to painful stimuli and studies in twins have estimated

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

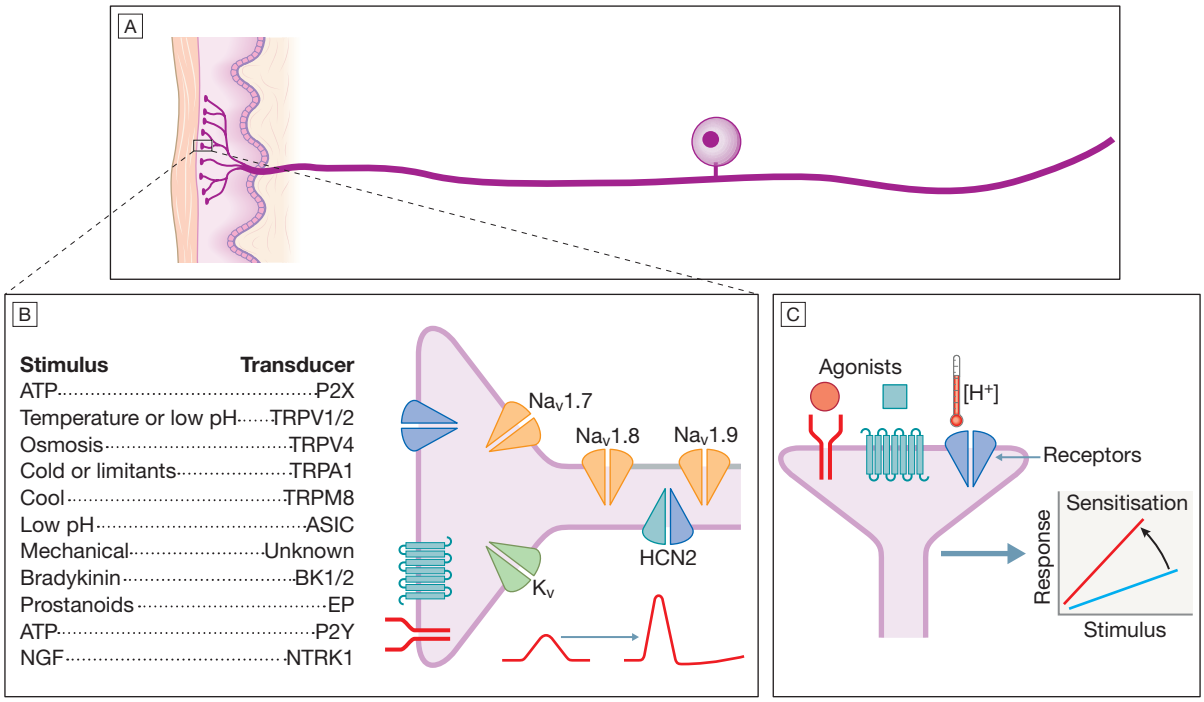

Fig. 34.3 Mechanisms of peripheral sensitisation. A Sensory nerve terminating with nociceptor in skin. B Peripheral nociceptors express various receptors and ion channels that act as mediators of pain. They include sodium channels implicated in congenital pain syndromes; the purinergic 2X (P2X) receptor for adenosine triphosphate (ATP); members of the transient receptor potential (TRP) superfamily of ion channel receptors, which detect changes in osmolality and temperature; acid-sensing ion channel (ASIC) receptors, which detect hydrogen ions; G-protein-coupled receptors, which detect bradykinin (BK), prostaglandins and ATP; and the neurotrophic tyrosine kinase 1 (NTRK1) receptor, which detects nerve growth factor (NGF). C Activation of these receptors by ligands, hydrogen ion [H^+] and high temperature (>42°C) amplifies action potentials, which increase pain signals and cause peripheral sensitisation. *Adapted from Bennett DL, Woods CG. Painful and painless channelopathies. Reprinted with permission from Elsevier (The Lancet Neurol 2014; 13:587–599).*

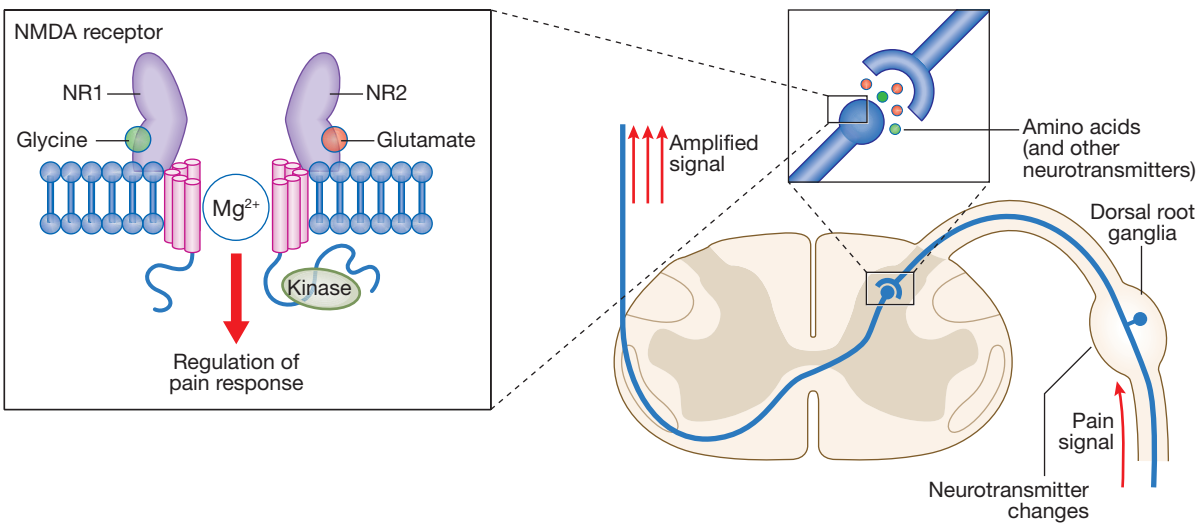

Fig. 34.4 Mechanisms of central sensitisation. Post-synaptic activation of the *N*-methyl-D-aspartate (NMDA) receptor requires the amino acids glycine and glutamate, which bind to the NR1 and NR2 subunits, respectively; these amplify pain signals at the level of the spinal cord. In contrast, magnesium ions block receptor activation.

that the heritability of CWP ranges between 30% and 50%. In the general population, the individual variants in response to pain and perception of pain are most likely due to a complex interaction between genetic and environmental influences. Few variants have been identified with robust evidence of association with CWP. Several rare syndromes have been described, however, in which insensitivity to pain or heightened pain responses occur as the result of a single gene disorder, as summarised in Box 34.3. Most are due to mutations affecting ion channels that play a key role in neurotransmission (see Fig. 34.3), but other causes include mutations in the *NTKR1* gene, which encodes the receptor for nerve growth factor, and mutations in the *PDRM12* transcription factor, which is involved in neuron development.

Investigations

Pain can be a presenting feature of a wide range of disorders and the first step in evaluation of a patient with pain should be to perform whatever investigations are required to define the underlying cause of the pain, unless this is already known. However, with most chronic pain syndromes, such as fibromyalgia, complex regional pain syndrome and CWP, investigations are negative and the diagnosis is made on the basis of clinical history and exclusion of other causes. Specific investigations that are useful in the assessment of selected patients with chronic pain are discussed below.

Magnetic resonance imaging

Magnetic resonance imaging (MRI) can be helpful in the assessment of an underlying cause in patients with focal pain that follows a nerve root or peripheral nerve distribution. Imaging is seldom helpful in individuals with CWP.

Blood tests

Blood tests are not generally helpful in the diagnosis of chronic pain, except in patients with peripheral neuropathy; in this case, a number of blood tests may be required to investigate the underlying causes of the neuropathy. Full details are provided in Box 25.86 (p. 1139). Genetic testing may be of value in patients with clinical features that point to an inherited disorder of pain processing (Box 34.3).

Quantitative sensory testing

Quantitative sensory testing can be helpful in the detailed assessment of patients with chronic pain. A simple set of tools can be used in the clinical setting (Fig. 34.5). Lightly touching the skin with a brush, swab or cotton-wool ball can be used to test for abnormalities of fine touch (allodynia). Assessing the patient's response to a pin-prick can be used to test for abnormalities in mechanical hyperalgesia. Finally, touching the patient's skin with warm and cool thermal rollers can be used to test for abnormalities of thermal sensation. An unaffected area of skin should be tested first, to establish normal sensation, before testing the affected area.

Nerve conduction studies

Nerve conduction studies can be helpful in demonstrating and quantifying a definitive nerve lesion, either peripherally or centrally. They can be used to help differentiate between central and peripheral neuropathic pain. They do not, however, effectively examine small nerve fibre function.

Nerve blocks

Performing a nerve block with infiltration of a local anaesthetic such as 1% lidocaine can be used diagnostically, in assessing whether a pain syndrome is due to involvement of a specific nerve or nerve root. Where inflammation and or swelling may be contributing to the underlying pain – for example, if there is compression of a nerve root – then a mixture of local anaesthetic

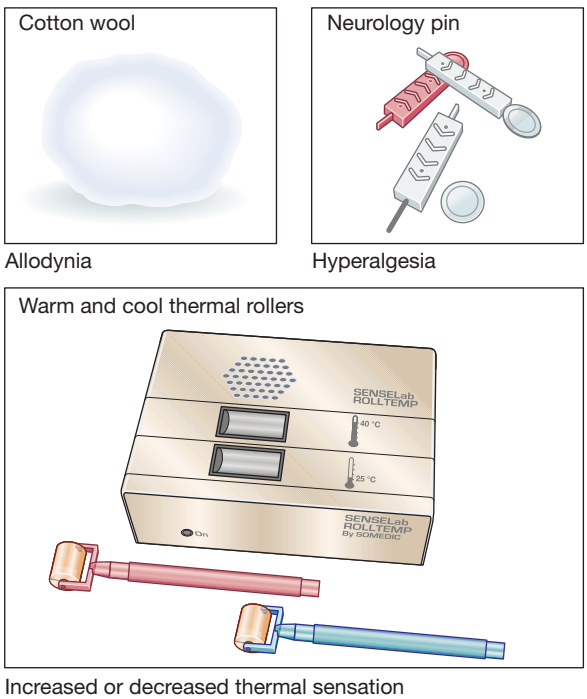

Fig. 34.5 Equipment for bedside sensory testing.

i 34.3 Genetic regulators of pain perception

Gene (protein)	Mutation (inheritance)	Protein function	Phenotypes
SCN9A **(Na,1.7)**	LoF (AR)	Ion channel	Absent pain, hypohydrosis, anosmia
SCN9A **(Na,1.7)**	GoF (AD)	Ion channel	Erythromelalgia, paroxysmal pain, burning pain, autonomic dysfunction
SCN11A **(Na,1.9)**	GoF (AD)	Ion channel	Absent pain, hyperhydrosis, muscular weakness, gut dysmotility
SCN10A **(Na,1.8)**	GoF (AD)	Ion channel	Burning pain, autonomic dysfunction
TRPA1 **(TRPA1)**	GoF (AD)	Ion channel	Absent pain
PDRM12 **(PDRM12)**	LoF (AR)	Transcription factor; neuron development	Absent pain
NTRK1 **(high-affinity NGF receptor)**	LoF (AR)	Tyrosine kinase; promotes neuron development	Absent pain; anhydrosis, mental retardation, increased cancer risk

(AD = autosomal dominant; AR = autosomal recessive; GoF = gain of function; LoF = loss of function; NGF = nerve growth factor)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

and depot glucocorticoid may be helpful in alleviating pain. Nerve blockade can also be used to determine whether more radical therapies, such as nerve ablation, might be helpful in controlling pain, particularly that related to cancer.

Pain scoring systems

Various questionnaires and other instruments have been devised to localise pain, rate its severity and assess its impact on quality of life. Some of the most widely used are listed in Box 34.4. The distribution of pain can be documented on a diagram of the body, on which the patient can mark the sites that are painful. Similarly, other methods have been developed with which to assess the severity of pain using verbal, numerical and behavioural rating scales. Visual scoring systems employing different facial expressions may be of value in paediatric patients and those with cognitive impairment. Documenting changes in pain scores using questionnaires can be helpful in indicating to what extent drug treatments have been successful and can reduce the time taken to achieve pain control.

Principles of management

Effective management of chronic pain depends in part on the underlying cause but some general principles can be applied. In general terms, the treatment goals are to:

- educate the patient
- promote self-management
- optimise function
- enhance quality of life
- control pain.

Clinical history

Biopsychosocial assessment

A full biopsychosocial assessment should be performed in all patients with chronic pain. Although this is time-consuming, the time invested is likely to pay dividends in improving the long-term outcome for patients. A biopsychosocial assessment takes account of the underlying neurobiology of the condition in the context of wider influences, including cognition and beliefs, emotions, and social and cultural factors. For example, an individual with abdominal pain might respond differently if a close relative had recently died of gastric cancer than if a colleague had been off work with gastric upset.

An accurate clinical history is important, taking note of the duration of pain, any precipitating and relieving factors, its location and, if the pain is located at more than one site, which site is the one that impacts most on the patient's quality of life. The characteristics of the pain should be documented, by assessing whether it is described as dull, sharp, aching or burning. Associated features, such as hypersensitivity to fine touch or temperature, numbness, paraesthesia, tingling and formication (the feeling of insects crawling over the skin), should be noted. It is important to determine to what extent the pain is interfering with normal daily activities, such as work, leisure pursuits and sleep. The patient's social circumstances and cultural background should be documented, including any caring responsibilities, employment status and social and family support. The intensity of pain should also be recorded, preferably using a validated questionnaire (Box 34.4). The patient's mood should be assessed and, if evidence of low mood is detected, a suicide risk assessment should be considered (see Box 28.12, p. 1187).

The past medical and medication history should be recorded and specific enquiry made about substance misuse and any previous history of physical or mental abuse. It is also useful to enquire specifically about the patient's beliefs as to what is causing their pain, as well as what their expectation of treatment is; unless these are addressed, management may be less effective. There are some patient populations in whom particular challenges arise, often related to differences in communication ability. Strategies that can be used to overcome these difficulties are summarised in Box 34.5.

Examination

The patient's general appearance should be noted, including ability to walk and use of a walking aid. In those with focal pain, neurological examination should be performed, focusing particularly on any areas of abnormal sensation, reflexes and evidence of muscle wasting. A general examination should be carried out to determine whether there is any evidence of an underlying physical disorder that can account for the pain. In addition to the use of investigations to find the underlying cause of pain, patients with persistent or chronic pain may benefit from sensory testing or diagnostic nerve blocks to explore the underlying mechanisms and direct treatment. For example, a combined femoral and sciatic nerve block may be used in a patient with lower limb amputation to assess whether the pain is predominantly peripherally or centrally generated. If the pain is not improved by an effective nerve block, then peripherally directed therapies are unlikely to be effective.

i 34.4 Instruments used in the assessment of pain and its impact

Instrument	Comments
Brief Pain Inventory	Developed for use in cancer pain, validated and widely employed for chronic pain; based on 0–10 ratings of pain intensity and the impact of pain on a range of domains, including sleep, work and enjoyment of life
Pain Detect, s-LANSS, DN-4	A number of screening questionnaires to aid diagnosis of neuropathic pain
Pain Catastrophising Scale	Developed to assess individual levels of catastrophising, encompassing three different domains: helplessness, rumination and magnification
Tampa Scale of Kinesiophobia	Measures how much an individual is fearful of movement
Pain Self-efficacy Questionnaire	Assesses individual beliefs about self-efficacy in the context of chronic pain, and how this impacts on function
Visual analogue scale (VAS)	Patient marks pain intensity on a horizontal line
Localisation of pain	Body chart, allowing the patient to indicate where pain is situated
Beck Depression Inventory	Assesses emotional function
SF-36/EQ-5D	Assesses health-related quality of life

(DN-4 = Douleur Neuropathique questionnaire; EQ-5D = EuroQol 5-Domain questionnaire; SF-36 = Short Form 36; s-LANSS = self-completed Leeds Assessment of Neuropathic Signs and Symptoms)

34.5 Challenges in pain assessment in particular patient populations

Patient population	Challenges	Solutions
Paediatric	Assessment needs to be appropriate to developmental stage	Consider visual tools to aid pain assessment
Elderly	May have impaired cognitive function Cultural factors may reduce self-reporting of pain Risk of adverse effects of medication increased	Consider formal assessment of cognitive function Consider non-verbal assessment Consider visual tools to assess pain Employ a number of tools assessing pain behaviours
Cognitive impairment	Reporting and expression of pain may change Increased sensitivity to central nervous system effects of analgesics	Perform formal assessment of cognitive function Use non-verbal assessment: facial expressions, vocalisations, body movements, changes in social interactions
Substance misuse	Response to analgesics altered Increased tolerance Increased risk of addiction Substance misuse may affect reporting of pain	Seek specialist support early Ensure prescribing is safe

Interventions

Probably the most effective mode of treatment for pain is to identify the underlying cause. Examples include the use of immunosuppressive medication in inflammatory disease, chemotherapy, radiotherapy or hormone therapy in cancer, and antimicrobial therapy in patients with infection. There are many circumstances, however, in which the underlying cause of pain cannot be treated or the treatments available are incompletely effective. Under these circumstances, several management options are available. In all cases, a multidisciplinary approach is necessary that combines pharmacological management with supported self-management, and other specific interventions when appropriate.

Supported self-management

Self-management strategies are useful in the treatment of chronic pain. Self-management works best if the patient has some understanding of their chronic pain, and acceptance that it is unlikely to resolve completely. The aim is for patients to maximise their quality of life and function *despite* ongoing pain. Support for self-management can be delivered by health-care professionals, patients who suffer from the same condition or lay people, either on an individual basis, in a group setting or, increasingly, through web-based resources. There is a strong educational component to supported self-management, which seeks to generate an interaction between patient and tutor. The key aspects include:

- increasing activity levels, while understanding and practising pacing techniques (not overdoing things and cycling between over- and under-activity)
- using relaxation and mindfulness techniques as part of daily management
- using medication when appropriate
- having a plan to manage pain flares.

There are a number of useful online self-help resources (see 'Further reading').

Physical therapies

There is strong evidence that exercise can help in the management of chronic pain. Several types of exercise have been successfully used delivered in various ways, through physiotherapists, exercise classes or individual tuition. In choosing a form of exercise therapy, it is important to tailor the approach most likely to be acceptable to the individual patient. A successful exercise programme can help overcome 'fear avoidance', a well-recognised problem in chronic pain, where patients associate activity with an increase in pain and therefore do progressively less activity, with resultant deconditioning. Because of this it is important to pace physical activity to ensure that patients do not cycle from over-activity, with a flare in pain, to fatigue and deconditioning. This can be done by working with patients to establish their baseline level of activity and using an individually tailored, graded exercise programme (Box 34.6). This may include normal household activities, as well as targeted exercises and stretches. Manual therapy covers a variety of hands-on treatments, including manipulation, mobilisation and massage. Manual therapy can be provided by a range of therapists, including physiotherapists, osteopaths and chiropractors. There is some evidence of short-term benefit for manual therapy but limited evidence of long-term efficacy.

34.6 Physical therapies for chronic pain

Land-based

- Walking
- Gym work
- Exercise classes
- Yoga
- Pilates
- Tai-chi

Water-based

- Hydrotherapy
- Swimming
- Exercise classes

Pharmacological therapies

A range of analgesics can be used in the management of chronic pain but, for most of these, the evidence of long-term benefit is limited. In general, it is advisable to use a multimodal approach in the treatment of chronic pain, choosing different drugs to target pain processing at multiple points (Box 34.7). By employing different classes of analgesic, it is possible to use lower doses of each, thereby improving the side-effect profile. There is considerable inter-individual variability in response to analgesics, even within the same class. There are many reasons for this, including genetic variations in the enzymes that metabolise drugs. For example, the *CYP2D6* gene encodes for a liver enzyme, cytochrome P450 2D6, which metabolises a number of commonly used analgesics. Genetic variation in *CYP2D6* can influence circulating levels of many drugs, depending on whether

34.7 Pharmacological management of chronic pain

Drug or class of drug	Mechanism of action
Paracetamol	Central inhibition of COX-1 and COX-2 enzymes Mechanisms of action incompletely understood
Non-steroidal anti-inflammatory drugs	Inhibition of prostaglandin production
Opioids	Agonists at OP3 receptors at multiple levels in the central nervous system Blockade of ascending pain pathways
Ketamine	Antagonist of NMDA receptors Reduction of central sensitisation
Gabapentin **Pregabalin**	Inhibition of glutamate release by primary afferent neurons at first central synapse Decrease of excitatory neuronal activity
Tricyclic antidepressants	Inhibition of serotonin and noradrenaline (norepinephrine) re-uptake at synapses in the spinal cord, and also potential effects in the limbic system Inhibition of Na^+ channels in neurons
Serotonin (5-hydroxytryptamine, 5-HT) and noradrenaline (norepinephrine) re-uptake inhibitors	Inhibition of serotonin and noradrenaline re-uptake at synapses in the spinal cord, and also potential effects in the limbic system
Lidocaine patches	Inhibition of Na^+ in sensory neurons
Capsaicin patch	Activation of TRPV1 channels on subset of C fibres, causing selective pharmacological denervation, with a decrease in intra-epidermal nerve fibre density
Nerve blocks with lidocaine and glucocorticoids	Temporary denervation due to blockade of Na^+ channels in sensory neurons Local anti-inflammatory effect

(COX = cyclo-oxygenase; NMDA = *N*-methyl-D-aspartate; OP = opioid; TRPV1 = transient receptor potential vanilloid 1)

someone is a rapid or poor metaboliser. This is particularly important if metabolites are active, as is the case with codeine and tramadol, which are metabolised to morphine. Genetic variations have also been described in the opioid receptors and downstream pathways that they affect, with good pre-clinical evidence that variations in mu opioid receptors alter analgesic response to different opioids. Because of this there is a good rationale to try different drugs, even ones from the same class, if there is an inadequate response or there are unacceptable side-effects with one agent.

Whatever drug or combination of drugs is chosen, the key to successful pharmacological management is careful assessment and review, aiming for an acceptable balance between the benefits of treatment in providing pain relief, maximising function, and improving quality of life and adverse effects. Specific drug treatments are described below.

Non-opioid analgesics

Paracetamol

Paracetamol is widely used in the treatment of mild to moderate pain. Its mechanism of action is incompletely understood but it is known to be a weak inhibitor of the cyclo-oxygenase type 1 (COX-1) and cyclo-oxygenase type 2 (COX-2) enzymes, providing weak anti-inflammatory properties. There is also some of evidence that it activates inhibitory descending spinal pathways, via a serotonergic mechanism. Other postulated mechanisms include endocannabinoid re-uptake inhibition, and inhibition of nitric oxide and tumour necrosis factor alpha. For migraine and tension-type headache it has moderate efficacy at a dose of 1000 mg. It is used widely for musculoskeletal disorders and osteoarthritis, with very little high-quality evidence that it is much better than placebo, even at doses of up to 4000 mg per day. Acute liver failure is a well-recognised complication of paracetamol overdose but this risk may also be increased with long-term use, even within the recommended dose range. In view of this, it should be employed with caution in elderly patients and those weighing less than 50 kg.

Non-steroidal anti-inflammatory drugs

Non-steroidal anti-inflammatory drugs (NSAIDs) are widely used in the treatment of inflammatory pain and osteoarthritis. These drugs can be given systemically or locally and are discussed in more detail on page 1002. They are also useful in the management of pain in cancer patients, as discussed later in this chapter (p. 1350). Although widely prescribed, there is limited high-quality evidence of long-term efficacy in chronic pain, with a need for further studies in this area.

Topical analgesics

Topical capsaicin cream (0.025 or 0.075%) has some efficacy for osteoarthritis and may be used for neuropathic pain, although evidence of benefit is limited. A single application (done by a trained health-care professional) of a high-dose 8% capsaicin patch can give around 12 weeks of pain relief for neuropathic pain and can be repeated thereafter. Capsaicin is an agonist at the transient receptor potential vanilloid 1 (TRPV1) ion channel, found on some C fibres. Capsaicin activates the channel, causing an initial sensation of heat, but an analgesic effect subsequently results due to desensitisation of the channel.

Lidocaine 5% patches can also be helpful in focal neuropathic pain and should be applied for 12 hours out of 24 hours, with up to 4–6 weeks before maximum benefit is seen. The mode of action is blockade of sodium channels in primary afferent neurons and nociceptors, which reduces peripheral input to the spinal cord.

Adjuvant analgesics

Adjuvant analgesics is the term used to cover a range of agents that are used in the treatment of neuropathic pain, usually in combination with classical analgesics. Typically, these agents

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

do not produce an immediate reduction in pain, but rather exert an analgesic effect over a longer timeframe through their effects on central processing of pain. They are of particular value when used in combination in the management of pain with a neuropathic component but require careful dose titration over a number of weeks, to reach a dose that balances efficacy with side-effects. While the response to individual agents is variable, it is often possible to find an agent or combination of agents that works for most patients.

Opioid analgesics

Opioids are a class of drugs that target opioid receptors. The original receptor classification was based on pharmacological activity (mu, delta, kappa), with the more recent International Union of Basic and Clinical Pharmacology (IUPHAR) classification being generally accepted in current use (Box 34.8). Opioid receptors are G-protein-coupled receptors. Ligand binding activates several intracellular signalling pathways, increasing cyclic adenosine monophosphate (cAMP) levels, as well as altering calcium and potassium permeability of neurons. Opioids are traditionally divided into subclasses of weak opioids, such as codeine and dihydrocodeine, and strong opioids, such as morphine and oxycodone. While tramadol is a weak agonist at the mu opioid receptor, it is classified as a strong opioid in some countries. The dosages and characteristics of commonly prescribed opioids are shown in Box 34.9. There has been a large increase in the use of strong opioids for chronic pain over the last 10–20 years. A number of factors contribute to this, including a rising incidence of chronic pain with an ageing population, reluctance to use NSAIDs because of cardiovascular and gastrointestinal adverse effects, changes in patient expectation, societal attitudes and availability of new formulations of opioids. There is evidence of short- to medium-term benefit for strong opioids in low back pain and osteoarthritis but there have been very few good-quality studies of long-term use. Additionally, there is increasing concern about potential harm from long-term use. This includes addiction, dependence, opioid-induced hyperalgesia, endocrine dysfunction, fracture risk (especially in the elderly), overdose and cardiovascular

i 34.8 Opioids and opioid receptors

Endogenous ligand	Receptor (IUPHAR)	Alternative classification	Potential sites	Pharmacological effects
Endomorphin 1 and 2 Met-enkephalin Dynorphin A Dynorphin B	MOP	Mu; OP3	Brain, spinal cord, peripheral nerves, immune cells	Analgesia, reduced gastrointestinal motility, respiratory depression, pruritus
Leu-enkephalin Met-enkephalin β-endorphin	DOP	Delta; OP1	Brain, spinal cord, peripheral nerves	Analgesia, cardioprotection, thermoregulation
Dynorphin A Dynorphin B β-endorphin	KOP	Kappa; OP2	Brain (nucleus accumbens, neocortex, brainstem, cerebellum)	Analgesia, neuroendocrine (e.g. on hypothalamic–pituitary axis), diuresis, dysphoria
Orphanin FQ (nociceptin)	NOP	Orphan; ORL-1; OP4	Nucleus raphe magnus, spinal cord, afferent neurons	Opioid tolerance, anxiety, depression, increased appetite

(IUPHAR = International Union of Basic and Clinical Pharmacology; OP = opioid; ORL = opioid-like receptor)

i 34.9 Commonly used opioids

Opioid	Typical starting dose	Route	Oral morphine equivalent	Comments
Morphine	10 mg	Oral	10 mg	Most widely used
Codeine	100 mg	Oral	10 mg	Metabolised to morphine
Dihydrocodeine	100 mg	Oral	10 mg	Semi-synthetic
Tramadol	100 mg	Oral	10 mg	Synthetic
Oxycodone	6.6 mg	Oral	10 mg	More predictable bioavailability than morphine
Buprenorphine	5 μg/hr	Transdermal	30 mg/day	Patch change usually every 7 days (frequency of change dependent on manufacturer and dose); advantages in impaired renal function
Fentanyl	12 μg/hr	Transdermal	30 mg/day	Use with care in opioid-naïve patients; patch change usually every 72 hrs
Tapentadol	50 mg	Oral	20 mg	Use with care in opioid-naïve patients
Hydromorphone	2 mg	Oral	10 mg	Semi-synthetic; hepatic metabolism
Diamorphine	3 mg	Subcutaneous, intramuscular, intravenous	10 mg	Mainly used for acute pain or palliative care

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

34.10 Use of opioids in chronic pain

Step	Factors to take into account	Comment
1. Assess suitability for opioids	Type of pain	Neuropathic pain less likely to respond
	Likelihood of dependence	History of substance or alcohol misuse, including stimulant misuse
	Co-morbidity	Avoid use in conditions where adverse effects more likely: Chronic obstructive pulmonary disease Chronic liver disease Chronic kidney disease
2. Discuss with patient	Discuss potential benefits	Improvement in pain Improvement in function
	Discuss adverse effects	Nausea Constipation Drowsiness
	Establish treatment goal	Improvement in function
3. Plan treatment trial	Set timescale	Define duration of treatment Agree frequency of review
	Agree on dose	Aim for lowest effective dose Set upper dose limit
	Agree on stopping rules	Consider stopping if: Treatment goal is not met There is no dose response Tolerance develops rapidly

events, with many of these adverse effects being dose-related. There is evidence that doses of more than 120 mg morphine equivalents per day are associated with increased harm, and regular review to assess ongoing benefit is needed in this patient group. A suggested strategy for using strong opioids in chronic pain is shown in Box 34.10.

Psychological therapies

The aims of psychological therapy are to increase coping skills and improve quality of life when facing the challenges of living with chronic pain. There are a range of ways in which psychological therapies can be delivered, including individual one-to-one sessions, group sessions, multidisciplinary pain management programmes, or web-based or telephone-based programmes.

There is a good evidence for the use of a cognitive behavioural therapy (CBT)-based approach for chronic pain, delivered either individually or in a group. The overall aim is to reduce negative thoughts and beliefs, and develop positive coping strategies. The interaction between thoughts, behaviours and emotions is explored, and a problem-focused approach is used in therapy delivery.

Relaxation techniques, such as biofeedback and mindfulness meditation, require a degree of stillness and withdrawal, with regular practice required for sustained benefit (see 'Further information'). Acceptance and commitment therapy (ACT) is based on CBT principles but also uses components of mindfulness to improve psychological flexibility in the context of living with chronic pain.

Stimulation therapies

These range from minimally invasive procedures like acupuncture and transcutaneous electrical nerve stimulation (TENS) to more invasive techniques such as spinal cord stimulation.

Acupuncture (Fig. 34.6) has been used successfully in Eastern medicine for centuries. The mechanisms are incompletely understood, although endorphin release may explain, in part, the analgesic effect. Acupuncture is particularly effective in pain related to muscle spasm, with some evidence of short-term benefit for patients with low back pain. Similar mechanisms probably apply to TENS, which is worth considering in many types of chronic pain. Neuromodulation, using implanted electrodes in the epidural space (or, more recently, adjacent to peripheral nerves), has been shown to be an effective option for neuropathic pain, including failed back surgery syndrome and chronic regional pain syndrome (see below). Specialist assessment and ongoing support is necessary, as there are many potential complications, including infection, malfunction and battery failure. The likelihood of success is increased when this technique is used within the context of multidisciplinary assessment and management.

Fig. 34.6 Acupuncture.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

Complementary and alternative therapies

Complementary techniques, such as herbal medicines, vitamins, homeopathy and reflexology, have been used for the treatment of chronic pain but with little evidence of efficacy. It should be noted that herbal medications may interact with conventional drugs, causing adverse effects as the result of drug–drug interactions. St John's wort (*Hypericum perforatum*) interacts with many drugs, including many antidepressants used in chronic pain, with increased serotonergic effects. Grapefruit may also increase the risk of serotonergic effects with some antidepressants. *Ginkgo biloba* may interact with paracetamol to increase bleeding time.

Nerve blocks and nerve ablation

The use of specialist nerve blocks and nerve ablation therapy can be considered for pain that is unresponsive to less invasive approaches. If these are being considered, they should form part of a multidisciplinary management plan, with the aim of restoring function and reducing pain. Local anaesthetic with or without depot glucocorticoid (non-particulate for neuraxial administration) can be effective in some circumstances. Examples include occipital nerve blocks for migraine or cervicogenic headache and trigger point injections for myofascial pain. If there is limited compression of a spinal nerve root, the nerve root injections into the epidural space may help settle symptoms and avoid the need for surgical intervention. Neurodestructive procedures can also be employed for intractable pain but are rarely used outside the palliative care setting.

Chronic pain syndromes

Chronic pain is a feature of several recognised syndromes, which are discussed in more detail below.

Neuropathic pain

Neuropathic pain is defined as 'pain associated with a lesion or disease of the somatosensory nervous system'. Neuropathic pain may be acute, such as in sciatica, which occurs as the result of a prolapsed disc, but is most problematic when it becomes chronic. Neuropathic pain causes major morbidity; in a recent study, 17% of those affected rated their quality of life as 'worse than death'. The clinical features of neuropathic pain are summarised in Box 34.11. The diagnosis is easily missed and so careful assessment is vital, in order to make the diagnosis in the first place and then to direct management appropriately. An algorithm for the management of neuropathic pain is provided in Figure 34.7. It is important to recognise the negative impact of neuropathic pain on quality of life, which has been shown to be greater than with other types of chronic pain. As a result, appropriate support and multidisciplinary management should always be considered in addition to pharmacological therapies.

Complex regional pain syndrome

Complex regional pain syndrome (CRPS) is a type of neuropathic pain that affects one or more limbs. It was previously termed reflex sympathetic dystrophy (RSD), reflecting the fact the disease is thought to be caused in part by an abnormality in the autonomic nervous system. It is a rare syndrome, occurring in about 20 per 100 000 individuals, and is more common in females, typically presenting between the ages of 35 and 50. It is classified into type I CRPS, which may be precipitated by a traumatic event

i 34.11 Clinical features of neuropathic pain

Characteristic	Symptom or clinical feature*	Descriptive term
Spontaneous pain	No stimulus required to evoke pain	
Positive sensory disturbance	Light touch painful Pressure painful Increased pain on pin-prick Cool and warm temperatures painful	Dynamic allodynia Punctate allodynia Hyperalgesia Thermal allodynia
Negative sensory disturbance	Numbness Tingling Loss of temperature sensitivity	Loss of sensation Paraesthesia
Other features	Feeling of insects crawling over skin Affected area feels abnormal	Formication Dysaesthesia

*Symptoms may cluster, with a predominance of either positive or negative symptoms, or a mixture of both, reflecting differences in underlying mechanisms.

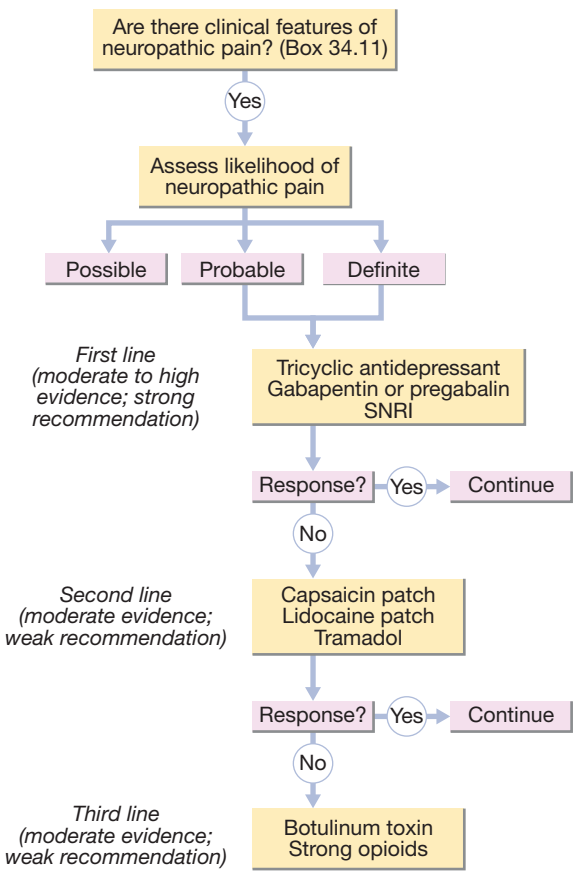

Fig. 34.7 Algorithm for pharmacological management of neuropathic pain. (SNRI = serotonin noradrenaline (norepinephrine) re-uptake inhibitor) *Adapted from SIGN 136 and NeuPSIG recommendations (Finnerup NB, Attal N, Haroutounian S, et al. Pharmacotherapy for neuropathic pain in adults: a systematic review and meta-analysis. Reprinted with permission from Elsevier (The Lancet Neurol 2015; 14:162–173)).*

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

34.12 Criteria for diagnosis of complex regional pain syndrome (CRPS) type 1*

Category	Symptom or sign
Sensory	Allodynia to: Temperature Light touch Deep somatic pressure Movement Hyperalgesia to pin-prick
Vasomotor	Temperature asymmetry Skin colour change and asymmetry Skin colour asymmetry
Oedema/sudomotor	Oedema Sweating change or asymmetry
Motor/trophic	Reduced range of motion Motor dysfunction: Weakness Tremor Dystonia Trophic changes: Hair Nails Skin

*The diagnosis of CRPS type 1 can be made if a patient has at least one symptom in at least three out of the four categories and at least one sign in two out of the four categories, and no other diagnosis can explain the symptoms.

such as a fracture but is not associated with peripheral nerve damage, and type II CRPS, which is associated with a peripheral nerve lesion. The diagnosis is primarily clinical, based on the features shown in Box 34.12. Imaging with MRI or radionuclide bone scan may provide support for the diagnosis of type I CRPS in showing bone marrow oedema or increased tracer uptake localised to an affected site (p. 1055).

Prompt diagnosis and early treatment with physiotherapy may prevent progression of symptoms. Management is as for neuropathic pain, additional approaches including graded motor imagery. Bisphosphonates have been used empirically for treatment but the evidence base for efficacy in controlling pain is weak. If medical management is incompletely effective, consideration should be given to the appropriateness of a spinal cord stimulator.

Phantom limb pain

Phantom limb is a common complication of amputation, occurring in up to 70% of patients. It is a form of neuropathic pain but can be particularly distressing, as the pain is felt in the area where the absent limb was previously. Although usually presenting after limb amputation, reports of phantom pain in other body parts have been reported, such as phantom breast pain following mastectomy. It is very often associated with phantom sensations, which are described as non-painful sensations in the absent body part and pain in the stump.

Diagnostic nerve blocks may be helpful in directing therapy, with use of anti-neuropathic medications as outlined in Box 34.7. If there is a definite neuroma at the stump site that is interfering with prosthesis use, surgical review may be necessary.

Chronic widespread pain

Chronic widespread pain (CWP) is often associated with other features, such as fatigue and irritable bowel syndrome. Fibromyalgia is a subtype of CWP in which there are myofascial trigger points, and is often associated with sleep disturbance. Clinical features and management of fibromyalgia are discussed in more detail on page 1018.

Joint hypermobility syndrome

Hypermobility can be associated with chronic musculoskeletal pain that often targets the joints and periarticular tissues. It is thought to be caused by abnormal stresses being placed on the joints and surrounding soft tissues due to ligament laxity, although the mechanisms are poorly understood since many people with hypermobile joints do not suffer pain. It is described in more detail on page 1059.

Palliative care

Palliative care is the term used to describe the active total care of patients with incurable disease. It can be distinguished from end-of-life care, which refers to the care of patients with far advanced, rapidly progressive disease that will soon prove fatal. The focus of palliative care is on symptom control alongside supportive care. While palliative care can and should be delivered at any stage of an incurable illness alongside optimal disease control, the focus of end-of-life care is on quality of life rather than prolongation of life or cure. Palliative care encompasses a distinct body of knowledge and skills that all good physicians must possess to allow them to care effectively for patients. Palliative care is traditionally seen as a means of managing distress and symptoms in patients with cancer, when metastatic disease has been diagnosed and death is seen as inevitable. There is, however, a growing recognition that the principles of palliative care and some of the interventions it uses are equally applicable in other conditions. Palliative may therefore be applied to any chronic disease state.

For conditions other than cancer, the challenge is recognising when patients have entered the terminal phase of their illness, as there are fewer clear markers and the course of the illness is much more variable. Different chronic disease states progress at different rates, allowing some general trajectories of illness or dying to be defined (Fig. 34.8). These trajectories are useful in decision-making for individual patients and also in planning services.

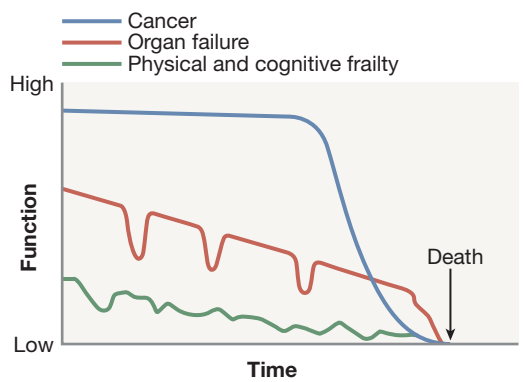

Fig. 34.8 Archetypal trajectories of dying. *Reproduced from Murray SA, Kendall M, Boyd K, et al. Illness trajectories and palliative care. BMJ 2005; 330:7498; reproduced with permission from the BMJ Publishing Group.*

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

The 'rapid decline' trajectory following a gradual decline, as occurs in cancer, is the best-recognised pattern of the need for palliative care, although a similar trajectory may be observed in other conditions, such as motor neuron disease can. Many traditional hospice services are designed to meet the needs of people on this trajectory. Over recent years, improvements in management of malignant disease mean that some types of cancer may follow an erratic or intermittent decline trajectory.

Many chronic diseases, such as advanced chronic obstructive pulmonary disease (COPD) and intractable congestive heart failure, carry as high a burden of symptoms as cancer, as well as psychological and family distress. The 'palliative phase' of these illnesses may be more difficult to identify because of periods of relative stability interspersed with acute episodes of severe illness. However, it is still possible to recognise those patients who may benefit from a palliative approach to their care. The challenge is that symptom management needs to be delivered at the same time as treatment for acute exacerbations. This leads to difficult decisions as to the balance between symptom relief and aggressive management of the underlying disease. The starting point of need for palliative care in these conditions is the point at which consideration of comfort and individual values becomes important in decision-making, often alongside management of the underlying disease.

The third major trajectory is categorised by years of poor function and frailty before a relatively short terminal period; it is exemplified by dementia but is also increasingly true for patients with many different chronic illnesses. As medical advances extend survival, this mode of dying is being experienced by increasing numbers of people. The main challenge lies in providing nursing care and ensuring that plans are agreed for the time when medical intervention is no longer beneficial.

In a situation where death is inevitable and foreseeable, palliative care balances the 'standard textbook' approach with the wishes and values of the patient and a realistic assessment of the benefits of medical interventions. This often results in a greater focus on comfort, symptom control and support for patient and family, and may enable withdrawal of both futile and burdensome interventions. In cases of prognostic uncertainty, open, honest and gentle communication with the patient and family is important. The most common symptoms in palliative care are discussed in the next section.

Presenting problems in palliative care

Pain

Pain is a common problem in palliative care. It has been estimated that about two-thirds of patients with cancer experience moderate or severe pain, and a quarter have three or more different sites of pain. Many of these are of a mixed aetiology and about half of patients with cancer-associated pain have a neuropathic element.

Clinical assessment

Careful evaluation to identify the likely mechanisms of pain is important so that the most appropriate treatment can be given. Clinical features and suggested management strategies for common types of pain in cancer are shown in Box 34.13. The majority of patients with cancer-associated pain can be effectively managed using a stepwise approach, as outlined below.

i 34.13 Common types of pain in cancer

Type of pain	Features	Management options
Bone pain	Tender area over bone Possible pain on movement	NSAIDs Bisphosphonates Radiotherapy
Increased intracranial pressure	Headache, worse in the morning, associated with vomiting and occasionally delirium	Glucocorticoids Radiotherapy Codeine
Abdominal colic	Intermittent, severe, spasmodic, associated with nausea or vomiting	Antispasmodics Hyoscine butylbromide
Liver capsule pain	Right upper quadrant abdominal pain, often associated with tender enlarged liver Responds poorly to opioids	Glucocorticoids
Neuropathic pain	Spontaneous pain Light touch, pressure and temperature changes are painful; increased pain on pin-prick Numbness, tingling or loss of temperature sensation Skin feels abnormal	Anticonvulsants: Gabapentin Pregabalin Antidepressants Amitriptyline Duloxetine Ketamine
Ischaemic pain	Diffuse, severe, aching pain associated with evidence of poor perfusion Responds poorly to opioids	NSAIDs Ketamine
Incident pain	Episodic pain usually related to movement or bowel spasm	Intermittent short-acting opioids Nerve block

(NSAIDs = non-steroidal anti-inflammatory drugs)

Management: pharmacological treatments

Pharmacological treatments are the mainstay of management in cancer-associated pain. A stepwise approach is adopted, following the principles of the World Health Organisation (WHO) analgesic ladder (Fig. 34.9), in which analgesia that is appropriate for the degree of pain is prescribed first. Patients with mild pain should be started on a non-opioid analgesic drug, such as paracetamol (1 g 4 times daily) or an NSAID (step 1). If the patient fails to respond adequately or has moderate pain, a weak opioid, such as codeine (60 mg 4 times daily), should be added (step 2). This can be prescribed separately or in the form of the compound analgesic co-codamol. If pain relief is still not achieved or if the patient has severe pain, a strong opioid should be substituted for the weak opioid (step 3). If the pain is severe at the outset, strong opioids should be prescribed and increased or titrated according to the patient's response. It is important not to move 'sideways' (change from one drug to another of equal potency), which is a common problem during step 2 of the analgesic ladder.

Opioids

Opioid analgesia plays a key role in patients with moderate to severe pain. Its successful use depends on appropriate assessment and a detailed explanation to the patient and carer about the benefits and potential side-effects of therapy. Morphine

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

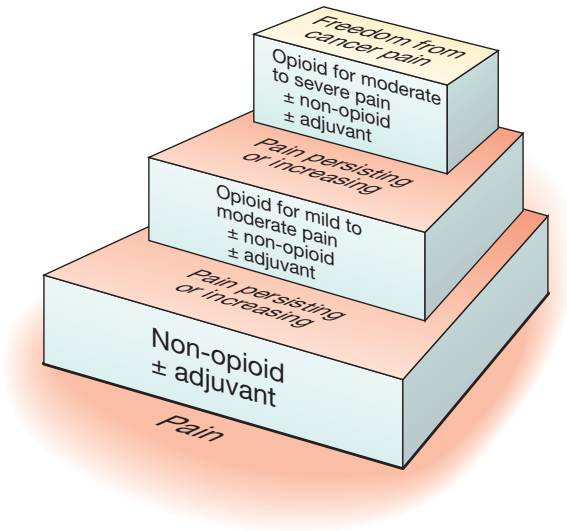

Fig. 34.9 The WHO analgesic ladder. *From WHO. Cancer pain relief, 2nd edn. Geneva: WHO; 1996.*

34.14 Opioid side-effects

Side-effect	Management
Constipation	Regular laxative Opioid/naloxone oral combination, in resistant constipation
Dry mouth	Frequent sips of iced water, soft white paraffin to lips, chlorhexidine mouthwashes twice daily, sugar-free gum, water or saliva sprays
Nausea/vomiting	Oral haloperidol 0.5–1 mg at night, oral metoclopramide 10 mg 3 times daily or oral domperidone 10 mg 3 times daily If constant, haloperidol or levomepromazine may be given parenterally to break the nausea cycle
Sedation	Explanation is very important Symptoms usually settle in a few days Avoid other sedating medication where possible Ensure appropriate use of adjuvant analgesics that can have an opioid-sparing effect May require an alternative opioid

is the most commonly prescribed strong opioid, although there are several alternatives, as outlined in Box 34.9.

Oral morphine takes about 20 minutes to exert an effect and usually provides pain relief for 4 hours. Most patients with continuous pain should be prescribed oral morphine every 4 hours initially, as this will provide continuous pain relief over the whole 24-hour period. Controlled-release morphine lasts for 12 or 24 hours, depending on the formulation, and if clinical circumstances dictate, a controlled-release formulation can be used to initiate and titrate morphine. The median effective morphine equivalent dose for cancer pain is about 200 mg per 24 hours.

In addition to the regular dose of morphine, an extra dose of immediate-release (IR) morphine should be prescribed 'as required' for the treatment of breakthrough pain that has not been controlled by the regular prescription. As a rule of thumb, this additional dose should be one-sixth of the total 24-hour dose of opioid. The frequency of breakthrough doses should be dictated by their efficacy and any side-effects, rather than by a fixed time interval. A patient may require breakthrough analgesia as frequently as hourly if pain is severe, but this should lead to early review of the regular prescription. The patient or carer should note the timing of any breakthrough doses and the reason for them. These should be reviewed daily and the regular 4-hourly dose increased for the next 24 hours on the basis of:

- the frequency of and reasons for breakthrough analgesia
- the degree and acceptability of side-effects.

The regular dose should be increased by adding the total of the breakthrough doses over the previous 24 hours, unless there are significant problems with unacceptable side-effects. When the correct dose has been established, a continuous release (CR) preparation can be prescribed, usually twice daily. Breakthrough analgesia used for movement-related pain is generally not included in background opioid dose titration. Attempts to control movement-related pain with background opioid dose will usually lead to over-medication and opioid-related side-effects. This can be a risk in metastatic bone pain.

Some patients may have concerns about using opioids and it is vital for these to be explored. Patients should be reassured that psychological dependence is rare when opioids are used for cancer pain, unless a pre-existing dependence problem exists. Pharmacological tolerance is not usually a clinically relevant problem; however, physical dependence, which is physiological, as manifest by a physical withdrawal syndrome, can occur if opioids are suddenly discontinued.

Nearly all types of cancer pain respond to morphine to some degree but there is a spectrum of response, such that in some patients the dose of opioid required to control neuropathic pain and all elements of metastatic bone pain may be high and associated with unacceptable side-effects. In these situations, other methods of analgesia, both pharmacological and non-pharmacological, should be explored and considered at an early stage.

The most effective and appropriate route of morphine administration is oral but transdermal preparations of strong opioids (usually fentanyl) are useful in certain situations, such as in patients with dysphagia or those who are reluctant to take tablets on a regular basis. Diamorphine is a highly soluble strong opioid used for subcutaneous infusions, particularly in the last few days of life, but is only available in certain countries.

Opioid-related adverse effects

Adverse effects are a common problem with opioids, especially on initiating treatment and on increasing the dose. The most common side-effects are nausea, drowsiness, constipation and dry mouth, as summarised in Box 34.14. Nausea and vomiting can occur initially but usually settle after a few days. Drowsiness is usually transient at opioid initiation and dose increase. If it is persistent, an alternative opioid and/or a non-opioid should be considered. In acute dosing, respiratory depression can occur but this is rare in patients on regular opioids or in those starting on small, regular doses with appropriate titration.

Tolerance usually develops to nausea, vomiting and drowsiness but not to constipation or dry mouth. All patients should therefore be prescribed a laxative, unless suffering from diarrhoea, and have access to an antiemetic and good mouth care, along with rationalisation of any concomitant medication that might exacerbate drowsiness. Newer developments include the use of preparations in which opioids are combined with opioid

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

antagonists, such as naloxone. The naloxone is poorly absorbed and does not antagonise the systemic analgesic effect but rather acts locally to block opioid receptors in the gut, thereby reducing opioid-related constipation. Vivid dreams, visual hallucinations (often consisting of a sense of movement at the periphery of vision), delirium and myoclonus are typical of opioid-related toxicity and, if present, require urgent reassessment of the opioid dose. Biochemistry should also be checked to exclude renal impairment, dehydration, electrolyte disturbance or hypercalcaemia.

Since opioid toxicity can occur at any dose, side-effects should be assessed regularly, but particularly after a dose increase. Pain should be reassessed to ensure that appropriate adjuvants are being used. Parenteral rehydration is often helpful to speed up excretion of active metabolites of morphine. The dose of opioid may need to be reduced or the opioid changed to a strong alternative.

Different opioids have different side-effect profiles in different people. If a patient develops side-effects, switching to an alternative strong opioid may be helpful. Options include oxycodone, transdermal fentanyl, alfentanil, hydromorphone and occasionally methadone, any of which may produce a better balance of benefit against side-effects. Fentanyl and alfentanil have no renally excreted active metabolites and may be particularly useful in patients with renal failure. It is possible to switch between opioids but great care must be taken when doing so to make sure the dose is correct and to avoid prescribing too much or too little opioid.

Adjuvant analgesics

An adjuvant analgesic is a drug that has a primary indication other than pain but which provides analgesia in some painful conditions and may enhance the effect of the primary analgesic. Commonly used adjuvant analgesics in the palliative care setting are shown in Box 34.15. Some adjuvant analgesics may enhance the side-effect profile of the primary analgesic, and dose reductions of opioids may be required when an adjuvant analgesic is added. At each step of the WHO analgesic ladder, an adjuvant analgesic should be considered, the choice depending on the type of pain.

Management: non-pharmacological treatments

Neurodestructive interventions

Neurodestructive techniques have an important role in the management of cancer pain, where life expectancy is limited. They should be used as part of an overall management plan and considered when the response to drug treatment has been inadequate. Intrathecal analgesia, delivered via either an external pump or a fully implanted device, is a good option, particularly where life expectancy is more than 3 months. Coeliac plexus blocks can be helpful for visceral pain, such as in pancreatic cancer. Lateral cordotomy to disrupt the spinothalamic tracts (either open or percutaneous) may be considered for unilateral chest wall pain, such as may occur in mesothelioma, where life expectancy is limited.

Radiotherapy

Radiotherapy is the treatment of choice for pain from bone metastases (see Box 34.13) and can also be considered for metastatic involvement at other sites. All patients with pain secondary to bone metastases should be considered for palliative radiotherapy, which can usually be given in a single dose.

Physiotherapy

Physiotherapy has a key role in the multidisciplinary approach to a wide spectrum of cancer-related symptoms, including the prevention and management of pain, muscle spasm, reduced mobility, muscle wasting and lymphoedema. Rehabilitation in palliative care has expanded and now includes pre-habilitation, which involves the use of proactive focused exercise to maintain muscle mass during cancer chemotherapy and in other chronic conditions such as COPD.

Psychological techniques

As with chronic pain, there is increasing use of psychological techniques in cancer pain management, which train the patient

i 34.15 Adjuvant analgesics in cancer pain

Drug	Example	Indications	Side-effects*
NSAIDs	Diclofenac	Bone metastases, soft tissue infiltration, liver pain, inflammatory pain	Gastric irritation and bleeding, fluid retention, headache Caution in renal impairment
Glucocorticoids	Dexamethasone 8–16 mg per day, titrated to lowest dose that controls pain	Raised intracranial pressure, nerve compression, soft tissue infiltration, liver pain	Gastric irritation if used together with NSAID, fluid retention, proximal muscle myopathy, delirium, Cushingoid appearance, candidiasis, hyperglycaemia
Anticonvulsants	Evidence strongest for: Gabapentin Pregabalin Duloxetine	Neuropathic pain of any aetiology	Mild sedation, tremor, delirium Exacerbation of opioid-related side-effects
Tricyclic antidepressants	Amitriptyline	Neuropathic pain of any aetiology	Sedation, dizziness, delirium, dry mouth, constipation, urinary retention Avoid in cardiac disease Exacerbation of opioid-related side-effects
NMDA receptor blockers	Ketamine	Severe neuropathic pain (only under specialist supervision)	Delirium, anxiety, agitation, hypertension

*In old age, all drugs can cause delirium.
(NMDA = *N*-methyl-D-aspartate; NSAIDs = non-steroidal anti-inflammatory drugs)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

to use coping strategies and behavioural techniques. Other issues related to the specific experience of a cancer diagnosis and cancer treatment may be complex, and individual therapy in addition to group-based approaches can be helpful.

Stimulation therapies

Acupuncture and TENS are low-risk stimulation therapies that may be useful in palliative care for management of pain and nausea.

Complementary and alternative therapies

Palliative care patients often seek symptom relief from both complementary and alternative therapies. While the evidence base is poorly developed, individual patients can gain significant benefits from the complementary therapies outlined on page 1348. It is critically important that patients are encouraged to discuss any alternative medicines they are considering, given the potential interactions with other therapies.

Breathlessness

Breathlessness is one of the most common symptoms in palliative care and is distressing for both patients and carers. Patients with breathlessness should be fully assessed to determine whether there is a reversible cause, such as a pleural effusion, heart failure or bronchospasm; if so, this should be managed in the normal way. If symptoms persist, additional measures may be necessary. There are many potential causes of dyspnoea in cancer patients and in other chronic diseases; apart from direct involvement of the lungs, muscle loss secondary to cachexia, anxiety and fear can all contribute. A cycle of panic and breathlessness, often associated with fear of dying, can be dominant. Exploration of precipitating factors is important and patient education about breathlessness and effective breathing has been shown to be effective. Non-pharmacological approaches that include using a hand-held fan, pacing, and following a tailored exercise programme can help. There is no evidence to suggest that oxygen therapy reduces the sensation of breathlessness in advanced cancer any better than cool airflow, and oxygen is indicated only if there is significant hypoxia. Opioids, through both their central and their peripheral action, can palliate breathlessness. Both oral and parenteral opioids are effective. A low dose should be used initially and titrated against symptoms, unless opioids are already being prescribed for pain, in which case the existing dose can be increased further. If anxiety is considered to be playing a significant role, a quick-acting benzodiazepine, such as lorazepam (used sublingually for rapid absorption), may also be useful.

Cough

Persistent unproductive cough can be helped by opioids, which have an antitussive effect. Troublesome respiratory secretions can be treated with hyoscine hydrobromide (400–600 µg every 4–8 hours), although dry mouth is a common adverse effect. As an alternative, glycopyrronium can be useful and is given by subcutaneous infusion (0.6–1.2 mg in 24 hours).

Nausea and vomiting

The presentation of nausea and vomiting differs depending on the underlying cause, of which there are many (p. 780). Large-volume vomiting with little nausea is common in intestinal obstruction, whereas constant nausea with little or no vomiting is often due to metabolic abnormalities or adverse effects of drugs. Vomiting related to raised intracranial pressure is worse in the morning. Different receptors are activated, depending on the cause or causes of the nausea (Fig. 34.10). For example, dopamine receptors in the chemotactic trigger zone in the fourth ventricle are stimulated by metabolic and drug causes of nausea, whereas gastric irritation stimulates histamine receptors in the vomiting centre via the vagus nerve. Reversible causes, such as hypercalcaemia and constipation, should be treated appropriately. Drug-induced causes should be considered and the offending drugs stopped if possible. As different classes of antiemetic drug act at different receptors, antiemetic therapy should be based on a careful assessment of the probable causes and a rational decision to use a particular class of drug (Box 34.16).

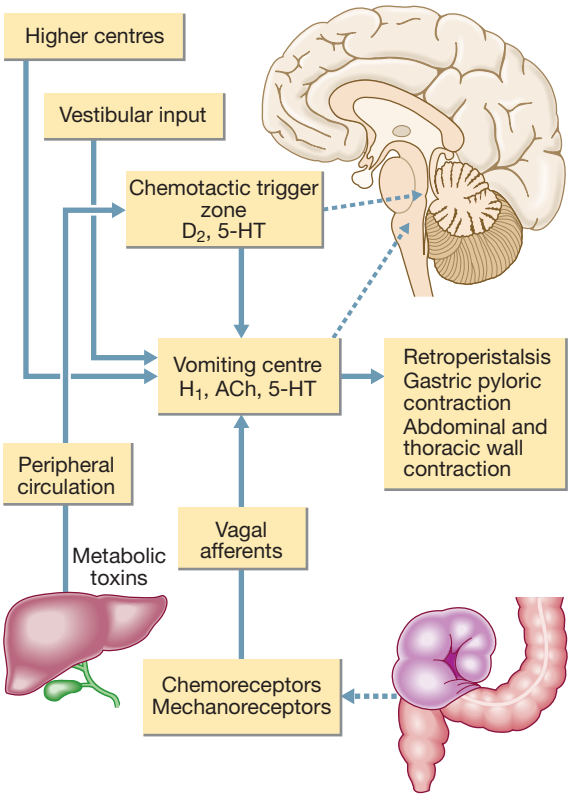

Fig. 34.10 Mechanisms of nausea. (ACh = acetylcholine; D_2 = dopamine; 5-HT = 5-hydroxytryptamine, serotonin; H_1 = histamine)

i 34.16 Receptor site activity of antiemetic drugs

Area	Receptors	Drugs
Chemotactic trigger zone	Dopamine$_2$ 5-HT	Haloperidol Metoclopramide
Vomiting centre	Histamine$_1$ Acetylcholine	Cyclizine Levomepromazine Hyoscine
Gut (gastric stasis)		Metoclopramide
Gut distension (vagal stimulation)	Histamine$_1$	Cyclizine
Gut (chemoreceptors)	5-HT	Levomepromazine

(5-HT = 5-hydroxytryptamine, serotonin)

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

The subcutaneous route is often required initially to overcome gastric stasis and poor absorption of oral medicines.

Gastrointestinal obstruction

Gastrointestinal obstruction is a frequent complication of intra-abdominal cancer. Patients may have multiple levels of obstruction and symptoms may vary greatly in nature and severity. Surgical mortality is high in patients with advanced disease and obstruction should normally be managed without surgery. The key to effective management is to address the presenting symptoms – colic, abdominal pain, nausea, vomiting, intestinal secretions – individually or in combination, using parenteral drugs that do not cause or worsen other symptoms. This can be problematic when a specific treatment worsens another symptom. Cyclizine improves nausea and colic responds well to anticholinergic agents, such as hyoscine butylbromide, but both slow gut motility. Nausea will improve with metoclopramide, although this is usually contraindicated in the presence of colic because of its prokinetic effect. There is some low-level evidence that glucocorticoids (dexamethasone 8 mg) can shorten the length of obstructive episodes. Somatostatin analogues, such as octreotide, will reduce intestinal secretions and therefore large-volume vomits. Occasionally, a nasogastric tube is required to reduce gaseous or fluid distension.

Weight loss

Patients with cancer lose weight for a variety of reasons, including reduced appetite or the effects of drug treatment, or as a consequence of low mood and anxiety. There is, however, a particularly challenging syndrome associated with weight loss, which is known as cancer cachexia. This results from an alteration of metabolism caused by a complex interaction of tumour-related factors and the body's response to these factors, resulting in muscle loss, along with anorexia. Treatment involves prescribing exercise to maintain muscle mass and strengthen muscles, ensuring that there is an adequate calorie intake and providing nutritional supplements. Anti-inflammatory medication to attenuate systemic inflammation is the subject of research and many patients self-medicate with fish oil. Glucocorticoids can temporarily boost appetite and general well-being but may cause false weight gain by promoting fluid retention. Their benefits need to be weighed against the risk of side-effects, and glucocorticoids should generally be used on a short-term basis only.

Anxiety and depression

Anxiety and depression are common in palliative care but the diagnosis may be difficult, since the physical symptoms of depression are similar to those of advanced cancer. It is therefore important to realise that these symptoms are not inevitable in advanced cancer. Patients should still expect to look forward to things and to enjoy them, within the context of the situation. Simply asking the question 'Do you think you are depressed?' can be very useful in deciding with the patient whether antidepressants or psychological interventions may be of benefit (p. 1199). In this regard, psycho-oncology has been evolving rapidly and there is now good evidence for the role of 'talk therapy' in palliative care, along with other appropriate management of anxiety and depression. If antidepressants are required, citalopram and mirtazapine are good choices since they are generally well tolerated in patients with advanced disease.

Delirium and agitation

Many patients become confused or agitated in the last days of life. It is important to identify and treat potentially reversible causes (p. 183), unless the patient is too close to death for this to be feasible. Early diagnosis and effective management of delirium are extremely important. As in other palliative situations, it may not be possible to identify and treat the underlying cause, and the focus of management should be to ensure that the patient is comfortable. It is important to distinguish between behavioural change due to pain and that due to delirium, as opioids will improve one and worsen the other. The management of delirium is detailed on page 209. It is important, even in the care of the actively dying patient, to treat delirium with antipsychotic medicines, such as haloperidol, rather than to regard it as distress or anxiety and use benzodiazepines only.

Dehydration

Deciding whether to give intravenous fluids can be difficult when a patient is very unwell and the prognosis is uncertain. A patient with a major stroke, who is unable to swallow but is expected to survive the event, will develop renal impairment and thirst if not given fluids and should be hydrated. On the other hand, when a patient has been deteriorating and is clearly dying, parenteral hydration needs very careful consideration and it is very important to manage this on an individual basis. Comfort and avoidance of distress in the family are the primary aims. Where a patient and family are happy with meticulous oral hygiene and care to reduce the sensation of dryness in the mouth, this is usually more appropriate and effective at the end of life than parenteral hydration, which by itself will not necessarily improve the sensation of dryness. In some patients, parenteral hydration will simply exacerbate pooling of secretions, causing noisy and distressing breathing. Each decision should be individual and discussed with the patient's family.

Death and dying

Planning for dying

There have been dramatic improvements in the medical treatment and care of patients with cancer and other illnesses over recent years but the inescapable fact remains that everyone will die at some time. Planning for death should be actively considered in patients with chronic diseases when the death is considered to be foreseeable or inevitable. Doctors rarely know exactly when a patient will die but are usually aware that an individual is about to die and that medical interventions are unlikely to extend life or improve its quality significantly. Most people wish their doctors to be honest about this situation to allow them time to think ahead, make plans and address practical issues. A few do not wish to discuss future deterioration or death; if this is felt to be the case, avoidance of discussion should be respected. For doctors, it is helpful to understand an individual's wishes and values about medical interventions at this time, as this can help guide decisions about interventions. It is important to distinguish between interventions that will not provide clinical benefit (a medical decision) and those that do not confer sufficient benefit to be worthwhile (a decision that can only be reached with a patient's involvement and consent). A common example of this would be decisions about not attempting cardiopulmonary resuscitation.

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

In general, people wish for a dignified and peaceful death and most prefer to die at home. Families also are grateful for the chance to prepare themselves for the death of a relative, by timely and gentle discussion with the doctor or other health professionals. Early discussion and effective planning improve the chances that an individual's wishes will be achieved. There are two important caveats: firstly, wishes can and do change as the terminal situation evolves, and secondly, planning in general can only be done over time as patients form a relationship with professionals and evolve an understanding of the situation in which they find themselves.

Structures for assessment and planning around end-of-life care are for guidance only and the focus should evolve with the individual patient.

Diagnosing dying

When patients with cancer or other conditions become bed-bound, semi-comatose, unable to take tablets and only able to take sips of water, with no reversible cause, they are likely to be dying and many will have died within 2 days. Doctors are sometimes poor at recognising this and should be alert to the views of other members of the multidisciplinary team. A clear decision that the patient is dying should be agreed and recorded.

Management of dying

Once the conclusion has been reached that a patient is going to die in days to a few weeks, there is a significant shift in management (Box 34.17). Symptom control, relief of distress and care for the family become the most important elements of care. Medication and investigation are justifiable only if they contribute to these ends. When patients can no longer drink because they are dying, intravenous fluids are usually not necessary and may cause worsening of bronchial secretions; however, this is a decision that can be made only on an individual basis. Management should not be changed without discussion with the patient and/or family. Medicines should always be prescribed for the relief of symptoms. For example, morphine or diamorphine may be used to control pain, levomepromazine to control nausea, haloperidol to treat delirium, diazepam or midazolam to treat distress, and hyoscine hydrobromide to reduce respiratory secretions. Side-effects, such as drowsiness, may be acceptable if the principal aim of relieving distress is achieved. It is important to discuss and agree the aims of care with the patient's family. Poor communication with families at this time is one of the most common reasons for family distress afterwards and for formal complaints.

Ethical considerations

The overwhelming force in caring for any patient must be to listen to that patient and family and take their wishes on board. Patients know when health-care professionals are just receiving the information, as opposed to receiving and understanding the information in the context of the patient, their illness and needs, their carers and the socioeconomic context. It is impossible to provide holistic care for a patient without this comprehension. Every patient is unique and it is important to avoid slipping into a tick-box mentality in addressing items that should be covered in patients with advanced, incurable disease. While the key to successful palliative care is effective interdisciplinary working, every patient needs to know who has overall responsibility for their care. Trust in the whole team will come through a solid lead working with a team who are appropriately informed and in sympathy with the patient's situation, each having a clear role.

Families and other carers are often unprepared for the challenge of caring for a dying person. It can be an exhausting experience, both emotionally and physically, and without a critical number of carers battle fatigue can ensue, resulting in urgent admissions. With much discussion about advance directives, we should not lose sight of the reality of changing circumstances and wishes. Good anticipatory care means not just providing for new physical symptoms, but also planning for any time when care at home becomes no longer possible.

Capacity and advance directives

The wishes of the patient are paramount in Western societies, whereas in other cultures the views of the family are equally important. If a patient is unable to express their view because of communication or cognitive impairment, that person is said to lack 'capacity'. In order to decide what the patient would have wished, as much information as possible should be gained about any previously expressed wishes, along with the views of relatives and other health professionals. An advance directive is a previously recorded, written document of a patient's wishes (p. 1307). It should carry the same weight in decision-making as a patient's expressed wishes at that time, but may

34.17 How to manage a patient who is dying

Patient and family awareness

- Assess patient's and family's awareness of the situation
- Ensure family understands plan of care

Medical interventions

- Stop non-essential medications that do not contribute to symptom control
- Stop inappropriate investigations and interventions, including routine observations

Resuscitation

- Complete Do Not Attempt Cardiopulmonary Resuscitation (DNACPR) form
- Deactivate implantable defibrillator

Symptom control

- Ensure availability of parenteral medication for symptom relief

Support for family

- Make sure you have contact details for family, that you know when they want to be contacted and that they are aware of facilities available to them

Religious and spiritual needs

- Make sure any particular wishes are identified and followed

Ongoing assessment

- Family's awareness of condition
- Management of symptoms
- Need for parenteral hydration

Care after death

- Make sure family know what they have to do
- Notify other appropriate health professionals

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

not be sufficiently specific to be used in a particular clinical situation. The legal framework for decision-making varies in different countries.

Euthanasia

In the UK and Europe, between 3% and 6% of dying patients will ask a doctor to end their life. Many of these requests are transient; some are associated with poor control of physical symptoms or a depressive illness. All expressions of a wish to die are an opportunity to help the patient discuss and address unresolved issues and problems. Reversible causes, such as pain or depression, should be treated. Sometimes, patients may choose to discontinue life-prolonging treatments, such as diuretics or anticoagulation, following discussion and the provision of adequate alternative symptom control. However, there remain a small number of patients who have a sustained, competent wish to end their lives, despite good control of physical symptoms. Euthanasia is now permitted or legal under certain circumstances in some countries but remains illegal in many others; public, ethical and legal debate over this issue is likely to continue and is often influenced by many complex non-palliative care issues. The European Association for Palliative Care does not see euthanasia or physician-assisted suicide as part of the role of palliative care physicians.

Notes on the international system of units (SI units)

Système International (SI) units are a specific subset of the metre–kilogram–second system of units and were agreed on as the everyday currency for commercial and scientific work in 1960, following a series of international conferences organised by the International Bureau of Weights and Measures. SI units have been adopted widely in clinical laboratories but non-SI units are still used in many countries. For that reason, values in both units are given for common measurements throughout this textbook and commonly used non-SI units are shown in this chapter. The SI unit system is, however, recommended.

Examples of basic SI units

Length	metre (m)
Mass	kilogram (kg)
Amount of substance	mole (mol)
Energy	joule (J)
Pressure	pascal (Pa)
Volume	The basic SI unit of volume is the cubic metre (1000 litres). For convenience, however, the litre (L) is used as the unit of volume in laboratory work.

Examples of decimal multiples and submultiples of SI units

Factor	*Name*	*Prefix*
10^{6}	mega-	M
10^{3}	kilo-	k
10^{-1}	deci-	d
10^{-2}	centi-	c
10^{-3}	milli-	m
10^{-6}	micro-	μ
10^{-9}	nano-	n
10^{-12}	pico-	p
10^{-15}	femto-	f

Exceptions to the use of SI units

By convention, blood pressure is excluded from the SI unit system and is measured in mmHg (millimetres of mercury) rather than pascals.

Mass concentrations such as g/L and μg/L are used in preference to molar concentrations for all protein measurements and for substances that do not have a sufficiently well-defined composition.

Some enzymes and hormones are measured by 'bioassay', in which the activity in the sample is compared with the activity (rather than the mass) of a standard sample that is provided from a central source. For these assays, results are given in standardised 'units' (U/L), or 'international units' (IU/L), which depend on the activity in the standard sample and may not be readily converted to mass units.

Laboratory reference ranges in adults

Reference ranges are largely those used in the Departments of Clinical Biochemistry and Haematology, Lothian Health University Hospitals Division, Edinburgh, UK. Values are shown in both SI units and, where appropriate, non-SI units. Many reference ranges vary between laboratories, depending on the assay method used and on other factors; this is especially the case for enzyme assays. The origin of reference ranges and the interpretation of 'abnormal' results are discussed on page 3. No details are given here of the collection requirements, which may be critical to obtaining a meaningful result. Unless otherwise stated, reference ranges shown apply to adults; values in children may be different.

Many analytes can be measured in either serum (the supernatant of clotted blood) or plasma (the supernatant of anticoagulated blood). A specific requirement for one or the other may depend on a kit manufacturer's recommendations. In other instances, the distinction is critical. An example is fibrinogen, where plasma is required, since fibrinogen is largely absent from serum. In contrast, serum is required for electrophoresis to detect paraproteins because fibrinogen migrates as a discrete band in the zone of interest.

i 35.1 Urea and electrolytes in venous blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Sodium	135–145 mmol/L	135–145 mEq/L
Potassium*	3.6–5.0 mmol/L	3.6–5.0 mEq/L
Chloride	95–107 mmol/L	95–107 mEq/L
Urea	2.5–6.6 mmol/L	15–40 mg/dL
Creatinine		
Male	64–111 μmol/L	0.72–1.26 mg/dL
Female	50–98 μmol/L	0.57–1.11 mg/dL

*Serum values are, on average, 0.3 mmol/L higher than plasma values.

i 35.2 Analytes in arterial blood

	Reference range	
Analysis	**SI units**	**Non-SI units**
Bicarbonate	21–29 mmol/L	21–29 mEq/L
Hydrogen ion	37–45 nmol/L	pH 7.35–7.43
***Pa*CO_2**	4.5–6.0 kPa	34–45 mmHg
***Pa*O_2**	12–15 kPa	90–113 mmHg
Oxygen saturation	>97%	

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

35.3 Hormones in venous blood

Hormone	Reference range	
	SI units	Non-SI units
Adrenocorticotrophic hormone (ACTH) (plasma)	1.5–13.9 pmol/L (0700–1000 hrs)	63 ng/L
Aldosterone		
Supine (at least 30 mins)	30–440 pmol/L	1.09–15.9 ng/dL
Erect (at least 1 hr)	110–860 pmol/L	3.97–31.0 ng/dL
Cortisol	Dynamic tests are required – see Box 18.53, p. 680	
Follicle-stimulating hormone (FSH)		
Male	1.0–10.0 IU/L	–
Female	3.0–10.0 IU/L (early follicular)	–
	>30 IU/L (post-menopausal)	–
Gastrin (plasma, fasting)	<40 pmol/L	<83 pg/mL
Growth hormone (GH)	Dynamic tests are usually required – see Box 18.55, p. 682	
	<0.5 μg/L excludes acromegaly (if insulin-like growth factor 1 (IGF-1) in reference range)	<2 mIU/L
	>6 μg/L excludes GH deficiency	>18 mIU/L
Insulin	Highly variable and interpretable only in relation to plasma glucose and body habitus	
Luteinising hormone (LH)		
Male	1.0–9.0 IU/L	–
Female	2.0–9.0 IU/L (early follicular)	–
	>20 IU/L (post-menopausal)	–
17β-Oestradiol		
Male	<160 pmol/L	<43 pg/mL
Female: early follicular	75–140 pmol/L	20–38 pg/mL
post-menopausal	<150 pmol/L	<41 pg/mL
Parathyroid hormone (PTH)	1.6–6.9 pmol/L	16–69 pg/mL
Progesterone (in luteal phase in women)		
Consistent with ovulation	>30 nmol/L	>9.3 ng/mL
Probable ovulatory cycle	15–30 nmol/L	4.7–9.3 ng/mL
Anovulatory cycle	<10 nmol/L	<3 ng/mL
Prolactin (PRL)	60–500 mIU/L	2.8–23.5 ng/mL
Renin concentration		
Supine (at least 30 mins)	5–40 mIU/L	–
Sitting (at least 15 mins)	5–45 mIU/L	–
Erect (at least 1 hr)	16–63 mIU/L	–
Testosterone		
Male	10–38 nmol/L	290–1090 ng/dL
Female	0.3–1.9 nmol/L	10–90 ng/dL
Thyroid-stimulating hormone (TSH)	0.2–4.5 mIU/L	–
Thyroxine (free), (free T_4)	9–21 pmol/L	0.7–1.63 ng/dL
Triiodothyronine (free), (free T_3)	2.6–6.2 pmol/L	0.16–0.4 ng/dL

Notes

1. A number of hormones are unstable and collection details are critical to obtaining a meaningful result. Refer to local laboratory handbook.
2. Values in the table are only a guideline; hormone levels can often be meaningfully understood only in relation to factors such as gender, age, time of day, pubertal status, stage of the menstrual cycle, pregnancy and menopausal status.
3. Reference ranges are usually dependent on the method used for analysis and frequently differ between laboratories. Non-SI units also differ; those shown here are amongst those most widely used. Readers are encouraged to consult their local laboratory for non-SI units for individual analytes and their respective reference ranges.

35.4 Other common analytes in venous blood

Analyte	Reference range SI units	Non-SI units
α_1-antitrypsin	1.1–2.1 g/L	110–210 mg/dL
Alanine aminotransferase (ALT)	10–50 U/L	–
Albumin	35–50 g/L	3.5–5.0 g/dL
Alkaline phosphatase (ALP)	40–125 U/L	–
Amylase	<100 U/L	–
Aspartate aminotransferase (AST)	10–45 U/L	–
Bile acids (fasting)	<14 μmol/L	–
Bilirubin (total)	3–16 μmol/L	0.18–0.94 mg/dL
Calcium (total)	2.1–2.6 mmol/L	4.2–5.2 mEq/L or 8.5–10.5 mg/dL
Carboxyhaemoglobin	0.1–3.0% Levels of up to 8% may be found in heavy smokers	–
Caeruloplasmin	0.16–0.47 g/L	16–47 mg/dL
Cholesterol (total)	Ideal level varies according to cardiovascular risk (see cardiovascular risk chart, p. 511)	
HDL-cholesterol	Ideal level varies according to cardiovascular risk, so reference ranges can be misleading. According to the National Cholesterol Education Programme Adult Treatment Panel III (ATPIII), a low HDL-cholesterol is <1.0 mmol/L (<40 mg/dL)	
Complement		
C3	0.81–1.57 g/L	–
C4	0.13–1.39 g/L	–
Total haemolytic complement	0.086–0.410 g/L	–
Copper	10–22 μmol/L	64–140 μg/dL
C-reactive protein (CRP)	<5 mg/L Highly sensitive CRP assays also exist that measure lower values and may be useful in estimating cardiovascular risk	
Creatine kinase (CK; total)		
Male	55–170 U/L	–
Female	30–135 U/L	–
Creatine kinase MB isoenzyme	<6% of total CK	–
Ethanol	Not normally detectable	
Marked intoxication	65–87 mmol/L	300–400 mg/dL
Stupor	87–109 mmol/L	400–500 mg/dL
Coma	>109 mmol/L	>500 mg/dL

Analyte	Reference range SI units	Non-SI units
γ-glutamyl transferase (GGT)	Male 10–55 U/L Female 5–35 U/L	–
Glucose (fasting)	3.6–5.8 mmol/L See page 722 for definitions of impaired glucose tolerance and diabetes mellitus, and page 738 for definition of hypoglycaemia	65–104 mg/dL
Glycated haemoglobin (HbA_{1c})	4.0–6.0% 20–42 mmol/mol Hb See page 722 for diagnosis of diabetes mellitus	–
Immunoglobulins (Ig)		
IgA	0.8–4.5 g/L	–
IgE	0–250 kU/L	–
IgG	6.0–15.0 g/L	–
IgM	0.35–2.90 g/L	–
Lactate	0.6–2.4 mmol/L	5.4–21.6 mg/dL
Lactate dehydrogenase (LDH; total)	125–220 U/L	–
Lead	<0.5 μmol/L	<10 μg/dL
Magnesium	0.75–1.0 mmol/L	1.5–2.0 mEq/L or 1.82–2.43 mg/dL
Osmolality	280–296 mOsmol/kg	–
Osmolarity	280–296 mOsmol/L	–
Phosphate (fasting)	0.8–1.4 mmol/L	2.48–4.34 mg/dL
Protein (total)	60–80 g/L	6–8 g/dL
Triglycerides (fasting)	0.6–1.7 mmol/L	53–150 mg/dL
Troponins	Values consistent with myocardial infarction are crucially dependent on which troponin is measured (I or T) and on the method employed. Interpret in context of clinical presentation. See page 450	
Tryptase	0–135 mg/L	–
Urate		
Male	0.12–0.42 mmol/L	2.0–7.0 mg/dL
Female	0.12–0.36 mmol/L	2.0–6.0 mg/dL
Vitamin D (25(OH)D)		
Normal	>50 nmol/L	>20 ng/mL
Insufficiency	25–50 nmol/L	10–20 ng/ml
Deficiency	<25 nmol/L	<10 ng/mL
Zinc	10–18 μmol/L	65–118 μg/dL

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

35.5 Common analytes in urine

Analyte	Reference range	
	SI units	Non-SI units
Albumin	Definitions of microalbuminuria are given on page 394 Proteinuria is defined below	
Calcium (normal diet)	Up to 7.5 mmol/24 hrs	Up to 15 mEq/24 hrs or 300 mg/24 hrs
Copper	<0.6 μmol/24 hrs	<38 μg/24 hrs
Cortisol	20–180 nmol/24 hrs	7.2–65 μg/24 hrs
Creatinine		
Male	6.3–23 mmol/24 hrs	712–2600 mg/24 hrs
Female	4.1–15 mmol/24 hrs	463–1695 mg/24 hrs
5-Hydroxyindole-3-acetic acid (5-HIAA)	10–42 μmol/24 hrs	1.9–8.1 mg/24 hrs
Metadrenalines		
Normetadrenaline	0.4–3.4 μmol/24 hrs	73–620 μg/24 hrs
Metadrenaline	0.3–1.7 μmol/24 hrs	59–335 μg/24 hrs
Oxalate	0.04–0.49 mmol/24 hrs	3.6–44 mg/24 hrs
Phosphate	15–50 mmol/24 hrs	465–1548 mg/24 hrs
Potassium*	25–100 mmol/24 hrs	25–100 mEq/24 hrs
Protein	<0.3 g/L	<0.03 g/dL
Sodium*	100–200 mmol/24 hrs	100–200 mEq/24 hrs
Urate	1.2–3.0 mmol/24 hrs	202–504 mg/24 hrs
Urea	170–600 mmol/24 hrs	10.2–36.0 g/24 hrs
Zinc	3–21 μmol/24 hrs	195–1365 μg/24 hrs

*The urinary output of electrolytes such as sodium and potassium is normally a reflection of dietary intake. This can vary widely. The values quoted are appropriate to a 'Western' diet.

35.6 Analytes in cerebrospinal fluid

Analysis	Reference range	
	SI units	Non–SI units
Cells	$<5\times10^6$ cells/L (all mononuclear)	<5 cells/mm^3
Glucose[1]	2.3–4.5 mmol/L	41–81 mg/dL
IgG index[2]	<0.65	–
Total protein	0.14–0.45 g/L	0.014–0.045 g/dL

[1]Interpret in relation to plasma glucose. Values in CSF are typically approximately two-thirds of plasma levels. [2]A crude index of increase in IgG attributable to intrathecal synthesis.

35.7 Analytes in faeces

Analyte	Reference range	
	SI units	Non-SI units
Calprotectin	<50 μg/g	–
Elastase	>200 μg/g	–

۰۲۱-۶۶۱۹۸۵۱۴ www.myuptodate.com دریافت آخرین نسخه آپتودیت آفلاین

35.8 Haematological values

Analysis	Reference range	
	SI units	Non-SI units
Bleeding time (Ivy)	<8 mins	–
Blood volume		
Male	65–85 mL/kg	–
Female	60–80 mL/kg	–
Coagulation screen		
Prothrombin time (PT)	10.5–13.5 secs	–
Activated partial thromboplastin time (APTT)	26–36 secs	–
D-dimers		
Interpret in relation to clinical presentation	<200 ng/mL	–
Erythrocyte sedimentation rate (ESR)	Higher values in older patients are not necessarily abnormal	
Adult male	0–10 mm/hr	–
Adult female	3–15 mm/hr	–
Ferritin		
Male (and post-menopausal female)	20–300 μg/L	20–300 ng/mL
Female (pre-menopausal)	15–200 μg/L	15–200 ng/mL
Fibrinogen	1.5–4.0 g/L	0.15–0.4 g/dL
Folate		
Serum	2.8–20 μg/L	2.8–20 ng/mL
Red cell	120–500 μg/L	120–500 ng/mL
Haemoglobin		
Male	130–180 g/L	13–18 g/dL
Female	115–165 g/L	11.5–16.5 g/dL
Haptoglobin	0.4–2.4 g/L	0.04–0.24 g/dL
Iron		
Male	14–32 μmol/L	78–178 μg/dL
Female	10–28 μmol/L	56–157 μg/dL
Leucocytes (adults)	$4.0–11.0\times10^9$/L	$4.0–11.0\times10^3$/mm^3
Differential white cell count		
Neutrophil granulocytes	$2.0–7.5\times10^9$/L	$2.0–7.5\times10^3$/mm^3
Lymphocytes	$1.5–4.0\times10^9$/L	$1.5–4.0\times10^3$/mm^3
Monocytes	$0.2–0.8\times10^9$/L	$0.2–0.8\times10^3$/mm^3
Eosinophil granulocytes	$0.04–0.4\times10^9$/L	$0.04–0.4\times10^3$/mm^3
Basophil granulocytes	$0.01–0.1\times10^9$/L	$0.01–0.1\times10^3$/mm^3
Mean cell haemoglobin (MCH)	27–32 pg	–
Mean cell volume (MCV)	78–98 fl	–
Packed cell volume (PCV) or haematocrit		
Male	0.40–0.54	–
Female	0.37–0.47	–
Platelets	$150–350\times10^9$/L	$150–350\times10^3$/mm^3
Red cell count		
Male	$4.5–6.5\times10^{12}$/L	$4.5–6.5\times10^6$/mm^3
Female	$3.8–5.8\times10^{12}$/L	$3.8–5.8\times10^6$/mm^3
Red cell lifespan		
Mean	120 days	–
Half-life (^{51}Cr)	25–35 days	–
Reticulocytes (adults)	$25–85\times10^9$/L	$25–85\times10^3$/mm^3
Transferrin	2.0–4.0 g/L	0.2–0.4 g/dL
Transferrin saturation		
Male	25–50%	–
Female	14–50%	–
Vitamin B_{12}		
Normal	>210 ng/L	–
Intermediate	180–200 ng/L	–
Low	<180 ng/L	–

Laboratory reference ranges in childhood and adolescence

The levels of many analytes in blood vary due to the physiological changes that occur during growth and adolescence. Hospital laboratories may provide reference ranges that are age-adjusted or based on pubertal stage but this is not always the case. It is therefore important for the doctor requesting these tests to understand the impact of age and puberty on interpretation of the results. For example, a creatinine of 70 μmol/L (0.79 mg/dL) is perfectly normal for the majority of adults but may indicate significant renal impairment in a child. Reference ranges for hormone results are described according to the Tanner stages of puberty (p. 1290).

35.9 Analytes that may be significantly affected by growth and puberty*

Analyte	Age/Pubertal stage	Gender	Reference range
Alkaline phosphatase (ALP)	<1 year	M, F	80–580 U/L
	1–16 years	M, F	100–400 U/L
	16–20 years	M	50–250 U/L
		F	40–200 U/L
Creatinine	<1 year	M, F	12–39 μmol/L (0.14–0.44 mg/dL)
	1–4 years	M, F	13–42 μmol/L (0.15–0.48 mg/dL)
	4–12 years	M, F	20–57 μmol/L (0.23–0.64 mg/dL)
	12–15 years	M, F	31–67 μmol/L (0.35–0.76 mg/dL)
	15–18 years	M	39–92 μmol/L (0.44–1.04 mg/dL)
		F	34–72 μmol/L (0.38–0.81 mg/dL)
Follicle-stimulating hormone (FSH)	Prepubertal	M	<3.0 IU/L (<0.6 μg/L)
		F	<3.2 IU/L (<0.64 μg/L)
	Pubertal stage 2	M	<6.6 IU/L (<1.32 μg/L)
		F	<4.1 IU/L (<0.82 μg/L)
	Pubertal stage 3	M	0.7–5.0 IU/L (0.14–1 μg/L)
	Pubertal stages 4–5	M	1.5–6.0 IU/L (0.3–1.2 μg/L)
	Pubertal stages 3–5	F	2.5–13.5 IU/L (0.5–2.7 μg/L)
Insulin-like growth factor 1	<7 years	M	15–349 μg/L
		F	17–272 μg/L
	8–16 years	M	67–510 μg/L
		F	59–502 μg/L
Luteinising hormone (LH)	Prepubertal	M	<1.0 IU/L (<0.1 μg/L)
	Pubertal stage 2	M	<3.0 IU/L (<0.3 μg/L)
	Prepubertal and pubertal stage 2	F	<1.0 IU/L (<0.1 μg/L)
	Pubertal stage 3	M	1.0–4.0 IU/L (0.1–0.4 μg/L)
	Pubertal stages 4–5	M	1.0–5.0 IU/L (0.1–0.6 μg/L)
	Pubertal stages 3–5	F	1.0–8.0 IU/L (0.1–0.9 μg/L)
17β-Oestradiol	Prepubertal and pubertal stages 2–3	M	<75 pmol/L (<20 pg/mL)
	Prepubertal and pubertal stage 2	F	<100 pmol/L (<27 pg/mL)
	Pubertal stages 4–5	M	<130 pmol/L (<35 pg/mL)
	Pubertal stages 3–5	F	<150 pmol/L (<41 pg/mL)
Testosterone	Prepubertal	M	<0.5 nmol/L (<10 ng/dL)
		F	<0.6 nmol/L (<20 ng/dL)
	Pubertal stage 2	M	<10.6 nmol/L (<310 ng/dL)
		F	<1.4 nmol/L (<40 ng/dL)
	Pubertal stage 3	M	0.4–30 nmol/L (10–870 ng/dL)
	Pubertal stage 4	M	5.6–30 nmol/L (160–870 ng/dL)
	Pubertal stage 5	M	10–30 nmol/L (290–870 ng/dL)
	Pubertal stages 3–5	F	0.4–1.9 nmol/L (10–50 ng/dL)

*Non-SI equivalents are given in brackets where appropriate.

Laboratory reference ranges in pregnancy

The levels of many analytes in blood vary during pregnancy, when many hormonal and metabolic changes occur. The standard adult reference ranges may therefore not be appropriate and it is important for the clinician reviewing the results to be aware of this to enable appropriate interpretation and patient management.

35.10 Analytes that may be significantly affected by pregnancy*

	Reference range		
Analyte	**First trimester**	**Second trimester**	**Third trimester**
Alkaline phosphatase (ALP)	17–88 U/L	25–126 U/L	38–229 U/L
Packed cell volume (PCV) or haematocrit	0.31–0.41	0.30–0.39	0.28–0.40
Haemoglobin	116–139 g/L	97–148 g/L	95–150 g/L
Human chorionic gonadotrophin	4 weeks: 16–156 IU/L 4–9 weeks: 101–233 000 IU/L 9–13 weeks: 20 900–291 000 IU/L	4270–103 000 IU/L	2700–78 300 IU/L
17β-Oestradiol	690–9166 pmol/L (188–2497 pg/mL)	4691–26 401 pmol/L (1278–7192 pg/mL)	12 701–22 528 pmol/L (3460–6137 pg/mL)
Progesterone	25–153 nmol/L (8–48 ng/mL)	Not available	314–1088 nmol/L (99–342 ng/mL)
Prolactin	765–4532 mIU/L (36–213 ng/mL)	2340–7021 mIU/L (110–330 ng/mL)	2914–7914 mIU/L (137–372 ng/mL)
Thyroid-stimulating hormone (TSH)	0.60–3.40 mIU/L	0.37–3.60 mIU/L	0.38–4.04 mIU/L
Thyroxine (free), (free T_4)	10–18 pmol/L 0.77–1.40 ng/dL	9–16 pmol/L 0.70–1.24 ng/dL	8–14 pmol/L 0.62–1.09 ng/dL

*Non-SI equivalents are given in brackets where appropriate.

Hierarchy of systems, 93, 93*b*, 93*f*
High altitude, 168–169
  illnesses at, 168–169
    cerebral oedema (HACE), 168
    pulmonary oedema (HAPE), 168–169
  physiological effects of, 168, 168*f*
High-altitude cerebral oedema (HACE), 168
High-density lipoproteins (HDL), 1360*b*
High-energy fracture, 995*b*
High-flow nasal cannulae (HFNCs), 202
High-grade tumours, 961
High haemoglobin, 925, 925*b*
High-risk behaviour, transition medicine and, 1295
  history-taking in, 1295*b*
  personality and, 1295
  protective factors in, 1295
  theories in, 1295
Highly polyunsaturated long-chain n-3 fatty acids, 377
Hip
  osteoarthritis, 1010, 1010*f*
  pain, 998, 999*b*, 999*f*
Hippocampus, 1066
Hirschsprung's disease, 834–835
Hirsutism, 657–658, 658*b*, 1259–1260
His bundle, 445
Histamine, 767
Histidine, 698*b*
Histones, 38
Histopathology, in respiratory disease, 554
Histoplasma capsulatum, 303
Histoplasmosis, 303–304
  in HIV infection/AIDS, 314*f*
HIV infection/AIDS, 312
  antiretroviral therapy for, 324–327, 324*b*
  asymptomatic, 312, 312*f*
  CD4 counts in, 311
  chemoprophylaxis for, 323–324
  clinical examination of, 306*f*
  clinical manifestations of, 311–312
  counselling for, 311*b*
  diagnosis of, 310–311, 310*b*
  epidemiology of, 308
  global and regional epidemics of, 308, 308*b*
  hepatitis B and
    acute, 875
    co-infection with, 876–877
  immunisation for, 324
  immunology of, 309–310
  investigations of, 310–311, 311*b*
  life cycle of, 309*f*
  liver and, 879
  liver blood tests in, abnormal, 879*b*
  modes of transmission of, 308, 308*b*–309*b*
  musculoskeletal manifestations of, 1021*b*
  in old age, 326*b*
  pregnancy and, 1280
  presenting problems of, 312–322, 313*b*
    cancers, 322, 323*b*
    cardiac disease, 322
    fever, 313–314, 313*f*–314*f*
    gastrointestinal disease, 316–317
    haematological abnormalities, 322
    hepatobiliary disease, 317–318
    lymphadenopathy, 313
    mucocutaneous disease, 314–316, 314*b*
    nervous system and eye disease, 319–321, 319*f*
    renal diseases, 322
    respiratory disease, 318–319, 318*b*
    rheumatological diseases, 321–322
    weight loss, 313, 313*f*
  prevention of, 323–324, 327*b*
  primary, 311–312, 312*b*
  prophylaxis for, 119*b*
  pruritus and, 1219*b*
  staging classifications of, 307*b*
  testing of, 330
  tuberculosis and, 595
  viral load in, 311
  virology of, 309–310
HIV serology, acute kidney injury and, 416*b*
Hives, 1252
HLA antigen, transplant rejection, 88–89
HNF1-beta mutations, 406
Hoarseness, psychogenic, 624
Hodgkin lymphoma (HL), 961–964, 962*f*
  classification of, 962*b*
  clinical features of, 962
  epidemiology of, 961, 962*b*
  investigations of, 962, 963*f*
  management of, 962–964
  prognosis of, 964, 964*b*
  stages of, 962*b*
Holmes-Adie syndrome, 1092*b*
Home ventilation, for chronic respiratory failure, 567
Homocystinuria, 369–370
Honeycomb lung, 608*f*
Hookworm
  ancylostomiasis, 288–289, 288*f*
  dog, 294
Hookworm infestation, 233*b*
Hoover's sign, 1081–1082
Hormone replacement therapy
  amenorrhoea, 655
  cancer, 1332
  for osteoporosis, 1048*b*, 1049
Hormones
  gastrointestinal tract, 772
  production, ectopic, 1325*b*
  in venous blood, 1359*b*
Horner's syndrome, 1091*b*–1092*b*, 1091*f*
Hospital, under-nutrition in, 693*f*, 705–708, 706*b*
Host-pathogen interactions, 104
House dust mite, 570
Howell-Jolly bodies, 921*f*
Human albumin, 930
Human albumin solution (HAS), ascites and, 864
Human chorionic gonadotrophin (hCG)
  secretion of, pregnancy and, 1272
  as tumour markers, 1322, 1324*b*
Human herpesvirus 6 (HHV-6), 238, 238*b*
Human herpesvirus 7 (HHV-7), 238, 238*b*
Human herpesvirus 8 (HHV-8), 238*b*, 248
Human leucocyte antigen (HLA) molecules, 67
  antigen processing and presentation and, 70
Human papillomavirus (HPV), 342–343
  in pregnancy, 332*b*
  vaccines, 115
Human parvovirus arthropathy, 1020–1021
Human T-cell lymphotrophic virus type 1, 250
Humanitarian crisis, 171–172, 172*b*
Humidifier fever, 616*b*, 617
Humoral immunity, 68
Hunter's syndrome, 371*b*
Huntington's disease, 1115
  genetic testing of, 1077
Hurler's syndrome, 371*b*
Hutchinson's sign, 1233
Hyaluronic acid, intra-articular injections of, 1012
Hydatid cyst, liver and, 880
Hydatid disease, 298–299, 299*f*
Hydralazine, 467
  lupus syndrome, 1057*b*

  anatomy and physiology of, 1064–1072
    functional, 1065–1071, 1065*f*
  cells of, 1064–1065, 1064*f*
  clinical examination of, 1062–1064, 1062*f*
    in old age, 1079*b*
  in gastrointestinal function, 771–772
Nervous system disease
  cerebrovascular disease *see specific conditions*
  clinical examination of, 1062–1064, 1062*f*
  cranial nerves, 1063*b*
  emergencies, 1064*b*
  HIV-related, 319–321, 319*f*
  infections, 1117–1127, 1118*b*
  intracranial mass lesions/raised intracranial pressure, 1127–1133, 1128*b*
  investigation of, 1072–1078
  lesion localisation in, 1071–1072
  neuromuscular junction, 1141–1143
  paraneoplastic, 1110–1111, 1111*b*, 1132
  paraneoplastic syndromes, 1325–1326
  peripheral nerves, 1138–1141, 1139*b*
  presenting problems in, 1078–1094, 1079*b*–1080*b*
  spine/spinal cord, 1134–1137
Neural tube defects, prevention with folic acid, 712*b*, 945
Neuralgia
  migrainous, 1096
  post-herpetic, 239, 1080
  trigeminal, 1080, 1096–1097
Neuralgic amyotrophy, 1141
Neuro-endocrine tumours (NETs), 603*b*, 678–679, 678*b*, 679*f*, 813
Neuro-inflammatory diseases, 1106–1110
Neuroacanthocytosis, 1085*b*
Neurocognitive disorders, HIV-associated, 319
Neurodegenerative diseases, 1111–1117
Neurodestructive interventions, for cancer pain, 1352
Neurodevelopmental disorders, rare, genomics in, 56
Neurofibroma, 1129*b*, 1137*f*
Neurofibromatosis, 613*b*, 1131–1132, 1131*f*, 1132*b*, 1264
  and cancer predisposition, 1321*b*
  inheritance, 1131–1132
Neurogenic shock, description of, 206*b*
Neuroglycopenia, 739
Neuroimaging, 1072–1074, 1073*b*, 1151, 1151*f*, 1157–1158
Neuroleptic malignant syndrome, 1197–1198
Neurological disease
  in pregnancy, 1284
    epilepsy as, 1284
    idiopathic intracranial hypertension as, 1284
    migraine as, 1284
    stroke as, 1284
  rheumatological manifestations of, 1058, 1058*f*
  in systemic lupus erythematosus, 1035
  transition medicine and, 1296–1297
    cerebral palsy in, 1296
    epilepsy in, 1296
    muscular dystrophy in, 1297
Neurological support, in intensive care, 208
Neurology, 1061–1146
Neuroma
  acoustic, 1131
  Morton's, 999
Neuromuscular junction, diseases of, 1141–1143
Neuromyelitis optica, 1110
Neuromyotonia, 1111*b*
Neuronectomy, multiple sclerosis, 1110*b*
Neuropathic pain, 1084, 1348, 1348*b*, 1348*f*
Neuropathy
  ataxia and retinitis pigmentosa (NARP), 1144*b*
  autonomic, 760, 760*b*
  critical illness, 211
  diabetic, 758–761
    classification of, 759*b*
    clinical features of, 758–761
    management of, 761, 761*b*
    risk factors for, 757*b*
  entrapment, 1139–1140, 1139*b*
  hereditary, 1140
  leg ulcers due to, 1224
  motor, 503*b*, 1111*b*
  multifocal, 1140, 1140*b*
  peripheral, 1325
    cancer-related, 1325
    diabetic, 755, 756*b*
    drug-induced, 321
    HIV-related, 321
    leprosy, 268
    in rheumatoid arthritis, 1024
    sensorimotor, 321
  peripheral, cancer-related, 1325
  sensory, 503*b*, 1111*b*
Neuropeptides, 1338–1339, 1340*b*
Neurosensory retina, 1167
Neurosyphilis, 338, 1125, 1125*b*
Neurotoxic flaccid paralysis, 155
Neurotoxins, hepatic encephalopathy and, 865
Neurotransmission/neurotransmitters, 1065*f*
  in pain processing, 1340*b*
Neutral variants, 44
Neutrons, 164, 164*f*
Neutropenia, 925
  drug-induced, 926*b*
  fever in, 224, 1327–1328
  HIV-related, 322
Neutropenic fever, cancer and, 1327–1328
Neutrophil chemotactic factor, 75*b*
Neutrophil extracellular trap (NET) formation, 64
Neutrophil granulocytes, 1362*b*
Neutrophilia, 926, 926*b*
  asthma, 568–569
Neutrophilic dermatoses, 1262
Neutrophils, 64, 917, 926*b*, 926*f*
  asthma, 568–569
  count, 1362*b*
  toxic granulation, 64
Nevirapine, in pregnancy, 326–327
Newborn, haemolytic disease of, 933, 933*b*
Next-generation sequencing (NGS), 52–53
  capture, 53
  challenges of, 53–54
  methods of, 55*b*
  uses of, 54–56
Niacin (vitamin B_3), 714–715
  biochemical assessment of, 712*b*
  deficiency, 714, 715*f*
  dietary sources of, 711*b*
  reference nutrient intake of, 711*b*
  toxicity, 715
Nicardipine, angina, 491*b*
Nickel hypersensitivity, 83*b*, 1247*b*
Niclosamide, 129
Nicorandil, 790*b*
Nicotinamide, for pellagra, 714
Nicotinamide adenine dinucleotide (NAD), 881
Nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase enzyme complex, 64
Nicotine replacement therapy, 4
Nicotinic acid, 377
Niemann-Pick disease, 371*b*
Nifedipine
  altitude illness, 169
  angina, 490–491, 491*b*
    unstable, 500
  for high-altitude pulmonary oedema, 169
  hypertension, 513
  and neutropenia, 926*b*
  for oesophageal disorders, 795
  older people, 32*b*
  Raynaud's syndrome, 504–505
  sphincter of Oddi dysfunction, 909
Nifurtimox, for trypanosomiasis, 128
Night blindness, 713
Night sweats, 217*b*
Night terrors, 1094
Nightmares, 1094
Nikolsky sign, 1254–1255
Nimodipine, for subarachnoid haemorrhage, 1162
Nipah virus encephalitis, 250
Nitazoxanide, 129
Nitrates
  angina, 489–490
  duration of action, 490*b*
  heart failure, 467
  for oesophageal disorders, 795
Nitric oxide (NO), 386, 447
  anal fissure, 836
  hepatopulmonary syndrome and, 898
Nitrites, 428
Nitrofurantoin, 124
  and pulmonary eosinophilia, 611*b*–612*b*
  urinary tract infection, 428, 429*b*
Nitrogen narcosis, 170
Nitroimidazoles, 124
  mechanism of action, 116*b*
Nitroprusside reaction, 726
Nitrosamines, type 1 diabetes and, 729
'Nits', 1241
Nocardia, 587
  pneumonia, 319
Nocardiosis, 261

in old age, 801*b*
perforation, 789, 801
prophylaxis for, in intensive care, 211
Zollinger-Ellison syndrome, 802
Peptic ulcer disease, 798–802
Peptide YY, 772*b*
Peptides, antimicrobial, 62–63
Peptostreptococcus spp., 253*b*
Perceptions
abnormal, 1086, 1181
delusional, 1196–1197
Percussion
abdomen, 765*b*
in respiratory system, examination of, 546*f*
Percutaneous coronary intervention (PCI)
angina, 491–493, 491*f*–492*f*
myocardial infarction, 493*b*
vs. CABG, 493*b*
Percutaneous endoscopic gastrostomy (PEG), 707, 708*f*
Percutaneous therapy, for hepatocellular carcinoma, 891
Percutaneous transhepatic cholangiography (PTC), 854–855
Perforating dermatosis, acquired reactive, 1265
Perforin, 67
Perfusion, in respiratory system, 549–550
Perianal disease, inflammatory bowel disease and, 823
Pericardial disease, in tuberculosis (TB), 590
Pericardial effusion, 542*b*, 543, 543*f*, 1315*b*
Pericarditis
acute, 542, 542*b*, 542*f*
in acute coronary syndrome, 496
chronic constrictive, 543–544, 543*b*, 544*f*
tuberculous, 543
Pericardium, diseases of, 542–544
Perimetry, 1168
Perimysium, 987–988
Periodic fever syndromes, 81, 1059
Periodic limb movements, and sleep, 1106
Periodic paralysis
hyperkalaemic, 1145*b*
hypokalaemic, 1145*b*
Periostitis, 337, 600–601
Peripartum cardiomyopathy, pregnancy and, 1282
Peripheral arterial disease, 502–505, 502*b*
Peripheral nerves, 1338
disease of, 1138–1141, 1139*b*
HIV-related, 321
endings, 1338
lesions, 1083
Peripheral nervous system
motor, 1068
sensory, 1068
Peripheral neuropathy, 1325
cancer-related, 1325
diabetic, 755, 756*b*
drug-induced, 321
HIV-related, 321
leprosy, 268
in rheumatoid arthritis, 1024
sensorimotor, 321
Peripheral sensitisation, 1340, 1341*f*
Peripheral ulcerative keratitis, 1171–1172
Peripheral vascular disease, in diabetes, 503*b*
Perisinusoidal fibrosis, 884
Peristalsis, 772
Peritoneal cavity, disease of, 836–837
Peritoneal dialysis, 424
automated, 424
continuous ambulatory, 424
haemodialysis *vs*., 420*b*
problems with, 425*b*
Peritonitis, 836
spontaneous bacterial, 864
Permanent pacemakers, for arrhythmias, 483, 483*b*
Pernicious anaemia, 944
Persistent atrial fibrillation, 472–473
Persistent ductus arteriosus, 532*f*–533*f*, 533–534
Personality, 1071
change, 1094
high-risk behaviour and, 1295
psychiatric disorders and, 1183
Personality disorders, 1204–1205
prevalence of, 1180*b*
Pes cavus, 1140
Pesticides, 144–149
Petechiae, definition of, 1211*f*
Petechial purpura, 928–929, 928*f*
Petit mal, 1097
Pets
allergic rhinitis and, 622
asthma and, 568
HIV infection/AIDS and, 323

Weight loss, 785–786
after gastric resection, 801
anorexia nervosa and, 1203
cancer patients, 1323
causes of, 786*f*
diabetes and, 729–730, 732
diets, 701–702, 701*b*
HIV-related, 313, 313*f*
investigations, 786
musculoskeletal disease, 1001–1002
obesity, 701
in palliative care, 1354
pancreatitis and, 840
physiological causes of, 785
rheumatoid arthritis, 1023
Weight management, for diabetes, 744
Weil-Felix test, 108
Weil's disease, 258
Wells score, 187*b*
Wenckebach phenomenon, 477*f*
Werner's syndrome, 41, 689*b*
Wernicke-Korsakoff syndrome, 1195
prevention of, 1195
Wernicke's aphasia, 1088*f*
Wernicke's area, 1066
Wernicke's encephalopathy, 714
West Nile encephalitis, 250, 1121–1122
West Nile virus, 250
Western blot, 107
WG *see* Wegener's granulomatosis
Wheezing, asthma, 568
Whipple's disease, 809, 809*b*
Whipple's operation, under-nutrition and, 706
Whipple's triad, 676–677, 677*f*
Whipworm *(Trichuris trichiura)*, 290
White blood cells, 917
appearance of, 926*f*
count
acute fever without localising signs, 232*b*
differential, 1362*b*
high, 926–927
low, 925–926
viral hepatitis and, 872
formation, 917
polymorphonuclear *see* Neutrophils
reference values, 1362*b*
results of, interpreting, 926*b*
White eye, 1170
White spirit, poisoning, 148*b*
Whiteheads, 1242
Whitlow, herpetic, 247*f*
WHO *see* World Health Organization
Whole bowel irrigation, 136
Whole-exome sequencing, 54*b*
Whole-genome sequencing, 54*b*
Whooping cough, 582
antimicrobial prophylaxis, 119*b*
immunisation, 115*b*
incubation period, 111*b*
periods of infectivity, 111*b*
Wickham's striae, 1252
Williams' syndrome, 44*b*
Wills, living, 1307
Wilm's tumour, 1321*b*
Wilson's disease, 718, 896–897
investigations, 897
Kayser-fleischer rings and, 896–897
liver disease and, 896
liver function test (LFT) abnormality in, 854*b*
neurological aspects of, 1115
Windkessel effect, 447
Winterbottom's sign, 279
Withdrawal effects, 16, 16*b*
Wnt, in bone remodelling, 986*b*
Wolbachia spp., 291
Wolff-Parkinson-White (WPW) syndrome, 473–474, 474*f*
Wood's light, 1214
World Health Organization (WHO)
analgesic ladder, 1350, 1351*f*
classification of psychiatric disorders, 1180, 1180*b*
ICD-10, 1180
macronutrient recommendations, 698*b*
refeeding diet, 705*b*
Wound dressing, 1226–1227, 1227*b*
Wound infections
staphylococcal, 251, 251*f*
tetanus, 1126
WPW syndrome *see* Wolff-Parkinson-White (WPW) syndrome
Wrist
fracture, 1045*f*
pain, 998
Writer's cramp, 1086
Wuchereria bancrofti infection, 233*b*, 290, 291*f*

X
X chromosome, 38
abnormalities *see individual conditions*
inactivation, 48–49
see also X-linked
X-linked agammaglobulinaemia, 78
X-linked hypophosphataemic rickets (XLH), 1052
X-linked inheritance, 47*b*, 48–49
X-rays, 164, 164*f*
for acute respiratory distress syndrome, 198, 199*f*
for ankylosing spondylitis, 1030*f*
of body packers, 144*f*
cardiovascular system *see* Chest radiography/X-ray
for Charcot foot, 759*f*
chest *see* Chest radiography/X-ray
for chest pain, 178
for gastrointestinal disease, 772, 773*b*, 773*f*
achalasia, 795*f*
contrast studies, 773
inflammatory bowel disease, 818*f*, 819–820
hepatobiliary disease, 164
hyperparathyroidism, 663
for musculoskeletal disease, 988, 988*b*
bone fractures, 994–995, 1045*f*
bony metastases, 662
Charcot joint, 1058*f*
chondrocalcinosis, 1016*f*
complex regional pain syndrome (CRPS) type 1, 1055*f*
CPPD crystal deposition disease, 1017
fracture, 994–995
osteoarthritis, 1009*f*–1011*f*
osteomalacia, 1052, 1052*f*
osteonecrosis, 1055
osteoporosis, 1045*f*
osteosarcoma, 1056–1057
Paget's disease, 1054*f*
reactive arthritis, 1032
rheumatoid arthritis, 1025
supraspinatus tendon calcification, 1017*f*
of nervous system, 1073*b*
properties of, 164*f*
respiratory system *see* Chest radiography/X-ray
of skull, 1073
of spine, 1075*f*
Xa inhibitors, 472–473
Xanthelasma
cholestatic jaundice and, 861*b*
hyperlipidaemia and, 346*f*
Xanthomas, 1264
biliary cholangitis, 887
cholestatic jaundice and, 861*b*
hyperlipidaemia and, 346*f*
tendon, 375
Xanthomatosis, cerebrotendinous, 375*b*
Xeroderma pigmentosum, 1221*b*, 1321*b*
Xerophthalmia, 713
Xerostomia, 1038
XLH *see* X-linked hypophosphataemic rickets

Y
Y chromosome, 38
microdeletions of, 656
Yaws, 253–254, 254*b*
Yellow Card scheme, 23
Yellow fever, 243*f*, 244–245, 245*b*
incubation period of, 245*b*
vaccination, 245
Yersinia enterocolitica, 264
in Graves' thyrotoxicosis, 644
Yersinia pestis, 259
Young adults, diabetes mellitus in, 753–754
Young's syndrome, 550

Z
Zanamivir, 127, 127*b*, 241
Zero-order kinetics, 19
Zidovudine (ZVD), 324*b*
adverse reactions of
anaemia, 322
lipodystrophy, 326*f*
neutropenia, 322, 926*b*
for HIV/AIDS, 324–325, 324*b*
muscle pain/weakness from, 1000*b*
for onychomycosis, 316
Zika virus infection, 247
in pregnancy, 235*b*
Zinc, 717
deficiency, 717
dietary sources of, 717*b*
refeeding diet, 705*b*
reference nutrient intake of, 717*b*
reference range of
urine, 1361*b*
venous blood, 1360*b*
supplements, 717
for Wilson's disease, 897
Zinc phosphide poisoning, 148
Zinc therapy, for Wilson's disease, 897
Zoledronic acid
bone metastases, 1329
for osteoporosis, 1048*b*
for Paget's disease, 1054, 1054*b*
Zollinger-Ellison syndrome, 802
Zoonoses
transmission of, 110
viral haemorrhagic fevers, 245–246
Zoster sine herpete, 239
